TALANTA REVIEW

PLASMA EMISSION SOURCES IN ANALYTICAL SPECTROSCOPY—III*

S. GREENFIELD, H. McD. McGEACHIN and P. B. SMITH
Albright and Wilson Ltd., P.O. Box 80, Oldbury, Warley, West Midlands, B69 4LN, England

(*Received* 19 *May* 1975. *Accepted* 28 *August* 1975)

Summary—The development and properties of inductively coupled plasma sources are discussed and their applications to spectrochemical analysis are reviewed. Comparisons are made with other types of plasma source.

HIGH-FREQUENCY, ELECTRODELESS, INDUCTIVELY COUPLED PLASMAS

In 1942 Babat published the results of his researches into the properties of electrodeless discharges.[1] These researches became widely known when he published a later paper, in English,[2] in which he described capacitive electrodeless discharges excited by the electric field, and eddy electrodeless discharges excited by the alternating magnetic field, and drew a distinction between them. The first type, in which the elementary conductance currents are not closed and are continued by dielectric currents, he termed "E discharges": the second type with elementary conductance currents in the form of closed curves he termed "H discharges". He considered this distinction could be justified only if the wavelength of the exciting oscillations exceeded the dimensions of the cell containing the plasma; otherwise it was without meaning. Babat made a number of other points which are of interest. The higher the frequency of the generator the lower the current and power consumption required to form a stable plasma. The higher the inductive leakage resistance between the inductor and the "gaseous turn" then again the lower the current and power consumption for stability. (It is presumed that this means tight inductive coupling).

This paper was followed in 1961 by one by Reed[3] describing an inductively coupled plasma torch (ICPT) operating at atmospheric pressure on argon alone or mixed with other gases and powered by a 10-kW H.F. heating unit operating at a frequency of 4 MHz. The torch consisted of a quartz tube, with a brass base having a tangential gas entry, placed within the work coil of the generator. A pilot plasma was first formed by the insertion of a carbon rod into the torch, thus producing thermal electrons by the Joule heating effect of the alternating magnetic field. This provided the initial ionization of the argon, enabling coupling to occur and a plasma to form. Reed thought that a tangential gas entry was necessary in order to create a vortex which would cause some of the plasma to flow counter-current to the gas flow and so maintain the plasma. The equivalent circuit of this H discharge approximated to that of a transformer with the secondary closed by the gas discharge.

Reed followed this paper by another[4] in 1961 in which he described a torch with three concentric tubes with a centre powder feed which he used for crystal growing. There followed a paper[5] in 1962 describing many of the physical properties of these plasmas and suggesting their possible application as spectral sources for solids.

Reed made only passing mention in these and in a subsequent patent[6] of an annular plasma, finding that a doughnut plasma was formed at a frequency of 100 MHz and implying that this was undesirable. Although he claimed to inject solid particles into the plasma it would seem likely from the reviewers' experience that most of the material went round the outside of the plasma, forming a broad tail-flame.

A patent application was made in 1963 (issued later as U.K.[7] and U.S.[8] patents) by Greenfield and his colleagues for a torch adapted for use as a spectroscopic source. This consisted of three concentric tubes. The two outer quartz tubes were used to contain the plasma, and the inner tube, of borosilicate glass, was used to inject an aerosol through the plasma once this was formed. The torch was concentric with the work coil of the generator, which in this case was a 2·5-kW 36-MHz generator. Argon was fed tangentially into the inner quartz tube, the H.F. field applied by the work coil and a pilot plasma produced by a Tesla coil or graphite rod. Once the plasma formed, argon was introduced tangentially into the outer tube to stabilize the plasma and keep it off the walls of the cell. A hole was then punched through the flattened base of the plasma by the introduction,

through the injector, of an aerosol in argon. The aerosol entered the torch, passed through a tunnel of plasma, and a long narrow tail-flame resulted: it was this tail-flame which was used as a spectroscopic source.

This device was described in a paper[9] published in 1964 which constitutes the earliest reference to the actual use of this type of cell with an annular plasma and the utilization of the emission from the tail-flame remote from the intense continuous emission from the plasma. The same group recently stated that this cell was so successful that despite trying many other designs in the intervening decade they found no reason to change.[10] The particular merits of this torch stem from the annular shape of the plasma which, as discussed later, gives enhanced stability and sensitivity.

Orders of magnitude for detection limits[9] (D.L.) indicated that the source was capable of high sensitivity; no actual optimized D.L. were given. It was also established that the source exhibited freedom from matrix effects. The well-known interference of phosphorus and aluminium with the emission from calcium was completely eliminated. The introduction of gases, vapours, aerosols, liquids, powdered solids and slurries was accomplished.

This paper was followed in 1965 by an account[11] by Wendt and Fassel of an ICPT with laminar flow for which was claimed the advantage of less turbulence and perhaps greater stability than was obtained with vortex flow. This torch was used with a 3·4-MHz, 5-kW generator. It was further claimed that whereas tangential entry of the gases tended to cause sample particles to be thrown onto the walls of the cell, laminar flow did not. This is understandable for the solid type of plasma which they studied, where the sample aerosol flows round the outside of the plasma. In their torch the emission from a part of the plasma not in contact with the atmosphere was viewed through the quartz tube, and it was suggested that this reduced the N_2^+ radiation. D.L. were quoted and were very low. In view of the solid type of plasma employed it is probable that the use of an ultrasonic nebulizer contributed greatly to these low detection limits.

Greenfield *et al.*[12] described the effect of gases, gas-flows and power on the emission from their system. They found that the intensity decreased with the injector gas in the order $Ar > N_2 > air > O_2$. Oxygen had the advantage of removing C–C bonding. It was found that the intensity decreased with the plasma gas in the order $Ar\text{-}N_2 > O_2\text{-}Ar > He > Ar$, but that only a limited quantity of a diatomic gas, which requires to be dissociated, could be used with the power available (2·5 kW). It was concluded that a bigger generator was desirable to enable a plasma to be run on nitrogen alone.

High-speed cine films of the plasma demonstrated that, without smoothing in the rectification circuit, the plasma was extinguished in every half-cycle of the mains frequency. This effect could be used instead of a chopper to allow a.c. amplification in a simple filter photometer. It was suggested that several of these instruments could be grouped around a plasma, allowing simultaneous determination of a number of elements. A further suggestion was that a stroboscope could be used to select one stage in the growth of the plasma and possibly select a particular source temperature.

Later, in 1965, Greenfield *et al.* published[13] some exploratory work on a larger (6·0 MHz, 25 kW) generator using a cell and plasma configuration similar to that previously used. It was shown that the spectra changed from those expected from a flame to those obtainable from a spark as the power in the plasma was increased up to 6·4 kW, measured by a calorimetric method.[14] D.L. were given for a number of elements, and were one or two orders of magnitude better than those obtained with a d.c. arc. The need to find the correct observation height in the tail-flame in order to obtain maximum emission was noted. Practical analyses with the plasma torch were reported for the first time: these were the determination of aluminium in a phosphate rock with a 3-kW, 36-MHz generator and an Optica CF4N1 spectrophotometer, and the determination of phosphorus in phosphate rock with a 25-kW, 6-MHz generator and a Hilger and Watts Large Quartz Spectrograph. Coefficients of variation (COV) of 5% for aluminium at a level of 0·9% and 2·75% for phosphorus at a level of 15% were quoted.

Dunken and Pforr[15] used a three-tube torch similar to that of Greenfield[12] with a 1–2-kW, 40-MHz generator and an ultrasonic nebulizer. Liquids and solids were introduced into the plasma by means of an argon blast but it was not clear if the plasma was annular in shape. The atomic and ionic lines of the elements introduced were found in the spectrum and showed very good signal-to-background ratios.

The torch described by Britske *et al.*[16] consisted of a single tube having side-arms with quartz windows, powered by a 4-kW, 40-MHz generator. This torch had the disadvantage of fixed viewing positions and therefore any optimization of position would be fortuitous. The plasma was described as a long filament (15 cm) surrounded by a weak glow; when the power was reduced the filament disappeared and the glow filled the tube uniformly. Only easily excited lines were observed in the glow, while lines with high excitation energies were excited in the filament. This discharge differs markedly from most ICPT and was later[17] compared with a capacitive discharge. The stability was reported good, with only 1–2% fluctuation, but the analytical sensitivity was low.

An ultrasonic nebulizer with a facility for sample changing was used in conjunction with a 2·5-kW, 36-MHz generator and plasma torch of three-tube design, by Hoare and Mostyn.[18] The top of the outer tube was cut at an angle of 45° and it was claimed that this improved the stability of the gas-flows and led to more effective viewing of the emission. The authors also described a powder-injection system.

Using solution techniques, they determined boron and zinc in nickel alloys. The powder system, whilst very effective for qualitative work, was not very successful quantitatively. Freedom from matrix effects was reported.

A practical application of the plasma torch about this time, was to the determination of wear metals.[19] The oils were injected, in a solvent, by means of a motor-driven syringe and a pneumatic nebulizer. Aluminium, iron and nickel naphthenates were used as standards.

A two-tube torch was used by Mermet and Robin,[20] who demonstrated that greater sensitivity was obtained when an aerosol was injected into the plasma by means of a water-cooled injector, than when fed into the plasma gas stream. They found that with a low injector-gas velocity, the aerosol was entrained on the periphery of the plasma, while at higher velocities it penetrated the discharge to give a darker zone at the centre. Thus it seems at these higher velocities to be an annular plasma. They also found that the amount of aerosol influenced the electrical properties of the plasma so that the power dissipated in it was dependent on the rate of generation of aerosol. The reviewers would not have expected this if the aerosol passed through the tunnel of an annular plasma. There are two observations which might explain the anomaly. The first is that the frequency used (1·6 MHz) is unusually low, so that the skin-depth is unusually large; the tunnel therefore may not be electrically screened. The second observation is that with an injector-gas flow-rate of less than 0·8 l./min, the aerosol all flowed round the outside of the plasma. At 1·0 l./min, the dependence of power on aerosol uptake was very marked, but at 1·5 l./min it was much less so. It might be, therefore, that with these injector-gas flow-rates, only part of the aerosol traverses the tunnel and the rest flows round the outside and that a higher injector-gas flow-rate would be required to ensure that all the aerosol traversed the tunnel. The authors also commented on the relative efficiencies of ultrasonic and pneumatic nebulizers and the effect of changing the gas-flow through them.

Veillon and Margoshes[21] were the first to report the presence of matrix effects. They used a two-tube torch similar to that of Fassel[11] but omitting the central injector, which they claimed did not affect the performance of the torch. Clearly the significance of an annular plasma was not appreciated. It seems to the reviewers that the most likely explanation of the matrix effects is that the electrical properties of the discharge were modified by the sample aerosol flowing round it, thereby altering the power dissipated and hence the temperature. It is also possible that the temperatures encountered in this external path were insufficient to dissociate refractory species.

The axial distribution of temperature, electron concentration and argon continuum was studied along with the analytical lines and detection limits of aluminium, calcium, cobalt, chromium, iron and silicon by Bandyukova *et al.*[22] They used a single-tube torch operating on argon, with a 4-kW, 40-MHz generator.

An account of the ultrasonic nebulization of molten metal into the (previously described) torch was given by Fassel and Dickinson,[23] now using a variable-frequency generator operating at 30 MHz, 2·5 kW (nominal). With this equipment the authors determined arsenic and copper in tin-base solders.

In 1969 Dickinson and Fassel[24] published an account of their continuing investigations into the analytical applications of plasma torches. They now clearly recognized the importance of an annular plasma and suggested that increasing the frequency of the generator would produce an annular plasma because of the skin-depth effect. It was also suggested that introduction of material into the plasma produced a mismatch between the plasma and generator, thus decreasing the amount of power transferred to the plasma. The use of a coupling unit was advocated. This enabled them to get three times as much material into the plasma as was possible with their previous equipment. These authors commented on the matrix effects reported by Veillon and Margoshes and suggested that these were due to the experimental conditions used by these workers. These comments were expanded recently by Larson *et al.*[25] who also extended the work of Greenfield *et al.*[9] on freedom from matrix effects.

A new departure was that of Kleinmann and Svoboda[26] who used a low-power (120–220 W) generator at 40 MHz to power a single-tube torch with separate vaporization of the sample. In a later paper[27] it was demonstrated that this low-power plasma was not in local thermodynamic equilibrium, the electron temperature (11,400 K) being much higher than the gas temperature (about 2200 K). The electron density was $4 \times 10^{14}\ \mathrm{cm}^{-3}$.

Two papers by Truitt and Robinson[28,29] described the introduction of organic material into a torch similar to that of Wendt and Fassel[11] but with a long outer tube. They also described a number of plasma conditions and claimed this torch gave a lower continuum and greater freedom from band structure than that of Greenfield *et al.*[9] This was disputed by the latter workers[30] (with experimental evidence in the form of recorder tracings of spectra recorded with torches of various lengths) who suggested that the plasma conditions described by Truitt and Robinson were probably peculiar to the equipment used. The plasma did not appear to be annular and it was reported that the torch burned if power above 1·7 kW were used, a consequence of its length, no doubt. In the earlier paper, 3064 Å OH bands, Balmer series H_2 lines, 2800 Å OH, N^{2+}, N^-, N^+, NO and N_2^+ were found in the spectra. In the later paper, following the introduction of typical hydrocarbons, four molecular fragments were found in the spectra. These were C, H, C_2 and CN. Under their experimental conditions the point of introduction of the sample made no difference to the emission. The addition of nitrogen increased the CN and decreased the C line intensity. Oxygen diminished CN and C_2 band intensities (because of oxidation to CO or CO_2). When CO or CO_2 was added their emission bands were not noticed. As well as the expected increase in emission from C and Ar, the intensities of the CN and C_2 band systems increased with power (this is undoubtedly peculiar to the particular system used, since increased power usually causes increased dissociation).

In 1970, Pforr and Aribot[31] determined calcium, magnesium, titanium, iron and aluminium in quartz, using a powder-injection system. Borms *et al.*[32] compared an ICPT with flame emission. They had difficulty in operating their ICPT owing to lack of stability, but reported D.L. of 0·01–1 ppm for a number of elements. They also reported that their analytical curves were linear over three orders of magnitude, that 1000 ppm of aluminium, sodium and phosphate did not interfere and that a 1000-fold excess of calcium gave enhancement.

In a short review on plasma sources Greenfield[33] gave a table of spectra observed with a plasma torch operating with nitrogen, argon and oxygen coolant gases. He also listed the relative exposure-times to give comparable background in parts of the spectrum free from banding; these were, for the different coolant gases, nitrogen 60 sec, oxygen 30 sec and argon 7·5 sec. Under favourable conditions COV of the order of 0·3% were obtainable.

A demountable, laminar-flow torch was used by Dagnall *et al.*[34] to experiment with the injection of powders into an annular plasma. Nitrogen was used in the coolant. They found that only one direction of winding of the work coil (the opposite to that of the gas vortex) would allow coupling with the H.F. field.

Kleinmann and Polej[35] reviewed capacitively coupled and inductively coupled high-frequency plasma torches and microwave torches, from the point of view of the requirements of a source and the type of discharge. In commenting on tangential and laminar flow torches they, like Fassel,[11] overlooked the fact that particles are not thrown onto the torch walls by vortex flow if they are fed through the centre of an annular plasma.

Triché *et al.*[36] introduced powders into a single-tube torch. The system was not quantitative and they had difficulty in penetrating the solid plasma. An attempt was made to predict the position of maximum emission according to the ionization potential of the element under examination. They found that they had to take into account the excitation potential as well. In a later paper[37] Triché and his colleagues examined the effect of mass transfer on the emission.

A 6·6-kW, 5·4-MHz generator with a three-tube torch and a water-cooled metal injector was used by Souilliart and Robin[38] to determine rare earths in an iron matrix; they also gave tables of D.L.

The extreme sensitivity and versatility of the ICPT was demonstrated in a paper by Greenfield and Smith,[39] who in 1972 showed that determinations at the ppm level could be carried out on microlitre quantities of sample. Limits of detection for barium, $1{\cdot}7 \times 10^{-10}$ g, and aluminium, $1{\cdot}1 \times 10^{-9}$ g, were obtained with precisions between 3 and 5%.

In 1972, Boumans and de Boer[40] compared an ICPT with an argon-separated nitrous oxide–acetylene flame and gave D.L. for an argon plasma. They found the stability of the plasma to be comparable with that of the flame. Theoretical reasons were given for their choice of a free-running oscillator rather than a crystal-controlled generator. They pointed out that the lowest D.L. was not always associated with the operating conditions that gave the highest line-to-background ratio. A compromise must be sought in both the choice of the carrier-gas flow and the observation height when different elements are examined simultaneously. For some elements it was found that both line-to-background ratio and noise level tended to decrease if the observation zone was chosen lower in the tail-flame. Since a decrease in line-to-background ratio and a decrease in noise level have opposite effects on the D.L., it transpired that D.L. of the elements considered did not vary markedly with the location of the observation zone. These authors also defined limits of detection, representing the curve in the vicinity of the D.L. as a straight line. The authors of this review take leave to doubt the universal validity of this assumption at very low D.L.

By using a monochromator with a nitrogen path between it and a plasma torch, Kirkbright *et al.*[41] were able to obtain D.L. of 1·7 ppm for sulphur at a wavelength of 182·04 nm and 0·15 ppm for phosphorus at a wavelength of 214·91 nm. The linear range for these two elements extended over five orders of magnitude, to above 1000 ppm. Soil extracts were analysed for phosphorus and COV of 3–7% were obtained.

Fassel[42] reviewed "Electrical Flames" and concluded that the D.L. which could be obtained with ICPT were, with few exceptions, comparable with, or greatly superior to, the best which could be obtained with flame atomic absorption, emission or fluorescence. He also confirmed that a plasma similar in configuration to his own and that of Greenfield[9] was free from the matrix effects experienced by Veillon and Margoshes.[21]

In an extension of their previous work,[41] Kirkbright *et al.*[43] determined iodine, mercury, arsenic and selenium. They reported some spectral interferences and also some chemical interferences occurring in the nebulizer.

Alder and Mermet,[44] using a demountable three-tube torch, observed all the expected ArI lines but no ArII lines. The highest energy-level from which radiation was observed was about 15·4 eV. When methane was injected, atomic C and H were observed, together with C_2 and CN, but no emission from CO or CH (see refs. 28, 29). C_2 was seen in cooler regions of the tail-flame but not in the hot regions (see ref. 13) indicating decomposition of the molecule. They commented that since the bond strength of C_2 is 6·25 eV and that of CH 3·47 eV they may be too unstable to form. No enhancement of zirconium or hafnium emission was found in an argon-methane plasma compared with one of pure argon; this implies that reduction of the oxides by atomic carbon does not take place and that the temperature and enthalpy of the plasma are sufficient to break strong oxide bonds. Similarly when lanthanum was introduced into an argon plasma, no bands due to lanthanum oxide were observed. Sulphur dioxide, hydrogen sulphide, sulphur hexafluoride, bromine, chlorine and phosphorus were also introduced into the plasma, but the system was not suitable for determining sulphur or the halogens.

Boumans *et al.*[45] considered the design of a generator and torch in a paper which is referred to in the section on oscillators.

Scott *et al.*[46] used a three-tube torch with vortex stabilization without a "plasma gas" in what is described as a compact system. The aerosol was produced by a pneumatic nebulizer and desolvation was not used. They hoped to replace the single-channel spectrometer used, by a thirty-channel instrument. With an input power of 1·3 kW one might presume a power in the plasma of between 650 and 900 W. Temperatures of 5000 K, at 18 mm above the load coil, were reported. Linear calibration curves were obtained over concentration ranges of five orders of magnitude.

Using a similar generator to Boumans and de Boer[40] and a horizontal configuration of a similar three-tube torch with a wide-tube injector, Kornblum and de Galan[47] measured the radial distribution of temperature. They found that desolvation of the aerosol was mandatory as a 2-kW plasma could not be sustained with a high input of molecular compounds. This is so much at odds with the observations of other workers[10] that the geometry of their cell and injector must be at least a contributory factor in this phenomenon. The reviewers suspect the use of the wide-bore injector.

Dreher and Frank[48] describe a demountable torch operating at atmospheric pressure in argon, which they used for emission spectroscopy in the vacuum ultraviolet. The source was totally enclosed, with no gas flow. The power was very low (250 W) and the cell had to be dismantled and cleaned after each exposure.

Kirkbright and Ward[49] constructed ideal models for an ICPT and for a flame. They concluded that the self-absorption effects were much less in a plasma than in a flame and that the sensitivity was much higher. As a consequence of the former the plasma had a greatly extended linear working range. Other deductions made were that the maximum energy supplied to the analyte particles was 2·3 and 0·001 J for the plasma and the flame respectively, that a plasma can handle a concentration range of five or six orders of magnitude against three for the flame and that concentration ranges for the plasma can be increased by reducing the sample-uptake rate. Cu, Fe, Mg, Mn, Ti and Zn were determined in aluminium alloys with a flame and with a plasma. Non-linear calibration curves were obtained when using a flame without dilution. Precisions of the order of 5% were obtained with the plasma, as against 10% with a flame. Kirkbright reported this work at a later date in lecture form.[50]

Fassel and Kniseley[51] published a re-assessment of emission spectroscopy with ICPT as against flame-excited atomic absorption, fluorescence and emission spectroscopy, and concluded that ICPT were superior on most counts. They agreed with Boumans and de Boer[40] that the ICPT–optical emission spectrometer system "constitutes a most promising excitation source for simultaneous multi-element analysis of solutions".

Such a system, which has been in everyday use for practical analysis for four years, was described[10] in February 1975. The authors give details of an ICPT coupled to a 30-channel direct-reading spectrometer with fully automatic sequential sampling and read-out. The read-out is processed by an off-line computer. With this equipment they are able to do simultaneous multi-element analysis at both trace and assay levels on each exposure.

Some important points in its design are discussed.

Low-pressure inductively coupled plasmas

Papers have appeared describing ICPT operating at low pressure. One of these[52] describes a plasma, powered by a 42–60-kW, 0·54-MHz generator, which discharges into a vacuum chamber. In action it appears to be akin to an ICPT version of a plasma jet. The authors measured the electron density, excitation temperature and the gas temperature in the jet region and in the jet nozzle. The gas temperatures were substantially lower than the excitation temperature, indicating divergence from LTE, which is, of course, difficult to achieve at low pressure.

Runser and Frank[53] designed what they call a "radio-frequency electrodeless differential pressure cell" for studying the emission spectra of organic molecules. (All frequencies from 0·01 up to 30,000 MHz are radio-frequencies. Most ICPT operate in the range 3–50 MHz and are more aptly described as high-frequency ICPT.) Pressure, power and flow-rate studies as well as gas measurements were made with this cell. Low and medium resolution spectra of aromatic and non-aromatic chlorinated hydrocarbons and chlorinated pesticides were discussed.

Inductively coupled plasmas in atomic-absorption spectroscopy (AAS)

Wendt and Fassel[54] first reported the use of an ICPT as an atom reservoir in AAS. They used a multi-pass system with their previously reported torch.[11]

Low backgrounds were reported and some matrix interferences were also removed, such as the effect of phosphorus and aluminium on the absorption spectrum of calcium.

In 1967, Britske *et al.*[16] briefly mentioned the use of their single-tube torch as an atomizer in AAS.

Bordonali and Biancifiori,[55] also in 1967, described an ICP for use as an atomizer in AAS. Powered by a 10-kW, 5-MHz generator, the cell consisted of a single tube with a branch tube having water-cooled quartz windows. They claimed temperatures up to 20,000 K, the possibility of varying the high-temperature lifetimes of atoms, control of gases in the plasma and independence of maximum temperature with the composition of the gases. These authors published another paper in 1968 on the same subject[56] and in 1969 Bordonali, Biancifiori and Donato[57] described the determination of ytterbium in rare earths. These authors with Morello[58] also determined Zn, Mn, Pb, Cr and Cu in ferrous metals. A U.S. patent was granted to Bordonali *et al.* in 1970.[59]

Greenfield *et al.*[60] designed and used a T-shaped torch as an atomizer in AAS. They claimed this to be a simpler method of achieving a long path-length than the use of multi-pass systems. They also used an ICP as a source in AAS. Some experimental results were given for copper in the atomizer mode and calcium, magnesium and copper in the source mode.

Robin[61] determined Al, La, Mg, Nb, Ta, Ti, Zn and W by an ICP used in the AAS mode. He reported that satisfactory results were obtained for aluminium and magnesium but that better results were obtained with a nitrous oxide–acetylene flame in AAS or by an ICP in emission mode. An ICP in emission mode was also better than a flame in AAS mode. Souilliart and Robin[38] also reported results obtained by an ICP in the AAS mode.

The authors of the present review can, from their own experience, see little, if any, advantage in the use of an ICP in atomic-absorption spectroscopy.

THE HIGH-FREQUENCY GENERATOR

Type of oscillator

The choice of oscillator lies between a free-running oscillator, an oscillator with capacitive tuning and a crystal-controlled oscillator. In the first type, the frequency of the oscillator is fixed by the values of the components in the tank circuit, which includes the work-coil. These values are modified by any changes in plasma impedance and in the coupling of the plasma to the work-coil. Variation of these parameters affects the frequency of operation but has only a small effect on the power transfer. No tuning is necessary. With the second type, the output circuit containing the work-coil must be tuned by a variable capacitor to the frequency of the tank circuit. If there is a change in impedance in the plasma any self-compensating change in frequency may be less than in the case of the free-running oscillator, depending on the degree of coupling of the two circuits. In the third type, the oscillator valve is driven, by a crystal, at a fixed frequency and any change in impedance of the plasma will produce a serious loss of power unless the output circuit is retuned.

Some workers[10,40] in this field argue in favour of a free-running oscillator whereas others[46] favour a crystal-controlled unit. By arcane reasoning Bouman and his colleagues[45] claim that the free-running generator which they use is self-compensating for small changes in impedance.

Dickenson and Fassel,[24] using a crystal-controlled oscillator, find that the introduction of sample material changes the electrical character of the plasma and therefore the effective impedance of the load-coil. This results in mismatching, causing instability or extinction of the plasma unless the output circuit is retuned. On the other hand, Greenfield *et al.*[10] offer circumstantial evidence for believing that there is no change of impedance when aerosols are injected through an annular plasma in their system, and practical evidence that there is little change in the frequency of their free-running oscillator. (Thorpe[62] has also commented that the addition of an injector gas through an annular plasma did not change the plate power or the grid current, indicating that the plasma was not affected.) Unlike Scott *et al.*[46] with a crystal-controlled oscillator, they need no complicated starting procedures for the equipment nor do they have the difficulty sometimes[24] experienced in injecting large amounts of liquids and do not need to desolvate except to improve sensitivity. Boumans *et al.*[45] with a free-running oscillator, also seem to experience little difficulty in starting or in running the apparatus, but they desolvate the aerosol. It can be no more than conjecture, but it is possible that other factors, such as the amount of power in the plasma and the design of torch, may be the cause of these discrepancies between workers of experience in this field, rather than the type of generator used. It must be said however, that, all other conditions being equal, complicated tuning procedures are not desirable if the equipment is ultimately to be operated by technicians.

Power

A study of Table 1 shows that most workers have used generators of between 2 and 5 kW (nominal). (50–70% of this power will find its way into the plasma, depending on the coupling efficiency).[2,3,10,62] There has been a recent trend by at least two groups of workers[40,46] towards low-powered (1–2 kW) compact generators, on the grounds of convenience in use. Greenfield *et al.*[10] work with a large (15 kW) generator and cite a number of advantages more cogent than easy availability[46] or licence to work inefficiently.[63] Amongst these advantages are greater sensitivity, frequent improvement in precision, elimination of band spectra and elimination of chemical interferences. To these advantages may be added the fact that higher powers enable diatomic gases to be used with more

Table 1. Typical generating equipment, torches and operating parameters

freedom in the torch; furthermore the torch is not easily extinguished when high material loads, such as powders, are put through it. A disadvantage is that these generators are expensive and large, although the use of solid-state electronics may reduce their size.

Frequency

It now seems to be accepted by the principal workers in the field that it is desirable to use an annular plasma. Production of an annular plasma is often attributed[24,40,45,46] to the skin-depth effect whereby, as the frequency increases, the current is confined to a thinner skin on the circumference of the plasma. Thus it is claimed that frequencies of the order of 30–50 MHz are desirable.

Greenfield *et al.*[10] have shown that the central hole can be produced as easily in a plasma at 7 MHz as in one at 36 MHz and have shown photographs demonstrating that the two resultant annular plasmas are very similar. These authors are of the opinion that the tunnel effect is more a function of injector gas-flow than of skin-depth, and that since it is easier and cheaper to obtain high powers (which they favour) at lower frequencies, the optimum frequency is probably quite low, perhaps in the range 5–10 MHz. Some discussions of the optimum frequency (*i.e.*, the frequency at which a specified temperature is obtained with the minimum power) are referred to in the section on temperature. In any case, the frequency chosen should be high enough for the skin-depth to be substantially smaller than the plasma radius,[5] both to ensure that the tunnel of an annular plasma is electrically screened so that the sample will cause only minimal variations in the plasma impedance, and to keep the volume over which the power is dissipated reasonably small so that the power density required to sustain the discharge does not demand excessively high power inputs. An optimum ratio of plasma radius to skin-depth has been suggested,[46] but doubts have been expressed on the validity of the assumption of the plasma's similarity to a metallic cylinder[64] and on the validity of the expression for the magnetic field appropriate for a very long coil when applied to a short one.[10] The application of the optimum ratio to torch design has sometimes led to an unstable plasma.[10] Table 1 shows some of the generator frequencies which have been used, along with other experimental details.

INTRODUCTION OF LIQUIDS AND SOLIDS INTO THE PLASMA

The plasma

There is ample attestation[4,42,62,65,66] to the impenetrable nature of plasmas and the tendency for injected streams of material to by-pass rather than penetrate them. This tendency to deflect injected flows has been explained[67] in terms of excess of magnetic pressure inside the plasma.

Measurements of the radial distribution of the magnetic field in the plasma, by means of magnetic probes, have shown it to be at its greatest near the tube walls, falling to a low value in the centre.[68,69] Similarly the magnetic pressure exhibits this drop towards the centre. Chase[67] has pointed out that this drop from the boundaries to the axis will lead to an inward radial flow of plasma by "magnetic pumping". This will build up the kinetic pressure at the axis and cause an axial flow of plasma to both ends from whence it will return to the outer boundaries. In this way vortex rings will be formed, superimposed on the main axial flow and the thermal expansion of the gas.

Chase[70] later described how he had measured the pressures in and around a vortex-free plasma by means of probes and a micromanometer. He also obtained flow visualization and gas velocities by photographing injected solid particles; the thrust calculated from a model of the plasma was in agreement with the measurements. He concluded that in order for the injector flow to penetrate the plasma, the velocity must exceed the magnetohydrodynamic (MHD) thrust velocity. For an argon plasma at 10 kW a jet of velocity of 15 m/sec completely penetrated the plasma, whereas with a velocity of 3 m/sec it was completely deflected. Once the injector velocity is greater than the MHD thrust velocity an annular or tunnel plasma is formed and the injector stream passes through the tunnel, forming a long narrow tail-flame. It thus becomes possible to view the emission from the tail-flame remote from the intense continuum of the plasma. This gives increased sensitivity. In addition, since the sample particles flow through a tunnel which is electrically screened, they do not influence the plasma impedance. This leads to improved stability. Since this principle was first established[9] it seems to have been recognized[24,40,42] as the system giving the greatest sensitivity and freedom from matrix effects. The existence of the MHD thrust velocity may vitiate the assumptions on which some estimates[46,49] of residence times of sample atoms in the plasma have been based. In particular it would be expected to decrease the residence time in the tail-flame.

Plasma cell

It has been suggested[10] that it becomes easier to form an annular plasma by the introduction of a second gas stream which flattens the base of the ellipsoidal plasma and facilitates the entry of the injector stream. The torches used by most workers have two concentric silica tubes with a central injector. The gas streams in the outer and inner tubes have become known, respectively, as the coolant and plasma gases, although the demarcation between them is slight, since either can be turned off without extinguishing the plasma and both must contribute to the plasma process. Indeed, Scott *et al.*[46] appear to have dispensed with the plasma gas-flow although retaining its tube.

Greenfield *et al.*[10] found that most of the dimensions of the cell are unimportant as the gas velocities can be changed by altering the flow-rates. However, they emphasize that the bore and position of the injector are important. If the jet is too large or placed too far away from the plasma the resulting "fan" will not penetrate the plasma. They stress the greater importance of the dynamics of the gas flow rather than that of the skin-depth in the production of an annular plasma. This view is supported by Thorpe.[62]

Nebulizers

Most, if not all, workers introduce liquids into the plasma in the form of aerosols. These aerosols are produced either by the ultrasonic breakdown of the liquid surface or by use of pneumatic forces. In the former case the liquid may be directed onto the surface of an ultrasonic transducer[40] or the ultrasonic radiation may be focused through the liquid on to its surface.[11] A pneumatic, venturi nebulizer of the scent-spray type can be arranged to spray directly through an annular plasma,[7] or to spray into a separate chamber (often a cyclone chamber to remove the heavy droplets) and the aerosol piped to the injector in the plasma torch.[39,71] Direct injectors have to be of all-glass construction with long, fine, capillary tubes and are somewhat delicate and prone to damage.

There is little doubt that ultrasonic nebulizers give finer aerosols than do the pneumatic type and more material is conveyed to the plasma in unit time.[20] This is evidenced by the markedly superior limits of detection which can be obtained with these nebulizers. However, they have one marked disadvantage: sample-changing is difficult[20] and generally necessitates washing out the cell after each sample. This precludes automatic operation. Attempts have been made to overcome this problem by the use of pumps to change the sample.[33,45,72] Another approach was that of Hoare and Mostyn[18] who used a multicell sample vessel.

As might be expected, if the solvent water molecules are removed by the use of a heated desolvator, an increase in sensitivity results. Ultrasonic,[11,40,72] and pneumatic[73] nebulizers have been built with desolvators. Some workers[45] have found it essential to desolvate, otherwise the plasma may be extinguished, since energy is removed by the dissociation of the water molecules. Others[10] find no such difficulty and are able to introduce relatively large quantities of solvent molecules. The reason for this discrepancy may lie not only in the power available, but in the geometry of the injector and the cell. Several[10,40,46] workers have reported on the possibility of memory effects resulting from the use of desolvation techniques. Greenfield and Smith[39] have demonstrated that it is possible to inject 1–25 μl of solution from a micropipette or a syringe into a pneumatic nebulizer and for the resultant plug of aerosol to be injected into the plasma. They determined aluminium, chromium and copper at the ppm level in 25-μl

samples of oil, diluted 1:2 with xylene, and aluminium and magnesium in organophosphorus compounds. They also demonstrated the presence of ppm quantities of metals in μl samples of blood. Subsequently, Kniseley[74] also determined metals in blood by this technique.

A useful review of nebulizers is given by Mavrodineanu and Boiteux.[75]

Introduction of solids

The main difficulty in introducing powdered solids into a plasma is that of ensuring a constant, uniform feed of the material. It is doubtful whether this problem has been solved in a completely satisfactory manner. Another difficulty is that of ensuring that all the material goes through the plasma and at such a rate that it is all volatilized. These problems are not critical in crystal-growing, a field in which powder-feed to a plasma is successfully used.[4]

Greenfield *et al.*[9] used a direct pneumatic nebulizer to inject powders and slurries through an annular plasma and reported the tail-flame as being intense and the plasma stable. They did not carry out any quantitative work. Hoare and Mostyn,[18] using a similar torch, injected powders into what may have been an annular plasma from an agitated cup by upward gas displacement. The method was reported as qualitatively successful but it seems that quantitative results were not entirely satisfactory, in that the preparative history of the sample influenced the results obtained. Pforr[31] also used a powder system similar to that of Hoare and Mostyn. Lifshits *et al.*[76] fed iron and aluminium oxides into a plasma, *via* a central tube, in a stream of argon. They claimed a precision of 5–10% for the determination of impurities in these oxides.

Dickenson[77] injected powders into an annular plasma from a fluidized bed and this work was reported upon by Fassel.[42] Later, Dagnall *et al.*[34] used this technique and obtained COV of 6·5 and 10%, respectively, for twenty 10-ppm additions of beryllium and boron oxides to a magnesium oxide matrix. They also used a swirl cup similar in principle to that of Hoare and Mostyn.[18]

All the methods of introducing powders into plasmas suffer from segregation effects to varying degrees, because of the different densities and particle sizes of the powders under investigation. They also suffer from agglomeration and impacting of the powders. First-hand experience of the problems leads to the impression that the partial success so far gained has been obtained on carefully selected matrices, and that a general, practical solution to the several problems of injecting powders into plasmas and performing quantitative analysis, has yet to be found.

Separate vaporization

Kleinmann and his fellow workers[26,27] vaporized the sample before introducing it into the plasma; solids were volatilized by ohmic heating from graphite supports held by tantalum holders. They found that the emission was very dependent upon the shape and temperature of the support. Detection limits were very much better than with the d.c. arc. Kleinmann later[78] investigated the effects of pad temperature, of the molecular nature of cadmium and lithium compounds and of the presence of sodium, acids and complexing agents, on the spectral line intensity.

Nixon *et al.*[79] described a separate vaporization method with a tantalum filament and claimed to be able to examine 20–30 samples/hr. They also reported D.L. 2–3 times better than those obtainable with nebulized samples.

Bazhov and his colleagues,[80] in a method which may be thought of as a direct volatilization system, designed a horizontal plasma torch in which they introduced powders into the plasma in small graphite crucibles. They used a 40–50-MHz generator with 1·5-kW output power to form the plasma, which was initiated by a second similar generator giving a flash discharge between two electrodes. At an argon flow-rate of 7·5 cm/sec the discharge was ring-shaped. At 5 cm/sec it was egg-shaped.

Morrison and Talmi[81] described the microanalysis of solids by atomic absorption and emission spectroscopy. They used an H.F. furnace; in this device the sample was volatilized from a graphite crucible by induction heating, and excited in a helium plasma formed by the same field.

Temperature and other physical properties

Reed[3] calculated the local field strength from the properties of the plasma and thus obtained $\Delta T/T$ where ΔT is the difference between electron and mean gas temperatures. A value of 10^{-4} was obtained and from this and other circumstantial evidence he presumed that the plasma was in LTE. He then went on to determine the temperature of the plasma spectrographically. He calculated the variation with temperature of the intensity of an argon line, and noted that the maximum intensity would be produced at a temperature of 15,000 K. He then found by an Abel inversion that the maximum emission occurred at a position off the axis. He concluded that this region was at the temperature of 15,000 K and that the temperature at the centre would exceed this. It could be estimated by the ratio of the intensity of this region to the maximum intensity.

Babat,[2] on the basis that the energy flow is directed from the central part of the discharge towards its periphery, predicted that the temperature of the gas should have its maximum value on the tube axis and its minimum value near the walls.

Gol'dfarb and Dresvin,[82] however, argued that the electron temperature T_e and the gas temperature T_g become equal in a d.c. arc at a current of 10 A and this current corresponds to an electron density (n_e) of $\approx 10^{16}\,\mathrm{cm}^{-3}$. They went on to compare an arc with an ICP and obtained an electron density of $(0{\cdot}65\text{–}1{\cdot}2) \times 10^{16}\,\mathrm{cm}^{-3}$ over the major part of the plasmoid. They inferred that T_g and T_e were equal in their plasma, so this was in local thermodynamic equilibrium. They also concluded that the maximum temperature of the plasma was 9200–9700 K, the plasmoid had sharp boundaries at the tube walls and along the vertical, the temperature gradient at the tube walls was 5×10^4 deg/cm, and in the region near the axis, the temperature and electron density decrease. The highest temperature and electron density occurred about midway between wall and axis (at 0·4–0·6 of tube radius).

The existence of a maximum temperature (about 9000 K) at an off-axis position was also argued by Johnson[83] from a variety of temperature measurements. The explanation of this is that most of the power is dissipated in the outer skin-depth and if the plasma radius exceeds this, the centre is heated largely by radiation and thermal diffusion from the outer layer. Thorpe[62] and Eckert[64] also criticised Reed's values of temperature.

Gol'dfarb, Goikhman and Dresvin,[85] and Gol'dfarb and Goikhman,[86] in two similar papers, determined temperature spectroscopically on the basis of absolute intensity of the atomic spectral lines, by the recombination continuum, by the molecular bands and by the H(β) line broadening. An ICP was used in argon, nitrogen, oxygen and air. It was found that the temperature was 6800 K in nitrogen; between 8300 and 8900 K in argon; 8650 and 9100 K in oxygen; 7200 and 7600 K in air, the electron densities being 2×10^{14}, $3{\cdot}5 \times 10^{15}$, $5{\cdot}1 \times 10^{15}$ and $1{\cdot}2 \times 10^{15}$ respectively. The lengths of the plasma were 2·6, 4, 2 and 2·7 cm respectively. There was a decrease in temperature towards the axis.

Marteney *et al.*[87] determined the temperature of an argon plasma to be approximately 8500 K by the measurement of line intensity ratios by the method of Boltzmann. They confirmed this figure by the measurement of absolute argon and argon-ion continuum intensities. Radial measurements indicated a slight rise in temperature midway between wall and axis with the lowest temperature at the walls. Kasai *et al.*[88] measured the radial temperature distribution of a plasma by Boltzmann plots using line-to-line, line-to-continuum and continuum-to-continuum ratios, and found an off-axis peak. They reported a temperature of 12,000 K on the plasma axis.

Raizer,[89] on the basis of the results of many investigations at several kW power, found that the temperature of an argon plasma reaches 9000–10,000 K and that the distribution of temperature has in general a plateau at the centre of the tube, dropping off sharply near the wall. The plateau is not quite flat, however, and in the central part there is a slight dip of several hundred degrees, thus confirming the results already mentioned.[82–88] Raizer also measured the electron densities and showed that the state of the plasma at atmospheric pressure is close to thermodynamic equilibrium. He gave calculations of the plasma temperature, ohmic resistance and inductance as functions of the current in the solenoid, based on an infinitely long solenoid and metallic cylinder model, which were in fair agreement with experimental data. He concluded that to a good approximation the plasma temperature does not depend on the frequency, or on the radius of the tube, but is determined only by the number of ampere-turns and the electric and thermal conductivities of the gas, provided that the number of ampere-turns is not large and that the temperature does not exceed 13,000–15,000 K. One important conclusion reached by Raizer was that the power necessary to reach a given temperature increases quite rapidly with increasing temperature, even ignoring losses by radiation. He suggests that W, the power input to the plasma, is proportional to T^{γ} where $\gamma = 2{\cdot}5$–3. In addition, the power required increases rapidly as a result of the increasing radiation loss. It was not clear which of the two factors plays the decisive role.

Pridmore-Brown[90] came to roughly similar conclusions on the radial distribution of temperature. However, his calculated temperatures did seem to show some dependence on frequency and on the radius of the tube as well as on the number of ampere-turns.

Spectral measurements by Trekhov *et al.*[91] also tend to confirm the work of these investigators, *i.e.*, a temperature plateau of 9000–10,000 K with a slight dip in temperature towards the centre of the plasma. Also, the coincidence, within experimental error, of the ionization temperatures from the continuum and from the broadening of the Hβ line, and of the excitation temperatures, with the calculated temperatures, led these authors to believe the source was in LTE. Much the same pattern emerges from the work of Eckert[84] and Stokes.[92] Apsit[93] attempted to establish LTE in an ICP in steady state, by a relaxation method which involved a study, with time, of the decaying plasma after switching off. He found a two-stage drop in electron temperature, first a loss of kinetic energy of the electrons rather than of the atoms and heavy ions and, in the second stage, recombination and cooling of the gas. The first stage in argon lasted $\sim 10^{-7}$ sec and material changes in the gas temperature occurred over a period of $\sim 10^{-3}$ sec in the second stage. He concluded that the electron temperature can exceed the gas temperature by as much as 2500–1500 K in discharges of 1–10-kW power, the difference decreasing slightly as the power was increased. He also found that (T_e–T_g) in each cross-section of the discharge reached a maximum at the periphery and dropped rapidly towards the axis so that the central region is nearer to LTE than the outer. He found that when a gas was forced through the tube, (T_e–T_g) along the discharge axis became asymmetrical with respect to cross-section and the largest difference in T_e appeared on the side at which the cold gas entered.

Talayrach *et al.*[94] studied the bands arising from the radical BO and used them to calculate the rotational temperature of the plasma. (It seems likely that synthesis of TiB_2 was the prime object). A temperature of 5500 K was obtained from the lines of Ti, while the temperature of the argon was 7400 K. They concluded that the sample cooled the plasma. This may be correct, but it may be that the sample was in a region which was cooler in any case.

The Abel inversion, by which a radial distribution of emission intensity is derived from the integrated values obtained experimentally, was discussed by Mermet and Robin.[95] They used a method by which the integrated values are fitted, after smoothing, to a polynomial, the coefficients of which can be used to calculate the radial distribution. They then used this distribution to calculate the temperature; this required observations and calculations for at least two (and preferably several) wavelengths. They also found a maximum temperature off the axis of the plasma.

A plasma is normally heated by collision of charged particles and as the temperature rises this process becomes less efficient owing to decreased resistivity. Dubovoi *et al.*[96] found for a very high-power (200–400 kW) plasma at low pressures a heating efficiency much higher than they would have expected for pure Coulomb conductivity. To explain this they suggested that a small-scale ion-acoustic instability can develop in the region of the skin layer and that this leads to an additional growth of the resistivity, to a corresponding increase of the H.F. energy absorbed and to a more effective heating of the plasma. (Ion-acoustic waves are longitudinal and the expression for their velocity resembles that for a sound wave in a gas composed of neutral particles with masses which are those of the ions: hence the name. They are not conventional sound waves, however, for their energy derives not from collisions, but from the electrostatic effects of the difference in the amplitudes of the electron and ion oscillations. An ion-acoustic instability is a consequence of the transfer of energy between the ion-acoustic wave and electrons having the same velocity as the wave.)

Eckert and Pridmore-Brown[97] compared the measured[98] and calculated temperatures of column and annular plasmas. In the case of annular plasmas the experimental values were about 7000 K at the inner and outer boundaries, rising to about 8000–9000 K in between. The calculated values fell to 1000–2000 K at the boundaries. Stokes (in a private communication to the authors) attributed these discrepancies to non-equilibrium conditions at the boundaries, due to electron diffusion. The annular plasma referred to here was obtained by inserting another tube in the column and may not represent the conditions pertaining to an annular plasma formed by the action of an injector flow, where one might expect temperatures closer to the measured values.

Some very interesting relationships are given in a paper by Rovinskii and Sobolev.[99] They determined discharge parameters as functions of field frequency, *via* numerical solutions, for a steady induction discharge at atmospheric pressure without gas-flow; (note that the effect on temperature of the gas-flow is said to be small).[86] They give a theoretical estimation of the optimum frequency as being equal to $35/d^2$ MHz. This is the frequency giving a specified maximum temperature ($T_{\max}$) with minimal power input (W) and the minimal number of ampere-turns per unit length of coil (I_w); d is the diameter of the tube in centimetres.

A simple relationship is also given between I_w and $T_{\max}$ which does not contain the frequency or the radius:

$$\int_0^{T_{\max}} k(T)\sigma(T)\,\mathrm{d}T = \left(\frac{I_w}{2}\right)^2$$

where $k(T)$ and $\sigma(T)$ are respectively the thermal and electrical conductivities of the plasma. The skin-layer thickness is considered to be small relative to the tube radius.

Soshnikov and his co-workers[100] point out that these relationships do not take into account plasma radiation and they give numerical results for an argon plasma at atmospheric pressure in a tube of internal radius 1·5 cm, at various frequencies and an axial temperature of 8500 K. The results show that the best frequency range is 5–10 MHz which is close to the figure previously obtained by Rovinskii and Soboley,[99] ignoring the radiation. However, they show that the importance of radiation increases rapidly with I_w and W and the simple relationship becomes inapplicable.

Medvid[101] made some observations on the effect of gas-flows on the size of a plasma produced by a 2-kW generator at 3·5 MHz. Working with a torch which could be used with tangential or axial flow, he found that increasing the gas flow, in tangential mode, decreased the diameter, length and surface area of the plasma, while in axial mode the reverse was true. Thorpe[62] observed that the size of the plasma increased with increasing power and Capitelli *et al.*[102] noted that the plasma was reduced in length when working with nitrogen. These workers gave theoretical reasons why the heat transferred to Al_2O_3 particles should be greater in a nitrogen than an argon plasma. They found experimentally a smaller increase than that predicted theoretically because of the shorter residence time in the shorter nitrogen plasma.

Thorpe[62] also noted the effect of the thermal pinch on the size of the plasma when working with hydrogen and nitrogen coolant gases, and attributed this pinch to the increased thermal conductivity of nitrogen over argon and hydrogen over nitrogen. She observed that the radiation from the plasma increased considerably when mixtures of argon and hydrogen were used as plasma gases.

The thermal properties of a plasma torch were discussed by Trekhov *et al.*[103] They assumed a central temperature and offered two different approximations to give the radial distribution of the temperature.

bustion, claims there is a deep physical and mathematical analogy between a discharge in a gas stream and the process of flame propagation in a combustible mixture. Barnes,[104] on the other hand, has criticized the use of the terms "plasma torch" and "plasma flame" for systems which are not combustion processes. It seems to us that the value of these terms as descriptions of the appearance of the particular plasmas to which they refer outweighs considerations of linguistic rigour. It is doubtful if the suggestion[105] that all plasma sources be called "plasma jets" is any improvement on the present usage, as there is a marked difference between "plasma jets" and inductively coupled "plasma torches" on the one hand and microwave plasma and capacitively coupled plasmas on the other.

ANALYTICAL APPLICATIONS

It has been recorded in the review that ICPT have a wide linear dynamic range (some five orders of magnitude), high sensitivity and precision and freedom from many, if not all, true matrix effects. This, coupled with their freedom from contamination and ability to run continuously for as long as power and gas are supplied, makes them remarkable emission sources. It is therefore surprising that so few practical analyses have been recorded. Some of these analyses are shown in Table 2 and in Table 3 are shown the best of the detection limits. These detection limits have all been obtained with ultrasonic nebulizers and desolvation and would be expected to be one or two orders of magnitude worse if pneumatic nebulizers without desolvation were used.

CONCLUSION

A study of the papers reviewed here and in Parts I and II shows the ICPT to be superior to both plasma jets and microwave torches if detection limit is the criterion. The sensitivity of the source, with few if any exceptions, is greater than that of either of the other two sources over the whole range of elements so far determined; the plasma jet in turn is rather worse than the microwave torch. The same may be said, but to a lesser degree, if precision is the basis of comparison.

Table 3. Detection limits obtained with the H.F. ICP torch

The detection limits are 2σ for references 10, 24 and 40 and 6σ for reference 38, where σ is the standard deviation of the background.

When it comes to freedom from matrix effects, then both ICPT and plasma jets are inherently superior to microwave torches, since they both possess high gas temperatures; the ICPT is, in addition, free from contamination from electrodes. The linear range of the ICPT is greater than that of the plasma jet, which in turn is greater than that of the microwave torch. When it comes to cost the position is somewhat reversed; plasma jets and their associated equipment are cheaper than microwave torches and their supplies, which in turn are cheaper than ICPT and generators.

MULTIPARAMETRIC CURVE FITTING—I

COMPUTER-ASSISTED EVALUATION OF CHELATOMETRIC TITRATIONS WITH METALLOCHROMIC INDICATORS

MILAN MELOUN®

(*Received* 16 *September* 1974. *Revised* 22 *January* 1975. *Accepted* 16 *February* 1975)

Summary—A curve-fitting procedure has been developed for the photometric complex-formation titration of the metal–indicator complex MIn_N which is assumed to predominate in solution. By means of a least-squares procedure the following five parameters were determined: the end-point, the absorbance of the indicator complex A_{MIn_N}, the indicator concentration c_{In}, the stability constants and, if possible, K_{MY}. A modified version of Sillén's Letagrop Vrid has been used for the mathematical-statistical approach of the non-linear model based upon the non-transformed function $A = f(v)$. Additional information is obtained about the goodness of fit, indicating whether the chosen model with predominance of MIn_N is correct or not. The use of the program is demonstrated by application to chelatometric microtitrations of zinc and lead with EDTA, using Naphthylazoxine 6S and SNAZOXS as metallochromic indicators.

A number of authors[1–7] have been engaged in solving the problem of determination of the equivalence point, finding a suitable formulation of the fundamental equations or seeking optimum conditions for sharp end-point indication in photometric chelatometric titrations.

The theory of photometric titration with use of metallochromic indicators has been outlined in several basic contributions[1–3,6–17] Fortuin *et al.*[1] derived a general equation of the type $a = f(\alpha)$ where a is the titration parameter and $\alpha = [\mathrm{In'}]/c_{In}$, for the case where a single metal–indicator complex of 1:1 stoichiometry is formed. The theoretical discussion of the effect of various parameters on the shape of titration curves was illustrated by plots of families of curves calculated for different values of parameters K_{MIn}, K_{MY}, c_{In} and c_M. Ringbom and Wänninen[8] applied conclusions from the theory of photometric titrations using acid-base indicators, and pointed out the usefulness of pM for characterizing the system of a chelatometric titration. The pertinent equilibria were also solved in theoretical discussions[2,3] of visual end-point detection with metallochromic indicators in an attempt to characterize the sharpness of the indicator colour change. In both contributions the formation of a single MIn complex was considered and the plots of $\alpha = f(a)$ for various values of the parameters involved were also given. Kotrlý developed the theory of photometric titrations for a case where the indicator forms a predominating complex MIn_N (*cf.* ref. 6) or a stepwise equilibrium system of three indicator complexes[7] MIn_{N-2}, MIn_{N-1}, MIn_N. For a discussion of various effects on the shape of the titration curve he also used the transformation function $a = f(\alpha)$.

Several authors[9–17] have shown that M_2In_2 also occurs in solution and that large systematic deviations may occur when titrations are performed with very dilute solutions. For simplicity, graphical extrapolation of the linear parts of the titration curve close to the equivalence point is commonly used to locate the end-point. A computer program for this type of end-point evaluation can be conveniently based on the application of a simple linear regression (*e.g.*, see refs. 18, 19).

In some theoretical papers it is supposed that the equivalence point is known and that the parameter functions $a = f(\alpha)$ or $\alpha = f(a)$ can be studied. However, this condition is fulfilled only rarely in practical cases, and the evaluation of the end-point is sometimes complicated and accessible only by means of a graphical extrapolation.

An exception to graphical extrapolation is the approach by Sato and Momoki,[20] suggesting transformation of variables $g(1 - \alpha)/\alpha = f(v)$ and using graphical linearization without the stability constants K_{MIn} and K_{MY} being known beforehand. Corrections are made for volume change and indicator concentration and the paper appears to be, especially in practical cases, a most useful contribution.

A number of papers[4,8,21,22] use calculations of conditional stability constants, side-reaction coefficients, or their graphical interpretation, to explain the course of the chelatometric titration curve. In all the papers the indicator concentration c_{In} is supposed to be known. Chemical analyses using paper and thin-layer chromatography have revealed, however, that chelatometric indicators are substances that often contain considerable amounts of impurities from raw materials, synthesis by-products and various isomers. The removal of such impurities is difficult and sometimes impossible because of decomposition of the dye. In some cases the indicator is the only species of the mixture which reacts with the metal being titrated. A correction for indicator purity has not been taken into account in the calculations in any of these papers.

Early attempts at computation of parameters from titration curves, including chelatometry, are described in the book by Dyrssen *et al.*[23] and are based on an application of Ringbom's method.[21] Sato and Momoki[24] selected an entirely different approach to the computer evaluation of a chelatometric titration curve involving the MIn chelate. They determined three unknown parameters: the end-point, the conditional stability constant $K_{\text{MIn,cond}}$, and $K_{\text{MY,cond}}$, with a least-squares fitting method using Deming's subroutine for the minimization process. The algorithm was demonstrated for the titration of magnesium with EDTA, Calmagite being used as indicator.

The change of absorbance during a chelatometric titration involving a metallochromic indicator forming a 1:1 complex was calculated by means of a computer.[25] In addition to the absorbance, the transmittance, the free metal-ion and indicator concentrations, and the stability constants of the metal–titrant and the indicator–metal complexes were calculated.

The present paper presents a new algorithm for the evaluation of a chelatometric titration curve when the MIn_N complex predominates, and determination of the following parameters: the end-point, pIn, log K_{MIn_N} and (if possible) log K_{MY}, and the absorbance of the indicator complex A_{MIn_N}. Additional information about the goodness of fit indicates whether this model is correct or not. The least-squares method for the minimization process is based on a modified version of Sillén's Letagrop Vrid.[26] The statistical treatment is quite different from that suggested by Sato and Momoki,[24] the fundamental equation being based on Kotrlý's approach[6] but regression analysis is applied to the function $A = f(v)$. The algorithm has been applied to the titration of zinc and lead, using Naphthylazoxine 6S and SNAZOXS as metallochromic indicators.

THEORETICAL

Equation of the photometric titration curve

End-point indication in a chelatometric titration using a metallochromic indicator is based on the displacement reaction between the indicator complex MIn_N and the chelate-forming ion of a titrant Y, which can be expressed by the overall equation

$$\text{MIn}_N + \text{Y} \rightleftharpoons \text{MY} + N\,\text{In} \tag{1}$$

The equilibrium in equation (1), as written, presupposes that the metallochromic indicator forms only one complex, MIn_N. This complex has a colour different from that of the free form In, which may represent, however, a mixture of several differently protonated indicator species. The equilibrium is considerably affected by the hydrogen-ion activity, as this controls the concentration of the active forms of both competing ligands Y and In.

The chelatometric titration is usually carried out in a buffered solution. If the free indicator is predominantly in only one protonated form, *e.g.*, H_jIn, at a selected pH value, the absorbance of the titrated solution at a chosen wavelength, for a particular consumption of titrant v, is given by the equation

$$A = d\{\epsilon_{1N}[\text{MIn}_N] + \epsilon_{j1}[\text{H}_j\text{In}]\} \tag{2}$$

where d is the path-length of the cuvette, and ϵ_{1N} and ϵ_{j1} are the molar absorptivities of the species MIn_N and H_jIn, respectively. The dependence of the absorbance A on consumption of titrant v is represented by the photometric titration curve.

As the total concentration of indicator c_{In} is

$$c_{\text{In}} = [\text{H}_j\text{In}] + N[\text{MIn}_N] = c_{\text{In}}\,\alpha + N[\text{MIn}_N] \tag{3}$$

where $\alpha = [\text{H}_j\text{In}]/c_{\text{In}}$ is the fraction of indicator in the free form, equation (2) can be transcribed as a function of this relative variable:

$$\begin{aligned} A &= dc_{\text{In}}\cdot\frac{\epsilon_{1N}}{N} - dc_{\text{In}}\left\{\frac{\epsilon_{1N}}{N} - \epsilon_{j1}\right\}\alpha \\ &= A_{(\text{MIn}_N)} - \{A_{(\text{MIn}_N)} - A_{(\text{In})}\}\alpha \end{aligned} \tag{4}$$

As indicated in equation (4), the colour transition of an indicator is defined by the limiting values of the absorbance, for a point $\alpha = 0$, *i.e.*, $A_{(\text{MIn}_N)}$, where all the indicator is bound in the metal complex MIn_N, and for a point $\alpha = 1$ where the metallochromic indicator is completely converted into the free form In, *i.e.*, $A_{(\text{In})}$.

If v ml of titrant are added to the original volume V_0 ml of titrand, the measured absorbance A_{exp} should be corrected for the dilution by means of the factor $g = V/V_0$, where $V = V_0 + v$:

$$A = A_{\text{exp}}g = A_{\text{exp}}\left\{1 + \frac{v}{V_0}\right\} \tag{5}$$

To determine the theoretical value of the absorbance A from equation (4) for individual values of the titrant consumption v it is assumed that for the given set of conditional stability constants, *i.e.*,

$$K_{\text{MIn}_N\text{,cond}} = \frac{[\text{MIn}'_N]}{[\text{M}'][\text{In}']^N} \tag{6}$$

$$K_{\text{MY,cond}} = \frac{[\text{MY}']}{[\text{M}'][\text{Y}']} \tag{7}$$

where conditional concentrations are expressed by Ringbom's notation with respect to [M′], [In′], $[\mathrm{MIn}'_N]$, [Y′], [MY′], and for given total concentrations

$$c_{\mathrm{Y}} = ac_{\mathrm{M}} = [\mathrm{Y}'] + [\mathrm{MY}'] \tag{8}$$

$$c_{\mathrm{M}} = [\mathrm{M}'] + [\mathrm{MY}'] + [\mathrm{MIn}'_N] \tag{9}$$

$$c_{\mathrm{In}} = [\mathrm{In}'] + N[\mathrm{MIn}'_N] \tag{10}$$

it is then possible to calculate the values of the relative variable α for each value of v. A general explicit expression of $\alpha = f(v)$ as a function of individual parameters is not possible, as it represents a real, positive root of a polynomial in α of degree $(2N + 1)$. Many authors prefer to express the inverse functions $v = f(\alpha)$ and $a = f(\alpha)$, where a is the equivalent fraction of titrant consumed:

$$a = \frac{vf_{\mathrm{Y}}}{Vc_{\mathrm{M}}} \tag{11}$$

f_{Y} being the molarity of the titrant. For a given equilibrium system the titration-curve equation can be derived in the form of transformed variables[6] as follows

$$\begin{aligned} a = 1 &- \frac{c_{\mathrm{In}}(1-\alpha)}{Nc_{\mathrm{M}}}\left[1 + \frac{1}{K_{\mathrm{MIn}_N,\mathrm{cond}} \cdot c_{\mathrm{In}}^{N} \cdot \alpha^{N}}\right] \\ &- \frac{1}{K_{\mathrm{MY,cond}}\, c_{\mathrm{M}}} \\ &+ \frac{K_{\mathrm{MIn}_N,\mathrm{cond}} \cdot c_{\mathrm{In}}^{N-1}}{K_{\mathrm{MY,cond}}}\left[\frac{N \,.\, \alpha^{N}}{1-\alpha} - \frac{c_{\mathrm{In}} \cdot \alpha^{N}}{c_{\mathrm{M}}}\right] \end{aligned} \tag{12}$$

The values of the conditional stability constants $K_{\mathrm{MIn}_N,\,\mathrm{cond}}$ and $K_{\mathrm{MY,\,cond}}$ necessary for insertion into equation (12) can be calculated from the corresponding stability constants, provided that detailed information on all side-reactions is available. The side-reaction coefficients α_{M}, $\alpha_{\mathrm{Y(H)}}$, *etc.*, give a true picture of all competitive effects. The definitions of these coefficients,[4,21] their dependence upon experimental conditions and the method of calculation (*cf.* ref. 22) are clarified in the literature quoted.

Regression analysis

When analysing experimental photometric titration curves it should be considered that in general the values of the following parameters are known either not at all or only approximately: the titrant consumption at the end-point, v_{ep}, the indicator concentration c_{In}, the initial limiting value of the absorbance A_{MIn_N}, and the values of the stability constants K_{MIn_N} and K_{MY}. These five parameters have to be determined by numerical analysis of the titration curve.

The equation of the chelatometric titration curve is formulated as a function $a = f(\alpha)$, *i.e.*, in terms of transformed relative variables and as an inversion function with respect to the original set of variables (v; A). Considering that the reading of the volume on a microburette has a smaller error than the reading of the absorbance A, it is convenient for the application of a least-squares fitting method to take the volume v as an independent variable and absorbance A as a dependent variable. However, an explicit formulation of the absorbance from the equation of a chelatometric titration curve is not possible, as a polynomial function of degree $(2N + 1)$ would be obtained and an approximation method would be needed to find the particular real root of physical meaning. Therefore all previous authors usually worked with the inversion function $v = f(\alpha)$.

In applying the method of least-squares in order to determine the five unknown parameters of a chelatometric titration curve the assumption that the original error distribution of dependent variable A_{exp} is retained and that the original non-transformed function $A = f(v)$ can be used, should be fulfilled. An attempt was made to solve the problem by means of an indirect expression of a residuum ΔA when formulating the optimization criterion.[27] A more rigorous method is to use an approximation method, *e.g.*, the Newton iterative method.

In formulating the non-linear model it seemed convenient to make a formal rearrangement of equation (12) to give (13) for the *i*th point on the titration curve:

$$v_i = R\frac{\alpha_i^N}{1-\alpha_i} - S \,.\, \alpha_i^N - T\frac{1-\alpha_i}{\alpha_i^N} + Q \,.\, \alpha_i + W \tag{13}$$

where

$$R = \frac{K_{\mathrm{MIn}_N,\mathrm{cond}} \cdot c_{\mathrm{In}}^{N-1} \,.\, N \,.\, v_{\mathrm{eq}}}{KG_{\mathrm{MY,cond}}} \tag{14}$$

$$S = \frac{K_{\mathrm{MIn}_N,\mathrm{cond}} \cdot V \,.\, c_{\mathrm{In}}^{N}}{K_{\mathrm{MY,cond}} \cdot f_{\mathrm{Y}}} \tag{15}$$

$$T = \frac{1}{K_{\mathrm{MIn}_N,\mathrm{cond}} \,.\, N \,.\, c_{\mathrm{In}}^{N-1} \,.\, f_{\mathrm{Y}}} \tag{16}$$

$$Q = \frac{c_{\mathrm{In}} \,.\, V}{N \,.\, f_{\mathrm{Y}}} \tag{17}$$

$$W = v_{\mathrm{eq}} - \frac{V}{f_{\mathrm{Y}}}\left[\frac{c_{\mathrm{In}}}{N} + \frac{1}{K_{\mathrm{MY,cond}}}\right] \tag{18}$$

The chelatometric titration curve involves all the parameters to be determined in the expressions R, S, T, Q and W and so it is advantageous to investigate the contributions of these particular expressions to the shape of a titration curve. The members R, S, T, Q and W are useful for illustration how a change in the individual parameters can cause a change in the function U.

According to the optimization criterion the function U is given by

$$U = \sum_i w_i(A_i - A_{i,\mathrm{cal}})^2 = \sum_i w_i(\Delta A_i)^2 \tag{19}$$

where w_i is the statistical weight, usually taken as unity. Absorbance A_{cal} is calculated from the equation

$$f(v, A) - v = \phi(A) \tag{20}$$

and the modified Newton iterative method

$$A^{(k+1)} = A^{(k)} - \eta \cdot \frac{\phi(A^{(k)})}{\phi'(A^{(k)})} \tag{21}$$

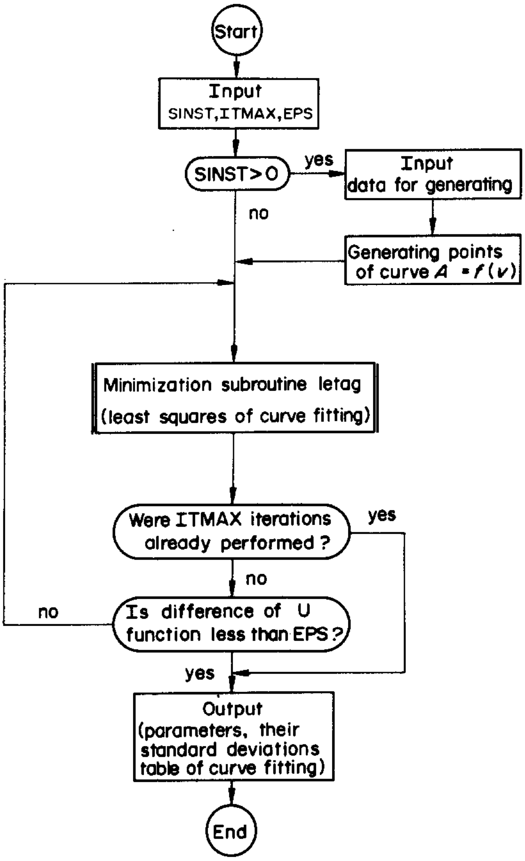

Fig. 1. Schematic flow chart of the program NCHEL-LETAG.

where η is a convergence coefficient, and ϕ' is the first derivative of ϕ. For the initial approximation the experimental value A_{exp} is used for $A^{(0)}$ in the iterative process.

COMPUTER PROGRAM

The schematic flow-chart of the program NCHEL-LETAG is given in Fig. 1. The program is written in Fortran and has been run on a Hewlett-Packard 2116 C computer, and is available on request.

NCHEL-LETAG consists of a main program which reads in a title and the part of the input needed for a simulation of titration curve points, if requested. It then calls subroutines as follows and organizes outputs of determined parameters, a table of curve fittings and a graph of curve fitting.

LETAG—this routine, which is Sillén's Letagrop Vrid adapted for a smaller computer and modified to the subroutine form,[28] performs the main minimization. The functional diagram of LETAG is given in Fig. 2. The subroutine contains "blocks" which are logical units; one of them, KNUT, is a switchboard to which the computer returns after fulfilling each task. Depending on which value for the control number Rurik it then reads, the computer jumps from KNUT to another block for a new task. The block DATA reads input data being called by Rurik 6. PUTS, a special block, follows the block DATA automatically (marked by a letter A) and may use these data to calculate some quantities which will be needed for further calculations. UBBE, called by subroutine LETAG or by the main program, calculates the error-square sum-function U defined by relationship (19). Block LASK, called by Rurik 7, reads in preliminary values for the parameters to be determined. STEG, called by Rurik 3 or 4, reads the general orders for systematic variation of parameters. (IK) means which parameter is to be varied, and by how much (W). LETA, called by Rurik 5, governs the systematic variation of the unknown parameters. Other blocks such as SKRIK or MIKO, PROVA, VRID, *etc.* are contained in the REST OF SUBROUTINE LETAG and their function is explained in another contribution[28] of this series.

RNDNR—a standard routine for the generation of errors having a normal Gaussian distribution—was adapted from Communications of the Association for Computing Machinery, Algorithm 314 (1968).

DATA—data input; some experimental constants describing titration condition are read in, then the calculation of side-reaction coefficients α_{MIn_N} and α_{MY}, follows and finally the matrix of titration data (v, A) or (v, T) is read in. The absorbance values are corrected for dilution and with regard to the reference solution. Titration curve points which are not contained in the interval $(\alpha_{min}, \alpha_{max})$ are then eliminated.

UBBE—this routine calculates A_{cal} for each volume v and a given set of parameters by the Newton iterative method. Then follows calculation of the error-square sum-function U.

Data input instructions

Simulated or experimental input data can be evaluated by the NCHEL-LETAG program. For a given set of parameters the absorbance ASIM, loaded by a calculated ERROR, is calculated for each volume v. Then a least-squares fit is applied to a set of (v; ASIM) and parameters XK(1), . . ., XK(5) are evaluated. Such input data are illustrated in Table 1a. (*a*) 1 card: SINST is optional and is the instrumental error of the measured absorbance; when experimental data are to be evaluated then SINST < 0 and the other data on this card are not read; EPS1 is the absolute criterion of convergence of A_{cal} in the Newton iterative process; if $(A_{cal}^{(n)} - A_{cal}^{(n-1)}) <$ EPS1 then the iteration process terminates; EP2 is the η coefficient of convergence in the Newton iterative method; NX is the

number of parameters to be read in for generation of simulated error; XK(1) is the value of the first parameter, *i.e.*, equivalence point v_{eq}, in ml; XK(2) is the value of the second parameter, *i.e.*, the concentration stability constant of the indicator complex, log K_{MIn_N}; XK(3) is the value of the third parameter, *i.e.*, the concentration stability constant of complex with the titration agent, log K_{MY}; XK(4) is the value of the fourth parameter, *i.e.*, the total indicator concentration ($-\log c_{In}$); IR is the initial value for subroutine RNDNR and is the optional value from an interval (5; 6000), this interval is given by the word-length of the computer used and the algorithm RNDNR.

(*b*) 1 card: N is the stoichiometric coefficient in the indicator complex MIn_N; VO is the initial volume of solution to be titrated, in ml; FY is the molar concentration of the titrant; VM is the atomic weight of the metal to be titrated; ALMIN is the lower limit α_{min}; ALMAX is the upper limit α_{max}; ASB is the correction to be made to the sample absorbance for the absorbance of the reference solution.

(*c*) 1 card: AI is the absorbance of the free indicator measured after the titration is completed; PH is the pH value of the solution to be titrated; NB is the total number of points on the titration curve; X5 is the absorbance of the indicator complex measured before the titration A_{MIn_N}.

(*d*) 1 card: A(1), . . ., A(4) are the four dissociation constants of the indicator acid; "−3" is written in place of any dissociation constant not available.

(*e*) 1 card: A(1), . . ., A(4) are the four dissociation constants of the titrant; "−3" is written in place of any dissociation constant not available.

(*f*) A number of NB/5 cards: these contain the co-ordinates of experimental points on the titration curve: VA(I) is the volume v of titrant added; VA(I + 1) is the absorbance or transmittance value, depending on the switch 6.

(*g*) 1 card: EPS is the absolute criterion of convergence of function U; when $U^{(n)} < \text{EPS}$ then the minimization process is terminated; ITMAX is the number of iterations in the minimization process; NGR is the number which controls the plotter output; when it is not equal to zero then a graph is printed; data for the plotter are given by XL for the length of the abscissa and YL for the length of the ordinate (in inches); UF is a fraction specifying the change in the iterative steps for all parameters after each iteration.

(*h*) 1 card: NAZX, the description of the abscissa.

(*i*) 1 card: NAZY, the description of the ordinate.

(*j*) 1 card: descriptive title.

(*k*) 1 card: 7, Rurik, which calls block LASK to read the initial estimation of the parameters to be determined.

(*l*) 1 card: NK is the total number of parameters to be determined in the course of the LETAG minimization process; NBYK is the number of non-negative parameters to be determined.

(*m*) 1 card: XK(1), . . ., XK(5), the initial guesses for the parameters to be determined.

(*n*) 1 card: ISKIN is the number of matrix elements to be read in; I or J denotes the co-ordinates of a matrix element; S(I, J) is the value of a matrix element.

(*o*) 1 card: 3, Rurik, which calls the block STEG where the minimization steps for each parameter are read in.

(*p*) 1 card: N is the number of parameters to be varied in an actual shot.

(*q*) 1 card: IK is the number of parameters for which the steps are read in; W is the value of a step; the pair (IK, W) is written for each varied parameter.

(*r*) 1 card: 5, Rurik, which calls the block LETA where a systematic variation of parameters is performed.

When the experimental titration curve is to be analysed, in part A, SINST is written equal to −1 and the values of parameters XK(1), . . ., XK(5) are not written. Then follows part C, which calls block DATA, part B and part D.

Interpretation of output

At the top of the table, the name of the titration system, the parameters for a simulation process and the titration conditions are printed together with the values of SINST, the five parameters, N, VO, FY, AW, ALMIN, ALMAX, PH, AI, and the pK_a values for the successive deprotonation of the indicator and the titrant, respectively, which are denoted as PK11, PK21, PK31, PK41. The proton side-reaction coefficients of the indicator and titrant are also printed as ALPHA IN(H) and ALPHA Y(H).

Experimental and simulated values are given in the following sequence: the volume of titration agent V(ML), the absorbance AEXP, the corresponding value of α, ALPHA, and last the simulated values of absorbance ASIM and calculated error ERROR if the simulation process is requested. Under the table the total number of experimental points is printed and the number of points within the interval α_{min}, α_{max} which are selected for regression analysis.

The outputs of the successive minimization processes can be controlled by switches and some parts of them can be omitted. The particular iterations are printed next and for each of them the standard deviation SIGY, the U-function, and the approximations of all parameters are given.

When the absolute criterion of the convergence of the U-function is fulfilled or when a declared number of iterations is reached, the minimization process terminates. In order to test the fit of the experimental points to the regression curve, the final table of curve fitting is printed.

EXPERIMENTAL

Spectrophotometer

A Spekol single-beam spectrophotometer (Zeiss, Jena) was equipped for photometric microtitrations with the multipurpose attachment TAL (*cf.* refs. 27, 29–31) with a thermostated cell and equipment for simultaneous measurement of pH. The design and function of TAL has been described previously.[31,32] The accuracy of the spectrophotometric measurements was checked with standard solutions of potassium chromate and copper(II) sulphate.[33] The pH of the titrand was recorded at the beginning and checked during the titration, with a Radiometer PHM 4d pH-meter (G202B glass electrode and saturated calomel electrode, calibrated with standard buffers[34]).

The titration cell was a 50-mm path-length cuvette, total volume 23 ml (type C, Zeiss, Jena). All the measurements were made at 25 ± 0·1°.

Burettes

A Metrohm E457 500-μl microburette was used, its polyethylene capillary tip being immersed in the titrand. Metal and indicator solutions were measured out with home-made microburettes[31] of 500 μl or 250 μl capacity, calibrated by weighing water delivered under medicinal paraffin (standard deviations for 25 deliveries of 200 and 100 μl were 0·3 and 0·2 μl, respectively).

Reagents and solutions

EDTA solution, 0·001M. Prepared in doubly distilled water. Standardized against twice recrystallized lead(II) chloride by photometric titration, using Naphthylazoxine 6S as indicator.

Naphthylazoxine 6S and SNAZOXS solutions, 0·001M. Both indicators were purified[35] and the effective concentration of indicator was determined by the molar-ratio method with copper.[35] The disodium salts of the indicators were fully protonated on a cation-exchanger column in H$^+$-form.

Zinc(II) solution, 0·001M. Prepared by dissolving 0·074 g of $Zn(NO_3)_2 \cdot 6H_2O$ in water and diluting to 250 ml. Standardized by chelatometric titrations using Xylenol Orange as indicator.

Hexamine buffer, 0·04M. Adjusted to pH 6·0 with 0·05M nitric acid and to ionic strength 0·02 with 0·1M potassium nitrate. Purified by extraction with dithizone solution in carbon tetrachloride.

The solutions titrated with 0·001M EDTA always contained the same amount of individual components and the same sample volume was used. The solution titrated had a constant ionic strength of 0·01 and pH 5·80 adjusted with hexamine buffer and potassium nitrate, and temperature 25°. The solutions titrated had the same metal-ion concentration $c_M = 1{\cdot}0 \times 10^{-5}M$ (except for investigation of effect of c_M) and the same indicator concentration $c_{In} = 1{\cdot}0 \times 10^{-5}M$ (except for investigation of effect of c_{In}).

Procedure

Take an aliquot of metal-ion solution and a suitable portion of indicator stock solution in a calibrated 50-ml flask, add a few ml of buffer solution and make up the volume to 50 ml with doubly distilled water. Transfer 20·00 ml of this mixture into the titration cell, place this in the apparatus and adjust the equipment. Fill the reference cell with a solution containing no indicator but the same amounts of all other components. Place the reference cell in the light-beam and adjust the meter scale (0 and 100% T). Put the measuring cell into position and take readings of absorbance (or transmittance) at the beginning of the titration and at every 10 μl (ever 5 μl in the vicinity of the end-point) of titrant added, until constant absorbance is reached. About 35 points are usually read.

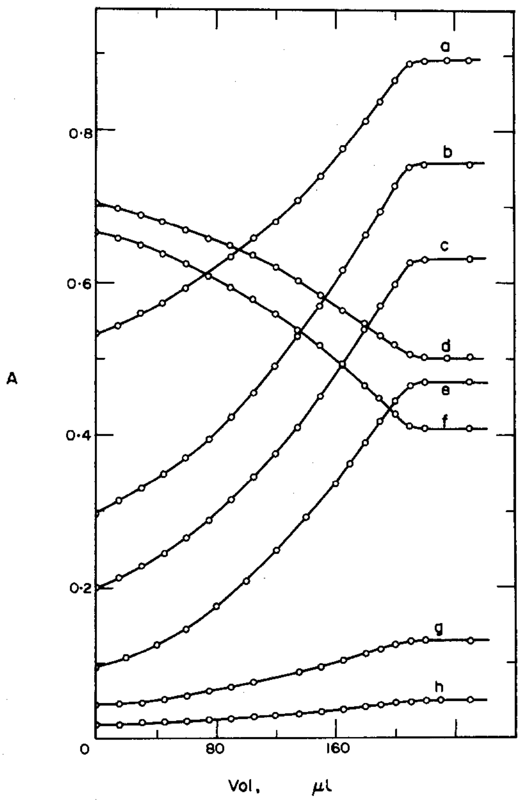

Fig. 3. Photometric titrations of zinc(II) with 0·001M EDTA, using Naphthylazoxine 6S as indicator, at various wavelengths. $c_{In} \approx 10^{-5}M$, $c_{Zn} = 1{\cdot}045 \times 10^{-5}M$, pH 5·80 (hexamine), $I = 0{\cdot}01$ (KNO_3), volume ≈ 20 ml, $d = 50{\cdot}0$ mm, temperature 25°. Theoretical equivalence point: 0·209 ml. Wavelengths, *nm*: (*a*) 500, (*b*) 525, (*c*) 540, (*d*) 450, (*e*) 550, (*f*) 425, (*g*) 565, (*h*) 575. Evaluations of the curves are listed in Table 2.

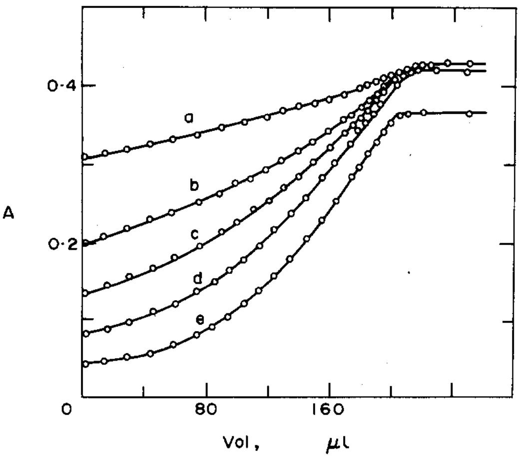

Fig. 4. Photometric titrations of zinc(II) with 0·001*M* EDTA, using SNAZOXS as indicator, at various pH values. $\lambda = 550$ nm, $c_{\mathrm{Zn}} = 1{\cdot}060 \times 10^{-5}M$, $c_{\mathrm{In}} \approx 10^{-5}M$, $I = 0{\cdot}01$ (hexamine + KNO_3), volume ≈ 20 ml, $d = 50{\cdot}0$ mm, temperature 25°. Theoretical equivalence point: 0·212 ml, value of pH (adjusted with 1*M* HNO_3): (*a*) 4·72, (*b*) 5·34, (*c*) 5·80, (*d*) 6·23, (*e*) 6·84. Evaluations of the curves are listed in Table 3.

RESULTS AND DISCUSSION

Photometric titrations of zinc(II) and lead(II) with 0·001*M* EDTA, using Naphthylazoxine 6S and SNAZOXS as indicators, were chosen as models because formation of MIn_2 complexes is expected. Both indicators form predominantly simple MIn_2 type complexes[27] and have been studied in our laboratory for several years. End-points were located by graphical extrapolation and also by numerical analysis of the curves. During the minimization process log K_{MY} was kept constant at a value taken from tables because MY was too stable for determination of K_{MY} to be considered certain.

The effect of choice of wavelength is demonstrated in Fig. 3. Only one component should absorb significantly so the difference between the molar absorptivities of the free indicator ϵ_{In} and its complex $\epsilon_{\mathrm{MIn}_N}$ should be as great as possible. The graphical and numerical evaluations of the curves are shown in Table 2. The end-points evaluated numerically are slightly but negligibly earlier than those obtained graphically. The evaluation of the indicator concentration and stability constant of the indicator complex was not substantially influenced by the choice of wavelength. The standard deviations of both parameters had low values. In some cases subroutine Letag was not able to determine a standard deviation.[26]

The effect of pH is shown in Fig. 4 and Table 3. At low pH the difference between the absorbance of the free form of the indicator and its complex is reduced and the sharpness of the titration curve is also decreased. However, at pH higher than 6·4, acid–base reactions interfere with the complexation equilibria. The end-points of the five curves evaluated were not substantially influenced except for those at the two extreme pH values 4.42 and 6·85 and were in good agreement with the equivalence point.

The evaluation of the indicator concentration was also not influenced by pH. Corrections for $\alpha_{\mathrm{In(H)}}$ at various pH values led to the same value of K_{MIn_2}.

The influence of indicator concentration is demonstrated in Fig. 5. The use of more indicator markedly

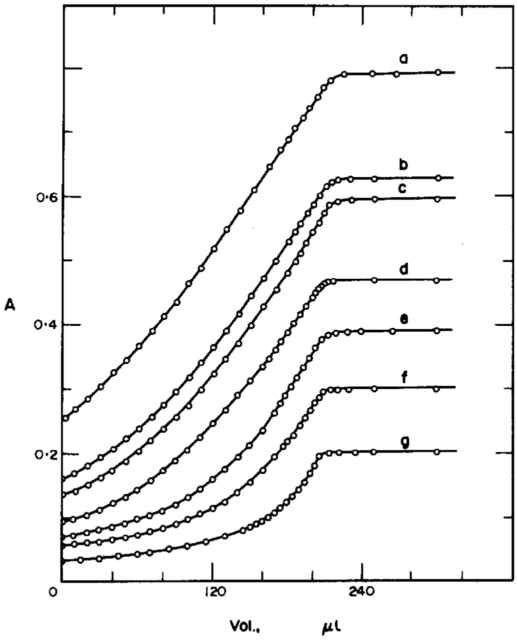

Fig. 5. Photometric titrations of zinc(II) with 0·001*M* EDTA, using Naphthylazoxine 6S, with various concentrations of the indicator. $\lambda = 555$ nm, $c_{Zn} = 1{\cdot}065 \times 10^{-5}M$, pH 5·75 (hexamine), $I = 0{\cdot}01$ (KNO_3), volume ≈ 20 ml, $d = 50{\cdot}0$ mm, temperature 25°. Theoretical equivalence point: 0·213 ml; indicator concentration, *M*: (*a*) $1{\cdot}78 \times 10^{-5}$, (*b*) $1{\cdot}41 \times 10^{-5}$, (*c*) $1{\cdot}20 \times 10^{-5}$, (*d*) $1{\cdot}0 \times 10^{-5}$, (*e*) $0{\cdot}79 \times 10^{-5}$, (*f*) $0{\cdot}60 \times 10^{-5}$, (g) $0{\cdot}40 \times 10^{-5}$.

improves the shape of the titration curve, mainly in the linearity before the end-point. The optimum amount to use is related to the accuracy in reading the absorbance. The indicator concentrations evaluated correspond to the actual analytical concentrations of the indicator in the solutions titrated. The indicator concentration does not influence the position of the end-point or the value of the stability constant of the indicator complex.

The effect of the metal-ion concentration is demonstrated in Fig. 6. The evaluated end-points were in agreement with the theoretical values. No marked difference was found between the graphical and numerical approach. The SIGY value[26] of the best curve fitting for a set of titrations of zinc(II) with SNAZOXS as indicator had the same value as the standard deviation of the absorbance, *i.e.*, 0·0035. The worst curve fitting was found for a family of lead(II) titrations, with the same indicator. Higher SIGY values indicate that the experimental points are subject to greater errors or that the curve does not correspond to the suggested mathematical model, *e.g.*, there may be consecutive complex-forming equilibria.

CONCLUSIONS

The application of the program is limited. When the shape of the titration curve contains a long linear part before the equivalence point the estimation of the parameter $\log K_{MY,cond}$ is not reliable. This parameter and $\log K_{MIn_N,cond}$ are ill-conditioned in the model. In such cases the $\log K_{MY,cond}$ value is kept constant during the minimization process.

The value of $c_{In}^2 K_{MY}$ determines the curvature of the titration curve before the equivalence point and $c_M K_{MY}$ can only be determined from the titration

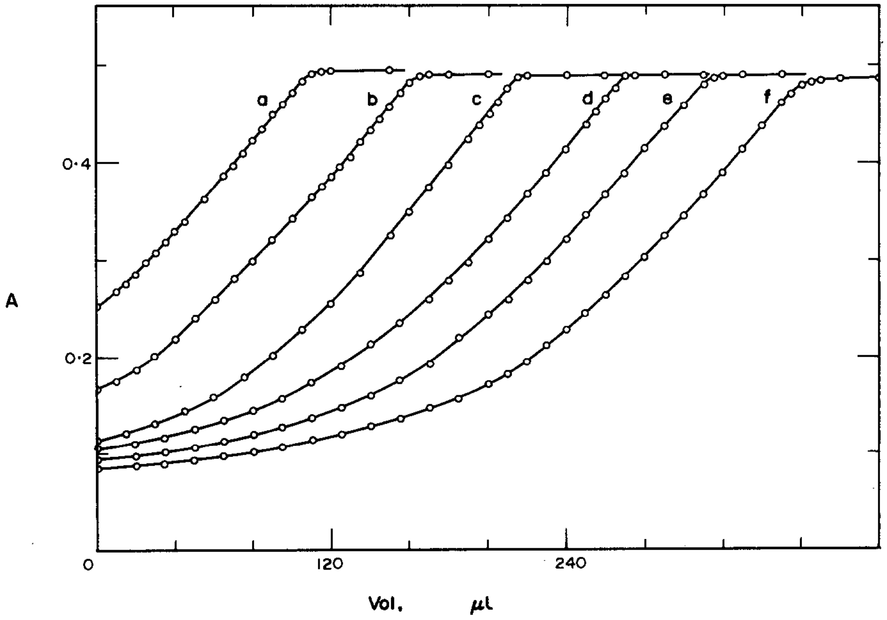

Fig. 6. Photometric titration of lead(II) with 0·001*M* EDTA, using Naphthylazoxine 6S as indicator, for various metal concentrations. $\lambda = 555$ nm, $c_{In} \approx 10^{-5}M$, pH 5·75 (hexamine) $I = 0{\cdot}01$ (KNO_3), volume ≈ 20 ml, $d = 50{\cdot}0$ mm, temperature 25°. Metal concentration c_{Pb}, *M*: (*a*) $0{\cdot}56 \times 10^{-5}$, (*b*) $0{\cdot}83 \times 10^{-5}$, (*c*) $1{\cdot}07 \times 10^{-5}$, (*d*) $1{\cdot}35 \times 10^{-5}$, (*e*) $1{\cdot}55 \times 10^{-5}$, (*f*) $1{\cdot}78 \times 10^{-5}$.

curve with an acceptable accuracy when the curvatures are large. In that case, however, the titration itself is inaccurate and no longer of analytical interest. When, as commonly in practice, we deal with "good" curves, it will hardly be possible to determine K_{MY}, and only K_{MIn_N} can be determined in particular cases (no impurities giving interactions, MIn_N the only indicator complex formed in solution, $c_{In}^2 . K_{MIn_N} < 10^4$).

A preliminary analysis of the metal-indicator and the metal-titration reagent system is necessary in order to obtain preliminary information on the stoichiometric coefficient N, the absence of consecutive equilibria, and all the competing equilibria occurring in the solution. For the NCHEL-LETAG program to be usable for evaluation of the titration curve it is necessary that the indicator complex predominantly formed is of the type MIn_N.

Acknowledgement—The authors wish to express their gratitude to Ing. Václav Říha and Doc. Ing. Stanislav Kotrlý, C.Sc. for valuable discussions on the experimental part of this contribution.

COMPARATIVE KINETIC STUDY FOR RATE CONSTANT DETERMINATION OF THE REACTION OF ASCORBIC ACID WITH 2,6-DICHLOROPHENOLINDOPHENOL

M. I. KARAYANNIS

Laboratory of Analytical Chemistry, University of Athens, 104 Solonos Str., Athens, Greece

(*Received* 15 *October* 1974. *Accepted* 18 *February* 1975)

Summary—The rate constant k of the reaction of ascorbic acid with 2,6-dichlorophenolindophenol (DCPI) in oxalic acid solutions is determined, by stopped-flow techniques. Four different methods are used to evaluate the results. The values and errors are compared statistically. The average of the rate constant is $56{\cdot}5 \times 10^3$ l. mole^{-1}. sec^{-1} and the overall standard deviation is $0{\cdot}6 \times 10^3$ l. mole^{-1}. sec^{-1} or 1·0% relative. The pH-dependence of the rate constant suggests that DCPI reacts with undissociated ascorbic acid.

The reaction of ascorbic acid and 2,6-dichlorophenolindophenol has been widely applied for the assay of ascorbic acid in various biological and food samples. The stoichiometry of the reaction was first proposed by Tilmans,[1] the products being dehydroascorbic acid and the leuco-compound of the indophenol. The reaction is very fast and first-order in respect to each of the participants. To our knowledge no kinetic study of the reaction has been undertaken in order to determine the second-order rate constant.

In the present investigation we have applied stopped-flow techniques to determine the rate constant and to study the effect of pH on the reaction. Oxalic acid solutions were used as reaction media, these being solvents commonly used for the extraction and isolation of ascorbic acid from natural or biological samples.

EXPERIMENTAL

Apparatus

A Durrum stopped-flow spectrophotometer, model D-131, was used. The course of the reaction was displayed on the screen of a storage oscilloscope (Tektronix R 564 B) and photographed with a "Polaroid" camera (Tektronix C-12).

Reagents

The solutions of ascorbic acid and 2,6-dichlorophenolindophenol (DCPI) were standardized volumetrically, with a 5-ml burette and class-A glassware. All runs were performed at 27°, the temperature being thermostatically controlled.

All solutions were prepared in distilled water from *p.a.* grade reagents. Ascorbic acid solutions were prepared from a 0·1000 *M* stock solution in 0·05 *M* oxalic acid. The buffers used were hydrochloric acid–potassium chloride for pH 1·3–2·0, 0·1 *M* potassium hydrogen phthalate–0·1 *M* hydrochloric acid (or 0·1 *M* sodium hydroxide) for pH 2·2–6·0, 0·1 *M* potassium dihydrogen phosphate–0·1 *M* sodium hydroxide for pH 6·0–7·5. Solutions of DCPI were prepared from a $1{\cdot}0 \times 10^{-3}$ *M* stock solution in a 210 mg/l. sodium bicarbonate solution. The DCPI solutions were standardized titrimetrically against prestandardized solutions of ascorbic acid, or photometrically on a Beckman DK double-beam spectrophotometer with a 1-cm cuvette. The molar absorptivity was taken to be $8{\cdot}60 \times 10^3$ l. mole^{-1}. cm^{-1} at 522 nm[2].

Procedure

The stopped-flow spectrophotometer was calibrated for zero and 100% transmittance with water in the observation cell. All measurements were performed at 522 nm which is the isosbestic point for DCPI at various pH values.[2] In all experiments the light-path was adjusted to give a signal of 800 mV with water in the observation cell (T = 1). The course of reaction was followed with the storage oscilloscope and the trace on the screen was photographed with a "Polaroid" camera.

Evaluation of the experimental data

All concentrations of ascorbic acid and DCPI given in the tables and diagrams are the actual values in the reacting mixtures at zero time after mixing.

In order to avoid systematic errors which may have been introduced during the experimental work, or appear during the evaluation of the data, four different techniques were applied for the calculation of the second-order rate constant k. The analytical conditions in each case were adjusted in such a way as to ensure the applicability of the treatment used.

Method A. For the bimolecular reaction

$$\mathrm{A} + \mathrm{B} \xrightarrow{k} \text{Products}$$

the rate law is given by the equation

$$\frac{-\mathrm{d}A_t}{\mathrm{d}t} = \frac{-\mathrm{d}B_t}{\mathrm{d}t} = kA_tB_t \tag{1}$$

where k, the rate constant, applies to a particular set of reaction conditions such as temperature, ionic strength and pH. If a spectrophotometric method is used and the transmittance T of the reacting mixture is monitored as the reaction progresses, the following mathematical expressions are valid, provided that the reactant B is the only absorbing species at the wavelength used:

$$\log\frac{V}{V_0} = -\epsilon_\mathrm{B}\,.\,b\,.\,B_t \tag{2}$$

where ϵ_B = molar absorptivity of B (l. mole^{-1}. cm^{-1}), b = light-path (cm), V_0 = output signal of the photomultiplier at transmittance $T = 1$ (800mV in the present work), V = output signal of the photomultiplier at transmittance T, and B_t = the instantaneous concentration of reactant B.

Differentiation of equation (2) with respect to time, and substitution of dB_t/dt from equation (1) gives

$$\frac{dV}{dt} = k\frac{(\mathrm{Abs})_t \cdot V}{0{\cdot}4343} \cdot A_t \tag{3}$$

where $(\mathrm{Abs})_t$ is the instantaneous absorbance of the reacting mixture, which is equal to $\epsilon_B . b . B_t$. At V = 294·3 mV the value of $(\mathrm{Abs})_t$ is 0·4343, the product $(\mathrm{Abs})_t . V$ has its maximum value and the value of the quantity $Q = (\mathrm{Abs})_t . V/0{\cdot}4343$ remains independent of V for the range 250–350 mV.[3] If the analytical concentration of B is adjusted to achieve the conditions above and $A_0 \gg B_0$ the simpler equation

$$\frac{dV}{dt} = k . Q . A_0 \tag{4}$$

can be used to determine k. This can be done by measuring the slope dV/dt of the reaction curve at signal level around 300 mV where the change of V with t is linear. The slope of the line $dV/dt = f(A_0)$ is the product kQ. Since values of Q can be calculated at each value of V, the rate constant k can be evaluated from the slopes in the diagrams.

Figure 1 is a typical oscilloscope picture of the reaction curves. A plot of dV/dt for the curves of Fig. 1, as a function of concentration of ascorbic acid, is a straight line, the slope of which is a measure of the rate constant and equal to Qk according to the theory above.

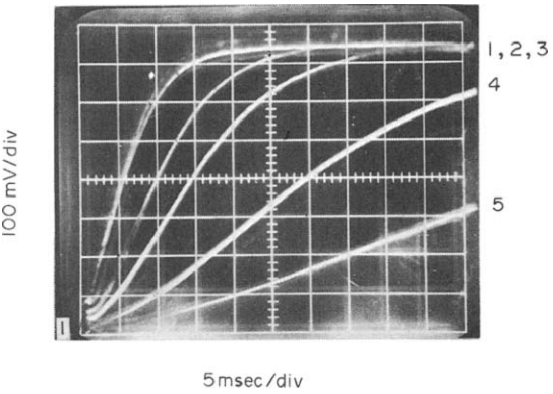

Fig. 1. Oscilloscope picture of the reaction of ascorbic acid and DCPI. DCPI, 1·0 × 10^{-4}M in NaHCO$_3$ solution; ascorbic acid, (1), 5 × 10^{-3}M; (2), 3 × 10^{-3}M; (3), 2 × 10^{-3}M; (4), 1 × 10^{-3}M; (5), 5 × 10^{-4}M.

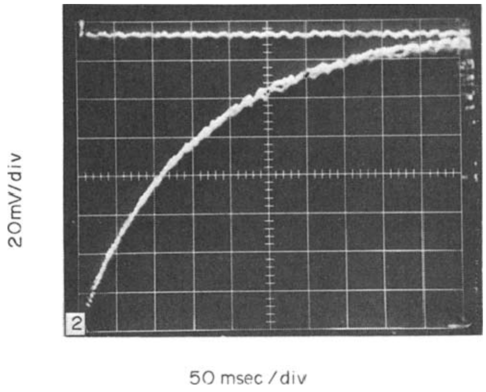

Fig. 2. Typical oscilloscope picture fot the application of methods B and D. DCPI, 5·0 × 10^{-6}M in NaHCO$_3$ solution; ascrobic acid, 12·5 × 10^{-5}M in 0·025M oxalic acid.

Table 1 lists the results of a series of eight such experiments evaluated by this method. The mean value of k is 55·9 × 10^3 l. mole^{-1}.sec^{-1}.

Method B. Starting from equation (3) and substituting ϵ_B = 8·60 × 10^3 l. mole^{-1}.cm^{-1} and b = 2 cm, we obtain:

$$\frac{2{\cdot}525 \times 10^{-5}}{V} \cdot \frac{dV}{dt} = kA_tB_t \tag{5}$$

A plot of the left-hand side of this equation against A_tB_t can be used to evaluate k, as follows. The slope dV/dt is measured at several values of V, then B_t is calculated at each V by calculating first the absorbance and then applying Beer's law. Finally A_t is calculated from

$$A_t = A_0 - B_0 + B_t \tag{6}$$

The starting concentrations A_0 and B_0 must be of the same order.

Three oscilloscope pictures, similar to the one shown in Fig. 2, were evaluated according to this method. When normalized, the results gave a linear plot for equation (5). Table 2 lists the results of 10 experiments which were evaluated by this method. The mean value of k is 56·8 × 10^3 l. mole^{-1}.sec^{-1}. The difference in the shape of the oscilloscope curves in Figs. 1 and 2 is due to the fact that the first shows the course of a pseudo first-order reaction, and the second that of a pure second-order reaction.

Method C. The oscilloscope pictures used in connection with method A were evaluated differently in this method. Since concentrations A_0 and B_0 are adjusted so as to create pseudo first-order conditions, with respect to B ($A_0 \gg B_0$), equation (1) can be written

$$\frac{dB}{dt} = -k_{ob} . B_t \tag{7}$$

		Mean k = 56·8
		s_k = 2·1
		$s_{\bar{k}}$ = 0·7

where $k_{ob} = kA_t \simeq kA_0$ is the observed rate constant. By the infinite time method,[4] k_{ob} can be determined from the oscilloscope pictures taken at different values of A_0 and at constant concentration B_0 (in all cases $A_0 \gg B_0$). On plotting k_{ob} against A_0 we can calculate k from the slope. A plot of ln $(A_\infty - A_t)$ *vs.* t, for the reaction curves of Fig. 1, gives a set of straight lines. From the slopes, k_{ob} values are calculated for each concentration of ascorbic acid. A plot of k_{ob} *vs.* A_0 gives k, since $k_{ob} = kA_0$. The results of 6 such experiments are shown in Table 3. The mean value is $k = 56·8 \times 10^3$ l. mole^{-1}.sec^{-1}.

Method D. The course of a second-order reaction of A and B, which is first-order with respect to each reactant and obeys the stoichiometric equation A + B = products, can be described mathematically by

$$\frac{1}{B_0 - A_0} \ln \frac{A_0 . B_t}{B_0 . A_t} = kt \qquad (8)$$

Experimental data may be presented linearly either by plotting the left-hand side of equation (8) against t, or with less calculation by plotting log B_t/A_t against t. The experimental data can also be evaluated without plotting, but just by solving equation (8) for k, after substitution of successive observed values of A_t, B_t and t.[5] This is also a test for second-order reaction kinetics, which was justified in our case.

A typical plot according to method D is linear. The final result of treating five such curves is shown in Table 4. The mean value of k obtained by this method is $56·2 \times 10^3$ l. mole^{-1}.sec^{-1}.

Effect of pH on the reaction rate constant k

The effect of pH was studied in four different experiments which were performed with various concentrations of the reagents DCPI and ascorbic acid. The pH range 1·1–6·0 was covered by mixing buffered solutions of ascorbic acid with solutions of DCPI in sodium bicarbonate ($NaHCO_3$ 210 mg/l.). The pH range 6·0–7·5 was covered by mixing aqueous unbuffered solutions of ascorbic acid with buffered solutions of DCPI. This procedure was followed to avoid prolonged exposure of the ascorbic acid to an alkaline environment, where it auto-oxidizes.

The results of these experiments are shown in Fig. 3.

RESULTS AND DISCUSSION

Tables 1–4 list the results of the evaluation of the experimental data according to methods A, B, C, and D as described above. In most of the cases shown in Table 1 the values of k were calculated by measuring dV/dt at $V = 300$ mV on the reaction curve, where Q has its maximum value. In some cases where the starting concentration of DCPI was lower than $2·0 \times 10^{-5}\,M$, the slope dV/dt was measured at $V > 360$ mV where $Q < 294·3$ mV and the linear part of the reaction curve is shorter. Both experimental conditions have their advantages and disadvantages, which are discussed elsewhere.[3] Column 2 of Table 1 lists the values of k corrected for a parameter Y.

$$Y = 1 - \frac{B_0}{A_0} + \frac{B_t}{A_0} \qquad (9)$$

appearing as a result of the substitution of A_0 for A_t in equation (3). These are the "apparent" values of the rate constant k. A second correction was applied to the "apparent" values for the contribution of species other than DCPI, in the absorbance of the

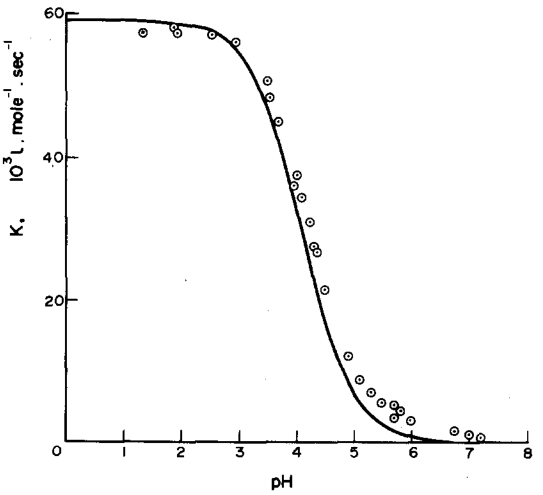

Fig. 3. Dependence of the rate constant k on the pH of the reaction mixture.

reacting mixture. This has a negative effect on the slope dV/dt which entails negative error in the final value of the slope kQ. The correction is based on the following considerations. In equation (3) magnitude (Abs) refers to the absorbance due to DCPI. We found that at 522 nm dehydroascorbic acid abbreviated DAA) also absorbs, having a molar absorptivity $\epsilon_{DAA} = 526$ l. mole^{-1}.cm^{-1}. This value is about 6% of ϵ_{DCPI}. If the contribution of DAA to the absorbance calculated from the oscilloscope pictures is considered, equation (3) must be replaced by

$$\frac{dV}{dt} = k.\frac{(\text{Abs})_t^m . V}{0{\cdot}4343}\left(1 - \frac{\epsilon_{DAA}}{\epsilon_{DCPI}}\right)A_0 Y \tag{10}$$

where $(\text{Abs})_t^m$ is the instantaneous absorbance of the reacting mixture. Equation (10) contains all corrections applied for the calculation of the k values given in column 3 of Table 1. Equation (10) shows that the Q values for each V must be corrected for the factor $1 - \epsilon_{DAA}/\epsilon_{DCPI}$, which has the value 0·939 for this particular case. The standard deviations of the means are calculated according to the equation

$$s_{\bar{k}} = \sqrt{\frac{\Sigma(k - k_i)^2}{N(N-1)}} \tag{11}$$

and the standard deviations for the method by using the equation

$$s_k = \sqrt{\frac{\Sigma(k - k_i)^2}{N - 1}} \tag{12}$$

Methods A and C give better reproducibility than methods B and D. This is obvious, since the measurement of the slope dV/dt in method A is accurate, because of the relatively long part of the reaction curves that is used. Method B requires the measurement of dV/dt at different points of a curved trace such as that shown in Fig. 2, which is less accurate.

The method of determining k_{ob} by the infinite-time method involves many points on the reaction curves and consequently the values obtained are accurate. This enhances the accuracy of method C. Methods B and D require the computation of the product A_tB_t of two small numbers, one of which is read from the trace and the other is computed by using equation (6). The probable error in B_t affects the accuracy of A_t as well as that of the product A_tB_t, thus introducing larger errors.

We have calculated the weighted average of the mean k values by using the relation[6]

$$k = \frac{\Sigma k_i w_i}{\Sigma w_i} \tag{13}$$

where w_i is the number of degrees of freedom for the ith method. The value of this average is $k =$ 56·5 × 10^3 l. mole^{-1}. sec^{-1}. The error associated with this average value was calculated by conventional methods of analysis of variance. The variance of the average k was calculated according to the equation[6]

$$s_k^2 = \frac{\Sigma s_i^2 w_i}{\Sigma w_i} \tag{14}$$

The result of this calculation is $s_k = 0{\cdot}6 \times 10^3$ l. mole^{-1}. sec^{-1} which is taken as the overall error for the average k.

Referring to Fig. 3, the S-shaped curve is reminiscent of titration curves and can be explained by the hypothesis that the main species participating is the product of a protolytic reaction. This suggests that the effect of $[H^+]$ on the reaction rate is indirect. Hydrogen ions do not participate directly in the reaction, but control the concentration of the reacting species in the mixture. Ascorbic acid acts as a weak diprotic acid with dissociation constants $K_{a_1} = 6{\cdot}17 \times 10^{-5}$ and $K_{a_2} = 1{\cdot}62 \times 10^{-12}$ ($pK_{a_1} = 4{\cdot}21$, $pK_{a_2} = 11{\cdot}79$) at 20°.[7] If we consider only the first dissociation, the experimental data can be explained by the hypothesis that the active species is undissociated ascorbic acid. The solid line in Fig. 3 is a theoretical curve which was derived by multiplying the value $k = 59{\cdot}0 \times 10^3$ l. mole^{-1}. sec^{-1} (extrapolated value of the experimental curve), by the ratio of the concentration of the acid form to the analytical concentration of ascorbic acid, at each pH. The two lines of Fig. 3 do not overlap fully at higher pH. Two explanations can be given for this disagreement. First, the experimental value $pK_{a_1} = 4{\cdot}25$ deviates from the theoretical (4·21) at higher pH values because of the effect of ionic strength. As stated above the measurements were carried out in buffers of relatively high ionic strength. Alternatively, the ascorbate ion may react with DCPI in a similar manner to ascorbic acid, but with a different rate constant, thus altering the overall value of the rate constant k. Both explanations can be justified by the experimental results.

Summary—Columns and papers of titanium arsenate have been utilized for chromatographic studies of several alkaloids in aqueous and mixed solvent systems. The results have been compared with those obtained with plain papers. A number of separations have been achieved on papers impregnated with titanium arsenate. Distribution coefficients of these alkaloids have been determined. A number of alkaloids have been separated quantitatively from nicotine on titanium arsenate columns.

Analytical applications of inorganic ion-exchange papers have considerably increased in number during the last few years,[1–4] but very few investigations of organic compounds have been made. Inorganic ion-exchange papers were first introduced in this field by Catelli,[5] who performed chromatography of amino-acids on zirconium phosphate papers. Chromatographic studies of alkaloids[6] on zirconium phosphate papers in a limited number of solvent systems have been reported. As far as we are aware no further attempt has been made to utilize inorganic ion-exchangers for the separation of organic compounds.

It has been found that titanium arsenate offers excellent ion-exchange properties and has a great separation potential for metal ions.[7] We decided to use titanium arsenate papers and columns for the separation of alkaloids and this paper summarizes the results of our studies.

EXPERIMENTAL

All chemicals used were of analytical grade.

Preparation of ion-exchange papers

Whatman No. 1 paper strips (15 × 3 cm) were first dipped in 0·5*M* titanium(IV) chloride for 10 sec and then dried on a sheet of paper for 15–20 min. The papers were then treated with 0·5*M* sodium arsenate solution for 20–30 sec to precipitate the ion-exchanger. The strips were again dried, washed with demineralized water to remove excess of reagents and finally dried at room temp. To check the reproducibility of the paper three sets were prepared and chromatography was performed on each. The results were found to be reproducible.

Preparation of solutions

Alkaloids. Solutions (1%) of all the alkaloids were prepared in ethanol, except for nicotine, which was dissolved in demineralized water.

Detection reagent. Dragendorff's reagent[8] was used for the detection of alkaloids, which give a red–orange spot with this reagent.

Chromatographic procedure

Ascending chromatography[1] was performed in ordinary glass jars (25 × 5 cm). The solvent was allowed to travel 11 cm from the point of application in all cases. The R_f values of the front and rear limits of the spot (R_L and R_T respectively) were recorded to determine the actual position of the spot. The developed chromatogram was air-dried and the spots detected by spraying with the reagent. Results are given in Tables 1–3.

Determination of distribution coefficients

Ion-exchanger in the H^+ form (0·5 g) was equilibrated at room temp (20 ± 5°) with solutions of the alkaloids,

in conical flasks. The total volume was adjusted to 50 ml with the desired solvents. The amount of alkaloid remaining in solution was determined spectrophotometrically.[9] The distribution coefficients were calculated according to the formula.

$$K_d = \frac{I - F}{F} \times \frac{50}{0{\cdot}5}$$

Where I = amount of alkaloid applied and F = amount of alkaloid found in solution after equilibration. The results are summarized in Table 4.

* Mixed with 2000 μg of nicotine.

solutions of nicotine (2000 μg) with other alkaloids (1000–2000 μg) were passed through the exchanger. Alkaloids other than nicotine were eluted with 0·1 M nitric acid, 40–50 ml (flow-rate 0·5 ml/min) being required. Nicotine interacts strongly with the exchanger and cannot be eluted. For each new separation, a fresh column was used. Results of the separations are given in Table 5.

RESULTS AND DISCUSSION

A comparison of the R_f values of the alkaloids on plain and ion-exchange papers reveals that in almost all the solvent systems the R_f values are lower on the ion-exchange papers. The R_f values generally increase with increasing hydrogen-ion concentration. On the basis of the R_f values, several separations are possible. Table 3 summarizes a number of binary separations.

The effect of reagent concentration on R_f was studied by using papers of different composition; the R_f values in general decrease with increase in the concentration of reagent. It was found that papers impregnated with 0·5 M titanium chloride and sodium arsenate solutions gave the best results. The affinity of various alkaloids for titanium arsenate in 10% acetic acid is in the order atropine > strychnine > brucine > cinchonine > quinine, which is the same as in the case of zirconium arsenate. However, the affinity trend observed in 1M hydrochloric acid on titanium arsenate is atropine > cinchonine > quinine > strychnine > brucine, which is different from the trend obtained on zirconium phosphate with the same solvent. It may be concluded that it is the anion of the exchanger which is responsible for the adsorption of the alkaloids.

Distribution coefficients of the alkaloids on titanium arsenate in various solvent systems were also determined and compared with the R_f values obtained on titanium arsenate papers. It is interesting to note that the sequence of K_d values is the reverse of the R_f values in almost all systems.

Codeine, atropine, strychnine, quinine and cinchonine have been recovered quantitatively from synthetic mixtures with nicotine, on titanium arsenate columns. Therefore titanium arsenate is specifically useful for the removal of nicotine impurities from a mixture containing a number of alkaloids.

QUELQUES APPLICATIONS DE LA COLORIMETRIE DE PRECISION A LA MICROANALYSE ELEMENTAIRE

DOSAGES DU TITANE, DU PLATINE, DU PALLADIUM, DU MOLYBDENE ET DU PHOSPHORE

Résumé—Le prélèvement analytique (organique et dans certains cas inorganique), de masse inférieure à 5 mg, est attaqué par voie humide, dans un micromatras, en vue de la mise en solution des éléments à doser. Le titane, le platine, le palladium, le molybdène et le phosphore sont dosés par colorimétrie spectrophotométrique en mettant respectivement en oeuvre les réactions suivantes: formation du complexe Ti(IV)–Tiron; formation de l'ion $[PtCl_4]^{2-}$ par réduction de l'ion $[PtCl_6]^{2-}$ par le chlorure stanneux; formation de l'ion $[PdI_4]^{2-}$; réduction ménagée de Mo(VI) en présence d'ions thiocyaniques; formation du complexe phosphovanadomolybdique.

La colorimétrie de précision déjà mise en oeuvre dans notre Service depuis plusieurs années pour le microdosage du fluor,[1–2] du phosphore[1] et du silicium[3] y est également appliquée à nombre d'autres microdosages dont, notamment, ceux du titane, du platine, du palladium et du molybdène, dans les composés organiques et certains composés inorganiques, après attaque par voie humide. Par ailleurs, le domaine de son application au microdosage du phosphore dans de semblables composés y est sensiblement élargi.

Les réactifs utilisés sont des produits classiques, commerciaux, qui présentent l'inconvénient d'un manque de spécifité; néanmoins, lorsque les produits soumis à l'analyse contiennent simultanément l'élément à doser et des éléments gênants, la quantité de ces derniers que peut contenir un prélèvement microanalytique est si petite qu'en général leur interférence sur le résultat du dosage est négligeable ou faible et peut alors être éliminée grâce à une correction appropriée ou à une légère modification du mode opératoire.

En vue d'appliquer à la microanalyse des méthodes colorimétriques jusqu'ici réservées à l'analyse de traces et dont, de ce fait, la sensibilité est trop élevée, nous avons été conduits à prélever 2 ou 3 parties aliquotes sur les solutions obtenues après attaque par voie humide; ces parties aliquotes fournissent le même nombre de résultats de dosage dont on effectue la moyenne qui est adoptée comme résultat définitif. Cette façon d'opérer permet d'éviter que l'analyse sur des parties aliquotes entraîne une réduction de la précision des résultats; elle permet, en outre, en jouant sur la diminution du volume des fioles jaugées définissant le volume initial de la solution obtenue après attaque par voie humide ou sur l'augmentation du volume de chacune des parties aliquotes, soit de diviser par 10 la masse des prélèvements milligrammiques du domaine microanalytique classique, soit d'effectuer les déterminations de très faibles teneurs.

Un autre intérêt de cette méthode est de permettre le dosage de nombreux éléments, hors séries, avec un même appareillage qui, à l'exception du spectrophotomètre, est peu coûteux; cet appareil doit permettre la détermination des absorbances à un ou deux millièmes d'unité près.

Les complexes ou ions colorés auxquels il est fait appel pour les dosages colorimétriques sont indiqués ci-après ainsi que les réactions qui permettent de les obtenir. Les références bibliographiques sont citées dans le tableau II.

Titane. Le Tiron (dihydroxybenzène-1,2 disulfonate de sodium-3,5), forme un complexe jaune avec le titane(IV) à pH 4,7; par ailleurs, l'addition d'acide oxalique permet d'éviter l'hydrolyse des sels de titane.

Platine. Le chlorure stanneux réduit l'ion $[PtCl_6]^{2-}$ en ion $[PtCl_4]^{2-}$ jaune.

Palladium. L'iodure de potassium forme un ion complexe $[PdI_4]^{2-}$, rose brunâtre, avec le palladium(II); l'iode produit est éliminé par réduction par le sulfite de sodium.

Molybdène. La réduction ménagée de Mo(VI) par l'iodure de potassium en présence d'ions thiocyaniques donne lieu à la formation de Mo(V) coloré en jaune; l'iode produit est éliminé par réduction par le sulfite de sodium.

Phosphore. La méthode déjà mise en oeuvre,[1] qui fait appel au complexe phosphovanadomolybdique, est adaptée en vue de son application élargie au domaine de la décimilligrammanalyse.

PARTIE EXPERIMENTALE

L'attaque, du type micro-Lorenz[4–5] ou micro-Lorenz modifié, est effectuée en micromatras, du type "Kjeldahl" (capacité du bulbe: 16 ml), sur une rampe de minéralisation à gaz[6] avec collecteur de fumées. Le chauffage au gaz peut être avantageusement remplacé par un chauffage électrique à faible inertie thermique (les dispositifs du type "grille électrique" trouvés sur le marché ne permettent pas, en effet, un refroidissement rapide des matras). A cette fin, conviennent des fours électriques tubulaires de 18 mm de diamètre intérieur, disposés comme l'a décrit Bigois.[7] L'ébullition est régularisée par l'introduction d'un petit morceau de plaque de verre fritté (porosité n° 1). La substance est pesée en tube pèse-substance de Lieb,[8a] en microampoule à un capillaire[8b] (à briser sous la surface du liquide) ou éventuellement en sachet de terphane.[9] Afin de pouvoir utiliser une microbalance électronique ou une ultramicrobalance permettant des pesées très précises (extension à la décimilligrammanalyse), le pèse-substance peut être remplacé par une micronacelle de platine. L'ensemble nacelle–prélèvement analytique est taré puis la nacelle est introduite horizontalement à l'intérieur du matras à l'aide de longues pinces droites à extrémités plates. Elle est alors renversée de telle sorte qu'une quantité maximale de produit tombe dans le bulbe du matras. Elle est ensuite retournée dans la position initiale et extraite du matras toujours horizontalement en évitant qu'à aucun moment elle ne touche les parois de ce dernier. Sa nouvelle pesée fournit, par différence avec la première, la masse de substance tombée dans le matras.

Après attaque par voie humide (*cf.* tableau 1) le contenu limpide de chaque matras est dilué avec de l'eau* et transvasé

—soit dans une fiole jaugée de capacité F (25, 50 ou 100 ml), dont le volume est ajusté avec de l'eau et de laquelle seront prélevées des parties aliquotes pour la colorimétrie,

—soit directement dans des fioles de colorimétrie† de capacité f dans lesquelles on peut d'ailleurs avoir préalablement introduit un réactif (acide oxalique dans le cas du dosage du titane).

Le terme "solution d'attaque" désigne la solution obtenue après attaque de l'échantillon par voie humide, et dans le cas de prélèvement de parties aliquotes, après dilution et ajustement du volume dans la fiole jaugée de capacité F.

L'option pour l'emploi ou non d'aliquotes est fonction de plusieurs facteurs dont le principal est la sensibilité de la méthode colorimétrique utilisée; en général, pour le phosphore et le molybdène, l'emploi d'aliquotes n'est pas recommandé.

En même temps que sont effectuées les attaques par voie humide, sont préparés des "blancs de solution d'attaque" en utilisant les mêmes réactifs, ainsi que le sachet de terphane si celui-ci doit être employé, et en suivant le même mode opératoire (avec dilution éventuelle lorsque la méthode comporte des prélèvements de parties aliquotes) que pour les attaques proprement dites; la seule différence est qu'il n'est pas procédé à l'introduction dans le matras, de substance à analyser. En effet, si l'influence desdits réactifs est négligeable dans les cas des dosages du titane, du platine et du phosphore à l'échelle milligrammique, elle ne l'est plus dans ceux des dosages du palladium et du molybdène; il faut alors en tenir compte.

A cette fin, il suffit alors d'introduire éventuellement dans chacune des fioles de colorimétrie les réactifs employés pour une attaque proprement dite après leur avoir fait subir un traitement identique à celui des conditions d'attaque§. Les quantités de réactifs à introduire doivent être telles que leurs concentrations finales soient égales entre elles dans toutes les fioles de colorimétrie (*cf.* remarque ci-après).

La colorimétrie est effectuée sans recours à une courbe d'étalonnage;[1] son usage est remplacé par celui de solutions étalons *cf.* tableau 2), contenant chacune une quantité connue (p mg) de l'élément à doser, introduite dans la fiole de colorimétrie sous la forme de v ml d'une solution titrée appropriée, préparées en même temps que les solutions inconnues contenant P mg de l'élément à doser. La solution inconnue est introduite dans une fiole de colorimétrie f sous forme de solution d'attaque soit en totalité (son volume est alors s), soit sous forme d'aliquotes (de volumes $a_1, a_2 \ldots a_i \ldots a_n$ ml) prélevées par pipettage dans la fiole F où la solution totale (de volume s) a été préalablement diluée.

La solution étalon étant toujours préparée en triple, en vue d'améliorer la précision, soit d', d'' et d''' les absorbances correspondantes et soit D celle de la solution inconnue, toutes mesurées par rapport à l'absorbance de la solution d'essai à blanc de réactifs (cette dernière est préparée comme une solution étalon, à l'exclusion de l'addition de solution titrée). La quantité inconnue P est calculée à partir de p par une simple règle de proportionnalité, d'après la formule:

$$P = \frac{pD}{(d' + d'' + d''')/3}$$

Il est recommandable que p et P aient des valeurs voisines; cependant, en ce qui concerne les éléments considérés dans le présent travail, la loi de Lambert–Beer étant assez bien suivie, la précision reste acceptable s'il arrive que l'écart croisse entre les valeurs de p et P, sous réserve que p demeure à l'intérieur des limites indiquées pour P dans le tableau 2.

Remarque. Lorsque les parties aliquotes prélevées ont des volumes $a_1, a_i \ldots a_n$ différents ($a_1 > a_i \ldots > a_n$), elles contiennent des quantités de réactifs d'attaque différentes, proportionnelles à leurs volumes respectifs. Lorsqu'il s'est avéré, au cours de l'étude préliminaire, que l'influence des réactifs d'attaque n'est pas négligeable, on s'arrange pour que la quantité totale de réactifs d'attaque soit égale, dans chacune des fioles de colorimétrie, à celle que contient l'aliquote a_1 dont le volume est le plus élevé.

A cette fin, on introduit:

—$w = a_1$ ml de "blanc de solution d'attaque" dans les "solutions d'essai à blanc de réactif" et les solutions étalons,

—$w = a_1 - a_1 = 0$, $w = a_1 - a_i$ ou $w = a_1 - a_n$ ml de "blanc de solution d'attaque" dans les solutions inconnues, lesquelles contiennent déjà respectivement a_1, a_i ou a_n ml de solution aliquote.

Pendant le temps (t) qui doit s'écouler entre la fin de la préparation des solutions (étalons, inconnues, d'essai à blanc) de colorimétrie et les lectures au spectrophotomètre (*cf.* tableau 2), les fioles sont laissées en attente à la température ambiante et à l'abri de la lumière (bien que cette dernière précaution puisse être superflue dans le cas de certains dosages).

Réactifs

Les réactifs sans mention spéciale sont des réactifs Prolabo "pour analyses", les réactifs employés tant pour l'attaque par voie humide que pour la colorimétrie sont uniquement cités sous la rubrique "attaque". L'eau utilisée est distillée au laboratoire dans un appareil en acier inoxydable.

---

* De l'eau bouillante doit être employée lors des dosages du phosphore et du titane.

† Le terme "fiole de colorimétrie" désigne la fiole jaugée dans laquelle est préparée la solution du complexe coloré, objet des mesures colorimétriques.

§ C'est cette possibilité de travailler dans des conditions identiques qui permet d'élargir le domaine d'application de la colorimétrie.

Titane

Attaque. Acide sulfurique (p.s. = 1,83); acide nitrique (p.s. = 1,38); eau oxygénée (110 vol).

Colorimétrie. Acide oxalique: solution aqueuse à 25%.

—Ammoniaque (p.s. = 0,90).

—Solution tampon à pH 4,7: solution aqueuse contenant 68 g d'acétate de sodium $NaCH_3COO.3H_2O$ (ou à défaut 50 g d'acétate de potassium KCH_3COO) et 30 ml d'acide acétique (p.s. = 1,05) par litre de solution.

—Tiron: solution aqueuse à 4% préparée au moins 4 à 5 h avant emploi. La solution doit être incolore; elle ne se conserve que quelques jours à l'abri de la lumière. La qualité du Tiron est très importante; le Tiron "Prolabo" a toujours donné satisfaction.

—Papier pH permettant de déterminer le pH à 0,5 unité près.

—Solution titrée de titane[10a] à 1 mg/ml: chauffer, à 200° au bain de sable jusqu'à dissolution complète (durée: environ 90 mn), 1,668 g de dioxyde de titane pur Prolabo (le lot utilisé s'est avéré de pureté suffisante), 10 g de sulfate d'ammonium et 55 ml d'acide sulfurique (p.s. = 1,83). Ajuster à 1 litre avec de l'eau. La solution est stable pendant plusieurs mois.

—Solution titrée de titane à 0,020 mg/ml: diluer avec de l'eau une partie de la solution précédente. Il n'est pas recommandé de préparer et de conserver une solution à 0,010 mg/ml par simple dilution de la solution à 1 mg/ml; en effet, la solution ainsi obtenue ne serait stable que pendant une quinzaine de jours (probablement parce que son pH est légèrement plus élevé: 2 au lieu de 1,5).

Platine

Attaque. Acide sulfurique (p.s. = 1,83); acide nitrique (p.s. = 1,38); acide chlorhydrique (p.s. = 1,19).

Colorimétrie. Chlorure stanneux: solution à 10% préparée tous les 8 jours. Peser 50 g de chlorure stanneux cristallisé, $SnCl_2.2H_2O$, ajouter 80 ml d'acide chlorhydrique (p.s. = 1,19) et compléter à 500 ml avec de l'eau; faire chauffer éventuellement jusqu'à température voisine de l'ébullition si la solution est hydrolysée; elle devient alors limpide. Arrêter aussitôt le chauffage et laisser refroidir.

—Fil de platine pur (à 99,95%) d'environ 0,05 mm de diamètre. Ce diamètre doit rester faible: la durée de dissolution d'un fil de 0,5 mm de diamètre, par exemple, serait, en effet, beaucoup trop longue dans les conditions décrites.

—Solution titrée de platine à 0,100 mg/ml: introduire dans un micromatras 100 mg de fil de platine préalablement grillé au rouge, dans la flamme d'un bec Bunsen, 1 ml d'acide nitrique (p.s. = 1,38) et 1 ml d'acide chlorhydrique (p.s. = 1,19). Faire bouillir sur la rampe de minéralisation jusqu'à évaporation presque à sec. Laisser refroidir et recommencer l'opération jusqu'à dissolution complète du platine; 3 ou 4 additions d'acides nitrique et chlorhydrique sont nécessaires. Faire ensuite bouillir 3 ou 4 fois avec 1,5 ml d'acide chlorhydrique jusqu'à disparition des vapeurs nitreuses. Evaporer chaque fois presque à sec sauf la dernière pour laquelle le volume résiduel doit être de 1 ml environ. Transvaser quantitativement le contenu du matras dans une fiole jaugée de 1 litre et ajuster avec de l'eau.

—Solution titrée de platine à 0,010 mg/ml: diluer avec de l'eau une partie de la solution précédente.

Palladium

Attaque. Mêmes réactifs que ceux utilisés pour le platine.

Colorimétrie. Ammoniaque (p.s. = 0,90).

—Iodure de potassium: solution à 50% préparée tous les 15 jours. Verser dans une fiole 2,5 ml d'ammoniaque (p.s. = 0,90), 250 g d'iodure de potassium et de l'eau en quantité suffisante pour dissoudre l'iodure. Compléter à 500 ml avec de l'eau. Conserver la solution à l'abri de la lumière.

—Sulfite de sodium anhydre Merck p.a.: solution aqueuse à 0,8% renouvelée par préparation tous les 2 jours.

—Mousse de palladium à 99,9%.

—Solution titrée de palladium à 0,100 mg/ml: introduire dans un micromatras 100 mg de mousse de palladium, 1 ml d'acide chlorhydrique (p.s. = 1,19) et 1 ml d'acide nitrique

Tableau 1. Attaques par voie humide

*E**	*m**	Type de substances analysées	Opérations successives effectuées en micromatras
Ti	0,5 à 5	Substances organiques	0,8 ml H_2SO_4 + 3 à 4 gouttes HNO_3; Eb* = 15; 2 fois 2 à 3 gouttes HNO_3; Eb = 15 + 15; 3 fois 3 à 4 gouttes H_2O_2; Eb = 15 + 15 + 30; 1,5 ml H_2O bouillante; Eb = 0.
	1 à 3	Substances inorganiques (nitrures, borures et boronitrures de titane...)	0,8 ml HNO_3 + 3 à 4 gouttes H_2O_2; Eb = 10; 0,8 ml H_2SO_4 + 3 à 4 gouttes H_2O_2; Eb = 15; 3 fois 3 à 4 gouttes H_2O_2; Eb = 15 + 15 + 15; 1,5 ml H_2O; Eb = 20.

P	0,4 à 5	Substances organiques	*cf.* Titane "organique"

* Signification des symboles.

E: Elément dosé.

m: Masse du prélèvement analytique en mg.

Eb: Durées d'ébullition exprimées en minutes; ces durées sont données à titre indicatif; les vapeurs nitreuses doivent être totalement chassées lors de la dernière addition d'acide chlorhydrique ou d'eau oxygénée; laisser refroidir après chaque ébullition (d'où l'intérêt d'un système de chauffage à faible inertie thermique). Eviter toute évaporation à sec.

(p.s. = 1,38). Porter à l'ébullition sur la rampe de minéralisation jusqu'à évaporation presque à sec. Laisser refroidir, introduire 1 ml d'acide chlorhydrique et faire bouillir jusqu'à ce que l'évaporation réduise le volume au 1/3 de sa valeur initiale. Recommencer l'opération 2 ou 3 fois jusqu'à disparition complète des vapeurs nitreuses. Transvaser le contenu du matras dans une fiole jaugée de 1 litre et ajuster avec de l'eau.

—Solution titrée de palladium à 0,010 mg/ml: diluer avec de l'eau une partie de la solution précédente.

Molybdène

Attaque. Mêmes réactifs que ceux utilisés pour le titane. *Colorimétrie.* Acide chlorhydrique (p.s. = 1,19).

—Iodure de potassium: solution aqueuse à 4% renouvelée par préparation quotidienne.

—Thiocyanate de potassium: solution aqueuse à 12%.

—Sulfite de sodium anhydre Merck p.a.: solution aqueuse à 1% renouvelée par préparation tous les 2 jours.

—Solution titrée de molybdène à 0,100 mg/ml: peser 0,1840 g de molybdate d'ammonium $(NH_4)_6Mo_7O_{24}.4H_2O$ et ajuster à un litre avec de l'eau.

Phosphore

Attaque et colorimétrie. Mêmes réactifs pour les prélèvements décimilligrammiques que ceux antérieurement décrits pour le niveau milligrammique[1] et pesages sans problèmes sur une ultramicrobalance grâce au transvase-

* Significations des symboles non définis dans le texte:

E: élément dosé.

F: capacité de la fiole dans laquelle est dilué le contenu du matras dans le cas de prélèvements aliquotes.

f: capacité de la fiole jaugée utilisée pour la colorimétrie.

P: masse d'élément à doser.

DO: absorbance.

e: épaisseur de la cuve de colorimétrie.

λ: longueur d'onde à laquelle est effectuée la mesure.

t: temps d'attente avant la lecture de l'absorbance sur le spectrophotomètre.

R: réactifs.

V: volume approximatif de solution à obtenir après addition d'eau.

ment dans le matras à l'aide d'une micronacelle de platine (*cf.* au dessus) ou à l'emploi de sachets de terphane.

Attaques par voie humide

Diverses méthodes sont mises en oeuvre selon l'élément à doser, elles sont réparties dans le tableau 1.

Colorimetrie

Les conditions de la colorimétrie sont indiquées dans le tableau 2, mais il reste toujours possible de modifier la capacité de la fiole utilisée pour la colorimétrie sous réserve de modifier également les volumes des réactifs qui y sont introduits. Les réactifs sont introduits dans la fiole jaugée de capacité f dans l'ordre indiqué dans la colonne R de ce tableau. Trois sortes de solutions sont ainsi préparées de façon similaire: solutions inconnues, solutions étalons, solutions d'essai à blanc.

Toutefois, introduire dans la fiole de colorimétrie

—*dans les cas des solutions inconnues*

(1) soit le volume total $A = s$ de la solution d'attaque, soit lors de prélèvements de parties aliquotes des volumes $A = a_1 \ldots A = a_i \ldots A = a_n$ de solution d'attaque avec $a_1 > \ldots > a_i \ldots > a_n$

(2) si nécessaire des volumes $w = s - s = 0$, $w = a_1 - a_1 = 0$, $w = a_1 - a_2 \ldots$, $w = a_1 - a_i \ldots w = a_1 - a_n$, de "blanc de solution d'attaque" selon que $A = s$, $A = a_1 \ldots$, $A = a_i \ldots$, $A = a_n$; lorsqu'il s'est avéré que l'influence des réactifs d'attaque est negligeable, on n'ajoute pas de "blancs de solution" dans les fioles de colorimétrie ($w = 0$ dans tous les cas), qu'il s'agisse de solutions inconnues,

de solutions étalons ou d'essai à blanc,

—*dans les solutions étalons*

(1) un volume $A = v$ de solution titrée

(2) éventuellement un volume $w = a_1$ ou $w = s$ de "blanc de solution d'attaque" selon que l'on procède, ou non, au prélèvement de parties aliquotes,

—*dans les solutions d'essai à blanc*

si nécessaire, un volume $w = a_1$ ou $w = s$ de "blanc de solution d'attaque".

Calculs

Teneur centésimale en élément E:

$$x\% = \frac{P \times F \times 100}{m \times a_i}$$

avec

$$P = \frac{p \times D}{(d' + d'' + d''')/3}$$

Lorsqu'il n'est pas procédé au prélèvement de parties aliquotes, la formule s'écrit plus simplement

$$x\% = \frac{P \times 100}{m}$$

RESULTATS ET DISCUSSION

Quelques résultats représentatifs de la méthode sont reportés dans le tableau 3.

Nous avons étudié l'influence de la présence simultanée d'éléments gênant le dosage de l'élément considéré, dans les produits soumis à l'analyse, au fur et à mesure que les problèmes se sont présentés; leurs listes reportées, ci-après, ne sont donc pas exhaustives. Les teneurs en éléments gênants sont de l'ordre de grandeur de quelques dixièmes de milligrammes pour 1 ou 2 mg de prélèvement analytique.

Dosage du titane

As, B, Br, Cl, Co, Cu, F, Hg, K, N, Na, P, Pt, S, Sb, Se, Sn ne gênent pa (*cf.* également Yoe[11] et Clark[13]). Ba ne gêne plus après filtration préalable de la solution d'attaque. Fe, I, Mo, Pd gênent.

Dosage du platine

Al, Br, Cl, Fe, K, N, Na, Ni, P, S, Ti ne gênent pas. Cs, Pd et Rb gênent.

Dosage du palladium

As, B, Br, Cl, I, Mo, N, P, S, Sn, Ti ne gênent pas. Se gêne.

Dosage du molybdène

As, B, Br, Cl, Cs, F, Hg, I, K, N, Na, P, S, Sb, Sn ne gênent pas. Ag, Pd, Pt, Se gênent. Si ne gêne plus après filtration en vue d'éliminer le précipité qui apparait lors de la dilution du contenu du matras.

Dosage du phosphore

Ag, B, Br, Ca, Cd, Ce, Cl, Co, Cu, F, Fe, Ga, Hg, I, K, La, Li, Mg, Mo, N, Na, Nd, Ni, Pb, Re, S, Sb, Se, Sn, Te, Th, Ti, V, Zn ne gênent pas. Ba, Ru ne gênent plus après filtration préalable de la solution d'attaque.

Ir gêne mais Ge et W ne gênent pas dans tous les cas; l'influence de leur présence dépend vraisemblablement de la forme moléculaire sous laquelle ils passent en solution qui dépend elle-même des compositions et structures des composés soumis à l'analyse.

En présence de Pd, Pt, Rh, la solution d'attaque est colorée en jaune ce qui conduit à l'obtention de résultats légèrement erronés par excès. Il est cependant possible de leur apporter une correction, fonction de la teneur en Pd, Pt, Rh; c'est ainsi que la présence de 0,6 mg de Pd, Pt ou Rh donne lieu à des corrections négatives respectives correspondant à 0,014, 0,004 et 0,007 mg de phosphore. Ces corrections étant faibles, il suffit de connaître approximativement la teneur en Pd, Pt ou Rh pour les calculer.

L'effet gênant de Si est éliminé (après filtration éventuelle de la solution d'attaque) comme l'indique Charlot[10c] en effectuant la colorimétrie en milieu acide nitrique (remplacer 2 ml de H_2SO_4 18M par 12 ml de HNO_3 13M lors de l'emploi de fioles de 200 ml) et en effectuant la lecture d'absorbance à une longueur d'onde de 420 nm au lieu de 410 nm; la loi de Lambert–Beer est alors un peu moins suivie.

L'effet gênant de As est éliminé en ajoutant au contenu du matras après attaque 2 ml d'eau, environ 100 mg de bromure de potassium[20] p.a. et en portant à l'ébullition pour bien concentrer le liquide. Ce liquide doit être incolore et le col du matras clair (le chauffer légèrement, à cette fin, si nécessaire, avec un bec Bunsen*).

CONCLUSION

Les méthodes spectrophotométriques, associées à une attaque par voie humide des composés à analyser sont faciles à mettre en oeuvre et susceptibles de s'appliquer aux microdosages d'un grand nombre d'éléments, dans les substances organiques et certaines substances inorganiques, non seulement sur des prélèvement milligrammiques mais souvent, également, décimilligrammiques. Elles rendent donc de précieux services, dans les laboratoires de microanalyse, du fait de la tendance actuelle à la diversification croissante des dosages élémentaires qui leur sont demandés.

SHORT COMMUNICATIONS

COMPUTER CALCULATION OF DISTRIBUTION DIAGRAMS

RICCARDO MAGGIORE, SALVATORE MUSUMECI and SILVIO SAMMARTANO
Instituto di Chimica Generale dell'Università, viale A. Doria,
8 - 95125 Catania, Italy

(*Received* 21 *November* 1974. *Revised* 21 *April* 1975. *Accepted* 19 *May* 1975)

To study equilibria in solutions containing several metals and ligands, we must know the concentrations of the various species. Generally, as the formation of the complexes is a function of acidity, a convenient way of representing the distribution of species is to plot the function $\alpha_j = f(\mathrm{pH})$, where α_j indicates the degree of formation of the *j*th species. If the formation constants of all the species and the analytical concentrations of the various components (metals and ligands) are known, they can be used to calculate distribution diagrams, which will (*a*) facilitate choice of experimental conditions for obtaining better values for the formation constants, (*b*) give the pH for maximum formation of certain species, (*c*) indicate which complexes are formed to a negligible extent.

In the last ten years various programs have been published for dealing with equilibrium systems; the most important are HALTAFALL[1], COMICS[2] and EQUIL.[3] HALTAFALL and COMICS use simple iterative methods, and EQUIL uses the Newton–Raphson method. As a rule the Newton–Raphson method is preferable as it requires fewer iterations; on the other hand, each of its iterations requires a longer calculation time, the program is more complicated and therefore requires more computer memory space, and finally, the program sometimes diverges more easily than other iterative methods.

We have developed a practical and simple program (DISDI) for obtaining quickly the distribution diagrams of systems containing up to one metal and two ligands, producing various species in equilibrium.

METHOD

The mass balance equations for the most complex case are

$$\mathrm{M} = \mathrm{m} + \textstyle\sum p\, \beta_{pqrs}\, \mathrm{m}^p\, \mathrm{a}^q\, \mathrm{b}^r\, \mathrm{h}^s$$

$$\mathrm{A} = \mathrm{a} + \textstyle\sum q\, \beta_{pqrs}\, \mathrm{m}^p\, \mathrm{a}^q\, \mathrm{b}^r\, \mathrm{h}^s$$

$$\mathrm{B} = \mathrm{b} + \textstyle\sum r\, \beta_{pqrs}\, \mathrm{m}^p\, \mathrm{a}^q\, \mathrm{b}^r\, \mathrm{h}^s$$

$$\mathrm{H} = \mathrm{h} + \textstyle\sum s\, \beta_{pqrs}\, \mathrm{m}^p\, \mathrm{a}^q\, \mathrm{b}^r\, \mathrm{h}^s$$

where M, A, B and H are the analytical concentrations of the metal, the two ligands and the hydrogen ions respectively, and the small letters indicate the free concentrations of these species.

All iterative methods require an initial guess. Starting at low pH, where we can assume that there is little formation of complexes, we have

$$\mathrm{m}^0 = \mathrm{M}$$

$$\mathrm{a}^0 = \mathrm{A}/(1 + \textstyle\sum \beta_s^{\mathrm{H}}\, \mathrm{h}^s)$$

$$\mathrm{b}^0 = \mathrm{B}/(1 + \textstyle\sum \beta_s^{\mathrm{H}}\, \mathrm{h}^s)$$

where the β_s^{H} terms represent the protonation oconstants of the two ligands. Successive approximations are obtained by means of these equations:

$$\mathrm{m}_i = \mathrm{m}_{i-1}\, (\mathrm{M}/\mathrm{M}_{\mathrm{calc}} + 1)/2$$

$$\mathrm{a}_i = \mathrm{a}_{i-1}\, (\mathrm{A}/\mathrm{A}_{\mathrm{calc}} + 1)/2$$

$$\mathrm{b}_i = \mathrm{b}_{i-1}\, (\mathrm{B}/\mathrm{B}_{\mathrm{calc}} + 1)/2$$

This iterative method is similar to the one used by Perrin and Sayce for the program COMICS $[\mathrm{m}_i = \mathrm{m}_{i-1}\, (\mathrm{M}/\mathrm{M}_{\mathrm{calc}})^{1/2};\ x \sim (x+1)/2 \text{ if } x \sim 1]$. For successive points, we generally use the preceding value of the free concentration as the initial value:

$$\mathrm{m}_k^0 = \mathrm{m}_{k-1};\ \mathrm{a}_k^0 = \mathrm{a}_{k-1};\ \mathrm{b}_k^0 = \mathrm{b}_{k-1}$$

If we consider, on the other hand, that $\mathrm{m} = g_{\mathrm{m}}(\mathrm{pH})$, $\mathrm{a} = g_{\mathrm{a}}(\mathrm{pH})$ and $\mathrm{b} = g_{\mathrm{b}}(\mathrm{pH})$ are monotonic continuous functions†, we can apply a simple method of interpolation to obtain an approximate value of m_k^0 (and analogously for a_k^0 and b_k^0):

$$\mathrm{m}_k^0 = \mathrm{m}_{k-1} - (\mathrm{m}_{k-2} = \mathrm{m}_{k-1})RW$$

$$R = (\mathrm{pH}_{k-1} - \mathrm{pH}_k)/(\mathrm{pH}_{k-2} - \mathrm{pH}_{k-1})$$

If the pH intervals are kept constant ($R = 1$), we can simplify the equation to:

$$\mathrm{m}_k^0 = \mathrm{m}_{k-1} - (\mathrm{m}_{k-2} - \mathrm{m}_{k-1})W$$

where W is a correction factor for non-linear functions. We should take a different W for every point, but in practice we obtain a good approximation by giving W a value of 0·85.

RESULTS

The program has been written in FORTRAN IV in two versions. In the first, DISDI, it calculates the concentrations of all the species present over a given pH range, starting from the analytical concentrations of the components, the formation constants, the initial pH, the pH increments and the pH range, and prints them in tabular form together with the degree of formation $\alpha_j = C_j/\mathrm{M}$ (for the species containing the metal) and $\alpha_j = C_j/\mathrm{A}$ or $\alpha_j = C_j/\mathrm{B}$ (for the species that do not contain the metal). The second, DISDI*, besides doing the same as DISDI, prints out the distribution diagram. To show species

---

† A function $y = f(x)$ is said to be monotonic in a certain range if, as x increases within this range, the change of y is always of the same sign, or zero, but not positive in one part of the range and negative in another.

Table 1. Some characteristics of the programs COMICS, EQUIL, DISDI and DISDI* used on a CDC 6600 computer

Program	S	Tco	Tca	M	D	M-D
COMICS	176	1·2	170	19·2	9·6	9·6
EQUIL	429	2·6	80–190	14·8	4·1	9·6
DISDI	154	1·2	100	9·3	0·3	9·0
DISDI*	237	1·6	135	17·0	7·6	9·4

S: number of cards. For the program COMICS and EQUIL there is a little difference from the original number, but only in the data input.

Tco: compilation time, *sec.*

Tca: calculation time referred to the program DISDI (= 100).

M: total number of memories (K storage locations) required for the programs in the version used.

D: total number of memories required by dimensions assigned to the variables.

M − D: difference between the total memories and those required by dimensions assigned to the variables. This parameter is more significant than either D or M because the dimensions can be easily varied according to the requirements of the program user.

formed in a minor or negligible quantity, a graph of log $\alpha = f(\mathrm{pH})$ can also be printed.

These two programs have been applied to more than 30 different systems and have never shown any convergence problem. They have also been compared with COMICS and EQUIL. DISDI used many fewer iterations than COMICS for most of the points, and although EQUIL converged faster, the calculation time was not lower. Table 1 gives some data for DISDI, DISDI*, COMICS and EQUIL.

In testing the program DISDI*, the dimensions used for the distribution diagrams were 32 × 23 cm, but were later reduced to 25 × 17 cm, which is sufficient in most cases. If the iterative process is stopped when the differences $M - M_{\mathrm{calc}}$, $A - A_{\mathrm{calc}}$ and $B - B_{\mathrm{calc}}$ are less than 0·01% (and not 0·001% as for the data reported in Table 1) the number of iterations and hence the calculation time is reduced by 20–60%, with a difference of 0·001, at most, in $-\log C_j$.

DISDI is simple to use, does not greatly encumber the computer memory and is rapid. The more complex version, DISDI*, has the advantage of giving immediate representation of the species distribution in the system considered.

The complete listing of the program DISDI* is available from the authors on request.

Acknowledgements—We thank Dr. C. Rigano for the valuable advice he has given us in developing the programs, and the C.N.R. for financial support.

DETERMINATION OF IRON IN SILICATE ROCKS BY SUBSTOICHIOMETRIC RADIOISOTOPE DILUTION ANALYSIS

E. Gundersen and E. Steinnes

Institutt for Atomenergi, Isotope Laboratories, Kjeller, Norway

(*Received* 5 *February* 1975. *Accepted* 16 *April* 1975)

Although substoichiometric isotope dilution analysis is considered most useful at trace element levels, it can also be advantageously used for the precise determination of major components.[1] This is so because the two most important factors for the overall precision of such a method, *i.e.*, the reproducibility of the substoichiometric separation and the counting statistics, may both be kept at a very low variablity where relatively large amounts of an element are to be determined. In a previous work by the authors[2] it was shown that the determination of iron in biological reference materials could be carried out with high precision at the concentration levels concerned. It was decided to see whether a similar method could be used for the determination of the total concentration of iron in rocks with satisfactory precision and accuracy.

The method for biological material is based on wet-ashing of the sample with nitric acid and sulphuric acid and subsequent extraction of iron from $3M$ sodium chloride medium and back-extraction with dilute nitric acid. A procedure similar to that of Starý and Růžička[3] is then followed. A substoichiometric amount of EDTA is added, and the solution is applied to a cation-exchange column, where the excess of iron is retained, while the Fe(III)–EDTA complex passes through quantitatively.

In testing the program DISDI*, the dimensions used for the distribution diagrams were 32 × 23 cm, but were later reduced to 25 × 17 cm, which is sufficient in most cases. If the iterative process is stopped when the differences $M - M_{\mathrm{calc}}$, $A - A_{\mathrm{calc}}$ and $B - B_{\mathrm{calc}}$ are less than 0·01% (and not 0·001% as for the data reported in Table 1) the number of iterations and hence the calculation time is reduced by 20–60%, with a difference of 0·001, at most, in $-\log C_j$.

DISDI is simple to use, does not greatly encumber the computer memory and is rapid. The more complex version, DISDI*, has the advantage of giving immediate representation of the species distribution in the system considered.

The complete listing of the program DISDI* is available from the authors on request.

Acknowledgements—We thank Dr. C. Rigano for the valuable advice he has given us in developing the programs, and the C.N.R. for financial support.

DETERMINATION OF IRON IN SILICATE ROCKS BY SUBSTOICHIOMETRIC RADIOISOTOPE DILUTION ANALYSIS

E. Gundersen and E. Steinnes

Institutt for Atomenergi, Isotope Laboratories, Kjeller, Norway

(*Received* 5 *February* 1975. *Accepted* 16 *April* 1975)

Although substoichiometric isotope dilution analysis is considered most useful at trace element levels, it can also be advantageously used for the precise determination of major components.[1] This is so because the two most important factors for the overall precision of such a method, *i.e.*, the reproducibility of the substoichiometric separation and the counting statistics, may both be kept at a very low variablity where relatively large amounts of an element are to be determined. In a previous work by the authors[2] it was shown that the determination of iron in biological reference materials could be carried out with high precision at the concentration levels concerned. It was decided to see whether a similar method could be used for the determination of the total concentration of iron in rocks with satisfactory precision and accuracy.

The method for biological material is based on wet-ashing of the sample with nitric acid and sulphuric acid and subsequent extraction of iron from 3*M* sodium chloride medium and back-extraction with dilute nitric acid. A procedure similar to that of Starý and Růžička[3] is then followed. A substoichiometric amount of EDTA is added, and the solution is applied to a cation-exchange column, where the excess of iron is retained, while the Fe(III)–EDTA complex passes through quantitatively.

Table 1. Concentration of iron in five U.S. Geological Survey standard rocks, determined by substoichiometric radioisotope dilution (% Fe)

	Andesite AGV-1	Basalt BCR-1	Granite G-2	Granodiorite GSP-1	Diabase W-1
	4·71	9·30	1·89	3·00	7·78
	4·71	9·39	1·90	2·95	7·80
	4·72	9·28	1·91	3·01	7·83
	4·71	9·43	1·88	3·00	7·87
	4·79	9·31	1·95	3·00	7·80
	4·81	9·32	1·92	3·01	7·85
Mean value	4·74	9·34	1·91	3·00	7·82
Relative standard deviation, %	0·97	0·62	1·26	0·78	0·45
Expressed as % Fe_2O_3	6·78	13·35	2·73	4·29	11·18
Johansen and Steinnes,[4] neutron activation	6·75	13·40	2·65	4·31	11·12
Fleischer,[5] recommended value					11·09
Flanagan,[6] average value	6·80	13·51	2·77	4·33	

After some preliminary experiments it appeared that the method, with some small modifications, could be applied to the determination of total iron in rocks after hydrofluoric acid dissolution of the sample.

EXPERIMENTAL

Apparatus

Counting equipment. A scintillation counter with a 75 × 75 mm NaI(Tl) crystal.

Cation-exchange columns. Tubes of 12 mm internal diameter filled with Dowex 50W-X8, 100–200 mesh, Na^+-form, to give a 50-mm height of resin bed. The column is prepared by treating the resin in the H^+-form with an excess of 1*M* sodium hydroxide and washing with water until the eluate is neutral.

Reagents

The reagents used were *pro analysi* grade.

EDTA solution. Prepared by dissolving the disodium salt of EDTA in water. The solution was standardized against Fe(III) solutions of known concentration, according to the substoichiometric procedure given below.

^{59}Fe tracer. A solution of specific activity 3000 mCi/g was diluted with 0·1 M hydrochloric acid to a concentration of about 1μCi/ml.

Boric acid solution, 30 *mg/ml.*

Procedure

Weigh accurately about 50 mg of finely divided rock powder into a 100-ml Teflon beaker. Add 10 ml of concentrated hydrofluoric acid, 2 ml of concentrated nitric acid and 1·00 ml of ^{59}Fe tracer solution. Evaporate the mixture to complete dryness on a hot-plate. Then add 5 ml of 6*M* hydrochloric acid and 1 ml of boric acid solution and evaporate to dryness again. Dissolve the residue in 5 drops of concentrated nitric acid and 15 ml of 4*M* sodium chloride, then extract with 15 ml of isopropyl methyl ketone. Back-extract the iron with 15 ml of 0·01*M* nitric acid. To the resulting solution add a known volume of EDTA solution corresponding stoichiometrically to an amount of iron (y) which is about 60% of the estimated amount of iron in the sample (1 molecule of EDTA corresponds to 1 atom of Fe).

Allow the solution to stand for 10–15 min at 30–40°, and then pass it through the cation-exchange column (flow-rate about 0·5 ml/min), taking care to transfer the solution quantitatively to the column. Wash the column with two 5-ml portions of water. Measure the activity of the combined eluates (A_s) with the scintillation counter, and the activity of 1·00 ml of ^{59}Fe tracer solution diluted to the same volume (activity A_r). Calculate the amount of iron (x) present in the sample from the relationship $x = y\,A_r/A_s$.

The reagent blank, determined in the same way as described above, was found to be insignificant when working in the concentration range in question.

RESULTS AND DISCUSSION

The method was tested on five U.S. Geological Survey standard rocks with composition ranging from basaltic to granitic and with iron contents in the range 1·9–9·3%. These standard rocks have been analysed in many laboratories by a variety of analytical techniques, and their iron contents can be assumed to be well known. Before this work the same rocks were analysed in the authors' laboratory by a radiochemical neutron-activation method[4] assumed to yield results of high accuracy. A comparison of the results obtained by substoichiometric isotope dilution with the literature values is given in Table 1. The agreement with the recommended values is within 1·5% relative in all cases. A similarly good agreement is evident with the work of Johansen and Steinnes,[4] except in the case of G-2 where the neutron-activation values seem to be about 3–4% low.

The good agreement with the literature values seems to indicate that no significant systematic errors were present in the analyses. The relative standard deviation is about 0·5–1% for iron contents exceeding 3%. This implies that the quality of data obtained by the substoichiometric isotope dilution method described in this work would be as good as that of most data produced by the conventional methods of rock analysis. The present method may not be well suited for routine analyses, but could be a useful supplement in cases where the results obtained by other methods are to be checked.

Summary—Iron is determined in rocks by an isotope dilution method involving dissolution with hydrofluoric acid, extraction of iron(III) chloride into isopropyl methyl ketone, stripping with dilute nitric acid, and substoichiometric separation of the Fe–EDTA complex on a cation-exchange column. The precision and accuracy are 1·5% relative or better, as indicated by analyses of some U.S. Geological Survey standard rocks.

SEQUENTIAL DETERMINATION OF THORIUM AND RARE EARTHS WITH EDTA AND KOJIC ACID

S. Y. SHETTY and R. M. SATHE

Analytical Chemistry Division, Bhabha Atomic Research Centre, Modular Labs.,
Trombay, Bombay-400085, India

(*Received* 23 *January* 1975. *Accepted* 20 *April* 1975)

The significant differences in the stabilities of the EDTA complexes of thorium and the rare earth metals can, in principle, be exploited for sequential determination of these ions. Thorium can be conveniently titrated at pH 2·0 followed by the rare earths at pH 5·5. Such a procedure, however, meets with difficulty in practice. The indicator suitable for this pH range is Xylenol Orange (XO). The free indicator is lemon-yellow and its complexes red-violet. After the initial titration of thorium, however, the Th-EDTA complex produces a pink colour when the pH is raised to 5·5, thus making titration of the rare earths impossible. Přibil and Veselý[1] ascribed this colour to the formation of a ternary complex Th–EDTA–XO and suggested the use of excess of acetylacetone to prevent its formation so that the rare earths could be titrated. We have found kojic acid to be a similar masking agent for this purpose and its use is described in this note. Though the use of ligands such as DTPA or TTHA obviates the need for such a masking agent, the ready availability of EDTA makes its use still attractive.

EXPERIMENTAL

Reagents

Rare earth solutions. Rare earth metal oxides (purity $\geqslant$ 99·9%) were dissolved in nitric acid and the solutions standardized by EDTA titration with hexamine as buffer and XO as indicator.

Thorium solution. Thorium nitrate ($\geqslant$99·9%) was dissolved and the solution standardized with EDTA.

Xylenol Orange. A freshly prepared 0·5% solution of sodium salt in water.

Kojic acid. The BDH (biochemical grade) product was recrystallized from alcohol (with animal charcoal added) to give buff needles.

All other reagents were analytical grade.

Procedure

Dilute the sample solution containing about 10 mg of thorium and 50–60 mg of rare earth metals to about 200 ml and adjust the pH to 1·9–2·0 with ammonia or nitric acid, using a pH-meter. Add a few drops of XO and titrate slowly with 0·05*M* EDTA till the colour changes from pink to lemon-yellow. Add kojic acid (solid) equivalent to about ten times the thorium content and stir well to dissolve it. Raise the pH to 5·5 (pH paper) with a saturated solution of hexamine. Titrate further with 0·05*M* EDTA till the pink colour again completely changes to yellow.

Analysis of monazite. Isolate thorium and rare earth metals from the sample as oxalates by the method of Schoeller and Powell.[2] Carefully ignite to the oxides at 650–700°, dissolve these in hydrochloric acid (to keep cerium in the 3+ state) and make up to standard volume. Titrate a suitable aliquot as above.

RESULTS AND DISCUSSION

Our potentiometric studies on mixed-ligand chelates of thorium have revealed that kojic acid forms a colourless ternary complex with Th–EDTA at a pH as low as 4·5, and can be used to suppress the formation of the pink Th–EDTA–XO chelate. If kojic acid is added after the first end-point, sequential titrations of mixtures containing different amount of Th^{4+} and Ln^{3+} can be successfully accomplished (Table 1).

The advantage of kojic acid over acetylacetone is its higher solubility in water and thus it can be used for higher concentrations of thorium. The colour change is quite sharp and no heating is necessary as in the case of acetylacetone. However, the heavier rare earths, if present in amounts higher than that of thorium, have been found to interfere in the thorium determination. The method has been found to work successfully for monazite, which mainly contains lanthanum, cerium, neodymium and praseodymium, the validity being established by titration of a second aliquot of solution with DTPA for comparison.

THE CHALCOCITE COPPER MEMBRANE ELECTRODE

A. HULANICKI, M. TROJANOWICZ and M. CICHY*

Institute of Fundamental Problems in Chemistry, University, Warsaw, Poland

(*Received* 18 *December* 1974. *Accepted* 30 *April* 1975)

Copper-sensitive membrane electrodes have been used several times recently as potentiometric sensors in complexometric titrations,[1–12] both of copper ions, and of other metals with copper as the indicator ion. Several electrodes are at present commercially available. In our studies a new type of electrode has been used, in which a single crystal of chalcocite—a copper(I) sulphide—has been employed as the membrane.

EXPERIMENTAL

Reagents and apparatus

A Radiometer PHM 26 pH meter was used for potential measurements, and a Radelkis OP-206 pH meter for pH measurements. A Metrohm Multidosimat E 415-10 G was used for the titrations. A Radiometer K 401 saturated calomel electrode was used as the reference electrode. The indicator electrode was made by mounting a 1-mm thick crystalline plate, 5 mm in diameter, at the end of a glass tube, by means of silicone rubber. An Ag/AgCl electrode was immersed in the internal solution containing copper(II) chloride.

All reagents were of analytical grade, except tetraethylenepentamine (TETREN) (Koch–Light) which was further purified.[13] Solutions were prepared with twice-distilled water. The copper(I) solutions were prepared from CuCl and the Cu(I)/Cu(II) ratio was determined by redox potential measurement.

The numerical calculations were carried out on the GIER computer of the Dept. of Numerical Calculations of this University.

RESULTS AND DISCUSSION

When calibrated in copper(II) solution prepared by successive dilution, a strictly Nernstian relationship with 29-mV slope was obtained down to pCu = 5. With the copper(II) ion buffers—the so called pCu buffers[14]—a linear plot was obtained over a much broader range, namely to below 10^{-20} M (Fig. 1). Buffers perfectly suitable for such purposes were obtained by varying the pH of a 10^{-3} M Cu^{2+} solution containing a fivefold amount of TETREN. The shape of the curve calculated by using the HALTAFALL program,[15] is in good overall agreement with the experimental results, but the position of the curve along the pCu axis depends significantly on the numerical values of the constants, which differ when taken from various references. This is especially severe at low pH values, where formation of protonated complexes makes the data less reliable.

Beside the dependence on the copper(II) ion activity, with a slope of about 29 mV per decade, a dependence on the activity of copper(I) ions has also been found, with a slope equal to 53 mV per decade. These results suggest that the following relationship holds for the copper electrode:

$$E = E^0 + \frac{RT}{F}\ln[a_{\mathrm{Cu}^+} + K_{\mathrm{Cu}^{2+},\mathrm{Cu}^+}(a_{\mathrm{Cu}^{2+}})^{1/2}] \qquad (1)$$

When

$$a_{\mathrm{Cu}^+} \ll K_{\mathrm{Cu}^{2+},\mathrm{Cu}^+}(a_{\mathrm{Cu}^{2+}})^{1/2} \qquad (2)$$

and

$$E^{0'} = E^0 + \frac{RT}{F}\ln K_{\mathrm{Cu}^{2+},\mathrm{Cu}^+} \qquad (3)$$

then an equation for the potential as a function of the activity of copper(II) ions can be obtained, having the form:

$$E = E^{0'} + \frac{RT}{2F}\ln a_{\mathrm{Cu}^{2+}} \qquad (4)$$

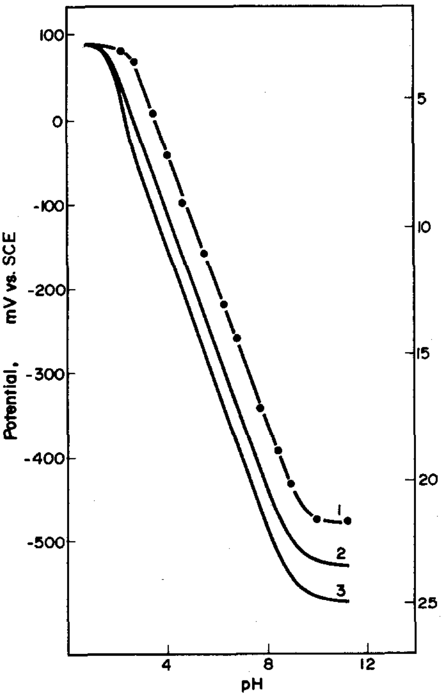

Fig. 1. Calibration curve for copper electrode in $10^{-3}M$ Cu, $5 \times 10^{-3}M$ TETREN, 0·1M $\mathrm{KNO_3}$. Curve 1—experimental, 2—theoretical acc. to Paoletti *et al.*,[20] 3—theoretical acc. to Ringbom.[21]

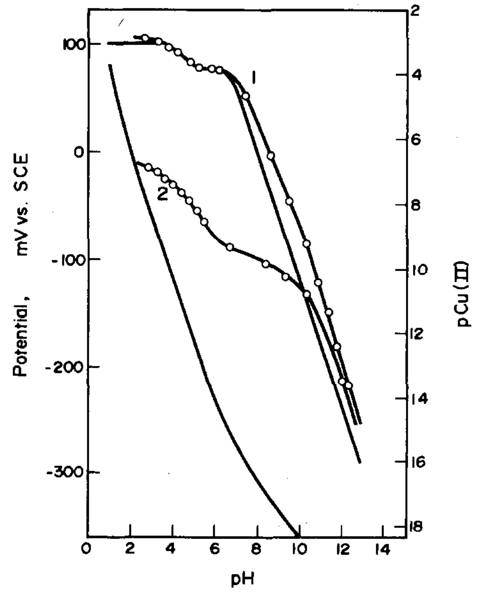

Fig. 2. Potential–pH diagram for copper electrode in 0·1M acetate buffer—curve 1 and for $10^{-3}M$ Cu–EDTA, $10^{-3}M$ EDTA solution—curve 2. The unprimed curves are experimental, the primed are calculated with the HALTAFALL program.

When the activity of copper(I) ions is relatively high, *i.e.*, of the order of 10^{-7}–10^{-8} M calculated on the basis of stability constants of the chloride complexes,[16] and the activity of copper(II) ions is as low as possible, the second term in the brackets in equation (1) may be neglected and the value of E^0 estimated. On the other hand from equation (4), in conditions when the copper(I) activity can be neglected, the value of $E^{0'}$ can be determined. Substituting these values into equation (3) gives the selectivity coefficient $K_{\mathrm{Cu}^{2+},\mathrm{Cu}^+}$ as $10^{-5.9}$. Using the Schmidt–Pungor procedure[17] and literature data[18,19] on the solubility products of $\mathrm{Cu_2S}$ and CuS one obtains a selectivity coefficient value of

$$K_{\mathrm{Cu}^{2+},\mathrm{Cu}^+} = \left(\frac{K_{\mathrm{so\,Cu_2S}}}{K_{\mathrm{so\,CuS}}}\right)^{1/2} = 10^{-6.6} \qquad (5)$$

which is in good agreement with our experimental findings.

In these experiments the effect of chloride ions on the response of the chalcocite electrode[21] is significantly low, most probably because the membrane does not contain $\mathrm{Ag_2S}$.

To establish the best conditions for the titration of copper with EDTA and TETREN in various buffers the potential *vs.* pH relationships were determined, by using different copper to titrant ratios. Such diagrams are shown in Fig. 2 for the acetate buffer. The experimental points are indicated by small circles, and the solid lines are calculated by the HALTAFALL program from published values for stability constants of Cu-EDTA complexes. Satisfactory agreement was obtained only in the absence of EDTA as a ligand. A similar discrepancy was found by Veselý[10] for the copper(I) selenide electrode, while Ross and Frant[1] and Hansen *et al.*,[4] who used the copper(II) sulphide membrane, did not mention such electrode response. Thus we can assume that the presence of copper(I) ions originating from the membrane is responsible for this behaviour. The experimental titration curve for copper(II) ions with EDTA in an acetate buffer (Fig. 3, curve 1), with the theoretical curve (curve 2) indicates that after the end-point an ion at constant activity must control the measured potential.

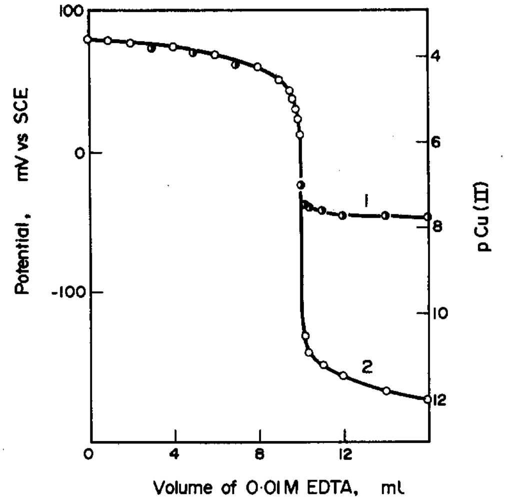

Fig. 3. Titration curves of $10^{-3}M$ Cu(II) with EDTA in 0·1M acetate buffer, pH 5. Curve 1—experimental, curve 2—theoretical.

Table 1. Complexometric titration of copper with the copper-sensitive electrode

Titrant	Buffer	pH	Copper, *mmole* Taken	Copper, *mmole* Found	Error, %
EDTA	Borate	9·2	0·1000	0·0999	−0·1
			0·1000	0·1003	+0·3
	Ammonia	9·0	0·1000	0·0999	−0·1
			0·1000	0·0999	−0·1
	Acetate	4·5	0·1000	0·1001	+0·1
			0·1000	0·1000	0
TETREN	Borate	9·2	0·0987	0·0987	0
			0·0987	0·0991	+0·4
			0·0973	0·0977	+0·4
	Ammonia	9·0	0·0987	0·0986	−0·1
			0·1104	0·1109	+0·5
	Acetate*	4·5	0·0973	0·0968	−0·5

*In presence of equimolar Al^{3+} and Fe^{3+}.

At the beginning of the titration ($f = 0$) the electrode potential (neglecting activity coefficients) is given by the equation:

$$E_{f=0} = E^0 + \frac{RT}{F}\ln[Cu^{2+}]^{1/2} K_{Cu^{2+},Cu^+} \qquad (6)$$

while after the end-point ($f = 2$), the copper(II) concentration is so strongly depressed that the potential should be described by the equation:

$$E_{f=2} = E^0 + \frac{RT}{F}\ln[Cu^+] \qquad (7)$$

Thus the total potential change in the titration is equal to:

$$\Delta E_{0,2} = E_{f=2} - E_{f=0} = 0{\cdot}059\log\frac{[Cu^+]}{[Cu^{2+}]^{1/2} K_{Cu^{2+},Cu^+}} \qquad (8)$$

When the potential change $\Delta E_{0,2}$ in a titration was measured, and the selectivity coefficient was assumed to be equal to $10^{-6{\cdot}6}$, the concentration of copper(I) ions was calculated to be $10^{-10{\cdot}6}M$, which corresponds to a potential of −35 mV *vs.* SCE. This is in good agreement with the potential found from the titration curve after the end-point ($f = 2$).

Such differences between experimental and calculated values were not observed when TETREN was used as titrant. In spite of the fact that none of the stability constants of the copper(I) complexes is known, it seems reasonable to assume that TETREN binds univalent copper much more strongly than does EDTA. When EDTA is used as titrant, however, an ammoniacal buffer is desirable, because of the strong tendency of ammonia to complex copper(I).

The experimental results from titrations with both titrants are presented in Table 1. They are relatively accurate and TETREN can also be used in the presence of other cations, such as iron or aluminium.

A similar decrease in the potential break at the end-point was also observed in EDTA titrations of other ions (Pb^{2+}, Zn^{2+}, Ca^{2+}) when copper was used only as the indicator ion. However in those cases the accuracy was

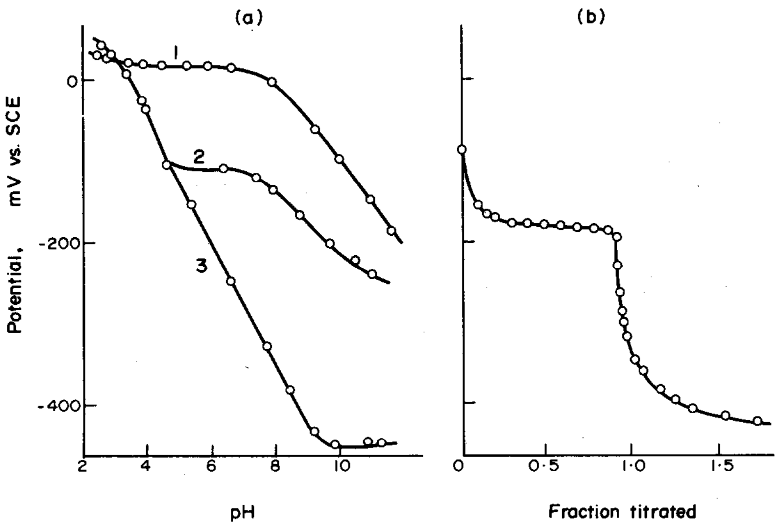

Fig. 4. (*a*) Potential–pH diagram for the copper electrode. (*b*) Titration curve of $10^{-3}M$ $Zn(NO_3)_2$ in presence of $10^{-6}M$ $Cu(NO_3)_2$ with $10^{-2}M$ TETREN in borate buffer, with a copper membrane electrode.

Table 2. Complexometric titration of various metals with the copper-sensitive electrode

Titrant	Ion determined	Buffer	pH	Metal, *mmole* Taken	Metal, *mmole* Found	Error, %
EDTA	Ca^{2+}	Borate	9·2	0·1011	0·1017	+0·6
				0·1011	0·1017	+0·6
		Hexamine	6·7	0·1011	0·1019	+0·8
	Pb^{2+}	Hexamine	7·0	0·1027	0·1031	+0·4
TETREN	Zn^{2+}	Borate	9·2	0·1025	0·1024	−0·1
		Ammonia	9·0	0·1040	0·1046	+0·6
	Cu^{2+} + Pb^{2+}	Borate	9·2	0·1038 (Cu + Pb)	0·1037	−0·1
	Cu^{2+} + Zn^{2+}	Borate	9·2	0·1025 (Cu + Zn)	0·1026	+0·1
				0·1025 (Cu + Zn)	0·1031	+0·6
		Ammonia	9·0	0·05194 (Cu)	0·05031	−3·1
				0·1040 (Zn)	0·1050	+1·0

also quite satisfactory (Table 2) when the titration conditions (buffer and pH) were selected on the basis of the potential–pH diagrams; such a diagram for the zinc-TETREN system is given in Fig. 4, together with the experimental titration curve, which in spite of its asymmetry may be advantageously used in practical analytical titrations.

Mixtures of ions may also be titrated in the same way. Satisfactory results were obtained using an ammoniacal buffer for the copper–zinc system. However when the borate buffer was used, advantageous because it complexes metal ions only weakly, the precipitate formed at the beginning and persisting nearly up to the end of the titration prevents determination of individual ions (*e.g.*, Cu^{2+} and Pb^{2+}).

Acknowledgements—The authors are greatly indebted to Prof. Andrzej Pomianowski (Polish Academy of Science, Kraków) for samples of chalcocite crystals.

Summary—The membrane electrode based on a synthetic chalcocite (Cu$_2$S) single crystal responds primarily to the activity of copper(I) ions in solution. The experimental selectivity coefficient with respect to copper(II) ions is in good agreement with the value calculated on the basis of solubility products of both sulphides. The electrode has been calibrated with metal-ion buffers containing a strongly complexing ligand, TETREN, and can be used as an indicator in titrations of copper with EDTA and TETREN. Comparison of an experimental titration curve with one calculated with the aid of the program HALTAFALL showed good agreement in the case of TETREN, but there were discrepancies for the EDTA titration, which are attributed to the presence and complexation of copper(I) ions. The electrode has also been applied in metal titrations with Cu^{2+} as indicator ion, though the potential changes observed were smaller than predicted. All titrations showed errors less than 1%.

SOLVENT EXTRACTION OF GALLIUM(III) WITH 2-THENOYLTRIFLUOROACETONE

P. V. DHOND and S. M. KHOPKAR
Department of Chemistry, Indian Institute of Technology, Bombay-76, India

(*Received* 11 *September* 1974. *Revised* 9 *April* 1975. *Accepted* 16 *April* 1975)

Acetylacetone has been used for the extraction of gallium[1,2] but the extraction was not quantitative. Gallium and indium have been separated with acetylacetone[3] but the process was time-consuming as it involved several steps. The complexes of gallium, indium and aluminium with trifluoroacetylacetone[4] have been separated by gas chromatography. Benzoylacetone and dibenzoylmethane[5] have also been used for the extraction of gallium. The synergistic extraction[6] of gallium with thenoyltrifluroacetone (TTA) and tetraphenylarsonium chloride is also reported, but the pH range for extraction was rather narrow. TTA has been used for extraction and determination of many elements,[7] and it is now shown that it affords clean-cut separation of gallium at microgram levels. The gallium can be determined by a Rhodamine B method.

EXPERIMENTAL

Reagents

Gallium nitrate solution. The octahydrate (0·563 g) was dissolved in 100 ml of distilled water containing 1% of nitric acid. The solution was standardized gravimetrically.[8] The stock solution was diluted tenfold (gallium concentration 98 μg/ml).

2-Thenoyltrifluoroacetone solution in xylene, 0·03*M*.

Rhodamine B solution, 0·5% *in* 6*M hydrochloric acid.*

General procedure

An aliquot (2 ml) of gallium nitrate solution was diluted and its pH adjusted to 4·5–6 with 0·01*M* nitric acid and 0·01*M* ammonia solution in a total volume of 25 ml. It was then shaken in a separatory funnel for about 10 min (wrist-action shaker) with 10 ml of 0·03*M* TTA in xylene. The two layers were allowed to settle and separate. The aqueous phase was carefully withdrawn. The colourless organic layer was then shaken with 10 ml of 6*M* hydrochloric acid containing 0·5% of Rhodamine B, for about 10 min.[9] The two layers were allowed to separate. The reddish violet complex of gallium was measured photometrically at 565 nm against a reagent blank.

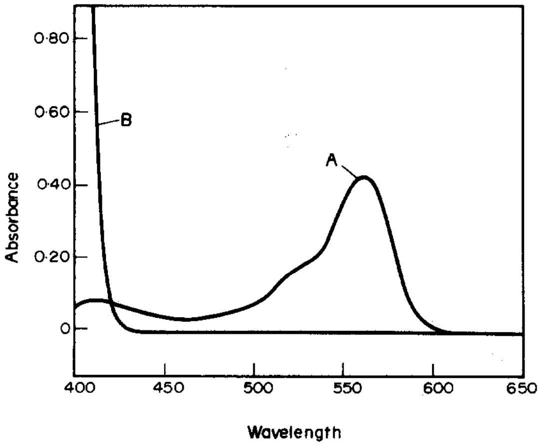

Fig. 1. Absorption spectra of Ga–Rhodamine B in TTA–xylene. A. Ga–Rhodamine B in TTA–xylene *vs.* reagent blank. B. Reagent blank *vs.* xylene Ga = $2{\cdot}81 \times 10^{-4}M$, TTA = $3 \times 10^{-2}M$.

RESULTS AND DISCUSSION

Spectral properties

The absorption spectrum of a solution of Ga(III)–TTA complex [Ga(III) = $2{\cdot}812 \times 10^{-4}M$] shows strong absorbance at 565 nm (Fig. 1). The reagent blank shows no absorbance at this wavelength. The molar absorptivity is $1{\cdot}07 \times 10^{3}$ l. mole^{-1}.cm^{-1} at 565 nm.

Extraction of various amounts of gallium at pH 4·5–6·0 and measurement of the absorbance at 565 nm showed that the system conforms to Beer's law over the gallium concentration range 2–60 μg/ml. The colour is stable for at least 24 hr.

Effect of pH and other parameters

The extraction was studied over the pH range 1–9 (Fig. 2). The results show that the optimum pH is 4·5–6·0.

All other factors being kept constant, the concentration and volume of the reagent were varied (Table 1). It was observed that the extraction of 196 μg of gallium was complete with 10 ml of 0·03*M* TTA in xylene, but incomplete

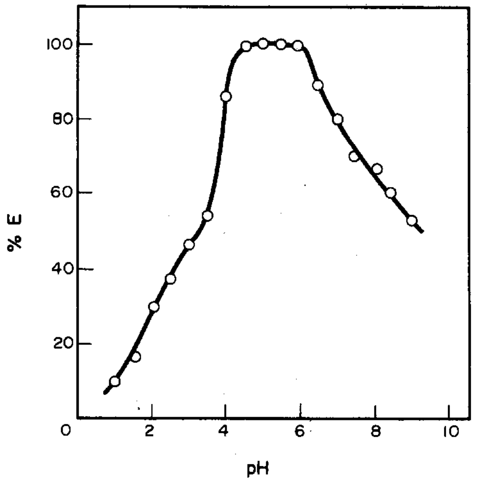

Fig. 2. Extraction as a function of pH.

Table 1. Effect of reagent concentration [Ga(III) = 196 μg; pH 5·0]

[TTA], *M*	TTA added, *ml*	Absorbance at 565 nm	Extraction, %
0·010	10	0·260	86·7
0·015	10	0·260	86·7
0·03	10	0·300	100
0·045	10	0·305	100
0·060	10	0·305	100
0·030	2·5	0·100	33·3
0·030	5·0	0·170	56·7
0·030	7·5	0·230	76·7
0·030	10	0·300	100
0·030	15	0·200	—
0·030	20	0·150	—

at lower concentrations of reagent. There was no significant increase in the absorbance when the concentration of reagent was increased from 0·01 to 0·06*M*. The use of varying volumes of 0·03*M* reagent showed that the extraction was quantitative with 10 ml of reagent.

The period of equilibration was varied from 2 to 20 min. The extraction was quantitative after 8 min of equilibration (Fig. 3). It is therefore recommended that the mixture be shaken for at least 10 min.

Ammonium, sodium, potassium, calcium and magnesium nitrates were tested as salting-out agents in the concentration range 1–3*M*, but none enhanced the extraction.

Effect of other ions

Several ions were examined for their effect on the extraction of gallium. The tolerance limit was taken as the amount required to cause a ±2% error in the gallium recovery (Table 2). The ions showing strong interference were EDTA, citrate and ascorbate. Several masking agents were used to eliminate the interference of some ions, *e.g.*, copper and osmium were masked with potassium cyanide, bismuth, chromium, aluminium, uranium, and zirconium were masked with sodium fluoride, iron was masked with alkali metal phosphate, cerium was masked with tartrate and indium was masked with thiocyanate.

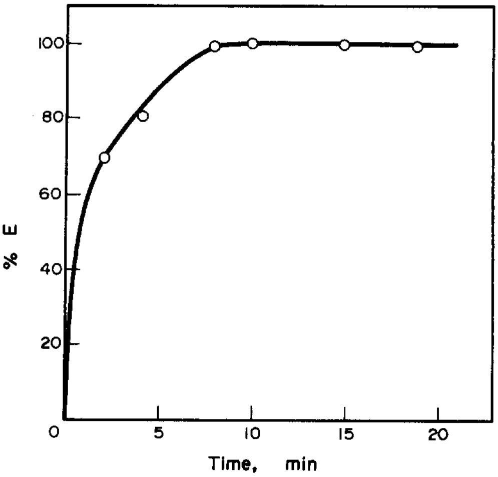

Fig. 3. Extraction as a function of period of equilibration.

The proposed method possesses several advantages, as it is possible to separate gallium from indium, thallium and aluminium, with which it is usually associated. The method is selective, as it is possible to separate gallium

Summary—Gallium can be quantitatively extracted at trace levels with 2-thenoyltrifluoroacetone in xylene at pH 4·5–6·0. Gallium is determined in the organic phase photometrically by complexation with Rhodamine B. The system conforms to Beer's law (at 565 nm) in the concentration range 2–59 μg/ml. The complex is stable for 24 hr. Salting-out agents have no effect on the extraction. Gallium can be extracted and determined in a single extraction in presence of many elements associated with it, such as indium, thallium and aluminium.

2-AMINO-3-HYDROXYPYRIDINE AS A CHROMOGENIC REAGENT FOR THE SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM

Y. L. Mehta, B. S. Garg and R. P. Singh

Department of Chemistry, University of Delhi, Delhi-110007, India

(*Received* 3 *December* 1974. *Accepted* 15 *April* 1975)

Several reagents have been suggested for the spectrophotometric determination of osmium.[1–6] Practically all the methods deal with the problem of interfering constituents. The methods available are dependent upon various factors such as temperature, acidity, concentration of the reagent and certain other anions and cations. However, none provides a method for the selective determination of osmium in the presence of the other platinum metals. In most, a prior separation of osmium as volatile osmium tetroxide is required. The present paper deals with the use of 2-amino-3-hydroxypyridine (AHP) as a chromogenic reagent for the spectrophotometric determination of osmium. This reagent has already been successfully used for the determination of iron[7] and ruthenium(III).[8] AHP reacts immediately with osmium(IV), (VI) and (VIII) solutions in the cold, forming different coloured species according to the acidity. The characteristics of the complexation have been studied spectrophotometrically and AHP has been used for selective and sensitive determination of osmium.

EXPERIMENTAL

Reagents

Standard osmium(*VIII*) *solution.* A 1-g ampoule of osmium tetroxide (Johnson Matthey) was broken beneath the surface of about 100 ml of 4*M* sodium hydroxide in a glass-stoppered flask, as described by Ayres and Wells.[9] The red-orange solution was washed into a 1-litre volumetric flask, made up to volume with doubly distilled water, and standardized by the modified method of Klobbie.[10]

Osmium(*VI*) *and osmium*(*IV*) *solutions.* Obtained by dissolving potassium osmate and potassium chloro-osmate in concentrated sodium hydroxide solution and hydrochloric acid respectively.

Standard reagent solution. Obtained by dissolving an appropriate quantity of AHP in 95% v/v ethanol or methanol or in 10% v/v acetic acid. The solutions were kept in coloured glass bottles in a cool place. Under these conditions the solutions remain stable for up to six months.

All other chemicals used were of analytical reagent quality.

Preliminary investigations

On mixing the AHP solution (in alcohol or acetic acid) with osmium(VIII), (VI) or (IV) solutions, an immediate colour development takes place in the cold, the nature of the species formed depending only on the acidity and not on the oxidation state of the osmium.

The absorption spectra of freshly prepared AHP solution in ethanol and of the osmium complexes formed under various conditions are shown in Figs. 1 and 2. The reagent absorbs only in the ultraviolet region, showing maximum absorption at 235 and 300 nm, the corresponding molar absorptivities being $2{\cdot}05 \times 10^{4}$ and $1{\cdot}90 \times 10^{4}$ l. mole^{-1}. cm^{-1}. The absorption maxima of the complexes from a large number of elements at trace concentrations. The method is rapid as the extraction and determination require only 30 min. Concentrations as low as 1·96 μg/ml can be determined. The results are reproducible. The average recovery of gallium is 99·9 ± 0·1% (relative standard deviation 1·0%).

Summary—Gallium can be quantitatively extracted at trace levels with 2-thenoyltrifluoroacetone in xylene at pH 4·5–6·0. Gallium is determined in the organic phase photometrically by complexation with Rhodamine B. The system conforms to Beer's law (at 565 nm) in the concentration range 2–59 μg/ml. The complex is stable for 24 hr. Salting-out agents have no effect on the extraction. Gallium can be extracted and determined in a single extraction in presence of many elements associated with it, such as indium, thallium and aluminium.

2-AMINO-3-HYDROXYPYRIDINE AS A CHROMOGENIC REAGENT FOR THE SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM

Y. L. Mehta, B. S. Garg and R. P. Singh
Department of Chemistry, University of Delhi, Delhi-110007, India

(*Received* 3 *December* 1974. *Accepted* 15 *April* 1975)

Several reagents have been suggested for the spectrophotometric determination of osmium.[1–6] Practically all the methods deal with the problem of interfering constituents. The methods available are dependent upon various factors such as temperature, acidity, concentration of the reagent and certain other anions and cations. However, none provides a method for the selective determination of osmium in the presence of the other platinum metals. In most, a prior separation of osmium as volatile osmium tetroxide is required. The present paper deals with the use of 2-amino-3-hydroxypyridine (AHP) as a chromogenic reagent for the spectrophotometric determination of osmium. This reagent has already been successfully used for the determination of iron[7] and ruthenium(III).[8] AHP reacts immediately with osmium(IV), (VI) and (VIII) solutions in the cold, forming different coloured species according to the acidity. The characteristics of the complexation have been studied spectrophotometrically and AHP has been used for selective and sensitive determination of osmium.

EXPERIMENTAL

Reagents

Standard osmium(VIII) solution. A 1-g ampoule of osmium tetroxide (Johnson Matthey) was broken beneath the surface of about 100 ml of $4M$ sodium hydroxide in a glass-stoppered flask, as described by Ayres and Wells.[9] The red-orange solution was washed into a 1-litre volumetric flask, made up to volume with doubly distilled water, and standardized by the modified method of Klobbie.[10]

Osmium(VI) and osmium(IV) solutions. Obtained by dissolving potassium osmate and potassium chloro-osmate in concentrated sodium hydroxide solution and hydrochloric acid respectively.

Standard reagent solution. Obtained by dissolving an appropriate quantity of AHP in 95% v/v ethanol or methanol or in 10% v/v acetic acid. The solutions were kept in coloured glass bottles in a cool place. Under these conditions the solutions remain stable for up to six months.

All other chemicals used were of analytical reagent quality.

Preliminary investigations

On mixing the AHP solution (in alcohol or acetic acid) with osmium(VIII), (VI) or (IV) solutions, an immediate colour development takes place in the cold, the nature of the species formed depending only on the acidity and not on the oxidation state of the osmium.

The absorption spectra of freshly prepared AHP solution in ethanol and of the osmium complexes formed under various conditions are shown in Figs. 1 and 2. The reagent absorbs only in the ultraviolet region, showing maximum absorption at 235 and 300 nm, the corresponding molar absorptivities being $2{\cdot}05 \times 10^4$ and $1{\cdot}90 \times 10^4$ l. mole^{-1}. cm^{-1}. The absorption maxima of the complexes

Table 1. Characteristics of complexes

Characteristics	Os–AHP complex in 50% ethanol		Os–AHP complex in the absence of ethanol

Colour	Green	Red–violet	Green	Violet
λ_{max}, *nm*	600	540	600	550
Adherence to Beer's law, *ppm*	0–15·3	0–15·3	0–14·3	0–14·3
Molar absorptivity at λ_{max} $l.mole^{-1}.cm^{-1}$	$5{\cdot}2 \times 10^3$	$8{\cdot}4 \times 10^3$	$9{\cdot}0 \times 10^3$	$7{\cdot}0 \times 10^3$
Molar ratio of reagent required for total complexation	4	20	8	10
Composition M:L	1:2	1:3	1:3	1:3

remain unaltered irrespective of the proportions of the reactants, indicating the formation of only one complex.

To find the effect of heating on the completeness of complexation, the solutions were heated on a boiling water-bath and the absorbance was measured after different intervals of time. The absorbance was constant and maximal even without the heating, showing that heating is unnecessary.

Variation in the order of addition of the reactants had no effect. The order used during investigations was osmium solution, interfering ions (if any), AHP, followed by adjustment of the acidity.

Solutions containing osmium and appropriate quantities of AHP were prepared at different pH values (sodium acetate–acetic acid buffer). The complex precipitated at pH between 2 and 8. It was observed that two distinct coloured species are formed at very high and very low pH. The intensity of colour of the complexes remains constant over the range 1·0–6·0*M* hydrochloric acid or sodium hydroxide. Further studies were therefore made with 3*M* acid or alkali.

Effect of reagent concentration, adherence to Beer's law and sensitivity

To a constant amount of osmium solution were added varying molar ratios of AHP at different acidities and in different media. The plot of absorbance (at λ_{max}) *vs.* concentration of the ligand shows that the amount of reagent necessary for complete complexation varies with the conditions and the medium. The range of application of Beer's law and the molar absorptivities were calculated (Table 1). The optimum range is 3–13 ppm.

Composition of the complexes

Various methods, *viz.* continuous variations,[11] mole-ratio[12] and slope-ratio,[13] were used to ascertain the composition of the complexes. The metal combines with the ligand in different stoichiometric ratios under different working conditions (Table 1). Ion-exchange studies showed that the complexes were anionic. In the absence of further evidence, no structure can be proposed for the complexes.

Recommended procedure

To a suitable aliquot, containing 10–100 μg of osmium, in a 10-ml standard flask, add 3 ml of 0·1% AHP solution (in ethanol or 10% acetic acid). Adjust the acidity of the solution to 3*M* by adding conc. hydrochloric or acetic acid, or the alkalinity to 3*M* by adding sodium hydroxide solution. Dilute to the mark, mix, and measure the absorbance at λ_{max} for the complex, *vs.* a water blank. Preparation of a reagent blank is not necessary.

Effect of diverse ions

To a suitable aliquot containing 100 μg of osmium and various amounts of foreign ion, an excess of AHP was added and the recommended procedure followed. The results are summarized in Table 2, the tolerance limit being taken as the concentration causing an error of not more than 3%. The interference of most ions can be avoided by choosing the conditions for colour development.

The interferences caused by various cations, including platinum metals, can be avoided by making use of the common masking agents, *viz.* EDTA, fluoride, citrate, tartrate, *etc.* Typical results are also summarized in Table 2.

Table 2. Effect of diverse species

Determination of osmium in various synthetic mixtures

As naturally occurring ores of osmium are not easily available, synthetic mixtures similar to these in composition were prepared and the amount of osmium was determined by taking an appropriate sample aliquot, adding 3 ml of 0·01M EDTA and 3 ml of 0·1% AHP solution in acetic acid, adjusting the acidity with acetic acid or sodium hydroxide, diluting to 10 ml and measuring the absorbance. The results are summarized in Table 3.

DISCUSSION

Several reagents, such as anthranilic acid,[4] sulphanilic acid,[5] 3-nitroso-2,6-pyridinediol[3] and 2-amino-8-naphthol-3,6-disulphonic acid,[14] have been used for the spectrophotometric determination of osmium. 1-Naphthylamine-3,5,7-trisulphonic acid,[15] though a good analytical reagent, requires at least 4 hr heating for maximum colour development. Other well-known reagents either require controlled conditions of heating and pH or a prior separation of osmium as volatile osmium tetroxide from other platinum metals. Similarly certain reagents, though quite sensitive, lack selectivity and require strict control of pH conditions. AHP overcomes many of these difficulties to a considerable extent.

Summary—2-Amino-3-hydroxypyridine forms two coloured complexes, green and violet, with osmium, depending on the pH of the solutions. Based on this reaction, a selective and sensitive spectrophotometric method for the determination of osmium (3–13 ppm in the final solution) alone and in the presence of other metal ions has been developed.

DETERMINATION OF TUNGSTEN WITH IRON(III) AFTER REDUCTION WITH MERCURY IN THIOCYANATE MEDIUM

V. YATIRAJAM and SUDERSHAN DHAMIJA

Department of Chemistry, Kurukshetra University, Kurukshetra-132110, Haryana, India

(*Received* 26 *March* 1975, *Accepted* 13 *April* 1975)

For the determination of macro amounts of tungsten gravimetric methods are preferred. In the most frequently used tungstic acid method, the precipitate is contaminated[1a] with antimony, chromium, iron, molybdenum, niobium, phosphorus, silica, vanadium, tantalum and tin present in the sample, and these have to be removed or accounted for. The generally used co-precipitation agent cinchonine is costly. The tungstate precipitation methods suffer from several interferences[2a] and the precipitate should be finally ignited to tungstic oxide. The oxinate method suffers interference from molybdenum, titanium and uranium and is also otherwise unsuitable.[3] All these methods require some hours for a single determination.

The volumetric methods[1b] are based on reduction to W(V) or (III) and reoxidation to W(VI), under an inert atmosphere. Some methods precipitate tungsten as lead tungstate and estimate the lead in the precipitate[4] or in excess,[5] or precipitate tungsten oxinate and estimate the oxine.[6] All these methods are tedious, subject to several interferences and give inconsistent and unreliable results.[2b]

Tungsten(VI) can be reduced to tungsten(V) by mercury metal[7] in hydrochloric acid in the presence of thiocyanate. We now describe a simple titrimetric method for the direct determination of the tungsten(V) with iron(III).

EXPERIMENTAL

Reagents and solutions

Tungsten solution. Sodium tungstate was dissolved to give a mg/ml level solution which was standardized by the oxine method.[8]

Potassium thiocyanate, 5 *M.*

Mercury. Purified with nitric acid.[9a]

Iron(III) solution, ca. 0·01 *M.* Iron(III) chloride was dissolved in 0·1 *M* hydrochloric acid and standardized.[9b] Further dilutions (to 0·05 and 0·02 *M*) were made, the solutions being adjusted to be 4 *M* in hydrochloric acid.

Procedure

Solution containing 5–80 mg of tungsten was placed in a separating funnel, and adjusted to be 0·4 *M* in potassium thiocyanate and 4 *M* in hydrochloric acid, in a final volume of 25 ml. This solution was shaken with 2 ml of mercury for 2 min[7] (3 min if silicic acid was present). The mercury was run off, and the aqueous phase was transferred quantitatively to the titration vessel with 4 *M* hydrochloric acid.

Titration to a visual end-point. A flask was used for the titration, and the solution, made up to about 100 ml with 4 *M* hydrochloric acid (for > 20 mg of tungsten) was titrated with standard iron(III) solution of appropriate concentration, with vigorous mixing by hand or, for > 40 mg of W, magnetically, with dropwise addition at 15–20 sec intervals towards the end-point (red colour of iron thiocyanate).

Titration to a potential end-point. A beaker was used and the titration solution had a volume of about 100 ml and was 7 *M* in hydrochloric acid. It was titrated with standard iron(III) solution, with magnetic stirring. The potential was measured with a tungsten wire electrode against an SCE. Equilibration of potential took 2–3 min.

RESULTS AND DISCUSSION

Tungsten(V) or (III) has to be protected from atmospheric oxidation unless stabilized, *e.g.*, by complexation with thiocyanate. Fluoride and nitrate should be absent.[7] The tungsten(V) in the complex is quantitatively oxidized by iron(III). The thiocyanate is not oxidized and acts as the indicator. Stronger oxidants oxidize the thiocyanate as well.

Titration to a visual end-point. Large amounts of tartrate, citrate, phosphate, acetate and up to 0·5 g of sulphate do not interfere, but oxalate does so slightly (Table 2). The end-point cannot be detected in the presence of EDTA. In the maximum amounts usually encountered in tungsten determinations, iron, nickel, chromium, zirconium, bismuth, antimony, cerium, aluminium, lead and calcium do not interfere (Table 3). Uranium (10 mg) and vanadium (5 mg) are tolerated. Arsenic spoils the mercury, and copper is precipitated as cuprous thiocyanate but up to 5 mg can still be tolerated. Niobium and manganese give high errors. Because of the colour of their thiocyanate complexes, molybdenum, cobalt and rhenium interfere with the end-point. Molybdenum can be tolerated up to only 50 μg. Silicic acid does not interfere if the solution is magnetically stirred during the titration, to prevent adsorption of the iron thiocyanate complex.

Titration to a potential end-point. The tungsten wire electrode gives a sharp potential rise at the end-point. It is poisoned irreversibly by copper, needs regular cleaning[10] and takes 2–3 min to give a constant reading. A platinum electrode does not work. The tungsten electrode is cleaned

* Spoils mercury.

† Poisons tungsten wire electrode.

‡ End-point cannot be detected.

by being rubbed occasionally with fine emery paper and washed with hydrochloric acid.

Sulphate, acetate and tartrate do not interfere but citrate, oxalate and phosphate in large amounts interfere increasingly in that order (Table 2). Besides the elements stated as non-interfering in the visual titration, cobalt, rhenium, niobium and manganese also do not interfere (Table 3). Interference by molybdenum is avoided by titration in 9 *M* hydrochloric acid and in the presence of a small amount (0·2–0·5 g) of ammonium, potassium, sodium, calcium or aluminium chloride. In the absence of any of these salts, there is no potential jump even if the acidity is increased to greater than 9 *M* or the chloride concentration to 9 *M* at an acidity of 7 *M*. The salts increase $\Delta E/\Delta V$ in the order $Na^+ < K^+ < Ca^{2+} \sim NH_4^+ < Al^{3+}$.

Titration to a visual end-point takes < 10 min, needs lower acidity, and tolerates citrate and phosphate, whereas that to a potentiometric end-point tolerates molybdenum, cobalt, rhenium, niobium and manganese and more sulphate.

The method gives accurate and reproducible results. In five determinations of 20 mg of tungsten the visual end-point method gave a standard deviation of 0·012 mg.

The wide applicability of the method is shown by satisfactory analysis of several alloys (Table 4).

Summary—Tungsten(V) is formed by shaking for 2 min sodium tungstate solution in 0·4 *M* potassium thiocyanate–4 *M* hydrochloric acid medium, with mercury. It is titrated with standard iron(III) solution. The thiocyanate present stabilizes W(V) to aerial oxidation and also acts as indicator. The W(V) can also be titrated potentiometrically in 7 *M* hydrochloric acid, a tungsten wire electrode being used. Fe, Ni, Cr, Zr, Bi, Sb, Ce, Al, Pb, Ca and U do not interfere. Cu, V and As can be tolerated up to 5 mg. Co, Mo, Re, Nb and Mn interfere, but not in the potentiometric determination. The method is direct, simple, rapid, accurate and reproducible.

RADIOISOTOPE STUDIES OF CARBOXYL SITES ON STRONG ACID AND STRONG BASE ION-EXCHANGE RESINS DERIVED FROM POLYSTYRENE

G. M. Armitage, S. J. Lyle® and V. C. Nair

Chemical Laboratory, University of Kent at Canterbury, Canterbury, Kent, U.K.

(*Received* 5 *February* 1975. *Accepted* 8 *April* 1975)

Recent[1,2] mass-spectrometric examination of age-induced deterioration of polystyrene–divinylbenzene copolymer ion-exchangers has indicated the presence of a small number of carboxylic acid functions in addition to the sulphonate or quaternary ammonium sites to which the resin owes most of its exchange capacity. These carboxyl groups may arise from the oxidation of ethyl groups, introduced by formation of the analogous resin from ethylstyrene,[3] a common contaminant of commercial divinylbenzene.[4] Such oxidation can occur at the sulphonation stage of manufacture,[5] although it may continue to occur after sulphonation is complete. It is possible, too, that some divinylbenzene is incorporated into the polymer chain at one end only,[1] leaving a readily oxidized ethylenic group on the polymer. When the resin is subjected to low pressures and moderately high (~150°) temperatures, such as are required for the operation of a mass spectrometer, some of these carboxyl groups become detached from the polymer matrix and are manifested by a peak at $m/e = 44$ in a mass spectrum, corresponding to the formation of the species CO_2^+. Such reactions are discussed fully elsewhere.[1,2] Interpretation of the mass spectra in these terms allows an explanation of hitherto anomalous characteristics of carrier-free radioisotope distribution between ion-exchangers and aqueous phases.

In order to obtain information about the carboxyl exchange function in resins, a study has been made of the distribution of metal ions between aqueous phases at constant ionic strength and the resin, as the pH of the system is varied. Polystyrene–divinylbenzene copolymers having sulphonate or quaternary ammonium functional groups were used. Attempts were made, on the one hand, to introduce additional carboxyl groups by oxidation and, on the other, to eliminate by esterification those already there. For comparison purposes some copolymer lacking either of the aforementioned major functional groups was also examined.

Commercially available resins from the Permutit Co. Ltd., the Dow Chemical Co. and Rohm and Hass were examined in the course of the work described and, although most of the results reported here refer to products from the first-mentioned source, resins from all three manufacturers showed the same general characteristics.

Recent[1,2] mass-spectrometric examination of age-induced deterioration of polystyrene–divinylbenzene copolymer ion-exchangers has indicated the presence of a small number of carboxylic acid functions in addition to the sulphonate or quaternary ammonium sites to which the resin owes most of its exchange capacity. These carboxyl groups may arise from the oxidation of ethyl groups, introduced by formation of the analogous resin from ethylstyrene,[3] a common contaminant of commercial divinylbenzene.[4] Such oxidation can occur at the sulphonation stage of manufacture,[5] although it may continue to occur after sulphonation is complete. It is possible, too, that some divinylbenzene is incorporated into the polymer chain at one end only,[1] leaving a readily oxidized ethylenic group on the polymer. When the resin is subjected to low pressures and moderately high (~150°) temperatures, such as are required for the operation of a mass spectrometer, some of these carboxyl groups become detached from the polymer matrix and are manifested by a peak at $m/e = 44$ in a mass spectrum, corresponding to the formation of the species CO_2^+. Such reactions are discussed fully elsewhere.[1,2] Interpretation of the mass spectra in these terms allows an explanation of hitherto anomalous characteristics of carrier-free radioisotope distribution between ion-exchangers and aqueous phases.

In order to obtain information about the carboxyl exchange function in resins, a study has been made of the distribution of metal ions between aqueous phases at constant ionic strength and the resin, as the pH of the system is varied. Polystyrene–divinylbenzene copolymers having sulphonate or quaternary ammonium functional groups were used. Attempts were made, on the one hand, to introduce additional carboxyl groups by oxidation and, on the other, to eliminate by esterification those already there. For comparison purposes some copolymer lacking either of the aforementioned major functional groups was also examined.

Commercially available resins from the Permutit Co. Ltd., the Dow Chemical Co. and Rohm and Hass were examined in the course of the work described and, although most of the results reported here refer to products from the first-mentioned source, resins from all three manufacturers showed the same general characteristics.

EXPERIMENTAL

Zeo-Karb 225 (SRC 15, 8% DVB, 100–200 mesh) was washed 3 times with 2*M* hydrochloric acid, then with 2*M* sodium chloride till free from acid and finally with water till free from chloride. It was dried at 80° for 8 hr; capacity 4·18 meq/g.

Bio-Rad AG50WX8 (400 mesh) was converted into the sodium form with 1*M* sodium perchlorate, washed with distilled water and dried at 80°.

De-Acidite FF (SRA 71, 7–9% cross-linked) was treated in sequence with 2*M* hydrochloric acid, water, 1*M* sodium hydroxide, 1*M* sodium perchlorate and water. It was dried at 80°.

Polystyrene resin (8% DVB, 15–50 mesh) was treated in a manner analogous to that used for the Zeo-Karb 225.

Carrier-free ^{144}Ce/^{144}Pr, ^{91}Y and ^{89}Sr were obtained from the Radiochemical Centre, Amersham, and used as supplied.

The distribution measurements were made by adding known amounts of resin (50 mg for cation-exchanger and 100 mg for all others), to clean, dry polyethylene bottles. The appropriate volume of aqueous phase containing the radioisotope and made up to the correct ionic strength (0·5) with sodium perchlorate solution was added to give a total volume of 40 ml. Samples were prepared in batches and equilibrated for 18 hr at 21 ± 0·5°, after which the contents of the polyethylene bottles were transferred to centrifuge tubes and the resin phases separated from the aqueous phases. The supernatant liquid was used for radioassay and the distribution ratio,

$$\phi = \frac{1}{m}\left(\frac{C'_m - C_m}{C_m}\right) - \delta,$$

where C'_m is the count-rate of the aqueous phase per unit volume before and C_m that after equilibration with resin m is the mass of resin, in g, and δ is the swelling factor[6] for the resin, was calculated. The swelling factor has been taken as unity in the present case in view of the experimental conditions used. The pH of each aqueous phase was taken after equilibration with the resin.

Some of the resin samples were treated with acidic potassium permanganate solution as follows: 10 g of conditioned resin were treated with saturated potassium permanganate solution in 1*M* sulphuric acid for 1 hr at 25°. The resin was then well washed with water and treated with nitrous acid to remove the last traces of permanganate, after which the resin was packed into a column, washed with water, 2*M* hydrochloric acid, water, 0·5*M* sodium hydroxide, water, 0·5*M* sodium perchlorate and finally water. The resin was air-dried as before. In an attempt to remove carboxyl groups from other samples, some experiments were done with resin which had been treated with diazomethane to esterify the carboxyl groups. Conditioned resin (5 g) was suspended in ice-cold ether. Diazomethane was liberated by the addition of ethanolic sodium hydroxide solution to *N*-nitroso-*N*-methyltoluene-*p*-sulphonamide at 30° and passed through the suspension of resin in ether for 8 hr; the resin was then filtered off, washed with distilled water and dried at 80° for 8 hr.

Table 1. ϕ obtained at two pH values as a function of varying weights of Zeo-Karb 225 resin equilibrated with a constant volume (40 ml) of 0·5*M* $NaClO_4$ containing carrier-free ^{144}Ce

RESULTS AND DISCUSSION

Values of ϕ are presented in Table 1 for systems containing free ^{144}Ce(III) and varying weights of Zeo-Karb 225 resin. It is seen that for a given pH, ϕ is independent of the weight of resin used and also of the resin loading which is, however, very light. The results suggest that physical adsorption of a general type is unlikely to be responsible. It may be noted that ϕ is considerably higher at the higher pH, an observation consistent with the creation of additional exchange sites as the pH is increased.

Results for the distribution of ^{144}Ce(III) between Zeo-Karb 225 and 0·5*M* sodium perchlorate over a range of pH are given in Fig. 1. In the pH range 2–3·5, ϕ is nearly constant, which is in keeping with the availability of sulphonate exchange sites, but above pH 4 it rises appreciably with increasing pH. It is seen that addition of very low concentrations of inactive Ce(III) suffices to reduce or eliminate the additional resin capacity, which must consequently be very low.

When the distribution of ^{144}Ce(III) between permanganate-treated Zeo-Karb 225 and 0·5*M* sodium perchlorate is examined (Fig. 2) it is seen that the pH-dependent increase in ϕ occurs at a lower pH; this is consistent with the introduction of additional carboxyl groups, some of which may be more readily ionized than those initially on the resin. Subsequent reaction of permanganate-treated resin with diazomethane did not significantly alter the distribution pattern. The effect of diazomethane-treatment on ϕ for Zeo-Karb untreated with permanganate was also negligible (Fig. 3). In neither instance was the overall resin capacity affected by the treatment. The behaviour of Bio-Rad AG50WX8 is substantially similar to that of Zeo-Karb 225 but the increase in ϕ is not so pronounced in the former (Fig. 4). The anion-exchanger De-Acidite FF exhibits (Fig. 5) behaviour somewhat similar to that of Zeo-Karb 225 and Bio-Rad AG50WX8 with a significant

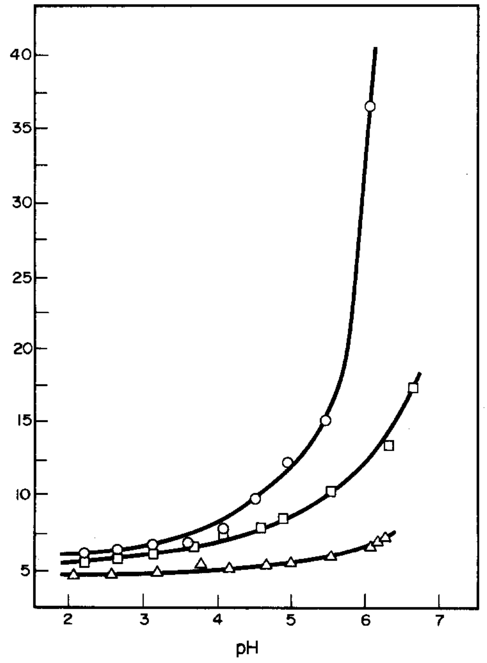

Fig. 1. Distribution of Ce(III) between Zeo-Karb and 0·5*M* $NaClO_4$. ○—Carrier-free ^{144}Ce(III); □—10^{-5}*M* Ce(III); △—5 × 10^{-5}*M* Ce(III).

suppression of the effect when $10^{-7}M$ carrier is added. The very much lower values of ϕ in this case are consistent with the carboxyl functions under discussion being the only negatively-charged fixed sites on the matrix. It is to be expected that anion-exchangers will exhibit only a slight effect of this kind since even though there may be carboxyl sites within the resin matrix, the Donnan potential should still operate to the exclusion of cations, because the overall fixed-site charge will be positive. Thus the observed cation-capacity probably results essentially from surface sites.

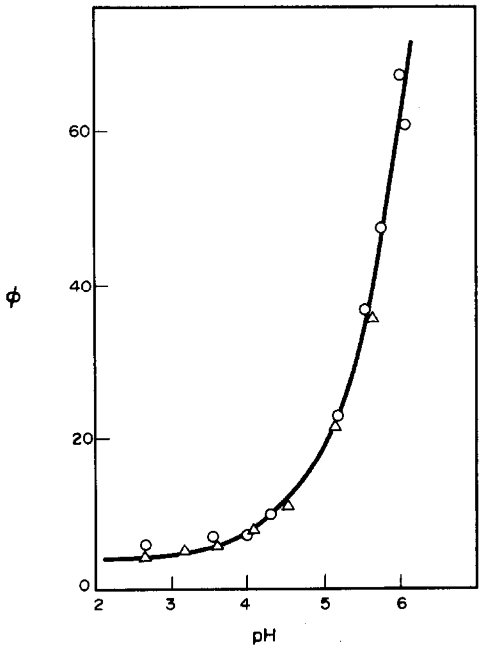

Fig. 3. Distribution of carrier-free ^{144}Ce(III) between Zeo-Karb 225 and 0·5*M* $NaClO_4$. ○—Untreated resin; △—diazomethane-treated resin.

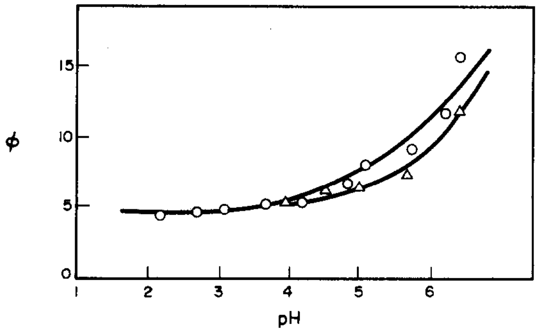

Fig. 4. Distribution of Ce(III) between Bio-Rad AG50WX8 and 0·5*M* $NaClO_4$. ○—Carrier-free ^{144}Ce(III); △—$10^{-6}M$ Ce(III).

In Fig. 6 it is seen that the polystyrene–DVB copolymer beads exhibit a pH-dependent distribution at ϕ-values much lower than those for cation-exchangers, but similar to those for De-Acidite FF. Again, it was found that the effect of treatment with permanganate is to lower the pH at which the increase in ϕ occurs. As with the anion-exchanger but for a different reason, namely lack of resin porosity, this is likely to be a surface effect.

Ce(III) would not be expected to hydrolyse at pH < 6, but if oxidation to Ce(IV) occurred then hydrolysis could perhaps account for the observations reported in Figs. 1–6. Experiments in which a reducing agent (hydroxylamine or hydrazine) was incorporated in the aqueous ^{144}Ce(III) showed that oxidation and subsequent hydrolysis was not responsible. Similar series of experiments were done with ^{89}Sr and ^{91}Y and the various resin samples available, and all results were comparable with those reported for Ce(III) except that, in every case, ϕ was lower and the increase in the region of pH 4–6 was less pronounced for the ^{89}Sr. This behaviour is to be expected if carboxyl groups are responsible.

Earlier processes for the preparation of resins led to the formation of appreciable levels of carboxyl groups on a nominally monofunctional sulphonate cation-exchanger[5] but it is tacitly assumed that more recent techniques produce entirely monofunctional resins. The exhibition of similar cation-exchange behaviour by anion-exchangers and hydrocarbon beads supports the premise that carboxyl groups still persist in polystyrene-based exchangers, but

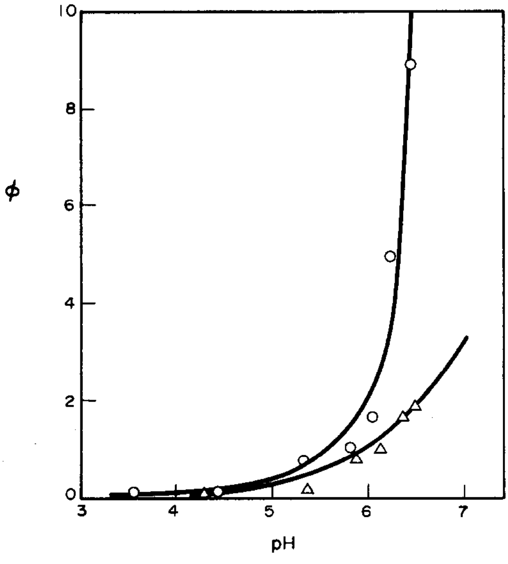

Fig. 5. Distribution of Ce(III) between De-Acidite FF and 0·5*M* $NaClO_4$. ○—Carrier-free ^{144}Ce(III); △—$10^{-7}M$ Ce(III).

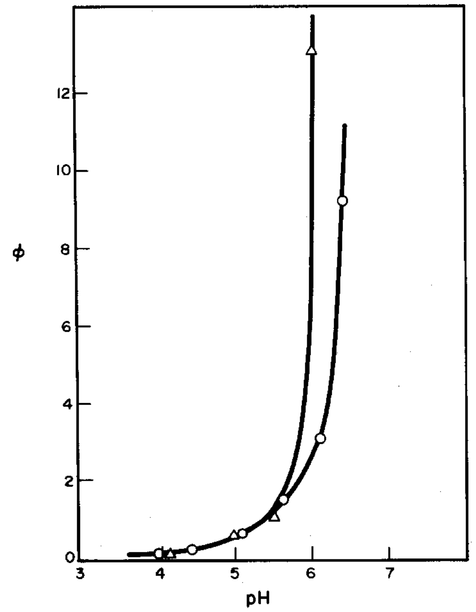

Fig. 6. Distribution of carrier-free ^{144}Ce(III) between hydrocarbon beads and 0·5*M* $NaClO_4$. ○—Untreated hydrocarbon beads; △—hydrocarbon beads treated with $KMnO_4$.

at very low levels. Thus the effect is only likely to be manifest under conditions where (1) there are very small amounts of ion available for exchange, to avoid saturation of the capacity and (2) the cation-exchange is not obscured by a normal exchange function such as is available on sulphonated polystyrenes. Thus evidence from the literature is most likely to come from studies in which anion-exchangers and trace amounts of ions are involved.

The freeing of ^{140}Ba from its daughter ^{140}La by passing the mixture through Dowex-1 in the hydroxide form[7] may well result from retention of the La(III) on carboxyl groups rather than hydroxide precipitation as hitherto assumed. Likewise, the previously obscure[8] affinity of ^{90}Y absorbed from sodium carbonate solutions by Dowex-1 may be explained. Tervalent lanthanides are not appreciably absorbed by a strong base anion-exchanger from nitric acid of a wide concentration range but at low acidity and in the presence of lithium nitrate absorption occurs readily and in an order expected for a cation-exchanger; a separation of ^{140}Ba from ^{140}La by eluting the former with 3–4*M* lithium nitrate was proposed.[9] While other factors such as changes in activity coefficients and electrolyte inversion may be important in this instance, the participation of carboxyl groups cannot be ruled out on the available evidence. Finally, there are several nuclear reactions[10,11] in which the required product-nuclide has a normal oxidation state higher than that of the parent following a change in atomic number, *e.g.* ^{7}Li(p,n)^{7}Be, ^{109}Ag(d,2n)^{109}Cd and ^{116}Cd(n,γ)^{117}Cd → ^{117}In. Carrier-free separations of the required product from the target might usefully be achieved in some instances by using the secondary cation-exchange capacity of an anion-exchanger.

Summary—The pH-dependent distribution of carrier-free radioisotopes between aqueous phases at constant ionic strength and polystyrene–divinylbenzene type exchangers reveals the presence of a secondary exchange function attributable to carboxyl groups. Cation- and anion-exchangers of the sulphonate and quaternary ammonium types possess this additional cation-exchange capacity which is, however, relatively very low in currently available commercial resins. Its influence on separations involving radioisotopes of high specific activity is discussed.

LE DOSAGE DE L'ETAIN DANS LES SEDIMENTS PAR SPECTROPHOTOMETRIE D'ABSORPTION ATOMIQUE*

J. GUIMONT, A. BOUCHARD et M. PICHETTE
Service Analyse et Contrôle, Centre de Recherches minérales, Ministère des Richesses naturelles,
Québec, Canada

(*Reçu le* 3 *janvier* 1975, *Accepté le* 2 *mars* 1975)

L'étain dans les sédiments agit comme collecteur de métaux lourds et joue donc le rôle d'indicateur de zones minéralisées en prospection géochimique. On le rencontre[1] dans le réseau silicaté, dans la cassiterite enrobée dans le silicate et dans la cassiterite aisément accessible. Comme c'est sous cette dernière forme qu'il est intéressant du point de vue géochimique et comme sa teneur moyenne[2] dans les sédiments est de l'ordre de 7 ppm, il nous fallait trouver une méthode sensible, précise et rapide nous permettant de le doser sous cette forme dans environ 20000 échantillons par année.

Plusieurs auteurs[3–5] ont utilisé dans leur méthode de l'iodure d'ammonium pour sublimer l'étain. La grande difficulté de cette attaque réside dans le fait qu'il apparaît difficile d'obtenir des résultats répétitifs puisque la température théorique de sublimation[5] de l'oxyde stannique en présence d'iodure d'ammonium se situe entre 425 et 475° et que la température de condensation de l'iodure stannique formé se situe aux environs de 145°. Le danger de perdre une partie du produit de la sublimation est grand si la température du chauffage est trop élevée et par contre un chauffage insuffisant peut conduire à une libération incomplète de l'étain. Ces problèmes ont été résolus grâce à la conception dans nos laboratoires d'un assemblage que nous appelons "appareil de sublimation–condensation". Cet appareil est constitué d'un four "Thermolyne" dont une paroi est remplacée par une plaque de fonte. La température à la surface de la plaque se rapproche de celle que l'on retrouve à l'intérieur du four auquel est superposé un boîtier réfrigéré à l'eau courante. De cette façon, on peut contrôler la température de la sublimation et de la condensation tout en volatisant l'étain de quarante échantillons simultanément. Nous donnons une description détaillée de cet appareil à la figure 1.

PARTIE EXPERIMENTALE

Appareillage

Spectrophotomètre d'absorption atomique Varian Techtron modèle AA-5 couplé à un numériseur DI-30, un brûleur air–acétylène de 10 cm modèle AB-51 de Varian Techtron et une cathode creuse d'étain ASL No. CA 739.

Appareil de sublimation–condensation schématisé à la figure 1.

Conditions opératoires

Longueur d'onde:	224·6 nm
Courant de la cathode:	8 mA
Fente:	150 μm
Débit d'aspiration:	5 ml/min
Position du brûleur:	9
Nature de la flamme:	air–hydrogène riche
Pression d'air:	9·5 l./min à 18 lb/po^2
Débit d'hydrogène:	13·5 l./min à 10 lb/po^2

Réactifs

Acide chlorhydrique concentré.

Acide ascorbique.

Iodure d'ammonium.

Chlorure stannique.

Solution d'acide ascorbique à 1% dans l'acide chlorhydrique 1:4.

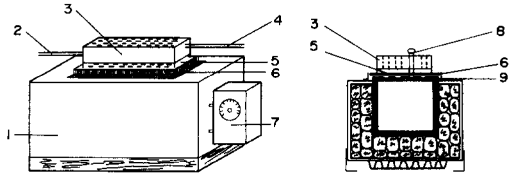
Solution de réglage. Sublimer 50 g d'iodure d'ammonium pendant 20 mn à 550°, reprendre le résidu avec la solution d'acide ascorbique à 1% dans l'acide chlorhydrique 1:4 et étendre à un litre avec la même solution.

Solution d'étain à 1000 μg/ml. Dissoudre 0,295 g de $SnCl_4.5H_2O$ dans 100 ml d'acide chlorhydrique 1:4.

Solutions étalons. Préparer cinq solutions contenant respectivement 0,2, 0,5, 1,0, 2,0 et 3,0 μg/ml d'étain par dilution de la solution à 1000 μg/ml d'étain avec la solution de réglage.

Mode opératoire

Calciner 1,0 g d'échantillon dans un creuset de porcelaine pendant une heure à 550°. Introduire l'échantillon calciné dans une éprouvette en Pyrex de 25 ml et ajouter 0,5 g d'iodure d'ammonium. Mélanger les deux substances en agitant bien l'éprouvette et la déposer dans l'appareil à sublimation–condensation. Laisser sublimer pendant 20 mn à 550°. Retirer l'éprouvette de l'appareil et reprendre le produit de la sublimation avec 10 ml de la solution d'acide ascorbique à 1% dans l'acide chlorhydrique 1:4. Agiter, filtrer sur un papier Whatman No. 40 et recueillir le filtrat dans une autre éprouvette de 25 ml. Régler le numériseur au zéro avec la solution de réglage ou de l'eau déminéralisée et étalonner l'appareil d'absorption atomique. Pour toute dilution de la solution de l'échantillon,



Vue d'ensemble Vue en coupe

utiliser la solution de réglage. Lire directement la concentration d'étain dans l'échantillon sur le numériseur.

RESULTATS ET DISCUSSION

Température et durée de la sublimation

On a mélangé 1 g d'échantillon à 0,5 g d'iodure d'ammonium et on a chauffé pendant 20 mn. Tout comme Heffernan *et al.*,[5] on a observé que la sublimation est complète à 500° et stable jusqu'à au moins 600°. Nous avons opté pour une température de 550° afin d'obtenir une sublimation entière. Pendant la sublimation, la température au milieu de l'éprouvette ne dépasse pas 65° alors qu'elle n'est que de 35° dans la partie supérieure. Le système de réfrigération est donc tout à fait efficace et permet une condensation maximum de l'iodure stannique formé. Comme l'indique la figure 2, une durée de sublimation de 20 mn est amplement suffisante pour obtenir une réaction totale.

Choix et conditions de la flame

On a calculé la sensibilité inverse pour différents types de flamme et les résultats apparaissent au tableau 1. La flamme hydrogène–azote est celle qui nous donne le plus de sensibilité mais les interférences cationiques y sont cependant beaucoup plus importantes qu'avec une flamme air–hydrogène.[6,7] De plus, on obtient un signal plus stable avec une flamme air–hydrogène de sorte que, malgré une sensibilité inférieure, la limite de détection est la même que pour une flamme hydrogène–azote. Ainsi, notre choix s'est porté sur une flamme air–hydrogène et la flamme réductrice s'est avérée la plus sensible.

Etude des interférences

Les interférences d'une part causées par les cations en solutions ont été étudiées par plusieurs auteurs[5,6,8–11] et sont en général peu importantes dans une flamme air–hydrogène; d'autre part, les seuls cations que l'on peut trouver en solution après une sublimation à l'iodure d'ammonium sont peu nombreux et sont ceux qui sont rapidement extractibles à froid dans une solution d'acide chlorhydrique 1:4 ou ceux qui peuvent former des oxydes qui se subliment en laissant des iodures solubles. Pour ces deux raisons notre étude des interférences n'a porté que sur l'influence des produits de la sublimation.

Tableau 1. Sensibilité inverse de l'étain dans différentes flammes

Flamme	Sensibilité inverse en µg/ml pour 1% d'absorption
air–acétylène	33·3
oxyde nitreux–acétylène	25·0
air–hydrogène	2·0
hydrogène–azote	1·0

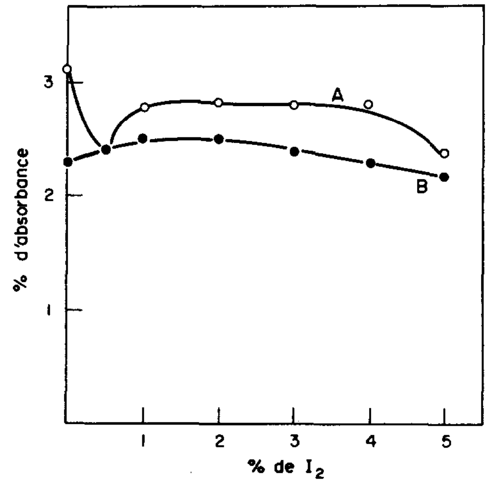

Fig. 3. Influence de I_2 et de l'acide ascorbique sur l'absorbance de l'étain. A—Solution de 5 ppm de Sn + % de I_2. B—Solution de 5 ppm de Sn dans une solution d'acide ascorbique à 1% + % de I_2.

Après la sublimation, on retrouve en solution NH_4^+, I^- et I_2. L'absorbance d'une concentration donnée d'étain augmente linéairement avec la concentration d'ions ammonium tandis qu'elle n'est pas affectée par la présence d'ions iodure. L'influence de l'iode est illustrée à la figure 3.

Dans le but d'augmenter la sensibilité de la méthode, on a concentré l'étain en solution en diminuant le volume recommandé de la solution d'acide chlorhydrique 1:4. Les courbes II et III de la figure 4 représentent les résultats obtenus en reprenant le produit de la sublimation par 5 et 10 ml respectivement de la solution acide. On se rend compte qu'il n'y a rien à gagner à vouloir concentrer la

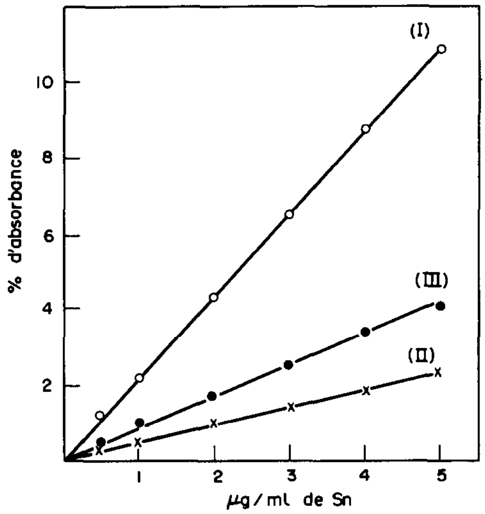

Fig. 4. Influence globale de toutes les substances ajoutées sur l'absorbance de l'étain. I—Etain présent dans une solution d'acide chlorhydrique 1:4. II—Etain présent dans une solution d'acide chlorhydrique 1:4 contenant 7% de NH_4I + 3% I_2 et 1% d'acide ascorbique. III—Etain présent dans une solution d'acide chlorhydrique 1:4 contenant 3·5% de NH_4I + 1·5% I_2 et 1% d'acide ascorbique.

Tableau 2. Récupération des ajouts

Numéro de l'échantillon	Teneur, *ppm*	Ajout, *ppm*	Teneur trouvée, *ppm*
18330	14	0	14
18330	14	2·5	17
18330	14	5·0	19
18330	14	10·0	22
18330	14	15·0	28
18330	14	25·0	36

solution d'étain en diminuant le volume de la solution d'acide. En effet l'accroissement du signal dû à la plus grande concentration d'étain est annulé par la diminution causée par l'augmentation des sels en solution. L'examen de ces trois courbes nous laisse entrevoir que l'influence totale des substances ajoutées est surtout liée à la quantité de sels en solution et non pas aux espèces elles-mêmes. Ceci implique que la quantité d'iodure d'ammonium employée pour la sublimation doit être la même pour chacun des échantillons et que les solutions étalons doivent contenir les mêmes quantités d'ions ajoutés que l'on retrouve dans la solution de reprise des échantillons après sublimation. La courbe III représente donc la courbe d'étalonnage correspondant aux solutions obtenues par la méthode proposée.

Récupération

Une série de sublimation de cassitérite pure a été faite par cette méthode et la récupération variait entre 85 et 100%. De plus des essais sur la récupération d'ajouts ont été effectués et les résultats sont présentés au tableau 2. Nous présentons en outre au tableau 3 une comparaison de nos résultats avec les valeurs recommandées pour une douzaine d'étalons géologiques internationaux et là encore les résultats sont très acceptables. Enfin, le tableau 4 nous indique une reproductibilité satisfaisante de la méthode.

Tableau 3. Dosage de l'étain dans différents étalons géologiques

Echantillon	Valeur admise, *ppm*	Valeur obtenue, *ppm*
AGV-1	4·2	4

DT-N	5	3
G-2	1·5	1
GH	10	7
GM	4·6	5
GSP-1	6·3	6
JG-1	3	3
Sy-1-0	11	9
Sy-2-0	2·5	4
Sy-3-0	4·8	6
TB-1	6	5

Tableau 4. Reproductibilité de la méthode

Echantillon	Nombre de dosages	Valeur moyenne, *ppm*	Ecart relatif, %
RC-1	133	2·4	25·9
MB-1	79	6·4	15·5
SN-1	30	8·0	13·6
G-1016	12	24·6	7·8

Les résultats présentés ont été obtenus à partir de quatre échantillons dosés pour l'étain par des techniciens différents à des jours différents et avec des appareils différents.

Conclusion

Même si l'addition d'acide ascorbique abaisse légèrement l'absorbance de la solution, elle a pour effet de stabiliser le signal émis et de réduire d'environ 50% l'iode formé donnant ainsi une solution limpide pouvant être atomisée. On doit remarquer en outre que la stabilité des solutions contenant de l'iode n'est que de 2 ou 3 jours. On note en effet une augmentation de l'absorbance d'environ 2% par jour et elle est régulière du moins pour les dix jours qui suivent la préparation des solutions.

Cette méthode a déjà été utilisée pour l'analyse de plus de 20000 échantillons de sédiments de ruisseaux et les résultats se prêtent bien à l'interprétation géochimique grâce à la précision qu'elle peut fournir pour les basses teneurs. Cette méthode pourrait aussi se prêter au dosage de l'étain dans les sols. Nous envisageons actuellement de doser l'antimoine à partir de la même solution et nous devrions présenter des résultats sous peu à ce sujet.

Remerciement—Les auteurs remercient M. Normand Rhéaume pour son ingénieuse assistance technique.

Résumé—On décrit une méthode simple, rapide et reproductible pour doser 1 à 50 ppm d'étain présent dans des sédiments. L'étain présent dans l'échantillon sous forme de cassiterite est sublimé en présence d'iodure d'ammonium. L'iodure stannique formé est dissous dans une solution d'acide chlorhydrique contenant de l'acide ascorbique. L'étain en solution est finalement dosé par spectrophotométrie d'absorption atomique. Aucune interférence n'a été observée et la méthode a été éprouvée en analysant quelques étalons géologiques. Dans tous les cas les résultats obtenus concordent avec les valeurs recommandées. Un technicien peut analyser 250 échantillons par jour en suivant la méthode proposée.

DETERMINATION OF ADRENALINE AND NORADRENALINE BY RESONANCE RAMAN SPECTROMETRY

Mohammed S. Rahaman* and Michael D. Morris
Department of Chemistry, University of Michigan, Ann Arbor, MI 48104, U.S.A.

(*Received* 25 *February* 1975. *Accepted* 25 *March* 1975)

Conventionally, determination of adrenaline and noradrenaline in urine and other matrices is carried out by fluorimetry after conversion of the catecholamines into the trihydroxyindoles.[1,2] The method suffers from certain disadvantages. First, as with other fluorimetric methods, it is susceptible to interference from a variety of quenching agents. Second, many pharmaceuticals give fluorescent products, which may interfere. Finally, adrenaline and noradrenaline are not differentiated by the procedure. However, adrenaline alone will undergo the initial oxidation in acidic solution, so noradrenaline can be determined by difference.

In the past few years, resonance Raman spectrometry has emerged as a sensitive and selective probe for many molecules of biological interest.[3] Most workers have confined their studies to molecules which themselves can show resonance-enhanced Raman spectra. A few attempts to prepare derivatives suitable for resonance Raman spectrometry have been reported.[4,5]

Moreover, the potential of resonance Raman appears to have been largely overlooked by analytical chemists, although the technique is simple, offers high resolution and freedom from the quenching effects which plague fluorescence.[6] The principal drawback of resonance Raman spectrometry is the fact that conventional spectrometers cannot distinguish between Raman scattering and fluorescence. With the advent of convenient instrumentation for fluorescence-rejecting techniques such as coherent anti-Stokes scattering,[7,8] inverse Raman spectrometry,[9] and time-resolved Raman spectrometry[10,11] the fluorescence problem appears tractable.

In the present communication we report the application of resonance Raman spectrometry to the determination of adrenaline and noradrenaline as the aminochromes. Aerial oxidation of these molecules, catalysed by copper(II), is well known.[12] The technique is simple, applicable to concentrations as low as 1 × $10^{-6}M$ and allows determination of adrenaline and noradrenaline on a single sample.

EXPERIMENTAL

Apparatus

A Spex 1401 double monochromator, a cooled RCA C31034A photomultiplier and both d.c. and photon-counting detection systems were used for these experiments. Slit-widths of 400 μm (9 cm^{-1}) were employed. Scan-rates of 20–50 cm^{-1}/min were used. The excitation source was a Coherent Radiation CR-5 argon-ion laser. Melting point capillaries were used as sample containers, with conventional transverse excitation and observation at 90° to the incident radiation. Absorption spectra were obtained with a Cary 14 spectrophotometer.

Reagents

Adrenaline hydrogen tartrate and noradrenaline hydrogen tartrate were obtained from the Sigma Chemical Company and used as received. Stock solutions of these reagents were stored under refrigeration and replaced at frequent intervals. All other reagents were of ACS reagent grade.

Procedure

The aminochromes were prepared by addition to the catecholamines of stock copper(II) sulphate, ammonium chloride and potassium nitrate solutions to make the solutions 0·01*M* in cupric ion, 0·04*M* in ammonium ion, and 0·05*M* in nitrate. The pH of the resulting solution was adjusted to 5 with ammonia. Raman scattering intensity was measured at 1480 cm^{-1} (adrenaline) and 1430 cm^{-1} (noradrenaline), the nitrate 1050-cm^{-1} line being used as an internal standard. Ar^+ 496·5-nm excitation is optimum, but Ar^+ 488·0 nm may be used.

RESULTS AND DISCUSSION

Absorption spectra of the aminochromes formed are shown in Fig. 1. The compounds have similar spectra, but the adrenaline product shows higher absorption. In the absence of ammonium ion similar spectra were observed, but with lower intensities, implying incomplete oxidation.

The resonance Raman spectra of the adrenaline and noradrenaline aminochromes are presented in Fig. 2. In addition to these bands, weaker bands occur around 1680, 1625, 1100 and 500 cm^{-1}. The two bands of the adrenaline species at 1480 and 1465 cm^{-1} and the single band of noradrenaline at 1430 cm^{-1} allow ready differentiation of these compounds. Interpretation of these spectra is in progress and will be reported at a later date.

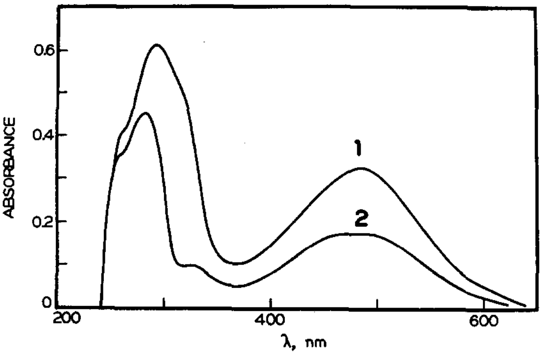

Fig. 1. Absorption spectra of aminochrome systems, pH = 5. 1—1 × $10^{-4}M$ adrenaline; 2—1 × $10^{-4}M$ noradrenaline.

---

* Present address: Department of Chem. & Chem. Eng. Michigan Technological University, Houghton, Michigan 49931.

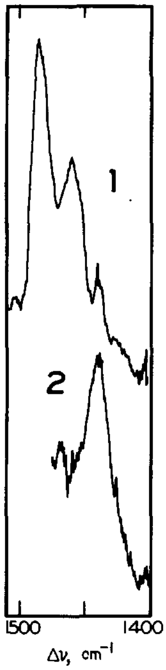

Fig. 2. Resonance Raman spectra of aminochromes, λ_e = 496·5 nm. 1—1 × $10^{-5}M$ adrenaline; 2—1 × $10^{-5}M$ noradrenaline.

Table 1. Concentration dependence of aminochrome resonance Raman scattering

Adrenaline		Noradrenaline	
$C, 10^{-5}M$	$I_{\text{sample}}/I_{\text{NO}_3^-}$	$C, 10^{-5}M$	$I_{\text{sample}}/I_{\text{NO}_3^-}$
0·45	0·032	0·55	0·025
1·05	0·082	1·00	0·045
1·60	0·122	4·0	0·140
2·03	0·158	6·0	0·205
3·00	0·230	7·5	0·260
6·0	$0{\cdot}47_5$	9·0	$0{\cdot}30_5$
7·0	$0{\cdot}56_0$	10·0	$0{\cdot}35_2$
8·0	$0{\cdot}64_2$		
10·0	$0{\cdot}80_5$		

Table 1 shows analytical data for these solutions. The working curve is linear over the range 5×10^{-6}–$2 \times 10^{-4}M$. Above the $10^{-5}M$ level, the precision of the measurements is about ±3%. Although signals are detectable down to about the $10^{-6}M$ level, the noise in our system is too great to allow analytical use of the signals below about $5 \times 10^{-6}M$. More sophisticated signal conditioning could probably lower the detection limits and the limit of the useful concentration range.

Our current studies have been limited to synthetic solutions. We have carried out some preliminary experiments on urine matrices. Prior concentration of the catecholamines by the conventional technique of adsorption on alumina and elution with acid[1] is necessary to bring the concentrations to a usable level. This step also serves to remove fluorescent substances from the sample. Our results show that adrenaline and noradrenaline from urine samples are detectable by this technique. Studies of various clinical specimens are now in progress to determine the relative merits of the resonance Raman and fluorimetric approaches to catecholamine determination.

Summary—Aminochromes of adrenaline and noradrenaline show resonance Raman scattering at 1480 and 1430 cm^{-1} respectively, with Ar$^+$ excitation. Scattering intensity is a linear function of concentration. Detection limits are $1 \times 10^{-6}M$. Both catecholamines can be determined in a single measurement.

SUR L'ETAT D'OXYDATION DE L'*o*-TOLIDINE

Camelia Ghimicescu et Florica Dima
Faculté de Pharmacie, Iassy, Roumanie

(Reçu le 12 février 1974. Révisé le 19 décembre 1974. Accepté le 27 mars 1975)

La benzidine et ses dérivés développent par oxydation des colorations bleue ou jaune.[1–11] Dans le cas de l'*o*-tolidine (diméthyl-3,3′ benzidine), l'oxydation par V^{5+} conduit, suivant le pH, à des colorations variables. La figure 1 montre qu'à pH > 3 la coloration est bleue, tandis qu'elle est jaune à pH inférieur. L'oxydation de la benzidine et ses dérivés, en particulier de l'*o*-tolidine, a fait l'objet de nombreux travaux tendant à élucider le mécanisme de la réaction et la structure des dérivés obtenus. Celle du colorant bleu formé n'était pas encore précisée.

Par spectrophotométrie infrarouge (Unicam SP 200) en nujol, nous avons constaté l'existence des bandes d'absorption caractéristiques de la fonction imine (1560–1570, 1620–1640, 3300–3350 cm^{-1}) ainsi que celles de la fonction $-NH_2$ (660, 680, 1260, 1620–1640, 3200–3500 cm^{-1}). Ces résultats, en accord avec ceux précédemment obtenus,[4–8] confirment pour le dérivé formé une structure de monoquinone imine.

Notre étude a été poursuivie par potentiométrie et photométrie au cours de l'oxydation de l'*o*-tolidine à différents pH par plusieurs oxydants ainsi que de la réduction du dérivé jaune, terme final de la réaction.

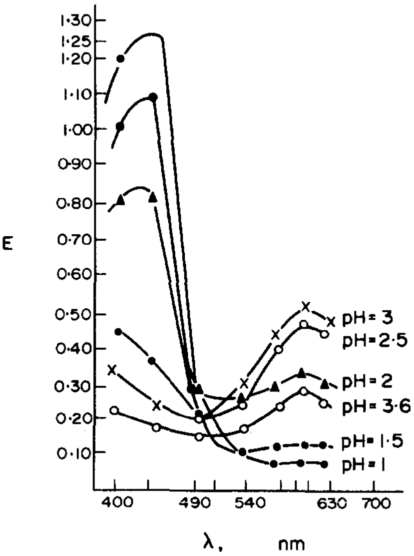

Fig. 1.

Oxydation de l'o-tolidine

Divers oxydants ont été utilisés: $K_2S_2O_8$, I_2, $KMnO_4$, $K_2Cr_2O_7$, $NaNO_2$, NH_4VO_3. Seul, le persulfate a permis la mise en évidence, au cours de l'oxydation quantitative, de deux sauts de potentiel.

(*a*) A pH > 3, par exemple à pH $= 4{,}0$ en tampon acétate–acide acétique, l'oxydation de l'*o*-tolidine en solution 0,005*M* par le persulfate 0,005*M* montre deux virages respectivement pour 2,7 et 5,65 ml de solution oxydante, soit par molécule d'amine l'échange final de deux électrons (figure 2). Les mêmes résultats ont été obtenus en solutions 0,02*M*.

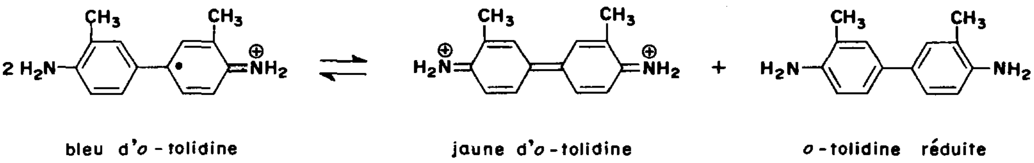
(*b*) A pH < 3, en acide sulfurique par exemple (pH $=$ 1,5–2) pour des solutions 0,01*M* d'*o*-tolidine et de persulfate, le tracé de la courbe de titration (figure 3) montre également deux sauts de potentiel correspondant respectivement à l'échange d'un (virage de la coloration du jaune au brun), puis de deux (virage du brun à l'orange) électrons par mole d'amine.

Lors du premier virage, les colorations différentes obtenues à pH > 3 ou pH < 3 peuvent s'expliquer, à pH < 3, par dismutation de l'*o*-tolidine oxydée en bleu d'*o*-tolidine.

L'oxydation de l'*o*-tolidine (0,005*M*) par des quantités croissantes de persulfate (0,005*M*) a été suivie également par spectrophotométrie à 597 nm (coloration bleu) ou 434 nm (coloration jaune). Les lectures, après 5 minutes, ont permis le tracé du graphique, représentant les valeurs d'extinction en fonction du volume de solution oxydante (figure 4).

On voit que l'extinction due à la coloration jaune (courbe 2) augmente jusqu'à réaction complète et équimoléculaire entre l'*o*-tolidine et $K_2S_2O_8$, la coloration finale est jaune.

L'extinction due à la coloration bleue (courbe 1) qui se forme intermédiairement augmente jusqu'à consommation de 0,5 mole $K_2S_2O_8$ puis diminue: le colorant bleu, état intermédiaire de la réaction s'oxydant ensuite en dérivé jaune.



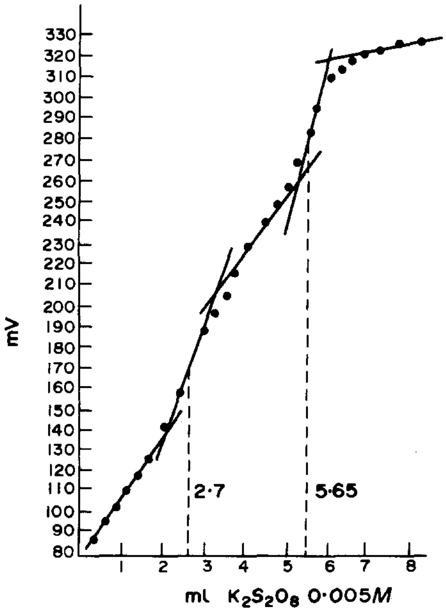


Fig. 2.

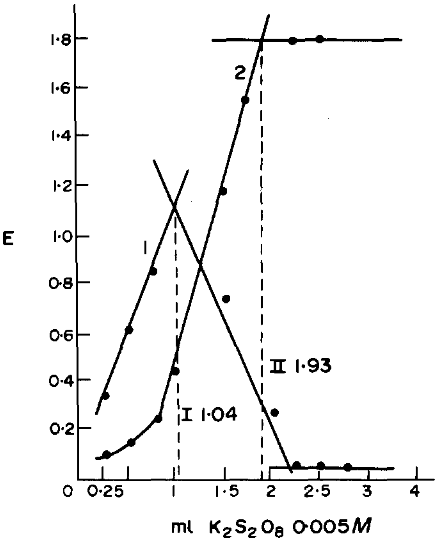

Fig. 4.

Réduction du produit d'oxydation (à pH > 3) de l'o-tolidine (colorant jaune)

Le jaune d'*o*-tolidine a été préparé en traitant 5 ml d'*o*-tolidine 0,005*M* par 2 ml de solution tampon acétate–acide acétique pH = 4,0, 5,65 ml $K_2S_2O_8$ 0,005*M* et 18 ml d'eau.

Par titrage potentiométrique à l'aide de la solution à 1,5% d'iodure de potassium, la courbe de titration montre un seul saut de potentiel (figure 5), la coloration de la solution virant du jaune au bleu.

Le même résultat a été obtenu en titrant potentiométriquement la solution d'*o*-tolidine oxydée par le thiosulfate 0,01*M*. La courbe de titration (figure 6) montre encore un seul saut de potentiel correspondant au virage du jaune au bleu. L'équivalence a également été obtenue avec $Na_2S_2O_3$ 0,1 ou 0,002*M*. Dans tous les cas, la réduction quantitative correspond à l'échange d'un électron.

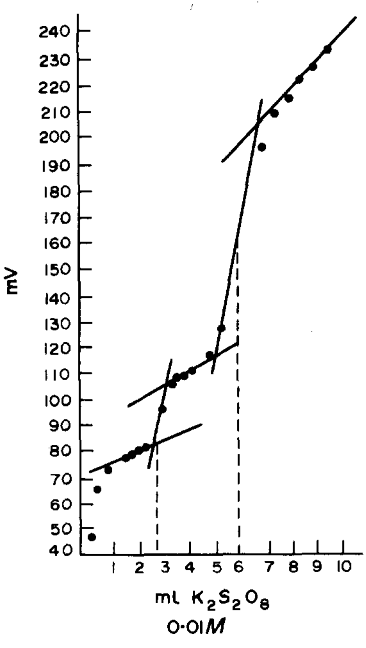

Fig. 3.

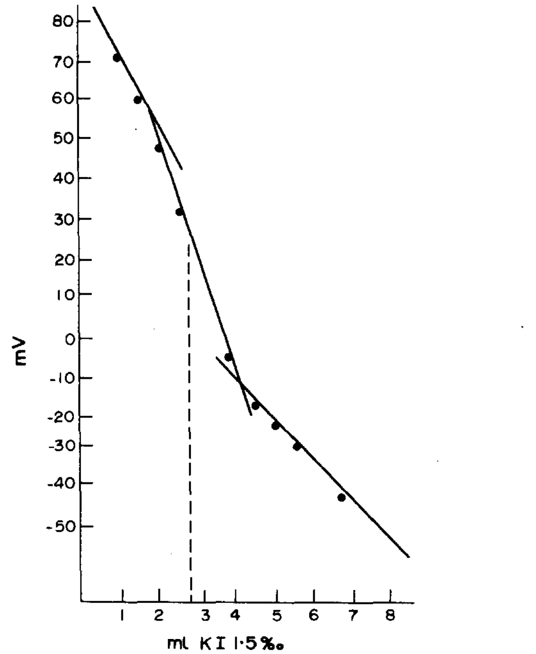

2·9ml KI 1·5‰≈25ml KI 0·01M≈10ml KI 0·025M

Fig. 5.

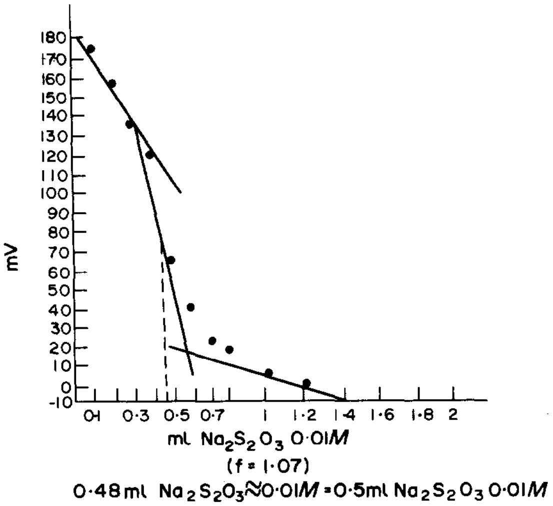

Fig. 6.

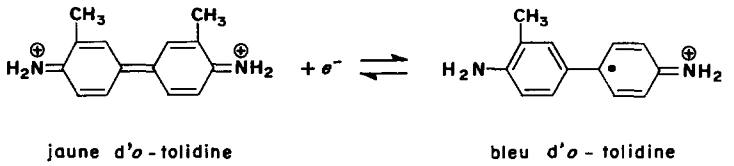
Avec les réserves d'usage, on peut proposer le schéma réactionnel suivant:



Conclusion

Pour l'étude de l'*o*-tolidine, c'est avec le persulfate que la mise en évidence des deux sauts de potentiel est la plus nette. A pH > 3, les deux sauts de potentiel correspondent à la formation de deux composés: un colorant bleu, forme intermédiaire d'oxydation avec perte d'un électron, et un colorant jaune correspondant à la perte de deux électrons. A pH < 3, deux sauts de potentiel ont été observés mais la coloration demeure jaune, la forme bleue intermédiairement formée subissant une dismutation. La réduction du jaune d'*o*-tolidine, forme finale d'oxydation, s'effectue par l'iodure ou le thiosulfate avec un seul saut de potentiel correspondant au retour au colorant bleu.

Résumé—L'oxydation de l'*o*-tolidine s'effectue en deux temps avec formation successive d'un colorant bleu puis d'un colorant jaune correspondant respectivement chacun à la perte d'un électron. La réduction de la forme jaune en colorant bleu a également lieu avec échange d'un électron.

ANALYTICAL DATA

SENSITIVE TESTS FOR NITRITE THROUGH AZO-DYE FORMATION

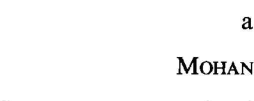
B. S. GARG and Y. L. MEHTA
Department of Chemistry, University of Delhi, Delhi 110007, India
and
MOHAN KATYAL
St. Stephen's College, University of Delhi, Delhi 110007, India

(*Received* 2 *April* 1975. *Accepted* 28 *April* 1975)

Nitrite reacts with sulphanilic acid, forming the diazonium cation **I**. When the cation is coupled with pyridinols (2-amino-3-pyridinol, 2,3-pyridinediol and 5-chloro-2,3-pyridinediol), the red azo-dyes **II–IV** result. Their formation is used in detection and determination of nitrite (or nitrate after its reduction with zinc dust). The method affords more sensitivity and selectivity than many of the similar methods[1,2] of nitrite detection.

(I)

(II)



(III) when R = H
(IV) when R = Cl

EXPERIMENTAL

Solutions of the pyridinols were prepared by dissolving 500 mg in 100 ml of ethanol. Other solutions employed were: 1% w/v sulphanilic acid in 30% acetic acid, ammonia solution (1 + 1) and 50 μg/ml nitrite (sodium nitrite was used). All other solutions were prepared from reagent grade chemicals in doubly distilled water.

Procedure for detection of nitrite

Place a drop of the nitrite solution on a spot-plate, add 2 or 3 drops of ammonia solution and 1 drop each of the sulphanilic acid and 2-amino-3-pyridinol solutions, whereupon a red colour develops instantaneously. With the other two pyridinols, the order of addition should be nitrite, sulphanilic acid, pyridinol, ammonia.

With 2-amino-3-pyridinol as coupling agent, the tolerance limits (in μg/ml) of various ions are: 10000 each of Cl^-, NO_3^-, ClO_4^-, SO_4^{2-}, $SO_2O_8^{2-}$; 7500 of Al^{3+}; 7000 of F^-, 5000 each of I^-, CNS^-, BO_3^{3-}, PO_4^{3-}; 4000 each of Br^-, SO_3^{2-}, $C_2O_4^{2-}$, tartrate, MoO_4^{2-}, thiourea; 3500 of citrate; 1500 each of Mg^{2+}, In^{3+}, Fe^{3+}; 1000 each of Ca^{2+}, Sr^{2+}, Ba^{2+}; 280 of UO_2^{2+}; 200 of Pb^{2+} and 50 of Sc^{3+}. With 2,3-pyridinediol as coupling agent, they are: 10000 each of Cl^-, Br^-, I^-, NO_3^-, ClO_4^-, $S_2O_8^{2-}$, thiourea; 7500 of $C_2O_4^{2-}$; 7000 of SO_4^{2-}; 5000 each of F^-, tartrate; 4000 of citrate; 3500 of SO_3^{2-}; 2500 each of BO_3^{3-}, PO_4^{3-}; 1200 of In^{3+}; 1000 of Mg^{2+}; 800 each of Ca^{2+}, Sr^{2+}, Ba^{2+}; 120 each of Al^{3+}, UO_2^{2+}, Fe^{3+} and 100 of Sc^{3+}. With 2-chloro-3-pyridinol, the tolerances are: 10000 each of Cl^-, Br^-, I^-, CNS^-, NO_3^-, $S_2O_8^{2-}$, SO_4^{2-}, thiourea; 7500 of $C_2O_4^{2-}$; 5000 each of F^-, SO_3^{2-}, tartrate, citrate; 4000 of BO_3^{3-}; 1000 each of Ca^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, PO_4^{3-}, 600 of UO_2^{2+}; 500 of In^{3+}; 150 each of Mg^{2+}, Fe^{3+} and 100 of Sc^{3+}. In certain cases, the red colour fades after some time, and for determinations, the absorbance should be measured immediately. In presence of Fe^{3+}, the red colour soon changes to that of hydrous ferric oxide. With all pyridinols, Cu^{2+} interfered by producing a violet colour with the dye. Bivalent Zn, Cd, Hg, Co and Ni produced a magenta colour. It seems probable that in these cases the metals displace the hydrogen atom of the —OH group in the dye molecule (**II**, **III** or **IV**) and subsequently co-ordinate through the nitrogen atom of the diazo group marked with an asterisk.

Nitrate determination in water samples

Evaporate the water sample to an appropriate volume. To 1 ml of the sample solution, add 1 ml of ammonia solution, 2 ml each of the sulphanilic acid and 2-amino-3-pyridinol solutions, and finally make up the volume to 10·0 ml. Measure the absorbance at 480 nm. Construct a calibration curve.

The method has been successfully employed in determination of the nitrite content of water samples from wells and pumps.

The limits of identification are 0·02 μg/ml (with 2-animo-3-pyridinol) and 0·01 μg/ml (with the other two pyridinols). The limits of dilution are $1:5 \times 10^7$ (with 2-amino-3-pyridinol) and $1:10^8$ (with the other two pyridinols). The molar absorptivities are $2{\cdot}8 \times 10^4$ $l.mole^{-1}.cm^{-1}$ at 470–485 nm (2-amino-3-pyridinol); $1{\cdot}4 \times 10^4$ at 445–460 nm (2,3-pyridinediol); $2{\cdot}1 \times 10^4$ at 460–475 nm (5-chloro-2,3-pyridinediol).

Summary—The diazonium cation resulting from the interaction of nitrite with sulphanilic acid is coupled with pyridinols to give red azo-dyes. Compared to many other colour reactions employed for detection of nitrite, the present systems afford greater sensitivity. Many ions do not affect the colour; thus detection and determination are selective. The method is applied in determination of nitrite in water samples.

PRELIMINARY COMMUNICATIONS

THE DETERMINATION OF WEAK ACIDS IN AQUEOUS SOLUTION BY CATALYTIC THERMOMETRIC TITRIMETRY

E. J. Greenhow* and A. A. Shafi

Chemistry Department, Chelsea College, University of London, Manresa
Road, London, SW3 6LX

(Received 16 October 1975. Accepted 31 October 1975)

Acetone and acrylonitrile are convenient indicator reagents for use in the determination of weak organic acids in non-aqueous solution by the method of catalytic thermometric titrimetry. The end-points of the titrations are indicated by a sharp rise in temperature caused by the heat evolved in the titrant-catalysed dimerization of acetone[1] and anionic polymerization of acrylonitrile,[2] respectively. Vaughan and Swithenbank[1] have shown that the presence of water in the sample solution has an adverse effect on the end-point sharpness when acetone is used as the thermometric indicator, and it is recommended that the water content of the acetone, which is used as both the indicator and the sample solvent, should not exceed 0.2%. Water and alcohols are regarded as being undesirable impurities in monomers undergoing polymerization by an anionic process because they are proton donors and terminate the growing polymer chains.[3] However, it has been shown[2] that acrylonitrile functions effectively as a thermometric indicator when the solution being titrated contains up to about 1% of water and/or 5% of methanol. The titrants used in conjunction with the acrylonitrile indicator themselves contain alcohols, and the alcohol content of the solution at the end-point is, therefore, dependent on the volume of titrant added.

In the present investigation, it has been established that weak acids can be determined in low concentration in aqueous solution by using the previously-described thermometric procedure with acrylonitrile as the thermometric indicator[2] and a dipolar aprotic

*To whom requests for reprints should be addressed.

solvent, dimethyl sulphoxide, as a co-solvent. Titration curves for glycine, cysteine, valine, benzoic acid, phenol, resorcinol, oxalic acid, phosphorous acid, phosphoric acid and boric acid are shown in Fig. 1. It can be seen that sharp end-point inflexions are obtained in the determinations of 0.1 mmole amounts of strong and weak acids in aqueous solution, in concentrations ranging from 1 to 10%. The volume of the 0.5M titrant required to neutralize 0.1 mmole of a dibasic acid is 0.4 ml, while the volume of water in a 1% aqueous sample is about 1 ml. If an aqueous 0.5M titrant were used for the titration of a 2% aqueous sample, containing about 0.5 ml of water, the solution after neutralization would contain less than 1 ml of water. Thus the possibility arises of using aqueous titrants, and this was investigated. In Fig. 2 are shown the titration curves obtained when 2% aqueous solutions of arginine, phenol, resorcinol, benzoic acid, phosphorous acid and phosphoric acid are titrated with 0.5M aqueous potassium hydroxide. The end-point inflexions are distinct but there is a sharp rise in temperature preceding the inflexion, *i.e.*, during the neutralization of the acid. This can be attributed to the exothermic heat of mixing of the water in the titrant with the dimethyl sulphoxide in the titration solution. In contrast, the addition of propan-2-ol to a mixture of water, dimethyl sulphoxide and acrylonitrile results in a fall in temperature at the neutralization stage in most of the titrations shown in Fig. 1.

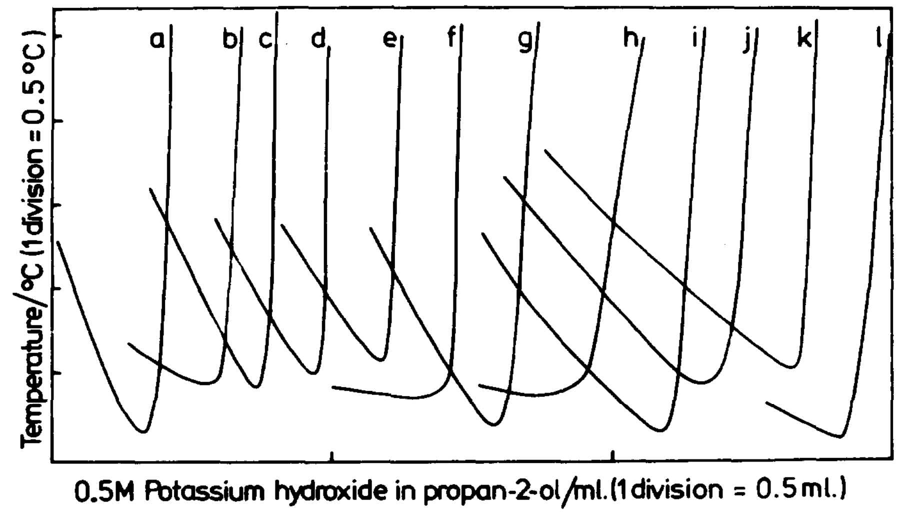

Fig. 1. The catalytic thermometric titration of acids in aqueous solution with 0.5M potassium hydroxide in propan-2-ol.

a, glycine (1.5%);[*] b, cysteine (2%); c, valine (2%); d, benzoic acid (2%); e, phenol (2%); f, phenol (10%); g, resorcinol (2%); h, resorcinol (10%); i, oxalic acid (2%); j, phosphoric acid (1%); k, phosphorous acid (1.1%); l, boric acid (1%).

Conditions: titrant is added at 0.2 ml/min to a mixture of the aqueous sample containing 0.1 mmole of the acid, 4 ml of dimethyl sulphoxide and 2 ml of acrylonitrile.

Conditions: as in Fig. 1, apart from the titrant. The acid samples are 2% aqueous solutions. a, arginine; b, phenol; c, resorcinol; d, benzoic acid; e, phosphoric acid; f, phosphorous acid.

It has been established[4] that the measured reaction stoichiometry of resorcinol is dependent on the titrant and the solvent system when the catalytic thermometric procedure is used. Thus, resorcinol is determined as a monofunctional acid in solvents that promote the ionization of the potassium hydroxide titrant, and as a difunctional acid in solvents in which potassium hydroxide exists mainly as an ion-pair. In the solvent mixtures used in the present study, resorcinol shows an intermediate reaction stoichiometry of about 1.5, although a value of 1 might have been expected in the presence of the strongly cation-solvating dimethyl sulphoxide. Apparently, hydrogen bonding with water reduces the ionizing power of the former solvent. The effect of the proportions of water, dimethyl sulphoxide and acrylonitrile on the measured reaction stoichiometry when resorcinol is determined in these mixtures will be discussed in a later contribution. In the present study, phosphoric, phosphorous and oxalic acids are titrated as dibasic acids while boric acid is determined as a monobasic one.

One advantage of using this catalytic thermometric procedure in preference to visual-indicator or potentiometric titrimetry is that weak acids in aqueous solution can be titrated directly. Before determining very weak acids by the visual-indicator or potentiometric methods it is usually necessary to enhance their acidities, either by extracting them into an appropriate non-aqueous solvent, as in the case of phenols, or by adding reagents, such as formaldehyde to amino-acids and mannitol to boric acid.

The exothermic reaction marking the end-point in the titrations is unlikely to be a simple anionic polymerization process because, as noted above, water and alcohols terminate the growing polymer chains. Zilkha and Feit[5,6] have shown that chain transfer and cyanoethylation reactions occur when sodium and potassium alkoxides are used as catalysts for the polymerization of acrylonitrile in the presence of methanol, and they identified the cyanoethylation product of methanol and acrylonitrile in the polymerization mixtures. In their evaluation of quaternary ammonium hydroxides as polymerisation catalysts, they deduced that water can function as a chain transfer reagent in the polymerization of acrylonitrile. The results of these investigations suggest that chain transfer and cyanoethylation reactions, involving water and/or propan-2-ol, are responsible for the temperature rise marking the end-point in the titrations discussed in the present communication.

A NOVEL COLOUR REACTION FOR ALDEHYDES AND KETONES

K.L. Bajaj*

Department of Chemistry and Biochemistry, Punjab Agricultural University, Ludhiana, India

(Received 23 September 1975. Accepted 24 October 1975)

During some experiments with ethanolamine it was found that when formaldehyde was added to it, followed by formic acid, the reaction was exothermic with instantaneous production of a yellow colour. This novel colour reaction was further investigated, with different aliphatic and aromatic aldehydes and mineral acids. The substances tested included reducing sugars (glucose, galactose, xylose, ribose and lactose), aliphatic aldehydes (formaldehyde, butyraldehyde, crotonaldehyde, citronellal and acrolein), heterocyclic aldehydes (furfural), aromatic aldehydes (benzaldehyde, *o*- and *p*-hydroxybenzaldehyde, vanillin, *p*-dimethylaminobenzaldehyde, anisaldehyde and cinnamaldehyde) and ketones (acetone, methyl isobutyl ketone, dimedone, quinone, and levulinic acid). All gave a positive reaction.

The colour was obtained whether the aldehyde or ketone was first treated with ethanolamine, followed by formic acid, or formic acid was reacted with ethanolamine followed by the aldehyde or ketone, but the intensity was higher by the first method. Addition of excess of formic acid or slight warming increased the sensitivity. At low concentrations, a yellow colour was usually obtained, but at higher concentrations of formaldehyde, crotonaldehyde, cinnamaldehyde and furfural, an intense red colour was obtained. Addition of alkali generally decreased the colour intensity; in some cases the colour disappeared. Electron-releasing groups such as hydroxyl, dimethylamino or a double bond conjugated with the carbonyl group, increased the sensitivity. Thus *p*-dimethylaminobenzaldehyde, cinnamaldehyde and crotonaldehyde gave very sensitive reactions, the first being detectable even at the 0.5-μg level.

Amino-acids, phenols (*o*-aminophenol, catechin, catechol, pyrogallol), esters (ethyl acetate), amides (dimethylformamide, asparagine, glutamine), hydrazines, uric acid, alcohols (inositol, geraniol, linalool) and formic acid gave no reaction.

Investigations of the analytical use and the mechanism of this colour reaction are in progress. The colour reaction does not involve quinone formation since aliphatic compounds also gave a positive reaction. It is very likely that the reaction proceeds *via* Schiff's base formation, since no colour reaction was observed when the product obtained after addition of aldehyde to ethanolamine was reduced with $LiAlH_4$. Probably the Schiff's base is rapidly converted into oxazolidine derivatives[1] which react with formic acid to form coloured compounds. The reaction appears to be greatly accelerated in the presence of formic acid, which could not be replaced by mineral acids, and no colour was obtained without it.

CHROMATOGRAPHIC SEPARATION OF OPTICAL ISOMERS BY MEANS OF OUTER-SPHERE COMPLEX FORMATION REACTIONS

J. Gaál and J. Incédy

Institute of Analytical Chemistry, University of Chemical Engineering,
Veszprém, Hungary

(Received 13 September 1975. Accepted 10 October 1975)

It was shown earlier that there are differences between the stability constants of outer-sphere complexes formed between the D- and L-forms of an asymmetric anion and an optically active cobalt(III) cation.[1,2] This type of stereoselective complex formation reactions has not so far been used for chromatographic separation of optical isomers.

In our experiments the outer-sphere complex-formation reactions between the optically active $[Co(en)_3]^{3+}$ cation (en = ethylenediamine) and the D- and L-forms of aspartic and mandelic acids were investigated by potentiometric titration and ion-exchange methods, and the stability constants of the outer-sphere complexes were determined. For aspartic acid the stability constants were log $\underline{K}_1$ = 3.06 ± 0.01 for the D-aspartate complex, and log $\underline{K}_1$ = 2.24 ± 0.01 for the L-aspartate complex.

On the basis of the difference between the stability constants of these complexes a new ligand-displacement chromatographic method was developed for the separation of the optical isomers of aspartic and mandelic acid. From the results of our experiments it was established that the nature and concentration of the displacement anion (sulphate, chloride, perchlorate) in the eluent, and the pH, are very important factors affecting the selectivity and efficiency of separation of the optical isomers.

Figure 1 shows the separation of the D- and L-forms of aspartic acid on a weakly acidic cation-exchange resin column loaded with the D-form of optically active $[Co(en)_3]^{3+}$. Stepwise elution with 0.116 and 0.715$\underline{M}$ sodium sulphate was used for the separation. The mandelic acid isomers were similarly resolved.

LETTERS TO THE EDITOR

COLORIMETRIC DETERMINATION OF NYSTATIN

SIR,

Recently a communication[1] dealing with a new colorimetric method for analysis of the polyene antibiotic nystatin was published. That communication, I feel, highlights and reflects some important facts pertaining to nystatin which are of particular interest to analysts and require pointing out.

Most publications (including that of Amer *et al.*) give the impression that nystatin is a single compound. This, in fact, is not true, as is reflected by the work of Shenin[2] and Borowski *et al.*[3] Furthermore, the ratio and (possibly) the nature of the constituents is variable.[4] Nystatin is a natural metabolite of micro-organisms arising through secondary metabolism, which means that there is a high likelihood of impurities being associated with the substance.

None of the literature on analysis of nystatin defines the composition of the substance tested. Hence comparisons of methods of analysis should be treated with caution. The literature also contains little or nothing on the intermediate products of the chemical reactions used for qualitative and quantitative analysis of nystatin. If the nature of nystatin were better known then more sensitive and specific methods of analysis could be devised.

Some authors[5,6] have reported mass spectrometry studies and given fragmentation schemes based (apparently) on the assumption that nystatin is a single compound. The interpretation of these results is therefore also open to question.

Two other factors are worthy of mention. First, it has been reported that nystatin is surface-active and forms micelles.[7] Care should therefore be taken when spectrophotometric experiments are conducted. Secondly, much of the work reported on the molecular mode of action of nystatin has been done with material of undefined composition.[8,9]

In my opinion any reported work (particularly of an analytical nature) should try to include the composition of the nystatin used.

IMPROVEMENT IN SAMPLE PREPARATION FOR ALPHA LIQUID-SCINTILLATION SPECTROSCOPY

SIR,

Since the publication of our paper,[1] "Plutonium and Uranium Determination in Environmental Samples: Combined Solvent Extraction - Liquid Scintillation Method," we have developed an improvement in one of the analytical steps that results in a simplification of the procedure as well as a considerable increase in its reliability and reproducibility.

In Procedure, the paragraph entitled Fuming with perchloric acid, a method is described for converting a mixed nitrate-perchlorate system into the perchlorate, in which essentially all the perchloric acid is evaporated to yield a lithium perchlorate fusion. We have now replaced this step with an evaporation at controlled temperature. We found that the fusion step occasionally resulted in the removal of so much perchloric acid that some of the plutonium was converted into a form not amenable to recovery by extraction into the scintillator containing di(2-ethylhexyl)phosphoric acid (i.e., the extractive scintillator). We suspect that the plutonium was being precipitated as an oxide or hydrous oxide since it is possible to precipitate iron oxide during the lithium perchlorate fusion. Results obtained over a period of a few months in our laboratory indicate that an experienced operator fails to recover 100% of the plutonium about one out of ten times in this step; the failure rate is somewhat higher for an inexperienced operator.

Our present procedure, which eliminates the difficulty associated with the fusion step, is as follows. The 0.3M tertiary amine nitrate solution is stripped with an equal volume of a solution that is 1.5M in lithium perchlorate and 0.325 - 0.350M in perchloric acid. In the stripping operation the amine nitrate is converted into perchlorate, releasing an equivalent amount of nitric acid to the aqueous phase. The strip solution is then heated by radiant heaters at a controlled temperature of 150 - 170° for 30 - 60 min to remove the nitric acid. While still warm, the concentrated product (about a quarter of the original volume) is diluted approximately 1:1 with a 2.5% w/v solution of sodium peroxysulphate. The final solution is approximately 3M in perchlorate and 0.05 - 0.10M in perchloric acid. Plutonium is extracted directly from this solution into the extractive scintillator. The organic scintillator sample prepared in this way has good pulse-height, pulse-shape, and energy resolution characteristics. Plutonium recovery by this procedure has routinely been 100%, within counting statistics. A similar procedure has been designed for obtaining plutonium and other alpha-emitting nuclides in a perchlorate medium for extraction into an extractive scintillator for gross alpha-counting in a beta liquid-scintillation counter, and a method of stripping from this scintillator and re-extracting into a scintillator for alpha spectroscopy has been developed. These procedures will be reported more fully in a forthcoming publication.

TALANTA MINI-REVIEW*

CHEMICAL PHASE-ANALYSIS OF ORES AND ROCKS

A REVIEW OF METHODS

H. F. STEGER

Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology,
Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 25 *March* 1975. *Accepted* 27 *March* 1975)

Summary—The methods employed in the chemical phase-analysis of rocks, ores and their treatment products are reviewed. An attempt has been made to be critical, selective and thorough in the choice of methods available in the literature, in order to provide a convenient manual for workers interested in this aspect of analytical chemistry.

Chemical phase-analysis (also called rational or practical analysis) is the determination, by a chemical dissolution technique, of the distribution of an element in an ore or rock on the basis of minerals or oxidation states. The goal of the analysis is the selective dissolution of one or more minerals present in the ore, but because no solvent is completely selective in its action, a quantitative separation is seldom achieved and it is necessary to correct the result to allow for the partial dissolution of other minerals. Because the reactivity of a mineral with a particular solvent varies from specimen to specimen, a truly constant correction is not possible and an error of 1–10% is considered to be acceptable.

The importance of chemical phase-analysis to the mining industry, *e.g.*, in process control, and to hydrometallurgists has ensured its being a valuable aspect of analytical chemistry. Chemical phase-analysis has enjoyed an appreciable increase in interest since 1960. Reviews, both comprehensive and partial, have appeared at irregular intervals in the literature of the Soviet Union[1–6] but unfortunately English translations are not available and access to the original is often difficult. The need for a review in English was apparent.

During the preparation of this manuscript, a book entitled "Chemical Phase Analysis" appeared in print.[7] Although there must of necessity be some duplication, the aim and contents of the present review and of the book are significantly different. This review considers only the phase-analysis of ores and rocks and is intended for publication in the open literature as a guide for analysts to the methods employed. The references given herein were selected on the following basis. Emphasis was placed on methods developed within the past 25 yr. Most older methods have since been modified (and are included in the modified form) or appear in standard analytical texts such as Low,[8] Hillebrand and Lundell,[9] and Maxwell.[10] References to Soviet journals which are not readily available to Western readers are omitted wherever subsequent publication of the method has occurred in a more widely circulated journal.

References in this review are made to the English edition of Soviet journals wherever possible. Recourse to the Russian edition was necessary where the English edition either does not exist for the complete series of a journal or was not reasonably accessible to the reviewer.

Finally it must be mentioned that information on procedures of chemical phase-analysis may be hidden away in the body of papers and is, therefore, effectively inaccessible because titles and references do not convey its existence. It is suggested, therefore, that future authors should strive to prevent the recurrence of this problem by deliberate mention of chemical phase-analysis either in the abstract or, preferably, in the title of their publication.

SUMMARY OF METHODS

Aluminium

The bauxite minerals, gibbsite $Al(OH)_3$, boehmite, $AlO(OH)$, and diaspore, $AlO(OH)$, can be determined on the basis of different rates of dissolution in potassium hydroxide solution or sulphuric acid under controlled conditions.[11,12] Sodium hydroxide solution and hydrochloric acid can be used if only the gibbsite component is determined.[13,14] Gibbsite, boehmite and diaspore can be separated by successive chlorinations with carbon tetrachloride vapour at 400, 500 and 600° respectively.[15] The $AlCl_3$ formed at each temperature is distilled and collected in ammonia

---

* For reprints of this Review see Publisher's announcement near end of this issue. TALMR2.

solution. The accuracy of the method is improved if the result for a mineral is corrected for the partial conversion of other minerals at a particular temperature.[16]

Aluminium phosphate minerals such as crandallite, millesite, *etc.*, are easily separated from kaolinite by dissolution in boiling hydrochloric acid (1 + 1).[17] Approximately 1% of the aluminium in kaolinite also dissolves.

Antimony

Antimony oxides and sulphides in ores can be separated by treatment with tartaric acid.[18] The sulphides are not attacked. A method for selectively determining Sb, Sb_2O_3, Sb_2S_3 and $Sb_2O_4 + Sb_2O_5$ in pyrometallurgical samples has been developed.[19] The method is subject to an error of 2–3%.

Beryllium

A method of determining certain beryllium minerals in beryllium ores and concentrates has been described.[20] Helvine, $3(Mn,Fe)O.3BeO.SiO_2.MnS$, and danalite, $3(Fe,Zn,Mn)O.3BeO.3SiO_2.(Fe,Zn)S$, are dissolved in 3% hydrochloric acid. However, 5–15% of the beryllium vesuvianite, $2(Mg,Mn,Zn)O.6CaO.4BeO.Al_2O_3.6SiO_2$, also dissolves. The residue is roasted at 700–800° and the remainder of the vesuvianite becomes soluble in hydrochloric acid (1 + 1). Beryl, $3BeO.Al_2O_3.6SiO_2$, and chrysoberyl, $BeO.Al_2O_3$, are determined in the final residue after fusion.

Bismuth

Bismuth oxide minerals can be extracted from ores by treatment with a 5% thiourea solution in 0·5N sulphuric acid[21] or a 3% phenylacetic acid solution in 0·4M hydrochloric acid.[22] Native bismuth in the residue is dissolved with 0·1M silver nitrate in 0·5–1·0M nitric acid. Bismuth sulphides are then decomposed with nitric acid or hydrofluoric acid–nitric acid mixture. An error of approximately 20% is obtained for individual bismuth components.

Calcium

Free CaO is extractable from $Ca_3(PO_4)_2$, CaF_2, $CaCO_3$, $CaSO_4$ or calcium silicate ores with an aqueous sucrose solution.[23,24] Calcite, $CaCO_3$, can be selectively dissolved in the presence of fluorite, CaF_2, by 5–10% acetic acid.[25,26] Approximately 0·3% of the fluorite also dissolves and, therefore, the appropriate correction should be made to the calcite result. This method is applicable to both fluorspars and complex sulphide ores.

Carbon

Carbonate and carbonaceous carbon in rocks and ores is readily determined. Carbonates are decomposed by heating with hydrochloric or phosphoric acid and the liberated carbon dioxide is absorbed in dilute barium hydroxide solution[27] or in a preweighed tube containing anhydrous magnesium perchlorate.[28] The residue may be treated with chromium trioxide in phosphoric acid to oxidize the carbonaceous carbon to carbon dioxide,[27] or the carbonaceous carbon may be assumed to be the difference between the total and carbonate carbon. The latter method becomes unsatisfactory when the sample contains much carbonate carbon and little carbonaceous material.[28]

Copper

Native copper, cuprite and tenorite. Cuprite, Cu_2O, can be selectively extracted from ores which contain native copper and tenorite, CuO, by dilute hydrochloric acid in ethanol plus stannous chloride,[29] or by a hot saturated potassium iodide solution.[30] The native copper is then dissolved with a solution of ferric chloride in 3M hydrochloric acid. Tenorite is given by the difference between the total copper and cuprite + native copper.

Cuprite can also be extracted with a 1% aqueous solution of unithiol, sodium 2,3-dimercaptopropane-1-sulphonate.[31] The residue is treated with a 1% solution of unithiol in 5% ammonium chloride to extract tenorite. The native copper is dissolved in nitric acid. The cuprite result must be corrected to take into account the solubility of tenorite and native copper, 5 and 8% respectively, in the 1% unithiol solution.

Copper sulphides and oxidation products. Oxidized copper minerals can be extracted from sulphide ores with a reagent consisting of 2 g of sodium sulphite and 1 g of phenylacetic acid in 20 ml of acetone and 100 ml 3% H_2SO_4.[32] Native copper in the residue is dissolved in 15% ammonium carbonate or bicarbonate solution. The copper sulphides may be dissolved in acid or analysed for mineral phases as in the next section.

Treatment of copper ores with a 1% unithiol solution dissolves azurite, $Cu_3(CO_3)_2(OH)_2$, malachite, $Cu_2(CO_3)(OH)_2$, and cuprite.[33] Chrysocolla, $Cu_2H_2Si_2O_5(OH)_4$, can be extracted from the residue with a 2% sodium sulphite solution in 3% sulphuric acid or extracted together with tenorite with a 1% solution of unithiol in 5% hydrochloric acid. Copper sulphides are unattacked. An error of 3–8%, depending on the copper content of the ore, is expected.

Malachite can be extracted from copper ores with a 10% sodium potassium tartrate solution in 10% sodium hydroxide solution in a nitrogen atmosphere.[34] The residue is treated with this reagent in an oxygen atmosphere to dissolve cuprite. The residue contains the copper sulphides.

Copper sulphides. The following methods apply to copper sulphide ores from which oxidized forms of the copper sulphides are either absent or have been previously extracted (*vide supra*). Successive treatment of the ore with 2% ferric sulphate in 5% sulphuric acid and a saturated silver sulphate solution in 5% acetic acid will dissolve bornite, Cu_5FeS_4, and chalcocite, Cu_2S.[34] The residue is treated with a 1:1 hydrochloric acid–nitric acid mixture to dissolve chalcopyrite, $CuFeS_2$.

Bornite, chalcocite and covellite, CuS, can also be extracted from ores with a 2–3% potassium cyanide solution[35,36] or with an acidic solution of thiourea.[37,38] Only 0·07% of the chalcopyrite dissolves. The analytical results are corrected to take into account either the incomplete dissolution of the mineral(s) being determined or partial dissolution of other minerals. The phase-analysis for malachite, chalcocite, covellite and chalcopyrite by the successive use of sulphuric acid, ferric sulphate in sulphuric acid and potassium cyanide has been critically assessed and errors arising from the partial selectivity of the solvents have been estimated.[39]

Chalcocite can be separated from bornite, covellite and chalcopyrite by a 5% solution of unithiol in 5% ammonia solution.[40] A correction for the slight solubility of the last three minerals must be made. An error of 3–9%, depending on mineralogical composition, is expected. Chalcocite can be determined in mixtures with bornite by dissolution in neutral silver nitrate solution.[41] This method, however, is only semiquantitative. A scheme has been devised whereby a copper ore may be analysed for chalcocite, covellite, bornite, chalcopyrite, stannite [Cu_2FeSnS_4], bournonite [$PbCuSbS_2$] and the tetrahedrite–tennantite group [$(Cu,Fe)_{12}(As,Sb)_4S_{13}$].[42]

Germanium

The germanium compounds that are present in coal-ash may be determined[43] if the sample is treated successively with 0·1*M* ammonia to dissolve GeO_2 (including that in solid solution with SiO_2), 0·3*M* EDTA to dissolve $CaGeO_3$ and $MgGeO_3$, 3*M* sodium hydroxide to dissolve aluminium germanates, and 1*M* oxalic acid to dissolve $Fe_6Ge_2O_{13}$. The final residue, which consists of silica and mullite, $3Al_2O_3 . GeO_2 . SiO_2$, is dissolved in nitric acid, hydrofluoric acid and phosphoric acid. The result for a particular germanium compound must be corrected to take into account the partial solubility of other germanium compounds in the solvent.

Indium

Indium compounds in metallurgical dusts can be determined as follows.[44] The dust is treated successively with water to extract $In_2(SO_4)_3$, a 3% bromine solution in methanol to dissolve In_2S_3 and 3*M* hydrochloric acid to dissolve In_2O_3. The components are determined with an error of approximately 3%.

Iron

Fe, FeO, Fe_2O_3 and Fe_3O_4 in reduced ores. Metallic iron can be selectively extracted from reduced iron ores with a solution of mercuric chloride in water[45] or alcohol,[46–48] by aqueous copper sulphate solution,[49–52] ammonium dithiocyanatoargentate[53] or lead chloride[54] or by bromine in alcohol.[55–58] The use of bromine in alcohol is superior to that of mercuric chloride or silver thiocyanate.[59] Further, the use of bromine in methanol is preferable to that in ethanol.[60]

Metallic iron can also be determined indirectly (*a*) by conversion into FeS and subsequent determination of H_2S on acid treatment[61] and (*b*) measurement of the hydrogen evolved by the dissolution of metallic iron in an acid.[62] The latter technique gives a metallic iron content with an error less than 3%.

To determine FeO and Fe_2O_3 in reduced iron ores, a sample from which metallic iron has been removed is dissolved in hydrochloric acid in an inert atmosphere.[46,56,57] The iron(II) in solution is determined either by titration with dichromate[46] or vanadate,[57] or spectrophotometrically.[56] The same solution is analysed for total iron, and iron(III) is obtained by difference. The error in determining each oxidation state is 1–2%.

Free FeO can be distinguished from Fe(II) in magnetite, Fe_3O_4.[48] Metallic and total FeO are extracted from the sample with a 6% ferric chloride solution. The metallic iron is readily determined (*vide supra*) to give total FeO. Another sample is treated successively with ethanolic stannous chloride and a 4% ferric chloride solution to dissolve Fe_2O_3 and metallic iron. The magnetite in the residue is collected magnetically and dissolved in hydrochloric acid in an inert atmosphere. The Fe(II) in the magnetite is determined as stated above. The error in these determinations is 1–5%.

Magnetite is selectively extracted from mixtures with hematite, Fe_2O_3, by 1% hydrochloric acid in phosphoric acid and an oxidant such as hydrogen peroxide or permanganate.[63,64] Approximately 1% of the hematite iron is also dissolved.

Ferrous and ferric iron in rocks and ores. For the determination of ferrous iron, the sample is decomposed with sulphuric–hydrofluoric acid mixture either with the exclusion of air and direct determination of ferrous iron[65–68] or in the presence of a known excess of ammonium vanadate,[69,70] potassium permanganate,[71,72] potassium dichromate[73] or silver perchlorate[74] and indirect determination of ferrous iron by back-titration of the oxidant. The sample decomposition in the presence of excess of ammonium vanadate was found to be very reliable.[75] For samples that dissolve in the acid mixture with great difficulty, fusion with sodium fluoroborate is recommended.[76,77] The use of platinum crucibles, however, yields low results for ferrous iron.[78] It should be noted that the determination of ferrous iron is subject to error in the presence of Ti(III), V(III), Mn(IV), sulphides and organic matter.

Ferric iron in rocks and ores is, in general, assumed to be the difference between the total and ferrous iron. Ferric iron in acid-soluble samples can, however, be determined directly.[79,80] After dissolution of the sample in hydrochloric acid (1 + 1) in an inert atmosphere, ferric iron is titrated with EDTA at pH 1·2–2·0. The error is 0·6–3% depending on the iron content and nature of the sample. The presence of Bi, Tl and large amounts of Cu interferes in the titration. Sulphides and higher oxides of Mn and V interfere during decomposition.

Iron oxides in iron sulphide ores. Hydrogen will easily reduce iron in iron oxides, silicates and other oxygen-bearing minerals to metallic iron but it will only slightly attack pyrite.[81] The metallic iron may then be removed by aqueous copper sulphate solution. Magnetite is easily separated from chalcopyrite with phosphoric acid.[82] Pyrrhotite can be extracted from mixtures with FeO and Fe_2O_3 by bromine in alcohol.[83]

Iron sulphide ores. Pyrrhotite can be determined in the presence of pyrite by dissolution in 4% stannous chloride solution in 6*M* hydrochloric acid.[84] The inertness of pyrite to this reagent is variable, however, and appreciable errors can arise.[85] Pyrrhotite, chalcopyrite and bornite can be extracted from ores with bromine in methanol.[86] Pyrite in the residue is dissolved by hydrogen peroxide in methanol. An error of approximately 2% is obtained.

Lead

A method for the determination of lead minerals in ores has been developed.[87,88] The sample is treated with 25% sodium chloride solution to dissolve anglesite, $PbSO_4$, and then with 15% ammonium acetate solution in 3% acetic acid to dissolve cerussite, $PbCO_3$. Successive treatment of the residue with 2% sodium hydroxide solution and ammonium acetate solution extracts the combined lead of crocoite, $PbCrO_4$, and wulfenite, $PbMoO_4$. Mimetite, $Pb_5(AsO_4)_3Cl$, pyromorphite, $Pb_5(PO_4)_3Cl$, and vanadinite, $Pb_5(VO_4)_3Cl$, are then extracted with a 25% solution of sodium chloride in 0·5% hydrochloric acid [containing approximately 5 mg of mercury(II) per litre to inhibit the dissolution of galena].[88] The galena, PbS, in the residue may be dissolved either with a 25% solution of sodium chloride in 6% ferric chloride solution or with hydrogen peroxide.[88] The final residue contains beaverite, $Pb(Cu,Fe,Al)_3(SO_4)_2(OH)_6$, beudantite, $PbFe_3(AsO_4)(SO_4)(OH)_6$, and plumbojarosite, $PbFe_6(SO_4)_4(OH)_{12}$ and is dissolved in hydrochloric acid (1 + 3).

The determination of cerussite by 15% ammonium acetate in 3% acetic acid gives high results for ores containing galena, pyrite and organic matter.[89] The addition of ascorbic acid will suppress the oxidation and dissolution of galena.

Galena may be determined in mixtures with betekhinite, $Cu_{10}(Fe,Pb)S_6$, by dissolution with 4% hydrogen peroxide in 4*M* ammonium acetate in 5% acetic acid.[90] Because of the slight dissolution of betekhinite in this reagent, the determination is subject to an error of 1–4%.

Manganese

Manganese carbonate minerals can be selectively dissolved in the presence of manganite, MnO_2, by 6*N* ammonium sulphate acidified with sulphuric acid to pH 2.[91] Manganite in the residue is dissolved with a 2% solution of sulphosalicylic acid in 0·1–1·0*N* sulphuric acid.

The treatment of carbonate–oxide ores with 1% acetic acid completely dissolves manganocalcite, $(Mn,Ca)CO_3$, and 7–8% of rhodochrosite, $MnCO_3$, and oligonite, $(Fe,Mn)CO_3$.[92] The complete dissolution of rhodochrosite and oligonite is accomplished with 8% sulphuric acid. Manganese oxides are separated from manganese silicates in the residue, with 15% hydrochloric acid. The results for manganocalcite, rhodochrosite and oligonite must be adjusted to take into account the 7–8% solubility of the last two in 1% acetic acid.

Mercury

Mercury compounds in pyro- and hydrometallurgical products may be determined semiquantitatively.[93] Leaching of the sample with 5% nitric acid selectively dissolves HgO. Metallic mercury in the residue is extracted with nitric acid (2 + 1). HgS in the residue is then dissolved in a 5% sodium hydroxide–5% sodium sulphide solution. The compounds may be determined with an error of less than 20%.

Molybdenum

Molybdenum oxide, MoO_3, can be extracted from roasted molybdenite ore with 20–50% ammonia solution.[94,95] The molybdenite, MoS_2, in the residue is then roasted to MoO_3 and determined as above or is assumed to be given by the difference between total Mo and the MoO_3.[94]

The partial roasting of MoS_2 at 450–550° gives a product which contains Mo(IV) and Mo(VI) as well as sulphide and sulphate.[96] Mo(VI) compounds, MoO_3 and MoO_2SO_4, are dissolved in boiling 20% sodium hydroxide solution. Mo(IV) can be determined in the residue. Sulphate is extracted from the roasted MoS_2 on heating with 15% hydrochloric acid. Sulphide in the residue is determined by oxidation to sulphate.

Nickel, cobalt

Chondritic meteorites (and lateritic nickel ores) can be analysed for the metallic, sulphide and silicate phases of nickel and cobalt.[97] Metallic nickel and cobalt are dissolved in a 12% solution of mercuric chloride in 6% ammonium chloride solution, in an inert atmosphere. The sulphides are extracted from the residue with 2% bromine in methanol. The silicates are decomposed with hydrofluoric acid. The error in the determination is approximately 1%.

Ascorbic acid–hydrogen peroxide selectively dissolves Ni, Co and Cu sulphide minerals in rocks.[98] A total and sulphide-phase metal determination permits the calculation of the distribution of metal(s) over the mineral phases in the rock.

Silicon (*quartz in silicates*)

Quartz in silicates may be determined as follows.[99] The sample is roasted at 600–650° and treated with a 1:3 mixture of nitric and hydrochloric acids to dissolve oxide minerals. The residue is heated to 250–275° with freshly prepared pyrophosphoric acid to dissolve the silicates. The quartz is then dissolved with hydrofluoric–sulphuric acid mixture. An error of 0·5% is claimed.

Quartz may also be determined in rocks by pyrosulphate fusion followed by fluorosilicic acid treatment.[100] The latter must be repeated if much feldspar is present in the sample. A decrease in the recovery of quartz with each dissolution stage must be taken into account in calculating the result for quartz. Both pyrophyllite, $Al_2Si_4O_{10}(OH)_2$ and zircon, $ZrSiO_4$, offer significant resistance to this procedure.

Sulphur

Elemental sulphur in ores and minerals. Karchmer[101] has reviewed several methods for the determination of elemental sulphur. In addition, spectrophotometric[102,103] and chromatographic[104,105] methods are available. In the spectrophotometric method, the elemental sulphur is extracted from the sample with a solvent such as carbon disulphide or acetone and the absorbance due to sulphur is measured at the appropriate wavelength. The presence of other sulphur compounds may interfere. Also sulphur, if present in the amorphous form, may be incompletely dissolved.[101]

After extraction from the sample with acetone, elemental sulphur is determined by thin-layer chromatography.[105] A carbon disulphide extract of the sample may be analysed for both elemental and xanthate sulphur.[104] Total sulphur in the extract (in a fixed volume of carbon disulphide) is determined by oxidation of all sulphur compounds to sulphur dioxide. Xanthate sulphur is determined in a second portion of extract by thermal decomposition of all combined-sulphur compounds. All measurements are by gas chromatography. Elemental sulphur is the difference between total and xanthate sulphur.

Sulphide. Sulphide in the presence of sulphate is usually determined by evolution of hydrogen sulphide on treatment of the sample with acid.[82,106] Sulphate may then be determined directly as barium sulphate or as the difference between total and sulphide sulphur. Sulphide may also be determined by pyrolysis of the sample, mixed with reduced copper, at 700° in a stream of nitrogen.[107] Oxidized forms of sulphur are converted into sulphur dioxide, which is collected. Sulphide forms CuS which, of course, gives hydrogen sulphide on addition of acid.

Pyrrhotite sulphur can be determined in the presence of pyrite sulphur by its evolution as hydrogen sulphide by a 4% stannous chloride solution in hydrochloric acid (1 + 1).[84] This reagent may, however, also partially decompose pyrite and it is recommended that a solution of hydrazine in 4*N* sulphuric acid be used instead.[85]

Tantalum, niobium

A mixture of hydrofluoric and hydrochloric acids, used at slightly elevated pressure, decomposes pyrochlore, $(Na,Ca)_2(Ta,Nb)_2O_6(OH,F)$, and microlite, $(Na,Ca)_2(Ta,Nb)_2O_6(O,OH,F)$, but only slightly attacks simpsonite, $Al_4(Ta,Nb)_3(O,OH,F)_{14}$.[108] Hydrofluoric acid (4*M*) dissolves 98% of microlite but only 7–15% of columbite–tantalite.[109] Correction for the degree of dissolution of these minerals in this reagent permits the determination of the distribution of Ta_2O_5 and Nb_2O_5 in microlite and columbite–tantalite, $(Fe,Mn)(Ta,Nb)_2O_6$, with an error of 2–6%.

Tin

A method has been developed for differentiating and determining free cassiterite, SnO_2, cassiterite occluded in the silicate lattice and silicate-bound tin in rocks.[110] The sample is decomposed with a 2:1 hydrofluoric–hydrochloric acid mixture and subsequently heated with ammonium iodide to give total tin. Lattice-bound tin is determined by decomposition with the same acid mixture and subsequent heating with hydriodic acid to dissolve the freshly formed tin oxide. The rock is heated with ammonium iodide to determine the free cassiterite. The difference between total and free cassiterite and lattice-bound tin is the occluded cassiterite. An error of 5–20%, depending on tin content, is obtained.

Stannite, Cu_2FeSnS_4, may be selectively decomposed in the presence of cassiterite with concentrated nitric acid,[111] bromine in ethanol or carbon tetrachloride[112] or sodium nitrate in glacial acetic acid.[113] The cassiterite may be determined directly in the residue or by difference between total and stannite tin. The error in the determination is 1–2%.

Titanium

Ilmenite, $FeTiO_3$, titanomagnetite, $(Fe,Ti)_3O_4$ and sphene $CaTiSO_5$, may be extracted from mixtures with rutile, TiO_2, with a 2% solution of sodium fluoride in 8 *M* hydrochloric acid.[114] Because 1–2% of the rutile also dissolves, the results for these minerals must be corrected accordingly. Sphene can be determined in the presence of ilmenite and titanomagnetite. The sample is reduced in a stream of hydrogen at 880° and then treated with 1*M* hydrochloric acid to dissolve iron oxides. Subsequent treatment with a 1·5% solution of sodium fluoride in 8*M* hydrochloric acid dissolves sphene, leaving ilmenite and titanomagnetite in the residue. Rutile, if present, also remains in the residue but may be determined as above. The error in these determinations is 1–10%, depending on the mineral and its content in the ore.

Tungsten

Members of the wolframite group, ferberite, $FeWO_4$, and huebnerite, $MnWO_4$, can be determined in scheelite.[115] The sample is first roasted at 400° to oxidize all ferrous minerals soluble in hydrochloric acid, other than wolframite, to their ferric counterparts, and is then completely dissolved in concentrated hydrochloric acid, in an inert atmosphere. Ferrous iron in the solution represents ferberite. Also, experimental studies[115] indicate that huebnerite is the only manganese mineral of appreciable amount in scheelite and, therefore, the determination of manganese will yield the huebnerite content of the scheelite.

Uranium

The ratio of U(IV) to U(VI) in rocks and ores can be evaluated.[116,117] The sample is decomposed with a non-oxidizing acid in an inert atmosphere. U(IV) is precipitated with cupferron, Ti(IV) being used as carrier, and is determined by fluorimetry.[118] Otherwise, U(VI) is separated from U(IV) by extraction as an anionic phosphate complex with a 5% solution of tri-n-octylamine in benzene[116] or xylene.[117] A total uranium determination gives by difference the amount of the oxidation state of uranium not determined directly. The error in the determination is 2–3%.

Zinc

Oxidized zinc minerals such as smithsonite, $ZnCO_3$, willemite, Zn_2SiO_4 and hemimorphite, $Zn_4Si_2O_7(OH)_2 . H_2O$, are easily separated from sphalerite, ZnS, by dissolution in boiling 5% acetic acid.[119] The result must be corrected for the 5–10% of ZnS which also dissolves. The error in this determination is 10–15% for the oxidized minerals and 2–5% for ZnS. ZnS is easily determined in the presence of zinc spinel by dissolution in acidic hydrogen peroxide.[120] The error in the determination is approximately 3%.

AN AUTOMATED SUBMICROGRAM DETERMINATION OF SELENIUM IN VEGETATION BY QUARTZ-TUBE FURNACE ATOMIC-ABSORPTION SPECTROPHOTOMETRY

P. N. VIJAN and G. R. WOOD

Air Quality Laboratory, Ministry of the Environment (Ontario), Toronto, Ontario, Canada

(*Received* 24 *March* 1975. *Accepted* 19 *April* 1975)

Summary—An automated method for the determination of submicrogram amounts of selenium in vegetation is described. A weighed sample of vegetation is digested with a 4:1 nitric–perchloric acid mixture, and made up to a known volume. The digested sample is placed in a Technicon sampler and reacted with sodium borohydride solution. The selenium converted into the gaseous hydride is swept by an argon stream into a gas–liquid separator. The mixed gas stream is passed through a heated quartz cell, positioned in the light-path of an atomic-absorption spectrophotometer. The absorption by the atomized selenium is recorded. The method is capable of analysing 50 samples a day by the use of a calibration curve or 25 a day by the standard addition technique. A relative standard deviation of better than 10% and a detection limit of 0·025 μg/g were obtained.

There is a need for a simple, precise and fast method for determining selenium in biological materials for pollution monitoring and surveillance. The most commonly used and recommended method for trace levels of selenium is based on the formation of the piazselenol complex with diaminonaphthalene and its subsequent extraction into a non-polar solvent such as hexane. The fluorescence of the extract is measured at a specific wavelength.[1,2] The method involves time-consuming procedures such as distillation with bromine before the complexation, or coprecipitation with arsenic.[3] It demands more than average analytical skills to obtain accurate results and is not ideally suited for high-volume routine work.

The application of flame atomic-absorption techniques to selenium determination has been reported.[4] The sensitivities of the various flame methods are not sufficient to measure selenium levels much below 1 ppm. Improved sensitivities have been achieved by directing the flame into long tubes held in the path of the hollow-cathode light-beam,[3] but the stability of the signals deteriorates and offsets the advantage.

Dagnall *et al.*[5] measured the atomic fluorescence of selenium and obtained a limit of detection of 0·1 μg/ml.

Better sensitivities were achieved by the carbon-rod atomization technique designed around the principle of the graphite furnace described by L'vov,[6] Massmann,[7] and West.[8] Baird *et al.*[9] have determined selenium in different matrices by this technique. The technique is not very precise and is subject to matrix interferences that are difficult to control.

The ability of selenium and a few other elements of groups IVA, VA and VIA of the periodic table to form volatile hydrides, has been used recently for their separation and measurement by atomic-absorption spectrophotometry.[10–12] The subject has been recently discussed in a paper on the determination of arsenic in air particulate matter.[13] The present method uses a similar approach for the determination of selenium in vegetation samples.

EXPERIMENTAL

Reagents

Sodium borohydride (Fisher Scientific Company, 98% pure) solution, 1% w/v in distilled water; perchloric acid, 70%; nitric acid, conc.; hydrochloric acid, conc. All the acids used were analytical-reagent grade. A 4:1 mixture of nitric and perchloric acids was used for sample decomposition.

A 1000-ppm stock solution of selenium was prepared by dissolving 1 g of selenium (analytical-reagent grade) in a minimum quantity of hot nitric acid and diluting to 1 litre with distilled water.

Apparatus

Aluminium metal blocks, 26 × 11 × 4 cm, drilled with 40 holes (3 cm deep) to accommodate 18 × 150 mm test-tubes, were used as test-tube holders as well as a uniform means of heating for sample decomposition.

The sampler, with a 40-sample capacity, and the proportioning pump used were obtained from Technicon Corporation. Other components used were a gas–liquid separator, a 0–2 l./min flowmeter in the argon line and appropriate tubings, connectors and mixing coils to build the proportioning pump manifold. The complete system is illustrated in Fig. 1.

A Varian Techtron model AA5 atomic-absorption spectrophotometer equipped with an ASL selenium hollow-cathode lamp and a (W & W Electronics, Switzerland) linear–log integrating recorder was used. The recorder range was set at 2 mV full-scale deflection. The quartz tube was 10 cm long and 10 mm in internal diameter with a 17-cm long and 4-mm bore inlet tube fused at the mid-point. The quartz tube had hooks, 0·5 cm from each end, to serve as anchors for the heating wire. It was wound with approximately 2 m of No. 75 chromel-C heating wire

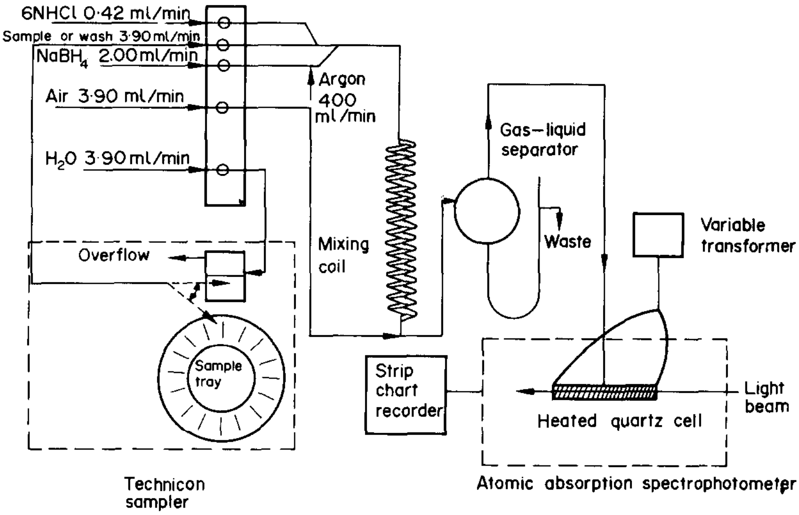

Fig. 1. Diagram of autoanalysis system for selenium determination.

(resistance 3·48 Ω/m) and insulated by wrapping with asbestos tape and a layer of asbestos cord. Insulated terminals were provided for the power supply. The finished cell was mounted on the burner head of the spectrophotometer and secured by metal clips. This allowed the use of burner alignment controls to position the quartz cell in the optical path. The temperature of the heated cell was controlled by means of a 0–140 V variable transformer.

Procedure

Exactly 0·200-g portions of vegetation samples previously dried at 80° and ground to 40-mesh were weighed in duplicate into 18 × 150 mm borosilicate glass test-tubes calibrated at the 10-ml mark and placed in the aluminium block. Then 0·100 ml of 1·00-ppm selenium standard solution was dispensed into one tube of each pair from a 2-ml microburette or with an Eppendorf pipette, and 4 ml of nitric–perchloric acid mixture were added to each test-tube. The aluminium block containing 40 test-tubes was heated at 125° surface temperature until the organic matter was completely oxidized or, preferably, overnight. Distilled water was then added to the test-tubes to bring the volume to within 1 ml of the calibration mark. The contents of the test-tubes were allowed to cool to room temperature and the volumes were brought to the 10-ml mark with distilled water. The test-tubes were sealed with "parafilm" and the contents were thoroughly mixed. Blanks and standards were incorporated in the batch and taken through the entire decomposition procedure.

The solutions were poured into sample-cups held in the sampler tray. The instrumental parameters were optimized and are shown in Tables 1 and 2. The entire system, except the sampler, was turned on and allowed to equilibrate, with the reagents being pumped, the argon flow adjusted to optimum, and the sampling probe taking up distilled water from the wash-well. The recorder pen was set at the base-line and the sampler was then switched on for unattended operation.

Table 1. Atomic-absorption spectrophotometer settings (Techtron model AA-5)

Wavelength	196·0 nm
Slit	300 μm
Lamp current	10 mA
Mode	absorbance
Scale expand	no expansion
Damping	4 (maximum)
Exhaust vent	closed
Recorder sensitivity	2 mV full-scale deflection
Recorder chart speed	5 mm/min

The zero-selenium vegetation sample was prepared by taking a low selenium sample through the prescribed digestion procedure with added amounts of bromine and hydrobromic acid to volatilize any selenium. The halides were fumed off and the digested material was treated like a normally decomposed sample.

The concentration of selenium in the samples was calculated by using the following expression:

$$\mathrm{Se}(\mu g/g) = \frac{cb}{(a-b)W}$$

where a = peak height due to sample + added selenium
b = peak height due to sample only
c = the amount of added Se (μg)
W = weight of the sample (g)

RESULTS AND DISCUSSION

Effect of acid matrix on selenium signal

The absorbance of a 10-ppb (parts per billion) selenium standard in various acid matrices was determined to ascertain their suitability for hydride generation and to select the acid concentration for optimum performance. Table 3 contains the results of this

Table 2. Technicon system

Sampler	
Sample tray	40-position

study. Hydrochloric acid seems to be the best for the purpose. Figure 2 shows that 6*M* is about the optimum concentration. However, it was the least suitable acid for sample decomposition. Various acid mixtures were tried for sample decomposition. Halogen acids had to be excluded from this operation because of the volatility of selenium in such media. The choice was narrowed down to the use of sulphuric–nitric or perchloric–nitric acid mixtures. After preliminary experimentation, it was decided to use a 4:1 mixture of perchloric and nitric acids for the digestion of vegetation because it gave relatively complete digestion of organics at reasonably low temperature. A stream of 6*M* hydrochloric acid was introduced into the system just before the confluence of sample and the sodium borohydride streams to provide a suitable medium for proper hydride generation.

Effect of sodium borohydride concentration on selenium signal

Figure 3 shows that 0·5% w/v sodium borohydride concentration is the optimum, but a 1% solution was used in this work because sodium borohydride in solution undergoes gradual breakdown with time. The potency of a 1% solution was adequate after 4–5 days of storage under refrigeration. One pellet of sodium hydroxide added for each 100 ml of sodium borohydride solution slowed down the rate of decomposition.

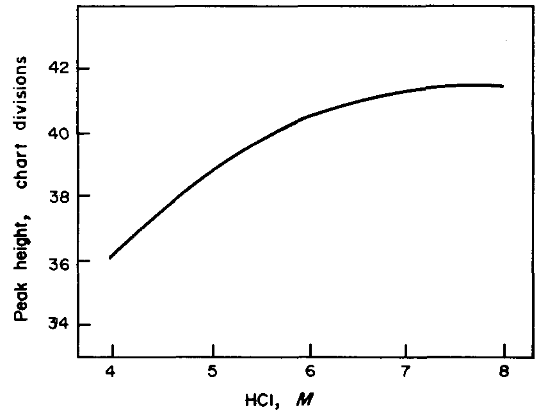

Fig. 2. Effect of HCl concentration on sensitivity (10-ppb Se standard).

Effect of argon flow and cell temperature

The argon flow-rate adjustment is very critical in this method. Too low a flow yields good sensitivity but noisy signals while too high a flow-rate considerably reduces the sensitivity. The temperature of the quartz cell is also important as too high a temperature causes loss of sensitivity. This is apparent from Figs. 4 and 5. The argon flow-rate chosen as best

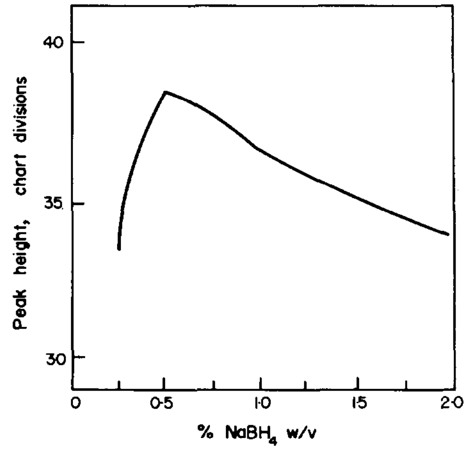

Fig. 3. Effect of $NaBH_4$ concentration on sensitivity (10-ppb Se standard).

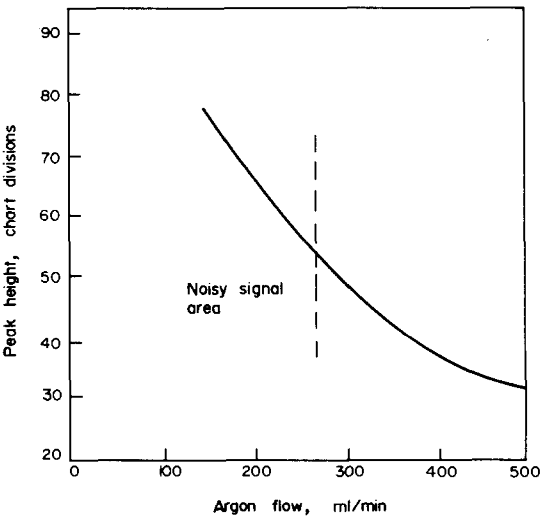

Fig. 4. Effect of argon flow-rate on sensitivity (10-ppb Se standard).

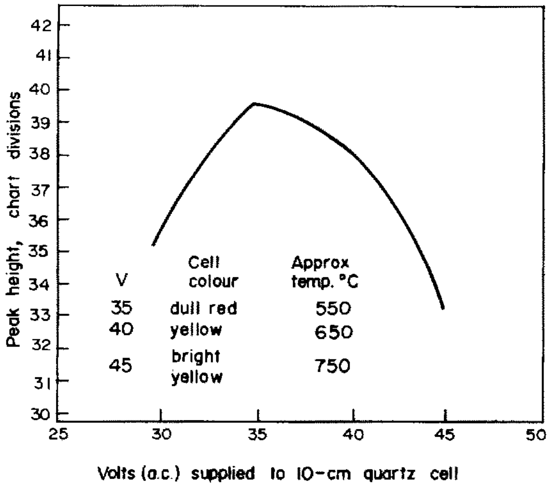

Fig. 5. Effect of quartz cell temperature on sensitivity (10-ppb Se standard).

compromise between signal and noise was around 400 ml/min. The optimum temperature range was 570 ± 20°, controlled by means of a variable transformer.

Effect of quartz-cell size on selenium signal

Three other cells were tried besides the one used in this work. Two open-ended cells 16 and 28 cm in length, constructed in the same way as the 10-cm cell, were investigated. A 16-cm cell with end-windows of quartz and having an inlet and an outlet tube adjacent to the ends, was also studied. All were operated at the specified temperature (570 ± 20°). It was expected that the 28-cm cell would give rise to the highest peak, but the 10-cm cell generated a signal which was 25% higher than that from either the 16-cm or the 28-cm cell under similar conditions of operation. The latter two gave about the same peak heights. The 16-cm cell with quartz windows generated a negligible peak which was lower by an order of magnitude than that obtained with the 10-cm cell. These observations suggest that the effective path-length is perhaps determined by the burning hydrogen slug inside the cell rather than by the length of the cell. The entrained air–hydrogen flame is visible at the two ends of the open cells. The addition of an air-line to the manifold is necessary and improves the signal strength considerably. The cell with quartz windows does not show any burning hydrogen slug inside the cell, which is probably the cause of the weaker signal. The removal of the air-line reduces the signal by approximately 50%.

Table 4. Effect of interfering elements on selenium determination

Element added, *ppm*	Recovery, %
K 20	107

Sb 2	78
Sb 20	49

Indicated element was added to a 20-ppb selenium solution in $HClO_4$-HNO_3. A 20-ppb Se solution was run alongside as the reference standard.

Effect of the oxidation state on selenium signal

The absorbance signals of 5, 10 and 20 ppb Se(IV) and Se(VI) standards were recorded under similar experimental conditions. Se(VI) was prepared from Se(IV) by oxidation with potassium permanganate. The Se(VI) absorbance signals were approximately 66% lower than the corresponding Se(IV) signals.

Vegetation samples spiked with 100 ng of Se(IV) and Se(VI) were taken through the digestion procedure and the absorbance signals were recorded. Six replicate measurements gave the ratio of signal peak-

heights due to the added amounts of Se(IV) and Se(VI) of 1·2:1, suggesting that the vegetation matrix caused some conversion of Se(VI) into Se(IV). However, selenium is known to occur in its most common oxidation state (*i.e.*, +IV) in its organo-complexes.

Interferences

Some of the interfering elements likely to occur in decomposed vegetation, and their effect on selenium determination are given in Table 4. Copper happens to be the worst interferent, causing strong signal depression at the 2-ppm level. This concentration corresponds to 100 ppm of copper in the solid sample. Levels higher than this are unlikely to occur in normal vegetation samples. Up to a 10-fold amount of copper and other metals in solution may be compensated for by the addition technique, as evidenced by the results in Table 5.

Attempts were made to eliminate interfering metals by an on-line ion-exchange technique, but the results were not very encouraging. Dowex 50W, a strong acid cation-exchange resin, was used to cope with the relatively high acidity of the sample stream, but without much success. Separation of selenium by co-precipitation and distillation was found to be cumbersome and time-consuming.

All results were obtained without background correction because when a hydrogen lamp was used there was no absorption at 196 nm. Standard solutions were run with and without digestion, to study loss of selenium during decomposition. No significant losses were observed.

Zero-selenium vegetation samples were run to confirm the absence of background interference.

Precision and accuracy

The standard curve was linear up to 30 ppb. The range may be extended by using different sample aliquots or adequate dilution. Undigested and digested standards gave signal peaks of equal height, suggesting that there is no loss of selenium due to volatility.

The 5, 10 and 15 ppb selenium peaks were high enough for a 0·5 ppb level to be easily measured, giving a peak of two chart divisions above the baseline noise. This corresponds to a selenium level of 0·025 μg/g in a vegetation sample, based on a 0·2-g sample in 10 ml of solution. The difference in peak-heights for samples with and without addition of selenium (10 ppb) was the same as the peak height for the digested 10–ppb standards. Thus in the majority of cases, there is no evidence of interference due to matrix background. Problems could arise, however, with vegetation samples contaminated with interfering metals such as copper, nickel, *etc.* Table 5 clearly illustrates this point and at the same time demonstrates the value of the standard addition technique in compensating for these interferences.

The relative standard deviation (R.S.D.) by the standard addition technique shown in Table 5 is 9·8% which is quite satisfactory. Triplicate analyses of 52 different vegetation samples by the standard addition technique, run in batches of seven a day, gave an overall S.D. of 0·025 μg/g, calculated as the square root of the mean variance. The highest and the lowest

Table 7. Comparison of the automated method results with those of fluorimetric and neutron-activation methods

	Se, *ppm*		
Sample No.	Present method	N.A.	Fluorimetric
5524W	0·11	0·14 ± 0·03	0·10
5537W	0·47	0·41 ± 0·08	0·40
5580W	0·15	0·14 ± 0·03	0·15
5713W	0·15	0·13 ± 0·03	0·14
5740W	0·06	0·07 ± 0·02	0·05
5956W	0·11	0·12 ± 0·03	0·10
5963W	0·42	—	0·47
5974W	0·67	0·56 ± 0·09	0·56

mean Se values were 0·673 and 0·027 μg/g. Individual relative standard deviations ranged from 0 to 28%, but showed no correlation with the selenium content. The analyses of NBS Orchard Leaves standard gave results in good agreement with the certified value. Table 6 contains information which supplements these findings and also suggests that within-run precision is better than day-to-day precision. The use of an electrodeless discharge lamp and R106 photomultiplier tube instead of R213 may considerably increase the signal-to-noise ratio.

Table 7 shows a satisfactory overall agreement between results obtained by this method and those obtained by neutron activation and fluorimetry. These samples were selected for this study because the neutron activation data were already available. The fluorimetric method used was a modification of the AOAC[14] procedure using diaminonaphthalene complexation. The results for a further 18 samples showed equally good agreement between the fluorimetric and atomic-absorption results.

Results were calculated from both peak-height measurement and integration of the area under the peaks. No significant differences were found. The peak-height method was used for convenience. The readability of peak heights is poor at low selenium levels and in these cases area-integration might give slightly better results.

Conclusions

The method described is faster than the conventional procedures, suitable for handling a large volume of samples, and sufficiently sensitive and accurate for determination of submicrogram quantities of selenium in vegetation and possibly other types of matrices. A single-point standard-addition compensates for interferences, although most uncontaminated samples can be analysed twice as fast by the use of a calibration curve. The argon flow-rate is critical within narrow limits. The high signal-to-noise ratio obtained allows further amplification of the signal should lower detection limits be desired. The method can be performed on a semiautomatic basis by manual presentation of the sample solution to the system.

Acknowledgement—The authors thank Mr. David Sturgis for assisting in the experimental work.

ANWENDBARKEIT DER FLAMMENLOSEN ATOMABSORPTION IN DER MESSENDEN KOMPLEXCHEMIE—II*

ÜBER LÖSLICHKEIT, STABILITÄT UND VERTEILUNG DES Cd-OXINATES

B. MAGYAR und P. WECHSLER
Laboratorium für Anorganische Chemie, Eidg. Techn. Hochschule, Zürich, Schweiz

(*Eingegangen am* 28. *Januar* 1975. *Angenommen am* 10. *Juni* 1975)

Zusammenfassung—Die Atomabsorption in einer Graphitrohrküvette wurde zur Bestimmung der Löslichkeit des Cadmiumoxinates bei verschiedenen freien Oxinatkonzentrationen [L] verwendet. Die Löslichkeitskurve $\log[\mathrm{Cd}]_t$, pL kann mit den Bildungskonstanten β_1, β_2, β_3 und dem Löslichkeitsprodukt K_{s0}, deren Logarithmen der Reihe nach 7,34, 13,44, 17,96 und −21,39 (μ = 0,1, Tetramethylammoniumnitrat, 25°) betragen, beschrieben werden. In mit Wasser gesättigtem Chloroform tritt neben dem $\mathrm{CdL_2(H_2O)_2}$ bei höheren Oxinkonzentrationen ($[\mathrm{HL}]_0 > 5\cdot 10^{-2}M$) $\mathrm{CdL_2(HL)_2}$ auf. Die Logarithmen der Sättigungskonzentration $[\mathrm{CdL_2(H_2O)_2}]_{o,s}$ bzw. der Adduktbildungskonstante β_A^o in der organischen Phase betragen −6,88 bzw. 3,33. Die Rolle des Dihydrates bei der Extraktion von Cd(II) wird diskutiert.

Die Anwendbarkeit der flammenlosen Atomabsorption zum Studium des Extraktionsgleichgewichtes von Cu(II)-Oxinat in Anwesenheit von 0,1*M* Tetramethylammoniumnitrat wurde kürzlich bewiesen.[1] Da atomabsorptiometrisch wie auch radiochemisch die totale Metallkonzentration $[\mathrm{M}]_t$ erhalten wird, muß zur Ermittlung von Stabilitätskonstanten schwerlöslicher Komplexe ein Zweiphasen-System untersucht werden. Prinzipiell hat man zwei Möglichkeiten: entweder die Ermittlung des Verteilungsverhältnisses $q = [\mathrm{M}]_{t,o}/[\mathrm{M}]_t$ (o: organische Phase) zwischen zwei flüssigen Phasen, in Abhängigkeit der freien Ligandkonzentration [L], oder die Bestimmung der Löslichkeit bei verschiedenen [L]-Werten. Die Auswertung der beiden Kurven $\log q$, pL bzw. $\log[\mathrm{M}]_t$, pL liefert dann die Gleichgewichtskonstanten. Extraktionsmessungen haben den Vorteil, daß sich im allgemeinen ein konstanter *q*-Wert schnell einstellt. Schwierigkeiten treten aber dann auf, wenn sich während der Verteilung des Metalls eine in beiden Phasen schwerlösliche Verbindung bildet. Das war der Fall in dem hier untersuchten System. Wenn Cd(II) mit Oxin extrahiert wird, bildet sich an der Phasengrenze ein Niederschlag[2] von $\mathrm{CdL_2\cdot 2H_2O}$. Wasserfreies $\mathrm{CdL_2}$ löst sich in Chloroform, welches Oxin enthält und an Wasser gesättigt ist. Die Lösung ist aber nicht stabil und es bildet sich fortwährend $\mathrm{CdL_2\cdot 2H_2O}$.

Abbildung 1 zeigt die zeitliche Abnahme der Konzentration des gelösten Cadmiums bezogen auf die Anfangskonzentration. Die Letztere sinkt innerhalb von 2 bis 3 Stunden auf *ca.* die Hälfte, wobei die Abnahmegeschwindigkeit in erster Linie von der Oxinkonzentration abhängt. 10^{-4}M $\mathrm{CdL_2}$-Lösungen sind über längere Zeit nur bei sehr hohen Oxinkonzentrationen ($[\mathrm{HL}]_0 > 0{,}5M$) haltbar. Die Anwendung von so stark konzentrierten HL-Lösungen bei Gleichgewichtsstudien ist jedoch ungünstig. Man muß nämlich annehmen, daß die Aktivität des Oxins mit seiner Konzentration nicht mehr übereinstimmt. Wie die Abb. 1 zeigt, bildet sich die feste Phase relativ langsam. Bei den Extraktions-bzw. Rückextraktionsversuchen kann sich daher ein partielles Gleichgewicht zwischen den beiden flüssigen Phasen einstellen, sodaß nach einigen Minuten ein konstantes *q* beobachtet wird. Mit einer 0,1*M* Oxinlösung konnte man[3] sogar bei einer Extraktionsdauer von einigen Minuten, Extraktionsausbeuten von 100% erzielen.

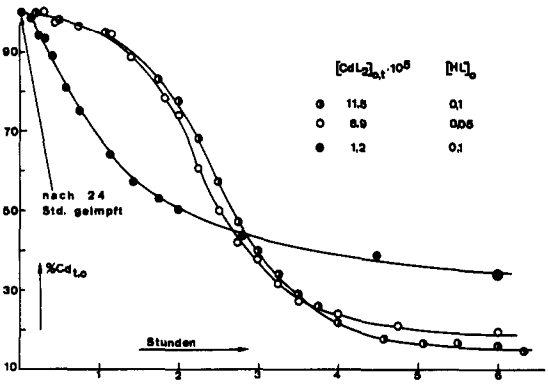

Abb. 1. Zeitliche Abnahme der Cadmiumkonzentration in Lösungen des entwässerten Cd-Oxinates in oxinhaltigem Chloroform.

---

* Part I—*Talanta*, 1974, **21**, 539.

Nach unserer Ansicht ist es jedoch thermodynamisch sinnvoller, die Gleichgewichtsversuche ausgehend aus der stabilsten Verbindung $CdL_2 \cdot 2H_2O$ durchzuführen. Mit dieser schwerlöslichen Verbindung können aber nur Löslichkeitsuntersuchungen angestellt werden, d.h. es muß die zweite der oben genannten Möglichkeiten realisiert werden.

Löslichkeitsbestimmungen zwecks Bestimmung von Stabilitätskonstanten wurden bereits an einer ähnlichen Verbindung ($ZnL_2 \cdot 2H_2O$) radiochemisch[4] durchgeführt. Nach unserer Kenntnis wurden die Bruttostabilitätskonstanten β_2 und β_3 von Cd–Oxinat in rein wäßrigem Medium bisher noch nicht bestimmt. In der Datensammlung[5] "Stability Constants" wird für log β_2 ein geschätzter Wert[6] von (2 log $\beta_1 - 1$) angegeben. Bisher wurden auch die Löslichkeit des $CdL_2 \cdot 2H_2O$ in Chloroform sowie seine Verteilung zwischen Chloroform und Wasser nicht untersucht. Wie später gezeigt wird, sind aber diese Daten für die Interpretation von Verteilungsmessungen sehr wichtig. Zudem kann Cadmium mit der flammenlosen Atomabsorption in einer Graphitrohrküvette sehr empfindlich bestimmt werden. Daher schien uns das System $CdL_2 \cdot 2H_2O/H_2O$ bzw. $CHCl_3$ sehr geeignet um die Anwendbarkeit der Atomabsorption in der messenden Komplexchemie weiter zu prüfen.

EXPERIMENTELLER TEIL

Apparatives

Verwendeter Atomabsorptionsspektrophotometer, pH-Einstabmesskette und pH-Meter wurden bereits beschrieben.[1] Zur Messung der optischen Dichte von CdL_2-Lösungen diente ein Einstrahl-Spektrophotometer (Unicam).

Chemikalien

$CdL_2 \cdot 2H_2O$ und CdL_2 wurden nach gravimetrischen Standardmethoden hergestellt. Man benutzte doppeltdestilliertes Wasser, Tetramethylammoniumnitrat[1] $[Me_4N]NO_3$, $[Me_4N]OH$ und HNO_3, welche sich bei der Prüfung in der Graphitrohrküvette als Cd-frei erwiesen. Chloroform (Merck) wurde kurz vor dem Gebrauch durch Ausschütteln mit Wasser alkoholfrei gewaschen und mit Wasser gesättigt.

Abnahme des Cd-Gehaltes frisch präparierter CdL_2-Lösungen

Es wurden verschieden konzentrierte Oxinlösungen (0,05 und 0,1M) in alkoholfreiem, an Wasser gesättigtem Chloroform hergestellt. In einem Teil der Lösungen wurde CdL_2 gelöst, und mit der übrigen Lösung füllte man die Referenzküvette. Die Abnahme der Cadmium konzentration (s. Abb. 1) wurde in der Küvette durch Messung der optischen Dichte bei 380 und 390 nm direkt verfolgt. Die gemessenen optischen Dichten D_{380} und D_{390} mußten allerdings korrigiert werden, da sich während der Messungen festes $CdL_2 \cdot 2H_2O$ bildete, welches Lichtstreuung verursachte. Die relative Konzentration wurde mit $(D_\lambda\text{-}D_{\lambda,s})/D_{\lambda,a}$ gleichgesetzt, wobei $D_{\lambda,a}$ die anfängliche optische Dichte bei der betreffenden Wellenlänge und $D_{\lambda,s}$ den Beitrag der Lichtstreuung bei der gleichen Wellenlänge bedeuten. Zur Ermittlung von $D_{\lambda,s}$ wurde angenommen, daß das Raleigh'sche Gesetz näherungsweise gilt, d.h. daß zwischen $D_{\lambda,s}$ und log λ eine lineare Beziehung besteht. Für die lineare Extrapolation benötigte Koeffizienten ermittelte man durch die gleichzeitige Messung der optischen Dichte bei den zusätzlichen Wellenlängen von 500 und 600 nm, bei welchen das gelöste Cadmiumoxinat kein Licht mehr absorbiert. Proben aus sämtlichen Lösungen wurden nach gewisser Zeit (*ca.* 2 Wochen) an einem Membranfilter (Sartorius 11605, Porengröße 0,6 μm) filtriert gewogen, das Lösungsmittel abgedampft und die Rückstände in soviel Salpetersäre aufgelöst, daß nach Protonierung des Oxins noch 0,1M freie Salpetersäure vorlag. Der Cadmiumgehalt wurde schließlich nach dem unten beschriebenen Programm atomabsorptiometrisch ermittelt (log $[Cd]_{t,o}$ wird in Abb. 4 mit Gleichgewichtsdaten verglichen).

Atomabsorptiometrische Bestimmung von Cadmium in der Graphitrohrküvette

$[Me_4N]NO_3$ wurde[1] als Inertsalz bei der Rückextraktion von Cu(II)–Oxinat gewählt, da es sich bei 400° bis 500° aus der Küvette verflüchtigte und die Cu-Bestimmung nicht störte.

Allerdings mußte—wegen sich widersprechenden Angaben[7–11] über die Flüchtigkeit von Cadmium—geprüft werden, ob eine Zersetzungsstufe mit einer Temperatur zwischen 400° und 500° genügend tief liegt damit keine nennenswerten Cadmiumverluste auftreten. Um dies festzustellen, wurden Cadmiumbestimmungen mit je 10 bzw. 20 μl einer $5 \cdot 10^{-8}M$ $Cd(NO_3)_2$-Lösung in 0,1M Salpetersäure mit dem folgenden Programm ausgeführt: 1. Trocknen: 96°, 30–60 Sek; 2. Abdampfen von HNO_3: 136°, 30 Sek; 3. Thermische Zersetzung durch Temperaturerhöhung von 138° auf T_4 während *ca.* 60 Sek; 4. Vervollständigung der thermischen Zersetzung: T_4, 60 Sek; 5. Atomisierung:[12] 1900° 10 Sek.

Zur Berechnung der Cd-Verluste, welche in der 4-ten Stufe auftraten, wurde eine Eichung bei $T_4 = 300°$ (% Verlust = 0) vorgenommen, wobei die Peakhöhen (% ABS) bezogen[1] auf die Basislinie bei T_4 verwendet wurden. Diese Versuche zeigten, daß merkliche Cadmiumverluste erst oberhalb 500° auftraten. Alle späteren Bestimmungen wurden mit $T_4 = 450°$ ausgeführt. Zur Berechnung der Cadmiummenge Q mußte jeweils die entsprechende optische Dichte D in ein parabolisches Eichpolynom $Q = a + bD + cD^2$ eingesetzt werden, da eine Linearität zwischen Q und D nicht einmal in einem engen Meßbereich bestand.

Mit diesem Programm wurden nun Eichkurven bei verschiedenen Lampenströmen aufgenommen. Der Einfluß des Lampenstromes auf die Eichkurven ist sehr ausgeprägt (s. Abb. 2). Die starke Abnahme der meßbaren optischen Dichte mit der zunehmenden Belastung der Hohlkathodenlampe wird vermutlich durch Selbstabsorptionsverbreiterung der Emissionslinie verursacht. Man arbeitete in der Regel mit Lampenströmen von 9–10 mA, da hier zwischen Empfindlichkeit und Schwankung des Basissignals das

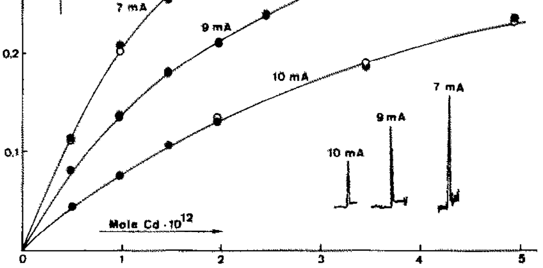

Abb. 2. Einfluß vom Strom der Hohlkathodenlampe auf die Empfindlichkeit der Cadmiumbestimmung in der Graphitrohrküvette.

günstigste Verhältnis vorlag. $[Me_4N]\,NO_3$ beeinflußt nicht in nachweisbarem Maß die gemessenen optischen Dichten. In der Folge wurden daher Eichlösungen ohne $[Me_4N]NO_3$ verwendet.

Auf die ständige Benützung des Deuterium-Untergrundkompensators wurde ebenfalls verzichtet, da offensichtlich keine nicht-spezifische Absorption vorlag. Gelegentlich wurden jedoch mit der Deuteriumlampe Kontrollmessungen durchgeführt.

Ausführung der Löslichkeitsbestimmungen im Wasser

Es wurden 10 bis 30 mg $CdL_2 \cdot 2H_2O$ in je 10 ml einer Oxinlösung beigegeben, deren pH-Wert mit HNO_3 bzw. $[Me_4N]OH$ und deren ionale Stärke mit $[Me_4N]NO_3$ auf 0,1 eingestellt war. Vorversuche auf einer Schüttelmaschine mit *ca.* 200 Schüttelbewegungen pro Minute zeigten, daß ein Gleichgewicht zwischen fester und flüssiger Phase innerhalb einer nützlichen Frist—besonders im neutralen und alkalischen Gebiet—mit genügender Genauigkeit nicht angenähert werden konnte. Alle Löslichkeitsbestimmungen wurden daher unter den folgenden standardisierten Meßbedingungen ausgeführt.

Je 6 der anfangs genannten Ansätze wurden in Pillengläsern von *ca.* 30-ml Fassungsvermögen auf einem Gestell, welches mit einem Vibromischer in Bewegung gehalten wurde, 5 Tage bei 25° equilibriert. Die Pillengläser enthielten noch zusätzlich zur besseren Dispergierung der festen Phase in der Lösung einige kleine Glasperlen. Der Vibromischer wurde mit einer solchen Amplitude betrieben, daß das feste Oxinat ständig in Dispersion blieb. Diese Technik gewährleistete eine recht schnelle Einstellung des Auflösungsgleichgewichtes. Dieses wurde in meisten Fällen nach 24 Stunden erreicht. In allen Fällen wurde $[Cd]_t$ nach 3 Tagen konstant und war für verschiedene $CdL_2 \cdot 2H_2O$-Präparate und verschiedene $CdL_2 \cdot 2H_2O$-Mengen innerhalb der Fehlergrenzen bei gleichem pL-Wert immer dieselbe. Man erhielt zudem eine sehr gute Reproduzierbarkeit. Die durchschnittliche, einfache Standardabweichung einer Meßserie unter standardisierten Versuchsbedingungen betrug 6,2% und niemals wurde 10% überschritten. Diese entspricht einer einfachen Standardabweichung des log $[Cd]_t$-Wertes von 0,028.

Nach Ablauf von 5 Tagen wurden die pH-Werte gemessen (für Eichung der Meßkette s. Zitat[1]). Die durchschnittliche, einfache Standardabweichung σ(pH) innerhalb einer Serie (6 Ansätze) mit je gleicher Konzentration an $[HL]_t$ und HNO_3 bzw. $[Me_4N]OH$ betrug bei genügender Pufferkapazität (pH $< 5{,}8$ bzw. pH $> 8{,}9$) 0,013. Da diese ungefähr dem Meßfehler der pH-Messung in einer und derselben Lösung entspricht, wurde pL mit dem Mittelwert der pH-Werte innerhalb einer Serie berechnet, wobei die kürzlich ermittelten[1] Protonierungskonstanten K_1 und K_2 von L^- benutzt wurden. Nach dem Fehlerfortpflanzungsgesetz beträgt die Reproduzierbarkeit [$= \sigma$(pL)] 2σ(pH) für pH $< 4{,}3$, und 1σ (pH) für pH > 9 [für dazwischenliegende pH-Werte: 2σ (pH) $> \sigma$(pL) $> 1\sigma$ (pH)].

Nach erfolgter pH-Messung wurden die Proben nochmals 6 Stunden equilibriert und hierauf durch einen Membranfilter (Sartorius 11107, Porengrösße 0,2 μm) abfiltriert und das Filtrat durch Zugabe von konz. Salpetersäure auf 0,1*M* angesäuert. Obwohl in saurer Lösung keine Cadmiumverluste infolge Cd-Absorption an Gefäßwänden auftreten,[13] wurden die atomabsorptiometrischen Cd-Bestimmungen gleich anschliessend ausgeführt. Nötigenfalls wurden die angesäuerten Filtrate mit 0,1*M* Salpetersäure weiterverdünnt. Die Konzentration der Eichlösungen wurde jeweils der zu bestimmenden Cadmiumkonzentration angepaßt, sodaß für gleiches Einspritzvolumen der zu analysierenden Proben bzw. der Eichlösung ungefähr gleich große Absorptionssignale resultierten. Jede Probe wurde mehrfach eingespritzt, wobei die eingespritzten Cadmiummengen variiert wurden.

Bei der Ausführung der Löslichkeitsbestimmungen wurde der Kontaminationsgefahr besondere Aufmerksamkeit geschenkt: sämtliche benutzten Glaswaren wurden mit einer Säuremischung von je 2*M* Salpeter- und Salzsäure vorgereinigt und mit doppelt-destilliertem Wasser gespült. Weiterhin wurde das Referenzelektrolyt der kombinierten pH-Elektrode häufig gewechselt.

Bestimmung der Löslichkeit von $CdL_2 \cdot 2H_2O$ in Chloroform

Die Löslichkeitsversuche wurden genau auf die selbe Art und Weise wie in wäßrigem Medium durchgeführt. Es wurde die eingesetzte Oxinkonzentration $[HL]_0$ variiert, wobei je zwei Ansätze mit der gleichen $[HL]_0$-Konzentration jedoch mit verschiedenen $CdL_2 \cdot 2H_2O$-Einwaagen gemacht wurden. Die Filtrierung der Proben erfolgte ebenfalls durch ein Membranfilter (Sartorius 11605, Porengröße 0,6 μm).

RESULTATE UND DISKUSSION

Der Logarithmus der atomabsorptiometrisch bestimmten, totalen Cadmiumkonzentration log $[Cd]_t$ im Wasser ist in Abb. 3 gegen den negativen Logarithmus der freien Oxinatkonzentration pL aufgetragen. Da die Löslichkeit nicht nur bei kleinen, sondern auch bei hohen Konzentrationen [L] des freien Oxinations L^- zunimmt, muß neben den Partikeln Cd^{2+}, CdL^+ und CdL_2 auch das koordinativ gesättigte CdL_3^- berücksichtigt werden. Die Löslichkeit beträgt daher bei einer bestimmten Oxinatkonzentration:

$$\begin{aligned}[Cd]_t &= [Cd] + [CdL] + [CdL_2] + [CdL_3] \\ &= K_{s0}/[L]^2 + \beta_1 \cdot K_{s0}/[L] \\ &\quad + \beta_2 \cdot K_{s0} + \beta_3 \cdot K_{s0} \cdot [L] \qquad (1)\end{aligned}$$

In dieser Gleichung bedeutet K_{s0} das Löslichkeitsprodukt des Cd–Oxinates ($= [Cd]\,.\,[L]^2$) und β_n die Bruttostabilitätskonstante ($= Cd(L)_n/[Cd]\,.\,[L]^n$ mit $n = 1, 2, 3$).

Die Ermittlung dieser Konstanten aus den Löslichkeitsdaten erfolgte rechnerisch, wobei aber gewisse

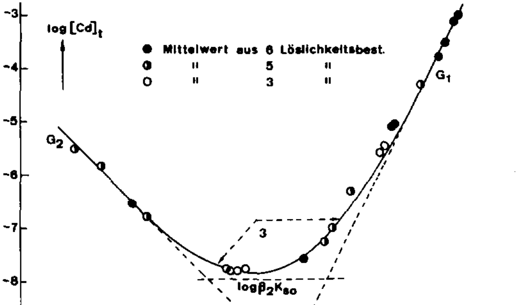

Abb. 3. Löslichkeit des Cd-Oxinates ($CdL_2 \cdot 2H_2O$) als Funktion der Konzentration des freien Oxinations (25°C, $\mu = 0{,}1$).

Aspekte der graphischen "curve fitting"-Methode von Sillén[14] berücksichtigt wurden. Die Auswertung und die Abschätzung der Reproduzierbarkeit (Standardabweichung, σ) von den Konstanten sollen nun kurz beschrieben werden.

Wenn unter den Partikeln Cd^{2+} stark dominiert, hängt log $[Cd]_t$ von pL gemäß Gleichung (1) linear ab (Assymptote A_1):

$$\log [Cd] = \log K_{s0} + 2 \cdot pL \qquad (A_1)$$

Die Punkte in stark sauerem Gebiet mit $pL > 8{,}2$ (s. Abb. 3) ergaben eine Neigung von 1,90 ± 0,12, was die Molzahl 2 des Oxinations pro Cd in der Auflösungsreaktion eindeutig bestätigt.

Bei sehr hohen Oxinatkonzentrationen herrscht CdL_3^- vor, sodaß die Funktion $\log[Cd]_t$, pL die Assymptote A_2 annähert:

$$\log[CdL_3] = \log \beta_3 \cdot K_{s0} - pL \qquad (A_2)$$

Die Messungen mit $pL < 4{,}5$ (s. Abb. 4) liegen an einer Regressionsgerade mit der Neigung von −0,95 ± 0,09. Das Cadmiumoxinat geht also in diesem Gebiet durch Aufnahme von 1 Mol Oxination pro Cd in Lösung. Damit ist die Arbeitshypothese gemäß Gleichung (1) bestätigt und kann beibehalten werden.

Zur Bestimmung von log β_3 und log K_{s0} werden die Assymptoten A_1 und A_2 durch die Geraden G_1 und G_2 angenähert, deren Schwerpunkte $(\bar{x}_1, \bar{y}_1)$ und $(\bar{x}_2, \bar{y}_2)$ aus den oben genannten Punkten bestimmt und deren Neigung 2 bzw. −1 gesetzt wird:

$$y_1 = \log[Cd]_{t,1} = \bar{y}_1 + 2 \cdot (x_1 - \bar{x}_1) \qquad (G_1)$$

$$y_2 = \log[Cd]_{t,2} = \bar{y}_2 - (x_2 - \bar{x}_2) \qquad (G_2)$$

Hierbei wurde pL im Gebiet G_1 bzw. G_2 mit x_1 bzw. x_2 bezeichnet.

Der Schnittpunkt S_{12} der beiden Geraden G_1 und G_2 fällt innerhalb der Fehlergrenzen mit dem Schnittpunkt der beiden Assymptoten A_1 und A_2 zusammen. Für diesen gemeinsamen Punkt gilt daher die folgende Beziehung [2]:

$$3 \cdot pL_{12} = \log \beta_3 = 2 \cdot \bar{x}_1 - \bar{y}_1 + \bar{x}_2 + \bar{y}_2 \qquad (2)$$

Die Schwerpunkte $(\bar{x}_1, \bar{y}_1)$ und $(\bar{x}_2, \bar{y}_2)$ betrugen (8,916 ± 0,026, −3,554 ± 0,030) und (2,741 ± 0,013, − 6,164 ± 0,051). Gleichung (2) ergab mit diesen Werten log β_3 zu 17,96 ± 0,08.

Da der Ordinatenabschnitt y_1^0 der Geraden G_1 mit dem Ordinatenabschnitt der Assymptote A_1 innerhalb der Fehlergrenzen zusammenfällt, gilt Beziehung (3), welche zur Berechnung von log K_{s0} verwendet wird:

$$y_1^0 = \log K_{s0} = \bar{y}_1 - 2 \cdot \bar{x}_1 \quad (= -21{,}39 \pm 0{,}06) \quad (3)$$

Der Ordinatenabschnitt y_2^0 der Geraden G_2 beträgt:

$$y_2^0 = \log K_{s0} \cdot \beta_3 = \bar{y}_2 + \bar{x}_2 \quad (= -3{,}42 \pm 0{,}05) \quad (4)$$

[Diese Beziehung ermöglicht natürlich keine Kontrolle der bereits erhaltenen Werte für β_3 und K_{s0}, da sie von Beziehung (2) nicht unabhängig ist].

Der gefundene Wert für log K_{s0} stimmt mit dem Literaturwert[15] von −21,96 ($\mu = 0$, 25°) überein, welcher in einer Fällungstitration potentiometrisch bestimmt wurde.

Um β_1 und β_2 zu erhalten substrahiert man [Cd] und $[CdL_3]$ von $[Cd]_t$ und ermittelt die Koeffizienten A und B der resultierenden Beziehung (5):

$$[Cd]_t - K_{s0}/[L]^2 - K_{s0} \cdot \beta_3 \cdot [L] = A + B \cdot \frac{1}{[L]} \qquad (5)$$

A bzw. B bedeutet $\beta_2 \cdot K_{s0}$ bzw. $\beta_1 \cdot K_{s0}$. Damit A genügend genau erhalten wird, dürfen nur Punkte einbezogen werden, für welche $[Cd]_t$ die minimale Löslichkeit $[Cd]_{t,min}$ nicht mehr als (5–10)-fach überschreitet (s. Meßbereich 3 in Abb. 4).

$$\log \beta_2 = \log (A/K_{s0}) \pm \{[0{,}434 \cdot \sigma(A)/A]^2 + [\sigma(\log K_{s0})]^2\}^{1/2} \qquad (6)$$

$$\log \beta_1 = \log (B/K_{s0}) \pm \{[0{,}434 \cdot \sigma(B)/B]^2 + [\sigma(\log K_{s0})]^2\}^{1/2} \qquad (7)$$

Mit den Meßpunkten im Gebiet 3 erhielt man log β_2 zu 13,44 ± 0,08 und log β_1 zu 7,34 ± 0,07.

Aus Fällungstitrationen[6,15] ermittelte man für log β_1 die Werte 7,2 ($\mu = 0{,}01$, 20°) bzw. 7,78 ($\mu = 0$, 20°). Der abgeschätzte Wert[6] für log β_2 von 13,4 ($\mu = 0{,}01$, 20°) stimmt erstaunlich gut mit dem hier experimentell bestimmten Wert überein.

Die erhaltenen Konstanten wurden schließlich in Gleichung (1) eingesetzt und $\log[Cd]_t$ berechnet (s. voll ausgezogene Linie in Abb. 3). Die berechnete Kurve ergibt eine recht gute Übereinstimmung mit den experimentellen Punkten und zeigt ein Minimum bei pL = 5,4. Das gelöste Cd ist hier zu 75, 15 bzw. 10 Mol % in Form von CdL_2, CdL^+ bzw. CdL_3^- vorhanden. Die Assymptote log $\beta_2 \cdot K_{s0}$ (s. Abb. 3) kann daher durch experimentell bestimmte Punkte nicht angenähert werden, was eine graphische Bestimmung von log β_2 und log β_1 verunmöglicht. Im allgemeinen ist die graphische Auswertung anwendbar, wenn (log β_2/β_1 − log β_3/β_2) größer als 2 ist, wie z.B. im Falle[4] von Zn(II).

Die Resultate von den Löslichkeitsversuchen in

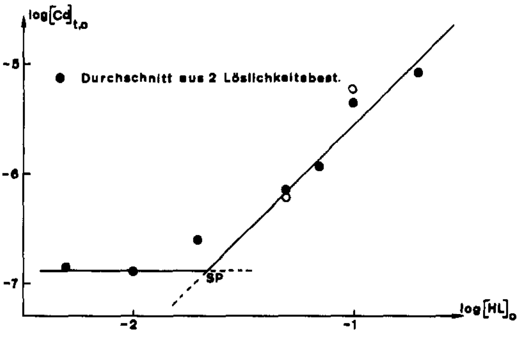

Abb. 4. Löslichkeit des Cd-Oxinates ($CdL_2 \cdot 2H_2O$) in Chloroform in Abhängigkeit der Oxinkonzentration (25°C).

Chloroform sind in Abb. 4 eingezeichnet, und die Auswertung wurde folgendermaßen durchgeführt.

Die totale Cadmiumkonzentration $[Cd]_{t,o}$ einer Chloroformlösung, welche sich mit der festen Phase $CdL_2 \cdot 2H_2O$ im Gleichgewicht befindet, an Wasser gesättigt ist und deren Oxinkonzentration $[HL]_o$ beträgt, Kann wie folgt beschrieben werden:

$$[Cd]_{t,o} = [CdL_2]_o + [CdL_2HL]_o + [CdL_2(HL)_2]_o \qquad (8)$$

Bei höheren $[HL]_o$-Konzentrationen dominiert das Diaddukt, sodaß sich die Funktion $\log[Cd]_{t,o}$, $\log[HL]_o$ der Assymptote A_1^o annähert:

$$\log[Cd]_{t,o}([HL]_o \to \infty) = \log[CdL_2]_{o,s} + \log\beta_A^o + 2\cdot\log[HL]_o \qquad (A_1^o)$$

Hier bedeuten:
$\beta_A^o = [CdL_2(HL)_2]_o/[CdL_2]_o \cdot [HL]_o^2$, die Adduktbildungskonstante in der organischen Phase; $[CdL_2]_{o,s}$, die Sättigungskonzentration des Dihydrates in Chloroform.

Bei sehr niedrigen $[HL]_o$-Konzentrationen wird $[Cd]_{t,o}$ von der $[HL]_o$-Konzentration unabhängig und man erhält eine zweite Assymptote:

$$\log[Cd]_{t,o}([HL]_o \to 0) = \log[CdL_2]_{o,s} \qquad (A_2^o)$$

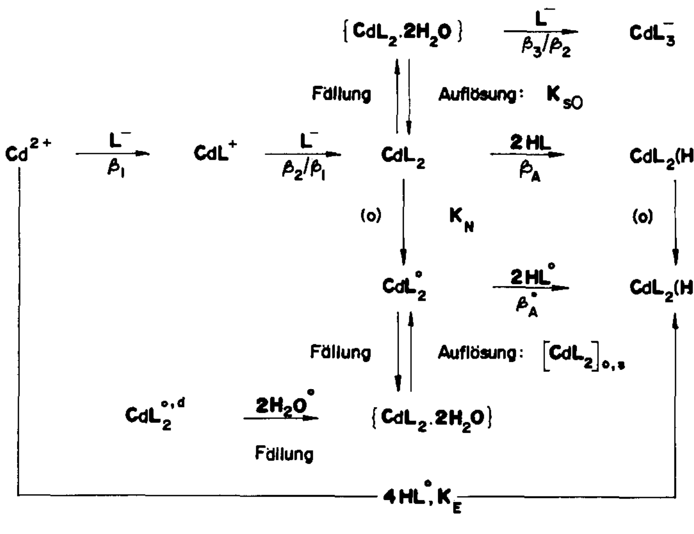
Der Schnittpunkt SP beider Assymptoten liefert die Adduktbildungskonstante:

$$\log\ \beta_A^o = -2\cdot\log[HL]_{o,SP} \qquad (9)$$

Die Neigung der Geraden $\log[Cd]_{t,o}$, $\log\ [HL]_o$ bei $\log[HL]_o \geq -1{,}3$ beträgt 1,85 ± 0,39 d.h. 2 innerhalb der Fehlergrenzen, was die Bildung der Spezies $CdL_2(HL)_2$ bestätigt. Bei $-2{,}3 \leq \log[HL]_o \leq -2$ wird $[Cd]_{t,o}$ von der Oxinkonzentration unabhängig und entspricht $[CdL_2]_{o,s}$ ($\log[CdL_2]_{o,s} = -6{,}882 \pm 0{,}056$). Bei $\log[HL]_o \leq -2{,}3$ erhält man schlecht reproduzierbare Werte für $[Cd]_{t,o}$, was wahrscheinlich auf die Entstehung neuer Spezies durch hydrolytische Spaltung zurückzuführen ist. Zur Berechnung von log β_A^o aus der Beziehung (9) wurden die Assymptoten A_1^o und A_2^o wie vorne durch Geraden mit der Neigung 2 bzw. 0 und den experimentell bestimmten Schwerpunkten ($-1{,}039 \pm 0{,}028$, $-5{,}628 \pm 0{,}086$) bzw. ($-2{,}150 \pm 0{,}029$, $-6{,}882 \pm 0{,}056$) angenähert. Man erhielt aus dem Schnittpunkt dieser Geraden log β_A^o zu 3,33 ± 0,16. Die abgeschätzte Standardabweichung enthält den fortgepflanzten Fehler von $\log[CdL]_{o,s}$ und vom Schwerpunkt der A_1^o repräsentierenden Geraden. Der Verlauf von $\log[Cd]_{t,o}$, $\log[HL]_o$ in der Nähe des Schnittpunktes deutet darauf hin, daß die Spezies $CdL_2 \cdot HL$ in vernachlässigbar kleiner Konzentration auftritt. Eine Ermittlung ihrer Adduktbildungskonstante ist daher nicht möglich. Das Auftreten der Spezies $CdL_2(HL)_2$ wurde bei Extraktionsversuchen[3,16,17] ebenfalls beobachtet. Die Stabilität des Adduktes konnte jedoch aus Verteilungsmessungen nicht ermittelt werden. Merkwürdigerweise bildet sich beim Zn-Oxinat nur ein Monoaddukt[18,19] mit dem Logarithmus 2,17 der Adduktbildungskonstante.

In Abb. 4 sind auch zwei $\log[Cd]_{t,o}$-Werte eingezeichnet, welche in der Mutterlauge von $CdL_2 \cdot 2H_2O$-Fällungen aus Lösungen von wasserfreiem Cadmiumoxinat (s. auch Abb. 1) gemessen wurden. Da man durch Fällung bzw. Auflösung praktisch die gleichen $[Cd]_{t,o}$-Werte erhielt, handelt es sich bei diesen Angaben mit absoluter Sicherheit um Gleichgewichtskonzentrationen.

Mit den ermittelten Daten kann nun auch die Verteilung von Cadmiumoxinat zwischen Chloroform (o, organische Phase) und Wasser (kein Index) richtig interpretiert werden. Die folgende Skizze zeigt die wichtigsten Stufen der Komplexbildung, ausgehend vom Aquokomplex Cd^{2+} bzw. vom dehydratisierten Cd–Oxinat $CdL_2^{o,d}$.



Die bisher nicht difinierten Konstanten bedeuten:

$\beta_A = [CdL_2(HL)_2]/[CdL_2]\cdot[HL]^2$ = die Adduktbildungskonstante im Wasser.

$K_N = [CdL_2]_o/[CdL_2]$ = Nernst'-sche Verteilungskonstante des neutralen Komplexes.

$K_A = [CdL_2(HL)_2]_o/[CdL_2(HL)_2]$ = Nernst'-sche Verteilungskonstante des Diadduktes.

$K_E = [CdL_2(HL)_2]_o\cdot[H]^2/[Cd]\cdot[HL]_o^4$ = Extraktionskonstante.

Die Extraktion von Cd(II) kann entweder durch Verteilung des neutralen Komplexes CdL_2 mit anschliessender Adduktbildung in der organischen Phase, oder durch primäre Adduktbildung in der wäßrigen Phase mit nachfolgender Verteilung des Adduktes beschrieben werden. Obwohl die zweite Möglichkeit bisher bevorzugt wurde,[16,17] schlagen wir den ersten Reaktionsweg vor, da dieser über experimentell nachweisbare Stufen verläuft.

In dieser Arbeit konnten β_1, β_2, β_3, K_{s0} und β_A^o sowie die Sättigungskonzentration $[CdL_2]_{o,s}$ in der organischen Phase aus Löslichkeitsversuchen ermittelt werden. Zudem kann K_N aus diesen Daten berechnet werden. Die Verteilung von CdL_2 stellt sich nämlich so ein, daß seine Aktivität bezogen auf den gemeinsamen Standardzustand des festen Oxinates in beiden Phasen gleich wird. Somit kann K_N dem Verhältnis der beiden Sättigungskonzentration $[CdL_2]_{o,s}$ bzw. $[CdL_2]_s$ gleichgesetzt werden:

$$\begin{aligned} K_N &= [CdL_2]_{o,s}/[CdL_2]_s \\ &= [Cd]_{t,o}([HL]_o \rightarrow 0)/K_{s0}\cdot\beta_2 \qquad (10) \end{aligned}$$

$[CdL_2]_{o,s}$ bekommt man durch Extrapolation der bei verschiedenen $[HL]_o$-Konzentrationen bestimmten Löslichkeiten von $CdL_2.2H_2O$ in Chloroform. Die direkte Bestimmung scheitert an der Hydrolyse (s. vorne) des Cadmiumoxinates in Abwesenheit von Oxin. Mit den bereits mitgeteilten Daten erhielt man für log K_N 1,07 ± 0,11. Bei dieser Fehlerangabe handelt es sich um einen maximalen Fehler, da er durch Fehlerfortpflanzung abgeschätzt wurde. Der niedrige K_N-Wert deutet darauf hin, daß sich eine hydratisierte Spezies zwischen den beiden Phasen verteilt. Wenn man die Koordinationszahl 6 als gegeben annimmt, kann es sich nur um $CdL_2(H_2O)_2$ handeln. K_N bedeutet daher die Verteilungskonstante $[CdL_2(H_2O)_2]_o/[CdL_2(H_2O)_2]$. Wir verzichteten jedoch auf Angabe der koordinierten Wassermoleküle, da diese in der messenden Komplexchemie gewöhnlich weggelassen werden. Ähnlich verhält sich das Zinkoxinat mit einem K_N-Wert[19] von $10^{1,41}$. Dagegen dürfte bei Kupferoxinat kein Wasser als Ligand vorhanden sein, da der K_N-Wert[1] $10^{3,38}$ beträgt.

Eine Bestimmung von K_N durch Extraktion kann nicht ausgeführt werden, da CdL_2 bei keinem [L], $[HL]_o$-Wertepaar als in beiden Phasen gleichzeitig dominierende Partikel auftritt. Diese Bedingung trifft auf $CdL_2(HL)_2$ noch weniger zu, da die Konzentration von HL im Wasser nicht genügend hoch gewählt werden kann. [HL] beträgt maximal $5\cdot10^{-3}M$, sodaß die Adduktbildungskonstante im Wasser mindestens $10^{6,6}$ betragen sollte, damit das Verhältnis $[CdL_2(HL)_2]/[CdL_2]$ auf 100 steigt. Es ist aber sehr unwahrscheinlich, daß die Adduktbildungskonstante in Wasser mehr als 1000-mal größer ist als in Chloroform. Die Zerlegung der leicht meßbaren Extraktionskonstante K_E in β_2, β_A und K_A kann daher nicht durchgeführt werden. Die Auftrennung von K_E wurde trotzdem versucht,[16,17] wobei ein K_A-Wert von $10^{4,1}$ verwendet wurde, welcher als Verteilungsverhältnis q_{Cd} $(= [Cd]_{t,o}/[Cd]_t)$ ermittelt worden ist und somit sicherlich zu niedrig ist. Gleichzeitig ist das angegebene Produkt $\beta_2.\beta_A$ $(=K_c$ im Zitat[17]) zu hoch. Nichtsdestoweniger stimmt das Produkt $K_A.\beta_2.\beta_A$ bzw. K_E. Nach unserer Ansicht sollte K_A bei $CdL_2(HL)_2$ wesentlich größer sein als bei einem Monoaddukt, wie z. B. ZnL_2HL bzw. ZnL'_2HL' (HL' = 8-Hydroxychinaldin), welche einen abgeschätzten, minimalen K_A-Wert[18] von $10^{3,6}$ bzw. $10^{4,8}$ besitzen. Das Zentralion ist nämlich in $CdL_2(HL)_2$ vollständig vom voluminösen in Chloroform gut löslichen Oxin umhüllt, was einen grossen K_A-Wert ergeben sollte.

Um unsere Daten mit Literaturangaben zu vergleichen berechneten wir daher mit den hier bestimmten β_2, β_A^o und K_N die Extraktionskonstante K_E:

$$\begin{aligned} K_E &= \beta_2\cdot\beta_A\cdot K_A/K_{HL}^4\, K_1^2 \\ &= \beta_2\cdot\beta_A^o\cdot K_N/K_{HL}^2\cdot K_1^2 \qquad (11) \end{aligned}$$

wobei K_{HL} $(= [HL]_o/[HL])$ die Nernst'-sche Verteilungskonstante des Oxins ist. Diese Beziehung ergibt für log K_E −6,5 Radiochemisch[3,17] wurden aus Verteilungsmessungen Werte von −6,1 bzw. −5,3 gefunden.

Eine wichtige Regel kann nun für die Anreicherung von Cd(II) aus verdünnten Lösungen durch Extraktion mit einer HL-haltiger Chloroformlösung abgeleitet werden: $[Cd]_{t,o}$ darf im Laufe der Extraktion den Wert $[CdL_2]_{o,s}\cdot(1 + \beta_A^o\cdot[HL]_o^2)$ nicht überschreiten, da sonst eine Fällung von $CdL_2.2H_2O$ auftreten kann. Die Entstehung der festen Phase geht allerdings kinetisch sehr träge vor sich, sodaß in einer "schnellen Extraktion" höhere Anreicherungen erreicht werden können. Anreicherungsmethoden, welche mit übersättigten Lösungen arbeiten, sind jedoch störanfällig, da der plötzliche Beginn einer Kristallisation von vielen zufälligen Faktoren abhängt.

Entwässertes Cd(II)-Oxinat löst sich in H_2O- und HL-haltigem Chloroform relativ gut. Es handelt sich auch hier um übersättigte Lösungen, falls die Cadmiumkonzentration $[Cd]_{t,o}$ den oben angegebenen Grenzwert überschreitet (d.h. $[Cd]_{t,o} > 10^{-6,88}\cdot(1 + 10^{3,33}\cdot[HL]_o^2)$). Dies konnte durch ein Impf-Experiment eindeutig bewiesen werden: eine $1{,}2\cdot10^{-5}M$ Lösung von dehydratisiertem Cd-Oxinat, in Chloroform welches an Wasser gesättigt und an HL 0,1*M* war, zeigte während 24 Stunden keine Abnahme des Cd-Gehaltes. Nach dem Impfen mit $CdL_2\cdot2H_2O$ sank aber $[Cd]_{t,o}$ innerhalb von *ca.* 2 Stunden auf die Hälfte (s. Abb. 1).

Wie aus der vorliegenden Arbeit ersichtlich ist, können aus Löslichkeitsbestimmungen alle benötigten Informationen gewonnen werden, welche zur Ausarbeitung von Fällungs- bzw. Extraktionsmethoden für die Anreicherung von Metallionen notwendig sind. Aus Löslichkeitsversuchen kann beurteilt werden, ob eine einzige Spezies gleichzeitig in zwei verschiedenen Lösungsmitteln bei einer bestimmten Ligandkonzentration die dominierende Partikel ist, und damit ihre Nernst'-sche Verteilungskonstante als Verteilungsverhältnis des Metalls direkt bestimmt werden kann. Dadurch können Unsicherheiten bei der Interpretation von Verteilungsdaten vermieden werden.

Das Hauptproblem besteht bei Löslichkeitsuntersuchungen in der genügenden Annäherung des Gleichgewichtes zwischen der Lösung und der festen Phase. Dies wird am besten erreicht, wenn die feste Phase in kristalliner Form vorgegeben wird. So vermeidet man nämlich die Bildung von übersättigter Lösungen, und die Trennung der Phasen nach dem Equilibrieren gestaltet sich auch leichter. Zur Separation beider Phasen sollten unbedingt Membran-Filter eingesetzt werden, da diese eine sichere und schnelle Trennung ermöglichen. Die Bestimmung des aufgelösten Metalls kann in vielen Fällen mit flammenloser Atomabsorption durchgeführt werden. Jedenfalls hat sich diese Technik für die Bestimmung von Cadmium sehr gut bewährt.

ELECTROREDUCTION OF URANIUM (VI) AT A PLATINUM ELECTRODE AND ITS ANALYTICAL APPLICATIONS

P. ZANELLO, G. RASPI and A. CINQUANTINI
Institute of General Chemistry, University of Siena, Italy

(*Received* 20 *January* 1975. *Accepted* 5 *May* 1975)

Summary—Under normal conditions, the reduction of uranium(VI) at a platinum electrode, in acid solutions, is masked by the reduction of the hydrogen ion. If the working electrode is subjected to hydrogen evolution (at a current density of about 7 A/cm^2 for 90–120 min) the H_{ads} on the platinum surface, acting as a bridge in the electron transfer, shifts the reduction wave of uranium(VI), in 1*M* sulphuric acid solutions, to potentials ($E_{1/2} \simeq -0{\cdot}03$ V) less negative than that of the hydrogen discharge (about $-0{\cdot}25$ V). The wave corresponding to the reduction of uranium(VI) to uranium(IV) is well shaped, diffusion-controlled, and can be used for the determination of uranium down to $2 \times 10^{-5}M$ or $3 \times 10^{-6}M$ if a rotating electrode is used. Interferences arise from those ions with similar $E_{1/2}$ [*i.e.*, Cu(II) and Bi(III)], or from those such as permanganate and dichromate, which oxidize the H_{ads} on the platinum electrode. Because of the time required for the electrode pretreatment, the determination is time-consuming but in some respects it appears a useful improvement over the DME.

A mercury electrode is often used for the polarographic or coulometric determination of uranium(VI),[1] but sometimes it is preferable to use solid electrodes.[2,3] Zittel and Miller[4] have employed graphite, in the pyrolytic and glassy carbon form; the latter provides the better definition. Inconclusive results have been obtained with a boron carbide electrode.[5]

The platinum electrode, the commonest among solid electrodes, has severe limitations because of the evolution of hydrogen at the potential needed for the reduction of uranium(VI). A ring platinum electrode[2] has been used for the determination of uranium(VI) in sulphuric acid solutions at pH 3·2. Davies *et al.*[3] have reported a coulometric determination of uranium(VI) in hydrochloric acid media with a platinum-gauze electrode, but they resorted to a small amount of bismuth(III) to increase the hydrogen overvoltage at the electrode.

The present note demonstrates that the platinum electrode, both smooth and platinized, can be used for the direct determination of uranium(VI) in strongly acidic solutions and in the presence of diverse ions, when it has been subjected to a vigorous reduction. A rotating platinum electrode or one with periodical renewal of the diffusion layer has been employed. It is possible by combining this and an earlier method,[6] to determine simultaneously uranium(VI) and uranium(IV), whereas, with rare exceptions, the DME fails.

The proposed techniques are sensitive, easy to work and give good reproducibility in various acidic media.

EXPERIMENTAL

Apparatus

The voltammetric behaviour of uranium was investigated in a cell with periodically renewed diffusion-layer electrode (DLPRE).[8] The voltammograms for analytical applications were also measured with a rotating platinum electrode.

The dropping mercury electrode used had the following characteristics: $m = 1{\cdot}24$ mg/sec, $t_d = 4{\cdot}75$ sec.

The mean voltammetric currents were recorded with a three-electrode system. Electrochemical measurements were made with a PAR Mod. 170 Electrochemistry System. The potentiostatic current–time curves were measured on the screen of a Tektronix Type 502 dual-beam oscilloscope.

The reference electrode was a saturated mercury(I) sulphate electrode connected with the polarographic cell through a glass bridge with a sintered filter, filled with saturated sodium sulphate solution. The auxiliary electrode was a platinum electrode with an area of 1 cm^2. The platinum working microelectrode, when necessary, was platinized by cathodic treatment at a current density of 1·2 A/cm^2 in a 3% solution of chloroplatinic acid containing 0·025% of lead acetate.

Unless otherwise specified, measurements were performed at 25 ± 0·1°. The ionic strength was kept constant with an inert salt. Solutions were deaerated with purified nitrogen. All potentials reported are referred to the saturated calomel electrode.

Reagents

All chemicals used were of reagent grade.

Uranium(IV) solutions were prepared by electrolytic reduction of uranium(VI) at a mercury-pool electrode, and standardized by permanganate titration.

Preliminary work

Effects of the pretreatment of the smooth platinum electrode. The current–voltage curve (scan-rate 60 mV/min) from +0·225 to −0·300 V, at a smooth platinum electrode (DLPRE), of deaerated 1*M* sulphuric acid solution is shown in Fig. 1B, curve a.

To see whether the hydrogen evolution really makes it impossible to obtain a reduction wave for uranium(VI) at the platinum electrode, we tried to pretreat the electrode so as to displace the hydrogen discharge to more negative potentials. The pretreatment consisted of: (*a*) cleaning of the electrode in hot nitric acid (1 + 1) for about 10 min;

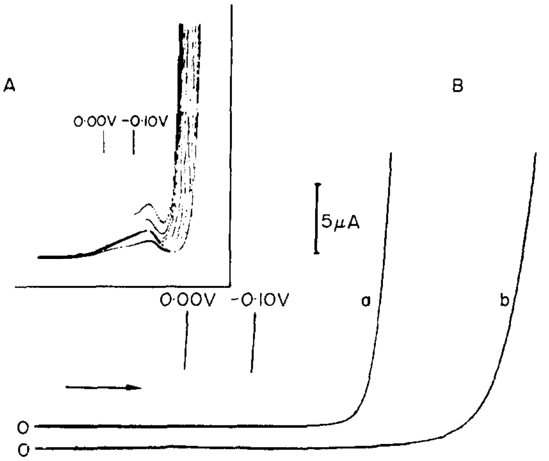

Fig. 1. A: Voltammograms of 1*M* HNO_3 during pretreatment. B: Voltammograms of 1*M* H_2SO_4 before (curve a) and after (curve b) pretreatment.

(*b*) dipping the electrode in the polarographic cell containing deaerated 1*M* nitric acid and making repeated recordings of the current–voltage curves in the cited potential range with a slow scan-rate (≤ 30 mV/min). In the course of this tedious operation (it took 3–4 hr), the hydrogen discharge shifted towards negative potentials, by about 0·1–0·2 V as seen in Fig. 1A, which shows the electroreduction of platinum oxides. The comparable curve for deaerated 1*M* sulphuric acid solution is curve b in Fig. 1B.

When a platinum electrode, so pretreated, is dipped in a deaerated 1*M* sulphuric acid solution, $7 \times 10^{-4}M$ in uranium(VI), the voltammogram shown in Fig. 2 (curve a) is obtained.

Under the same conditions, the reduction at the DME takes place at the same potential (Fig. 2, curve b). This seems to confirm the impossibility of obtaining a reduction wave for uranium(VI) at the platinum electrode; however, if the electrode is polarized at -2 V for 1 min (at a current density of about 4 A/cm^2) the well-shaped cathodic wave shown in Fig. 2 (curve c, $E_{1/2} = -0{\cdot}080$ V) is obtained temporarily.

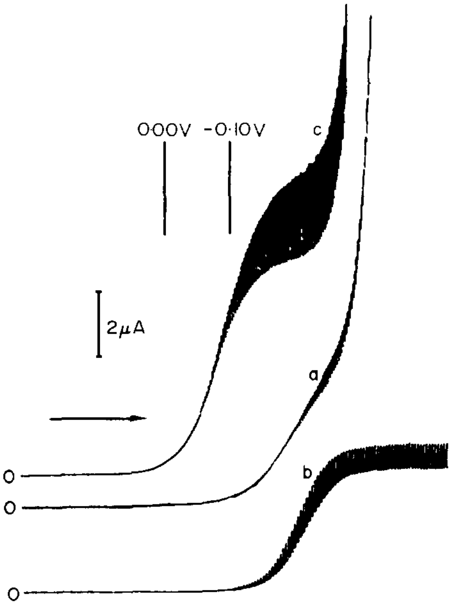

Fig. 2. Voltammetric curves of $7 \times 10^{-4}M$ uranium(VI) after the pretreatment of Fig. 1 (curve a) and the subsequent cathodic treatment at -2 V for 1 min (curve c); the same solution polarographed with DME (curve b).

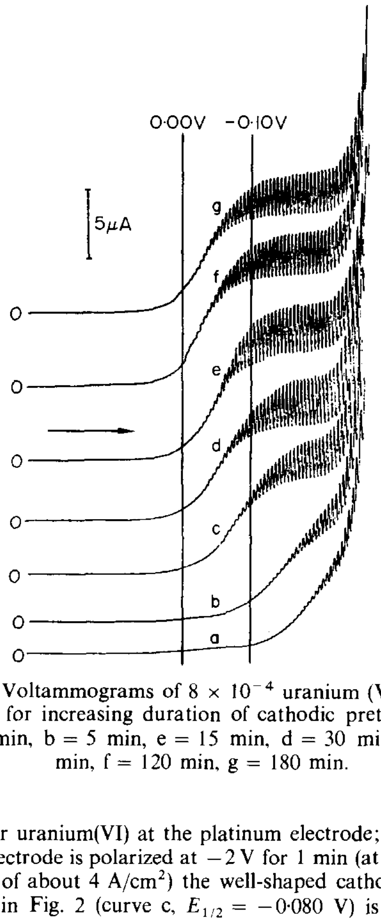

Fig. 3. Voltammograms of 8×10^{-4} uranium (VI) in 1*M* H_2SO_4 for increasing duration of cathodic pretreatment: a = 0 min, b = 5 min, e = 15 min, d = 30 min, e = 60 min, f = 120 min, g = 180 min.

The polarization may be carried out after pretreatment in nitric acid or directly in the sulphuric acid solution of uranium(VI). The latter is easier and was the procedure adopted.

We assume that hydrogen adsorbed on the electrode surface plays an important role in the detection of the cathodic wave of uranium(VI).

Figure 3 shows the voltammograms obtained with a smooth platinum electrode in a deaerated 1*M* sulphuric acid solution that is $8 \times 10^{-4}M$ in uranium(VI), when the applied voltage changes from $+0{\cdot}225$ to $-0{\cdot}300$ V, (scan-rate 60 mV/min) after hydrogen evolution at about $-3{\cdot}2$ V (at a current density of 7 A/cm^2) for the periods indicated in Table 1. As deducible from Fig. 3 and Table 1, the reduction wave of uranium(VI) is already well shaped after hydrogen evolution for 60 min, and after 120 min there is no sensible improvement. Essentially the same results

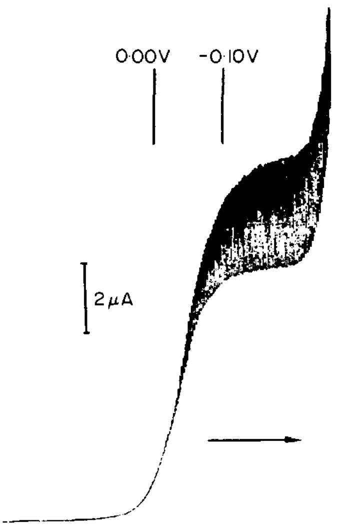

Fig. 4. Voltammograms of $8 \times 10^{-4}M$ uranium(VI) in $1M$ H_2SO_4 under optimal condition of pretreatment.

are obtained when the hydrogen evolution is performed with current densities of 5–9 A/cm^2; at lower current densities a more protracted time of prehydrogenation is necessary.

Under these conditions no anodic current arises from hydrated oxides of uranium.[9,10]

The cathodic wave for uranium(VI), obtained through sufficiently prolonged hydrogen evolution (120 min) is well shaped (Fig. 4) ($E_{1/2} = -0{\cdot}032$ V), and strictly proportional to uranium(VI) concentration down to $2 \times 10^{-5}M$. The best-shaped waves were obtained when the curves were registered for increasingly negative potentials, after the working electrode had been held for 1 min at the starting potential of $+0{\cdot}225$ V.

Potentiostatic curves obtained at potential values between $-0{\cdot}030$ and $-0{\cdot}200$ V show that the mean reduction currents of uranyl ions remain practically constant for about 80 min, when the platinum electrode has been prehydrogenated at a current density of about 7 A/cm^2 for at least 90 min. Then gradually the cathodic wave shifts towards negative potentials, so that it is necessary to repeat the hydrogenation cycle. The regenerative cycle (type B) described by Gilman[11] is not sufficient to give a well-formed cathodic wave of uranium(VI).

Effect of the supporting electrolyte. Various supporting electrolytes, including hydrochloric, nitric, perchloric and phosphoric acids, were tried with the prehydrogenated electrode.

Hydrochloric acid and its mixtures with other acids suppressed the reduction wave of uranium(VI); this can be attributed to the complexing action of chloride ions on platinum oxides,[12] and consequent modification of the electrode surface.

In perchloric acid the cathodic wave of uranium(VI) is sufficiently well-shaped and diffusion-controlled; however, it is very near to the hydrogen discharge (in $2M$ perchloric acid $E_{1/2} = -0{\cdot}105$ V).

The same results were obtained for nitric acid medium, in the presence of sulphamic acid.

Phosphoric acid gives a well-formed and diffusion-controlled cathodic wave for the reduction of uranium(VI) (in $0{\cdot}66M$ phosphoric acid $E_{1/2} = 0{\cdot}00$ V), but in this electrolyte, seemingly, the hydrogen is not so strongly adsorbed on the electrode surface as for sulphuric acid medium and subjection to a new hydrogen evolution does not provide quite reproducible results.

Concentrations of sulphuric acid greater than $1M$ were tested and good results were obtained up to $5M$ (in $4M$ sulphuric acid $E_{1/2} = +0{\cdot}015$ V); however, when the electrode prehydrogenation is performed in such strongly acidic solutions, it is best to minimize the effects of oxygen by screening the platinum counter-electrode from the solution with a sintered disk.

Effect of platinizing the electrode. Electrodes which have been platinized for 2–8 sec behave like the smooth electrode and do not shorten the hydrogenation times required. Electrodes platinized for >15 sec distort the wave because the capacity of the electrode–solution condenser system is too high.

Procedure for the pretreatment of the electrode

In order to obtain a well-formed cathodic wave for uranium(VI) at a platinum electrode it is necessary to hydrogenate the electrode itself. Such a pretreatment must be carried out in sulphuric acid with or without uranium(VI). During the voltammetric measurements it is convenient to avoid any handling of the solution that may cause the electrode to come into contact with air, because of the possible oxidation of adsorbed hydrogen.

The best conditions are the following: with nitrogen passing through a known volume of $1M$ sulphuric acid, keep the assembly (DLPRE or RPE) at constant cathodic current and a current density of about 7 A/cm^2 for at least 90 min.

In the rest of this paper any reference to the electrode pretreatment means such experimental conditions.

RESULTS AND DISCUSSION

Voltammetric behaviour

The reduction of uranium(VI) at a pretreated platinum electrode is diffusion-controlled, as shown by the dependence of the mean limiting current on the concentration of uranium(VI), and on the temperature over the range 20–55°. The temperature coefficient of the half-wave potential of the cathodic wave is $+1{\cdot}93$ mV/deg. The mean limiting diffusion current increases by 1·45%/deg.

The oscillographic investigation shows the limiting current follows the equation[8]

$$\overline{i_d} = KC$$

where

$$K = nFAD/r + nF\,AD^{1/2}(2t_{tot}^{1/2} - 1{\cdot}5t_p^{1/2})/\pi^{1/2}t_{tot}$$

and n, F, A, D, C have their usual meaning, t_p is the washing period of the electrode (0·025 sec), t_{tot} the period between two subsequent washings (5 sec), and r the radius of the platinum sphere (0·0972 cm). Substitution of the value of D obtained from a DME[13,14] in the same solution, allowed evaluation of n from which it was concluded that the uranium(VI) reduction is represented by:

$$UO_2^{2+} + 4H^+ + 2e^- \rightarrow U^{4+} + 2H_2O$$

The ratio $\Delta E/\Delta \log i/(\overline{i_d} - i)$ is 50 mV, whereas 29·5 mV is expected for a reversible process.

At an ionic strength of 3, and an acidity of 0·1–2N, $E_{1/2}$ shifts by -123 mV per pH unit in accordance with the proposed process.

The experimental necessity of the hydrogenation of the electrode for the uranium(VI) reduction process to occur, correlates with the presence of adsorbed hydrogen (H_{ads}) on the platinum surface. Something of the sort has been found for the VO^{2+}/V^{3+} couple.[15]

By analogy, it is reasonable to suppose that the mechanism of UO_2^{2+} reduction implies the intervention of H_{ads}, which acts as a "bridge" in the electron transfer. The electroreduction of UO_2^{2+} to U^{4+} on the DME, in the same experimental conditions,[13,14] at the same potential as on a non-hydrogenated platinum electrode ($W_{1/2} \simeq -0·190$ V, see Fig. 2), may be explained on this basis, since hydrogen is not adsorbed on mercury in the potential range considered.

Because both VO^{2+} and UO_2^{2+} are affected by H_{ads}, we suppose the formation of the hydrogen bridge involves a decrease in the bond energy between the central metal atom and the co-ordinated oxygen atoms, these bonds being broken during the reduction process. It is more difficult to explain the need for a prolonged hydrogenation before reduction of the uranyl ion. Two types of H_{ads} have been observed,[16,17] one very active, the other less so; a surface rearrangement (time-dependent) of the active hydrogen to the less active has also been reported.[17] This may imply that the less active H_{ads} is involved in the uranium(VI) electroreduction. However, unavoidable competitive adsorption of contaminants from the solution poisons the platinum electrode and the subsequent deactivation causes a change in the mechanism of the electroreduction of hydrogen ions[18] and hinders the rapid combination of H_{ads}.

ANALYTICAL APPLICATIONS

Voltammetric determination of uranium(VI)

Uranyl ions, in strongly acidic solutions other than hydrochloric acid, give a well-shaped anodic wave at a hydrogenated platinum electrode. The limiting current is strictly proportional to the uranium(VI) concentration, and thus the voltammetric determination of uranium(VI) is feasible. Sulphuric acid is the most convenient medium.

The proposed method gives reproducible results for uranium(VI) concentrations down to $2 \times 10^{-5}M$ if the DLPRE is used.

As an analytical example we deal with the determination of uranium(VI) in $1M$ sulphuric acid with an electrode prehydrogenated for 120 min as previously indicated ($E_{1/2} = -0·032$ V).

Depending on the nature of the interfering ions the hydrogenation of the electrode can be carried out previously or directly in the test-solution.

The effects of foreign ions on the determination of uranium(VI) are summarized in Table 2. Since the reduction of cadmium(II) occurs at $E_{1/2} \simeq -0·22$ V, it does not interfere if the electrode is previously hydrogenated. When the electrode hydrogenation is performed in the presence of chromium(III) and manganese(II), it is convenient to isolate the platinum counter-electrode from the solution to avoid the formation of dichromate and permanganate ions, which, by oxidizing the H_{ads}, prevent the appearance of the reduction wave of uranium(VI). The reduction of titanium(IV) takes place at about $-0·18$ V and does not interfere. Silver(I) gives a cathodic wave due to reduction to metallic silver ($E_{1/2} \simeq +0·3$ V) and if the electrode hydrogenation is performed in its presence a black deposit of metallic silver forms. Fluoride shifts the cathodic wave of uranium(VI) to more positive potentials, but owing to its corrosive effects, it was not further investigated. The half-wave potentials of copper(II), molybdenum(VI) and bismuth(III) are close to that of uranium(VI) and consequently these species interfere.

*$E_{1/2}$ for reduction wave of Ce(IV) $\simeq +1·1$ V.

†$E_{1/2}$ for reduction wave of Fe(III) $\simeq +0·4$ V.

‡ Only on prehydrogenated electrode.

§$E_{1/2}$ for reduction wave of V(V) $\simeq +0·7$ V.

Rotating platinum electrode. The use of the rotating platinum electrode gives the same results as the DLPRE, if previously hydrogenated (Fig. 5). The wave-heights are strictly proportional to the uranium concentrations and the sensitivity of the method is increased by about an order of magnitude, allowing the determination of uranium(VI) down to $3 \times 10^{-6}M$.

Recommended procedure. Perform the determination with nitrogen bubbling through the solution. Pretreat the working electrode as previously indicated, in 40 ml of $1M$ sulphuric acid. Replace 15 ml of the acid with 15 ml of deaerated test-solution. Record the polarogram of the solution over the potential range from $+0·20$ to $-0·30$ V at a scan-rate of 60–120 mV/min. When the rotating platinum electrode is used, it should rotate at about 800 rpm. Determine the uranium(VI) by the standard addition

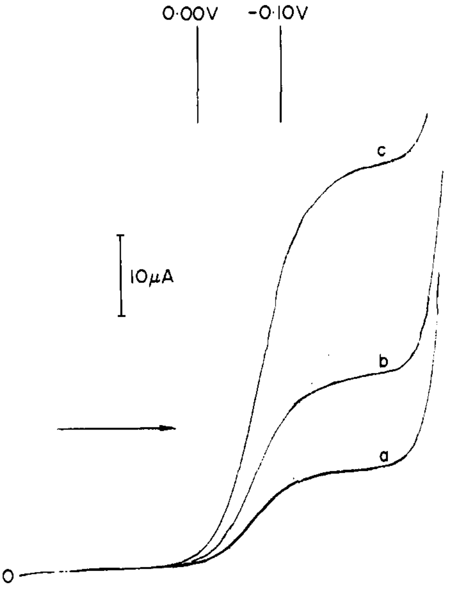

Fig. 5. Voltammograms (hydrogenated RPE) of 5 × $10^{-5}M$ (a), 1 × $10^{-4}M$ (b) and 2 × $10^{-4}M$ UO_2^{2+} in 1M H_2SO_4.

method. Amounts of 0·2–9·5 mg of uranium(VI) were determined with a relative standard deviation of 2·8–0·3% and a relative error of 2·1%.

Simultaneous voltammetric determination of uranium(VI) and uranium(IV)

The electro-oxidation of uranium(IV), at a platinized platinum microelectrode in strongly acidic solutions, has already been reported.[6] A smooth platinum electrode, hydrogenated according to the present paper, enables the oxidation wave of uranium(IV) to be obtained. The two methods differ in the half-wave potential of the oxidation process: in 1M sulphuric acid $E_{1/2}$ = +0·575 V for the platinized electrode, and +0·910 V for the smooth hydrogenated electrode; logarithmic analysis of the ascending part of the wave yields a straight line with slope of 85 mV, compared with 130 mV previously found.

The present method offers the following advantages over the preceding one: (*a*) a simplified procedure because platinizing is unnecessary (appreciable improvement in the analysis of radioactive samples); (*b*) removal of the interference due to vanadium(IV), since it does not take place on the smooth electrode;[19] (*c*) direct determination of uranium(IV) in the presence of small amounts of iron(II) ($E_{1/2}$ = +0·45 V).

From the foregoing it is possible to perform a simultaneous determination of uranium(IV) and (VI) in strongly acidic media, for which no literature references have been found.

In Fig. 6 is shown the voltammogram of 1·30 × 10^{-3} M uranium(VI) and 9·20 × $10^{-4}M$ uranium(IV) in 1M sulphuric acid; it was obtained with a smooth electrode (DLPRE), prehydrogenated for 120 min, the applied potential changing from −0·275 to +1·20 V at 30 mV/min.

Because of the electro-oxidation of H_{ads} at the potential needed for the oxidation of uranium(IV) (> +0·85 V), the determination must be performed by means of calibration curves. The recommended procedure is similar to the preceding one, but as a precaution the potentials are run from negative to positive; the scan-rate can be increased up to 120 mV/min. The rotating platinum electrode gives the same reproducible results.

TRACE CHARACTERIZATION OF POWDERS BY ATOMIC-ABSORPTION SPECTROMETRY

THE STATE OF THE ART*

B. V. L'vov

Department of Analytical Chemistry, Polytechnical Institute, Leningrad, U.S.S.R.

(*Received* 3 *June* 1975. *Accepted* 10 *June* 1975)

Summary—A review is made of the progress achieved in the last 15 years in the field of trace characterization of powders by direct atomic-absorption spectrometry. The studies covered include the development of novel atomization devices, modification of existing atomic-absorption spectrometers, and the use of closed-cavity vaporizers. A description is given of the capsule-in-flame and circular-cavity furnace type atomizers designed on this principle, of the procedure employed in powder-sample analysis and of some analytical features of the methods used. In conclusion, various modern analytical methods are compared as to the possibilities they offer for the determination of ultratraces in solids, and suggestions are made concerning the possible role of atomic-absorption spectrometry.

Direct trace characterization of various powder materials is undoubtedly one of the most urgent, and at the same time most complicated, problems in atomic-absorption spectrometry and analytical chemistry. This problem has been the subject of continuous study in our laboratory for about 15 years, but only now can we be satisfied that promising ways for its solution finally appear to be seen.

In this work we will consider briefly the most important steps made in this direction in the past, and we will then try to review the progress achieved in some areas of interest, including the most recent achievements. In conclusion we will discuss the role of atomic-absorption spectrometry among other methods of instrumental analysis in the solution of this problem.

METHODS OF ATOMIZATION OF POWDERED SAMPLES

Using the conventional technique of atomic-absorption analysis of liquids[1] for direct trace characterization of powdered samples is impossible primarily because of the inapplicability of the nebulizer-flame type atomizer for these purposes. Although attempts of this kind involving the pulverization of the powder mixed with solid propellant,[2] delivery of the powder to the burner channel by a miniature spiral conveyor[3] or nebulization of a suspension[4] were undertaken, no definite achievements were claimed.

We believe such a technique to be in principle inadequate for a total solution of this problem, on the following grounds. First, the absolute limits of detection of elements in the flame are too high to provide the desirable detection limits for impurities in powders. Indeed, in order to reach a relative detection limit of $10^{-6}\%$ by means of high-temperature flames (for which the average absolute limit of detections of elements is about 10^{-8} g/sec), the powder sample should be introduced into the flame at a rate of about 1 g/sec, which is inconceivable on both technical and economical grounds (the material being frequently quite expensive). Secondly both theoretical[5,6] and experimental[7–9] studies show that sufficiently complete vaporization of aerosol particles of medium- and low-volatility substances in a flame requires thorough grinding of the powder to a size below 1 μm. This operation is complicated and time-consuming and carries the risk of contaminating the sample during the pretreatment. Therefore the only practicable means of vaporization of powder samples remains up to now the use of the graphite furnaces of various types employed widely in the emission analysis of powders.

Another aspect of the problem of developing an atomizer capable of determining as large a number of elements as possible, consists in providing conditions favouring the existence of the sample vapour in the atomized state in the analysis zone (analytical cell). Experiments show that this may be achieved by employing either a hot inert medium inside the furnace or a high-temperature flame. Thus one may conceive at least two different types of atomizer, using

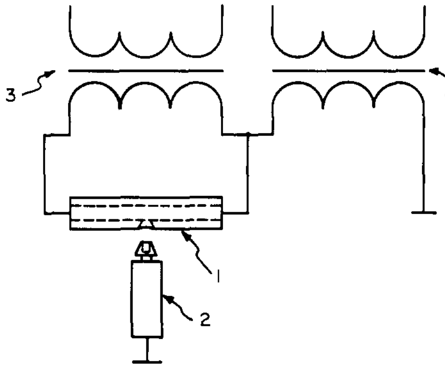

Fig. 1. Graphite cuvette. 1. Graphite tube furnace. 2. Graphite electrode with sample. 3. Step-down transformer (3 kW). 4. Step-down transformer (1 kW).

the graphite vaporizer in combination with either a furnace or a flame.

The first type of atomizer based on an independently heated graphite electrode with the sample, combined with a graphite-tube furnace (the graphite cuvette), was described in 1959.[10,11] Electrode-heating with a d.c. arc, used in the initial version,[10–12] was later replaced by a simpler and more effective a.c. heating with a step-down transformer (Fig. 1).[5,13] The second conceivable type of atomizer, utilizing the combination of a graphite rod with a Mèker burner, was realized in 1969 (Fig. 2).[14] Replacing the air–acetylene flame employed in the first experiments[14] by the nitrous oxide–acetylene flame[15] permitted extension of this method to the determination of elements of low- and medium-volatility.

While the two atomizers are primarily applied in the microanalysis of dry residues from liquid samples, they have also been used in the analysis of powders. Powder samples were placed in the channel of a graphite electrode introduced into a graphite furnace,[5,6,16–20] or in the channel of a graphite rod mounted in the flame.[14,20]

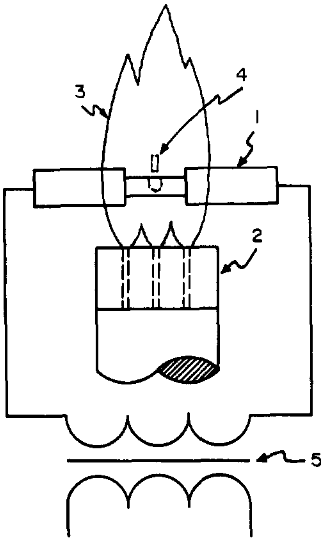

Fig. 2. Furnace-in-flame atomizer. 1. Graphite rod with sample. 2. Mèker burner. 3. Flame. 4. Cross-section of light beam. 5. Step-down transformer (3 kW).

Later, several other powder atomizers, representing modified versions of the cuvette or the furnace-in-flame type were described. The atomizers of the first type are vertical-crucible[21–30] and horizontal-tube furnaces[31–34] heated by a.c.[21–24] or rf[25–30] current, while those of the second type utilize the method of vaporization of powder samples from an iron screw[34,35] into the flame of a slot-burner, and the method of vaporization of solid samples from a graphite microprobe[36] introduced into the flame of the Mèker burner. In contrast to the graphite cuvette and the furnace-in-flame types, in the case of these atomizers[21–36] vaporization of the sample and heating of the analytical zone are performed by a single heater. This not only limits the possibility of separate control of the sample-vaporization regime and of the temperature in the analytical zone in order to ensure optimum conditions for the analysis of particular samples, but also does not provide the temperature required for the atomization of many medium- and low-volatility elements. Therefore despite the successful utilization of these atomizers for the solution of some problems in the area of powder analysis, they are still inferior to the cuvette and the furnace-in-flame in terms of power of detection and range of elements determined.

MODIFICATIONS TO ATOMIC-ABSORPTION SPECTROMETERS

The application of the cuvette and the furnace-in-flame atomizers for the analysis of powder samples entailed considerable changes in the design of other typical units of the atomic-absorption spectrometers used, *viz.* the recording system, optical system and light sources. The reasons for this are as follows.

First, in contrast to affairs in the conventional flame version of the method, the absorption signal resulting from a powder sample vaporized by means of the atomizers described above may represent a pulse of a fairly arbitrary shape with several peaks (Fig. 3). As shown in 1968,[37,38] the only parameter of such a signal which is connected unambiguously with the content of the element in a sample is the pulse area, *i.e.*, the integrated absorbance.

$$Q_A \equiv \int_0^{\tau_1} A\,dt \qquad (1)$$

measured during the total time τ_1 of vaporization of the element in question. This quantity is proportional to the total number of atoms of the element η_0 in the sample and the average time of residence of the atoms τ_2 in the analytical cell:

$$Q_A = A_0\tau_2 \propto \eta_0\tau_2. \qquad (2)$$

The magnitude of A_0 is actually the absorbance for the hypothetical case in which all atoms of the element in question which passed through the analytical

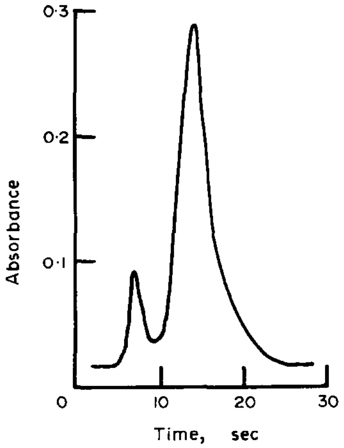

Fig. 3. The recording of an absorption pulse for the Sb 231·1 nm line with antimony vaporized out of graphite powder with a furnace-in-flame atomizer.

cell are considered to be residing in it at the same time.

The pulses can be integrated either by weighing the parts of the chart corresponding to the area of the pulses recorded by a recording potentiometer, or by using electronic integrating devices. The latter method possesses higher precision and speed.

Secondly, the determination of low concentrations of an element in the presence of an excess of the concomitant components in the sample has specific features associated with the appearance of considerable non-selective optical interference resulting from partial scattering and molecular absorption of the light-beam by the vapour of the matrix. The substantial role of this interference in the case of the graphite cuvette was pointed out even in the very first works on the subject.[11,12] The author[5] proposed a method for their automatic correction involving simultaneous recording of absorption from light-sources emitting line and continuum radiation (Fig. 4). This suggestion was based on the work by Koirthyohann and Pickett[39] who employed successive measurement of absorption of light from the same two sources to correct for non-selective interference in the flame. The research carried out by the author and his co-workers[40,41] serves as a basis for the further realization of the method of correcting for non-selective interference in commercial spectrometers.[42]

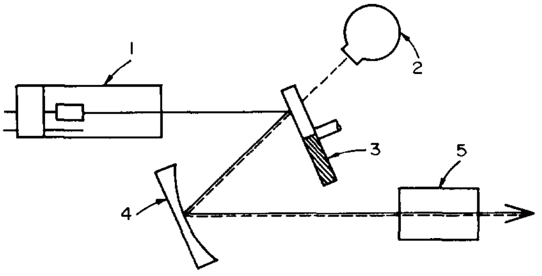

Fig. 4. Deuterium background corrector. 1. Hollow-cathode lamp. 2. D_2-lamp. 3. Rotating chopper. 4. Mirror. 5. Absorption cell.

The third feature which is primarily specific for the cuvette consists in a limited aperture of the traversing light-beam (as compared to the flame) and a strong continuum background from the hot furnace walls. These factors result in a considerable increase of noise in the recording, *i.e.*, in deterioration of the capability of low-level signal detection. The most efficient way to sidestep this limitation lies in the use of brighter light sources.

With this purpose in mind, Kirillova, Levikov and L'vov[5] used spherical radiofrequency lamps (Fig. 5) of the type employed for the optical pumping of lasers.[43] At present, a wide assortment of such lamps suitable for the analysis of more than 30 elements is manufactured in the USSR.[44]

To increase the brightness of conventional hollow-cathode lamps, Bodretsova, L'vov and Mosichev[5,45] proposed to use radiofrequency (60 MHz) rather than d.c. current for the lamp-supply. Later, Dawson and Ellis[46] showed that the same effect can be attained by feeding the lamps with a high-amplitude pulsed current of a few hundred Hz frequency. A comparative study[47] of the characteristics of hollow-cathode lamps supplied with pulsed and continuous currents revealed considerable advantages of the pulsed-power supply when the graphite cuvette was used. Owing to their relative simplicity and versatility, both these techniques turned out to be preferable to using the boosted-output lamps proposed earlier by Sullivan and Walsh.[48]

The brightness of the light-sources chosen as a result of these studies, *viz.* of the spherical radiofrequency and hollow-cathode lamps supplied with rf or pulsed current, exceeds, on the average, by two orders of magnitude that of the d.c. hollow-cathode lamps, and in most cases turns out to be sufficient for practically complete elimination of interference originating from the hot furnace and for compensation for the loss of light in its passage through the cuvette.

LIMITATIONS OF CONVENTIONAL METHODS OF POWDER VAPORIZATION FROM THE CHANNEL

At the beginning of the 70's we not only possessed two essentially different atomizers capable of atomizing powder samples but also had at our disposal quite efficient means of recording absorption signals of arbitary shape against the strong non-selective interference from the matrix and radiation interference

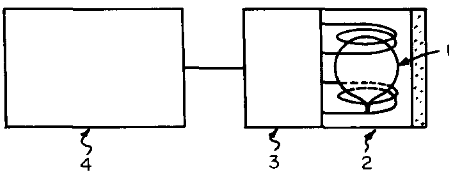

Fig. 5. High-intensity line-source with a spherical electrodeless lamp. 1. Lamp inside an RF-coil. 2. Protective screen. 3. Radio-frequency generator. 4. Power supply.

from the graphite heaters. However, despite the fact that both atomizers were successfully utilized for the analysis of some powder materials,[49] the general state of the art could hardly be considered satisfactory.

Indeed, the application of both atomizers was limited to cases of determining highly-volatile elements in less volatile material where fractional vaporization of impurities could be used. Pulse vaporization of medium-volatility and low-volatility elements from volatile matrices resulted in uncontrollable losses from the sample because of swelling and ejection of the powder from the channel as a result of violent liberation of vapours produced by highly-volatile components present in the sample.

Another serious drawback of both atomizers consisted in their capacity being limited to samples of only a few mg in weight, because of inefficient heating in the vaporizer channel. This produced an adverse effect on the representativeness of sampling and the relative limits of detection.

Both these drawbacks are to a certain extent inherent in all vaporizers used in practical spectral analysis where the vaporized sample is delivered to the analytical zone through a hole provided for this purpose over the cavity with the sample. Therefore they could be eliminated only by designing a vaporizer of a completely new kind which would preclude the possibility of uncontrollable mechanical losses of the sample from the cavity while at the same time providing efficient heating and transport to the analytical zone of much larger amounts (up to a few tens or even hundreds of mg) of the substance being analysed.

As frequently happens, the solution to this problem was quite close. Indeed, every experimenter working on emission spectral analysis is familiar with the phenomenon of partial diffusion of the sample vapour through the walls of graphite electrodes.[50] We also try to overcome this drawback of graphite in atomic-absorption measurements with graphite furnaces. For example, to eliminate vapour losses caused by diffusion through the walls of the graphite cuvette, the walls were lined with tantalum or tungsten foil,[13] and later the walls were coated with pyrolitic carbon impermeable to gas.[5]

The essence of the solution to this problem found and realized by the author together with Katskov and Kruglikova[51,52] consisted of vaporizing powder samples in a closed cavity with graphite walls permeable to gases (Fig. 6). The porosity of the graphite used as material for the heater now changed from a drawback to an advantageous property. It should be noted that using this property of graphite in analytical work is not novel. Indeed, there are reports on the application of graphite capsules for the extraction of gases from metals,[53] and of porous graphite partitions to separate the zones of sample vaporization and excitation in the hot hollow-cathode discharge.[54,55]. Nevertheless, the problems solved in those works appear to be much more modest than the one that faced us.

THE DESIGN OF ATOMIZERS INVOLVING SAMPLE VAPORIZATION FROM A CLOSED CAVITY

To apply the proposed principle of vaporization in practical work, it was necessary to design heaters for the furnace-in-flame and cuvette atomizers combining the use of large samples, fast and complete vaporization of the element of interest from the sample, and efficient use of the sample vapour for measuring absorption, with simplicity of the analytical procedure and reliability of the equipment. As a result of comparison of various solutions to this problem, the following atomizer designs were chosen.

The furnaces used in the furnace-in-flame atomizers are ordinarily hollow cylinders (capsules) aligned along the spectrometer optical axis (Fig. 7). The effective volume of the cavity can be varied from 45 to 60 mm^3 by changing the diameter. Owing to the large ratio of the heated surface of the sample to its volume, such a shape of capsule ensures fast and uniform heating and vaporization of samples at a maximum rate of vapour diffusion through the furnace walls. The sample vapour emerging from the capsule walls is carried by the laminar flow of the flame gases and enters the analytical zone through which the light-beam passes.

The material chosen for the capsules was fine-grained graphite combining satisfactory gas permeability (0·5–0·9 cm^2/sec) with high mechanical strength and purity.

The capsule with the sample is mounted horizontally between two cylindrical graphite washers with holes for passing the light-beam above the capsule. The washers serve to deliver current from a step-down transformer and preclude the ejection of material during vaporization. The washers are set inside water-cooled holders. To facilitate replacement of capsules and to exclude the possibility of their deformation because of expansion of the graphite, one of the holders is spring-loaded and can be moved along the optical axis.

The burner with the flame can be shifted in the direction perpendicular to the optical axis. The burner has interchangeable nozzles of the Méker type with 60 holes and can be used with the acetylene–air or acetylene–nitrous oxide flame. The actual choice of flame, just as in the case of element-determination in solution, depends on the volatility of the metal and the thermal stability of the compounds forming in the course of vaporization. To prevent oxidation of the capsules, a reducing flame is used. The total gas flow-rate does not exceed 6 l./min. There is no danger of the flame striking back at any combination of the component flow-rates. The general view of an atomizer stand is shown in Fig. 8.

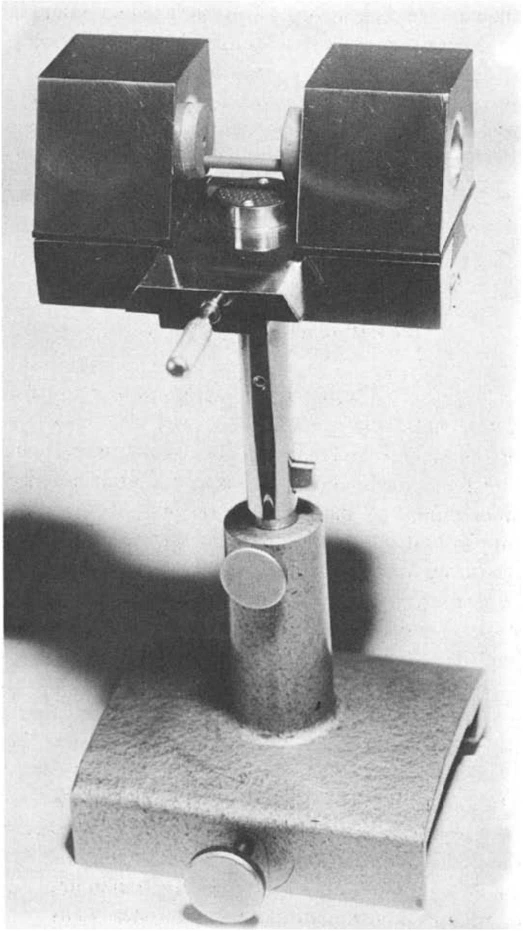

Fig. 8. Stand for the capsule-in-flame atomizer.

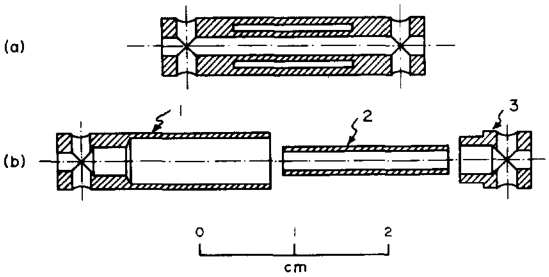

Fig. 9. Circular cavity furnace; (*A*) assembled, (*B*) dismantled. 1. Casing. 2. Inner tube. 3. Stopper.

The furnace with a circular cavity[51] turned out to be the simplest and most efficient combination of the graphite cuvette with a new kind of vaporizer. The furnace consists of a casing, a tube and a stopper (Fig. 9). The sample to be analysed is placed in a circular cavity about 1 mm wide between the casing and the tube. The total volume of the circular cavity is about 150 mm^3. When the furnace is heated, the vapour of the sample passes through the porous walls of the inner tube (made of porous graphite) and enters the analytical zone traversed by the light-beam. Thus the direction of motion of the sample vapour in this case is to some extent opposite to that from the cavity to the analytical zone in the capsule-in-flame atomizer.

To exclude partial loss of vapour through the outer furnace walls, the casing and the stopper are made of uniform pyrolytic carbon impermeable to gases. To preclude the vapour emerging from the furnace from condensing on the graphite washers, transverse holes are cut at the ends of the furnace, through which the vapour is forced by convection to flow in the vertical direction.

The dimensions of the circular-cavity furnace are chosen so as to make it interchangeable with the capsule. To minimize the oxidation of the outer furnace walls, reducing flames can be used, just as in the case of the furnace-in-flame atomizer, or an argon sheath can be used. In the latter case, the furnace can be isolated still more effectively from the atmosphere by shielding the space between the holders with a protective screen.

Note that although the same heater is used here both for sample vaporization and for maintaining the analytical zone at a high temperature, the design of the circular-cavity furnace, because of the different heat capacities and thermal insulation of the inner and outer tubes, provides a possibility of heating the inner zone before the vapour to be analysed starts to enter it, conditions which are optimal for complete dissociation of thermally stable oxides.

ANALYTICAL PROCEDURE

In most cases where these atomizers are used for analysis of solids it is expedient to mix the sample with graphite powder. By preventing the sample in the cavity from melting or sintering into a bead, the presence of graphite thus provides a faster and more complete vaporization of impurities. In the case of low-melting matrices graphite reduces the possibility of direct leakage of the melt through the vaporizer walls. Besides, in the powder analysis graphite acts as a diluting agent (similar to the solvents used when analysing solutions) thus permitting the sample to be brought to the optimum mass.

Grinding the sample and simultaneously mixing it with graphite can be conveniently performed with a laboratory-type vibrating mill with several containers 100 ml in volume mounted on it. The containers and the grinding balls are made of "Plexiglass" to reduce the contamination hazard. The procedure of grinding and mixing takes about 5–10 min. When determining abundant elements, one should first run a blank analysis on pure graphite to check for possible contamination of the ground sample by impurities present in "Plexiglass" or remaining on the surface of the balls and of the container because of incomplete cleaning after the previous samples.

The samples are loaded into the capsules by means of the device shown in Fig. 10. The capsule (after a preliminary burn-cycle), or the circular-cavity furnace with the stopper removed, is mounted in the holes of a stand fixed onto an electromagnetic vibrator. A preset amount of the ground material is placed with a measuring scoop of about 40 mm^3 capacity into a "Plexiglass" funnel. When the vibrator is turned on, the material will uniformly fill the cavity. The upper part of the capsule cavity (not less than 3–5 mm) is then filled with pure graphite powder, preventing the sample from coming into contact with the graphite washer.

The capsule thus prepared is fixed between the graphite washers on the atomizer stand, and the measurements are begun. The flame is moved under the capsule, and the heating is turned on. The integrated absorbance is measured by means of an electronic integrator. The integration time is chosen in advance in accordance with the volatility of the element of interest and the vaporizer heating power selected. On completion of the absorption pulse integration, the heating is switched off and the flame moved aside. After cooling, the capsule is taken out of the atomizer stand and the next capsule with the sample is put in place. The capsule should be cleaned from the remains of the sample and subsequently ignited, after which it may again be used in the analysis.

This procedure of sample loading and absorbance measurement refers equally to the circular-cavity furnaces, the only difference consisting in the possible use of a weak argon flow as a shielding atmosphere for the furnace.

With the heating power limited to 1 kW for the capsule and 2 kW for the circular-cavity furnace, each is capable of withstanding several tens of measurements.

THE ANALYTICAL CHARACTERISTICS OF THE METHODS

Elements determined

A list of elements determined with the capsule-in-flame atomizer[52] is presented in Table 1. The high efficiency of heating and vaporization of material placed in the capsule enables reliable determination of

of such low volatility elements as titanium, vanadium, molybdenum and silicon, which boil at temperatures in excess of 3500° to be carried out. The time needed to extract an impurity, depending on its volatility and heating characteritics, varies from a fraction of a second to a few tens of seconds. As an illustration, Fig. 11 presents recordings for titanium determined in various materials at a maximum allowable power of 2·6 kW. A further increase of capsule heating power in order to determine elements forming the most thermally stable carbides (hafnium, niobium, tungsten and so on) turns out to be impossible because of the fast burn-out of the capsule. From the data available, about 50 elements can be determined in this way.

The range of elements that can be determined with the circular-cavity furnace is more limited (Table 2). This is due to the lower limiting temperature to which the circular cavity can be heated compared with that for the capsule cavity. It may be assumed that 30–40 elements can be determined with this atomizer.

Materials analysed

Tables 3 and 4 give lists of materials which have been analysed with the capsule-in-flame atomizer.[52] It includes chemical reagents, rocks, metals, slags, semiconductors, carbon and graphite materials. Non-selective spectral interference is not an obstacle to analysis provided it is corrected for automatically. Experimental determinations of impurities in substances of organic nature (biological material, tissue, paper, technical oil, etc.) did not reveal any sample loss during the preliminary pyrolysis of organic substances in the capsule cavity, so the method can be extended to these materials.

The circular-cavity furnace has so far been used only to determine impurities in graphite powder[51] and in silica. However, the method can apparently also be employed as successfully in other cases where the volatility of the impurities of interest exceeds by far that of the major components of the matrix. The possibility of extending the method to volatile materials is limited by the extremely strong non-selective absorption of the light-beam after partial vaporization of the matrix. This may result in a practically complete absorption of the light-flux.

Table 4. Trace characterization of powder samples by different methods

Material	Element determined	Result of chemical or spectral determination, %	Result of AA-analysis (capsule-in-flame), %
Open-hearth slag*	V	$4{\cdot}5 \times 10^{-2}$	$4{\cdot}0 \times 10^{-2}$
Open-hearth slag*	P	$4{\cdot}3 \times 10^{-1}$	$4{\cdot}5 \times 10^{-1}$
Manganese ore*	Co	$4{\cdot}0 \times 10^{-3}$	$5{\cdot}0 \times 10^{-3}$
Zirconium dioxide*	Sb	$1{\cdot}2 \times 10^{-4}$	$1{\cdot}4 \times 10^{-4}$
Fusible quartz	Au	$1{\cdot}4 \times 10^{-4}$	$1{\cdot}6 \times 10^{-4}$
Granite gneiss	Co	$1{\cdot}0 \times 10^{-4}$	$0{\cdot}9 \times 10^{-4}$
Tantalum	Fe	$5{\cdot}0 \times 10^{-2}$	$4{\cdot}0 \times 10^{-2}$

* Standard samples

Sensitivity and detection limits

The absolute amounts of elements corresponding to integral values of 1% absorbance in 1 sec are presented in Tables 1 and 2 for both atomizers. A comparison of these data with the corresponding data[49] available for the furnace-in-flame atomizer and the graphite cuvette shows them to be in good agreement, thus indicating that replacing the conventional vaporizer (the channel with a hole) by a closed-cavity type did not reduce the absolute sensitivity of the two methods. This is equally true for a comparison of the absolute detection limits provided by the modified and original atomizers.

At the same time, the possibility of using 10–100 times larger samples than previously possible[5,14] permits the relative sensitivity and relative power of detection to be raised by this factor. The recording (Fig. 12) of the determination of cadmium in silica at the level of $7 \times 10^{-8}\%$ illustrates the inherent capabilities of the circular-cavity furnace.

Calibration and accuracy

As noted above, measuring the absorbance Q_A permits, in principle, exclusion of the effect of the kinetics of liberation and transport of the analyte to the analytical cell, on the results obtained. The necessary requirements to be met here are the completeness of extraction of the element from the sample, constant time of residence of the atoms in the analytical cell and a linear dependence of absorbance on the atom concentration n over the range of variation of n in the course of vaporization of the element.

If the conditions above are satisfied, the spectrometer readings can be calibrated by means of any substance containing a known amount of the element to be determined, including pure solutions transferred into the capsule or the circular cavity. The calibration method which was found to be most convenient from the practical standpoint involves the use of several standards of graphite containing the elements of interest in the range 10^{-3}–$10^{-7}\%$ (for the circular-cavity furnace additional standards with impurity contents down to $n \times 10^{-9}\%$ were prepared).

The correctness of the analyses performed with this calibration technique was checked many times on samples with known impurity content. As an example, Table 4 presents the results of such a comparison obtained with the capsule-in-flame atomizer.

The most serious sources of systematic error may come from incomplete extraction of the element in question in the course of fractional vaporization of impurities from a sample, and from deviation of the $A = f(n)$ relationship from linearity. The effect of the first of these sources of error can be revealed and eliminated by increasing the vaporizer heating rate, while that of the second can be readily eliminated by reducing the heating power to the level at which the maximum values of A remain within the range of linearity between A and n. It should be noted, however, that the effect of non-linearity on the value of Q_A is always much smaller than in the case of pulse-peak recording.[38]

Precision

The scatter of the measurement data about the mean value, for both methods, is mainly associated with non-homogeneous distribution of the element of interest in the powder sample. For instance the relative standard deviation of determination of 3×10^{-7} g of lead with the capsule-in-flame atomizer was 4% when samples were taken from an aqueous solution of lead nitrate by means of a micropipette (sampling error 2·5%). When lead was determined in standard powder samples prepared by repeated dilution of the original standard ($3 \times 10^{-3}\%$ lead) with pure graphite powder, the relative standard deviation was 8% for a sample with $1 \times 10^{-3}\%$ lead, and 14% for a sample with $3 \times 10^{-4}\%$ lead.[56]

Taking into account the decisive effect of sample inhomogeneity on the precision, sample-weighing can be replaced by the faster and simpler method of taking a fixed volume of powder. The error of volume-sampling is about 4%[56] at a scoop capacity of 40 mm^3. One should, of course, consider possible differences between the apparent density of the mixture to be analysed and that of the standard (pure graphite).

Thus, on the average, at element contents 10–20 times the detection limit, the relative standard deviation is 5–10% for a homogeneous sample. For samples with inhomogeneous impurity distribution the error increases.

The precision reached with the circular-cavity furnace is, on the average, the same.

Speed of analysis

In the determination of elements in several samples, the major part of the time is taken up by the preparation of the substances to be analysed and their

Table 5. A comparison of instrumental methods for direct determination of impurities in powder samples*

† With a sample of 1–10 g irradiated for 1 hr by a thermal neutron flux of $1{\cdot}8 \times 10^{12}$ n.cm^{-2}.sec^{-1}.

loading into the vaporizer cavity. We have succeeded[52] in cutting down this time by grinding and loading several samples at a time. Thus, determination of 10 elements in 10 samples, with use of an electronic integrator, takes 5 hr, including the time needed to prepare and load the samples, to change hollow-cathode lamps, and to set the chosen analytical lines, so the mean time taken for one determination is 3 min.

THE STATE OF THE ART

The problem of direct trace and ultratrace characterization of powder samples is solved in modern analytical chemistry more or less successfully by several methods of instrumental analysis, among them emission optical spectroscopy, activation analysis and mass spectrometry.[57–63] It is instructive to compare the methods of atomic-absorption analysis described in this work, in particular its more versatile version employing the capsule-in-flame atomizer (CF–AAS) with the methods above. Of the various methods used in activation, optical emission and mass spectrometric analysis we will choose for our comparison the most efficient versions, *i.e.*, neutron activation (NA), emission spectrography with a d.c. carbon arc (DCA-ES) and spark-source mass spectrometry (SS–MS). The most essential characteristics of these methods are compared in Table 5.

The most promising results in the trace characterization of powder samples are undoubtedly obtained in spark-source mass spectrometry and especially in neutron-activation analysis, the latter providing non-destructive analysis of the samples with the maximum representativeness of sampling. The methods of optical emission and absorption spectroscopy are inferior both in the number of the elements covered and in the power of detection. (An exception is the circular-cavity furnace, which has potential detection-limit capabilities which in some cases considerably exceed those of the non-optical methods.)

At the same time, in some respects optical spectroscopy may turn out to be preferable to the non-optical methods. For example, the relative simplicity of the equipment and procedure in spectral analysis makes this easy to learn and operate by personnel of medium and low qualification, and the cost of the equipment is moderate, *i.e.*, $10,000–20,000 for the optical as compared with $50,000–100,000 for the non-optical methods. Note that it is these factors that are responsible for emission spectroscopy being more popular than the non-optical methods of analysis.

As for a comparison of the emission and atomic-absorption methods of analysis, one should bear in mind the following considerations. The most serious limitation of the atomic-absorption method which manifests itself most of all in the analysis of expensive high-purity materials is the impossibility of simultaneously determining a group of impurities of interest. At the same time, in speed and precision, as well as in the reliability of the simplified calibration techniques (*e.g.*, involving synthetic standards based on graphite powder) the atomic-absorption method possesses certain advantages over emission spectroscopy. This is associated with differences in the techniques of recording analytical signals (by photoelectric and photographic means) and with the much greater effect of the matrix on the conditions of atomization and spectral excitation in emission as compared with atomic-absorption spectroscopy.

The considerations above suggest that despite some limitations of the atomic-absorption method it should become no less popular in the trace characterization of powder samples than in other areas of analytical chemistry where the atomic-absorption technique has already gained recognition, *i.e.*, the determination of major components and of traces of elements in solutions, and in microanalysis. It will apparently find widest application in the research groups which are not directly connected with specialized analytical laboratories and which are therefore interested in solving their particular analytical problems without outside help.

Further progress in atomic-absorption spectroscopy depends to a considerable extent on the availability of commercial equipment to perform such analyses and further accumulation of experimental data supporting the capabilities of the method. One may hope that considering the present popularity of atomizers utilizing resistance furnaces in the field of microanalysis, the techniques described in the present paper will be recognized in the very near future.

Acknowledgements—The author expresses his gratitude to his colleagues Dr. D. A. Katskov and Mrs. L. P. Kruglikova who during many years participated actively in this

research and who shared with him all ups and downs in the work.

Résumé—La méthode décrite s'applique au microdosage du silicium dans les composés organosiliciés stables (solides ou liquides à faible tension de vapeur). Le composé contenant du silicium est pyrolysé dans une atmosphère d'azote chloré à 1100°, ce qui donne lieu à la formation quantitative de tétrachlorure de silicium qui passe en phase gazeuse. Séparé du chlore en excès par condensation dans un piège froid à $-78°$ suivie d'une évaporation fractionnée, le tétrachlorure de silicium (Eb = 56,8°) est injecté dans la flamme protoxyde d'azote–acétylène d'un spectrophotomètre d'absorption atomique. L'intégration de la variation de transmittance mesurée, en fonction du temps, fournit une valeur numérique qui permet de déterminer la masse de silicium contenue dans le prélèvement analytique. Les résultats obtenus sont satisfaisants.

Le dosage du silicium dans les composés organosiliciés n'a pas fait l'objet de nombreux travaux à l'échelle microanalytique; Reverchon et Legrand les ont brièvement rappelés.[1]

Diverses méthodes de "minéralisation" de ces composés conduisent à l'obtention du silicium à doser, combiné sous forme de silicates; ce sont, par exemple, la combustion dans l'oxygène, suivant la technique de Schöniger, soit en fiole de polyéthylène,[2] soit en fiole de nickel,[1] ou l'attaque par le peroxyde de sodium en bombe de Wurzschmitt.[3] En ce qui concerne le dosage du silicium dans les silicates ainsi formés, il semble qu'à l'échelle microanalytique la méthode la plus appropriée soit le titrage de l'ion silicomolybdique par colorimétrie spectrophotométrique.[1,3]

La spectrophotométrie d'absorption atomique semble également se prêter au titrage du silicium combiné sous forme de silicates, mais, malgré l'emploi de lampes à cathodes creuses alimentées par un courant de haute intensité et de flammes à protoxyde d'azote–acétylène, à hautes températures et fortement réductrices, l'application de cette méthode demeure des plus délicates du fait de sa faible sensibilité, surtout lorsque les solutions à titrer contiennent moins de 10 μg/ml de silicium, comme c'est le cas en microanalyse organique; c'est pourquoi, nous n'avons pu appliquer cette méthode classique, telle quelle, au microdosage du silicium dans les composés organiques.

Une possibilité d'augmenter la sensibilité du dosage du silicium par absorption atomique a été développée par Trudell et Boltz;[4] ces auteurs mettent en oeuvre la formation de complexe silicomolybdique, l'extraction de celui-ci, puis la précipitation du silicomolybdate par un excès de nitrate de plomb; le dosage du silicate se ramène ensuite au dosage, par absorption atomique, de l'excès de plomb restant.

Cette méthode permet de doser des quantités de silicium comprises entre 0,5 et 7 μg, à l'aide de courbes d'étalonnage, tandis que ces valeurs limites s'élèvent à 10 et 200 μg lorsque les solutions aqueuses d'ions silicates sont injectées directement dans la flamme du spectrophotomètre d'absorption atomique; elle oblige, cependant, l'opérateur à effectuer des extractions et des centrifugations successives, augmentant, de ce fait, la durée de la détermination et la rendant plus difficile à appliquer, en raison de la multiplicité des opérations qu'elle comporte.

Toutes les méthodes citées impliquent un traitement du silicate formé, après minéralisation, en vue de sa mesure quantitative, suivant divers principes d'analyse, ce qui conduit à un mode opératoire discontinu.

Afin de pouvoir appliquer directement le principe de l'absorption atomique au dosage spécifique du silicium à l'échelle microanalytique, il nous est apparu intéressant de combiner cet élément, initialement porté par une substance organique siliciée, dans une molécule gazeuse, grâce à une "minéralisation" appropriée. L'injection de ce gaz silicié dans la flamme du spectrophotomètre permet alors d'effectuer la mesure d'absorption sur la totalité des molécules siliciées contenant le silicium du prélèvement analytique alors qu'en solution aqueuse, la mesure n'est effectuée, pratiquement, que sur un dixième de cette quantité.

Nous avons choisi le tétrachlorure de silicium (point de fusion: $-68,3°$; point d'ébullition: $56,8°$) comme molécule gazeuse intermédiaire*.

La minéralisation correspondante est effectuée par pyrolyse des prélèvements des composés organiques siliciés dans une atmosphère chlorée†. Dans les composés oxygénés, le tétrachlorure de silicium peut se former à partir de la silice (qui peut être produite, intermédiairement), en présence de carbone et de chlore, suivant la réaction d'Oerstedt:[5]

$$SiO_2 + 2\,C + 2\,Cl_2 \rightarrow SiCl_4 + 2\,CO$$

Le carbone est, ici, engendré *in situ* par la pyrolyse de la substance organique.

Dans les composés non oxygénés, le tétrachlorure de silicium peut se former directement par chloration du silicium ou des silanes formés lors de la pyrolyse du prélèvement microanalytique.

PRINCIPE

Le prélèvement microanalytique (200–700 μg) est pyrolysé à 1100° dans une atmosphère d'azote chargée en chlore; la chambre de pyrolyse est, ensuite, balayée par un courant d'azote chloré, puis par de l'azote pur. Le tétrachlorure de silicium formé est condensé dans un piège refroidi à $-78°$ rempli de grains d'alumine frittée.

L'excès de chlore retenu dans le piège est séparé du tétrachlorure de silicium par élution dans un courant d'azote annexe; le tétrachlorure de silicium est volatilisé par réchauffage du piège, entraîné par le courant d'azote annexe et introduit dans la flamme protoxyde d'azote–acétylène du spectrophotomètre d'absorption atomique, après avoir traversé une garniture de laine d'argent sur laquelle il est préalablement débarrassé du chlore résiduel.

La transmittance du rayonnement de la lampe à cathode creuse, après absorption dans la flamme du spectrophotomètre d'absorption atomique, varie lors de la présence dans cette dernière, de silicium élémentaire provenant de la dissociation thermique du tétrachlorure de silicium. La variation de cette transmittance en fonction du temps est intégrée, dans l'intervalle de temps correspondant à la présence du silicium dans la flamme. L'expérience montre que le logarithme de la grandeur numérique obtenue par intégration varie linéairement en fonction du logarithme de la quantité de silicium (10 à 60 μg) initialement présent dans le prélèvement analytique.

PARTIE EXPERIMENTALE

Appareillage (Figure 1)

Dispositif de purification de l'azote. Un tube d'azote comprimé pourvu d'un manodétendeur alimente les deux circuits d'azote principal (chlorocarbopyrolyse de la substance) et annexe (injection du tétrachlorure de silicium dans la flamme du spectrophotomètre d'absorption atomique). Chacun des deux circuits est pourvu d'un régulateur de pression constitué par un tube en T plongeant à profondeur réglable dans une éprouvette remplie d'huile de vaseline pure à travers laquelle l'excès de gaz s'échappe dans l'atmosphère.

Afin d'obtenir de l'azote rigoureusement pur, il traverse dans chacun des deux circuits un tube purificateur (25, 8) garni de fragments de fils de cuivre obtenu par réduction d'oxyde de cuivre en "fils" portés à la température de 490° dans un four tubulaire (9, 26), puis un tube absorbeur (10, 24) comportant une garniture d'amiante sodée et de perchlorate de magnésium, assurant la rétention du dioxyde de carbone et de l'eau; le gaz traverse, ensuite dans chacun des circuits, un rotamètre (11, 23) dont l'un (23) est muni d'une vanne à pointeau‡ permettant un réglage fin du débit gazeux, la vanne (13) permettant le réglage du circuit d'azote chargé en chlore, et passe par une vanne à commande électromagnétique (12, 18).

Générateur de chlore. Le chlore est produit par électrolyse d'une solution de chlorure de sodium dans un mélange eau–acide perchlorique (volume à volume) entre deux électrodes de platine (plaques de platine de 200 mm^2 dont l'une est disposée dans un compartiment séparé de la solution par un verre fritté de porosité n° 4 et de surface égale à 10 mm^2).

Le chlore issue de l'électrolyseur (14) traverse un tube dessicateur à perchlorate de magnésium (15), puis est condensé dans un piège constitué par un tube en U de 6 mm de diamètre intérieur refroidi à $-78°$ par le système acétone–carboglace (16). Une heure d'électrolyse sous une intensité de 2 A permet de préparer la quantité de chlore nécessaire à une semaine de travail.

Le chlore, ainsi produit par électrolyse, est purifié par passage d'un courant d'azote pendant 30 mn dans le piège refroidi; l'azote chargé des impuretés du chlore se dégage dans une solution de soude par l'intermédiaire du barboteur (17).

Le courant d'azote passant à travers le piège se charge de 6% de chlore, en volume.

Tube à pyrolyse. Le tube à pyrolyse (3), en carbone vitreux de qualité V25§, a 750 mm de longueur et 15 et 19 mm de diamètres; son extrémité d'amont est ouverte et son extrémité d'aval, initialement fermée, est percée d'un orifice de 0,3 mm de diamètre; il est protégé de l'oxydation par l'air par un tube en silice transparente (4), de qualité étirée, de 26 et 22 mm de diamètres. Ce dernier comprend un évasement garni de polychlorure de vinyle permettant de réaliser, en amont, un joint étanche entre lui-même et le tube de carbone.

A cette fin, on introduit dans l'évasement une solution de polychlorure de vinyle (initialement en poudre) dans le tétrahydrofurane que l'on chauffe ensuite doucement afin d'évaporer le solvant.

Le tube à pyrolyse comporte 3 parties essentielles:

—une partie d'amont refroidie par un réfrigérant (7), de 100 mm de longueur, constitué par un bloc de laiton à double parois où circule un courant d'eau froide,

—une chambre à pyrolyse de 80 mm de longueur portée à une température de 1100° par un four électrique approprié (6),

—une chambre de réaction de 360 mm de longueur, portée par le four (5) à 1100°, contenant, dans sa partie d'aval, un tampon conducteur thermique de 50 mm de longueur constitué par une feuille rectangulaire de carbone "Papiex" (de 50 × 100 mm) enroulée sur elle-même, suivie

---

* En fait, il est possible que d'autres chlorures de silicium volatils se forment également au cours de la "chlorocarbopyrolyse" du prélèvement analytique, ci-après décrite, ce dont il sera fait état dans notre exposé. En vue d'en simplifier l'écriture, nous n'y citerons conventionnellement que le tétrachlorure de silicium.

† Nous proposons de dénommer *chlorocarbopyrolyse* le traitement d'un prélèvement analytique, en atmosphère de chlore (avec ou sans addition de charbon), visant à l'obtention du chlorure d'un élément initialement combiné dans la substance inorganique ou organique de ce prélèvement, en vue de son dosage.

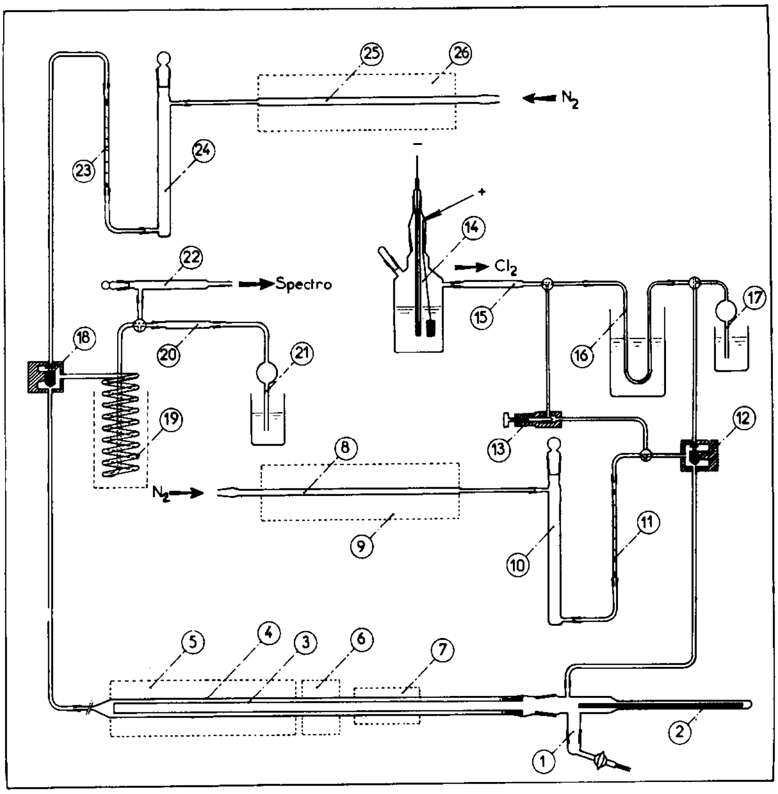

Fig. 1

d'une garniture de feutre de carbone[*] de 150 mm de longueur qui se sature superficiellement de chlore, lors du passage du courant d'azote chloré.

Le tube à pyrolyse est complété par un système à poussoir (2) d'introduction de la nacelle porteuse du prélèvement analytique dans la chambre de pyrolyse; il est constitué par un barreau cylindrique de carbone, de qualité spectrographique de 8 mm de diamètre. A son extrémité d'amont, le barreau est percé et fileté, ce qui permet d'y introduire, de fixer et de protéger par un bouchon de carbone fileté un aimant cylindrique de fer doux; son extrémité d'aval est creusée de façon à constituer une cavité cylindrique coaxiale servant de logement aux nacelles de platine, porteuses des prélèvements analytiques.

Le tube à pyrolyse comporte, en outre, un dispositif de balayage débouchant dans l'atmosphère par un ajutage à robinet s'adaptant par un rodage conique à l'orifice d'introduction de la nacelle (1) et permettant de balayer l'air, introduit en même temps que le prélèvement analytique dans ladite nacelle de platine, à l'aide du courant d'azote principal.

Condensation du tétrachlorure de silicium. A la sortie du tube à pyrolyse, le tétrachlorure de silicium est condensé dans un piège en verre "Pyrex" (19), plongé dans un bain à −78° constitué par le système acétone–glace carbonique. Ce piège est un serpentin, réalisé avec une canne de 150 mm de longueur et de 9 et 6 mm de diamètres, enroulé en hélice autour d'une branche verticale; il est rempli d'alumine frittée (qualité ALCEL[†]) de granulométrie 20–30 mesh, préalablement calcinée à 1000° pendant 2 hr.

Un enroulement chauffant constitué par 8 m de fil de cuivre de 0,35 mm de diamètre bobiné sur le piège parallèlement à son axe vertical et alimenté sous 10 V, permet de réchauffer celui-ci en vue d'évaporer le tétrachlorure de silicium.

Rétention du chlore. Entre le piège et le spectrophotomètre d'absorption atomique est disposé un tube purificateur (22) de 8 et 11 mm de diamètres et de 150 mm de longueur, rempli de laine d'argent,[‡] qui absorbe le chlore résiduel, susceptible de rester mélangé au tétrachlorure de silicium, avant l'injection de ce dernier dans la flamme du spectrophotomètre. Les barboteurs (17 et 21) permettent d'absorber le chlore en excès balayé par l'azote, dans une solution alcaline (soude 6*N*).

Vannes électromagnétiques à commande automatique programmée. Les vannes électromagnétiques (12 et 18) à trois voies sont commandées par des minuteries Crouzet dont les temps sont réglables. La vanne (18) permet de balayer le piège (19) soit par le courant gazeux principal sortant du tube à pyrolyse, soit par le courant d'azote annexe.

Appareillage de mesure

Spectromètre d'absorption atomique (Unicam SP90 série 1) avec une lampe à cathode creuse au silicium (intensité: 6 mA; largeur de fente: 0.08 mm; longueur d'onde 2516 Å); mesure effectuée en transmittance. Enregistreur Kipp et Zonen BC 5 (12 gammes de tension, échelle utilisée: 5 mV). Intégrateur Kipp et Zonen BC 1, couplé à l'enregistreur pour l'intégration des courbes pendant l'enregistrement.

L'introduction des gaz s'effectue dans la chambre de prémélange des gaz par un tube droit en acier inoxydable de 1 mm de diamètre intérieur remplaçant le dispositif de nébulisation. Du fait de la pression qui règne dans la chambre de prémélange, il est nécessaire d'introduire l'azote de balayage du piège sous une pression de 0,8 bar; une vanne réglable intercalée entre la partie amont du circuit d'azote et le régulateur de pression, permet l'utilisation de ce dernier sous une telle pression.

Protoxyde d'azote: qualité industrielle, tube de 6 m^3 livré sous pression de 40 bars; débit 5 l./mn sous pression de 4 bars.

Acétylène: qualité industrielle, tube de 4 m^3, livré sous pression de 15 bars; débit 0,25 l./mn sous pression de 1,5 bar.

[‡] Lyon-Alemand, Paris.

Mode opératoire

L'appareillage de minéralisation étant balayé par le courant d'azote principal, le spectrophotomètre est mis sous tension; une demi-heure est suffisante pour obtenir un rayonnement stable de la cathode creuse.

La flamme protoxyde d'azote–acétylène est, alors, allumée, pendant 20 mn, afin que l'appareil de mesure atteigne sa température de régime; durant ce temps, une "minéralisation" préliminaire d'un prélèvement analytique est effectuée dans l'appareil, ce qui permet la mise en condition nécessaire du dispositif de minéralisation.

Analyse proprement dite

—Commander la vanne (18) (position basse) afin de faire balayer le piège (19) par le courant d'azote annexe; refroidir ce piège.

—Introduire la nacelle porteuse du prélèvement analytique dans le tube à pyrolyse par l'orifice (1) et la poser dans le logement du poussoir (2); boucher l'orifice (1) avec son capuchon à ajutage à robinet et ouvrir ce dernier afin de faire balayer la partie antérieure du tube à pyrolyse par le courant d'azote principal; ce courant s'écoule ainsi directement dans l'atmosphère, la vanne (18), en position basse, ne lui permettant pas de traverser le tube à pyrolyse.

—Fermer le robinet du capuchon à ajutage.

—Etablir le débit de pyrolyse (31 ml/mn) d'azote chloré pendant 2 mn par commande de la vanne (12) et fermeture du courant d'azote annexe par la vanne (18).

—Introduire rapidement la nacelle au centre de la chambre de pyrolyse en déplaçant le poussoir à l'aide d'un aimant extérieur.

—Rétablir le courant d'azote pur (56 ml/mn) au bout de 3 mn par commande de la vanne (12) (position basse); le laisser circuler pendant 5 mn.

—Commander la vanne (18) (position haute) afin de faire balayer le piège par le courant d'azote pur (80 ml/mn) pendant 5 mn, temps nécessaire à l'élimination quasi totale, par vaporisation et élution, du chlore liquéfié dans le piège.

—Extraire le poussoir de la chambre de pyrolyse à l'aide de l'aimant extérieur.

—Refroidir le poussoir à l'extérieur du tube, par soufflage d'air comprimé sur toute sa longueur, au moyen d'une rampe percée de trous.

—Réchauffer le piège, à la fin de ce temps.

—Allumer la flamme protoxyde d'azote–acétylène du brûleur du spectrophotomètre.

—Injecter les gaz de balayage dans le spectromètre par commande du robinet à trois voies situé en aval du piège.

—Remettre le compteur de l'intégrateur à zéro; l'intégrateur fonctionne lors du passage de tétrachlorure de silicium dans la flamme.

—Relever le nombre indiqué par le compteur de l'intégrateur dès le retour du traceur de l'enregistreur à la ligne de base initiale.

L'analyse dure environ 25 mn.

Courbe d'étalonnage. L'appareil est étalonné chaque jour par l'analyse de substances-types organosiliciées dont la teneur en silicium est connue et dont les masses de prélèvements doivent être telles qu'elles correspondent à des masses de silicium comprises entre 1 et 60 μg.

Si N représente le résultat numérique lu sur le compteur de l'intégrateur et si x est la masse de silicium, exprimée en μg, l'expérience montre que la courbe d'étalonnage peut être représentée par une équation bilogarithmique qui est linéaire lorsque la masse de silicium est inférieure à 60 μg et qui s'écrit

$$\log N = a \log x + b$$

dans laquelle a est la pente de la droite d'étalonnage tracée sur papier à coordonnées bilogarithmiques et b son ordonnée à l'origine (valeur de log N correspondant à 1 μg de silicium).

Pour une quantité de silicium supérieure à 60 μg la courbe s'infléchit vers une asymptote horizontale, ce qui correspond à la saturation de la flamme par les espèces siliciées.

La valeur de la pente a de l'équation d'étalonnage a pour ordre de grandeur 0,900, mais peut varier d'environ ± 0,1 principalement en fonction de la qualité des gaz de la flamme.

Essai à blanc. L'essai à blanc de l'appareil en fonctionnement (qui doit toujours être effectué après l'analyse d'un composé silicié) ne doit pas donner lieu à un comptage numérique de plus d'une quinzaine de pas du compteur de l'intégrateur, ce qui correspond à une quantité de silicium de l'ordre de grandeur de 1–1,5 μg.

Dans le cas où le comptage d'essai à blanc est supérieur à une quinzaine de pas, il importe de poursuivre le balayage du tube à pyrolyse, par un courant d'azote chloré, jusqu'à obtention d'un comptage "à blanc admissible".

DISCUSSION

Pesage et ordre de grandeur de la masse des prélèvements analytiques

Le pesage est effectué à l'aide d'une balance électromagnétique Mettler ME 22 qui permet de peser à 0,5 μg près les prélèvements microanalytiques en nacelles de platine. La masse des prélèvements analytiques doit être comprise entre 200 et 700 μg suivant la teneur en silicium, afin que la masse du silicium dosée soit elle-même comprise entre 1 et 60 μg. Il est à remarquer que les nacelles de platine perdent en moyenne de 100–200 μg de leur masse par analyse du fait de l'attaque de platine par le chlore.

L'ordre de grandeur décimilligrammique des prélèvements analytiques permet, d'une part, de combiner quantitativement le silicium sous forme de tétrachlorure de silicium lors de la chloropyrolyse de substances organiques, et, d'autre part, de n'injecter dans la flamme du spectromètre que des quantités de produits siliciés telles que la loi d'étalonnage bilogarithmique reste linéaire.

L'expérience montre, en effet, lorsque la masse des prélèvements analytiques dépasse 1 mg, notamment dans le cas des substances où un atome de silicium est lié à 1 ou 2 atomes d'oxygène (triphénlysilanol, par exemple), que la minéralisation n'est pas quantitative et donne donc lieu à des pertes de silicium; en outre, il apparait alors un phénomène de mémoire perturbant l'analyse suivante.

Essai à blanc

Sous réserve de maintenir les masses des prélèvements entre les limites définies sous la précédente rubrique, aucun phénomène de mémoire ne se manifeste au cours d'une série d'analyses. Le résultat positif d'un essai à blanc ne peut provenir, exclusivement, que de l'appareillage et, particulièrement, du tube à pyrolyse. En effet, il s'avère que le renouvellement de la garniture du tube à pyrolyse (papier et feutre de carbone) donne lieu à un résultat d'essai à blanc qui, exprimé en masse de silicium, peut atteindre 15–20 μg, mais que ce "blanc" peut disparaître si l'on prend la précaution de balayer le tube pendant 24 hr par de l'azote chloré.

Remarquons qu'une légère attaque du tube de silice protecteur du tube de graphite vitreux au voisinage de son extrémité d'aval est également susceptible de donner lieu à l'obtention d'un résultat positif d'essai à blanc.

Pyrolyse de la substance organique

Le prélèvement analytique est introduit dans la chambre de pyrolyse portée à une température d'environ 1100° au sein d'une atmosphère d'azote chloré. Les gaz de pyrolyse siliciés traversent le feutre de carbone où le chlore adsorbé permet d'achever la chloration quantitative du silicium donnant naissance à un composé chloré volatil.

Par contre, les produits solides de la pyrolyse susceptibles de retenir du silicium sous forme de résidus dans la nacelle de platine, ou de dépôts, sur les parois du tube de graphite, ne sont au contact du courant d'azote chloré, sous un débit de 21 ml/mn, qu'en la présence éventuelle de faibles quantités de charbon amorphe produit par la pyrolyse qui, d'ailleurs, à 1100°, se graphitise lentement en perdant sa réactivité.

Il est remarquable que le remplacement du feutre de graphite par une garniture de charbon amorphe du type Degussa (tel que celui qui est employé, par exemple, pour le microdosage de l'oxygène d'après le principe de Schütze-Unterzaucher) conduit à une rétention irréversible de silicium, sous la forme probable de carbure de silicium, du fait de la grande réactivité du charbon employé.

Par ailleurs, il n'a pu être démontré de façon formelle que le produit chloré du silicium formé lors de la chlorocarbopyrolyse soit exclusivement constitué par du tétrachlorure de silicium; cependant, si lors de la pyrolyse primaire, il peut se former des mono, di, ou trichlorosilanes, ceux-ci en passant sur la garniture de feutre de carbone, saturée de chlore à 1100° devraient être transformés en tétrachlorosilane; de même, l'excès de chlore disponible par rapport à la quantité de silicium à combiner rend peu probable la formation de composés tels que l'hexachlorodisilane (Si_2Cl_6) ou l'octochlorotrisilane (Si_3Cl_8) *etc.*

Le balayage du tube à pyrolyse par un courant d'azote, sous débit relativement élevé de 56 ml/mn, permet d'entraîner le chlore en excès ainsi que le tétrachlorure de silicium dans le piège froid où ce dernier se solidifie; l'expérience montre qu'un tel débit est nécessaire afin d'éviter toute rétention des composés chlorés du silicium au sein du dispositif de minéralisation, ce qui donnerait lieu soit à une augmentation de la durée d'analyse, soit à un phénomène de mémoire au sein du dispositif de minéralisation.

Condensation des gaz de pyrolyse et réchauffage du piège

Le piège refroidi à $-78°$ contient une garniture d'alumine frittée qui n'a pratiquement pas de propriétés adsorbantes, mais permet de retenir par filtration l'aérosol de tétrachlorure de silicium susceptible de se former par condensation et d'être entraîné par le courant d'azote sous le débit plus élevé (80 ml/mn) utilisé en vue de chasser du piège la majeure partie du chlore simultanément condensé à l'état liquide.

L'élimination du chlore est effectivement nécessaire afin d'éviter les effets nuisibles de sa présence dans les gaz (dont la vapeur de tétrachlorure de silicium) qui sont introduits dans la flamme du spectromètre d'absorption atomique. Le chlore gazeux serait, en effet, susceptible de réagir sur l'acétylène alimentant cette flamme pour former des composés très explosifs et, en outre, si sa concentration était trop élevée, de favoriser la recombinaison partielle du silicium atomique, produit par dissociation thermique du tétrachlorure de silicium suivant la réaction d'équilibre

$$SiCl_4 \rightleftharpoons Si + 2\,Cl_2$$

Quant au chlore résiduel subsistant dans le piège, il est éliminé, en phase gazeuse, après vaporisation du condensat, par passage dans le tube absorbeur à garniture de laine d'argent (qui n'est renouvelée qu'une fois par semaine), situé avant le spectrophotomètre.

La valeur (20 ml/mn) et la constance du débit du courant d'azote injectant les gaz issus du piège froid dans la flamme du spectrophotomètre conditionne la vitesse de passage du tétrachlorure de silicium dans cette flamme de façon reproductible, en fonction du temps.

Dosage du silicium dans le tétrachlorure de silicium

Le dosage du silicium par absorption atomique est effectué dans une flamme protoxyde d'azote–acétylène. L'obtention de résultats reproductibles est conditionnée par le maintien difficile de la constance absolue des conditions de mesure du signal fourni par le système spectromètre–intégrateur lors des différentes analyses effectuées au cours d'une même journée de travail.

Le réglage électronique de l'appareil d'absorption atomique doit impérativement permettre l'obtention d'une réponse très stable, et en particulier, d'une excellente ligne de base. Cette condition est réalisée grâce à la limitation de l'intensité d'alimentation de la lampe à cathode creuse au silicium à 6 mA, du choix de la tension d'alimentation du photomultiplicateur, telle que son gain ne dépasse pas 6, et du choix de la sensibilité de l'enregistreur correspondant à 5 mV pour la pleine échelle. Une plus grande sensibilité conduirait, en effet, à un comptage par l'intégrateur d'un nombre plus grand, pour une même quantité de silicium à doser, mais donnerait lieu simultanément à une dérive importante de la ligne de base, pendant chaque mesure, incompatible avec la précision requise des résultats.

La plus grande difficulté réside dans la nécessité de maintenir la constance des caractéristiques physiques et chimiques de la flamme protoxyde d'azote–acétylène pendant la durée d'une série d'analyses. On dispose, à cette fin, de débitmètres permettant de mesurer les débits du comburant et du combustible sous des pressions bien déterminées.

Par contre, la qualité du combustible évolue au cours de l'utilisation d'une même bouteille; corrélativement, la teneur en acétylène s'appauvrit pour un même débit et le pouvoir réducteur de la flamme décroit provoquant une perte de sensibilité de l'appareillage de mesure qui se traduit par une variation du coefficient de pente de la droite d'étalonnage. Pour pallier cet inconvénient, les bouteilles d'acétylène ne sont pas utilisées en deçà d'une pression de 6 bars.

RESULTATS

La méthode et l'appareillage décrits permettent essentiellement de doser le silicium dans les composés organiques stables, solides ou pâteux de tension de vapeur suffisamment faible pour que reste négligeable toute perte par vaporisation partielle du prélèvement analytique lors de son introduction dans le tube à pyrolyse sous l'effet du contrebalayage par le courant d'azote.

Dans le Tableau 1 sont rassemblés des résultats du dosage du silicium dans des composés organiques contenant exclusivement, outre le silicium, du carbone, de l'hydrogène et de l'oxygène; le silicium peut y être lié soit à des atomes de carbone, soit, simultanément, à 1 ou 2 atomes d'oxygène, soit à l'hydrogène, soit même à un autre atome de silicium.

Divers produits analysés sont des composés de recherches pour lesquels, à défaut de la structure moléculaire, la formule brute est communiquée.

La précision des résultats (exprimée *a contrario* en erreurs absolues) n'atteint pas toujours celle qui est admise pour le dosage des éléments courants en microanalyse organique élémentaire.

CONCLUSION

Le présent travail est une approche en vue de la mise au point d'une méthode de microdosage automatique rapide du silicium dans les composés organiques, voire inorganiques.

Elle a montré la possibilité de faire entrer le silicium dans un molécule gazeuse, le tétrachlorure de silicium, aisément transférable en phase gazeuse du site de traitement ("minéralisation" dans les cas des composés organiques) du prélèvement microanalytique au site du mesurage effectué sur la molécule de transfert. Elle a, d'ores et déjà, permis d'obtenir des résultats satisfaisants, dans le cas des composés organiques siliciés, en ce qui concerne la durée unitaire d'une détermination du silicium dans une série; la précision absolue des résultats des dosages reste en deçà de celle qu'il eût été souhaitable d'atteindre bien qu'elle puisse être considérée comme déjà satisfaisante, eu égard à la masse atomique du silicium, lorsqu'elle est comparée à la précision classique des microdosages du carbone, de l'hydrogène, de l'oxygène et de l'azote dans les composés organiques.

Par ailleurs, l'accroissement de sensibilité du dosage du silicium que permet d'atteindre l'injection de la totalité du silicium à doser, sous la forme de molécules siliciées gazeuses, dans la flamme d'un spectromètre d'absorption atomique, autorise à penser que cette méthode est susceptible d'être appliquée au dosage de traces de silicium dans des substances organiques ou inorganiques sous réserve d'effectuer préalablement une mise au point appropriée du dispositif de traitement (chlorocarbopyrolyse) du prélèvement analytique.

THE ANALYSIS OF COPPER REFINERY SLIMES

R. S. Young

1178, Beach Drive, Victoria, B.C. Canada

(*Received* 2 *April* 1975. *Accepted* 13 *May* 1975)

Summary—Methods are reviewed for the determination of the following constituents of copper refinery slimes: aluminium, antimony, arsenic, barium, bismuth, calcium, cobalt, copper, gold, iron, lead, magnesium, manganese, molybdenum, nickel, platinum metals, selenium, silicon, silver, sulphur, tellurium, tin and zinc.

Twenty-five years ago the writer outlined the analysis of copper refinery slimes.[1] Since then, a large expansion of world copper production has occurred, bringing with it a substantial widening of the range of elements in refinery slimes.[2,3] In the same period, many notable improvements in analytical procedures have been made; even completely new techniques such as atomic absorption have been introduced. A review of current practices in this specialized but important sphere might be useful to analysts who are concerned with complex metallurgical products.

In spite of the availability in recent years of high-speed pulverizing equipment and improved mixing devices, the preparation of a representative slime sample remains a time-consuming operation. Usually a number of sample portions are taken from the wet slime, combined and dried at 105°, lightly pulverized if necessary to break up small lumps, and given a brief mixing. After reduction of the sample bulk to a convenient size by riffling or similar means, the material is pulverized to pass a 100-mesh screen. Occasionally a small portion, largely metallic copper, may not pass through the screen; this fraction, and the main portion, must then be weighed and analysed separately. Finally, the 100-mesh material must be thoroughly mixed, an operation which is usually the weakest link in sample preparation. The frequent presence of metallic substances, and the range of specific gravity of slime constituents, from approximately 1 for the organic matter of electrolyte additives to over 21 for platinum, make imperative a complete mixing of the finely-pulverized sample.

The inherent heterogeneity of slimes, and the high value of this material in most copper refineries, leads many chemists to prefer, for most constituents, dissolution of a 5- or 10-g sample, dilution to standard volume, and withdrawal of a suitable aliquot, rather than a direct weighing of a 0·5–1 g sample.

Table 1 shows the range of constituents of copper refinery slimes. The data for alumina, barium, lime, magnesia, and silica in the anode mud from the electrolysis of blister copper may appear surprising. Usually the content of these constituents is very low, but it can be enhanced by additions from slag inclusions, refractories, fluxes, mould washes, or dust from an adjacent tailings area.

For most constituents of slimes, decomposition is effected by a suitable combination of acids, followed if necessary by fusion of any insoluble residue with carbonate, bisulphate or peroxide. For antimony and arsenic, the sample is heated in a Pyrex flask with a mixture of sodium sulphate, sulphuric acid, and a small piece of filter paper. Selenium and tellurium are brought into solution with nitric acid and potassium chlorate, with heating on a water-bath, followed by several evaporations with hydrochloric acid to eliminate nitric acid. It is often necessary to remove antimony, arsenic, selenium and tin from a slime sample; these may be readily volatilized by several evaporations with a mixture of hydrobromic and either sulphuric or perchloric acid.

Table 2. AAS data for copper refinery slimes

	Wavelength, *nm*	Sensitivity, *μg/ml*	Flame
Aluminium	309·3, 396·2	1	NOA
Antimony	206·8, 217·6, 231·2	1	AA
Arsenic	193·7	poor	all flames absorb strongly
Barium	553·6	1	NOA
Bismuth	223·1	1	AA
Calcium	422·7	0·1	AA
Cobalt	240·7	0·2	AA
Copper	324·8	0·05	AA
Gold	242·8	0·3	AA
Iron	248·3	0·1	AA
Lead	217·0, 283·3	0·3, 0·5	AA
Magnesium	285·2	0·005	AA
Manganese	279·5	0·05	AA
Molybdenum	313·3	1	AA or NOA
Nickel	232·0	0·1	AA
Palladium	247·6	0·5	AA
Platinum	265·9	3	AA
Selenium	196·0	poor	all flames absorb strongly
Silicon	251·6	2	NOA
Silver	328·1	0·03	AA
Tellurium	214·3	0·5	AA
Tin	286·3	3	AA or NOA
Zinc	213·9	0·02	AA

AA = Air–acetylene flame.
NOA = Nitrous oxide–acetylene flame.

In the presence of a substantial excess of a ferric salt, an ammonia/ammonium salt buffer will precipitate antimony, arsenic, bismuth, lead, selenium, tellurium, and tin. Treatment with sulphur dioxide and hydrazine hydrochloride in 10–20% hydrochloric acid medium will precipitate tellurium and gold.

The technique of atomic-absorption spectrophotometry is used extensively in the analysis of slimes, and Table 2 gives the wavelength, sensitivity and flame for these determinations. The acidity of standards and unknowns should match approximately, and sometimes the metal compositions should be roughly similar.

Aluminium

Interferences are removed by hydrobromic–sulphuric acid evaporation, separation by precipitation with ammonia, and sulphur dioxide treatment; electrolysis with a mercury cathode will then leave aluminium virtually alone in the solution. Final determination can be carried out photometrically with aluminon, at 525 nm,[4] or gravimetrically.[5,6]

Aluminium can be determined by atomic absorption; standards and samples should contain about 0·1% potassium or sodium.[7,8]

Antimony

After volatilization of tervalent arsenic from hydrochloric acid solution at 108°, antimony can be distilled at 165° and determined volumetrically with potassium bromate[5] or photometrically with Rhodamine B at 565 nm.[4,5]

Antimony can be determined by atomic absorption; the acidity and metal composition of standards and unknowns should match approximately if bismuth and zinc are present.[7]

Arsenic

Tervalent arsenic can be distilled from a hydrochloric acid solution at 108° and determined volumetrically with iodine or photometrically by the hydrazine sulphate–ammonium molybdate procedure, at 660 or 840 nm.[4,5]

The element can be determined by atomic absorption, using the line at 193·7 nm, but instrumental sensitivity is poor in this spectral region and little information exists on interferences.

Barium

Treatment of the sample with *aqua regia*, hydrofluoric acid, and evaporation to fumes of sulphuric acid, followed by dissolution in water and filtration, will leave barium sulphate in the precipitate together with lead sulphate, silver chloride, and a certain amount of the gold and platinum metals. Fusion with sodium carbonate, dissolution in water, and filtration will leave as a precipitate the carbonates of barium and lead. Dissolution of this precipitate in hydrochloric acid and treatment with hydrogen sulphide will precipitate lead, silver, gold and the platinum metals; barium in the filtrate can eventually be precipitated as sulphate.

Barium can be determined by atomic absorption, preferably with about 1000 μg/ml of potassium added to sample and standard solutions.

Bismuth

After removal of interferences by addition of hydrobromic and sulphuric acids, evaporation, and sulphur dioxide treatment, a precipitation with ammonia will leave bismuth with iron. Dissolution of this precipitate in hydrochloric acid and treatment with hydrogen sulphide will isolate bismuth; final photometric measurement by the thiourea method is done at 420 nm.[4,5]

Bismuth can be determined by atomic absorption without interference from an excess of antimony, copper, iron, lead, tin, or zinc.[8]

Calcium

This element, together with magnesium, is usually determined in the sample portion taken for aluminium. The filtrate from the final removal of aluminium hydroxide, described earlier, contains the calcium and magnesium. Ammonium salts are eliminated by evaporation with nitric acid, and the residue is dissolved in water containing a few drops of hydrochloric acid. A sodium hydroxide–sodium cyanide buffer is added, and, with Calcon as indicator, calcium is titrated with standard EDTA solution.[5,9,10]

Calcium can also be determined by atomic absorption; addition of lanthanum chloride will overcome the interference of aluminium.

Cobalt

Cobalt can be conveniently determined in the solution remaining after the electrolysis of copper, described later, by the nitroso-R-salt photometric procedure, at 520 nm.[4,5] The only interfering element in slimes which must be considered is nickel, if it occurs in amounts substantially more than 25 times that of cobalt. For such samples, it is preferable to remove nickel by means of dimethylglyoxime and destroy organic matter by evaporating the filtrate with nitric and sulphuric acids before proceeding with the nitroso-R-salt reaction.

Atomic absorption can be employed for cobalt; copper, iron, magnesium, manganese, molybdenum, nickel, and silicon do not interfere.

Copper

This element is nearly always the major constituent of anode slimes, and the electrolytic procedure is the most appropriate. This necessitates the removal of elements which deposit, wholly or partially, on the cathode in a nitric–sulphuric acid solution. Silver is initially removed as chloride, and an evaporation with hydrobromic–sulphuric acid mixture volatilizes antimony, arsenic, selenium and tin. Sulphur dioxide and hydrazine hydrochloride in hydrochloric acid precipitate gold and tellurium, and in the presence of an excess of a ferric salt an ammonia precipitation will remove bismuth.

If platinum metals are present in significant quantities, the preliminary acid treatments will volatilize ruthenium and osmium; iridium is not deposited from a nitric–sulphuric acid electrolyte. Platinum and rhodium can be removed by digesting the sample with hot sodium nitrite solution at pH 1·5, neutralizing with sodium hydroxide to pH 10 to precipitate copper and other base metals, and filtering. A reprecipitation passes the platinum metals except palladium, into the filtrate.[11] The palladium is readily separated from copper by dimethylglyoxime in 3% hydrochloric acid.

The amount of molybdenum in slimes is too low for this element to be deposited to a significant extent on the cathode along with the copper.

For a rapid control determination, atomic absorption can be used; aluminium, calcium, cobalt, iron, lead, magnesium, manganese, nickel, silver, tin and zinc do not interfere.

Gold

In most slimes, gold is best determined, together with silver, by a combined wet and fire assay. Treatment with sulphuric acid and mercuric sulphate dissolves copper and other base metals, silver is precipitated with a chloride solution, and the residue is filtered off. The precipitate is transferred to lead foil in a scorifier, an addition of test lead, borax and silica is made, and the sample is heated in an oxidizing muffle until the basic oxides are slagged. The contents of the scorifier are poured into a mould, then the lead button is placed in a cupel and heated until only the gold–silver bead remains. Gold and silver are parted in a porcelain cup first with 2·5 M (1 + 6) and finally with 8·5 M (1 + 1) nitric acid; the gold residue is dried, ignited and weighed.

When the gold content of the bead is less than ten times the platinum content, much of the latter remains with the gold on parting. For these rare occasions, the bead is dissolved in *aqua regia* and evaporated several times with hydrochloric acid to eliminate all nitric acid. The sample is digested with a hot sodium nitrite solution at pH 2, then the solution is neutralized with sodium hydroxide to pH 8 and boiled; the residue is filtered off, ignited in a porcelain crucible at 900° and weighed as pure gold.[12]

Gold can be determined by atomic absorption; no interferences are normally encountered.

Iron

After elimination of interferences by evaporation with hydrobromic–sulphuric acid and precipitations with hydrogen sulphide and ammonia, iron can be determined titrimetrically with potassium dichromate or photometrically with 1,10-phenanthroline, at 508 nm.[4,5]

Atomic absorption can be used for iron; no interference is caused by aluminium, cobalt, copper, magnesium, or nickel.

Lead

Lead may be conveniently determined by evaporating a sulphuric acid solution of the sample to fumes, filtering off and washing the precipitate, dissolving the lead sulphate in hot concentrated ammonium acetate solution, and discarding the residue of silica, gold, silver chloride *etc.* Evaporation of the lead acetate solution with sulphuric–nitric acid to fumes will give a final precipitate of lead sulphate. Polarography may also be used to determine lead in slimes.[13]

Lead may be determined by atomic absorption; no interference arises from copper, iron, tin or zinc. There is less flame background at 283·3 nm than at 217·0 nm.

Magnesium

This element is usually determined, like calcium, in the sample taken for aluminium. After the latter has been separated as hydroxide and the filtrate containing calcium and magnesium made up to a convenient volume, an aliquot is withdrawn. Ammonia–ammonium chloride buffer and Eriochrome Black T indicator are added, and the solution is titrated with standard EDTA solution. This gives calcium + magnesium; the volume of EDTA used in the titration for calcium alone, described earlier, is deducted to give the amount of EDTA required for magnesium.[9,10]

Atomic absorption may be used advantageously for magnesium; no interference arises from copper, iron, tin or zinc. The sensitivity is high; a value of 0·005 μg/ml is frequently quoted.[8,14]

Manganese

By oxidation with bromine, manganese can be precipitated with an ammonia ammonium salt buffer, cobalt, copper, nickel and zinc passing into the filtrate. After dissolution of the precipitate in acid, treatment of the solution with hydrogen sulphide, and filtration, manganese is obtained in the filtrate, free from any element which will interfere with the potassium periodate photometric procedure.[4,5]

Manganese can be measured by atomic absorption; no interference can normally be expected from the calcium, cobalt, copper, iron, lead, magnesium, molybdenum, nickel or zinc in slimes.

Molybdenum

Interferences are removed by addition and evaporation of hydrobromic–sulphuric acid mixture and precipitation with sulphur dioxide. Addition of α-benzoinoxime to the cold oxidized filtrate to complex molybdenum, followed by a chloroform extraction and destruction of the chloroform with nitric–sulphuric acid mixture will isolate molybdenum for subsequent determination by the thiocyanate–stannous chloride photometric method; an isopropyl ether extraction to concentrate the colour for measurement at 540 nm is usually desirable.[4,5,15]

Atomic absorption offers an alternative technique for molybdenum; negligible interference may be expected from copper, iron, lead, manganese, nickel or tin.

Nickel

Most copper slimes have a nickel content of 0·1–8%; if a chemical method is desired, the gravimetric dimethylglyoxime procedure is preferred, following the determination of copper by electrolysis.

For lower concentrations of nickel, the photometric dimethylglyoxime method with measurement at 530 nm, after copper removal, is thoroughly reliable.

A few slimes contain such a high quantity of nickel that electrolytic deposition on a platinum cathode, from an ammoniacal solution containing ammonium sulphate is preferred.

Atomic absorption may be used to determine nickel; no interference will be encountered from aluminium, calcium, cobalt, copper, iron, lead, magnesium, manganese, molybdenum, silver, tin or zinc.

Platinum metals

With a few exceptions, the platinum metals in copper slimes are almost entirely platinum and palladium. They are usually determined by a combined wet and fire assay.[12]

An appropriate sample is dissolved in the manner described earlier for gold. Slimes nearly always contain more than ten times as much silver as gold + platinum metals, but if not, sufficient silver as nitrate or sulphate should be added initially to give this ratio. After the filtration, the filtrate, which contains a good part of the palladium, is retained. The precipitate, which contains all the gold and platinum, is scorified and cupelled as described previously for gold. The gold–silver–platinum bead, containing a small quantity of palladium, is parted in hot concentrated sulphuric acid. The residue contains gold and platinum; silver and palladium are in the filtrate. Silver is determined as chloride, and palladium with dimethylglyoxime in 3% hydrochloric acid. The major part of the palladium, in the original filtrate, is also determined with dimethylglyoxime but with a reprecipitation to remove occluded ions. If the palladium content is low, it may be measured photometrically by a dimethylglyoxime–chloroform method, at 375 nm.[5]

The residue of gold and platinum from the sulphuric parting, after weighing, is dissolved in *aqua regia*. Gold is determined by sodium nitrite, as described earlier. The balance is platinum, possibly with traces of iridium and rhodium. The platinum figure may be confirmed by adding *aqua regia* to the filtrate from the gold separation, evaporating to dryness, and then adding hydrochloric acid and evaporating to dryness again, this last step being repeated several times. The residue is dissolved in 1% hydrochloric acid containing several grams of sodium acetate, and platinum is precipitated by formic acid.[11] If the platinum content is low, it can be measured photometrically with stannous chloride, at 403 nm.[5]

Atomic absorption can also be used to determine the platinum metals; very few elements interfere.

Selenium

This element is almost invariably determined in slimes by precipitation from concentrated hydrochloric acid solution with sulphur dioxide. After prior removal of silver as chloride, and of lead as sulphate if necessary, passage of a stream of sulphur dioxide into a 70–90% hydrochloric acid solution will precipitate only selenium and gold. Treatment of this precipitate with nitric acid will dissolve the selenium, leaving gold as a residue. Repeated evaporations of the selenium-containing solution after additions of hydrochloric acid, followed by a repetition of the previous precipitation by sulphur dioxide from concentrated hydrochloric acid will yield pure selenium.[5,11,16] The filtrate and washings from the precipitation of selenium + gold should be retained for the tellurium determination.

Selenium can be measured by atomic absorption, but the sensitivity for this element is poor. The selenium content of slimes is nearly always above the preferred range for a photometric method, but if the latter is applicable, the 3,3′-diaminobenzidine procedure is thoroughly reliable.[4,5,16]

Silicon

The classic gravimetric method of dehydration with perchloric acid and volatilization of silica with hydrofluoric acid remains the preferred chemical procedure for most slimes.[17]

The element can also be determined by atomic absorption; no interference occurs from aluminium, calcium or iron.

Silver

Silver is usually determined by the wet and fire assay described for gold. The element may also be found by the conventional precipitation and weighing of silver chloride, if the first precipitate is leached with ammonia solution to dissolve silver and leave impurities behind.

Silver may also be determined by atomic absorption; no interference occurs from aluminium, bismuth, calcium, cobalt, copper, iron, lead, magnesium, manganese, molybdenum, nickel, tin or zinc.

Sulphur

The classic gravimetric procedure, oxidation of sulphur to sulphate followed by precipitation with barium chloride, remains the preferred procedure for this complex material. The sample is treated with potassium bromide and bromine, then nitric acid, the solution is evaporated to dryness, the residue moistened with hydrochloric acid and then heated to dryness again (this step being repeated several times), and finally the residue is treated with hydrochloric acid, the solution is diluted, and the precipitate filtered off and washed. Because the precipitate contains insoluble sulphates in addition to silica, it is digested for 30 min in boiling sodium carbonate solution, filtered off and washed, and the filtrate is added to the original filtrate.

If the slimes contain an appreciable amount of antimony, this should be removed by digesting for an hour in warm 20% hydrochloric acid solution with ingot-iron filings, before adjustment of the acidity to about 1% hydrochloric acid and precipitation of barium sulphate in the usual manner.

Tellurium

Tellurium is nearly always determined by precipitation from dilute hydrochloric acid with sulphur dioxide. After the removal of selenium and gold in concentrated hydrochloric acid medium by sulphur dioxide, dilution to about 10–20% hydrochloric acid and the addition of hydrazine hydrochloride will precipitate tellurium.

Atomic absorption can be used to determine tellurium; no interference is normally encountered from aluminium, antimony, cobalt, copper, iron, lead, magnesium, selenium or zinc.

Tin

After isolation by distillation, tin can be readily determined titrimetrically or photometrically. With slimes, the same sample can usually serve for arsenic, antimony and tin. From hydrochloric acid containing a reducing agent, arsenic is distilled at 108° and antimony at 165°; if hydrobromic acid is then added to give a 3:1 mixture of hydrochloric and hydrobromic acids, tin can be distilled at 145–160°.

In the distillate, tin can be determined titrimetrically with iodine after reduction by metallic nickel. For a small quantity of tin, the photometric dithiol procedure is rapid and reliable; measurement is made at 530 nm. Polarography offers another suitable technique for tin in slimes.[13]

Tin can also be measured by atomic absorption; a large excess of antimony will interfere.

Zinc

If a chemical determination is desired, the classic potassium ferrocyanide titrimetric method may be employed for higher levels of zinc, whereas for traces a photometric procedure using dithizone is satisfactory.[4,5] In both cases the analysis is carried out on the solution remaining after the electro-deposition of copper.

Atomic absorption may be used to determine zinc, conveniently after the electrolysis of copper. The remaining constituents in the sample, aluminium, calcium, cobalt, iron, magnesium, manganese, molybdenum, and nickel, do not interfere.

KAREL MAŘÍK

The Institute of Nuclear Fuels, 255 48 Zbraslav n. Vlt., Czechoslovakia

(*Received* 8 *April* 1975. *Accepted* 10 *May* 1975)

Summary—Concentrations of cadmium of the order of 0·1 ppm in alloy steels containing large concentrations of chromium and nickel (*ca.* 17 and 13% respectively), about 0·1% of copper and a number of metals at low concentrations, were determined by anodic stripping voltammetry with a hanging mercury-drop electrode in $1M$ hydrochloric acid. Cadmium was separated on Dowex 50W-X8 cation-exchanger in a medium at pH 1·3 containing excess of EDTA. Mercury-film electrodes cannot be used for this determination, because the peak for cadmium is distorted by evolution of hydrogen on the electrode support. The relative standard deviation of the determination of 0·44 ppm of cadmium in steel is 3·2% and the confidence limits for 95% probability are 0·44 ± 0·02 ppm. The error in the cadmium recovery does not exceed + 8%.

The content of cadmium in special alloy steels employed in nuclear technology is very significant because of its very high neutron-absorption cross-section. The amounts of cadmium typically present in these steels are so low that they cannot be determined by conventional atomic-absorption spectroscopy in this complex matrix. However, this metal is readily determinable by anodic stripping techniques with mercury electrodes.[1,2] The main drawback of stripping techniques is the poorer selectivity compared with atomic absorption spectroscopy. This problem can sometimes be overcome by employing mercury-film electrodes, which yield much sharper stripping peaks. However, in such complicated matrices as steels containing large amounts of alloying metals, preliminary separation of interfering elements is usually necessary. In this study, stripping voltammetry employing mercury-film and hanging mercury-drop electrodes was combined with an ion-exchange separation.

EXPERIMENTAL

Reagents

All chemicals employed were of *p.a.* purity (Lachema, Czechoslovakia), except for hydrochloric and nitric acids which were labelled as chemicals for semiconductors. Solutions were prepared with redistilled water and were found to be free from traces of cadmium determinable by stripping voltammetry; all the chemicals contained trace concentrations of lead and copper, which, however, were low enough not to interfere in the determination of cadmium.

A standard 1-mg/ml cadmium solution was prepared by dissolving 1·0000 g of spectrographically pure metal in 10 ml of concentrated hydrochloric acid with addition of several drops of hydrogen peroxide. Excess of peroxide was expelled by boiling for 10 min and the cooled solution was diluted to 1000 ml with redistilled water. Less concentrated standard solutions were prepared from this stock solution immediately before use.

For the cation-exchange separation procedure, Dowex 50W-X8 resin (50/100 mesh) was employed. The column used was 1 cm in internal diameter and 7 cm high.

The solutions were deaerated before electrolysis, with nitrogen which had been freed from oxygen by passage through a heated column packed with copper filings and through traps containing a solution of a vanadium(II) salt and amalgamated zinc.

Apparatus

The stripping voltammetric determinations were carried out with the LP-60 (Laboratorní přístroje, Czechoslovakia) and PO-4 (Radiometer, Denmark) polarographs with a two-electrode circuit, using a saturated calomel reference electrode. Measurements with the hanging mercury-drop electrode (HMDE) (Metrohm, Switzerland) were carried out on 40 ml of solution in the Metrohm electrolysis cell. The measurements with mercury-film electrodes (MFE's) were carried out in a 10-ml electrolysis cell (Radiometer, Denmark). In all cases, the solutions were stirred during the pre-electrolysis with a glass stirrer, driven by a Radiometer synchronous motor at a speed of *ca.* 600 rpm, and a 1-min rest period followed the pre-electrolysis before the potential scan.

MFE's were prepared in the laboratory by depositing mercury on a graphite or glassy carbon support. Spectral-grade graphite (Kablo, Czechoslovakia) was impregnated with paraffin for 4 hr at 100° *in vacuo*. Then a rod 3 mm in diameter was cemented in glass tubing with silicone-rubber cement and the electroactive disk area was polished with metallographic papers (2/0, 4/0, 6/0; SIA, Switzerland) and with damp velvet. A 3-mm thick rod of glassy carbon (Le Carbone Lorraine, France) was cemented in glass tubing and polished similarly. Mercury was used as a contact

Table 1. Typical composition of alloy steel studied, with the half-wave potentials on mercury and the stability constants of the complexes with EDTA for the individual components

Component	Approx. conc., %	Half-wave potential on Hg, *V vs.* SCE	Stability constant of the EDTA chelate, log β^5
Fe	> 60	Fe(III): ↑ (1*M* HCl)	Fe(III): 25·1

↑ reduction wave merges with the current of mercury anodic dissolution; → no reduction within the accessible potential range.

for these electrodes. A mercury film was deposited on the polished support either *in situ*, according to Florence,[3] at the chosen pre-electrolysis potential, with mercuric nitrate added to the sample solution to yield a final concentration of mercury of $2 \times 10^{-5}M$, or beforehand by a 3-min electrolysis at E between − 0·2 and − 1·5 V in a solution 1*M* in nitric acid and 10^{-3}–$10^{-2}M$ in mercuric nitrate.

All measurements were performed at 20 ± 2°. The potentials are referred to the SCE at the experimental temperature. Small volumes of cadmium standard solutions were delivered from Hamilton syringes.

RESULTS AND DISCUSSION

A typical steel composition for the analysis is given in Table 1. Of the components given, the non-metallic elements will obviously not interfere in the electrochemical determination. If stripping of cadmium is carried out in the usual manner[1,2] in an acidic medium, then the half-wave potentials of the metals present (the third column of Table 1) indicate that Mn(II), Cr(III), Ni(II) and Co(II) will also not interfere, provided that the pre-electrolysis potential is made as positive as possible for this determination (about − 0·8 V). Fe(III), which arises from oxidation of Fe(II) formed during the pre-electrolysis, Mo(VI) and Cu(II), which have stripping peaks which lie between − 0·1 and − 0·2 V, must be removed.

Cation-exchange separation

It can be seen from the fourth column of Table 1 that the chelates with EDTA can be utilized for the separation on a cation-exchanger. If the medium is made sufficiently acid for the Cd–EDTA chelate to dissociate, Cd^{2+} ions will be retained on the resin, while the more stable Cu(II) and Fe(III) chelates will pass through the column because of their negative charge. It is obvious that Cr(III), Ni(II) and Mo(VI) will also be separated in this way. We used this principle previously for the separation of indium, cadmium and lead.[6]

The separation of cadmium and copper, which is critical because of the small difference in the stability constants of the corresponding EDTA chelates, was studied in detail. The resin in the H^+-cycle was first

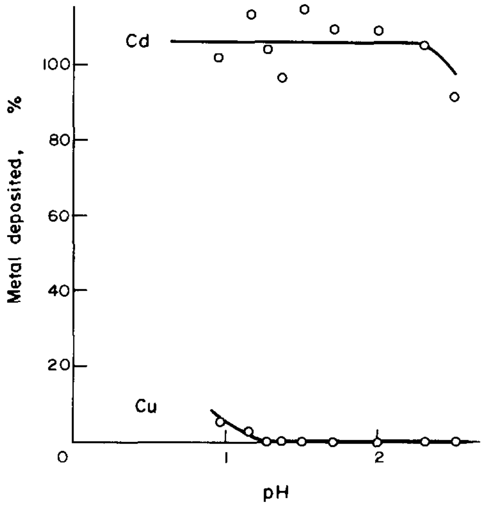

Fig. 1. The separation of 10 μg of Cd and 20 μg of Cu on Dowex 50 W-X8 cation-exchanger as a function of pH. For the conditions see the text.

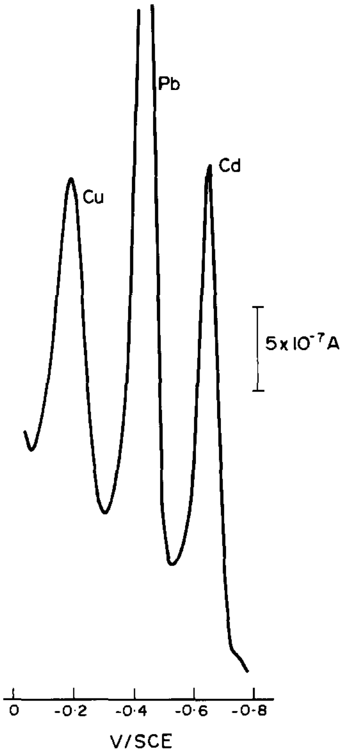

Fig. 2. The separation of 1 μg of Cd from 1000 μg of Cu on Dowex 50 W-X8 cation-exchanger at pH 1·23. $1·25 \times 10^{-3}M$ EDTA; HMDE; 15 min pre-electrolysis at −0·8V; scan-rate, 400 mV/min.

washed with 200 ml of an acetate buffer at the given pH and $1·25 \times 10^{-3}M$ in EDTA. Then 200 ml of a 0·1*M* acetic acid–$1·25 \times 10^{-3}M$ EDTA solution containing known amounts of cadmium and copper, with pH adjusted to the required value with dilute nitric acid, was passed through the column at a rate of 3 ml/min. The column was washed again with 300 ml of the acetate buffer at the required pH (and $1·25 \times 10^{-3}M$ in EDTA) and then cadmium was eluted with 40 ml of 1*M* hydrochloric acid. Cadmium and copper were then determined in the eluate by anodic stripping with the HMDE (pre-electrolysis potential and time, − 0·8 V and 10 or 15 min, respectively, scan-rate, 400 mV/min, the concentration being determined by the standard addition method). The dependence of the separation of 10 μg of Cd and 20 μg of Cu on the pH is given in Fig. 1, and the separation of 1 μg of Cd from 1000 μg of Cu at pH 1·23 is depicted in Fig. 2. Therefore, the separation can be performed over the pH range 1·2–2·0. At these pH values Fe(III), Cr(III), Mo(VI) and possibly Ni(II) will still be firmly complexed and will not be retained on the resin. The concentration of EDTA in practical analyses should be as high as possible, in order to complex all the major components.

Repeated separations of 1 μg of Cd from 1000 μg of Cu showed that the reproducibility of the cadmium recovery is generally better than 7% relative and that the recoveries are on average 7% higher than the theoretical value. There is no difference in the results whether the standard addition is made before or after the ion-exchange separation.

Anodic stripping determinations

The determinations of cadmium in the eluate from the ion-exchanger column, 1*M* in hydrochloric acid, by use of the HMDE, gave good results (see the previous section). However, as the actual amount of cadmium measured in the analyses of the steel samples is less than a twentieth of this, an attempt was made to use MFE's, which are known to have a lower detection limit and yield much sharper peaks.[1,2] Mercury was deposited on polished impregnated graphite and glassy carbon supports both before the determination and *in situ* (see Experimental). However, satisfactory results were not obtained because of a general drawback of MFE's, namely, the interfering effect of the support. It has been shown both for graphite[7] and glassy carbon[8] that, owing to heterogeneity of the support surface, mercury is deposited in the form of tiny droplets rather than as a smooth film. On the uncovered support surface hydrogen is evolved at more positive potentials, especially in acidic solutions, obscuring stripping peaks more negative than about −0·7 V. The cadmium stripping peak appears on the voltammetric curve, but is distorted and the sensitivity is poor. No significant difference was found between the results obtained with impregnated graphite and with glassy carbon. We did not even succeed in reproducing Florence's results[3] in the neutral medium of 0·1*M* potassium nitrate, for which the author reported perfect cadmium peaks. The results are slightly better when the mercury film is deposited before the determination, as the film is thicker and hence the support coverage is higher. However, it must be concluded that mercury-film electrodes are unsuitable for the determination of very low concentrations of cadmium; on the other hand, the determinations of elements yielding more positive stripping peaks (*e.g.*, Pb, Cu, Bi, *etc.*) give excellent results.[9] An example of the determination of 1 μg of Cd and 1 μg of Cu on a mercury-film electrode is given in Fig. 3.

Therefore, the HMDE was used for the measurements on steel samples.

The determination of cadmium in steel samples

The ion-exchange separation and the stripping measurement were carried out on steel samples under the conditions described above. The pH for the cation-exchange separation was adjusted to 1·3 and the EDTA concentration was ten times that in the previous measurements, *i.e.*, $1·25 \times 10^{-2}M$, in order to complex Fe, Cr, Cu and Cd quantitatively (1-g steel samples were used). The solution was boiled briefly before the pH adjustment to enhance the formation of the inert chromium–EDTA chelate. It was again found that there is no difference between the results obtained with the standard addition made

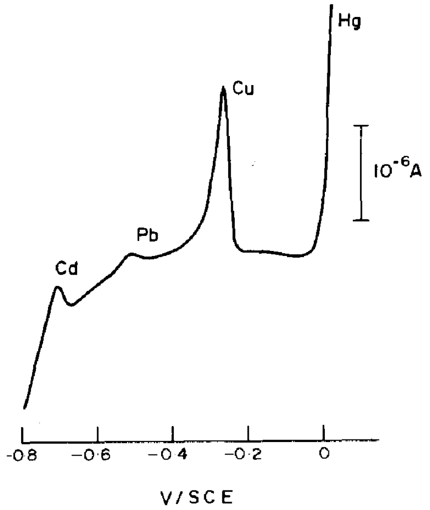

Fig. 3. The stripping voltammogram of 1 μg of Cd and 1 μg of Cu in 10 ml of 1*M* HCl on a mercury-film electrode. Impregnated graphite support, mercury deposited *in situ*; $2 \times 10^{-5}M$ Hg^{2+}; 10 min pre-electrolysis at −0·8V; scan-rate, 400 mV/min.

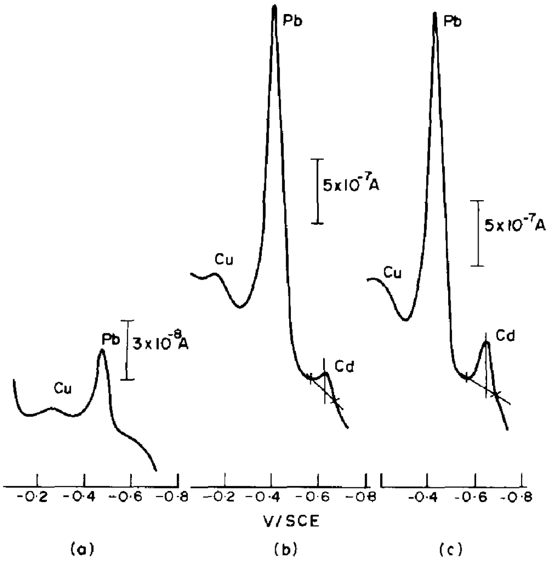

Fig. 4. The stripping voltammetric curves for the determination of cadmium in alloy steel after cation-exchange separation. (*a*) blank; (*b*) the sample; (*c*) the sample with 0·1 μg of Cd added to the electrolysed solution. pH during the cation-exchange, 1·3; EDTA concentration, $1{\cdot}25 \times 10^{-2}M$. Cadmium was eluted with 40 ml of 1*M* HCl; 15-min pre-electrolysis at −0·8 V on the HMDE; scan-rate, 400 mV/min.

before and after the ion-exchange separation. Therefore, a small volume of a standard cadmium solution can be added to the eluate after recording of the voltammetric curve of the sample, and a parallel determination of the sample plus the standard addition can be omitted. Typical voltammetric curves obtained for a steel sample and the blank are given in Fig. 4. It can be seen from Fig. 4 that the steel also contains some lead. However, for the determination of lead, the conditions of the cation-exchange separation would have to be modified, as the retention of lead on the resin is not quantitative (owing to the very similar values of the stability constants of the copper and lead EDTA chelates, $\log \beta_{Cu} = 18{\cdot}8$, $\log \beta_{Pb} = 18{\cdot}3$). The separation from copper and iron is quantitative.

The results of four parallel determinations of cadmium in steel are given in Table 2. The reproducibility of these particular determinations is excellent, better than achieved in separations with pure cadmium and copper solutions. It can thus be expected that the reproducibility will generally not be worse than that described for the separation of pure cadmium and copper, *i.e.*, *ca.* 7%.

Unfortunately, a suitable standard was not available for checking the accuracy of the method. Therefore, the procedure was carried out with several sample solutions containing various amounts of added cadmium. The relative error in the cadmium recovery did not exceed + 8%.

Therefore, the following procedure can be recommended for the determination of traces of cadmium in alloy steels.

Pass 200 ml of a solution containing 40 ml of 0·5*M* acetic acid and 5 ml of 0·05*M* EDTA adjusted to pH 1·3 with dilute nitric acid, through a column 1 cm in diameter, containing the Dowex 50W-X8 cation-exchanger (50–100 mesh) in the H^+-form, at 7 ml/min.

Dissolve 1 g of the steel in a warm mixture of 10 ml of concentrated hydrochloric acid—4 ml of concentrated nitric acid and 10 ml of water. If niobium is present in

Table 2. Results of four parallel determinations of cadmium in steel. For conditions see text

No.	Cd found, *ppm* x_i	$\bar{x}$ *ppm*	$x_i - \bar{x}$ *ppm*	Relative standard deviation, %	Confidence limits (95% probability, *ppm*
1	0·44	0·44	0·00	3·2	0·44 ± 0·02
2	0·43		− 0·01		
3	0·45		+ 0·01		
4	0·46		+0·02		

the sample, add 1–2 ml of concentrated hydrofluoric acid to this solution and heat the mixture again. Transfer the cooled solution to a 100-ml volumetric flask and dilute with water to the mark.

Add to a 10-ml aliquot 50 ml of 0·05*M* EDTA and 40 ml of 0·5*M* acetic acid, dilute with water to *ca.* 200 ml and boil for 10 min. After cooling, adjust the volume to 200 ml, and the pH to 1·3 with dilute nitric acid. Pass the sample solution through the column at 5 ml/min and then wash the resin with 300 ml of a solution containing 5 ml of 0·05*M* EDTA and 60 ml of 0·5*M* acetic acid and adjusted to pH 1·3 with dilute nitric acid, at the same flow-rate. Then elute the cadmium with 40 ml of 1*M* hydrochloric acid. Transfer the eluate, or an aliquot thereof, to the electrolysis cell and deaerate by passing nitrogen for 15 min. Electrolyse at − 0·8 V *vs.* SCE for 15 min with stirring and 1 min further without stirring, at the HMDE. Record the voltammogram from − 0·8 to − 0·2 V at 400 mV/min. During the whole procedure pass nitrogen over the solution.

Add 0·1 or 0·2 μg of cadmium to the solution in the electrolysis cell (use a syringe to add as small a volume as possible) and repeat the stripping determination. Calculate the cadmium content from the difference in the peak-heights before and after the standard addition. The peak-heights are measured as indicated in Fig. 4: the inflexion points on the curve before and after the cadmium peak are connected by a straight line and the vertical distance is measured from this line to the top of the peak.

STUDIES ON SYNTHETIC INORGANIC ION EXCHANGERS—V

PREPARATION, PROPERTIES AND ION-EXCHANGE BEHAVIOUR OF AMORPHOUS AND CRYSTALLINE THORIUM TUNGSTATE

ANIL K. DE and KAILAS CHOWDHURY
Department of Chemistry, Visva-Bharati, Santiniketan, West Bengal, India

(*Received* 2 *December* 1974. *Accepted* 10 *May* 1975)

Summary—Amorphous and crystalline thorium tungstate have been prepared by mixing $0{\cdot}1M$ thorium nitrate and $0{\cdot}1M$ sodium tungstate under different conditions. The physico-chemical properties, chemical stability, composition, TGA, DTA, X-ray, infrared absorption and ion-exchange behaviour of thorium tungstate are reported and discussed. Distribution coefficients of metal ions on thorium tungstate have been determined at pH 2–3 and 5·5–6·5. Selective ion-exchange separations of bismuth and mercury from other metal ions have been achieved on a column of thorium tungstate.

The importance of synthetic inorganic ion-exchangers has been reviewed.[1] In our earlier papers,[2–5] thorium phosphate was studied as an ion-exchanger. The present report deals with amorphous and crystalline thorium tungstate as an ion-exchanger.

This compound has been examined for ion-exchange properties by Turnov and Kovba[6] and by Qureshi *et al.*[7] The latter prepared non-crystalline thorium tungstate having composition $Th(OH)_2(HWO_4)_2 . nH_2O$. They found that the distribution coefficients were higher for Ga^{3+}, In^{3+}, Zr^{4+}, Pb^{2+} and La^{3+} but they did not investigate the effect of heat treatment on these exchangers. Although crystallization of inorganic ion-exchangers is tedious and difficult, crystalline thorium tungstate offers many advantages. We have prepared and investigated a number of both amorphous and crystalline thorium tungstates of varying compositions, the crystalline variety being the more stable for column operation. The crystalline thorium tungstate prepared by us permits ion-exchange separations much superior to those reported by Qureshi.[7] The crystalline thorium tungstate is stable in water, methanol, ethanol, acetone, dilute mineral acid and dilute alkalis at room temperature and can be used in these media for analytical separations of metal ions.

EXPERIMENTAL

Reagents

All chemicals were of analytical reagent grade.

Apparatus

For separation studies, a glass tube (bore 1·1 cm) was filled with 10 g of thorium tungstate (hydrogen form) on a glass-wool support. The column length was 4·5 cm; the flow-rate was 0·2 ml/min for all separations.

Preparation of thorium tungstate

Thorium tungstate was prepared by adding $0{\cdot}1\ M$ thorium nitrate in $1M$ nitric acid dropwise to $0{\cdot}1M$ sodium tungstate in different volume ratios, with constant stirring. The mixture was kept at room temperature (for crystalline material) or digested on a steam-bath (for the amorphous product) for several hours. Then the product was filtered off and washed with water till the pH of the filtrate was 2·5–3, and dried over phosphorus pentoxide. If the crystalline product was washed until the pH was >3, it became amorphous. Even on digestion for 140 hr on the steam-bath, the product was amorphous, but the crystalline variety was obtained after standing for only 12 hr at room temperature.

Composition

The products were analysed by standard methods,[8–9] and the results are shown in Table 1. Qureshi *et al.*[7] reported compositions varying from 1:1 to 1:1·8 Th:W.

Heat treatment

Thorium tungstate (batch No. 9) was heated in an electric muffle furnace for 1-hr periods at various temperatures up to 1000°. The colour of the sample changed with temperature, from colourless at room temperature, to yellow at 400° and deep green at 900°. Samples of batches 1 and 9 were subjected to thermogravimetric analysis at a heating rate of 8°/min with a MOM (Hungary) thermobalance. Figures 1 and 2 show the TGA and DTA curves. The influence of heat treatment of the ion-exchange capacity was also determined.

pH titration

Topp and Pepper's method was employed,[10] 500 mg of thorium tungstate (batch 9) being shaken with 100 ml of solution containing different amounts of MOH (M = Li, Na and K) for three days at $30 \pm 2°$ with intermittent shaking. After attainment of equilibrium the pH was measured. The experiment was repeated in the presence of sodium chloride, the total sodium concentration being kept at $0{\cdot}1M$. The results (identical for both experiments) are shown in Fig. 3.

Ion-exchange capacity

The exchange capacity was determined by titration of hydrogen ion eluted from the exchanger (1 g) in hydrogen form by sodium chloride solution, with Methyl Orange as indicator. The capacity was also determined by batch operation by shaking 100 ml of $1M$ alkali metal or

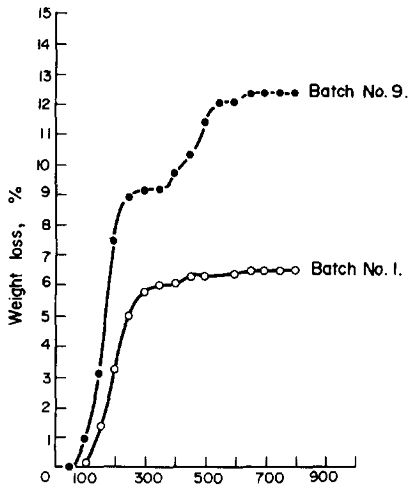

Fig. 1. Thermograms (TGA) of thorium tungstate.

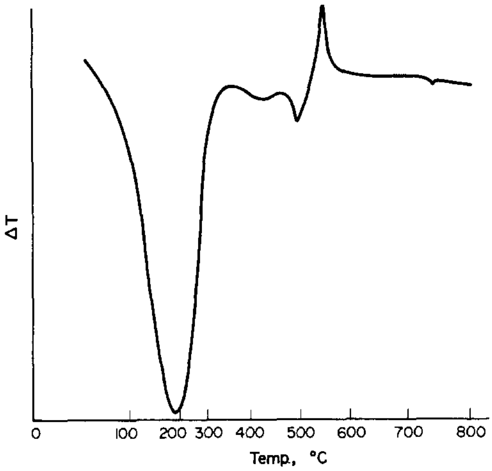

Fig. 2. DTA curve for thorium tungstate (batch 9).

ammonium chloride with 1 g of sample for 4 days with intermittent shaking, and titrating 50 ml of the solution with standard alkali.

Distribution coefficients

The distribution coefficients (K_d) of metal ions were determined by shaking 500 mg of exchanger with 50 ml of $2 \times 10^{-4}M$ metal ion solution ($5 \times 10^{-4}M$ for bismuth, uranium, vanadium and thorium) intermittently during 3 days at 27 ± 2°. The distribution coefficients were determined at pH 2–3 and 5·5–6·5, the pH being adjusted with dilute perchloric acid. The K_d values were calculated from

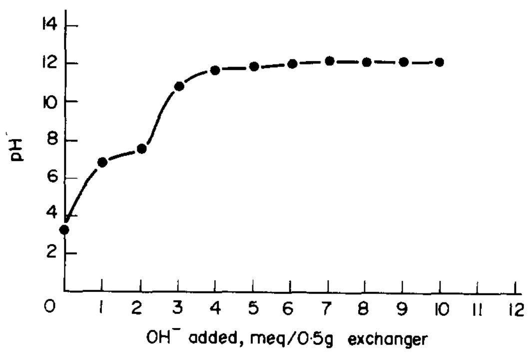

Fig. 3. pH-titration curve for thorium tungstate (batch 9) with 0·1*M* NaOH or NaOH + NaCl.

$$K_d = \frac{\text{Amount of element in exchanger}}{\text{Amount of element in solution}} \times \frac{\text{ml of solution}}{\text{g of exchanger}}$$

Uranyl ions were determined spectrophotometrically with hydrogen peroxide.[11] All other cations were estimated by titration with $2 \times 10^{-3}M$ EDTA.[9–12]

RESULTS AND DISCUSSION

Preparation and composition

The molar ratio of the reagents used in the preparation of the exchanger has little effect on the ion-exchange capacity and the composition of the exchanger (Table 1). A poor yield was obtained of batch 10, which was also difficult to filter.

Properties

The amorphous products are white powders and the crystalline varieties are colourless. X-Ray diffraction data for crystalline thorium tungstate are given in Table 2.

The exchanger (batch 9) remains unaffected after contact for up to 72 hr at room temperature with concentrated ammonia solution, nitric acid, sulphuric acid, perchloric acid (60%) and sodium hydroxide solution. Batch 9 was also stable in ethanol, acetone and acetic acid for up to 60 hr at room temperature.

Sulphuric acid, 1*N*	Decomposed to yellow product	

The sample became yellow after a few days in concentrated hydrochloric acid at room temperature or after refluxing with 1*N* mineral acid.

The solubility of the exchanger was determined as reported earlier.[2] Thorium was determined spectrophotometrically with thoron at 545 nm[10] and tungsten with thiocyanate at 420 nm.[10] The solubility is shown in Table 3.

Both amorphous and crystalline thorium tungstate, when heated at high temperature (~800°) became green. On heating above 100°, the colour changed from white to grey. The weight loss of thorium tungstate on heating is due to elimination of water and ceases above 650° (Fig. 1). There is an endothermic change at 100–300°, and an exothermic peak at 500–580°, corresponding to formation of oxides (Fig. 2). At 650°, the weight loss is 12·43%. On the assumption that the composition of batch 9 after heating to 650° was $ThO_2.6WO_3$, it was calculated that 13 moles of water were present per mole of exchanger. For batch 1 the result was 4·6 moles of water, on the basis of a composition of $ThO_2.4WO_3$ at 750°.

The infrared spectrum of batch 9 had three well-defined peaks which were similar to those reported by Qureshi.[7] On the basis of the spectra of thorium oxide and sodium tungstate,[13–14] we can postulate that the first and second peaks (at 2820–2990 cm^{-1} and 1500–1700 cm^{-1}) are due to interstitial water molecules. The third peak (at 300–900 cm^{-1}) corresponds to the metal-oxygen bonds, probably in a polymeric compound.

The pH-titration curves of thorium tungstate resemble those of titanium tungstate.[15]

Ion-exchange capacity

The exchange reaction is slow, about 32 hr being required for attainment of equilibrium with 1*M* sodium chloride in batch operation. In column operation the rate of exchange is a function of the salt concentration in the feed stock. The ion-exchange capacity for univalent and bivalent cations is shown in Table 4. The capacity increases as the radius of the hydrated ion decreases, as expected.

The exchange capacity decreases as the temperature of heat treatment of the exchanger increases. The amorphous thorium tungstate (batch 1) is more stable than the crystalline form (batch 9) towards heat, but both lose all ion-exchange character if heated to 500°.

Distribution coefficient studies and ion-exchange separations

Some distribution coefficients are shown in Table 5. Thorium is totally adsorbed from 5 × 10^{-4}*M* solution as was the case with thorium phosphate.[3] Comparison of the selectivity based on the K_d values of metal ions on our thorium tungstate and thorium phosphate[3] ion-exchangers shows that bismuth and lead are more strongly adsorbed than other metal ions in both the exchangers.

The K_d values change with pH of the metal ion solution, as in the case of other inorganic ion-exchangers, especially with strontium and cobalt. The

selectivity of our thorium tungstate is in general quite different from that obtained by Qureshi *et al.*[7] On the basis of the K_d values, some separations of binary mixtures were attempted. Reasonably quantitative separations of bismuth or mercury from some other metals are shown in Table 6. Bismuth was eluted with 1% potassium iodide solution in 0·03*M* sulphuric acid, after the other ion had been eluted with 0·15*M* nitric acid. Mercury was eluted first with $10^{-3}M$ nitric acid, followed by elution of the second ion with 0·15*M* nitric acid.

The K_d values show that crystalline thorium tungstate is a useful ion-exchanger and many interesting separations are possible, especially of bismuth. The method of preparation of inorganic ion-exchangers has a considerable effect on the degree of hydration and the composition of the exchanger since these factors are responsible for the shape and size of the cavities inside the exchanger and for other properties of the exchanger. The exchanger also has good regeneration capacity, so it can be used repeatedly in column operation.

IRON (III) DERIVATIVES OF 4,7-DIHYDROXY-1,10-PHENANTHROLINE

Donald P. Poe* and Harvey Diehl
Department of Chemistry, Iowa State University, Ames, Iowa 50011, U.S.A.

(*Received* 7 *April* 1975. *Accepted* 23 *April* 1975)

Summary—The chemistry of the iron(III) derivatives of 4,7-dihydroxy-1,10-phenanthroline has been studied in detail. Oxidation of the intensely red tris(4,7-dihydroxy-1,10-phenanthroline) iron(II) ion results in a grey compound, tris(4,7-dihydroxy-1,10-phenanthroline)iron(III), which is stable below pH 10. Above pH 10 the grey compound is partially converted into an amber compound in which the ratio of phenanthroline to iron is 2 : 1. The amber compound is the conjugate base of a purple 2 : 1 compound with $pK_a = 9{\cdot}77$. The visible absorption spectra of the three species at various pH values are reported. For 4,7-dihydroxy-1,10-phenanthroline pK_3, as determined by ultraviolet absorptometry, is $12{\cdot}62 \pm 0{\cdot}2$.

The usefulness of 4,7-dihydroxy-1,10-phenanthroline as a reagent for the spectrophotometric determination of iron in highly alkaline solutions was shown by Schilt, Smith and Heimbuch.[1] In recent publications[2,3] we have reported on the use of tris(4,7-dihydroxy-1,10-phenanthroline) iron(II) as a reagent for the spectrophotometric determination of dissolved oxygen, and of the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple as a low-potential oxidation reduction indicator. In the present paper we report on the nature of the iron (III) derivatives of 4,7-dihydroxy-1,10-phenanthroline.

Oxidation of the red tris(4,7-dihydroxy-1,10-phenanthroline)iron(II) ion by air or by potassium ferricyanide results in a grey iron(III) compound which is stable in solution below pH 10 and insoluble below pH 8. The grey compound is slowly converted into an amber compound in solutions of pH greater than 10, the rate of conversion increasing with temperature and concentration of alkali. The iron(III) compound exists solely in the amber form in solutions in which the concentration of sodium hydroxide is 2*M* or greater. Addition of acid to solutions of the amber compound results in the reversible formation of a purple compound, the transition range being pH 8·0—11·5. The purple compound is insoluble below pH 6·5. Solutions of the purple compound slowly decompose over a period of about one day to yield the grey compound. A graphical representation of the inter-relationships of the iron derivatives is shown in Fig. 1.

EXPERIMENTAL

Reagents and solutions

4,7-Dihydroxy-1,10-phenanthroline. Prepared by the method of Snyder and Freier[4] with improvements by Poe.[5] The final product, recrystallized from 6*M* hydrochloric acid, contained 95% w/w 4,7-dihydroxy-1,10-phenanthroline and 5% w/w hydrogen chloride, as determined by titration. Reagent solutions were prepared by adding a minimum amount of ammonia or sodium hydroxide to the recrystallized material in demineralized water.

Ferricperchlorate solutions. Prepared by dissolving electrolytic iron in hot, concentrated perchloric acid and diluting to a known volume with demineralized water.

Other chemicals were from commercial sources.

Buffer solutions. Prepared according to Bates.[6] Buffers at pH 10 and 11 contained sodium carbonate and sodium bicarbonate; those at pH 12 and 13 contained sodium hydroxide and potassium chloride.

Apparatus

A Corning No. 476022 triple-purpose glass electrode and a saturated calomel electrode were used in conjunction with a Beckman Zeromatic SS-3 pH-meter. The pH-meter was calibrated against NBS buffers of pH 6·86, 9·18 and 12·45, prepared as described by Diehl[7] and corrected for temperature as described by Bates.[8]

Beckman DU and Cary 14 spectrophotometers were used. Spectrosil cuvettes with 1·00-cm path-lengths were used throughout.

Visible absorption spectra and composition of the grey, purple and amber iron(III) derivatives of 4,7-dihydroxy-1,10-phenanthroline

Spectra at pH 6–14. To 0·0227 g of 4,7-dihydroxy-1,10-phenanthroline dissolved in 10 ml of 3·16M sodium hydroxide were added 10·5 ml of 1·00 × $10^{-2}M$ ferric perchlorate. The excess of iron, precipitated as ferric hydroxide, was filtered off and the solution diluted to 50·00 ml. A series of 5·00-ml aliquots of this solution was taken and the pH adjusted over the range 6–14 with hydrochloric acid or sodium hydroxide; the resulting solutions were diluted to 25·00 ml with demineralized water. The visible absorption spectra were recorded and the pH of each solution remeasured, Fig. 2. After 14 days the absorption spectrum and pH of each solution were recorded again, Fig. 3.

Spectra in highly alkaline solutions. Aliquots of 1·0 or 10·0M sodium hydroxide, 10·00 ml of 3·37 × $10^{-3}M$ 4,7-dihydroxy-1,10-phenanthroline and 1·00 ml of 3·363 × $10^{-3}M$ ferric perchlorate were placed in 25-ml volumetric flasks, diluted to volume and the visible absorption spectra recorded after 1 hr and 1 day, and again after heating at 80° for 2 hr. The spectra obtained after 1 day are shown in Fig. 4.

Continuous variations studies. Volumes of 3·37 × $10^{-3}M$ 4,7-dihydroxy-1,10-phenanthroline and 3·363 × $10^{-3}M$ ferric perchlorate, such that the sum of the two was constant, were delivered into 25-ml volumetric flasks, each flask containing the same buffer, chosen appropriately for the grey, amber and purple compounds respectively (see next few paragraphs), and diluted to volume. Any precipitate which formed was removed by centrifuging. The absorbance was then measured and the measurements interpreted in the usual way.[9] The results, together with information on the absorption in the visible region, are given in Table 1.

Purple compound. The solutions produced on mixing 4,7-dihydroxy-1,10-phenanthroline and iron(III) perchlorate

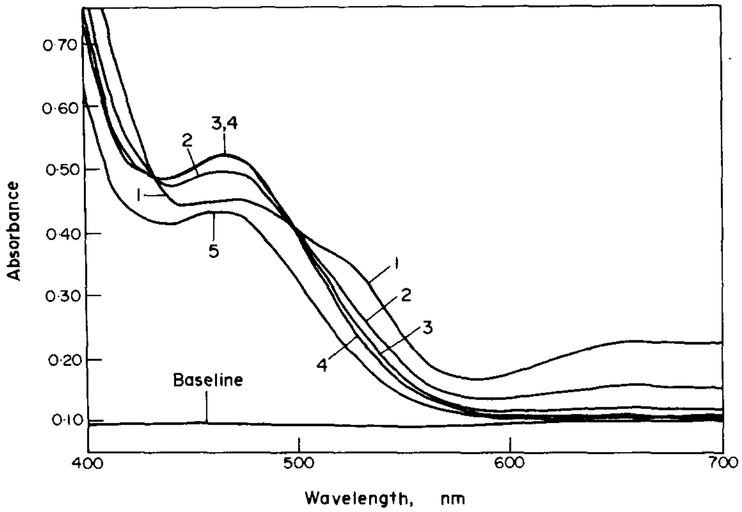

Fig. 4. Absorption spectra of the iron(III)-4,7-dihydroxy-1,10-phenanthroline compound in solutions of sodium hydroxide. Spectra obtained on day following preparation of solutions. Concentration of iron: 1·35 × $10^{-4}M$; concentration of 4,7-diOH-phen: 1·35 × $10^{-3}M$. Concentration of sodium hydroxide, *M*: 1, 0·2; 2, 0·5; 3, 1·0; 4, 2·0; 5, 4·0.

are purple at pH 7–9·5, or amber at pH > 10·5. The absorption spectra at various pH values are shown in Fig. 2.

The solutions for the continuous variations study of the purple compound were prepared by adding phenanthroline and iron(III) to 5 ml of 5·0*M* sodium hydroxide, heating in a hot water-bath to promote formation of the iron compound and coagulation of the small amount of ferric hydroxide formed, and then adding just enough 10*M* hydrochloric acid to cause precipitation of the purple compound, immediately neutralizing with dilute sodium hydroxide solution to yield a purple solution, and adding 5·0 ml of borate buffer (38 g of sodium tetraborate decahydrate per litre, pH 8·65). The solutions were finally diluted to 25·00 ml with demineralized water and the absorbances at 533 nm measured. The purple compound is 1 : 2 metal : ligand, Table 1.

Amber compound. Spectra obtained immediately after mixing 4,7-dihydroxy-1,10-phenanthroline and iron(III) in 0·2–2·0*M* sodium hydroxide were identical, Fig. 4, curve 4. After 1 day the composition of the solutions in 0·2–1·0*M* sodium hydroxide had changed to yield mixtures of the grey and amber compounds, Fig. 4, curves 1, 2, and 3, while the spectrum of the solution in 2·0*M* sodium hydroxide remained unchanged. Heating the solutions produced no further changes in the spectra. From these spectra and other observations, it is apparent that on mixing the phenanthroline and iron(III) in highly alkaline solutions the amber compound is formed first. If the concentration of sodium hydroxide is less than 2*M*, some conversion of the amber compound into the grey compound occurs. The ratio of amber to grey compound at equilibrium depends on the relative amounts of iron, phenanthroline and alkali present, the last of these having the greatest effect.

In the continuous variations study, the solutions were prepared in 0·2*M* sodium hydroxide. Absorbance measurements at 470 nm were made immediately following preparation, before appreciable conversion into the grey compound could occur. The amber compound is also 1 : 2 metal : ligand (Table 1).

Grey compound. The spectra are shown in Figs. 3 and 4. The spectra of the grey compound obtained from the purple compound on standing for two weeks at pH 8–10 were identical with the spectra of the grey compound obtained by oxidation of tris(4,7-dihydroxy-1,10-phenanthroline)iron(II) with oxygen.

In the continuous variations study, the pH used was 9·4, obtained by mixing equal volumes of 2*M* ammonia solution and 2*M* ammonium chloride. After preparation, the solutions were heated at 75° for 2 hr to ensure complete conversion of the iron compound into the grey form, and then cooled. The absorbance of each solution was then measured against a water blank at 526 nm. The grey compound is 1 : 3 metal : ligand (Table 1).

Acid dissociation constant of the purple compound. The rapid and reversible interconversion of the purple and amber compounds is governed by the hydrogen-ion concentration. The acid dissociation constant was determined spectrophotometrically.

A stock solution of the amber compound was prepared by dissolving 0·0456 g (2·04 × 10^{-4} mole) of 4,7-dihydroxy-1,10-phenanthroline in dilute sodium hydroxide solu-

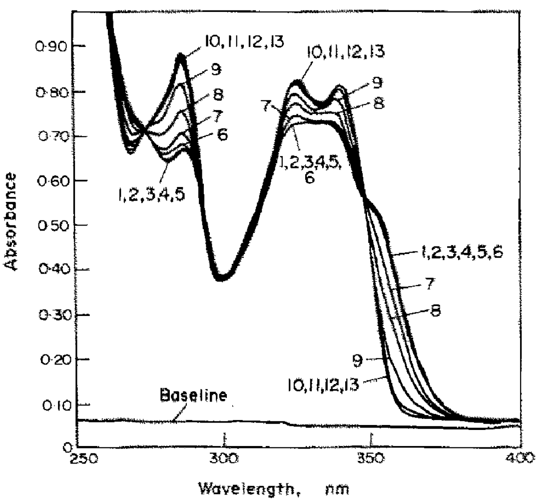

Fig. 5. Effect of pH on the ultraviolet absorption spectrum of 4,7-dihydroxy-1,10-phenanthroline. Concentration of 4,7-dihydroxy-1,10-phenanthroline: 5·00 × $10^{-5}M$. Ionic strength: 1·0. pH: 1, 9·10; 2, 9·59; 3, 10·12; 4, 10·62; 5, 11·08; 6, 11·30; 7, 12·02; 8, 12·55; 9, 13·05; 10, 13·66. NaOH, M 11, 1·0; 12, 2·0; 13, 5·0.

tion and adding 20 ml of 1·00 × $10^{-2}M$ ferric perchlorate (2·0 × 10^{-4} mole). The solution was heated almost to boiling to promote formation of the iron compound and the excess of iron was filtered off as ferric hydroxide. The filtrate was diluted to exactly 100 ml with 10M sodium hydroxide and water so that the final concentration of sodium hydroxide was 2M. Solutions for absorbance measurements were prepared by adjusting 5·00-ml aliquots of the stock solution to the approximate desired pH, adding 2 ml of the appropriate buffer (ammonia–ammonium chloride) to cover the pH range 6·5–12·0, and diluting to 25·00 ml with demineralized water. This gave an ionic strength of approximately 0·4 in each solution. The absorbance of each solution at 533 nm was measured within 30 min after preparation. The pH of each solution was then checked.

To evaluate the dissociation constant, K_A, from the absorbance *vs.* pH data, use was made of the equation

$$\text{pH} = (1/b)\text{p}K_A + (1/b)\log[(A_{HA} - A_{mix})/(A_{mix} - A_A)]$$

which is derived from the mathematical equation defining the overall acid dissociation constant of a multiprotic acid, $K_A = K_1K_2 \ldots K_b$, where b is the number of protons involved, A_{HA} is the absorbance when the compound is 100% protonated (*i.e.*, in this case, all in the purple form), A_A is the absorbance when the compound is 100% dissociated (all in the amber form), and A_{mix} is the absorbance when both the acid (HA) and anion (A^-) are present. The plot of $\log[(A_{HA} - A_{mix})/(A_{mix} - A_A)]$ *vs.* pH is linear with a slope of 0·88 (b = 1·1), and the intercept occurs at pH 9·77. Thus only one proton is involved and pK_A = 9·77 at 23° and an ionic strength equal to 0·4.

Ultraviolet absorption spectrum of 4,7-dihydroxy-1,10-phenanthroline and estimation of pK_3. Ultraviolet absorption spectra of 4,7-dihydroxy-1,10-phenanthroline were obtained over the range from pH 9·1 to 5·0M sodium hydroxide. The third acid dissociation constant, K_3, was estimated from the spectrophotometric data.

To each of thirteen 50-ml volumetric flasks were added 5·00 ml of 5·00 × $10^{-4}M$ 4,7-dihydroxy-1,10-phenanthroline, 10 ml of ammonia/ammonium chloride buffer solution or the amount of sodium hydroxide necessary to adjust the pH to the desired value, and 1·0M potassium chloride to a volume of 50·00 ml to maintain the ionic strength at 1. The ultraviolet absorption spectrum of each solution was obtained between 250 and 400 nm against a blank of distilled water. The pH of each solution was measured after the spectra were recorded.

The spectra are shown in Fig. 5. Two isosbestic points are present, at 274 and 347 nm. Absorbance data at 286 and 360 nm were subjected to the logarithmic treatment described in the preceding section. The values of pK_3 (and b, number of protons involved) obtained were 12·68 (b = 0·95) and 12·57 (b = 1·04), respectively. The average value of pK_3 = 12·62 is believed to be accurate to ±0·2 and applies to aqueous solutions of 4,7-dihydroxy-1,10-phenanthroline having an ionic strength of 1 and a temperature of approximately 25°. The conclusion that only one proton is involved is supported by alkalimetric titration in a mixture of propan-2-ol and dimethylsulphoxide.[10]

The ultraviolet absorption spectrum of 4,7-dihydroxy-1,10-phenanthroline in the presence of iron(III) was also obtained as a function of pH. Two sets of six solutions each 5·00 × $10^{-5}M$ in 4,7-dihydroxy-1,10-phenanthroline and 1·67 × $10^{-5}M$ in ferric perchlorate were prepared at integral pH values from 9 to 14. To one set was added 2·0 ml of sodium hydrosulphite solution (200 mg/ml) per 50 ml. The spectra of the reduced form were not obtained, owing to absorption by hydrosulphite at wavelengths shorter than 380 nm. The spectra of the solutions containing no hydrosulphite were similar to the spectra of uncombined 4,7-dihydroxy-1,10-phenanthroline at corresponding values of pH, Fig. 5. A logarithmic treatment of the absorbance data at 287 and 360 nm gave an average value of pK_3 = 11·9. This value is considerably lower than that for the uncombined phenanthroline, and is reasonable from the standpoint that the iron(III) ion should exert a considerable electron-withdrawing effect. The exact values of pK_3 and b under these conditions were not obtained, owing to incomplete formation of the iron(III) compound and equilibration of the iron(III) compound between the grey and amber forms.

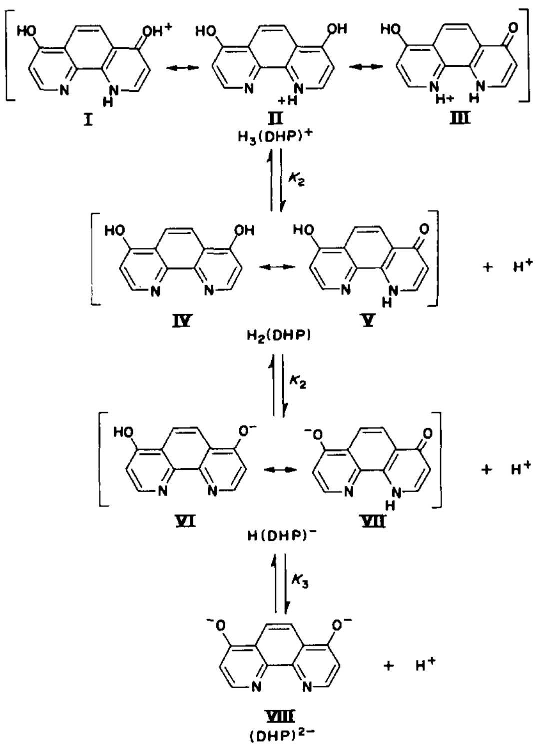
DISCUSSION

We adopt for the protonated, neutral and dissociated forms of 4,7-dihydroxy-1,10-phenanthroline the designations $H_3(DHP)^+$, $H_2(DHP)$, $H(DHP)^-$, and $(DHP)^{2-}$, and for the constants associated with the successive dissociation steps the symbols K_1, K_2 and K_3. Values for K_1, K_2 and K_3 in 1:1 dioxan–water solution were reported by James and Williams[11] (pK_1 = 2·55 ± 0·05, pK_2 = 7·28 ± 0·03, pK_3 = 11·5 ± 0·1). The value of pK_3 in aqueous solution is 12·6, according to the work reported in the preceding section.

Possible structures for the protonated, neutral, and singly-charged anionic forms are shown on the next page. Of the structures **I**, **II**, **III**, the last two appear most likely inasmuch as the positive charge on a ring nitrogen atom allows for better dissipation of the charge in the resonating electron system. Further, structure **II** is preferred over structure **III** because of the electrostatic repulsion developed by protonating both nitrogen atoms simultaneously.

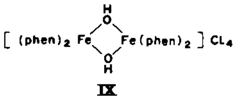
Structure **V** has been shown to be the actual structure of the neutral compound by interpretation of infrared spectra.[12,13]

We believe structure **VI** to be correct for the singly charged anionic form. This belief is based on the



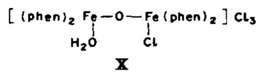
observations that the ultraviolet spectrum of 4,7-dihydroxy-1,10-phenanthroline is hardly affected by the presence of iron, and that the third acid function K_3 is still present in the iron(III) compound, although the value is somewhat altered (see preceding section). Thus the compound exists in the same form in both the uncombined and combined states. The presence of structure **VII** in the iron derivative is highly unlikely, leaving only structure **VI** as the logical choice.

The amber iron(III) derivative of 4,7-dihydroxy-1,10-phenanthroline is analagous to the brown iron(III) derivative of 1,10-phenanthroline. Both compounds are formed by direct addition of salts of iron(III) to solutions of the phenanthroline, and the ratio of phenanthroline to iron in each is two to one. Gaines, Hammett and Walden[14] isolated the brown derivative of 1,10-phenanthroline and reported a composition corresponding to the binuclear hydroxy-bridged species **IX**. Later investigators suggested structures **X** and **XI** on the basis of magnetic data and infrared spectra. Reduction-potential and pH measurements of aqueous solutions favour structure **IX**.[15] In the arguments which follow we have assumed no structures for the purple and amber derivatives of 4,7-dihydroxy-1,10-phenanthroline. The ratio of phenanthroline to iron in both is definitely two to one, however, and they are interconverted by the loss or gain of a single proton.



$[(phen)_2Fe(\mu\text{-}OH)_2Fe(phen)_2]Cl_4$

IX



$[(phen)_2Fe(H_2O)\text{—}O\text{—}Fe(Cl)(phen)_2]Cl_3$

X

$[(phen)_2Fe(Cl)\text{—}O\text{—}Fe(Cl)(phen)_2]Cl_2$

XI

The dissociation constant, $pK_A = 9{\cdot}77$, for the proton involved in this interconversion is associated with a hydroxy group bound directly to the iron atoms. The evidence for this is: (1) the second acid function, K_2, operates in the precipitation of both the combined and uncombined phenanthroline at about pH 8; (2) the third acid function, K_3, is still present in the iron(III) compound although the value for K_3 is somewhat altered [$pK_3 = 12{\cdot}6$ (no iron present); $pK_3 = 11{\cdot}9$ (iron(III) present)]; (3) no change in the visible absorption spectrum of the iron derivatives of 4,7-dihydroxy-1,10-phenanthroline is produced by the dissociation of the hydroxy proton on the phenanthroline ring (K_3); (4) no change in the ultraviolet spectrum of the iron(III) derivatives at wavelengths shorter than 400 nm accompanies the conversion of the purple into the amber compound.

TRIS(4,7-DIHYDROXY-1,10-PHENANTHROLINE)IRON(II) AS A LOW-POTENTIAL OXIDATION–REDUCTION INDICATOR

DETERMINATION OF HYDROSULPHITE

DONALD P. POE* and HARVEY DIEHL
Department of Chemistry, Iowa State University, Ames, Iowa 50011, U.S.A.

(*Received* 7 *April* 1975. *Accepted* 29 *April* 1975)

In recent papers[1,2] we have reported on the use of the iron(II) derivative and on the nature and inter-relations of the three iron(III) compounds (grey, amber, purple) of 4,7-dihydroxy-1,10-phenanthroline. In the present paper we report on the character of the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple and an application of it as a visual oxidation–reduction indicator for titrations in alkaline solutions with standard ferricyanide.

EXPERIMENTAL

Reagents

Buffer solutions were prepared according to Bates.[3] Those at pH 10 and 11 contained sodium carbonate and sodium bicarbonate; those at pH 12 and 13 contained sodium hydroxide and potassium chloride.

Solutions of potassium ferricyanide were prepared by dissolving 3·3–3·4 g of the anhydrous reagent—grade material in approximately 180 ml of buffer. The pH of the resulting solutions was adjusted to the desired values by the addition of hydrochloric acid or sodium hydroxide, if necessary. After the pH was adjusted, the solutions were diluted to 200 ml with water.

Measurement of formal reduction potential

The reduction potential of the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple in the alkalinity range from pH 10 to 3·2M sodium hydroxide was measured by following the potential of a bright platinum foil electrode in the titration of sodium hydrosulphite in appropriately buffered solutions containing enough of the phenanthroline–iron compound to give a separate feature on the titration curve. The standard oxidizing agent, potassium ferricyanide, was prepared for each titration in a solution identical in pH or alkali concentration with the solutions being titrated. The titrations were performed under an atmosphere of nitrogen.

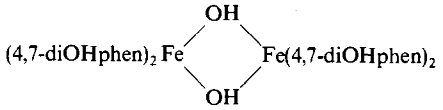
A representative titration curve is shown in Fig. 1. Values for the formal reduction potential at various pH values are given in Table 1.

Formal reduction potentials in solutions outside the pH range reported could not be determined; at lower pH, the oxidation of sodium hydrosulphite with potassium ferricyanide proceeded too slowly near the equivalence-point; in higher concentrations of alkali, the potential drifted considerably.

RESULTS AND DISCUSSION

The formal reduction potential does not change appreciably over the pH range 10–13. The more negative values obtained in 1–3·2M sodium hydroxide cannot be explained simply on the basis of the dissociation of an acid, and the drift observed indicates that the conversion

$(4,7\text{-diOHphen})_3\,\text{Fe(III)} \rightarrow$



$$(4,7\text{-diOHphen})_2\text{Fe}\overset{\text{OH}}{\underset{\text{OH}}{\lt\!\!\gt}}\text{Fe}(4,7\text{-diOHphen})_2$$

is involved. The rate of this reaction increases with increasing alkalinity. Under the conditions of the titrations, some 5–10 min elapsed from the time that the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III) was first formed until the mid-point of the titration was reached. Thus, the condition that the concentrations of the oxidized and reduced forms of the couple be equal at the mid-point was not met. The values obtained in solutions in which the concentration of sodium hydroxide was 1M or greater therefore do not represent the formal reduction potential of the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple. Because the conversion is slow at pH 13, and slower at pH 12, and occurs hardly at all at pH 10–11, the values reported in Table 1 closely reflect the true formal reduction potential.

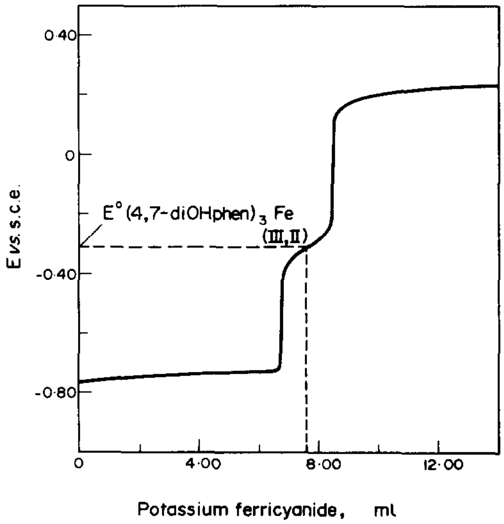


Fig. 1. Titration of sodium hydrosulphite plus tris(4,7-dihydroxy-1,10-phenanthroline)iron(II) with potassium ferricyanide at pH 11. Potassium ferricyanide, 0·0514M; sodium hydrosulphite, 0·0423 g; 4,7-dihydroxy-1,10-phenanthroline, 0·0621 g (0·278 mmole); ferrous ammonium sulphate hexahydrate, 0·0346 g (0·088 mmole).

Table 1. Formal reduction potential of the tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple as a function of pH

Conditions	Formal reduction potential, *V vs. N.H.E.*	Temperature, *°C*
pH 10	−0·064	28
pH 11	−0·063	27
pH 12	−0·053	27
pH 13	−0·070	28
1·0*M* NaOH	(−0·105, −0·115, −0·199)*	25
2·0*M* NaOH	(−0·33)*	
3·2*M* NaOH	(−0·260)*	25

* Serious drift owing to the slow conversion of the iron(III) form of the couple into another species.

Because of the errors inherent in these measurements, it seems best simply to average the values obtained at pH 10–13. We report therefore the value of the formal reduction potential over the pH range 10–13 to be −0·06 V *vs.* the normal hydrogen electrode (N.H.E.). The value we reported earlier, −0·11 V in 1*M* sodium hydroxide,[1] was obtained before the significance of the drift was appreciated, and is wrong. A value of −0·13 V *vs.* N.H.E, was reported earlier by George, Hanania and Eaton,[4] incidentally to a discussion of the reduction potentials of haemes and haemoproteins; no details were given other than that the pH was > 10.

This reduction potential is astonishingly low. The formal reduction potentials of almost all the iron–phenanthroline couples previously reported fall in the range from +0·85 to +1·26 V *vs.* N.H.E. Although those values were determined in acid solution, the phenanthroline–iron(III,II) couples do not involve hydrogen ions and the formal reduction potentials are independent of pH, *e.g.*, for the simplest member of the series, the ferriin–ferroin couple:

$$Fe(1,10\text{-phen})_3^{3+} + e^- = Fe(1,10\text{-phen})_3^{2+};\ E^\circ = +1{\cdot}06\ V$$

The lowest value previously reported is that of the iron(III,II) couple of 3-carbethoxy-4-hydroxy-1,10-phenanthroline, $E^\circ = +0{\cdot}71$ V *vs.* N.H.E.[5]

Use in the determination of hydrosulphite

The tris(4,7-dihydroxy-1,10-phenanthroline)iron(III,II) couple serves well as a visual indicator in the titration of sodium hydrosulphite with potassium ferricyanide in 0·1–3·2*M* sodium hydroxide media. The colour change at the end-point is very sharp, one drop or less of 0·05*M* potassium ferricyanide being required to change 70 ml of solution from a distinct pink to practically colourless.

Preparation of indicator solutions. A 2% solution of tris(4,7-dihydroxy-1,10-phenanthroline)iron(III) was prepared by dissolving 0·125 g of 4,7-dihydroxy-1,10-phenanthroline and 0·0669 g of ferric nitrate enneahydrate in 10 ml of a solution containing 1 ml of 16*M* sodium hydroxide.

Results. Variable results were obtained when solid samples of sodium hydrosulphite were titrated, indicating that the samples had undergone various degrees of oxidation before titration. Reproducible results were obtained when aliquots of a solution of sodium hydrosulphite in 2*M* sodium hydroxide, protected from air in, and delivered from, a Machlett burette, were titrated. The amount of indicator used had no effect on the position of the end-point, Table 2. The stoichiometry presumably corresponded[6,7] to the reaction

$$S_2O_4^{2-} + Fe(CN)_6^{3-} + 4OH^- = 2SO_3^{2-} + Fe(CN)_6^{4-} + 2H_2O \quad (1)$$

The indicator also functioned well in the titration of ferricyanide with hydrosulphite, the latter being delivered from a Machlett burette, but the results were not reproducible. The amount of sodium hydrosulphite required to reach the end-point varied inversely with the time taken to complete the titration, probably because of the slow oxidizing action of potassium ferricyanide on the sulphite produced in the oxidation. The reduction potential of the sulphate–sulphite couple in 1*M* sodium hydroxide is given as −0·93 V by Latimer, and that for the ferricyanide–ferrocyanide couple as 0·36 V.[8] The oxidation of sulphite in alkaline solution is therefore thermodynamically favoured. By direct test it was found that sodium sulphite in 2*M* sodium hydroxide is indeed slowly oxidized by potassium ferricyanide.

Neither sodium thiosulphate nor sodium sulphite interferes in the direct titration with potassium ferricyanide. Under the conditions specified, sodium thiosulphate is not oxidized at all by potassium ferricyanide, a very surprising finding inasmuch as the reduction potential of the sulphite–thiosulphate couple in alkaline solution is very low

Table 2. Titration of sodium hydrosulphite with potassium ferricyanide, visual end-point

Sodium hydrosulphite				
Form	Taken	Volume of indicator, *drops*	0·0520*M* potassium ferricyanide required, *ml*	Recovery, %

* Potentiometric end-point.

($-0{\cdot}58$ V) and that of the tetrathionate–thiosulphate couple is 0·08 V.[8] Although sulphite is produced by oxidation of hydrosulphite with ferricyanide, it does not interfere in the determination because the rate of oxidation of hydrosulphite is much greater than that of sulphite under the conditions specified. However, it is imperative that the solution of hydrosulphite be stirred efficiently while titrant is being added. Inefficient stirring leads to high results, owing to the slow oxidizing action of ferricyanide on sulphite. If the solution is continuously or fairly regularly stirred, the error is less than 0·3%, but if stirring is virtually omitted, errors of up to almost +5% occur.

Tris(4,7-dihydroxy-1-10-phenanthroline)iron(II) failed to function as an indicator in titrations of cobalt(II) sulphate, ascorbic acid, and sodium hypophosphite with potassium ferricyanide, and functioned very poorly as an indicator in the titration of sodium hydrosulphite with potassium octacyanomolybdate(VI). Addition of octacyanomolybdate(VI) to a solution containing the indicator gave an amber colour, and the end-point, from amber to yellow, was so gradual that it was almost impossible to detect. It is suspected that formation of a mixed complex, possibly dicyano-bis(4,7-dihydroxy-1,10-phenanthroline)iron(II), is involved.

CALCULATION OF ALL EQUILIBRIUM CONCENTRATIONS IN A SYSTEM OF COMPETING COMPLEXATION

G. Ginzburg
Chemistry Department, Ben Gurion University of the Negev, Beer-Sheva, Israel

(*Received* 22 *February* 1975. *Accepted* 8 *April* 1975)

It is often necessary to calculate the equilibrium concentration of each species in a multicomponent system of metal ions and ligands. As a rule, the starting data are the total (analytical) concentration of each reactant, the stability constant of each complex and the pH of the final solution. Some programs have been described for solving this problem.[1,2]

The following iterative method is used in the computer program COMICS:[1] the equilibrium concentration of each species is found at the kth approximation ($[A_i^k]$); from these, the total concentration of each of the reactants is calculated (A_i^{calc}); then the $(k+1)$th approximate equilibrium concentrations are determined by the equation:

$$[A_i^{k+1}] = [A_i^k]\left[\frac{A_i^{\text{tot}}}{A_i^{\text{calc}}}\right]^{1/2} \tag{1}$$

where A_i^{tot} is the total concentration of the ith reactant. With this program it turns out that the iterations do not always converge. Therefore it is of interest to examine the criteria for convergence in a more general case.

The present work will consider a somewhat modified program which gives improved intermediate results. Let us write the jth complex formation reaction in the following way:

$$\sum_{i=1}^{M} m_{ij}A_i = [(A_1)_{m_1}(A_2)_{m_2}\cdots(A_M)_{m_M}] \quad (i = 1,\ldots,N) \tag{2}$$

The concentration of this complex is given by:

$$c_j = \beta_j \prod_{i=1}^{M} [A_i]^{m_{ij}} \quad (j = 1,\ldots,N) \tag{3}$$

where A_i are the M different reactants, which may be metal ions, complexing agents, H^+ and OH^- ions; m_{ij} are the stoichiometric coefficients of the ith reactants in the jth complex; β_j is the cumulative stability constant and c_j the equilibrium concentration of the jth complex. For the system described by equations (2) and (3) it is possible to set up M equations for the material balance:

$$\text{ATOT}_i = [A_i] + \sum_{j=1}^{N} m_{ij}c_j \quad (i = 1,\ldots,M) \tag{4}$$

where ATOT_i is the total concentration of the ith reactant. Following COMICS,[1] the approximation to ATOT_i given by the kth iterative step will be denoted by ACALC_i^k. Using equations (3) and (4), it will be shown that

$$\text{ACALC}_i^k = [A_i^k] + \sum_{j=1}^{N} m_{ij}\beta_j \cdot \prod_{i=1}^{M} [A_i^k]^{m_{ij}} \tag{5}$$

$$(i = 1,\ldots M)$$

The $(k+1)$th iteration is obtained by modifying the method employed in COMICS,[1] from which the following general-

($-0{\cdot}58$ V) and that of the tetrathionate–thiosulphate couple is 0·08 V.[8] Although sulphite is produced by oxidation of hydrosulphite with ferricyanide, it does not interfere in the determination because the rate of oxidation of hydrosulphite is much greater than that of sulphite under the conditions specified. However, it is imperative that the solution of hydrosulphite be stirred efficiently while titrant is being added. Inefficient stirring leads to high results, owing to the slow oxidizing action of ferricyanide on sulphite. If the solution is continuously or fairly regularly stirred, the error is less than 0·3%, but if stirring is virtually omitted, errors of up to almost +5% occur.

Tris(4,7-dihydroxy-1-10-phenanthroline)iron(II) failed to function as an indicator in titrations of cobalt(II) sulphate, ascorbic acid, and sodium hypophosphite with potassium ferricyanide, and functioned very poorly as an indicator in the titration of sodium hydrosulphite with potassium octacyanomolybdate(VI). Addition of octacyanomolybdate(VI) to a solution containing the indicator gave an amber colour, and the end-point, from amber to yellow, was so gradual that it was almost impossible to detect. It is suspected that formation of a mixed complex, possibly dicyano-bis(4,7-dihydroxy-1,10-phenanthroline)iron(II), is involved.

CALCULATION OF ALL EQUILIBRIUM CONCENTRATIONS IN A SYSTEM OF COMPETING COMPLEXATION

G. Ginzburg
Chemistry Department, Ben Gurion University of the Negev, Beer-Sheva, Israel

(*Received* 22 *February* 1975. *Accepted* 8 *April* 1975)

It is often necessary to calculate the equilibrium concentration of each species in a multicomponent system of metal ions and ligands. As a rule, the starting data are the total (analytical) concentration of each reactant, the stability constant of each complex and the pH of the final solution. Some programs have been described for solving this problem.[1,2]

The following iterative method is used in the computer program COMICS:[1] the equilibrium concentration of each species is found at the kth approximation ($[A_i^k]$); from these, the total concentration of each of the reactants is calculated (A_i^{calc}); then the $(k+1)$th approximate equilibrium concentrations are determined by the equation:

$$[A_i^{k+1}] = [A_i^k]\left[\frac{A_i^{\text{tot}}}{A_i^{\text{calc}}}\right]^{1/2} \qquad (1)$$

where A_i^{tot} is the total concentration of the ith reactant. With this program it turns out that the iterations do not always converge. Therefore it is of interest to examine the criteria for convergence in a more general case.

The present work will consider a somewhat modified program which gives improved intermediate results. Let us write the jth complex formation reaction in the following way:

$$\sum_{i=1}^{M} m_{ij}A_i = [(A_1)_{m_1}(A_2)_{m_2}\cdots(A_M)_{m_M}] \quad (i = 1,\ldots,N) \qquad (2)$$

The concentration of this complex is given by:

$$c_j = \beta_j \prod_{i=1}^{M} [A_i]^{m_{ij}} \quad (j = 1,\ldots,N) \qquad (3)$$

where A_i are the M different reactants, which may be metal ions, complexing agents, H^+ and OH^- ions; m_{ij} are the stoichiometric coefficients of the ith reactants in the jth complex; β_j is the cumulative stability constant and c_j the equilibrium concentration of the jth complex. For the system described by equations (2) and (3) it is possible to set up M equations for the material balance:

$$\text{ATOT}_i = [A_i] + \sum_{j=1}^{N} m_{ij}c_j \quad (i = 1,\ldots,M) \qquad (4)$$

where ATOT_i is the total concentration of the ith reactant. Following COMICS,[1] the approximation to ATOT_i given by the kth iterative step will be denoted by ACALC_i^k. Using equations (3) and (4), it will be shown that

$$\text{ACALC}_i^k = [A_i^k] + \sum_{j=1}^{N} m_{ij}\beta_j \cdot \prod_{i=1}^{M} [A_i^k]^{m_{ij}} \qquad (5)$$

$$(i = 1,\ldots M)$$

The $(k+1)$th iteration is obtained by modifying the method employed in COMICS,[1] from which the following general-

Table 1. Calculation of the equilibrium concentrations in a multicomponent system. The total concentration of each reactant is equal to $5 \times 10^{-3} M$. pH = 8·0. The stability constants were taken from refs. 4 and 5.

Equilibrium concentrations below $10^{-7} M$ were not included. NTA is the tertiary anion of nitrilotriacetic acid

31	$1·42 \times 10^{-5}$	—	—	—	—	—	—	1	—
32	562	—	—	—	—	—	—	—	1

ization of equation (1) is obtained:

$$[A_i^{k+1}] = [A_i^k] \cdot \left[\frac{ATOT_i}{ACALC_i^k} \right]^{1/p} \tag{6}$$

where $[A_i^k]$ and $[A_i^{k+1}]$ are consecutive approximations to the equilibrium concentration of the ith reactant. Let us write $[A_i^k]$ as

$$[A_i^k] = A_i + \epsilon_i^k \tag{7}$$

It follows from equations (5), (6) and (7) that

$$\epsilon_i^{k+1} = \left(\frac{ATOT_i}{[A_i] + \epsilon_i^k + \sum_{j=1}^{N} m_{ij} . \beta_j . \prod_{i=1}^{M} ([A_i] + \epsilon_i^k)^{m_{ij}}} \right)^{1/p} \times ([A_i] + \epsilon_i^k) - [A_i] \tag{8}$$

Dividing the numerator and the denominator of the first bracketed expression in equation (8) by $ATOT_i$, one obtains for the first iteration:

$$\epsilon_i^1 = \left[\frac{1}{L_i^0} \right]^{1/p} . ([A_i] + \epsilon_i^0) - [A_i] \tag{9}$$

where

$$L_i^0 = \frac{[A_i] + \epsilon_i^0 + \sum_{j=1}^{N} m_{ij} . \beta_j . \prod_{i=1}^{M} ([A_i] + \epsilon_i^0)^{m_{ij}}}{ATOT_i} > 0 \tag{10}$$

It is known[3] that for $L > 0$:

$$(L)^{-q} = 1 - h \quad \text{where} \quad \lim_{q \to \infty} h = 0 \tag{11}$$

In conformity with condition (11), equation (9) for the first iterative cycle may be rewritten:

$$\epsilon_i^1 = (1 - h)([A_i] + \epsilon_i^0) - [A_i] = \epsilon_i^0 - h([A_i] + \epsilon_i^0) \tag{12}$$

Owing to condition (11), a value of p may be selected such that:

$$|h([A_i] + \epsilon_i^0)| < |\epsilon_i^0| \quad \text{or} \quad |\epsilon_i^1| < |\epsilon_i^0| \tag{13}$$

If $[A_i^k]$ and ϵ_i^k were already chosen, these values in the $(k + 1)$th iteration would be determined by equation (8). Furthermore:

$$|\epsilon_i^0| > |\epsilon_i^1| > \ldots > |\epsilon_i^k|$$

$$\begin{aligned} |L_i^k| &= \frac{\left| [A_i] + \epsilon_i^k + \sum_{j=1}^{N} m_{ij} \beta_j \prod_{i=1}^{M} ([A_i] + \epsilon_i^k)^{m_{ij}} \right|}{ATOT_i} \\ &\leqq \frac{|[A_i]| + |\epsilon_i^k| + \left| \sum_{j=1}^{N} m_{ij} \beta_j \prod_{i=1}^{M} ([A_i] + \epsilon_i^k)^{m_{ij}} \right|}{ATOT_i} \\ &\leqq \frac{|[A_i]| + |\epsilon_i^0| + \left| \sum_{j=1}^{N} m_{ij} \beta_j \prod_{i=1}^{M} ([A_i] + \epsilon_i^0)^{m_{ij}} \right|}{ATOT_i} \\ &\leqq L_i^0 \end{aligned} \tag{14}$$

It follows from equation (14) that the value of p may be fixed for all iterations and depends only on the value of L. It also follows from equations (14) and (8) that p generally increases as m_{ij} increases.

Table 2. Dependence of pX on the quantity of Cu^{2+} added to a "buffer" system of ZnX^-/Zn^{2+} ($c_{Zn^{2+}} = 0{\cdot}3M$; $c_{NTA} = 0{\cdot}2M$)

		Total $[Cu^{2+}]$, *M*				
		0	2×10^{-4}	5×10^{-4}	1×10^{-3}	2×10^{-3}
pH = 6·00	pX =	10·10	10·10	10·10	10·11	10·11
pH = 10·00	pX =	7·79	7·79	7·79	7·80	7·80

An iterative computer program was developed to calculate the equilibrium concentrations of all species in a system of many competing complexation reactions in a single phase; this program is based on equations (5) and (6). The total analytical concentration of each reactant was used as a first approximation of its equilibrium concentration.

The use of generalized forms for the equations of complexation reactions [equation (2)] and a series of other transformations made it possible to reduce the number of commands to 55 from the 140 used in COMICS. It decreases the number of iterations and the computer time. The usefulness of this program has been proved on a series of multicomponent systems. As an example the results of one of these calculations is given in Table 1.

For the parameter $p(i)$ it is enough, as a rule, to employ the largest stoichiometric coefficient of the ith reactant in equation (2). The rate of convergence slows up slightly as $p(i)$ increases. For the system given in Table 1, for example, the parameters $p(i)$ were chosen in accordance with the above; then the parameter for each reactant of the same system was arbitrarily assigned the value $p = 5$. The number of iterations increased in the latter case from 151 to 476.

It is frequently necessary to fix the concentration of one reactant (either metal or ligand) of a system in such a way that it does not change during the course of a reaction. Traditionally, a large excess is introduced, so that its concentration is not altered substantially by the reaction.

A new procedure[6] using an auxiliary "buffering" system eliminates this necessity. For example, let $[X^{3-}]$ be fixed throughout the course of the reaction

$$Cu^{2+} + X^{3-} \rightleftharpoons CuX^- \qquad (15)$$

where X^{3-} is the tertiary nitrilotriacetate anion, $N(CH_2COO)_3^{3-}$. The auxiliary reaction

$$Zn^{2+} + X^{3-} \rightleftharpoons ZnX^- \qquad (16)$$

for which the stability constant β is expressed by

$$\beta_{ZnX} = \frac{[ZnX]}{[Zn^{2+}][X^{3-}]} \qquad (17)$$

may be used to fix the concentration of X^- in the system. From (17) is obtained

$$\log \beta_{ZnX} = pX + \log \frac{[ZnX]}{[Zn^{2+}]} \qquad (18)$$

Equation (18) shows that it is possible to fix various low concentrations of X^{3-} by use of relatively large concentrations of ZnX^- and Zn^{2+}. Copper(II) ions may be added to this "buffer" solution as long as $C_{Cu^{2+}} \ll [Zn^{2+}], [ZnX^-]$ and reaction (15) will proceed with $[X^{3-}]$ constant.

The program COMPLEX was used to calculate the equilibrium concentrations in the system described by equations (15) and (16), taking into account the possible hydrolysis of all reactants. The results, as presented in Table 2, demonstrate that a wide range of total Cu^{2+} concentrations cause no change in $[X^{3-}]$.

APPENDIX

The computer program COMPLEX is used to read data, to make consecutive approximations for adjusting the equilibrium concentrations of reactants and complexes and to print the results after a satisfactory degree of convergence. The listing of the program includes a description of the input data. In this program the following variables were used:

NE	Number of separate experiments.
M	Number of reactants (up to 18).
TITLE(I)	Array used to print headings.
ATOT(I)	Analytical concentration of each reactant.
AK(I), A(I)	Equilibrium concentration of I-th reactant, as used by iteration, and as calculated.
ACALC(I)	Calculated total concentration of I-th reactant.
N	Number of complex species in system under study (including protonated and hydrolysed forms).
MA(I,J)	Number of units of reactant (I) in complex (J).
MOH(J), MH(J)	Number of hydroxyls and protons in complex species (J).
C(J)	Equilibrium concentration of J-th complex.
E(J)	Log of cumulative stability constant of J-th complex.
SUM(J)	Conditional stability constant of species (J) at a given pH in the log form.
TERM(J)	The same, but in the exponential form.
Y1(I)	Degree of convergence of the I-th reactant.
Y2(I)	Absolute difference between real and calculated total concentration of I-th reactant.
BK(I)	Parameter p (see text) for I-th reactant.
INDEX	Index = 0 for all cards bearing pH values, up to last card when index = 1.

Summary—An iterative method and a computer program are presented for calculating equilibrium concentrations of all species in a multicomponent system of many competing complexation reactions. The initial data required are: pH, total concentration of each reactant, stability constant of each complex, and pK_a values. Convergence of the iterations is proved. As an example a system of 7 reactants and 27 complexes is given. A second example for the use of this program, including so-called "ligand buffering", is also shown.

THE SIGNIFICANCE OF THE $CrO_4^{2-} \rightleftharpoons HCrO_4^-$ EQUILIBRIUM IN THE DETERMINATION OF CHROMIUM(VI) BY FLAME SPECTROMETRY

M. S. CRESSER and R. HARGITT

Department of Soil Science, University of Aberdeen, Old Aberdeen, Scotland

(*Received* 24 *February* 1975. *Accepted* 22 *May* 1975)

It is widely known[1,2] that the sensitivity (1% absorption) for Cr(III) may be significantly different from that for Cr(VI) when chromium is determined by atomic-absorption spectrometry in an air–acetylene flame. However, it is not often realized that the atomic-absorption of Cr(VI) is pH-dependent. This fact has been mentioned briefly by Angino and Billings,[3] quoting a private communication as source, but the extent of, or reason for, the pH effect has not been investigated in detail. The purpose of this communication is to establish that the chromate–dichromate equilibrium is responsible for the pH-effect and to investigate the extent of possible interference in some of the flames which are used for the determination of chromium by flame spectrometry.

EXPERIMENTAL

Reagents

Chromium (VI) and (III) stock solutions, 1000 μg/ml. Prepared from analytical-reagent grade potassium chromate and chromic potassium sulphate respectively.

Buffer solutions. A series of buffer solutions was prepared from sodium acetate or ammonium acetate with acetic acid, ammonia or sodium hydroxide added as appropriate to adjust the pH, so that after 100-fold dilution, the final solutions covered the pH range 3–9.

Apparatus

Atomic-absorption spectrophotometer. An EEL model 240 with normal flat-top 100-mm air-acetylene and 50-mm nitrous oxide–acetylene burners, and a chromium hollow-cathode lamp (357·9 nm).

The flame conditions used were as follows:

Air–acetylene. Air flow, 6·0 l./min; acetylene flow, 1·1 l./min; height of measurement (above burner), 5 mm.

Air–hydrogen. Air flow, 6·6 l./min; hydrogen flow, 9·7 l./min; height of measurement, 3 mm.

Nitrous oxide–acetylene. Nitrous oxide flow, 7·0 l./min; acetylene flow, 3·3 l./min; height of measurement, 4 mm.

Procedure

A series of solutions was prepared containing 4 μg/ml of Cr(III) or Cr(VI), and covering the pH range 3–9. Each solution also contained 4 μg/ml of lithium, to act as an internal standard. The pH of each solution was measured immediately before the nebulization.

RESULTS AND DISCUSSION

The effect of pH on chromium atomic absorption at 357·9 nm at optimum heights and fuel flows when solutions of Cr(III) and Cr(VI) were nebulized into air–hydrogen and air–acetylene flames is shown in Fig. 1. The absorbance of Cr(VI) solutions changes quite significantly over the pH range 5–8 in the air–acetylene flame, and the effect is even more pronounced in the air–hydrogen flame. The extent of the effect can be reduced, but not eliminated, by decreasing the fuel-to-oxidant ratio, or by increasing the fuel and oxidant flow-rates.

If the solutions had stood for more than 1 hr, the absorbance of the Cr(III) solutions at pH above 6 could be increased by shaking them immediately before nebulization. This is a clear indication that the shape of the Cr(III) curves is attributable to precipitation.

With the nitrous oxide–acetylene flame, there was no detectable pH-effect when the Cr(VI) solutions were nebulized. Provided the Cr(III) solutions were shaken vigorously immediately before nebulization, even the effect of precipitation on the absorbance of these solutions could be virtually eliminated by use of the hotter flame. Cr(III) and Cr(VI) also gave similar sensitivities in this flame.

Over the pH range 3–9, when the total level of Cr(VI) is low (as is normally the case when the element is determined by atomic-absorption spectrometry), the equilibrium

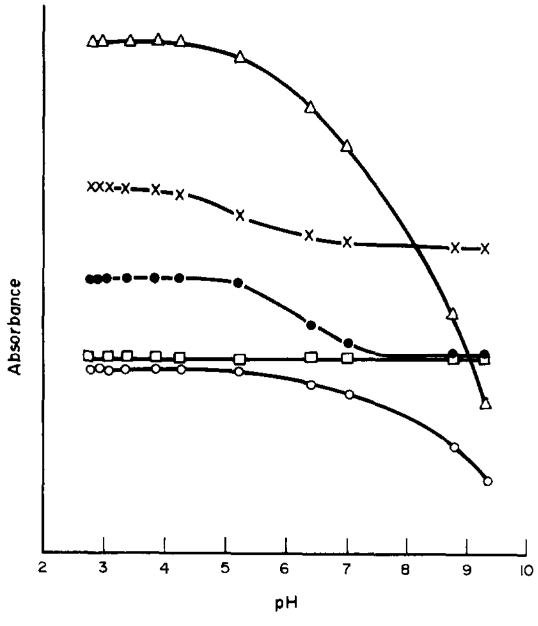

Fig. 1. Effect of pH on chromium atomic absorption; △, Cr(III), air–acetylene; ×, Cr(VI), air–acetylene; ●, Cr(VI), air–hydrogen; Cr(III), air–hydrogen; □, Cr(VI), nitrous oxide–acetylene.

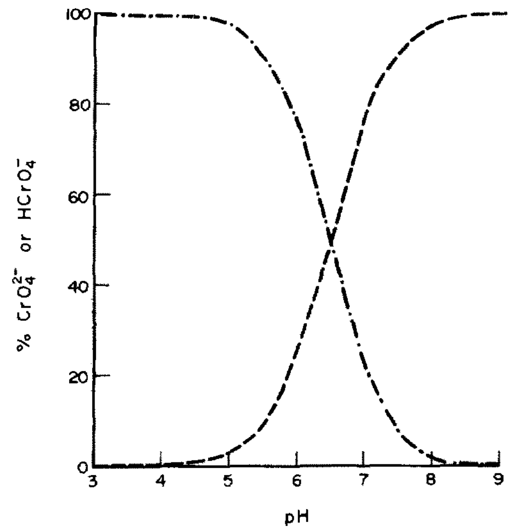

Fig. 2. Distribution diagram for CrO_4^{2-} (---) and $HCrO_4^-$ (-·-·-) as a function of pH for 4 μg/ml Cr(VI).

constants quoted by Perrin[4] show that the equilibria governing the anionic forms present at significant levels are:

$$HCrO_4^- \rightleftharpoons H^+ + CrO_4^{2-}$$
$$Cr_2O_7^{2-} + H_2O \rightleftharpoons 2HCrO_4^-$$

The equilibrium constants for these two equilibria are $3{\cdot}24 \times 10^{-7}$ and $3{\cdot}03$ and 10^{-2} respectively at 25°. Combining the dissociation constant expressions with the mass-balance for Cr(VI) species leads to a quadratic equation for $[HCrO_4^-]$.[5] This may be solved provided the total Cr(VI) concentration and the pH are specified. The theoretical effect of pH on the concentrations of $HCrO_4^-$ and CrO_4^{2-}, calculated by this method for a 4-μg/ml Cr(VI) solution, is shown in Fig. 2. At this concentration the $Cr_2O_7^{2-}$ concentration is not significant. The results indicate that unless the sensitivities for Cr as $HCrO_4^-$ and CrO_4^{2-} are identical, a change in absorbance might be expected as the pH as increased from 5 to 8, which is in close agreement with the results reported above. Assuming that all of the chromium is present as $HCrO_4^-$ at pH 3 and below and as CrO_4^{2-} at pH 9 and above, it is possible to calculate the sensitivities for chromium in the two forms. Summation of the absorbances of the two forms calculated from these sensitivity values and the data in Fig. 2, gives theoretical curves which are indistinguishable from the empirical curves shown in Fig. 1, thus confirming the hypothesis that the $CrO_4^{2-} \rightleftharpoons HCrO_4^-$ equilibrium is responsible for the effect.

To confirm that the results were not attributable to interference from the ions used in the preparation of the buffer solutions, the effects of sodium and ammonium ions and acetic acid on the absorbance of chromium(VI) solutions were studied. The pH of the solutions used lay in (or was adjusted to) the range 2·5–4·2. No effect was found at levels up to twice those employed in any of the diluted buffer solutions used. Moreover, plots of absorbance *vs.* pH over the range 4–7 were found to be the same for the air-hydrogen flame, whether the pH was adjusted with sodium acetate/acetic acid or with ammonium acetate/acetic acid, again confirming that the effect is indeed due to variation in pH. The lithium internal standard gave results which showed that no solvent–matrix interaction caused any interference.

Conclusion

Variation in pH can cause a small but significant interference when Cr(VI) is determined by flame spectrometry in an air–acetylene flame. The interference due to the $HCrO_4^- \rightleftharpoons CrO_4^{2-}$ equilibrium is much more severe when the air–hydrogen flame is used, and in this instance accurate pH buffering of sample and standard solutions is essential unless strongly acidic or strongly basic solutions are being nebulized. This flame is often used to determine chromium by atomic-fluorescence spectrometry, where the problem should be equally as severe as that encountered in atomic-absorption spectrometry.

Summary—Chromium atomic absorption for Cr(VI) solutions in the air–acetylene and air–hydrogen flames is pH-dependent, but not in the nitrous oxide–acetylene flame. The effect is shown to occur as a result of the $HCrO_4^- \rightleftharpoons CrO_4^{2-}$ equilibrium, and may cause significant errors in the determination of chromium by atomic-absorption spectrometry unless the pH of sample and standard solutions is controlled.

EFFECTS OF AUXILIARY COMPLEX-FORMING AGENTS ON THE RATE OF METALLOCHROMIC INDICATOR COLOUR-CHANGE—III*

MECHANISM OF THE COLOUR CHANGE OF TAC IN NICKEL–EDTA TITRATIONS

GENKICHI NAKAGAWA, HIROKO WADA and OSAMU NAKAZAWA
Laboratory of Analytical Chemistry, Nagoya Institute of Technology,
Showa-ku, Nagoya 466, Japan

(*Received* 14 *May* 1975, *Accepted* 22 *May* 1975)

In chelatometric titrations of nickel, the indicator colour-change at the equivalence point being usually slow, the titration should be done at about 80° or higher. In our previous work,[1] it was found that the addition of a small amount of 1,10-phenanthroline improves the rate of indicator colour-change of TAC [2-(2-thiazolylazo)-4-methylphenol] or Xylenol Orange.

In the work described in this paper the rate of the substitution reaction of Ni–TAC with EDTA or 1,10-phenanthroline was studied, and the mechanism of the indicator colour-change is discussed.

EXPERIMENTAL

Reagents

TAC was purified by vacuum sublimation.

A nickel(II) solution was prepared from reagent-grade nickel nitrate.

EDTA was recrystallized from water.

1,10-Phenanthroline was dissolved in dioxan purified as described earlier.[2]

2-(*N*-Morpholino)ethanesulphonic acid (MES) mixed with potassium hydroxide solution was used as buffer.

All other reagents used were of reagent grade.

Procedures

The rate of the substitution reaction was measured under the following conditions: pH 5·7–6·3 (0·01 *M* MES buffer); ionic strength 0·1 (KNO_3); dioxan = 20% v/v; 25 ± 1°.

Substitution reaction of nickel–TAC chelate with EDTA. A solution (100 ml) that was $5{\cdot}25 \times 10^{-6}$ *M* in nickel and $1{\cdot}5$–$3{\cdot}0 \times 10^{-4}$ *M* in TAC was placed in a 50-mm photometric cell, and 1 ml of $1{\cdot}0$–$2{\cdot}0 \times 10^{-2}$ *M* EDTA solution was added rapidly by syringe with stirring. The absorbance of the solution at 590 nm (the absorption maximum of the Ni–TAC chelate) was measured as a function of the reaction time.

Substitution reaction of nickel-TAC chelate with 1,10-*phenanthroline.* The following solutions *A* and *B* were mixed, and the absorbance at 590 nm was recorded as a function of the reaction time by the stopped-flow method. The dead-time of mixing was about 20 msec.

Solution *A*: Ni = $1{\cdot}05 \times 10^{-5}M$, $TAC = 3{\cdot}0$–$4{\cdot}5 \times 10^{-4}M$.
Solution *B*: 1,10-phenanthroline = $2{\cdot}0$–$200 \times 10^{-5}M$.

RESULTS AND DISCUSSION

Substitution reaction with EDTA

In the presence of a large excess of TAC, nickel forms a 1:2 chelate quantitatively over the pH range from 5·7 to 6·3. When a large excess of EDTA relative to nickel is added, the following substitution reaction proceeds to completion.

$$\mathrm{Ni(TAC)_2 + EDTA \rightleftharpoons Ni(EDTA) + 2TAC} \qquad (1)$$

The rate law is expressed as

$$-\frac{d[\mathrm{NiR_2}]}{dt} = k_{0(\mathrm{R,Y,H})}[\mathrm{NiR_2}] \qquad (2)$$

where R is the fully dissociated form of TAC and $k_{0(\mathrm{R,Y,H})}$ is the conditional rate-constant involving the concentrations of TAC, EDTA and hydrogen ion. By representing the absorbances at the reaction times 0, t and ∞ by A_0, A_t and A_∞, we obtain equation (3) from equation (2):

$$\log(A_t - A_\infty) = -\frac{k_{0(\mathrm{R,Y,H})}}{2{\cdot}303}t + \log(A_0 - A_\infty) \qquad (3)$$

The plots of log $(A_t - A_\infty)$ *vs.* the reaction time (t) yielded straight lines for at least 90% of the total reaction at the various concentrations of TAC, EDTA and hydrogen ion used, thus the reaction was pseudo first-order with respect to NiR_2. The conditional rate-constants $k_{0(\mathrm{R,Y,H})}$ were obtained from the slopes. The data summarized in Table 1 indicate that the values of $k_{0(\mathrm{R,Y,H})}$ are proportional to the concentration of EDTA and the reciprocal of the concentration of TAC. The plots of $k_{0(\mathrm{H})}$ *vs.* $[H^+]$ gave a straight line with an intercept on the *y*-axis. Hence

$$-\frac{d[\mathrm{NiR_2}]}{dt} = (k'_1[\mathrm{H^+}] + k'_2)\frac{[\mathrm{NiR_2}][\mathrm{Y'}]}{[\mathrm{HR}]} \qquad (4)$$

where [Y′] is the total concentration of EDTA not combined with nickel ion, and we propose the following reaction mechanism.

$$\left(\begin{array}{ll} \mathrm{NiR_2 + H^+ \rightleftharpoons NiR^+ + HR} & (5) \\ \mathrm{NiR^+ + Y' \xrightarrow{k_1} NiY^{2-} + HR} & (6) \end{array}\right.$$

$$\left(\begin{array}{ll} \mathrm{NiR_2 + H_2O \rightleftharpoons NiR(OH) + HR} & (7) \\ \mathrm{NiR(OH) + Y' \xrightarrow{k_2} NiY^{2-} + HR + OH^-} & (8) \end{array}\right.$$

The equilibria (5) and (7) precede the reactions (6) and (8), and the reaction of NiR^+ or NiR(OH) with EDTA

---

		6·14	4·42
		6·24	3·76

might be the rate-determining steps. This mechanism is similar to that of the substitution reaction of the mercury(II)–PAR chelate with DCTA.[3] Equation (4) can be rewritten as

$$-\frac{d[\mathrm{NiR_2}]}{dt} = k_1[\mathrm{NiR^+}][\mathrm{Y'}] + k_2[\mathrm{NiR(OH)}][\mathrm{Y'}] \qquad (9)$$

where

$$k_1 = k_1' \frac{K^{R}_{NiR_2}}{K^{H}_{HR}} \qquad (10)$$

$$k_2 = k_2' \frac{K^{R}_{NiR_2}}{K^{H}_{HR}\, K^{OH}_{NiR(OH)}\, K_W} \qquad (11)$$

With k_1' and k_2' obtained from the slope and *y*-intercept of the plot, the values 2·1 × 10^3 and 7·9 × 10^6 l. mole^{-1} sec^{-1} for k_1 and k_2 were obtained by the use of equations (10) and (11) and $K^{R}_{NiR_2} = 10^{7\cdot2}$,[4] $K^{H}_{HR} = 10^{8\cdot3}$,[4] $K^{OH}_{NiR(OH)} = 10^{4\cdot5}$,* $K_W = 10^{-14\cdot4}$.*

Substitution reaction with 1,10-*phenanthroline*

The rate of this substitution reaction was determined under the same experimental conditions as in the case of EDTA.

$$\mathrm{Ni(TAC)_2 + 3phen \rightleftharpoons Ni(phen)_3 + 2TAC} \qquad (12)$$

The rate of decrease of $[\mathrm{NiR_2}]$ with reaction time was linear for over 90% of the reaction. The rate law is expressed as

$$-\frac{d[\mathrm{NiR_2}]}{dt} = k_{0(R,X,H)}[\mathrm{NiR_2}] \qquad (13)$$

where X is 1,10-phenanthroline.

The conditional rate-constants $K_{0(R,X,H)}$ for various experimental conditions are summarized in Table 2. Plots of

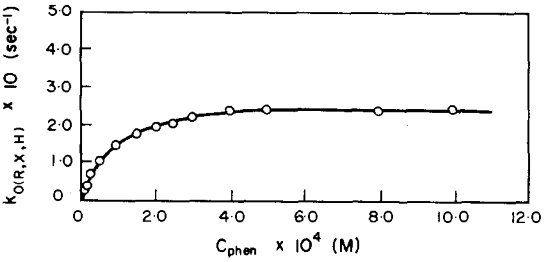

Fig. 1. Plots of $k_{0(R,X,H)}$ *vs.* C_{phen}. C_{Ni}: 5·25 × 10^{-6} *M*; C_{TAC}: 1·50 × 10^{-4} *M*. pH 6·00, μ = 0·1 (KNO_3), 20% v/v dioxan, 25°C.

$k_{0(R,X,H)}$ *vs.* $[H^+]$ gave straight lines with zero intercept, and $k_{0(R,X,H)}$ was independent of TAC concentration. As shown in Fig. 1, $k_{0(R,X,H)}$ shows first-order dependence on the concentration of 1,10-phenanthroline, but becomes independent of it when more than a large enough excess of 1,10-phenanthroline is present. From these results, the following mechanism may be proposed.

$$\mathrm{NiR_2 + H^+ \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} NiR^+ + HR} \qquad (14)$$

$$\mathrm{NiR^+ + X \rightleftharpoons NiRX^+} \qquad (15)$$

$$\mathrm{NiRX^+ + X \xrightarrow{k_4} NiX_2^{2+} + R^-} \qquad (16)$$

The reaction (15) is much more faster than reactions (14) and (16) because one molecule of 1,10-phenanthroline may easily co-ordinate with the Ni–TAC complex to form a stable octahedral configuration. Also it is reasonable to assume that the formation constant K^{X}_{NiRX} may be of the same order as K^{X}_{NiX} and so equilibrium (15) lies far to the right, *i.e.*, $[\mathrm{NiR^+}] = [\mathrm{NiRX^+}]$.

When a sufficient excess of 1,10-phenanthroline is present, reaction (16) may proceed much faster than equation

---

* $K^{OH}_{NiR(OH)}$ was estimated spectrophotometrically and K_W was determined by pH-titration under the experimental conditions.

(14) and the release of TAC from NiR_2 may be the rate-determining step. The value of k_3 was calculated to be $2{\cdot}4 \times 10^5$ $1.mole^{-1}.sec^{-1}$.

When 1,10-phenanthroline is in smaller excess, $k_{0(R,X,H)}$ depends on both $[H^+]$ and [1,10-phenanthroline]. The steady-state approximation for $NiRX^+$ was applied, *i.e.*,

$$-\frac{d[NiR_2]}{dt} = \frac{d[NiX_2^{2+}]}{dt} \tag{17}$$

where

$$-\frac{d[NiR_2]}{dt} = k_3[NiR_2][H^+] - k_{-3}[NiR^+][HR] \tag{18}$$

$$\frac{d[NiX_2^{2+}]}{dt} = k_4[NiRX^+][X] \tag{19}$$

and

$$[NiR^+] = [NiRX^+] \tag{20}$$

From equations (13) and (17)–(20) we obtain

$$\frac{[H^+]}{k_{0(R,X,H)}} = \frac{k_{-3}}{k_3 k_4}\frac{[HR]}{[X]} + \frac{1}{k_3} \tag{21}$$

Since $k_3/k_{-3} = K^{H}_{HR}/K^{R}_{NiR_2} = 10^{1{\cdot}1}$, the values of k_3 and k_4 can be calculated. The value of k_3 is in good agreement with that obtained from $k_{0(R,X,H)}$ when 1,10-phenanthroline is present in sufficient excess, and $k_4 = 5{\cdot}1 \times 10^4$ $1.mole^{-1}.sec^{-1}$.

The rate-constant k_3 compares reasonably with the rate-constant $k = 1 \times 10^6$ $1.mole^{-1}.sec^{-1}$ for the reaction[5]

$$Ni(dien)_2^{2+} + H^+ \overset{k}{\rightleftharpoons} Ni(dien)^{2+} + Hdien^+ \tag{22}$$

The rate of the substitution reaction of Ni–TAC with 1,10-phenanthroline is much faster than that with EDTA and the Ni–phen complex formed by reactions (14)–(16) may undergo fast substitution with EDTA. In the titration of nickel with TAC as indicator a very sharp colour-change could be obtained at 50° by the addition of a small amount of 1,10-phenanthroline ([phen]/[Ni] = 1/200).

Summary—The rate of the ligand-substitution reaction of nickel(II)–TAC chelate (NiR_2) with EDTA (Y) and 1,10-phenanthroline (X) has been determined spectrophotometrically in 20% v/v dioxan over the pH range 5·7–6·3 at $\mu = 0{\cdot}1$ (KNO_3) and 25 ± 1°. The substitution reaction with EDTA proceeds through the following two pathways:

$$NiR_2 + H^+ \rightleftharpoons NiR^+ + HR,$$

$$NiR^+ + Y' \xrightarrow{k_1} NiY^{2-} + HR,$$

and

$$NiR_2 + H_2O \rightleftharpoons NiR(OH) + HR,$$

$$NiR(OH) + Y' \xrightarrow{k_2} NiY^{2-} + HR + OH^-.$$

The reaction of NiR^+ or NiR(OH) with EDTA is the rate-determining step, and $k_1 = 2{\cdot}1 \times 10^3$ $1.mole^{-1}.sec^{-1}$ and $k_2 = 7{\cdot}9 \times 10^6$ $1.mole^{-1}.sec^{-1}$. The substitution reaction with 1,10-phenanthroline proceeds as follows:

$$NiR_2 + H^+ \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} NiR^+ + HR,$$

$$NiR^+ + X \rightleftharpoons NiRX^+,$$

$$NiRX^+ + X \xrightarrow{k_4} NiX_2^{2+} + R^-.$$

At higher concentrations of 1,10-phenanthroline the release of TAC from NiR_2 by hydrogen ion is the rate-determining step, and $k_3 = 2{\cdot}4 \times 10^5$ $1.mole^{-1}.sec^{-1}$. At lower concentrations of 1,10-phenanthroline $-d[NiR_2]/dt$ is proportional both to $[H^+]$ and [X]. The value $k_4 = 5{\cdot}1 \times 10^4$ $1.mole^{-1}.sec^{-1}$ was calculated by the use of the steady-state approximation for $[NiRX^+]$. The substitution with 1,10-phenanthroline proceeds much faster than that with EDTA. By the addition of a small amount of 1,10-phenanthroline, Ni can be titrated with EDTA at 50°, with TAC as an indicator.

MINIATURE POTASSIUM-SENSITIVE ELECTRODES WITH NEUTRAL CARRIERS IN A POLY(VINYL CHLORIDE) MATRIX

O. RYBA and J. PETRANÉK

Institute of Macromolecular Chemistry, Czechoslovak Academy of Sciences, 162 06 Prague 6 Czechoslovakia

(*Received* 31 *March* 1975. *Accepted* 20 *May* 1975)

The bulky nature of commercial potassium ion-selective electrodes[1] restricts their use in microanalytical applications and in certain biological and clinical measurements. However, use of the neutral carrier sensor in softened poly(vinyl chloride) membranes[2] allows more scope in the preparation of ion-selective electrodes. This is illustrated by the coated wire electrode,[2–4] although the thermodynamically poorly defined potential at the platinum-PVC interface is reflected in the long-term drift and the unequal potentials of different electrodes.

Electrodes can also be miniaturized by reduction in the membrane area, and in this paper we describe the preparation and properties of potassium ion-selective electrodes made with valinomycin or dimethyldibenzo-30-crown-10 in a thin PVC membrane[2,5,6] less than 0·2 mm^2 in area.

EXPERIMENTAL

Electrode preparation

Valinomycin or dimethyldibenzo-30-crown-10 (1 mg) is dissolved in 0·1 ml of dipentylphthalate and mixed with 1 ml of 5% high-molecular weight PVC in cyclohexanone. The solution is poured onto a microscope slide on an area of 1 cm^2. Free evaporation of cyclohexanone at room temperature yields a membrane approximately 0·15 mm thick. The electrode body (Fig. 1) consists of a glass tube 4 mm in diameter, drawn out at the end to a capillary about 3 cm long, inner diameter 0·5 mm. A membrane, 2 × 2 mm in size, is placed on the capillary tip and fixed by slipping over it a polythene sleeve, about 8 mm long. The electrode is completed by filling it with $10^{-3}M$ potassium chloride and inserting a silver–silver chloride wire reference electrode. If flexibility of the whole electrode body is required, it may be constructed from polythene.

Apparatus

All measurements of potentials were made at 25° against a saturated calomel electrode (Radelkis OP 815) connected with the measured solutions by a salt bridge of 0·1*M* ammonium nitrate with an asbestos-fibre junction. A Radiometer PHM 64 pH-meter and a Metrohm E 336 potentiograph connected through a Keithley electrometer 610 C were used. The measuring techniques have been described earlier.[4]

RESULTS AND DISCUSSION

Electrodes with a miniature membrane exhibited surprisingly good properties, resembling those of the electrodes with an 8-mm effective diameter studied earlier.[2,5] The electrode response in solutions of potassium ions over a concentration range of 10^{-1}–$10^{-6}M$ potassium chloride was examined. The calibration curves for electrodes with both neutral carriers were linear for the range 10^{-1}–$10^{-5}M$ potassium chloride and near to Nernstian in this region. The values of the constant E_0 in the Nernst equation, referred to the double-junction SCE, and the slopes calculated by means of regression analysis for the linear parts of calibration curves, are given together with the standard error estimates S_{yx} in Table 1. The correlation coefficient was in all cases better than 0·99997, which proves the outstanding linearity of response over the concentration range under investigation. The constant E_0 has the same value both for valinomycin and the crown-compound if the same experimental conditions are maintained in electrode preparation.

The potassium/sodium selectivity of the electrodes was studied by the mixed-solutions method at a constant level of 0·1*M* sodium chloride and a varied concentration of potassium ion. The selectivity coefficient $k_{K,Na}$ obtained by graphical evaluation for the valinomycin electrode was $2{\cdot}30 \times 10^{-4}$, that for the electrode with dimethyldibenzo-30-crown-10 was $2{\cdot}38 \times 10^{-3}$. Both values are in accordance with the selectivity of standard-size electrodes.[2,5]

The speed of response of both electrodes was followed by the dynamic method for a tenfold increase in the potassium ion concentration from initial levels of 10^{-5}, 10^{-4} and $10^{-3}M$ and for a thousandfold increase in concentration from $10^{-5}M$ in vigorously stirred solutions. The

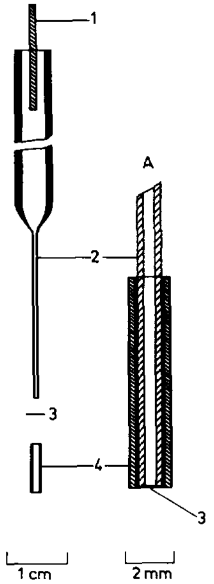

Fig. 1. Miniature potassium electrode. (1) Ag/AgCl reference electrode, (2) glass tube, (3) PVC membrane, (4) polythene sleeve. (A) Detail of assembled electrode tip.

Table 1. Calibration parameters of miniature potassium electrodes

Electrode	E_0, mV vs. SCE	Slope mV/$-\log a_{K^+}$	S_{yx}, mV
Valinomycin—initial	324·6	58·8	0·61
Crown—initial	325·5	58·5	0·43
—150 hr use	324·4	58·1	0·44
—200 hr use	324·5	57·9	0·53
—350 hr use	324·2	58·3	0·54
—500 hr use	322·0	58·4	0·36

time needed for attaining the final value of the potentials was 15 sec for the electrode with valinomycin and 5 sec for the electrode with the crown-compound. For the electrode with dimethyldibenzo-30-crown-10 the response-time was also examined. A newly prepared electrode reaches stable potentials after preconditioning for 30 min. The standard deviations calculated from 60 readings of the potentials at concentration levels of 10^{-2}, 10^{-3} and $10^{-4}M$ potassium chloride, taken during a period of 1 hr, were 0·07, 0·10, and 0·46 mV respectively. The long-term stability of the continuously used electrode was followed by recalibrating it regularly over a period of three weeks. The parameters obtained by linear regression analysis of the calibration plots are given in Table 1. They show that the maximum long-term drift of the potential amounts to 2 mV per week, the slope remaining practically without change. These results with the miniature electrode fully agree with our earlier findings,[4] while being in contrast with the recently published results of Semler and Adametzová.[7] These authors have observed for the electrode with dimethyldibenzo-30-crown-10 in a PVC matrix (without further details as to the membrane composition and electrode construction) linearity of the response over a narrower concentration range, a considerable drift of the potential, and a low selectivity. In our opinion, these results are open to question.

Summary—A miniature version of the potassium ion-selective electrode with valinomycin or dimethyldibenzo-30-crown-10 in a poly(vinyl chloride) matrix is described. Electrodes having an effective membrane area of <0·2 mm^2 exhibit Nernstian behaviour within a range of activities of the potassium ion of 10^{-1}–$10^{-5}M$, a rapid response and good long-term potential stability.

ANALYTICAL DATA

THE THERMODYNAMICS OF ETHYLENE-DIAMINE COMPLEXES OF SILVER

L. C. VAN POUCKE
Department of Chemistry, Biology and Microbiology, Limburgs Universitair Centrum,
B 3610 Diepenbeek, Belgium

(*Received* 16 *May* 1975, *Accepted* 21 *May* 1975)

In its complexes with amino-groups as donors, Ag(I) has a characteristic co-ordination number of two. These complexes are assumed to be linear. When the ligand is bidentate there is some tendency to form chelates, but the formation of polynuclear complexes with a chain or even a ring structure is more likely, and mononuclear complexes are always possible. Moreover one of the two donor groups can be protonated.

The system ethylenediamine–Ag(I) has been investigated by Schwarzenbach *et al.*,[1] who reported the formation of $AgHL^{2+}$, Ag_2L^{2+}, AgL^+, AgL_2^+ and $Ag_2L_2^{2+}$. The reason for a new investigation of this system was to search for the presence of the complexes $Ag(HL)_2^{3+}$ and $AgHL_2^{2+}$. The likelihood of these complexes can be argued from the fact that for such Ag(I) complexes the stability constant of AgL_2 is usually greater than the constant of AgL. This has been confirmed for Ag(I) complexes with positively charged ligands.[2] A second aim was determination of the thermodynamics of formation of these complexes, in particular to obtain information about the structure of these complexes.

EXPERIMENTAL

Ethylenediamine was converted into the dinitrate and purified by repeated crystallization.

To all solutions enough potassium nitrate was added to give a nitrate concentration of 0·5*M*.

Potentiometric measurements were performed with a Radiometer pHM52, using an Ingold HA 201 glass electrode for pH measurements and a solid state Coleman Ag/AgS electrode for pAg. As a reference a double-junction Ingold electrode was used, with 3*M* potassium chloride in the inner compartment. Standardization was done with solutions having an ionic strength of 0·5. All measurements were performed in vessels kept at a temperature of 25 ± 0·1° in a room at 25 ± 1°.

Calorimetric measurements were made with an LKB 8700–2 titration calorimeter.

Calculations were done on a Siemens 4004/15 computer.

RESULTS

Since polynuclear and protonated complexes were expected, a relatively large amount of experimental data with a wide range of values for C_{Ag} and C_L, the total concentrations of silver and ligand, was needed. C_{Ag} was varied from 10^{-4} to $10^{-2}M$ and C_L from 10^{-3} to $10^{-1}M$.

In addition to the indifferent electrolyte, each solution contained a certain amount of the ligand in the acid form, silver nitrate and potassium hydroxide. The pH and pAg values of each solution were determined experimentally. The experimental data for about 200 solutions were analysed by a computer program very similar to that described by Sillén.[3]

Table 1. The stability constants of the complexes

Complex	$\log \beta_{pqy}$
$AgHL^{2+}$	2·34
$AgH_2L_2^{3+}$	4·90
$AgHL_2^{2+}$	6·47
AgL_2^+	7·64
$Ag_2L_2^{2+}$	13·15

The following complexes were proved to be present in reasonable amount over at least part of the concentration range studied: $AgHL^{2+}$, $AgH_2L_2^{3+}$, $AgHL_2^{2+}$, AgL_2^+ and $Ag_2L_2^{2+}$. There was no evidence for the complexes Ag_2L^{2+} and AgL^+.

The stability constants β_{pqy} are defined by the reaction

$$p'L + yHL^+ + qAg^+ \rightleftharpoons Ag_qH_yL_p{}^{(y+q)+} \qquad (1)$$

with $p = p' + y$. β_{pqy} (in Table 1) is given in concentration units:

$$\beta_{pqy} = \frac{[Ag_qH_yL_p^{(q+y)+}]}{[Ag^+]^q\,[L]^{p'}\,[HL^+]^y}$$

The standard deviation of these stability constants is estimated to be 0·02.

The enthalpy change $\Delta H^\circ{}_{pqy}$, for the reaction in equation (1), was calculated from calorimetric data. The reaction vessel was filled with a solution containing silver nitrate, diprotonated ethylenediamine and enough potassium nitrate to ensure a final nitrate concentration of 0·5*M*. A certain amount of potassium hydroxide was added and the evolved heat *Q* was measured. Several such experiments were performed. A least-squares procedure using equation (2) gives the value for $\Delta H^\circ{}_{pqy}$.

$$\begin{aligned} -Q = {} & \Delta H_1^0 K_1 [H^+][L] + (\Delta H_1^0 + \Delta H_2^0)[L] \\ & + \sum_p \sum_q \sum_y \{[\Delta H_{pqy}^0 + y\Delta H_1^0 + (p-y)(\Delta H_1^0 \\ & + \Delta H_2^0)]\,K_1\,\beta_{pqy}\,[Ag^+]^q [L]^p [H^+]^y\} \qquad (2) \end{aligned}$$

Table 2. Free-energy, enthalpy and entropy changes

Complex	ΔG°_{pqy}, *kJ/mole*	ΔH°_{pqy}, *kJ/mole*	ΔS°_{pqy}, *J.mole^{-1} deg^{-1}*
$AgHL^{2+}$	−13·35	−25·4	−41
$AgH_2L_2^{3+}$	−27·99	−50·8	−77
$AgHL_2^{2+}$	−36·94	−56·9	−66
AgL_2^+	−43·60	−52·5	−30
$Ag_2L_2^{2+}$	−75·02	−97·1	−74

A preliminary interpretation of these results seems to indicate that the $Ag_2L_2^{2+}$ complex mainly exists as a closed ring.

K_1 is the protonation constant of HL^+, ΔH_1° is the enthalpy change of the reaction $H_2L^{2+} + OH^- \rightleftharpoons HL^+ + H_2O$ and ΔH_2° that of the reaction $HL^+ + OH^- \rightleftharpoons L + H_2O$. The values for ΔH_1° and ΔH_2° were reported earlier.[4] The values for $[Ag^+]$, $[L]$ and $[H^+]$ were calculated by using the computer program BDTV.[5]

The results are summarized in Table 2 together with the corresponding values for $\Delta G^\circ_{pqy} = -RT\ln\beta_{pqy}$ and $\Delta S^\circ = (\Delta H^\circ_{pqy} - \Delta G^\circ_{pqy})/T$.

AN EVALUATION OF FOUR TITRIMETRIC METHODS FOR THE DETERMINATION OF LEAD IN ORES

ELSIE M. DONALDSON
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 11 *June* 1975. *Accepted* 19 *August* 1975)

Summary—Four titrimetric methods for the determination of lead in ores were evaluated. In the absence of bismuth and indium, a method based on EDTA titration of lead, after chloroform extraction of lead diethyldithiocarbamate, yields accurate and more precise results than the other methods evaluated. Interference from indium can be avoided by di-isopropyl ether extraction of its bromide from 6*M* hydrobromic acid. Interference from bismuth can be eliminated by separating it from lead by chloroform extraction of its xanthate from 2*M* hydrochloric acid–tartaric acid media.

The preparation and characterization of ores for use as certified reference materials is a continuing project [Canadian Certified Reference Materials Project (CCRMP)] sponsored by the Canada Centre for Mineral and Energy Technology. As part of this project, a zinc–tin–copper–lead ore, MP-1, and a zinc–lead–tin–silver ore, KC-1, have been issued with recommended values for lead.[1,2] As shown in Tables 1 and 2, the ranges of lead values obtained in the interlaboratory certification programme for MP-1, and especially KC-1, were unexpectedly large. In a number of cases the participating laboratories were requested to repeat their analyses because their results were not in accord with the tentative consensus values, but even after corrected results were submitted, the spread of the lead results was twice that of the zinc results in the same materials.[1–3] It was therefore considered imperative to evaluate the titrimetric methods used and to delineate their inherent errors.

The methods are: the molybdate method using tannic acid as an external indicator;[4,5] the chromate method in which iodine, liberated after dissolution of lead chromate and reduction of chromium(VI) with potassium iodide, is titrated with sodium thiosulphate solution;[6] the ASTM EDTA method;[7] and another EDTA method in which lead is separated from the matrix elements by chloroform extraction of its diethyldithiocarbamate complex.[8,9]

EXPERIMENTAL EVALUATION OF METHODS

Reagents

Sodium thiosulphate solution, 0·05*M*.

Lead solution (~4 *mg/ml*). Approximately 8 g (accurately weighed) of high-purity lead pellets were dissolved in 200 ml of concentrated nitric acid, with precautions to avoid loss by spray, and the solution was diluted to 2 litres with water.

Potassium dichromate solution (5 *mg/ml*). Pure potassium dichromate (0·5000 g) was dissolved in water and the solution was diluted to 100 ml.

Iodine indicator, 5% *w/v solution*. Approximately 5 g each of iodine indicator and potassium iodide were dissolved in water and the solution was diluted to 100 ml.

Sodium acetate–acetic acid solution. Approximately 25 ml of concentrated acetic acid and 325 ml of saturated sodium acetate solution were diluted to 1 litre with water.

Hydrochloric acid–sodium chloride solution. Approximately 150 ml each of water and concentrated hydrochloric acid were mixed with 1000 ml of saturated sodium chloride solution.

Sodium acetate wash solution. Approximately 50 ml of saturated sodium acetate solution were mixed with 1000 ml of water.

Ammonium molybdate solution, 0·007*M*. Ammonium paramolybdate tetrahydrate (8·8 g) was dissolved in water and the solution was diluted to 1 litre.

Ammonium acetate–acetic acid solution. Approximately 250 ml of concentrated ammonia solution were added, slowly with stirring, to 300 ml of concentrated acetic acid.

EDTA solution, 0·01*M*.

Acetate buffer solution, *pH* 6. Approximately 27 g of sodium acetate trihydrate were dissolved in 1 litre of water and the pH of the solution was adjusted to 6·0 ± 0·1 (pH-meter) with 5% v/v acetic acid.

Sodium diethyldithiocarbamate (*NaDDTC*), 5% *w/v solution*. Prepared fresh as required, stabilized by adding several drops of concentrated ammonia solution and filtered before use.

Tartaric acid–potassium cyanide wash solution. Approximately 25 ml of water were mixed with 20 ml of 20% tartaric acid solution, the pH of the solution was adjusted to 10·0 ± 0·1 (pH-meter) with concentrated ammonia solution, then 10 ml were added in excess followed by 30 ml each of water and freshly prepared 20% potassium cyanide solution.

Pre-equilibrated di-isopropyl ether

Analytical-reagent grade chemicals were used for all other solutions.

Choice of reference materials

KC-1 and MP-1 were chosen for use in the evaluation tests because of their accurately known lead contents (6·98 and 1·93%, respectively) and because other reference lead

ores were not available. The approximate chemical composition of these ores is shown in Table 3. In all the evaluation tests to be described, five replicate samples of KC-1 (1 g) and MP-1 (2 g) were used.

Procedure for the decomposition of KC-1 and MP-1

The samples were heated with 15 ml of concentrated hydrochloric acid for 5–10 min in a covered 400-ml Teflon beaker, then 10 ml each of water and concentrated nitric acid and 5 ml of concentrated hydrofluoric acid were added and the solution was heated for ~30 min. After the addition of 10 ml more of concentrated nitric acid and 3 ml of concentrated hydrofluoric acid, the solution was heated for 20–30 min, the cover was removed, 15 ml of 50% v/v sulphuric acid were added and the solution was evaporated to fumes of sulphur trioxide. After cooling, 10 ml each of concentrated hydrochloric and hydrobromic acids were added and the solution was evaporated to fumes of sulphur trioxide to remove arsenic and tin. After heating with 10 ml more of concentrated hydrobromic acid to ensure the complete removal of arsenic and tin, the solution was evaporated to fumes of sulphur trioxide twice, after washing down the sides of the beaker with water each time, to ensure the complete removal of nitric, hydrochloric, hydrobromic and hydrofluoric acids, and finally until 3–5 ml of sulphuric acid remained.

Chromate Method

Standardization of sodium thiosulphate solution

Three 10-ml aliquots of standard potassium dichromate solution were diluted to ~150 ml with water. After addition of 6 ml of concentrated hydrochloric acid and 10 ml of freshly prepared 20% potassium iodide solution, each solution was titrated with sodium thiosulphate solution until the brown colour of the liberated iodine had almost disappeared and the solution was yellowish-green. After addition of 5 ml of freshly prepared 5% iodine indicator solution, the titration was continued until the solution was clear green. The normality and the "true" lead equivalent (mg/ml) of the sodium thiosulphate solution were calculated from the mean.

The sodium thiosulphate solution was also standardized with four aliquots of standard lead solution containing approximately the same amount of lead as would be derived from samples of the certified reference ore to be analysed. These solutions, except for the additions of nitric, hydrochloric, hydrofluoric and hydrobromic acids described in the decomposition procedure, were evaporated to fumes of sulphur trioxide three times, the sides of the beaker being washed down with water each time, to remove nitric acid, and carried through the procedure described. The "apparent" lead equivalent of the solution was calculated from the mean.

Procedure

Fifty ml of water were added to the solution obtained as described under "decomposition", the solution was heated to dissolve the soluble salts, then diluted to about 100 ml with water and cooled in an ice-bath for 45 min. The lead sulphate (and insoluble material) was filtered off on Whatman No. 42 paper. The beaker was washed 3 times with cold 1% v/v sulphuric acid, the paper and precipitate were washed once with the same solution, then the beaker and precipitate were each washed once with cold water.

The precipitate was transferred to the original beaker with a jet of water, and a small piece of moistened filter paper was used to clean the lip of the funnel. After addition of 25 ml of hot sodium acetate–acetic acid solution, the solution was boiled for at least 20 min to ensure complete dissolution of the lead sulphate. The hot solution was filtered through the original filter paper and the beaker, and paper plus residue, were each washed twice with ~ 10-ml portions of hot sodium acetate–acetic acid solution, and again twice with hot water. The filtrate and washings were collected in a 400-ml beaker, diluted to ~ 150 ml with water, if necessary, heated to boiling and then treated with 10 ml of saturated potassium dichromate solution added slowly by pipette. The solution was boiled gently for 15–20 min until the precipitate became orange-red. The precipitate was allowed to settle until the supernatant solution was clear, then filtered off by suction on a fine-porosity porcelain crucible containing a $\frac{1}{4}$-in. layer of paper pulp. The beaker and crucible plus precipitate were each washed 5 times with 10–15-ml portions of sodium acetate wash solution. The sides of the beaker were washed down with 25 ml of hydrochloric acid–sodium chloride solution and the solution was added to the crucible containing the bulk of the precipitate. After about 5 min (for the precipitate to dissolve) suction was applied and the solution collected in a clean 500-ml suction flask. The beaker was washed twice with ~ 10-ml portions of the hydrochloric acid–sodium chloride solution (from a wash-bottle) and the crucible once with 10–15 ml of the same solution. The beaker and crucible were then each washed twice with water, the walls of the flask were washed down with a little water, 10 ml of freshly prepared 20% potassium iodide solution were added and the solution was titrated as described above.

Recovery of lead from the lead sulphate filtrate. The combined filtrate and washings from the separation of lead sulphate were evaporated to dryness to remove sulphuric acid, then 10 ml of concentrated nitric acid and 25 ml of water were added and the solution was heated to dissolve the salts. The solution was diluted to ~ 150 ml with water and sufficient concentrated ammonia solution was added to precipitate hydrous ferric oxide, then several drops were added in excess followed by 20 ml of freshly prepared saturated ammonium carbonate solution. The solution was boiled for several minutes to coagulate the hydrous ferric oxide–lead carbonate precipitate, which was then filtered off on Whatman No. 541 paper, and the beaker, and paper plus precipitate, were washed 3 and 4 times, respectively, with hot water. The filtrate and washings were discarded. The bulk of the precipitate was transferred to the original beaker with a jet of water, and 10 ml of concentrated nitric acid were added to dissolve it. The solution was filtered through the original filter paper into a 200-ml volumetric flask, the beaker and the paper were each washed twice with small portions of hot 10% v/v nitric acid and then once with water. The paper was discarded, the solution was diluted to volume with water, and the lead was determined by atomic-absorption spectrophotometry (AAS).

Recovery of lead from the filter paper after separation and dissolution of lead sulphate. The filter paper containing the acid-insoluble material remaining after the dissolution of lead sulphate was transferred to a covered 250-ml beaker, 10 ml each of concentrated nitric and perchloric acids were added, the mixture was heated to decompose the paper, and the solution was evaporated to dryness. Five ml of concentrated nitric acid and 25 ml of water were added, then the solution was heated to dissolve the soluble salts and diluted to ~ 100 ml with water. After the addition of 1 ml of 20% ferric nitrate (9-hydrate) solution as a collector for lead, hydrous ferric oxide and residual lead were precipitated and the lead determined (100-ml final volume) by AAS as described above.

Recovery of lead from the lead chromate filtrate. The combined filtrate and washings obtained after the separation of lead chromate were allowed to stand for 24 hr, then filtered through Whatman No. 42 paper and the beaker washed once with a small portion of water. The sides of the beaker were washed down with ~ 20 ml of 25% v/v nitric acid to dissolve any residual lead chromate, and the solution was poured into the filter paper and collected in a 50-ml volumetric flask. The beaker and paper were each washed with small portions of water, the solution was diluted to volume with water and lead determined by AAS.

Molybdate Method

Standardization of ammonium molybdate solution

Three aliquots of standard lead solution, containing approximately the same amount of lead as would be derived from samples of the ore to be analysed, were transferred to 400-ml beakers, 15 ml of 50% v/v sulphuric acid were added and the solutions evaporated to fumes of sulphur trioxide twice, the sides of the beaker being washed down with water each time, to remove nitric acid, and then to dryness to remove sulphuric acid. Ten ml of ammonium acetate–acetic acid solution were added, the beaker was covered, the solution diluted to ~ 150 ml with water, and boiled until all the lead sulphate had dissolved. The hot solution was titrated with ammonium molybdate solution, with freshly prepared 0·5% tannic acid solution as external indicator, until a drop of solution turned a drop of tannic acid solution yellow. The "true" lead equivalent of the ammonium molybdate solution was calculated from the mean.

The ammonium molybdate solution was also standardized with four aliquots (same as above) of standard lead solution which were evaporated to fumes of sulphur trioxide, as described under "standardization of thiosulphate", and carried through the procedure described below. The "apparent" lead equivalent of the solution was calculated from the mean.

Procedure

Following sample decomposition and dissolution of the salts as described for the chromate method, a small amount of filter pulp (~ 1/8 of a tablet) was added, the solution was cooled in an ice-bath for 45 min and the lead sulphate *etc.* was filtered off on Whatman No. 42 paper. The beaker was washed 3 times with cold 1% v/v sulphuric acid, the paper plus precipitate were washed once with the same solution, then the beaker and precipitate were each washed once with cold 1% v/v methanol.

The precipitate was transferred to the original beaker with a jet of water and the paper was shredded and added to the beaker. A small piece of moistened filter paper was used to clean the funnel and added to the beaker containing the lead sulphate. After addition of 10 ml of ammonium acetate–acetic acid solution and dilution to ~ 150 ml with water, the beaker was covered, the solution boiled for at least 20 min to ensure complete dissolution of the lead sulphate, then the solution was titrated as described above.

Recovery of lead from the filtrate. The combined filtrate and washings were evaporated to dryness to remove sulphuric acid, and lead was separated as the carbonate and determined by AAS as above.

ASTM (E-16) EDTA Method

Standardization of EDTA solution

Three aliquots of standard lead solution, containing approximately the same amount of lead as would be derived from samples of the ore to be analysed, were treated as described under "standardization of molybdate". Fifty ml of hydrochloric acid–sodium chloride solution were added, the solution was heated to boiling and boiled gently for 3–5 min to ensure complete dissolution of lead sulphate. After cooling to room temperature, 3 drops of concentrated fluoboric acid, 2 ml of freshly prepared 2·5% ascorbic acid solution and 6 drops of 0·2% Xylenol Orange solution were added, with stirring after each addition, then ~ 1-g portions of hexamine were added until the solution turned pale purple. The solution was titrated with EDTA solution, more hexamine being added as the colour began to fade. Near the end-point, 2 g of hexamine were added and the solution was titrated to a pure yellow. The "true" lead equivalent of the EDTA solution was calculated from the mean.

The EDTA solution was also standardized with four aliquots (same as above) of standard lead solution which were evaporated to fumes of sulphur trioxide, as described under "standardization of thiosulphate", and carried through the procedure described below. The "apparent" lead equivalent of the solution was calculated from the mean.

Procedure

Following sample decomposition as described above, 150 ml of water and 3 or 4 drops of 30% hydrogen peroxide solution were added and the solution was boiled vigorously for 10–15 min to destroy the excess of peroxide and dissolve the soluble salts. A small amount of filter paper pulp was added and the lead sulphate (and insoluble material) was filtered off as in the molybdate method. The beaker, and the paper plus precipitate, were each washed twice with 0·5% v/v sulphuric acid–1% sodium sulphate solution, then the beaker and precipitate were each washed once with cold water.

The precipitate and paper were transferred to the original beaker, as described above, 50 ml of hydrochloric acid–sodium chloride solution were added, the solution was boiled to dissolve the lead sulphate and subsequently titrated as described above.

The lead in the filtrate was recovered and determined as before.

NaDDTC–EDTA Method

Standardization of EDTA solution

Three 15-ml portions of standard lead solution were transferred to 250-ml beakers, 5 ml of concentrated perchloric acid were added to each and the solutions evaporated to dryness to remove the nitric and perchloric acids. Ten g of ammonium chloride and ~100 ml of water were added and the solution was heated to dissolve the lead salts. After addition of 30 ml of pH-6 acetate buffer solution, the solution was cooled to room temperature, then the pH was adjusted to 5·8–6·0 (pH-meter) with concentrated and 10% v/v ammonia solutions and 10% v/v hydrochloric acid, if necessary. Six drops of 0·2% Xylenol Orange solution were added and the solution was titrated with EDTA solution. Near the end-point the pH of the solution was re-adjusted, if necessary, to 5·0–5·5 with 10% ammonia solution and the titration was continued to a pure yellow end-point. The lead equivalent of the EDTA solution was calculated from the mean.

Procedure

Following sample decomposition as described above, 25 ml of water were added to the sample solution and it was heated to dissolve the soluble salts. After addition of 20 ml of 20% tartaric acid solution, the solution was cooled to room temperature, 30 ml of concentrated ammonia solution were added (carefully to avoid spattering) and the solution was allowed to stand for several hr to ensure the complete dissolution of lead sulphate. The pH was adjusted to 10·0 ± 0·1 (pH-meter) with concentrated ammonia solution, 10 ml were added in excess and the whole was transferred to a 250-ml separatory funnel. After addition of 30 ml of freshly prepared 20% potassium cyanide solution, the solution was allowed to stand for at least 5 min to ensure complete complexation of copper, zinc, iron and other interfering elements. Sufficient 5% NaDDTC solution was added, during three extraction stages, to ensure the complete precipitation of lead (4, 3 and 2 ml for KC-1, and 2, 1 and 0·5 ml for MP-1) and the lead complex was extracted by shaking for ~1 min each time, first with 15 ml, then with 10-ml portions of chloroform. The aqueous phase was washed by shaking for ~30 sec with 10 ml of chloroform, then the combined extracts were washed by shaking them in a 125-ml separatory funnel for ~30 sec with 10 ml of tartaric acid–potassium cyanide wash solution, containing 1 ml of 5% NaDDTC solution, to remove co-extracted interfering elements. The chloroform phase was drained into a 250-ml beaker and the aqueous layer washed 3 times by shaking for ~15 sec each time with 5-ml portions of chloroform. Ten ml each of water and concentrated nitric acid were added to the combined chloroform phases and the chloroform was removed by evaporation in a hot water-bath. After the addition of 10 ml of concentrated perchloric acid, the solution was covered and boiled to destroy organic material, then carefully evaporated to dryness to remove the nitric and perchloric acids. If organic material was still present, the residue was again treated with 10 ml each of concentrated nitric and perchloric acids and the solution boiled and evaporated to dryness. Following the addition of 10 g of ammonium chloride and 100 ml of water, the dissolution of the lead salts, and the addition of 30 ml of pH-6 acetate buffer solution, the solution was titrated as described above.

Modified NaDDTC–EDTA Method

Procedures for the separation of indium and bismuth

The following procedures were employed for the separation of indium and bismuth in MP-1 because it is known that they interfere in the determination of lead by the NaDDTC–EDTA method.

Separation of indium. After extraction of the lead diethyldithiocarbamate complex and evaporation of the final solution to dryness, 25 ml of 6*M* (~68%) hydrobromic acid were added to the residue and the solution was heated gently, if necessary, to dissolve the salts. The solution was transferred to a 125-ml separatory funnel and diluted to 50 ml with 6*M* hydrobromic acid. Fifty ml of pre-equilibrated di-isopropyl ether were added and the funnel was shaken for 2 min. The aqueous phase containing the lead was drained into a second 125-ml separatory funnel, the stem of the first funnel was washed with 6*M* hydrobromic acid (from a plastic wash-bottle), and the remaining indium was extracted as described above with a second 50-ml portion of the ether. The aqueous phase was drained into a 400-ml beaker and the stem of the funnel was washed with water. The ether in the first funnel was added to that in the second, and the first funnel was washed 3 times with 5-ml portions of 6*M* hydrobromic acid. The washings were drained into the second funnel, which was shaken for ~15 sec, and the aqueous phase was then added to the beaker. The ether phase was washed twice more with 5-ml portions of 6*M* hydrobromic acid, then the combined aqueous phases were heated gently to remove the residual ether. Five ml of concentrated perchloric acid were added and the solution was evaporated to dryness to remove the hydrobromic and perchloric acids.

Separation of bismuth. Ten g of ammonium chloride, 1 ml of 20% tartaric acid solution and ~100 ml of water were added to the residue obtained as just described and the solution was heated to dissolve the salts. After addition of 25 ml of concentrated hydrochloric acid, the solution was cooled to room temperature, transferred to a 250-ml separatory funnel, and diluted to ~150 ml with water. Fifteen ml of chloroform were added, followed by 3 ml of freshly prepared 5% potassium ethyl xanthate solution, and the yellow bismuth complex was extracted immediately (because of its instability) by shaking for ~1 min. The chloroform phase was discarded. The solution was

extracted three more times with 10 ml of chloroform and 0·5 ml of xanthate solution each time. The aqueous phase was drained into a 400-ml beaker, heated gently to remove the residual chloroform and evaporated to ~100 ml. Fifteen ml each of concentrated nitric and perchloric acids were added, the beaker was covered and the solution boiled to destroy the organic material and ammonium salts, then evaporated to ~75 ml. The solution was boiled with a further 15-ml portion of concentrated nitric acid, then carefully evaporated to dryness in an aluminium (beaker-style) evaporator to remove the nitric and perchloric acids. After addition of 10 g of ammonium chloride and 100 ml of water, dissolution of the lead salts, and addition of 30 ml of pH-6 acetate buffer solution, the solution was titrated as described above.

RESULTS AND DISCUSSION

The results obtained for lead in KC-1 and MP-1 by the four titrimetric methods are shown in Tables 4–7. No difficulties were encountered in applying the EDTA methods to the analysis of the certified ores. However, in initial tests with the chromate method,[6] in which filter paper (Whatman No. 42) was used for the filtration of the lead chromate precipitate, a considerable and variable amount of precipitate (equivalent to 0·3–1·1 mg of lead) was lost because of its tendency to creep up the sides of the funnel and then be washed down behind the paper during the washing stage. Further work showed that lead chromate was also lost during filtration, by suction, through a fine-porosity porcelain crucible. When a fine-porosity crucible containing a pad of filter paper pulp was used the loss of lead was 0·09–0·16 mg. In initial tests with the molybdate method[4,5] no end-point could be obtained with tannic acid as indicator when the recommended concentration of ammonium molyb-

date was used (*i.e.*, 1 ml ≡ 5 mg of lead). Even with double the concentration the end-point was rather indistinct.

Table 8 shows that only the molybdate method gives really good agreement with the recommended values for both ores. Tables 4–6 show that the solubility losses inherent in the first three methods during the separations of lead are a significant source of negative error if the titrant is standardized directly against pure potassium dichromate in the chromate method and against pure lead in the other methods. The relative error is substantially greater for MP-1 than for KC-1 because of its lower lead content. In most cases, the precision is slightly poorer when the titrant is standardized against pure lead carried through the procedure in order to cancel out solubility losses, because the amount of lead remaining in the lead sulphate filtrate is not constant. This is why, in the evaluation tests, four aliquots of standard lead solution, containing approximately the same amount of lead as would be derived from the ore samples, were carried through the procedure and averaged for standardization purposes.

Theoretically, the molybdate and ASTM EDTA methods are prone to positive error because of the co-precipitation or retention of sulphates and hydrolysis products of interfering elements (calcium, strontium, bismuth, antimony, silver, copper, iron and zinc)[10–12] and the subsequent co-titration of these elements.[4,13,14] This readily explains the high results obtained for lead in both KC-1 and MP-1 by the ASTM EDTA method because large amounts of zinc and iron are present in both ores, and a relatively large amount of copper is present in MP-1 (Table 3). Similarly, the higher result obtained for MP-1 by the molybdate method than by the chromate method could be due to the high calcium content of this ore. Retention of calcium sulphate with lead sulphate would result in the formation of insoluble calcium molybdate during the titration with ammonium molybdate solution.[13] Positive error due to retention of interfering elements with lead sulphate would not occur readily in the chromate method because of the additional separation of lead from interfering elements by precipitation as the chromate.

Table 8. Correlation of overall mean lead results for KC-1 and MP-1 with the titrimetric method employed

Method	Overall mean lead results, % KC-1	MP-1
Chromate	6·97$_9$	1·89$_5$
Molybdate	6·97$_1$	1·93$_0$
ASTM (E–16) EDTA	7·04$_5$	1·96$_0$
NaDDTC–EDTA	6·96$_6$	2·02$_6$
CCRMP recommended value	6·98	1·93

The high result obtained for MP-1 by the NaDDTC–EDTA method (Table 7) is caused by the presence of bismuth and indium in this ore. These elements are completely co-extracted with the lead as diethyldithiocarbamate complexes from ammoniacal potassium cyanide media (pH 10) and, because of hydrolysis, are subsequently only partly co-titrated with EDTA.[8,9] When bismuth and indium are not present, this method is considered to be the best of the methods evaluated because it is based on complete separation and titration of lead. For this reason, an attempt was made to modify the method to obviate the interference of indium and bismuth. A search of the literature did not reveal any method for the simultaneous separation of indium and bismuth from lead, but it is known that indium can readily be separated from lead by ether extraction of its bromo-complex from 4–6*M* hydrobromic acid media.[15,16] Although bismuth and lead can be determined in the same solution by successive titration with EDTA at pH 2 and 5·5 with Xylenol Orange as indicator,[8] the author experienced difficulty in determining the end-point for the bismuth titration and did not pursue this approach. It is known that bismuth can be extracted as the xanthate complex from acidic media.[17,18] Tests (Table 9) showed that bismuth can be separated from lead by chloroform extraction of its xanthate from ~2*M* hydrochloric acid–tartaric acid media, and confirmed that indium can be separated from lead by di-isopropyl ether extraction of its bromo-complex from 6*M* hydrobromic acid media.[16]

Table 10 shows the results obtained for MP-1 by the NaDDTC–EDTA method modified for separation of indium and bismuth. The mean value is lower than the recommended value but in reasonably good agreement with that obtained by the chromate method and the mean value obtained by Laboratory

Table 9. Recovery of lead in synthetic solutions after the separation of indium and bismuth by extraction as the bromo- and xanthate-complexes, respectively

2	$1{\cdot}89_6$
3	$1{\cdot}88_4$
4	$1{\cdot}88_6$
5	$1{\cdot}88_4$
Mean	$1{\cdot}88_3$
Standard deviation, %	0·010
95% Confidence limits	$1{\cdot}87_0$–$1{\cdot}89_6$

12 (Table 2). This laboratory also used a modification of the NaDDTC–EDTA method in which indium was separated from lead by butyl acetate extraction from 5*M* hydrobromic acid, followed by titration of bismuth at pH 2 and lead at pH 5·5.[19] Laboratory 12 also obtained a mean value of $1{\cdot}88_9\%$ for lead in MP-1 by atomic-absorption spectrophotometry (Table 2), and a mean value of $6{\cdot}96_7\%$ for lead in KC-1 (Table 1) by the NaDDTC–EDTA method. The latter value is in excellent agreement with the recommended value and the mean value obtained during the evaluation of this method (Table 7).

The foregoing results suggest that the recommended value for lead in MP-1 (1·93%) may be too high. This is also indicated by the results of a test in which a solution containing the same amounts of lead, bismuth and indium that are present in 2 g of MP-1 was titrated with standard EDTA solution to determine the approximate magnitude of the positive error due to bismuth and indium in the results shown in Table 7. Direct calculation of this error on the basis of the lead equivalents of the bismuth and indium present in the sample (Table 3) is not feasible because some hydrolysis of indium and particularly of bismuth occurs under the conditions employed for the titration of lead. The results of this test showed that the positive error due to bismuth and indium was equivalent to 0·140% lead. Consequently, on the basis of the mean value (2·026%) obtained for lead in MP-1 by the NaDDTC-EDTA method in the presence of bismuth and indium (Table 7), the value obtained after correcting for the positive error due to bismuth and indium ($1{\cdot}88_6\%$) is in good agreement with the mean value obtained (Table 10) after the separation of bismuth and indium.

CONCLUSIONS

This investigation has shown that the nature of the titrimetric method employed can cause a significant difference in the results obtained for lead. It is the author's opinion that the NaDDTC–EDTA method, modified, when necessary, to eliminate the interference of indium and/or bismuth, is the most satisfactory of the methods evaluated because it is based on complete separation of lead and direct standardization of the titrant against pure lead. Although this method is also subject to interference from thallium, which is co-extracted with lead as the diethyldithiocarbamate complex,[9] this element can be separated from lead in the same way as indium.[15] Moreover, the final titration procedure is superior to the ASTM procedure because sodium acetate has better buffering capacity than hexamine and because a sharper and more distinct end-point is obtained.

The molybdate and ASTM methods are not recommended for the exact, non-routine determination of lead in ores because these methods are prone to positive error resulting from the retention of interfering elements in the lead sulphate precipitate. Furthermore, the molybdate method is severely prone to "operator" error because of the difficult end-point. The high concentration of titrant required also causes error, when small or moderate amounts of lead are to be determined, because of the small volume needed.

Although the chromate method, as do the molybdate and ASTM methods, involves the incomplete separation of lead as the sulphate, further separation of lead from most of the interfering elements that are retained with the lead sulphate precipitate (with the exception of barium) is achieved during the subsequent precipitation of lead as the chromate. This method is recommended for the non-routine determination of lead in ores, if the titrant is standardized directly against pure potassium dichromate, and if the residual lead remaining in the filtrates and in the filter paper is determined by atomic-absorption spectrophotometry and appropriate corrections are made. The recovery and determination of the residual lead can be facilitated by combining all of the solutions obtained after the treatment of the filtrates and paper as described under "chromate method" and subsequently separating the lead as the carbonate.

(*Received* 2 *June* 1975. *Accepted* 31 *July* 1975)

Summary—Gold(III) can be separated from Cd, In, Zn, Ni, Cu(II), Mn(II), Co(II), Mg, Ca, Al, Fe(III), Ga and U(VI) by adsorbing these elements on a column of AG50W-X8 sulphonated polystyrene cation-exchange resin from 0·1*M* HCl containing 60% v/v acetone, while Au(III) passes through and can be eluted with the same reagent. Separations are sharp and quantitative. The amounts of gold retained by the resin are between 1 and 2 orders of magnitude lower than encountered during adsorption from aqueous 0·1*M* HCl. Recoveries for mg amounts of gold are 99·9% or better and for ng amounts are still better than 99%, as shown by radioactive tracer methods. Hg(II), Bi, Sn(IV), the platinum metals and some elements which tend to form oxy-anions in dilute acid accompany gold. All other elements, though not investigated in detail, should be retained, according to their known distribution coefficients. Relevant elution curves, results of quantitative separations of binary mixtures and of recovery tests are presented.

It has been shown that gold can be eluted from a column containing a sulphonated polystyrene cation-exchange resin by aqueous 0·2*M* hydrochloric acid and thus separated from cadmium which is retained under these conditions.[1] The separation is not quite quantitative, and μg amounts of gold are retained on a column of 30 ml of AG50W-X8 resin when 100 ml of gold(III) chloride solution in 0·1*M* hydrochloric acid containing 100 mg of gold are passed through it and the gold is eluted with another 300 ml of aqueous 0·1*M* hydrochloric acid.[2] When only μg amounts of gold are present a considerably larger fraction of the total gold can be retained. Pitts and Beamish[3] have investigated the separation of gold(III) from base metals in chloride solution and found that substantially low recoveries of gold occur when the base metal chloride concentration is above 0·05*M*. Losses are of the order of several per cent of the total gold present. Even at the lower base metal concentrations suggested by the authors, gold recoveries, according to their results, tend to be low by a few tenths of a per cent. Kutil and Čůta[4] also found that a small fraction of the gold(III) present is retained on a cation-exchange resin after elution with dilute hydrochloric acid. On the other hand, when gold is passed through a cation-exchange column in 0·2*M* hydrochloric acid containing 90% v/v acetone, the amount of gold retained becomes negligible (<0·5 μg out of 100 mg).[2] Apparently an association complex between $HAuCl_4$ and acetone is formed which tends to remain in the acetone-rich phase outside the resin particles, thus preventing interaction between gold(III) and the resin. Cadmium and indium are eluted together with gold(III) under these conditions. Toerien and Levin[5] have separated gold(III) and platinum metals from base metals by elution with 0·1*M* hydrobromic acid containing 60% v/v tetrahydrofuran from AG50W-X8 cation-exchange resin. Cadmium and indium were not included in their study. Cadmium will probably accompany gold(III). The distribution coefficient of cadmium in 0·1*M* hydrobromic acid containing 60% v/v acetone is 7·1,[6] and that in 0·1*M* hydrobromic acid containing 60% v/v tetrahydrofuran should not be greatly different, because the distribution coefficients of elements in mixtures of hydrobromic acid with these two solvents are very similar.[7] For retention of cadmium, hydrochloric acid would be preferable to hydrobromic acid as the medium because the chloride complexes of cadmium are less stable than the bromide complexes. In 0·1*M* hydrochloric acid containing 90% v/v acetone the distribution coefficient of cadmium is only 2·1,[2] but when the acetone concentration is decreased to 60% the coefficient increases to 93, while that for gold remains less than 1.[2] This seems to offer prospects for a good separation provided the amounts of gold retained by the column remain negligible at the lower acetone concentration. The quantitative aspects of this separation have not received attention and therefore were investigated in detail.

EXPERIMENTAL

Reagents and apparatus

Chemicals used were of analytical-grade purity. Water was distilled and then passed through an Elgastat deminer-

alizer. The resin was the AG50W-X8 sulphonated polystyrene cation-exchanger of 200–400 mesh particle size (Bio-Rad Laboratories, Richmond, California). Resin used for column work was stirred in a beaker with 0·1*M* hydrochloric acid containing 60% v/v acetone and the slurry transferred to the column with the same reagent.

Borosilicate glass tubes of either 21 or 15 mm bore with fused-in glass sinters of No. 2 porosity and a burette tap at the bottom, and either a B19 or a B14 ground-glass joint at the top, were used for making the columns.

Atomic-absorption measurements were carried out either with a Perkin-Elmer 303 or with a Varian-Techtron AA-5 instrument, and for spectrophotometric determinations a Zeiss PMQ II spectrophotometer was used.

Elution curves

Fifty ml of a solution containing 0·25 mmole of gold(III) chloride and 1 mmole of cadmium chloride in 0·10*M* hydrochloric acid containing 60% v/v acetone were passed through a 30-ml column containing 10 g of AG50-X8 resin (200–400 mesh). The resin column was 15 cm long and 1·5 cm in diameter and had been equilibrated by passage of 50 ml of 0·1*M* hydrochloric acid containing 60% v/v acetone (*i.e.*, 0·25*M* aqueous hydrochloric acid mixed with acetone in a volume ratio of 2:3, disregarding volume changes during mixing). The elements were washed onto the column with 3 portions of about 10 ml of the same solution, the solution being drained to the top of the resin bed after each washing. Elution was then carried out with the same solution with a flow-rate of 2·0 ± 0·3 ml/min. Fractions of 25 ml were taken with an automatic fractionator from the beginning of the adsorption step and, after evaporation to remove acetone and suitable dilution with 0·1*M* hydrochloric acid, the amounts of the elements in the fractions were determined by atomic-absorption spectrometry using an air–acetylene flame and the 242·3 and 228·8 nm lines for gold and cadmium respectively. The experimental elution curve is shown in Fig. 1.

Figure 2 shows an elution curve for the Au(III)–In pair, obtained by using the same column and similar experimental conditions. Other elements such as Zn, Cu(II), Co(II), Ni, Mn(II), Mg, Ca, Al, Ga, U(VI) and Fe(III) are more strongly retained than indium and are not eluted in the first 1200 ml of eluate from a 30-ml resin column. When the column size was increased to 60 ml (20 g of resin) no cadmium or indium was found in the first 1000 ml of elutate when 1 mmole of either of these elements was present. Figure 3 shows an elution curve for the Au(III)–Cd pair with a column 20 cm in length and 2·0 cm in diameter, containing 20 g of resin. The flow-rate was 3·0 ± 0·3 ml/min in this case and elution with 0·1*M* hydrochloric acid containing 60% v/v acetone was interrupted after 400 ml had been passed. The cadmium was then eluted with 0·2*M* hydrobromic acid containing 50% v/v acetone.

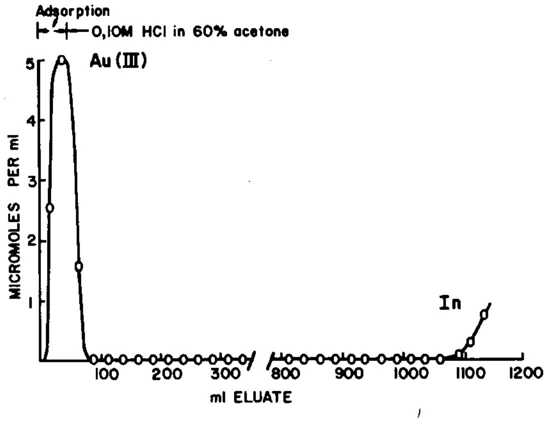

Fig. 2. Elution curve for Au(III)–In with 0·10*M* HCl in 60% v/v acetone. Column (15 × 1·5 cm), AG50W-X8 resin, 200–400 mesh. Flow-rate 2·0 ± 0·3 ml/min.

Retention of gold on the resin

About 50 mg of gold(III) as the chloride in 50 ml of 0·1*M* hydrochloric acid containing 60% v/v acetone were passed through a column containing 20 g of resin as described above. The gold was washed onto the resin and eluted with 300 ml of 0·1*M* hydrochloric acid containing 60% v/v acetone. The resin was then removed from the column and ashed in a new silica dish which had been cleaned by boiling in *aqua regia*. Ashing was carried out at low temperature (about 500°) initially, the temperature being finally increased to 650°. The ash was dissolved in *aqua regia* and the solution after evaporation to a small volume was transferred into a 50-ml beaker. It was evaporated almost to dryness, a few drops of nitric acid being added a few min before the evaporation was stopped, and made up to 5 ml with 1*M* hydrochloric acid in a volumetric flask. The amount of gold was then determined by atomic-absorption spectrometry using an air–acetylene flame, the 242·3 nm line and scale expansion. A similar experiment was carried out with a gold(III) solution in 0·1*M* aqueous hydrochloric acid and eluting with 300 ml of 0·1*M* aqueous hydrochloric acid. The results are shown in Table 1.

Quantitative separation of gold(III) from binary mixtures

Suitable aliquots of a standard solution of gold(III) chloride in dilute hydrochloric acid and of one other element were measured out and mixed. The mixtures were

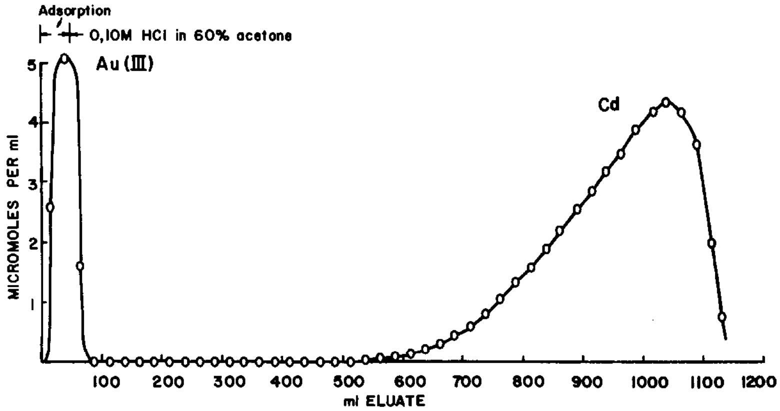

Fig. 1. Elution curve for Au(III)–Cd with 0·10*M* HCl in 60% v/v acetone. Column (15 × 1·5 cm), AG50W-X8 resin, 200–400 mesh. Flow-rate 2·0 ± 0·3 ml/min.

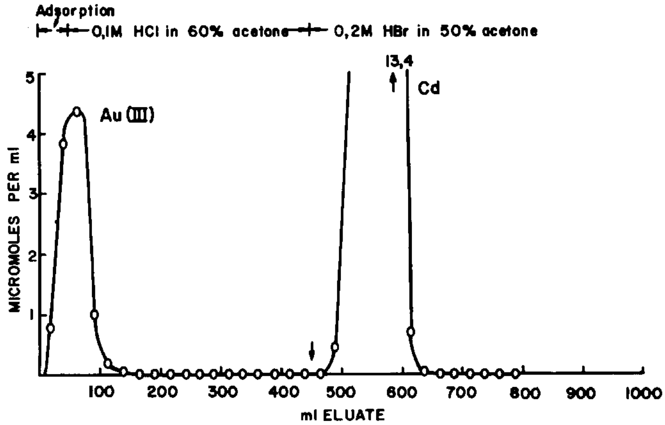

Fig. 3. Elution curve for Au(III)–Cd. Column (19 × 2·0 cm), AG50W-X8 resin, 200–400 mesh. Flow-rate 3·0 ± 0·3 ml/min.

Table 1. Amount of gold retained by resin

0·1*M* aqueous HCl Column no.	Au, μg	0·1*M* HCl in 60% acetone Column no.	Au, μg
1	13·3	4	$0{\cdot}4_0$
2	8·4	5	$0{\cdot}4_8$
3	17·1	6	$0{\cdot}2_8$

adjusted to contain 0·1*M* hydrochloric acid and 60% v/v acetone (volume of about 150 ml) and were passed through columns containing 20 g of AG50W-X8 resin (200–400 mesh). When 5 g of gold were present the solutions were adjusted to a volume of about 500 ml before being passed through the columns. The columns were 20 cm in length and 2·0 cm in diameter and had been equilibrated by passage of 50 ml of the eluting agent. Gold(III) was then eluted with 300 ml of 0·1*M* hydrochloric acid containing 60% v/v acetone, followed by the elution of the other element with 300 ml of 1·0*M* hydrochloric acid in the case of Cd and In and 300 ml of 3·0*M* hydrochloric acid in the case of Zn, Cu(II) and other elements. The flow-rate was 3·0 ± 0·5 ml/min. The gold(III) and "other element" fractions were collected separately, the effluent from the adsorption step being included in the gold(III) fraction, and after evaporation to dryness on the water-bath the amounts of the elements in the fractions were determined (Table 2). The results of the analyses are presented in Table 3.

Table 2. Analytical methods used

Element	Method
Au	Gravimetrically as the metal after precipitation with SO_2. Small amounts by atomic-absorption spectrometry.
Cd	Complexometrically with EDTA in slight excess of ammonia with Methylthymol Blue as indicator. Small amounts by atomic-absorption spectrometry.
In, Ga, Fe(III), Al	Complexometrically with DCTA; back-titration with $ZnSO_4$ at pH 5·5 with Xylenol Orange as indicator. Small amounts of indium by atomic-absorption spectrometry.
Zn	Complexometrically with EDTA at pH 5·5 with Xylenol Orange as indicator.
Co(II)	Complexometrically with EDTA, Naphthyl Azoxine S as indicator at pH 6 (pyridine buffer).
Ni	Complexometrically in slight excess of ammonia with EDTA; Murexide as indicator.
Cu(II)	Complexometrically with EDTA, Methylthymol Blue in presence of trace of 1,10-phenanthroline as indicator at pH 5.
Ca, Mn(II)	Complexometrically with EDTA in presence of excess of ammonia, Methylthymol Blue as indicator. Hydroxylamine hydrochloride present for Mn(II)
Mg	Complexometrically with EDTA at pH 10 with Eriochrome Blueblack B as indicator.
U(VI)	Gravimetrically as U_3O_8 after precipitation with CO_2-free ammonia.

Separation of nanogram amounts of gold(III)

Triplicate 1-g samples of the standard granite rock NIM-G were weighed out accurately and dissolved as described previously.[8] To the resulting solution were added 5 ml of a solution containing a mixture of radioactive gold isotopes, mainly gold-196 (6·2 d) and gold-194 (39·5 hr). These had been obtained by bombarding a target of pure platinum with 16-MeV deuterons in the cyclotron of the NPRL in Pretoria and separating gold from platinum by solvent extraction as chloride into ethyl acetate. The total amount of gold present was less than 500 ng originating from impurities in the platinum target (according to specifications) and 9 ng present in 1 g of granite as determined by neutron-activation analysis.[9] The solutions were adjusted to about 150 ml in volume, 0·1*M* in hydrochloric acid and 60% v/v in acetone concentration and gold was separated from the major rock-forming elements as described in the previous paragraph. The eluate was evaporated to dryness and the residue taken up in *aqua regia*. The resin was removed from the columns and ashed in silica dishes at low temperature after the rock-forming elements had been eluted, and the ash was dissolved in *aqua regia*. Undissolved material was fused with a small amount of potassium bisulphate before dissolution in dilute hydro-

chloric acid. The activity of the gold-containing fractions, the solutions of the ash and 3 solutions containing 5 ml of the radioactive gold standard, which had been measured out together with the solutions added to the dissolved rock samples, was then measured with a gamma-spectrometer under identical conditions (solution volume and counting position). Results are presented in Table 4.

RESULTS AND DISCUSSION

The method described provides a useful means for the separation of micro or macro amounts of gold from Cd, In, Zn, Ni, Cu(II), Mn(II), Co(II), Mg, Ca, Al, Fe(III), Ga, U(VI). Many other elements which have not been investigated in detail should also be separated according to their known distribution coefficients.[2] They include Be, Sr, Ba, Li, Na, K, Rb, Cs, Ti, Zr, Hf, Th, Sc, Y, lanthanides and Cr(III). The only species to accompany gold are the platinum metals, Hg(II), Bi(III), Sn(IV) and some of those elements which tend to form oxy-anions in dilute acids. The mixed-solvent eluting agent reduces the amount of gold retained by the resin by more than an order of magnitude (Table 1), while Cd and In are still retained. For large amounts of gold, recoveries are better than 99·9%, while even for ng amounts, 99% or more can be recovered (Table 4). In another experiment in which special precautions were taken to keep gold(III) in the oxidized state, only 0·1% of 500 ng of gold were found to be lost by adsorption on the resin and on the walls of beakers. When 5 g of gold were present (Table 3) 27·5 μg were found with the cadmium and 18·3 μg were found to be still on the column. Certain precautions always have to be taken to minimize losses of gold on the column. Evaporation in hydrochloric acid of high concentration reduces and precipitates gold. With small gold concentrations this is not visible. Solutions of gold in hydrochloric acid should therefore always be reoxidized after evaporation. The most convenient way is to add 5 or 6 drops of nitric acid to the last ml of hydrochloric acid which remains and heat the solution for several min before dilution and addition of acetone.

Separation of the other elements from gold is sharp and recoveries are quantitative. Cadmium is the most critical of the elements separated and shows fairly severe "heading" (Fig. 1), but the separation factor and distribution coefficient of cadmium are large enough to guarantee a quantitative recovery, provided a large enough column is used. No cadmium (<0·2 μg) was found in the gold-containing eluate after 48·8 μg of gold had been separated from 254·6 mg of cadmium on a 60-ml column. Smaller columns can be used when smaller amounts of cadmium are present. The separation of other elements is less critical and much smaller columns can be used for separating small amounts of Cu(II), Co(II), Mn(II), Ni, Zn, Fe(III) *etc.* from large amounts of gold.

The method is very well suited for the separation of small or trace amounts of many other elements from large amounts of gold. It is also quite useful for separating small amounts of gold from large amounts of other elements and in this respect compares quite well with a recently published method using DEAE-cellulose for the selective adsorption of gold.[10] The chloride concentration in the DEAE-cellulose method is limited to below 0·05*M*. This restricts the amounts of other elements from which the gold can be separated, because the distribution coefficient of gold is not very high (about 200 in 0·05*M* hydrochloric acid). Only a limited amount of solution therefore can be passed through a 1-g (about 15 ml) column before gold breaks through, and the 100-mg amounts of other elements separated from gold by Kuroda *et al.*[10] are near the maximum which a column of that size can handle. On a 60-ml column of AG50W-X8 resin, 1 g of Cu(II) (Table 3) and many other species can be retained, and a 90-ml column can quantitatively absorb more than 2 g of many ions. About 384 μg of Cu were found with the gold when about 1 g of Cu(II) was separated from 24·4 μg of Au(III), and no copper was found (<0·4 μg) when 1 mmole of copper was separated from 1 mmole of gold. The amount of Cu(II) passing through the column seemed to be much more dependent on the Cu(II) concentration during the adsorption step than on the total amount of Cu(II) present. Furthermore, in the cation-exchange separation the gold passes through the column directly, whereas it has to be eluted in the second step when DEAE-cellulose is used. In the cellulose method Se(IV) and, by a special extra step, also Pd(II), Pt(IV) and Hg(II), which accompany gold in the resin procedure, can be separated. The resin procedure, on the other hand, seems to be useful for the group separation of the precious metals Au, Pt, Pd, Ir and Rh from minerals and rocks, before their combined determination by sensitive methods such as spark-source mass-spectrometry or neutron-activation analysis.

An apparently very selective method for the separation of gold from other elements has been published by Fritz and Millen[11] who used an Amberlyst XAD-7 polyacrylic anion-exchanger. Indium has not been included in their investigation, but will probably also be separated. Unfortunately the quantitative investigations were carried out only on about 0·6-mg amounts of gold, and data on the quantitative analytical behaviour of large or very small amounts of gold were not included. However, in a patent it has been shown that about 100% recovery of gold can be obtained from $2{\cdot}79 \times 10^{-6}M$ solution, with the same resin.[12] The present method is more suitable for the separation of most elements in trace and ultratrace amounts from large amounts of gold. The method is also applicable to the separation of very small amounts of gold (< 1 μg), and is useful over a very wide concentration range of gold and other elements.

TRACE METALS SPECIES IN SEA-WATER—I

REMOVAL OF TRACE METALS FROM SEA-WATER BY A CHELATING RESIN

T. M. FLORENCE and G. E. BATLEY
Australian Atomic Energy Commission Research Establishment, Lucas Heights, N.S.W., Australia

(*Received* 26 *March* 1975. *Accepted* 16 *August* 1975)

Summary—A significant fraction of the copper, lead, cadmium and zinc in sea-water exists in a form which is not retained by a chelating resin (Chelex-100) or extracted by ammonium pyrrolidinedithiocarbamate. Anodic stripping voltammetric results suggest that the major part of the unavailable trace metal is adsorbed on, or occluded in, organic or inorganic colloidal particles. An ionic equilibria computer program was used to predict the effect of various complexing agents on trace metal species in sea-water. Citric acid and amino-acids, with the exception of *l*-cysteine, were shown to be unimportant as complexing agents, and the ability of an EDTA-like ligand to complex Cu, Pb, Cd and Zn is controlled entirely by the concentrations of the ligand and of "labile" Fe(III) and Cr(III) in sea-water, since these two ions together will react quantitatively with EDTA. *l*-Cysteine, if present in sea-water, would also complex the trace metals.

Atomic-absorption spectrophotometry (AAS) is commonly used to determine many trace heavy metals in sea-water.[1] Because of interference by the sodium chloride matrix, and because their concentrations are too low for direct determination, the heavy metals must first be separated and concentrated from the sea-water sample.

Although liquid–liquid extraction of the trace metals by using a chelating agent such as ammonium pyrrolidinedithiocarbamate (APDC) often provides sufficient concentration for the non-flame AAS techniques, solvent extraction is inadequate for the less sensitive flame AAS methods. This is because the degree of extraction decreases as the aqueous-to-organic phase volume ratio is increased, effectively limiting the sample size which can be used, and the concentration factor which can be achieved.[1]

For this reason the application of chelating resins to sea-water analysis has become increasingly popular.[2–8] Chelating resins are simpler to use and less time-consuming than solvent extraction, and allow much higher concentration factors to be attained. In addition, the sample is not contaminated with heavy metal impurities from buffers and organic reagents. Most laboratories appear to use a chelating resin column in the manner originally described by Riley and Taylor,[2] *i.e.*, the sea-water at natural pH (pH 8·1) is passed through a 6 × 1·2 cm column of 50–100 mesh, hydrogen-form Chelex-100 resin. After passage of a sufficient volume of sea-water (1–10 litres), the adsorbed metals are eluted with a suitable solvent, usually 2*M* nitric acid. The nitric acid eluate is then analysed for trace metals directly, or after extraction.[6] Chelating resins have also been used by several workers for the preparation of "stripped" sea-water (*i.e.*, free from heavy metals) for productivity and other studies.[5,8]

Riley and Taylor[2] and later workers[5] checked the quantitative nature of adsorption of heavy metals from sea-water onto Chelex-100 resin, by spiking the sample with ionic radiotracers and measuring the activity of the effluent and eluent. Most metals were found to be quantitatively adsorbed at pH 8. This type of standard addition procedure using either active or inactive ionic tracers is commonly used for checking recoveries during the analysis of natural waters. The procedure, however, is prone to error because the heavy metal in the sample may not exist entirely in the free ionic form, but may be present partly as colloidal and/or complexed forms which will not equilibrate with the added ionic spike during the time of the separation experiment. In this case, measurement of the recovery of the spike will bear no relation to the recovery of the metal originally present in the water sample.

We have studied the retention of copper, lead, cadmium and zinc from sea-water on a column of Chelex-100 chelating resin by analysing the original sea-water and the column effluent for these metals, using direct anodic stripping voltammetry (ASV). Retention of the metals naturally present in sea-water was not quantitative.[9] We also did a few experiments to measure the efficiency of APDC extraction of these metals from sea-water. In addition, a computer study was made of the likely effect of several organic ligands on trace metal species in sea-water.

EXPERIMENTAL

Apparatus

The polarograph–voltammeter, used in conjunction with a Beckman electrode-rotator and a polished glassy-carbon electrode, has been described previously.[10] The hanging mercury-drop electrode assembly was used with a Princeton Applied Research Model 174 voltammeter.[11]

Table 1. Metal impurities in reagents used

Reagent	Impurity, μg/l.			
	Cu	Pb	Cd	Zn
Distilled, demineralized water*	0·18	0·14	0·05	0·36
2*M* Suprapur HNO$_3$	0·18	0·16	0·05	<1·0
2*M* Suprapur sodium acetate	—	—	—	<2·5
10^{-2}*M* G.R. mercuric nitrate	3·2	3·5	0·56	—

* Sample taken from polyethylene storage tank.

All separation experiments and voltammetric measurements were made at 25·0 ± 0·5°. Electrode potentials are referred to the SCE.

Reagents

The chelating resin used was Chelex-100 (Bio-Rad Laboratories), 50–100 mesh, supplied in the sodium form. To convert the resin into the H$^+$-form, a portion was suspended in 2*M* nitric acid, decanted several times to remove fines, then loaded into a 0·8-cm bore glass tube fitted with a Teflon stop-cock. After washing, the height of the column was 10 cm. The resin was washed with 30 ml of 2*M* nitric acid, then with water until the pH of the effluent was above 4·5.

Synthetic sea-water was prepared[12] from reagent-grade salts. The chlorides were first heated to 600° to remove any organic matter. The salts were then individually dissolved in water, mixed, and diluted to volume. The solution was filtered through an acid-washed 0·4-μm Nuclepore filter.

Water supplied from a commercial demineralizer plant was passed through a laboratory demineralizer, then distilled from permanganate and stored in a carefully-cleaned 25-l. polyethylene tank. Merck Suprapur nitric acid and sodium acetate, and general-reagent grade mercuric nitrate were used throughout. Table 1 shows the concentrations of trace metal impurities found in these reagents by direct ASV measurements.

Collection and treatment of sea-water samples

Pacific Ocean surface samples were collected near shore, off Wattamolla, a relatively unpolluted area in the Royal National Park, Sydney. The 15-l. high-density polyethylene sample bottles were initially cleaned by soaking in 2*M* hydrochloric acid for 2 weeks, then rinsed thoroughly with water. The same bottles were used for over 2 years for sea-water samples, and were rinsed with acid and water between samples. Surface sea-water samples were taken about 10 cm below the surface, the bottles being rinsed six times with sea-water before the sample was taken. The samples were filtered within 2 hr of collection, and were usually analysed the same day. The samples were filtered through an acid-washed 0·4-μm Nuclepore membrane filter, the first litre of filtrate being discarded. Filtrates were stored at the natural pH in clean polyethylene or Pyrex bottles which had been soaked overnight in 2*M* hydrochloric acid, then rinsed with water before use. No significant changes were observed in the concentrations of trace metals in samples stored for up to 2 weeks in either Pyrex or polyethylene.

Experimental procedure

Filtered sea-water was loaded into a 5-l. Pyrex reservoir above the chelating resin column. The column tap was adjusted to give a flow-rate of 1·5 ml/min, the first 25 ml of effluent being discarded. The flow-rate was varied between 0·5 and 3·0 ml/min, and in this range was found to have no effect on the retention of the trace metals. New resin was used for each experiment.

Labile* Cu, Pb and Cd were determined in the effluent by adding 0·1 ml of 2*M* nitric acid and 0·1 ml of 0·01*M* mercuric nitrate per 25 ml of sea-water (*i.e.*, bringing the pH to 2·2). Deposition at the glassy-carbon electrode, rotated at 2000 rpm, was carried out at −0·9 V, and the d.c. stripping ramp was applied at 5 V/min up to a potential of −0·15 V. A preliminary 5-min deposition was made, and after stripping, a 10-min deposition was used for quantitative measurements. The Cu, Pb and Cd peaks occurred at −0·31, −0·49 and −0·70 V, respectively. The peak heights were found to be unchanged if the acidified sea-water sample was allowed to stand at 25° for up to 3 hr before measurement.

Total Cu, Pb and Cd were measured after adding 2·00 ml of 2*M* nitric acid to 25 ml of effluent (pH 0·7) and boiling gently in a covered beaker for 10–15 min. We found, in agreement with other workers,[13] that this procedure liberated all the trace metals in a sea-water sample. No increase in trace metal content was found when 25 ml of sea-water were taken almost to dryness with 2 ml of 15*M* nitric acid, or with a mixture of nitric and perchloric acids.

Slightly different procedures were used for the determination of zinc at the hanging mercury-drop electrode. For labile zinc, 0·1 ml of 2*M* sodium acetate and 0·05 ml of 2*M* nitric acid were added per 25 ml of sea-water (*i.e.*, bringing the pH to 5). Deposition was carried out at −1·2 V for 5 min, and a differential pulse scan (10-mV pulse modulation) was made at 2 mV/sec. The zinc peak occurred at −1·0 V. Total zinc was measured after adding 2·00 ml of 2*M* nitric acid to 25 ml of sea-water, boiling for 10–15 min, cooling, then pipetting a 10-ml portion into a 25-ml flask, adding 1·0 ml of 2*M* sodium acetate, and diluting to volume. Corrections were made for the evaporation during boiling, measured by weighing the beaker and contents before and after the boiling.

RESULTS

Chelating resin and solvent extraction studies

The effect of pH on the determination of "free" Cu, Pb and Cd in sea-water is shown in Fig. 1. A similar study using synthetic sea-water yielded curves of almost identical shape. A pH of 2·2 was chosen

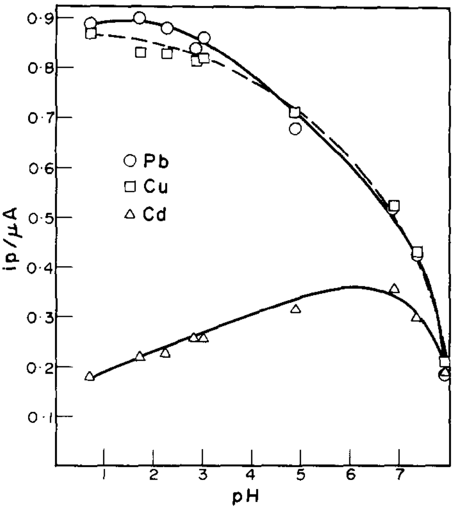

Fig. 1. Effect of pH on the sensitivity of the anodic stripping waves of Cd, Pb and Cu in sea-water. Sea-water contained (labile metal, μg/l.): Cd—0·15, Pb—0·45, Cu—0·46.

---

* By "labile" we mean an easily dissociated complex species.

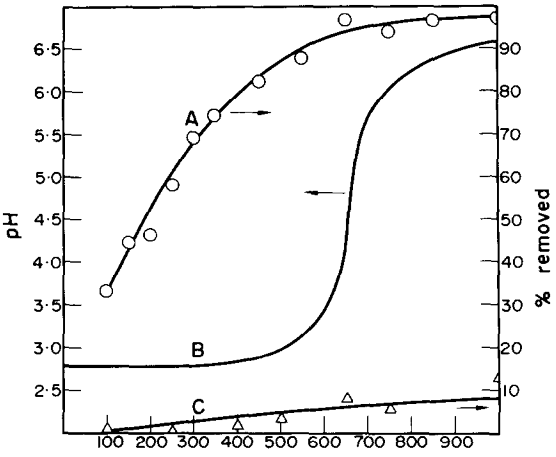

Fig. 2. Effect of volume of sea-water passed through column of Chelex-100 chelating resin (H^+-form) on pH of effluent and removal of zinc. *A*, removal of labile zinc; *B*, pH of effluent; *C*, removal of bound zinc.

for the determination of free metals, because at this pH all three metals give waves of reasonable sensitivity. Since the peak heights vary considerably with pH, both in natural and in organic-free synthetic sea-water, care should obviously be taken in ascribing such changes in sensitivity with pH to the presence of natural chelating agents in sea-water.

The pH of the effluent from a 10 × 0·8 cm column of Chelex-100 (H^+-form) was followed as a function of the volume of sea-water passed through the column. The results are shown in Fig. 2. The hydrogen form of Chelex-100 is gradually neutralized by the metals present in sea-water, and the plot of pH *vs.* volume of effluent had the shape of a typical acid–base titration curve, with the effluent pH finally rising to 7·4 after 4 litres of sea-water had been passed.

The effect of pH on the adsorption of trace metals by Chelex-100 has been studied by several workers.[7,14,15] To obtain greater than 98% retention of Cu, Pb, Cd and Zn, resin pH values higher than 1·7, 2·5, 2·9 and 2·5, respectively, are required. Retention of these metals increases with increasing pH until a constant distribution ratio is reached near pH 6.[7,14] We found that when a sample of sea-water was spiked with ionic Cu(II), Pb(II), Cd(II) and Zn(II), then passed through a column of Chelex-100 (H^+-form), the removal of the spikes from the first 100 ml of effluent (pH 2·8), was 99·7, 99·4, 80·0 and 97·3%, respectively. However, after passage of 1 litre of effluent, when the pH had risen to 6·6, the retention was greater than 99·5% for all four metals. If the Chelex-100 column was first buffered by treatment with 25 ml of 2*M* sodium acetate, then washed with water before passage of the sea-water sample, the initial effluent had a pH of 7·1. Under these conditions retention of Pb, Cd and Zn spikes in the first 100 ml of effluent increased to greater than 99·5%, but copper retention fell to 97·2%.

Figure 2 and Tables 2 and 3 show some of the results obtained for labile and bound (*i.e.*, total minus labile) metal in surface sea-water samples, and for the removal of these metals by Chelex-100. With the exception of copper, bound metals were very poorly extracted by the chelating resin, even at high pH. Labile zinc and copper were almost quantitatively retained after the passage of 1 litre of sample, but labile lead and cadmium were less efficiently removed. On the other hand, when synthetic sea-water was passed through a column of H^+-form Chelex-100, the metal impurities were removed to the same extent as ionic spikes. In the case of synthetic sea-water, values for labile and total metal are almost identical.

It was found possible to convert the trace metals in sea-water into a form which was retained on Chelex-100 by heating the sample after adjustment to pH 0·7, using the method described for determination of total metal. After cooling, the pH was adjusted to 8·1 with sodium hydroxide and the water passed through the column. However, the reagent-grade sodium hydroxide introduced such a high concentration of impurities that the blank value was higher than the natural heavy metal concentration.

The effect of irradiating a sample of sea-water with ultraviolet light before passing it through the resin column was also investigated. One litre of sea-water was treated with 1 ml of 30% hydrogen peroxide and irradiated in a narrow tube with a 35-W U-tube immersion ultraviolet lamp for 5 hr, with magnetic stirring. The temperature of the water rose to 60°, but the pH was found to be unchanged. Ultraviolet irradiation decreased the difference between the labile

† Samples were collected from the column and analysed after passage of the stated volume of effluent.

‡ Bound metal = total metal − labile metal.

and total metal measurements, and improved the retention of cadmium and copper, but not of lead. Spectrophotometric examination of the irradiated water[16] could not detect any residual dissolved organic carbon compounds.

Some limited work was also carried out on the ability of a commonly-used solvent extraction technique[1] to measure Cu, Pb, Cd and Zn in sea-water. Portions of filtered sea-water (200 ml) were adjusted to pH 4·5 with hydrochloric acid after addition of 1·5 ml of 1% APDC (recrystallized) solution. The mixture was then shaken for 3 min with 10 ml of methyl isobutyl ketone (MIBK). After the phases had separated, 50 ml of the aqueous phase were treated with 5 ml of 2*M* nitric acid, and boiled to reduce the volume to 25 ml. After cooling, the solution was then analysed for Cu, Pb, Cd and Zn by ASV. At the thin-film electrode the cadmium wave suffered some interference from residual organic matter in these solutions.

Analysis of the aqueous phase by ASV showed that copper naturally present in sea-water was extracted completely by APDC at pH 4·5 from all sea-water samples studied. Extraction of lead varied between 35 and 65%, and was highest when the sea-water had a high labile:total lead ratio. Zinc extraction ranged from 23 to 59% of total zinc. If the sea-water was adjusted to pH 0·7, then heated, cooled, and sodium acetate added to adjust the pH to 4·5 before extraction, complete extraction of all three metals was achieved.

Suitable radioisotopes of Cu, Pb, Cd and Zn were used to spike sea-water samples and measure the degree of extraction of *ionic* metal by APDC in the pH range 3·5–8·1. Copper and lead gave 100% extraction in this range, zinc gave 98%, while cadmium showed 100% extraction between pH 8·1 and 4·5, but only 80% at pH 3·5.

Metal species studies

The use of individual metal-ion stability constants, or pairs of constants, to calculate the equilibrium concentration of a particular species is not valid in such a complex mixture as sea-water. The correct equilibrium concentration can be computed only by simultaneously taking into account all of the possible competing equilibria. This task is too laborious to be attempted by manual calculation. The ionic equilibria program COMICS[17] was corrected, modified, and improved by Sylva,[18] and used to calculate equilibrium concentrations of ions in a model sea-water. A further improvement of the program[19] enabled the data to be presented both as final equilibrium concentrations of each species, and the per cent distribution of a particular metal between various species.

For all calculations, the following total ligand and metal concentrations (*M*) were held constant: Cl^- 0·548; SO_4^{2-} $2{\cdot}82 \times 10^{-2}$; CO_3^{2-} $2{\cdot}40 \times 10^{-3}$; citrate $5{\cdot}00 \times 10^{-7}$; glycine $3{\cdot}00 \times 10^{-7}$; Cd^{2+} $1{\cdot}00 \times 10^{-9}$; Cu^{2+} $1{\cdot}50 \times 10^{-8}$; Pb^{2+} $1{\cdot}00 \times 10^{-9}$; Zn^{2+} $3{\cdot}00 \times 10^{-8}$; Ca^{2+} $1{\cdot}00 \times 10^{-2}$; Mg^{2+} $5{\cdot}40 \times 10^{-2}$. In addition, varying concentrations of *l*-cysteine, EDTA, iron and chromium were used in the calculations. The final pH was varied between 0·7 and 8·1. Glycine was used to represent (with the exception of *l*-cysteine) the free amino-acid group. This was considered valid because glycine is the predominant free dissolved amino-acid in sea-water,[20] and in any case, there is little variation in the stability of the complexes formed by most of the common amino-acids with a particular metal.[21,22] Other organic compounds identified in sea-water, such as fatty acids, sugars and phenols,[23] generally form weaker complexes with metals than do the amino-acids and citric acid, so they were not included in the model. EDTA was used to simulate a particularly powerful chelating agent (*e.g.*, humic acid). Stability constants were selected from Sillén's compilations,[21,22] and were corrected for ionic strength by using published activity coefficients.[24]

Some of the results obtained from these calculations are shown in Tables 4–7. In the absence of EDTA and *l*-cysteine (Table 4) the distribution of the Cu, Pb, Cd and Zn species is similar to that calculated by Zirino and Yamamoto.[24]

The effects of EDTA, NTA, and a synthetic organic mixture on the anodic stripping behavior of Cu, Pb, Cd and Zn in sea-water, and on the extraction of copper and zinc from sea-water by APDC, were investigated. A synthetic organic mixture was prepared, containing (in mg/l.); citric acid (250), malic acid (250), palmitic acid (250), *p*-hydroxybenzoic acid (2), glycine (150), humic acid (10), aspartic acid (50), leucine (50), and *l*-cysteine (10). Two ml of this mixture added to 200 ml of sea-water had no effect on the extraction of Cu and Zn spikes. Also, EDTA and NTA at the 125 μg/l. level did not decrease the extraction of Cu and Zn, but with EDTA at the 1·25 mg/l. level, only 35% of the zinc spike was extracted, although copper extraction was still unaffected. If distilled water was substituted for sea-water, similar results were obtained; the extraction of copper was not decreased, even by the higher concentration of EDTA, but only small amounts of zinc were extracted at the higher level of EDTA.

Addition of the organic mixture to both natural and synthetic sea-water (0·2 ml per 200 ml of water) had no effect on the Cu, Pb, Cd or Zn anodic stripping waves at either pH 6·0 or 4·6. At pH 4·6, aspartic acid at concentrations as high as $4 \times 10^{-6}M$ did not affect any of the metal waves. At pH 6·0, $2 \times 10^{-7}M$ EDTA did not diminish or shift the metal stripping waves, but at pH 4·6 the waves, particularly those of lead, were diminished by EDTA concentrations higher than $1 \times 10^{-8}M$.

DISCUSSION

It is apparent that Chelex-100 chelating resin cannot be used in the manner described by Riley and Taylor[2] for the quantitative concentration of Cu, Pb,

§ Elution of the resin column with 2*M* HNO_3 after passage of 1 litre of sea-water gave the following apparent original metal contents (µg/l.): Cu—0·25, Pb—0·46, Cd—0·07.

¶ Sea-water adjusted to pH 1·8 (2 ml of 10*M* HC*l* per litre of sea-water) before passage through column.

Cd and Zn from sea-water. In a footnote to a later paper,[3] these authors mentioned that they had observed some initial leakage of zinc from a Chelex-100 column. They stated that the loss was equivalent to 3–4% of the zinc contained in the first litre of sea-water which passed through the column. We have found much greater losses, however. For example, from Fig. 2 it was calculated that the loss of labile zinc in the first litre was 25%, and the loss of bound zinc was 95%. This amounts to a 63% loss of total zinc in the first litre of sample. Conversion of the resin into the sodium or ammonium form improves the retention of labile metal, but has little effect on bound metal (Table 3). Because copper forms the strongest complex with Chelex-100,[15] it is removed from sea-water more efficiently than the other metals. However, at effluent pH values above 7, we found, in agreement with Holynska,[7] that the retention of copper decreases. Muzzarelli and Rocchetti[25] reported that Dowex A1 chelating resin removes only a small fraction of the total copper present in sea-water. Cadmium forms especially strong chloro-complexes,[21] and in saline waters its distribution ratio with Chelex-100 would be expected to be lower than in non-chloride media.[14]

Liquid–liquid extraction of sea-water with APDC–MIBK gave results similar to those obtained with the chelating resin, although removal of trace metals was generally more efficient by solvent extraction. Copper was extracted readily, but a preliminary acid treatment of the sample was necessary to attain complete extraction of lead and zinc with APDC.

Chelex-100 in the H^+-form removed trace metals from synthetic sea-water with an efficiency equal to the removal of ionic spikes, and there was very little difference between the ASV values for labile and total metal in synthetic sea-water. The entirely different behavior of natural sea-water shows that it contains a large fraction of the trace metals in a form which is not available to the resin. Even the "labile" metal in natural sea-water is not completely removed by the resin, indicating that the ASV method used to determine labile metal includes in the measurement some of the metal which will not react with the resin. Probably, at the low pH (pH 2·2) used for the determination of labile metal, some of the metal contained

in colloidal particles which pass through the column will dissolve, and contribute to the value for labile metal (Table 3). Use of a Chelex-100 column in the Na^+-form appears to be a promising method for separating the ionic and colloidal forms of trace heavy metals in sea-water.

The exact nature of the form in which "soluble" trace metals exist in sea-water has been the subject of many studies and discussions.[26–33] It seems reasonable to assume that the soluble "bound" metal is present either as organic chelates or adsorbed on or occluded in organic or inorganic particles. Irradiation of a sea-water sample with ultraviolet light decreased, but did not eliminate, the difference between labile and total metal, which suggests that not all the bound metal is combined with a simple organic ligand.

If the bound metal were present as a simple metal chelate, the ligand would need to be very powerful to compete with the iminoacetate groups in Chelex-100, which form very strong complexes with heavy metal ions.[15] Alternatively, the complex could be inert, and not dissociate in the time of the separation experiment. Lowman and Ting[32] found that they could free the cobalt–vitamin B-12 complex (cobalamin) from Co^{2+} impurity by passing a solution of the mixture through a column of Chelex-100. The Co^{2+} was adsorbed, while the cobalamin passed into the effluent.

Colloidal particles are not retained by most ion-exchange resins because the resin pore size (about 30 Å) is too small to allow the colloids to enter the resin network.[34] Cation-exchange resins have been used in this manner to remove ionic impurities from colloidal zirconia and other sols.[34] Organic or inorganic colloidal particles in sea-water would therefore be expected to pass through a column of Chelex-100, carrying with them adsorbed trace metals. On heating in a strongly acid solution they would dissolve, or at least release the trace metal, and so give rise to the analytical figure for "bound" metal. Breger[35] has presented persuasive arguments that most of the "dissolved" organic matter in natural waters exists as colloidal particles. He believes that the study of the properties of high molecular weight compounds in natural waters has been neglected because these compounds are so difficult to characterize. Slowey and Hood[26] found that in the Gulf of Mexico an average of 43% of the zinc and 8% of the copper was in a non-dialysable form. Solubility of organic colloidal particles in MIBK could explain why we found that solvent extraction was more efficient than Chelex-100 in removing trace metals from sea-water.

model sea-water provided some interesting results (Tables 4–7), which should, however, be interpreted with some caution because of the limitations of this approach. Perhaps the most serious problem is the choice of the correct values for the relevant stability constants. Published values for any metal complex stability constant usually cover a wide range,[21,22] and this is particularly so in the case of the chloro-complexes. Because of the high concentration of chloride in sea-water, the chloride stability constants have a profound effect on the calculated distribution of species. Other problems are the lack of information on the existence or stability of polymerized species, on the lability of the complexes, and on the presence of unidentified chelating agents. With these reservations in mind, the following conclusions can be drawn from Tables 4–7. (*a*) At pH 2·2, the pH used for the determination of labile metal, Cu, Pb, Cd and Zn exist entirely as free metal ion, or as chloro- and sulphato-complexes, even in the presence of EDTA and *l*-cysteine. (*b*) At the natural pH of sea-water (pH 8·1), and in the absence of EDTA and *l*-cysteine, zinc and copper exist principally as the dihydroxy complexes, lead as the carbonato-complex, and cadmium as chloro-complexes. (*c*) Citrate and amino-acids (except *l*-cysteine) do not complex any significant amounts of metals over the range pH 0·7–8·1. Siegel[27] quoted ASV results which showed that aspartic acid added to sea-water diminished the stripping peak of copper. In agreement with Duursma[28] and with the results calculated from our computer model, we found that $4 \times 10^{-6}M$ aspartic acid had no effect on the stripping waves of Cu, Pb, Cd and Zn. (*d*) Even in the presence of a high concentration of EDTA ($2 \times 10^{-7}M$), no significant reaction occurs between EDTA and calcium and magnesium over the pH range studied. (*e*) EDTA has maximum complexing effect near pH 4·5.[36] (*f*) The concentrations of iron(III) and chromium(III) completely dictate the behaviour of EDTA in sea-water, since these two ions together react quantitatively with EDTA over the pH range 2·2–8·1, and the other heavy trace metals will form EDTA complexes only after ionic Fe and Cr have reacted completely.

The possibility that iron and chromium control the complexing behavior of powerful EDTA-like ligands in sea-water was originally proposed by Duursma.[28] Siegel[27] criticized the choice of EDTA to simulate a strong chelating agent, on the basis that EDTA shows an unusual preference for Fe(III). Although Siegel's arguments were not entirely convincing (he used an incorrect value for the Fe(III)–NTA stability constant[22]), it is true that certain ligands (*e.g.*, *l*-cysteine) can, at the natural pH of sea-water, react with other metals in the presence of an excess of Fe(III) (Table 7).

The difficulty in predicting the behavior of Fe(III) and Cr(III) in sea-water is that the "labile" concentrations of these ions are not known. The total concentration of soluble iron is about 5μg/l., and of chromium(III) is 0·5 μg/l.[37] However, much of this iron and chromium may exist as polymerized or other species which will not react with the added ligand. Florence[38] reported that only 10% of the total iron in tap-water would chemically exchange with the Bi–EDTA complex, while Benes and Steinnes[39] found that only 19% of the iron, and 49% of the chromium in river water was dialysable.

Fulvic and humic acids have often been suggested as the compounds in sea-water which react most powerfully with trace heavy metals.[31] However, the small amount of quantitative data so far published[31,40] suggests that fulvic acid forms weaker complexes with the transition metals than does EDTA.[36]

The stability constants of the *l*-cysteine complexes of Cu, Pb, Cd and Zn are particularly large,[22] and any significant concentration of this amino-acid in sea-water will have an important bearing on the complexing of zinc and other trace metals, since it will compete even with EDTA (Table 7). Siegel and Degens[20] and Degens *et al.*[23] could not detect any free *l*-cysteine in sea-water, and their results suggest that its concentration is less than 0·5 μg/l. ($4 \times 10^{-9}M$).

Acknowledgements—We are indebted to J. J. Fardy for a great deal of assistance with the computer programming, and to Mrs. L. Janov for help with the experiments. We are also grateful to G. Major of CSIRO Division of Fisheries and Oceanography for collecting the 10-mile sea-water sample.

APPLICATION OF A SIMPLE PHOTOIONIZATION DETECTOR FOR NON-DISPERSIVE ATOMIC SPECTROMETRY IN THE VACUUM ULTRAVIOLET REGION

M. J. ADAMS, G. F. KIRKBRIGHT and R. M. TAYLOR
Chemistry Department, Imperial College, London, S.W.7, England

(*Received* 29 *May* 1975. *Accepted* 8 *July* 1975)

Summary—The construction and operation of a simple, solar-blind photoionization detector which responds to incident radiation between 125 and 140 nm is described. The detector, the response characteristics of which are controlled by the ionization potential of the ethylamine filler gas and the calcium fluoride window employed, is shown to provide for efficient detection of atomic line emission from carbon, oxygen and chlorine in this wavelength region. The spectral sources employed for non-dispersive work with this detector are a microwave-excited argon plasma and a demountable hollow-cathode lamp.

Because of the numerous problems associated with the production and detection of radiation at wavelengths shorter than 200 nm this region has been somewhat neglected for the purposes of routine analytical atomic spectrometry. The atoms of many elements, including the halogens, carbon, sulphur, oxygen, nitrogen, phosphorus and mercury, emit intense resonance-line radiation in this region. A simple, non-dispersive system for detecting the atomic-line emission of these elements would be attractive for their detection and determination by the techniques of atomic emission, absorption and fluorescence spectrometry. Conventional spectrometry in the "vacuum ultraviolet" region is usually undertaken with large vacuum spectrometers and photomultiplier detectors. By analogy with the advantages of non-dispersive detection systems rather than grating or prism/monochromator systems in analytical atomic spectroscopy in the near ultraviolet and visible regions of the spectrum, use of a non-dispersive detection system in the vacuum ultraviolet might be expected to yield advantages of simplicity, large aperture and suitability for operation in simultaneous multi-element analysis. The photoionization detector (PID) appears to offer such possibilities. A typical PID consists of a chamber containing a gas at low pressure and two electrodes across which a constant d.c. voltage is applied. When the chamber is irradiated by photons having sufficient energy to cause ionization of the gas, an ionization current is produced and may be registered in the external circuit. The magnitude of the current is proportional to the incident ionizing photon flux. The spectral response of a PID is controlled on the short wavelength (high energy) side by the transmission characteristics of the material from which the window is made and on the long wavelength side by the photoionization threshold of the filler gas. The construction and use of PID systems for physical research has been documented; detectors based on this principle have found application in the examination of the solar spectrum.[1,2] By careful selection of the window material and the filler gas, detectors with a spectral bandpass of only a few nm may be constructed, which will detect radiation in the range 105–200 nm. In addition to high spectral selectivity, detectors of this type have high quantum efficiencies, low noise levels and the capability of serving as gas-gain multipliers. They may also be made to have large optical aperture, are "solar-blind" and may be rugged and compact. This paper describes the construction and evaluation of a simple PID system designed for non-dispersive work in the spectral range 125–140 nm, and its use for the detection of such radiation from a microwave-excited argon plasma at atmospheric pressure or from a flow-through demountable hollow-cathode lamp source.

EXPERIMENTAL

Apparatus

Photoionization detector. The PID assembly used in this work is shown in Fig. 1. A Pyrex cylinder (90 mm in length, 29 mm diameter, 2 mm wall-thickness) fitted with a B14/23 ground-glass cone and socket at one end and a side-arm fitted with a three-way 2-mm bore tap was employed as the detector envelope. The electrode assembly, mounted onto glass-to-metal sealing rods through the ground-glass cone, consisted of a cylindrical sheet copper cathode (80 mm in length, 25 mm internal diameter, 0·19 mm thickness) along the central axis of which a 1-mm tungsten wire anode was located. The electrodes were insulated from each other by means of the glass and PTFE anode supports shown in Fig. 1. A polished calcium fluoride window (3 mm thickness, 25 mm diameter) was mounted in a cylindrical aluminium holder sealed with epoxy resin cement onto the end of the PID envelope. The aluminium window holder had an external annular depression in which an O-ring was positioned to permit vacuum sealing of the detector at the exit slit of the vacuum monochromator employed in some of the work. All components of the PID were carefully cleaned and degreased before assembly. The ground-glass joints were sealed with high-melting wax.

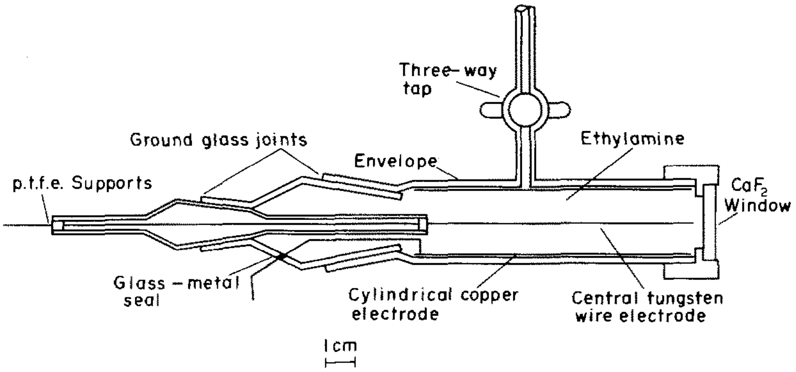

Fig. 1. Photoionization detector assembly.

A d.c. voltage (5–400 V) was provided across the detector from a dry battery supply. The photoionization current was registered on a picoammeter (P24, Knick, Berlin, Germany) and the voltage output from this device was displayed on a potentiometric chart recorder (Servoscribe Model RE 511).

Microwave plasma source. A microwave-excited argon plasma supported at atmospheric pressure in a fused silica tube (150 mm length, 2 mm i.d.) with a 1/4-wave resonant cavity, was employed. Power (*ca.* 50 W) was supplied at 2450 MHz from a 200-W microwave power supply (Microtron Mk III, EMS Ltd.). The argon flow-rate was variable between 0·5 and 1·0 l./min and the plasma discharge was viewed "end-on" along the central axis of the silica tube.

Demountable hollow-cathode lamp source. A commercial demountable hollow-cathode lamp source (Miniglow, Spectro Products Inc., North Haven, Conn., U.S.A.) was employed. The source was capable of operation at d.c. currents of between 5 and 50 mA and argon pressures between 2 and 10 mmHg. The lamp assembly was capable of accepting a variety of cathodes. The cathode shells used in this work were aluminium (22 mm length, 4 mm internal diameter, 1 mm wall thickness) into which the material to be examined was pressed. The cathode assembly was water-cooled. The silica window of the demountable hollow-cathode source was replaced by a calcium fluoride window (3 mm thickness) for the present studies.

Auxiliary equipment. The spectral emission characteristics of the source employed, and the spectral response characteristics of the PID, were established by using a 1-m normal-incidence vacuum grating monochromator (Model E760, Rank Hilger Ltd.). This was equipped with an end-window photomultiplier tube (EMI 625B) the silica window of which had been coated with sodium salicylate (1–1·5 mg/cm^2).

RESULTS AND DISCUSSION

For preliminary evaluation a PID was constructed to operate in the spectral range 120–140 nm, choice of this wavelength region being governed by the availability of suitable window materials and of filler materials having suitable ionization potential and vapour pressure to enable the PID to operate efficiently at room temperature. In addition, a number of useful atomic lines from carbon, oxygen, chlorine, bromine and sulphur lie in this wavelength range and were thus available for assessment of the response characteristics of the PID. The vapour of ethylamine, which has an ionization potential of 8·8 eV (141·0 nm) was employed as the filler material. The photoionization efficiency curve for ethylamine is shown in Fig. 2.[3] The short-wavelength response was controlled by the window material. In most of the work reported here a 3-mm calcium fluoride window was used. The transmission characteristics of this window are also shown in Fig. 2. The spectral response of the PID can be predicted to be between 120 and 140 nm.

A simple vacuum and purging system was constructed to permit the filling of the PID (Fig. 3.). Anhydrous ethylamine (10 ml), b.p. 16·6°, was placed in the pear-shaped flask and frozen by immersion of the flask in liquid nitrogen. The system was then evacuated with a two-stage rotary pump and flushed out several times with argon. After evacuation of the complete system tap A was closed to isolate the flask containing the ethylamine. The flask was then removed from the liquid nitrogen and allowed to warm to produce a steady increase in ethylamine vapour pressure. By first closing tap B and then opening tap A the system was flushed out several times with ethylamine vapour, followed each time by re-evacuation to a pressure of *ca.* 3 mmHg. Tap B was then finally closed and a preselected pressure of ethylamine vapour admitted to the system *via* tap A. With taps A and B both closed, the detector was sealed by closing tap C and removed from the system for use. Even with the simple PID system constructed for this study, the PID envelope would maintain a pressure as low as 1 mmHg for periods of over 8 hr and was simply and rapidly refilled when necessary.

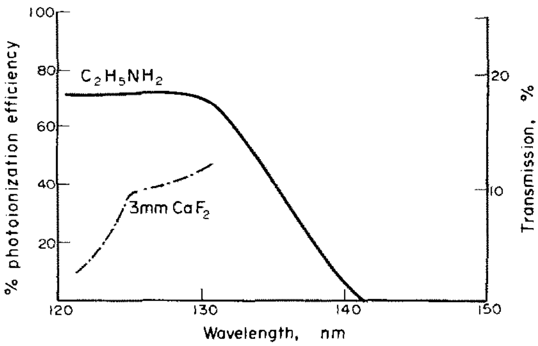

Fig. 2. Photoionization efficiency curve for ethylamine[3] and transmission characteristics of calcium fluoride window.

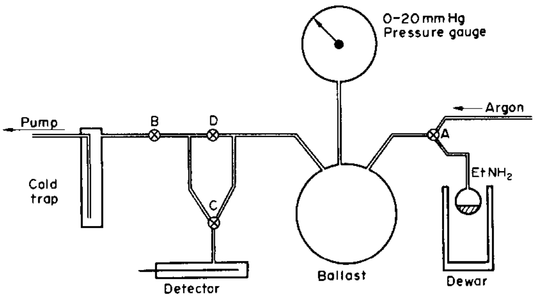

Fig. 3. Evacuation and purging system employed for filling PID detector.

Spectral response characteristics of the PID

The spectral response characteristics of the ethylamine PID were studied with both sources available, *i.e.*, a microwave-excited argon plasma and the demountable hollow-cathode lamp system. The background emission spectrum from the argon plasma in the wavelength range of interest was first examined with the vacuum monochromator and photomultiplier assembly. Figure 4 shows a typical spectrum obtained. The principal features of the emission spectrum may be identified as lines originating from impurities in the argon or from the walls of the silica plasma tubing, *i.e.*, lines of carbon and oxygen from carbon dioxide, hydrocarbons and water vapour. Emission spectra were then obtained from the plasma when small quantities of other vapours were introduced into the argon supply. Figure 5 shows the spectra obtained in the presence of carbon tetrachloride, sulphur dioxide and iodine. Though SO_2 and I_2 gave no emission in the wavelength range of interest, the emission spectra of the argon plasma alone or containing CCl_4 provided useful line emissions from carbon, oxygen and chlorine suitable for evaluation of the spectral response characteristics of the PID.

The PID was filled with ethylamine vapour at 2 mmHg and positioned at the exit slit of the vacuum monochromator; the window of the ionization chamber formed the vacuum seal with the monochromator. The argon plasma, operated at 65 W and an argon flow of 1 l./min, was viewed by the monochromator using a spectral half-band pass of 1·6 nm. The emission spectrum of the argon plasma was recorded with the PID operated at 85 V. The spectrum obtained is shown in Fig. 6, which also shows

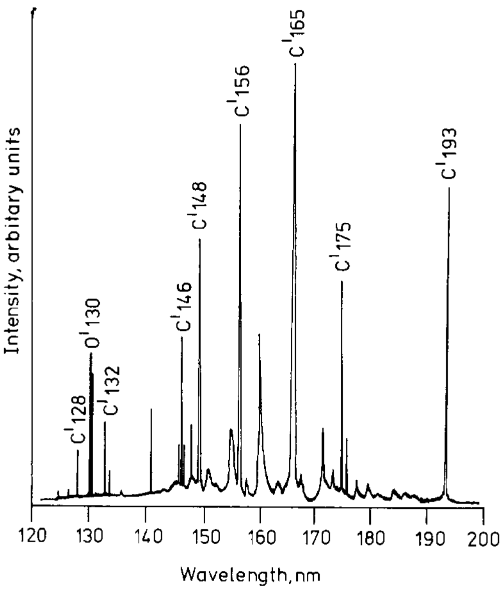

Fig. 4. Emission spectrum from microwave-excited atmospheric argon plasma between 120 and 200 nm. Microwave power, 65 W; E.M.I. 6256B photomultiplier at 1600 V, coated with sodium salicylate.

the spectrum of the argon plasma obtained by using the vacuum monochromator at the same spectral band-pass (1·6 nm) but with the photomultiplier detector. It is clear that the PID responds only to radiation in the wavelength range predicted. Whereas the carbon and oxygen line emissions in the region 128–132 nm are observed, the more intense longer-wavelength carbon lines between 140 and 193 nm are not detected.

As a further test of the response characteristics of the ethylamine PID the demountable hollow-cathode lamp source with argon filler gas and an aluminium cathode containing a mixture of tungsten and mercuric chloride was employed. The spectrum from this source in the range 130–200 nm (obtained with the vacuum monochromator and photomultiplier detector) consists principally of atomic line emission from chlorine, oxygen, carbon and mercury, as shown in Fig. 7*a*. This spectrum was obtained with an argon-purged optical path (3 cm) between the source and the monochromator entrance slit. The experiment was then repeated with this 3-cm path-length purged with argon containing 1% methane. As methane absorbs strongly at wavelengths shorter than 140 nm the emission intensity from the source at short wavelengths is attenuated. The spectrum obtained under these conditions is shown in Fig. 7*b* and clearly demonstrates the absorption of the oxygen and chlorine atomic line emission between 130 and 140 nm and the unaffected intensities at longer wavelengths. These experiments were repeated with the PID in the non-dispersive mode, *i.e.*, with the radiation from the demountable hollow-cathode lamp source falling directly on to the detector *via* the 3-cm purged path without use of the vacuum monochromator. The re-

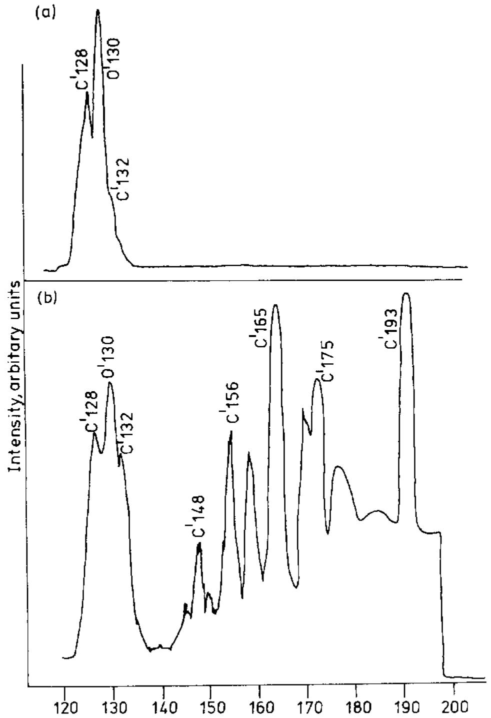

Fig. 6. Emission spectra from microwave-excited argon plasma, obtained by using vacuum monochromator (1·6 nm-bandpass) and (*a*) PID detector operated at 85 V, 2 mm Hg pressure of ethylamine. (*b*) E.M.I. 6256B photomultiplier at 700 V; coated with sodium salicylate.

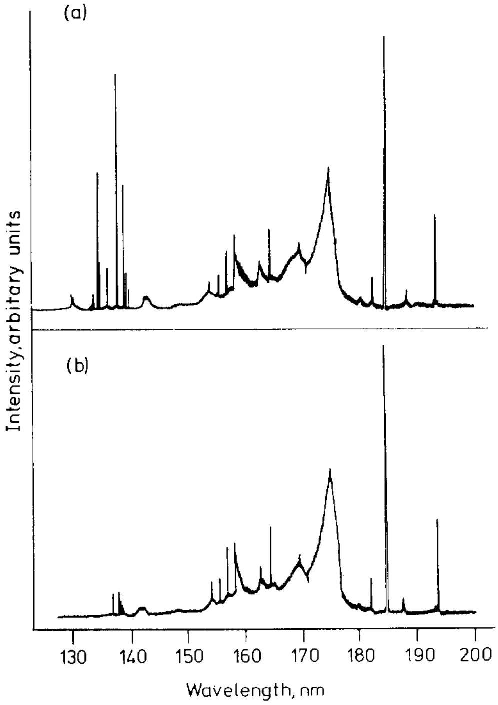

Fig. 7. Emission spectra from demountable hollow-cathode lamp source. Argon filler gas, $HgCl_2$/W cathode. (*a*) Optical path (3 cm) purged with argon. (*b*) Optical path (3 cm) purged with 1% CH_4 in argon.

sponse in the presence and absence of 1% methane in the argon purge-gas is shown in Fig. 8. The decrease in the presence of methane correlates well with that between 130 and 140 nm shown in Fig. 7. It is thus apparent that it is the incident radiation below 140 nm to which the PID responds.

Effect of ethylamine vapour pressure and applied voltage on response of PID

The radiation from the demountable hollow-cathode source with an aluminium cathode containing a mixture of tungsten powder and solid mercuric chloride was allowed to fall directly onto the PID in the non-dispersive mode. The effect of ethylamine pressure and the applied voltage on the response of the detector was examined. The current–voltage curves obtained are shown in Fig. 9.

For the detector geometry employed, in which a thin wire central electrode is located along the central axis of the large cylindrical electrode, the electric field E in the coaxial system at a distance r from the centre of the central wire electrode is given by

$$E = \frac{V}{r \ln [a/b]}$$

where V is the applied voltage and a and b are the radii of the cylindrical and central wire electrodes, respectively. In the applied voltage range between A and B (Fig. 9) for a given photon flux entering the detector the ions formed by the reaction.

$$C_2H_5NH_2 + h\nu \rightarrow C_2H_5NH_2^+ + e^-$$

are collected with increasing efficiency as the field strength in the chamber increases with increasing voltage. Further increase in applied voltage, in the range from B to C, can then not result in further collection efficiency for the given geometry and cell dimensions, and a "plateau region" of relatively constant output current is obtained. At higher applied voltages, as in the region of C and above in Fig. 9, the electrons produced by the initial photoionization of the ethylamine may achieve sufficient energy in the stronger field to cause secondary ionization on collision with ethylamine molecules, *i.e.*, the energy of a fraction of the photoelectrons becomes greater than the ionization potential of the filler material. As the applied voltage is increased the increasing field strength thus leads to increasing electron multiplication by secondary ionization and a consequent rapid increase in the current produced in the external circuit. This region is often referred to as the "gas-gain" region and can be employed to increase the sensitivity of the detector system. The effect shown in Fig. 9, where the PID current is inversely proportional to

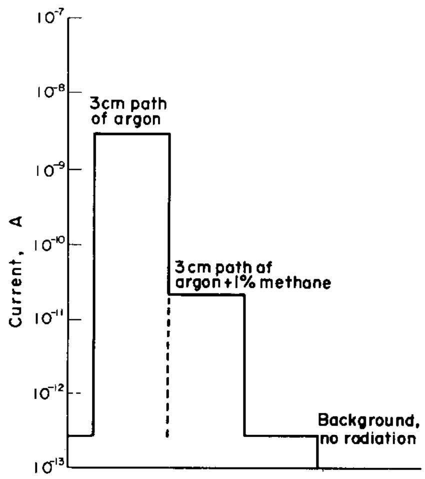

Fig. 8. PID currents observed in presence and absence of methane in optical path between hollow-cathode lamp ($HgCl_2$/W cathode) and detector.

Table 1. A selection of narrow bandpass PID systems in the wavelength range 105–184 nm

Window material	Approx. thickness, *mm*	Filler gas	I.P., *eV*	(Ref.)	Spectral range of PID, *nm*
Lithium fluoride	1	ethyl bromide	10·29	(2)	105–129
		nitric oxide	9·25	(2)	105–134
Calcium fluoride	3	benzene	9·25	(2,4)	122–134
		toluene	8·82	(2,4)	122–141
Sapphire	0·5	*p*-xylene	8·44	(2)	142–147
		trimethylamine	7·82	(5)	142–156
Fused quartz	1	dimethylaniline	7·14	(5)	160–172
		triphenylamine	6·89	(5)	160–180
		ferrocene	6·74	(5)	160–184

the pressure of ethylamine present over the range studied, can be explained on the basis of the mean free path of the photoelectrons. Thus, as the ethylamine pressure is increased, the mean free path of the electrons decreases so that there is insufficient time to permit their acceleration to energies sufficient to cause secondary ionization on collision with ethylamine molecules. This effectively delays the onset of the "gas-gain" region to higher applied voltages. The limiting case shown in Fig. 9 corresponds to the addition of helium as an inert filler gas at atmospheric pressure in the presence of 5 mmHg of ethylamine. Under these conditions the plateau region extends to above 300 V without significant secondary ionization.

Figure 9*b* demonstrates the dependence of the PID response on the incident radiation intensity from the source employed. An increase in operating current from 5 to 15 mA d.c. resulted in an increase in current of *ca.* one order of magnitude owing to the equivalent increase in observed intensity of the oxygen and chlorine atomic line emission between 125 and 140 nm. The proportionality between incident intensity and PID response is observed in both the plateau and gas-gain regions.

CONCLUSIONS

Our preliminary work reported here indicates that simple, high-efficiency, narrow spectral band-pass, solar-blind photoionization detectors may offer advantages for detection of radiation at short wavelengths in analytical atomic emission spectrometry. They should prove most valuable when used for non-dispersive, on-line detection systems. The most useful wavelength range for such detectors lies between 120 and 200 nm; Table 1 shows a selection of narrow spectral band-pass detectors which may be constructed with different window and filler materials. Detectors of this type may prove useful in continuous gas-analysis monitoring systems using plasma or glow-discharge sources, particularly for detection of oxygen, oxides of nitrogen and sulphur dioxide.

The detection and determination of low concentrations of organic compounds in the vapour phase, particularly those containing halogen, sulphur or phosphorus atoms, may also be facilitated by use of this type of detection system. Work is at present in progress on the development of such systems and the application of PID detectors in atomic-absorption and fluorescence spectrometry; this will be reported in a later communication.

STUDIES ON EXTRACTION OF THORIUM BY THE *N*-OXIDES OF 5-(4-PYRIDYL)NONANE AND TRIOCTYLAMINE FROM DIFFERENT MINERAL ACID SOLUTIONS AND ITS SEPARATION FROM RARE EARTH ELEMENTS AND YTTRIUM

M. EJAZ*

Department of Nuclear and Radiation Chemistry, University of N.S.W., Kensington, NSW, Australia

(*Received* 3 *March* 1975. *Accepted* 6 *July* 1975)

Summary—The *N*-oxides of 5-(4-pyridyl)nonane and trioctylamine have been evaluated for use in the extraction of thorium from different mineral acid solutions. The influence of the concentration of the solvents and salting-out agents has been investigated. The possible mechanism of extraction is discussed in the light of the results of extraction isotherms, loading-ratio data and log–log plots of reagent concentration *vs.* distribution ratio. Separation factors for a number of metal ions are reported and a method for the separation of thorium from rare earth elements and yttrium is also suggested.

In the search for new solvent extraction systems, the variable that can be most profitably exploited is the molecular configuration of the solvent extraction reagents: through the variation of molecular parameters such as the type of functional group and the molecular geometry, new and useful properties can be created. A class of extractants that has received much attention in the last twenty years is that of neutral organophosphorus compounds, especially tri-n-butyl phosphate (TBP).[1] TBP and other phosphorus derivatives such as trioctylphosphine oxide are similar in their extraction behaviour and the type of complex they form.

Other oxide-type compounds formed from the elements in the vicinity of phosphorus in the Periodic Table might also be expected to act as solvent extraction reagents, *e.g.*, ketones, silicon oxides, amine oxides, sulphoxides and arsine oxides. The alkyl silicon oxides readily hydrolyse, however, and are obviously unsuitable. The arsine oxides are useful extraction reagents,[2–4] but their synthesis is rather difficult.[5] Ethers, ketones and alcohols have been extensively investigated and surveyed.[6] Although the sulphoxides have been investigated and used for some years[7–17] only a few investigators[18–25] have examined *N*-oxides as extractants. This communication is a part of a programme of systematic studies of *N*-oxides as solvents, and reports recent fundamental data on the extraction of thorium by the *N*-oxides of 5-(4-pyridyl)nonane and trioctylamine and the separation of the metal from rare earth elements.

EXPERIMENTAL

Reagents

5-(4-Pyridyl)nonane *N*-oxide (PyNOx) and trioctylamine oxide (TOAO) were prepared and authenticated as reported elsewhere.[24]

Mineral acid solutions were generally prepared from standard volumetric solution ampoules and all other chemicals used were of analytical-reagent grade.

Nuclides

The ^{230}Th tracer had a ^{230}Th:^{232}Th ratio of approximately 0·085 and was isolated[26] from Australian South Alligator River pitchblende, and the ^{234}Th was milked from uranium.[27] The other tracers were obtained either from Radiochemical Centre, Amersham or through (n, γ) reactions or by separation of the daughter product from the initial nuclide without a carrier (^{140}La, ^{90}Y).[28]

Measurement of distribution coefficients

Equal volumes (2 ml) of the aqueous and organic phases were shaken mechanically for 3 min in test-tubes with ground-glass stoppers at 22 ± 2°. Preliminary experiments showed that 3 min are sufficient for attainment of equilibrium. Portions of the extracts and aqueous phases were placed on stainless-steel or glass planchettes in the case of α- and β-emitters and counted by proportional and end-window Geiger counters respectively. The γ-activities were measured with a scintillation counter and NaI(Tl) crystal.

RESULTS AND DISCUSSION

The extraction of thorium as a function of nitric, hydrochloric and sulphuric acid concentration in the aqueous phase was studied. The results are presented in Fig. 1. Thorium is quantitatively extracted only from nitric acid, with maximum extraction from 0·1–0·5*M* concentration. The decrease in extraction at higher acid concentrations is apparently due to a

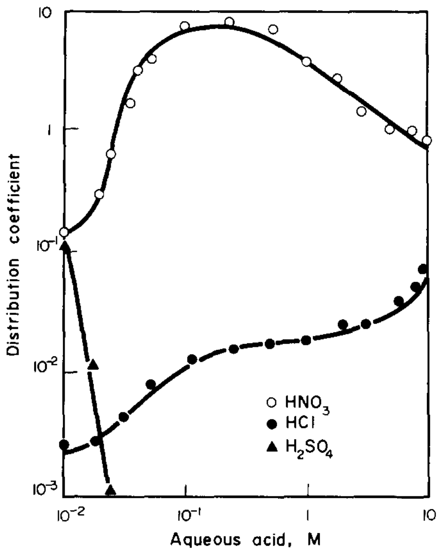

Fig. 1. Dependence of D_{Th} on the concentration of aqueous acids for extraction by 0·1*M* PyNOx in xylene.

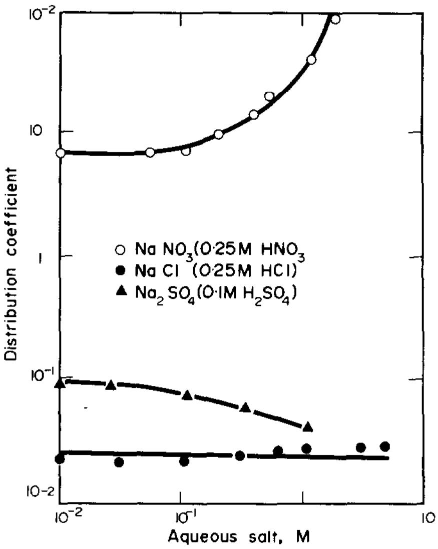

Fig. 2. Effect of salting-out agents on the extraction of thorium by 0·1*M* PyNOx in xylene.

decrease in the concentration of the free solvent through its combination with nitric acid and also to formation of inextractable anionic nitrate-complexes of thorium. Like sulphoxides,[29] PyNOx extracts thorium from very dilute nitric acid solutions much more efficiently than does TBP. In hydrochloric acid media extraction increases with concentration of the acid, possibly because neutral thorium chloride complexes are formed at high hydrochloric acid concentrations.[30] The poor extraction from sulphuric acid may be due to the formation of anionic sulphate complexes.

The effect of nitrate, chloride and sulphate ions on the extraction at constant acidity is shown in Fig. 2. The addition of nitrate ions to 0·25*M* nitric acid gives rise to high distribution coefficients similar to those with TBP,[31,32] probably because of salting-out action. In the hydrochloric acid system, chloride ions have little effect on extraction. This is in accordance with the fact that the thorium species present in up to 5*M* chloride solutions are reported to be the same irrespective of whether hydrogen ions or sodium ions are present.[33] Addition of sulphate ions to a dilute sulphuric acid solution gives rise to a steady decrease in the distribution coefficient of thorium, evidently because of the formation of anionic species which exist under these conditions.[34]

Extraction of thorium with PyNOx from nitric acid solutions can be represented as follows:

$$Th^{4+}_{aq} + 4NO^-_{3_{aq}} + n\text{PyNOx}_0 \rightleftharpoons Th(NO_3)_4.n\text{PyNOx}_0 \quad (1)$$

with equilibrium constant

$$K_1 = \frac{[Th(NO_3)_4.n\text{PyNOx}]_0}{[Th^{4+}]_{aq}\,[NO_3^-]^4_{aq}\,[\text{PyNOx}]^n_0} \quad (2)$$

The terms in brackets should be the activities, but concentrations may be used instead if they are low enough. Thus the metal distribution ratio is

$$D_{Th} = [(Th(NO_3)_4.n\text{PyNOx}]_0/[Th^{4+}]_{aq}$$
$$= K_1[\text{PyNOx}]^n_0 \quad (3)$$

Plots of log D_{Th} *vs.* log [PyNOx] are linear for 0·25*M* nitric acid medium, with a slope of about 2, indicating that a disolvate is formed, as with sulphoxides[29] and TBP.[31] Similar results were also obtained from the loading-ratio data.

Extraction of thorium by 0·1*M* TOAO in xylene from aqueous mineral acid solutions is shown in Fig. 3. In the nitric acid system, at low acidities thorium

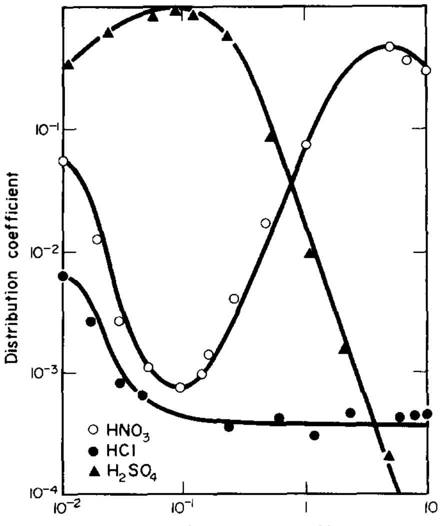

Fig. 3. Dependence of D_{Th} on the concentration of aqueous acids for extraction by 0·1*M* TOAO in xylene.

is highly hydrolysed and is probably extracted in the form of hydrolysed species. The extraction at high acidities of nitric acid resembles closely that with the unoxidized amine,[35] indicating that the extraction of hexanitrate complexes of thorium, which are present in this range of acidity,[35–38] is occurring by ion-pair formation. In the case of PyNOx, however, the extraction is considered to be of neutral complexes since the basicity of heterocyclic amine oxides is much lower than that of aliphatic amine oxides and the formation of the ion-pair structure may not be favoured in the case of PyNOx.

In hydrochloric acid media thorium extraction from low acid concentrations resembles the nitric acid system and can, therefore, be explained accordingly. The poor extraction from dilute and concentrated solutions is evidently due to absence of neutral or anionic chloro-complexes of thorium. Extraction from sulphuric acid solutions increases with increase in the acid concentration and reaches a maximum at about 0·1M hydrogen ion concentration before decreasing at higher acidities. Sulphate complexes of thorium are possibly extracted from dilute sulphuric acid solutions and the decrease in extraction may be considered as due to an increase in the bisulphate concentration in the aqueous phase.

Extraction of thorium by 0·1M TOAO/xylene from varying nitrate, chloride and sulphate concentrations at constant acidity is shown in Fig. 4. Chloride ions, added to 1M hydrochloric acid, have little effect on the extraction, as in the PyNOx system. The addition of nitrate ions to the nitric acid system increases the extraction. This may be explained as due to salting-out action and/or the increased formation of extractable complexes. The addition of sulphate ions to 0·1M sulphuric acid decreases the extraction, as in the PyNOx system.

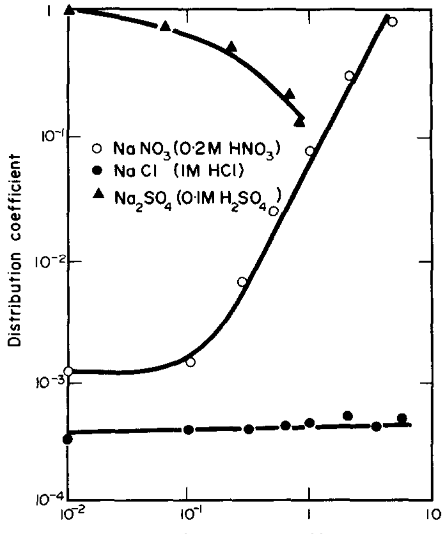

Fig. 4. Effect of salting-out agents on the extraction of thorium by 0·1M TOAO in xylene.

C.F. Carrier-free.

In the nitric and sulphuric acid systems plots of log D_{Th} *vs.* log [PyNOx] are linear for 6M nitric and 0·2M sulphuric acid, with a slope of about 2, suggesting that thorium is extracted as a disolvate in both cases.

Back-extraction of thorium

Thorium extracted into the organic phase from nitric acid solutions by PyNOx may be readily stripped with dilute sulphuric or hydrochloric acid. Quantitative stripping of thorium is achieved in 2 min with 0·5–1M sulphuric acid.

Extraction behaviour of other metal ions

The extraction behaviour of other heavy metal ions and fission products from 0·25M nitric acid by 0·1M PyNOx in xylene was investigated and the results are shown in Table 1. It is evident that thorium can be separated from the rare earth elements and yttrium. The data were tested by extracting thorium from a 0·05M thorium test solution containing not more than 0·5 mg/ml of Ce, La, Eu and Y in 0·25M nitric acid with an equal volume of a 0·1M solution of PyNOx in xylene. The equilibration time was 3 min. After centrifugation the organic phase was removed and thorium was stripped with an equal volume of 0·5–1M sulphuric acid. The γ-spectrum showed the absence of Ce, La, Eu and Y in the back-extract.

Acknowledgement—The author wishes to express his thanks to Professor D. J. Carswell for his kind suggestions during this work.

ANREICHERUNG VON SPUREN Au UND Pd AUS REINSTMETALLEN Cd, In, Ni, Pb UND Zn MIT NACHFOLGENDER BESTIMMUNG IN DER GRAPHITROHR-KÜVETTE

EWALD JACKWERTH und PAUL GÜNTER WILLMER
Institut für Spektrochemie und Angewandte Spektroskopie, D-4600 Dortmund,
Bunsen-Kirchhoff-Straße 11, Bundesrepublik Deutschland

(*Eingegangen am* 16. *Mai* 1975. *Angenommen am* 30. *Juni* 1975)

Zusammenfassung—Es wurde ein Verfahren zur Bestimmung von Spuren Au und Pd in Reinstmetallen Zn, Cd, In, Ni und Pb entwickelt. Nach Lösen des Probenmaterials werden die Spuren aus etwa 2*M* salzsaurer Lösung als Dithizon-Chelate ausgefällt, wobei überschüssiges Dithizon als Spurenfänger dient. Niederschlag und Cellulosenitrat-Membranfilter werden gemeinsam zu 1,0 ml in Dimethylsulfoxid gelöst. Anteile dieser Lösung (50 μl) werden durch flammenlose AAS in der Graphitrohr-Küvette analysiert. Für die relative Standardabweichung der Anreicherung und Bestimmung von etwa $5 \cdot 10^{-7}\%$ Au bzw. Pd wurden, je nach Probenmaterial, Werte zwischen 4% und 12% ermittelt; für Einwaagen von 10 g Metall wurden Nachweisgrenzen im Bereich $2–5 \cdot 10^{-8}\%$ Au bzw. $0,6–1 \cdot 10^{-7}\%$ Pd berechnet. Dabei wurde vereinfachend angenommen, daß vor allem der Störpegel der Bestimmungsmethode die Nachweisgrenze des gesamten Analysenverfahrens bestimmt.

Die "flammenlosen" Verfahren der Atomabsorptions-Spektrometrie (AAS) gehören heute zu den nachweisstärksten Bestimmungsmethoden für Elementspuren. Ihre Anwendbarkeit und Leistungsfähigkeit bei der Spurenanalyse von Reinststoffen ist jedoch durch eine Reihe von Merkmalen gekennzeichnet, die wesentlich durch Art und Menge des zu untersuchenden Materials in der Probenlösung mitbestimmt werden. Zum Beispiel gilt das hohe Nachweisvermögen des Verfahrens vor allem für Spuren*mengen*; wegen der nur im unteren Mikroliter-Bereich liegenden Volumina an eingesetzter Probenlösung ist das Nachweisvermögen für Spuren*konzentrationen* weniger ausgeprägt. Die Mehrzahl der flammenlosen AAS-Verfahren ist ihrer Natur nach deshalb eher zur Mikro- als zur Spurenanalyse geeignet.

Um Spurenverunreinigungen um $10^{-7}\%$—etwa in Reinstmetallen und Metallsalzen—bestimmen zu können, ist, von Ausnahmen abgesehen, die Abtrennung der Matrix sowie die Anreicherung der Spuren aus einer größeren Probeneinwaage unumgänglich. Die oft beträchtliche Störung der Spurenbestimmung durch Fremdsalze in der Probenlösung verlangt möglichst matrixfreie Spurenkonzentrate. Dabei sind Verbundverfahren aus chemischer Anreicherung und flammenloser AAS vor allem dann von Interesse, wenn nur einzelne Elemente im Probenmaterial zu bestimmen sind. Für Multi-Element-Analysen ist dieses Verfahren schon wegen der relativ langen Analysenzeiten und der für jedes Element notwendigen Umrüstung des AAS-Geräts (Wechsel der Hohlkathoden-Lampen sowie Änderung der Einstellungen an Monochromator, Meßelektronik und Heizautomatik für die Ofen-Anordnung) nur wenig geeignet.

Ziel der im folgenden beschriebenen Arbeit war, ein Verbundverfahren für Spuren Gold und Palladium in Reinstmetallen zu entwickeln, bei dem durch flammenlose AAS mit der Graphitrohr-Küvette Au bzw. Pd in Gehalten von $10^{-7}\%$ und darunter erfaßt werden können. Höchstens in so niedriger Konzentration werden diese Elemente—wenn überhaupt—in vielen im Handel befindlichen Materialien gefunden. Entsprechend dieser Analysenaufgabe und entsprechend der Leistungsfähigkeit des Bestimmungsverfahrens mußte ein Anreicherungsprozeß unter folgenden allgemeinen Gesichtspunkten entwickelt werden:

1. Trennung von Spuren und Matrix aus Einwaagen bis zu 10 g Probenmaterial;
2. Anreicherung der Spuren in ein weitgehend matrixfreies Spurenkonzentrat mit definiertem kleinen Probenvolumen (1 ml);
3. Vermeiden von Stoffen, die eine Störung der Spurenbestimmung verursachen.

Zur selektiven Abtrennung kleiner Mengen Gold und Palladium ist als chelatbildendes Reagenz das seit langem in der Spurenanalyse verwendete Dithizon geeignet.[1] Zwar reagiert Dithizon mit mehr als 30 Kationen zu stabilen Chelaten, Bildung und Stabilität hängen aber u.a. stark vom pH-Wert der Lösung ab. Dies wird in einer Vielzahl von Varianten vor allem zur extraktiven Trennung der Metalldithizonate ausgenutzt. In Lösungen mit pH-Werten <1 werden vor allem die Chelate der Metallkationen Hg^{2+}, Ag^{+}, Pd^{2+} und Au^{3+} gebildet; durch Einstellen einer hohen Acidität kann man erreichen, daß andere Metalle an der Reaktion mit dem Chelatbildner gehindert werden, auch wenn sie in wesentlich höherer Konzentration als die Edelmetall-Spuren in der Probenlösung enthalten sind.

Die Dithizon-Komplexe von Pd^{2+} und Au^{3+} sind sehr stabil: $PdDz_2$ (Dz = Dithizon), einmal gebildet, wird auch durch 12*N* Schwefelsäure nicht mehr zerlegt.[1] Auch das Gold-Dithizonat ist gegenüber Säuren sehr beständig, wobei, je nach Art der Arbeitsbedingungen, Verbindungen unterschiedlicher Ligandenzahl entstehen sollen.[2] In einer Arbeit von Cox und Servant[3] wird die Bildung definierter Gold-Dithizonate überhaupt infrage gestellt und die als solche beschriebenen Farbkomplexe eher als Oxidationsprodukte des Dithizons bedeutet. Au^{3+}- oder Au^{+}-Ionen werden von den Autoren lediglich als Oxidationsmittel in dieser Reaktion angesehen. Die Ergebnisse der folgenden Arbeit zeigen, daß Spuren Gold nach Reaktion mit Dithizon zumindest in einer in organischen Lösungsmitteln löslichen Form enthalten sind. Nähere Untersuchungen dazu haben wir nicht durchgeführt.

EXPERIMENTELLER TEIL

Beim augenblicklichen Entwicklungsstand der flammenlosen AAS-Verfahren sind Arbeitsvorschriften nur selten mit gleichbleibenden Ergebnissen auf Geräte anderer Laboratorien übertragbar. Wegen der komplizierten Vorgänge und Abhängigkeiten im Absorptionsvolumen des Graphitrohres[4] gilt dies auch für Geräte desselben Herstellers, oft sogar für zeitlich auseinanderliegende Wiederholungmessungen an demselben Gerät. Bei einer Übernahme von Arbeitsvorschriften aus der Literatur müssen in der Regel vor allem die Betriebsdaten für den Graphitrohr-Ofen (Temperatur–Zeit-Ablauf der Heizautomatik) überprüft und gegebenenfalls der eigenen Meßapparatur angepaßt werden. In diesem Sinne sind auch die hier mitgeteilten Apparate-Parameter unserer Untersuchungen zu verstehen.

Geräte

Perkin-Elmer Atomabsorptions-Spektrometer Modell 300 mit Untergrund-Kompensator und Hohlkathoden-Lampen für Gold und Palladium. Graphitrohr-Küvette mit Heizautomatik HGA 72.[5] Für vergleichende Untersuchungen wurde in Einzelfällen das neuere Modell HGA 74 verwendet. Die Meßsignale wurden mit einem Kompensations-Schreiber (Eingang 5 mV, Vorschub 3 cm/min) registriert.

Heizprogramm für den Graphitrohr-Ofen HGA 72

a	Verdampfen des Lösungsmittels:	60 sec bei 200°
b	Zersetzen organischer Rückstände:	in *ca.* 45 sec weiterer linearer Temperaturanstieg (Temperatur-Gleitprogramm) auf 750° (Au) bzw. 700° (Pd) danach jeweils 60 sec Verweilzeit bei der Endtemperatur
c	Atomisieren:	15 sec bei etwa 2600° (höchste am Meßgerät angezeigte Temperatur)

Alle Temperaturangaben sind Werte des Meßgeräts der Heizautomatik. Die Messungen wurden in N_2-Schutzgas-Atmosphäre (1,7 l./min) durchgeführt.

Untersuchungen zur selektiven Anreicherung von Spuren Au und Pd

Bei unserem Verfahren werden zur Anreicherung von Gold und Palladium die Dithizonchelate der Spuren aus saurer Lösung ausgefällt. Das Fällungsreagenz Dithizon wird zu wenigen Milligramm als Acetonlösung zugesetzt. Da es in nicht zu starken Säuren ebenfalls schwerlöslich ist, dient der Reagenzüberschuß zugleich als "Spurenfänger". Spuren und Matrix werden durch Filtrieren der Suspension über ein Membranfilter voneinander getrennt. Filter und Niederschlag werden in einem definierten Volumen eines geeigneten Lösungsmittels klar gelöst; in aliquoten Teilen der Lösung werden Gold und Palladium bestimmt.

Bei Auswahl der Arbeitsbedingungen wurden vor allem die Einflüsse der Acidität sowie die von Filtermaterial und Dithizonmenge auf den Anreicherungs- und Bestimmungsprozess untersucht. Dabei zeigte es sich, daß die Acidität der Probenlösung in weiten Grenzen variieren kann, ohne daß die Vollständigkeit der Spurenanreicherung beeinträchtigt wird. Der Säurezusatz muß lediglich so hoch gewählt werden, daß Matrixbestandteile nicht mehr mit Dithizon reagieren; andererseits muß der Spurenfänger zur Sorption der Edelmetall-Chelate in filtrierbarer Menge ausfallen. Beide Voraussetzungen sind im Bereich von etwa 1,5 bis 4*N* Säure erfüllt. Schwierigkeiten ergeben sich lediglich durch mitgerissenes Kupfer, das schon in Mikrogramm-Mengen bei der AAS-Bestimmung der Spuren stört. Da die Sorption so geringer Mengen Kupfer auch in stark saurer lösung nicht verhindert werden kann, muß die Störung durch ein besonderes Eichverfahren eliminiert werden. Spuren und Spurenfänger werden, für alle untersuchten Probenmaterialien einheitlich, in etwa 2*N* Säure ausgefällt. Wichtig ist, daß nitrose Gase aus dem Löseprozeß der Metallproben vollständig entfernt sind; andernfalls wird ein Teil des Dithizons oxidiert, und man erhält —vor allem beim Palladium—zu kleine Analysenwerte. Aus diesem Grunde wird die Salpetersäure nach Lösen der Metalle unter Zusatz konzentrierter Salzsäure jeweils sorgfältig abgeraucht. Die Spurenfällung wird deshalb auch in *salzsaurer* Lösung durchgeführt. Als Spurenfänger wird eine nur geringe Dithizonmenge verwendet, um den bei der nachfolgenden Spurenbestimmung durch "Rauchpeaks" verursachten Untergrund an unspezifischer Absorption möglichst niedrig zu halten. Abbildung 1 zeigt die Abhängigkeit der Anreicherungs-Ausbeuten (100 ng Au bzw. Pd) vom Reagenzzusatz. Zwei mg Dithizon reichen danach voll aus, um maximale Ausbeuten zu erzielen. Dies gilt auch dann, wenn Kupfer in Mengen bis zu 10 mg im eingewogenen Probenmaterial enthalten ist.

Menge und Beschaffenheit von Niederschlag und Filter

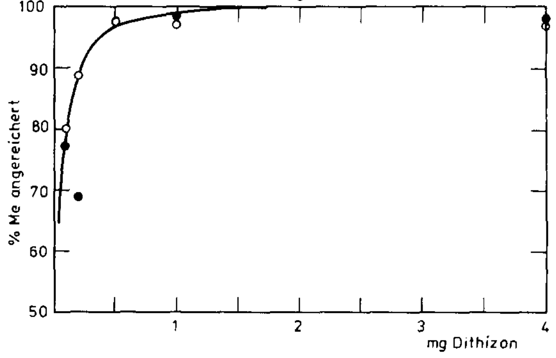

Abb. 1. Abhängigkeit der Anreicherung von 100 ng Au (○) bzw. Pd (●) von der als Spurenfänger eingesetzten Dithizonmenge.

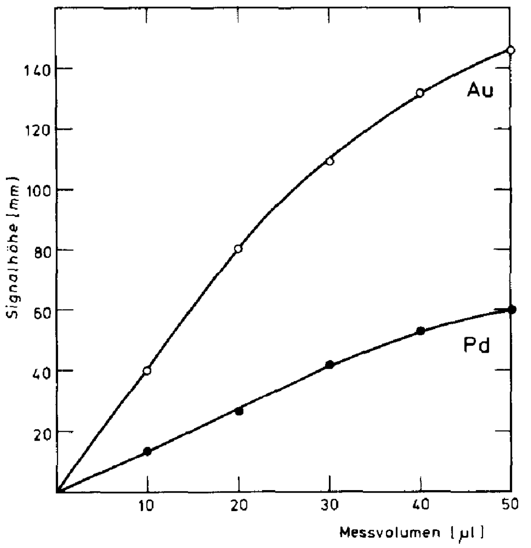

Abb. 2. Abhängigkeit der Signalhöhe (registrierte Peakhöhen) vom injizierten Probenvolumen bei der Bestimmung von Au und Pd in der Graphitrohr-Küvette HGA 72 (DMSO-Lösung mit 0,1 μg/ml Au bzw. Pd).

sind von besonderer Bedeutung, um klare homogene Spurenkonzentrat-Lösungen geringer Viskosität zu erhalten, aus denen ohne merklichen Verlust die zur Bestimmung notwendigen μl-Volumina dosiert werden können. Nach zahlreichen Voruntersuchungen mit unterschiedlichen Filtermaterialien sowie den zum Lösen von Filter und Niederschlag geeigneten Lösungsmitteln wurden Cellulosenitrat-Membranfilter sowie Dimethylsulfoxid (DMSO) gewählt. Durch Erwärmen im Wasserbad lösen sich Filter und Niederschlag in 1 ml DMSO zu einer für die Spurenbestimmung geeigneten Lösung, die, im Meßkolben verschlossen und unter Lichtausschluß aufbewahrt, auch bei nur wenigen Nanogramm angereicherter Edelmetalle über mehrere Wochen titerstabil bleibt.

Untersuchungen zur Dosierung der Meßlösungen

Zur Dosierung der Meßlösungen wurden Mikroliter-Pipetten (Eppendorf, Hamburg) verwendet. Abbildung 2 zeigt, daß die Signalhöhen bei ansteigend injizierten Probenvolumina (Lösung mit 0,1 μg/ml Au) nichtlinear größer werden. Oberhalb von etwa 50 μl wird die Reproduzierbarkeit der Meßwerte zunehmend schlechter. Ursache hierfür ist die unvollständige Verdampfung von DMSO im Graphitrohr: bei größeren DMSO-Volumina schlagen sich Teile des Dampfes bzw. höhersiedender Zersetzungsprodukte an kälteren Stellen des Rohres nieder und verursachen in der Atomisierungsstufe des Heizprogramms einen mehr oder weniger starken "Rauchpeak", dessen unspezifische Lichtabsorption durch den Untergrund-Kompensator nicht immer voll eliminiert wird. Auch mit den von der Gerätefirma angebotenen "Spezial-Graphitrohren" (Art.-Nr. 062628) mit innen ausgefrästem Ring zur Aufnahme größerer Probenvolumina wurden mit über 50 μl hinausgehenden Probenvolumina keine brauchbaren Ergebnisse erzielt. Sowohl für die Bestimmung von Gold als auch für die von Palladium wurde das Meßvolumen deshalb nach oben hin auf 50 μl begrenzt.

Zur Störung der Spurenbestimmung durch Kupfer

Es wurde bereits darauf hingewiesen, daß die Analyse von Spuren Gold und Palladium unter den Bedingungen unserer Arbeitsvorschrift durch Kupfer gestört wird: in Gegenwart von Kupfer erhält man deutlich verminderte Analysensignale (Abb. 3). Die erste Vermutung, daß Kupfer bereits die quantitative Anreicherung der Edelmetallspuren behindere, erwies sich als falsch; gestört wird vielmehr die eigentliche Bestimmung der Spuren und zwar durch dasjenige Kupfer, das im Anreicherungsprozeß als Dithizon-Chelat mit erfaßt wird und in die DMSO-Lösung der Spuren gelangt. Um das Ausmaß der Störung zu ermitteln, wurden zu einer Serie 2*N* salzsaurer Lösungen mit je 0,1 μg Au^{3+} und Pd^{2+} in 150 ml ansteigende Mengen Cu^{2+} (als $CuCl_2$-Lösung) gegeben. Die Edelmetallspuren wurden entsprechend der Arbeitsvorschrift angereichert und in der Graphitrohr-Küvette bestimmt. Die Höhe der Signale wurde gegen den Kupferzusatz aufgetragen. Nach Aussage der Diagramme (Abb. 3) sinken die Meßsignale sowohl für Gold als auch für Palladium zunächst rasch auf einen Wert, der nur etwa die Hälfte des Wertes für kupferfreie Probenlösungen erreicht, bleibt dann aber über einen Bereich mehrerer Milligramm Kupfer praktisch unverändert. Der Kurvenverlauf hängt jedoch von den Anreicherungsbedingungen, insbesondere von Acidität und Chelatbildner-Menge ab, so daß jede Veränderung der Parameter auch auf das Ausmaß der Kupferstörung einwirkt. Zahlreiche Versuche, die eigentliche Ursache für diese Störung zu finden bzw. sie zu beseitigen, brachten keinen Erfolg.

Um den Einfluß wechselnder Kupfermengen bei der Analyse unterschiedlich reiner Metalle zu stabilisieren, haben wir im folgenden jedem Probenmaterial mit Eigenverunreinigungen von mehr als 10 μg Kupfer pro Einwaage einheitlich 2 mg Cu^{2+} zugesetzt und den dadurch bedingten Verlust an Empfindlichkeit bei der Spurenbestimmung in Kauf genommen. Der Störeinnfluß des Kupfers wurde in diesem Fall als systematischer Fehler des Bestimmungsverfahrens bei der Eichung berücksichtigt.

Eichung des Analysenverfahrens

In der Graphitrohr-Küvette können Spuren nur anhand jeweils mitgeführter Leitproben sicher bestimmt werden. Bewährt haben sich das Eichzusatz-Verfahren sowie die sich der Analyse unmittelbar anschließende Eichung durch Standardlösungen mit abgestuften Spurengehalten. Wegen der Störungen durch viele Arten von Fremdstoffen muß besonders bei den flammenlosen AAS-Verfahren sorgfältig darauf geachtet werden, daß Proben- und Standardlösungen möglichst identisch zusammengesetzt sind. Für unser Verfahren bedeutet das, daß zur Eichung DMSO-Lösungen verwendet werden müssen, die neben den Spuren den Chelatbildner Dithizon sowie das Filtermaterial gelöst enthalten. Zu ihrer Herstellung haben wir entsprechend der

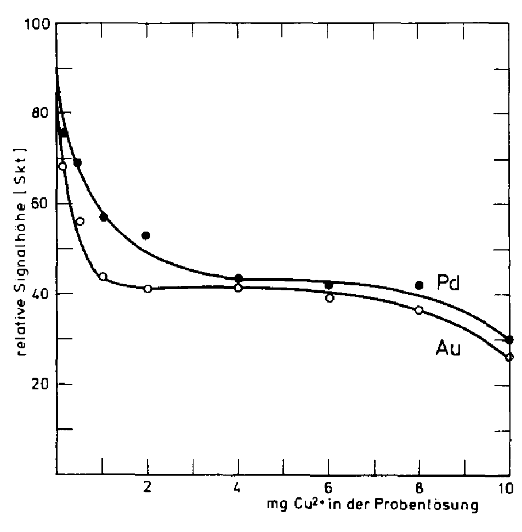

Abb. 3. Änderung der relativen Signalhöhen durch den Kupfergehalt des Probenmaterials (kupferfreie Lösungen zu 100 Skt angenommen).

Arbeitsvorschrift abgestufte Mengen Gold und Palladium aus etwa 2*N* salzsaurer Lösung (eventuell nach Zusatz von je 2 mg Cu^{2+} als $CuCl_2$) mit Dithizon ausgefällt und den Niederschlag einschließlich Filter in DMSO gelöst. Da solche Lösungen über mehrere Wochen titerstabil sind, können die Standardlösungen als Vorrat auch in größeren Volumina als 1 ml angesetzt werden. Sie müssen allerdings das Filtermaterial und Dithizon in der entsprechend erhöhten Menge enthalten.

Arbeitsvorschriften zum Lösen der Probenmaterialien

In den im folgenden beschriebenen Löseprozessen für die Reinstmetalle Zn, Cd, In, Ni und Pb sind vor allem zwei Gesichtspunkte bestimmend. 1. Die Edelmetallspuren müssen neben der unedleren Matrix quantitativ in Lösung gebracht werden. Obwohl sich die Probenmaterialien bereits in Salzsäure bzw. in Salpetersäure allein lösen, ist besonders für Gold eine Mischung aus beiden Säuren erforderlich. Im Verlaufe des Lösevorgangs muß deshalb "Königswasser" entstehen, damit sonst ungelöst bleibende Goldspuren sicher erfaßt werden. 2. Wegen der hohen Oxidationsempfindlichkeit des als Spurenfänger verwendeten Dithizons müssen nitrose Gase und andere oxidierende Stoffe vollständig aus der Probenlösung entfernt werden. Aus diesem Grund werden die Metallsalze nach Lösen der Proben mehrfach mit konzentrierter Salzsäure abgeraucht. Die Wirksamkeit der Salzsäure ist bei den verschiedenen Metallen sehr unterschiedlich; sie ist besonders groß, wenn das Nitrat bereits durch Bildung wenig dissoziierter Chloride oder Chlorokomplexe aus den Metallsalzen verdrängt wird. Aus diesem Grund ist die Behandlung des Nickels hier am langwierigsten. Die Umsetzung mit Salzsäure kann bei allen Salzen wesentlich beschleunigt werden, wenn man die Lösungen während des Einengens, etwa mit einem heizbaren Magnetrührer, intensiv durchmischt. Die beim Lösen des Bleis unvermeidbare $PbCl_2$-Suspension wird jedoch am besten mit Hilfe von Oberflächenstrahlern eingeengt. Sofern das Probenmaterial mehr als etwa 10 μg Cu pro Einwaage enthält, setzt man, um Störungen durch Kupfer bei der Eichung eliminieren zu können, zu Beginn des Löseprozesses 2 mg Cu in Form von $CuCl_2$-Lösung zu. Ein Kupferzusatz in gleicher Höhe muß anschließend auch bei der Herstellung der Eichlösungen verwendet werden (siehe auch dort).

Zink, Cadmium, Indium

10 g zerspantes Metall werden in einem 250-ml Becherglas (hohe Form) mit 5–10 ml Wasser sowie 30 ml 37%iger Salzsäure versetzt. Portionsweise werden nun insgesamt 5 ml 65%iger Salpetersäure zugesetzt (bei Zink sind 3 ml ausreichend), wobei die Größe der Portionen sowie die Temperatur dem Ablauf der Lösereaktion angepaßt werden. Wenn das Probenmaterial gelöst ist, werden weitere 2 ml 65%iger Salpetersäure zugegeben. Die Lösung wird weitgehend eingeengt. Nach Zusatz von 5 ml 37%iger Salzsäure (bei Cadmium sind 10 ml erforderlich) wird erneut eingeengt. Der Vorgang wird noch zweimal wiederholt. Der Kristallbrei wird anschließend mit 20 ml 37%iger Salzsäure sowie 50 ml Wasser gelöst und etwa 1 min zum Sieden erhitzt. Nach Abkühlen auf Raumtemperatur wird die Lösung mit Wasser auf 150 ml verdünnt. Aus dieser etwa 2*N* salzsauren Probenlösung werden Gold und Palladium entsprechend der Anreicherungsvorschrift abgetrennt.

Nickel

10 g Nickel werden in einem 250-ml Becherglas (hohe Form) mit 5 ml Wasser versetzt; portionsweise wird 65% ige Salpetersäure zugegeben, bis das Probenmaterial gelöst ist. Je nach Beschaffenheit des Materials (Pulver, Späne, Kugeln) benötigt man dazu 40–80 ml. Die Lösetemperatur wird dem Ablauf der Reaktion angepaßt. Die Lösung wird eingeengt, mit 30 ml 37%iger Salzsäure versetzt und unter Rühren (heizbarer Magnetrührer) erneut bis zur beginnenden Salzausscheidung eingeengt. Dieser Vorgang wird mit 10-ml Portionen wiederholt, bis auf Zusatz einiger Tropfen 48%iger Bromwasserstoffsäure kein Brom mehr freigesetzt wird (Gesamtverbrauch etwa 150 ml Salzsäure). Die Lösung wird nun bis fast zur Trockne gebracht. Der Kristallbrei wird in 20 ml 37%iger Salzsäure sowie 50 ml Wasser gelöst und etwa 1 min zum Sieden erhitzt. Nach Abkühlen auf Raumtemperatur wird die Lösung auf 150 ml mit Wasser verdünnt. Aus dieser etwa 2*N* salzsauren Probenlösung werden Gold und Palladium entsprechend der Anreicherungsvorschrift abgetrennt.

Blei

10 g zerspantes Blei werden in einem 250-ml Becherglas (hohe Form) mit etwa 20 ml Wasser erhitzt. Durch Zusatz von insgesamt 12 ml 65%iger Salpetersäure in mehreren Portionen wird das Probenmaterial vollständig gelöst. Dann werden 30 ml 37%iger Salzsäure zugesetzt. Mit Hilfe von Oberflächenstrahlern wird die $PbCl_2$-Suspension bis zur Trockne eingedampft; der Vorgang wird die Lösung auf 150 ml mit Wasser verdünnt. Aus Rückstand wird in 20 ml 37% iger Salzsäure sowie 50 ml Wasser suspendiert, die Suspension wird unter fließendem Wasser abgekühlt. Anschließend wird das Bleichlorid über ein weiches Filter abfiltriert. Das Filtrat wird etwa 1 min zum Sieden erhitzt. Nach Abkühlen auf Raumtemperatur wird die Lösung auf 150 ml mit Wasser verdünnt. Aus dieser etwa 2*N* salzsauren Probenlösung werden Gold und Palladium entsprechend der Anreicherungsvorschrift abgetrennt.

Arbeitsvorschrift zur Anreicherung von Spuren Au und Pd

Die etwa 2*N* salzsaure Lösung der zur Analyse eingesetzten Metalle wird unter intensivem Rühren mit 2,0 ml einer 0,1% igen Lösung von Dithizon in Aceton versetzt. Noch vorhandene Reste oxidierender Stoffe werden durch Zugeben von 1 ml 10%iger Ascorbinsäure-Lösung sofort nach Zusatz des Dithizons zerstört. Dithizon- wie Ascorbinsäure-Lösung müssen täglich frisch angesetzt werden. Unmittelbar nach der Fällung wird der Niederschlag mit Hilfe einer zerlegbaren Hahn'schen Nutsche[6] über ein Cellulosenitrat-Membranfilter (Schleicher & Schüll, Selectron AE 99; Porengröße 8 μm, Filterdicke 180 μm, Durchmesser 25 mm) abgesaugt. Probengefäß und Nutsche werden mit wenigen ml Wasser, dem etwas Netzmittel (z.B. "Zephirol") zugesetzt wurde, gespült. Durch das Netzmittel wird verhindert, daß fein verteilte Partikel des Niederschlags an den Gefäßwandungen hochkriechen.

Der Dithizon-Niederschlag wird zusammen mit dem Filter in ein 1 ml-Meßkölbchen gebracht, mit etwa 0,8 ml Dimethylsulfoxid (Merck, zur Analyse) versetzt und 5 min im Wasserbad bei etwa 80° erhitzt. Nach dem Abkühlen wird mit DMSO zur Marke aufgefüllt und die Lösung gut durchmischt. Nach einer Standzeit von etwa 1 Std. werden Gold und Palladium in Teilen von je 50 μl dieser Lösung bestimmt. Zur Analyse wurden aus jeder Lösung drei aufeinanderfolgende Parallelbestimmungen durchgeführt, deren Signale gemittelt wurden.

ERGEBNISSE DER UNTERSUCHUNGEN

Zur Entwicklung und Bewertung des Analysenverfahrens wurden handelsübliche Reinstmetalle eingesetzt. Analysenwerte der Hersteller über die Gehalte an Gold und Palladium standen nicht zur Verfügung. In Tabelle 1 sind Angaben über die Herkunft einiger Metalle mit den von uns ermittelten Daten zusammengestellt. Die Mehrzahl der Zahlenwerte gibt die aus den Untergrundstreuungen errechnete "Garantiegrenze für Reinheit" wieder.[7] Zur

Tabelle 1. Reinstmetallproben, deren Herkunft und Analysenwerte

Probenmaterial		Analysendaten Au, %	 Pd, %
Zink	Merck, Darmstadt, gekörnt, z.A. mind. 99,9% Zn Art.-Nr. 8780	$<6\cdot10^{-8}$*	$<2\cdot10^{-7}$*
Cadmium	Riedel-de Haën, Seelze-Hannover, Stangen, Art.-Nr. 11704	$<1\cdot10^{-7}$*	$<2\cdot10^{-7}$*
	Preussag AG, Metall, Goslar, Stangen, mind. 99,9998% Cd	$<1\cdot10^{-7}$*	$<2\cdot10^{-7}$*
Indium	Preussag AG, Metall, Goslar, Barren, 99,9995% In	$2\cdot10^{-7}$	$<1\cdot10^{-7}$*

Blei	Merck, Darmstadt, fein gekörnt, Art.-Nr. 7363	$3\cdot10^{-8}$	$<1\cdot10^{-7}$*
	Nordd. Affinerie, Hamburg, Feinblei-Muster 5A/72 fein gekörnt	$6\cdot10^{-8}$	$<1\cdot10^{-7}$*

* “Garantiegrenze für Reinheit”[7]

Ermittlung der relativen Standardabweichung $s/\bar{x}$ des Analysenverfahrens haben wir den Metalleinwaagen Spuren Gold und Palladium als Lösungen zugesetzt, so daß einheitlich für sämtliche Probenmaterialien Gehalte von $5\cdot10^{-7}$% Gold bzw. Palladium eingestellt wurden. Der Berechnung lagen 10 vollständige Analysen zugrunde (Tabelle 2). Ein Vergleich mit matrixfreien Probenlösungen zeigte, daß bei der Anreicherung der Spuren Gold und Palladium jeweils um 90% der zugesetzten Elementspurenmenge wiedergefunden werden. Der Wert für die Anreicherungsausbeute wurde bei der Verfahrenseichung berücksichtigt.

Die tabellierten Daten für die Nachweisgrenze (3σ-Grenze) wurden aus den Untergrundstreuungen allein des Bestimmungsverfahrens errechnet; sie stellen also nur Schätzwerte für die Nachweisgrenze des Gesamtverfahrens dar, die unter günstigen Umständen erreicht werden könnten. Dieses Vorgehen schien uns wegen der Kostbarkeit eines Teils der Probenmaterialien sowie wegen des Fehlens meßbarer Reagenzienblindwerte für Gold und Palladium in den benutzten “analysenreinen” Chemikalien vertretbar.

Tabelle 2. Analysenergebnisse

Probenmaterial (Au- bzw. Pd-gehalt: $5\cdot10^{-7}$%) (siehe Text)	rel. Standardabweichung $100\,s/\bar{x}$ %, ($N = 10$) Au	 Pd	Nachweisgrenze (3σ-Grenze) (siehe Text) Au, %	 Pd, %
10 g Zn	7,6	4,6	$3\cdot10^{-8}$	$1\cdot10^{-7}$
10 g Cd	5,4	5,2	$5\cdot10^{-8}$	$8\cdot10^{-8}$

10 g Pb	6,7	11	$2\cdot10^{-8}$	$6\cdot10^{-8}$
1 g Pb*	4,3	7,0	$6\cdot10^{-7}$	$1\cdot10^{-6}$

* mit $5\cdot10^{-6}$% Au bzw. Pd.

In einer Serie von Messungen wurde versucht, die mit der Graphitrohr-Küvette HGA 72 erhaltenen Ergebnisse auf das neuere Modell HGA 74 zu übertragen. Beide Geräte unterscheiden sich sowohl in der eigentlichen Küvette als auch in der Auslegung der Heizautomatik. Einflüsse auf Empfindlichkeit und Nachweisvermögen des Bestimmungsverfahrens waren vor allem durch die bei der HGA 74 abgeänderte interne Schutzgasführung, die veränderte Anstiegsrate im Temperatursprung der Atomisierungsstufe sowie durch die kleinere Dimensionierung des Graphitrohres zu erwarten. Ein unmittelbarer Vergleich beider Modelle sowie eine zu verallgemeinernde Aussage über die Leistungsfähigkeit sind mit wenigen Meßreihen kaum möglich.

Die Übertragung der unveränderten Arbeitsvorschrift unseres Bestimmungsverfahrens für Gold und Palladium erwies sich erwartungsgemäß als nicht möglich: 50 µl der an Dithizon und Cellulosenitrat relativ konzentrierten DMSO-Lösung des Spurenkonzentrats verursachten bei Verwenden der HGA 74 Rauchpeaks, die nur in Ausnahmefällen durch den Untergrundkompensator eliminiert werden konnten; stark streuende Signale waren die Folge. Gleichzeitig wurde die Lebensdauer der Graphitrohre durch die großen Stoffmengen merklich verringert. Erst bei Vermindern des eingegebenen Probenvolumens auf 20 µl konnten die angereicherten Elemente Au und Pd ohne Schwierigkeit bestimmt werden. Die Ergebnisse der mit beiden HGA-Systemen an 20 µl-Anteilen der Spurenkonzentrate durchgeführten Parallelmessungen können folgendermaßen zusammengefaßt werden.

Empfindlichkeit und Genauigkeit der Bestimmung beider Elemente ändern sich beim Wechsel der Graphitrohr-Küvette nur unwesentlich, sofern die durchfließende Inertgas-Menge (N_2) im Augenblick der Bestimmung etwa die gleiche ist. Die Gasströmung bestimmt die Verweilzeit der Atome in der Küvette und damit Empfindlichkeit und Nachweisvermögen der Messung. Bei der HGA 74 kann der Gasstrom in der Atomisierungsstufe der Heizautomatik wahlweise reduziert oder ganz abgestellt werden; die HGA 72 erlaubt die Messung nur bei vollem oder bei ganz abgestelltem Gasfluß. Das Erste ist u.U. günstig, um Reste organischer Stoffe noch im Temperaturanstieg der Atomisierungsstufe aus dem Meßraum zu entfernen. Sind Störungen durch Rauchpeaks nicht zu erwarten, so wird die Empfindlichkeit der Bestimmung des Goldes um mehr als das Doppelte verbessert, wenn bei abgeschaltetem Schutzgasfluß gemessen wird; die Signale des Palladiums verändern sich dagegen nur unwesentlich. Dies gilt für beide Systeme. Wegen der Möglichkeit, größere Probenvolumina mit entsprechend größeren absoluten Proben- und Spurenmengen störungsfrei bei der Bestimmung einsetzen zu können, haben wir die Küvette HGA 72 in den Untersuchungen dieser Arbeit dem neueren Modell vorgezogen: die höhere Probeneingabe erbrachte einen Gewinn an Empfindlichkeit und Nachweisvermögen um etwa den Faktor 2.

DEVELOPMENT AND PUBLICATION OF SOLVENT EXTRACTION METHODS

Y. Marcus
Department of Inorganic & Analytical Chemistry, The Hebrew University, Jerusalem, Israel

(*Received* 14 *May* 1975. *Accepted* 6 *June* 1975)

Summary—Guidelines are set for the development of solvent extraction separation methods and for their preparation for publication. The necessity of establishing the novelty of and need for the new method is emphasized. The various items that require specification are discussed, and the criteria for successful application of the method, *viz.* completeness of extraction, selectivity and freedom from interference, are laid down.

Solvent extraction is a separation method, and as such has been used for centuries in such enterprises as the perfume industry. Applications in analytical chemistry may quite arbitrarily be said to start with the observation by Peligot, of the extractability of uranyl nitrate by ether, in 1842.[1] An established item in the classical scheme of qualitative analysis of the metal cations is the extraction of cobalt thiocyanate into amyl alcohol to form a deep blue layer.[2,3] The separation of iron(III) chloride from hydrochloric acid media by extraction with ether[4] is another early instance of the application of solvent extraction in analytical chemistry. Recent interest is evidenced by the five hundred papers in the field published annually and their biennial review by Freiser in *Analytical Chemistry*,[5] (lamentably not since 1968). In this proliferation of papers many worthwhile new methods are published, but trivial work is not excluded, nor is faulty reporting of otherwise good work. It is the purpose of this paper to point out those features of the solvent extraction methods that must be considered in any investigation, and to set guidelines for proper reporting of the results, when indeed a significant piece of work in the field of analytical chemical solvent extraction has been accomplished.

Solvent extraction has basically two functions in analytical chemistry. One is as a selective separation method, capable of handling both macro and trace quantities of the substances to be determined. It is thus a step in the isolation, concentration and purification of the substance to be determined, and is followed by several other steps leading to the final determination. The other is as a penultimate step, serving to bring the substance to be determined into a particularly favorable environment, as for some spectrophotometric determinations or radioactive counting procedures with liquid scintillators. The requirements for both modes of application are essentially the same, and prospective authors should pay attention to the following points, so that their efforts can be appreciated and evaluated on a sound basis.

ESTABLISHMENT OF THE NOVELTY OF A METHOD

As has been mentioned above, solvent extraction had an early start. It has come of age in the forties and early fifties, when many chelating agents have been established as useful extractants,[6] following the pioneering work of Fischer on dithizone[7] and of Kolthoff and Sandell on the quantitative aspects of chelate extraction.[8] Since then, highly selective chelating extractants have been found for most of the elements, capable of separating them from almost all others. It is true that this statement should be limited to metallic elements, and among these are several which are selectively extractable only as a group, not individually, *e.g.*, the alkali metals or the rare-earth metals, and that there is certainly further scope for development. When a new method involving chelating extractants for metals is offered, the following questions must be answered satisfactorily, in order to establish the novelty of the method.

1. Do satisfactory separation methods already exist to deal with the problem at hand? If the answer is *no*, the researcher and author must satisfy himself that he has interpreted the word *satisfactory* properly. Thus, an existing method need not use solvent extraction to be satisfactory; it may use *e.g.* ion-exchange or precipitation. If the answer is *yes*, the next question must be conscientiously answered.

2. Is the proposed method indeed superior to the existing methods? If the answer is *yes*, this must be demonstrated clearly, in quantitative terms. *Superior* may apply within the existing limits of applicability of the methods, or it may mean a *significant* broadening of these to cover new ground. If the answer is *no*, it is very difficult to justify the development and publication of just another method, which does no better than established methods.

A solvent extraction method consists of a combination of an extractant, a diluent (if necessary), a modifying reagent (if necessary) and certain conditions in the aqueous solution, *e.g.* controlled pH, presence of a ligand, presence of a salting-out agent, and external conditions such as temperature, time of contact, intensity of agitation. The novelty of a method rests usually in the choice of the extractant, less often in the choice of the diluent or other constituents of the organic solvent phase, or the other conditions.

If, indeed, a new extractant is proposed, it should be demonstrated that it is superior for effecting the separations to which existing extractants are applied, under the optimal conditions for applying them. That is, the comparison should be fair, and a new extractant should not be deemed superior if it outperforms existing extractants only under conditions suitable for its own application.

REQUIRED SPECIFICATIONS

Having satisfied himself, in a manner that can withstand eventual critical examination by the scientific community, that a new solvent extraction method ought to be developed, the analytical researcher must obtain the information required to specify the following data for the method that he proposes.

The solvent

The solvent is usually a composite organic phase, which may consist of the extractant(s), and/or diluent(s), and/or modifier(s). Sometimes the solvent is a single substance, which may be the extractant, or a more or less inert solvent in which a complex (chelate) formed in the aqueous phase preferentially dissolves.

The *extractant*, or extracting agent, which is the active substance in the organic phase primarily responsible for the transfer of the solute from the aqueous phase, through chelation, solvation, ion-association or some other adduct formation, must be completely specified. The specification includes the chemical composition, the structure, and if necessary, the particular isomer or conformation intended, and not merely a trivial or a trade name. It is realized that sometimes this information is not available, that a natural substance or an undisclosed commercial substance may be used to good advantage, but these must be instances explicitly justified by the circumstances. If impure materials or mixtures of materials are used, this must be clearly specified. In fact, mixtures may be superior to pure substances as extractants, with respect to cost or to performance, The cost aspect is illustrated by the use of "amyl alcohol" in preference to n-pentanol; improved performance may be due to synergistic properties of the mixture. Thus, "oppa," octylpyrophosphoric acid prepared by reacting n-octanol with phosphorus pentoxide at a proper stoichiometry, is far superior to pure *P,P'*-dioctylpyrophosphate for the extraction of uranium (IV) from phosphoric acid solutions.[9]

The *extractant concentration* range must be specified. In many cases it must stand in some stoichiometric ratio to the solute to be extracted, and a certain excess must be established. On the other hand, a large excess should sometimes be avoided, in order to repress side-reactions with this solute (formation of non-extractable higher complexes), or to repress extraction of impurities, or simply to avoid waste. The minimal and maximal concentrations at which the extractant is to be usefully applied should be established and specified. This specification should preferably be expressed in a manner readily understood, *e.g.*, the weight or volume (at a specified temperature) of the extractant taken and the final volume it was diluted to. These manipulations are ordinarily carried out in the analytical laboratory by means of pipettes and volumetric flasks, and therefore specifications such a $1 + 4$ or $1:4$, when a volume x is diluted in a volumetric flask of capacity $5x$, are to be avoided. It should be noted that this specification does *not* yield the *equilibrium* concentration of the extractant in the liquid–liquid distribution equilibrium. This is an additional item of information which is useful to specify, and authors are urged to do so, but not instead of the initial composition of the solvent to be used.

The *nature of the diluent* employed must be specified. Sometimes it is immaterial which of a large class of diluents, *e.g.*, hydrocarbons, is utilized. This must be clearly indicated, together with the name of the diluent actually used. Care must be taken in this, since seemingly inert diluents often play an important role in the extraction. If no diluent is used, *i.e.*, the neat extractant is employed, this must also be specified.

The *nature and concentration range of modifiers*, when employed, must be specified. A modifier is a substance dissolved in the organic phase to improve its properties, *e.g.*, the solubility of the extractant, or the interfacial properties. It may also exert a synergistic effect. Again, if any one from a class of substances, *e.g.*, surface-active agents, may serve, this should be established, and the particular members of this class tested should be specified. It is useful, if possible, to find out the mode of action of the modifier and disclose it. Its concentration range, however, *must* be specified, since an excess may have a deleterious effect.

The aqueous phase

Ordinarily, the aqueous solution from which a solute is to be extracted contains besides this solute some acids and salts, more rarely some organic substances. These may arise from treatment of the matrix from which the solute is to be separated, or they may be added for a purpose. The purpose may be the enhancement of the extractability of the desired solute, and/or the masking or holding back of impurities or interferences.

The *matrix* present in the aqueous phase, and which must be tolerated in the extraction method, must be specified. It is useless for analytical purposes (though not for preparative ones) if the sample must be present in the form of an essentially pure substance. The samples to be analysed provide this matrix, and the kind of matrices for which the extraction method is intended, and which will contribute constituents to the aqueous phase (*e.g.*, sea-water, silicate rocks, ferrous alloys, environmental samples) must be specified. Furthermore, certain reagents are added in the initial treatment of the sample (dissolution, prior separations) and they ordinarily remain in the aqueous phase. These should also be specified; or certain combinations of them ruled out if incompatible with the extraction method.

The *acidity* or the *pH* of the aqueous phase is usually of cardinal importance and must be specified. Chelating extractants of metals, being as a rule weak acids, have limited ranges of pH where they may be applied. The pH control employed, the buffer used, the tolerance to presence of strong acids or bases must be established and specified. Other extraction systems, on the other hand, may require a high acidity, above some threshold value, to be operative. This must then be established. Specification of the acidity is facilitated by the concept of pH_{50}, *i.e.*, the pH at which the distribution coefficient is unity, and 50% of the solute is extracted if the phase (volume) ratio is unity.

The *ligands, complexing agents* or *masking agents* added to the aqueous phase and their required or permitted concentration ranges must be specified. Sometimes, ligands are a part of the matrix, or have been added in the course of sample preparation or previous separation steps. It may be obvious to the researcher and author that a particular ligand for the metal ion is present, say chloride if the sample is customarily dissolved in hydrochloric acid. However, if the presence of chloride in the extraction step is not specified, nor its role explained, an unwary reader may for his own reasons substitute another acid in the sample dissolution step, and find to his dismay that the extraction does not proceed as expected. Similarly, most ion-pair extraction methods require a large counter-ion, say perchlorate in a particular instance. The perchlorate would have been added "naturally" if the sample had been decomposed with perchloric acid, and though nitric acid could be substituted for the decomposition, its anion might not be adequate for the extraction.

The concentration range of the ligand, complexing or masking agents is of importance, since too little may not be adequate, and too much may lead to side-reactions leading to non-extractable species. The wider the tolerance of the method, the better it is in this respect.

Salting-out agents may be required, in order to "push" the extractable solute into the organic phase. Often the ligand provided also performs this role, but sometimes reagents with highly hydrated ions or functional groups have to be added, to lower effectively the water activity in the aqueous phase. The necessity to do this should be discerned by the researcher, but obviously it would be advantageous if the procedure can dispense with this reagent. However, some highly selective extractants are too water-soluble if a salting-out agent is not employed, and its nature and minimal concentration should be specified. The researcher, however, must clarify its role, since if its only function is as a salting-out agent, often any of a large group of reagents may be adequate, and the less restrictive the procedure, the more it can be adapted for wide use.

The extraction conditions

A range of conditions can be used for the extraction of the desired solute, but it is important to find those where the separation is best, *i.e.*, as much as possible of the desired solute and as little as possible of the impurities are transferred, while reagent consumption is tolerable. Attention must be paid to the achievement of a *clean* separation, so that neither of the liquid phases is contaminated by the other.

The *phase ratio, i.e.*, the ratio of the quantity (usually volume) of the organic phase to that of the aqueous phase, is often implicitly unity, and if the distribution coefficient (or distribution ratio D) is reported, this is of minor importance. However, if the recovery factor R, the fraction of the total quantity of solute which is extracted, or the extraction factor, the ratio of its quantity in the two phases, is reported, it is essential to report also the phase ratio. It is usually difficult under analytical conditions to work outside the range of phase ratios from 0·2 to 5·0, and a procedure that requires exceptionally small or large phase ratios is to be questioned.

The *duration* and *intensity of agitation* of the two liquid phases with each other are, again, of minor importance in the usual cases. Most liquid–liquid distribution equilibria are established within 30 sec with manual shaking. On the other hand, there are chelating agents where slow kinetics of isomerization or some other step, and metal ions where slow kinetics of loss of water from the hydration sphere, lead to an overall slow extraction. Examples are the rate-controlling enolization of thenoyltrifluoroacetate,[10] and the reluctant extraction of chromium(III), unless refluxed with an extractant such as acetylacetone.[11] Researchers must, therefore, ensure that prolonged mutual contact is unnecessary, or else specify its necessity. In the latter case, account must be taken of the possibility of extractant decomposition on prolonged agitation with the aqueous phase (and air) since some extractants, notably dithizone,[12] are unstable in solution. Furthermore, use may be made of differences in the rate of extraction of two solutes in order to effect a separation between them which could not be achieved under equilibrium conditions. It is useful if this possibility is pointed out, even if not utilized for a given problem, in cases where slow extraction steps can be identified.

It is difficult to specify the intensity of the agitation, and usually it is immaterial. Occasionally, however, problems may be encountered in this respect, in particular in the presence of surface-active agents. A cautionary remark in such cases should be included, in view of the following.

A *clean phase-separation* is an essential part of an extractive separation procedure. It is extremely difficult to prevent entrainment of less than 0·1% of the wrong liquid phase, as little droplets dispersed in the bulk, or as a film or discrete drops at the surface, which will contaminate a sampling device such as a pipette. On the other hand, this limit should be approached as best as one can, and therefore conditions which favour emulsification, such as violent agitation of the phases, or the presence of surface-active agents, should be avoided as far as possible. The means employed to effect a clean separation should be mentioned in the procedure. Since one advantage of solvent extraction methods is their rapidity, a procedure which produces clean phases after 30 sec of standing is to be preferred to one that requires considerably longer standing or centrifugation. Proper choice of diluent and/or modifier and/or salting-out agents can be of great help in this respect.

The *temperature* at which the solvent extraction is carried out is usually of little consequence provided it is near room temperature, understood in this context as anywhere between 15° and 35°, dictated by climate. It is urged, however, that the temperature limits at which the results were obtained are specified, so that other workers can utilize the data for other studies. It cannot be expected that extractions for analytical purposes should be carried out in a thermostat, but there is no rule against its employment during the development of the method. If the optimal temperature for a given extractive separation is not the ambient temperature, it should of course be specified, together with the tolerance, i.e., permissible deviation.

APPLICATION OF SOLVENT EXTRACTION

In order for a solvent extraction separation method to be useful, the following have to be established: completeness of the extraction, the required selectivity, and freedom from interferences. The method must be tested with respect to all three criteria, and the results must be reported, with a valid statistical evaluation of the numerical data.

Completeness of extraction

Few, if any, analytical determinations aim at an error of less than 0·1%, hence extraction should be 99·9% complete to satisfy ordinary requirements. With a phase ratio of unity, this means a distribution coefficient of $\geq 10^3$. Higher distribution coefficients, though occurring in systems with appropriate extraction equilibrium constants and concentration ranges of the reagents, can only rarely be measured, because of the entrainment problems discussed above. Lower distribution coefficients can be tolerated, if one of the following steps is taken: the phase ratio is varied in favour of the organic phase (within the limits delineated above); a numerical correction is applied for the fraction which was not extracted (the standard procedure of correcting for *chemical yield* in radiochemical methods); best of all, extraction is repeated with fresh portions of organic solvent. The lowest practical distribution coefficient for analytical solvent extraction is about 10.

If the method is to be applied within a wide range of *extrahend* (solute to be extracted) concentrations, it is necessary to establish that either the distribution coefficients are independent of the extrahend concentration within that range, or are sufficiently large anyway. It is one of the advantages of solvent extraction methods that they can handle trace concentrations of the extrahend, since only homogeneous solutions of it in liquid phases are involved. Solvent extraction methods, therefore, seldom have inherent lower limits, practical lower limits being dictated by the effects of impurities. The upper limit of applicability is usually given by the consumption of a stoichiometric quantity of the extractant, and the necessity of some excess of the latter, which may be limited by its solubility, and the procedure must be cognizant of this.

Selectivity

As a separation method, solvent extraction presupposes high selectivity for the solute of interest. Applications where this is unnecessary are known—extraction as a concentration procedure, which is limited by phase-ratio considerations, or the transfer of the solutes into an organic environment for spectrophotometric or radiometric (liquid scintillation counting) determinations which can take care of the selectivity requirements and do not require selectivity in the extraction step. Ordinarily, however, selectivity is an essential requirement, and its achievement must be demonstrated quantitatively. It is expressed by means of separation factors, which are the ratios of the distribution coefficients of the solute of interest and of the impurities, measured under the same conditions, or by means of the *enrichment factors*, *S*, which are the factors by which the original ratios of quantities of the solute of interest and the impurities must be multiplied to give the ratios after extraction. The selectivity desired depends on the ultimate determination methods to be used after the solvent extraction separation step. Usually, procedures in which the impurities have distribution coefficients $D > 0{\cdot}1$ should be avoided, and in cases where $0{\cdot}001 < D < 0{\cdot}1$ one or more *scrubbing* steps should be employed. In these, the loaded solvent is contacted with a suitable aqueous phase, which selectively removes the contaminants from it. This may entail a slight loss of the extrahend; likewise, a slight loss of extrahend may be brought about by choosing conditions (*e.g.*, pH or extractant concentration) which depress the D values of the impurities to below 0·001, without lowering that of the extrahend much below 10^3.

The actual selectivity attained by the method *under working conditions* must be reported, not that calculated from the equilibrium constants and the reagent concentrations. Although this calculation can provide a rough guide to the attainable selectivities, major deviations may be caused by the multicomponent nature of analytical samples, and the particular contributions to the extraction system from the sample matrix, which may not have been considered in the work that led to the equilibrium constants.

Since, however, it is impractical to test the selectivity under all possible conditions, and undesirable to limit unduly the applicability of the method, it is useful to provide not only the actually determined selectivities but also the equilibrium constants involved (see below), so that the application can be extended where appropriate.

Interferences

Extraction systems are seldom specific for a given solute, but those impurities which are co-extracted with the extrahend of interest because of insufficient selectivity cannot properly be called interferences as far as the solvent extraction separation itself is concerned. They may interfere, of course, in subsequent determination steps. Interferences are those solutes which make the extraction of the extrahend less complete. This can occur mainly through two processes: binding of the extrahend in the aqueous phase, or binding of the extractant in the organic phase. If the extrahend is a metal cation, then other ligands are interferents of the first kind, if they form competitive and non-extractable complexes. Other metal cations (or hydrogen ions) are then interferents of the second kind, if they form competitive extractable complexes with the extractant. Other cations may also interfere by removing the extractant from the organic phase into the aqueous phase, if they form strong, competitive non-extractable complexes with the extractant, binding it in the aqueous phase.

It is impractical to test for all possible interferences, and therefore, again, it is useful to know the extraction equilibrium constant and any other association constants which are relevant. With this knowledge it is possible to predict whether a given solute would constitute under given conditions a serious interference or not. A serious interference, in this context, is a reduction of the distribution coefficient D of the extrahend from above 10^3 to, say $< 10^2$. A predicted interference, or non-interference, should in any case be verified by a concrete experimental example.

ADDITIONAL CONSIDERATIONS

There are several additional points which it is worthwhile to consider when developing a solvent extraction separation method. Although not as essential to the proper operation of a separation procedure as those discussed above, they permit eventual future improvements, and a widening of the applicability of the method. These are on the one hand physico-chemical details of the liquid–liquid distribution equilibrium, and on the other hand considerations relating to multi-sample, on-line, or automatic analysis.

Physical-chemical details

It is recommended that the extraction equilibrium reaction be identified, with respect to the stoichiometries involved, and the species which the extrahend forms with the extractant in the organic phase. Any side-reactions occurring in the system, such as acid dissociation of the extractant or dimerization of the extracted species, should preferably also be identified. The extraction equilibrium constant[13] K_{ex} of the distribution reaction should be determined, either as a conditional equilibrium quotient or as the thermodynamic equilibrium constant. The value of the former is dependent on the conditions, such as the concentrations of reactants and the acidity, while the latter takes into account the relevant activity coefficients. Values of the equilibrium constants of the side-reactions mentioned above should also be known.

It should be understood that the determination of these constants is optional, and its lack does not necessarily detract from the usefulness of a solvent extraction method for the particular problem for which it has been developed. However, in view of the proliferation of existing solvent extraction methods, commented on at the beginning of this article, the justification of the development of an additional method rests mainly on the wider scope it may offer. For its realization the information discussed above is indispensable, whereas the elucidation of the actual mechanism of the extraction reaction, in terms of the sequence of steps that lead to the equilibrium distribution, usually is not. The mechanism of solvent extraction reactions is rarely known and more rarely required, except in those cases where differences in the rate of extraction are utilized. In this particular application, a detailed knowledge of the mechanism is of great help.

Practical details

Thought should be given to the implication of extending the solvent extraction separation to large series of samples. For the ultimate exploitation of a method, situations such as large numbers of samples from environmental studies, or from industrial quality-control stations, or the need for continuous on-line monitoring of a system, should be considered. The rapidity of the usual solvent extraction separations (*e.g.*, 30 sec phase mixing, 30 sec phase separation) recommends them for such applications. The on-line approach is now realized with devices such as the AK-UFVE.[14] For such multi-sample applications, considerations such as the cost and availability of the extractant and other reagents at the required purity become important. Also, the chemical stability of solvent phases (avoidance of the necessity to prepare daily fresh extractant solutions, as is the case with dithizone[12]), the flammability and toxicity of diluents (even simple diluents such as toluene become a problem in this respect if handled in large quantities over a prolonged period), *etc.*, must be considered. Often it is possible to choose reagents that are least problematic in this respect, even though they may not produce optimal results if only a single separation is to be performed.

It is urged that consideration be given to these points in any case when a solvent extraction method is developed, even if they are not directly relevant to the particular application envisaged for it. The superiority of a new method over existing ones is certainly measurable by practical criteria as discussed here.

PUBLICATION

When a new solvent extraction separation method is being made ready for publication, all the points above must have been taken care of. First the necessity for the new method must have been established. Then all the relevant items must have been specified, *i.e.*, the composition of the solvent, the composition of the aqueous phase, and the extraction conditions. A definite procedure for the separation must be worked out. The function of each item in this procedure, and the range within which quantities may be varied must also be specified. It must then be shown that the desired extraction has been achieved, and with it the desired separation from the other solutes, and that the method works with respect to completeness of extraction, its selectivity, and its freedom from interferences, when the reagents and conditions are within the specification. The optional information, such as equilibrium constants, if determined, must also be ready.

In order to convince readers of the merits of the new solvent extraction method, it must now be compared in a fair way with existing solutions to the separation problem at hand. A statistical analysis of the results must be included, to show the significance of a claimed quantitative superiority.

It is desirable that internationally agreed-on nomenclature, symbols, and units be used. As regards the names of reagents, common abbreviations (see, *e.g.*, ref. 15) may be used, but they must be defined where first used in the text. Trade names and trivial names should also be accompanied by chemical names. The sources of uncommon reagents should be given.

Some of the terms relating to solvent extraction have been used rather loosely in the past. This paper contains definitions of some of the important terms, following the recommendations of international bodies.[16,17] A clear distinction must be made, *e.g.*, between the extraction (equilibrium) constant, K_{ex} pertaining to the distribution reaction, the distribution or partition constant, K_D, which is the ratio of the activities of a definite chemical species in the two phases, and the distribution coefficient or ratio, D, which is the ratio of the total analytical concentrations of a solute in the two phases. Similarly, a clear distinction must be made between the separation factor, which is the ratio of the respective distribution coefficients of two solutes measured under the same conditions, and the decontamination or enrichment factor, S, which is the ratio of the proportions of contaminant to desired product before and after treatment.

Results from a comparative study of several extractants, or several sets of extraction conditions, applied to a series of extrahends (say metal cations) are profitably displayed in distribution charts.[18] These consist of a series of "distribution strips," one for each extractant or set of extraction conditions, each strip being a one-dimensional plot of the logarithms of the distribution ratios of the extrahends. From such charts distribution ratios D and separation factors between any two extrahends may be readily read, and extraction processes can be readily compared.

CONCLUSIONS

Solvent extraction is a very powerful analytical separation method, and many applications have been and are being published. Therefore, those intending to add yet another publication in this field will do well to follow this guide, so that their contribution is significant, and of real help to others, *i.e.*, the scientific community for which the intended publication is prepared.

X-RAY FLUORESCENCE SPECTROMETRY OF COPPER INTERMEDIATES

B. W. BUDESINSKY
Analytical Laboratory, Phelps Dodge Corporation, Morenci,
Arizona 85540, U.S.A.

(*Received* 18 *June* 1974. *Revised* 8 *April* 1975. *Accepted* 25 *June* 1975)

Summary—Iron, magnetite, copper, copper(II) oxide, calcium carbonate, sulphur, silicon dioxide and aluminium oxide as components of copper intermediates (concentrates, slags, mattes, calcines and fluxes) in powdered (300–400 mesh) binary mixtures obey the Lachance–Traill equation, so the coefficients α_{AX} of interelement effects can easily be determined experimentally. They show a reasonable agreement with the theoretical values calculated from mass absorption coefficients. This fact can be the basis of a convenient routine method for the determination of intermediates. Since the intermediates exhibit differences in the distribution of their atoms (microcosmic inhomogeneity) a correction factor k_{dist} has to be used. Its value for the main components (concentrations $>5\%$) is in the range 0·92–1·24 The highest relative average deviation of the results from those of the classical "wet" methods is 2·7% for the major and 30% for the minor components.

X-Ray spectrometry is a most convenient routine method for the analysis of copper intermediates (concentrates, slags, mattes, calcines, and fluxes) because of its speed. Fusion of samples with sodium and lithium tetraborate is a favourite technique used in X-ray analysis, giving accurate results. The weighings and fusions are, however, tedious operations that become very inconvenient if a hundred or more specimens are to be assayed daily. Then the powder-specimen technique, in spite of its lower precision and accuracy, is the only convenient approach.[1]

Variations in particle size, density and adhesivity (due to electrostatic, magnetic and other factors) are the main sources of error in the powder technique. The problem of particle size can be settled by use of an efficient grinder. The other sources of error are largely eliminated by the constant properties of individual intermediates. Powder specimens exhibit strong interelement effects, however, so a proper mathematical correction of those effects is necessary.

EXPERIMENTAL

Apparatus

The instrument used was a Norelco Corporation (Mount Vernon, New York), X-ray vacuum spectrometer, with a chromium target tube.

The specimens were ground and mixed by means of a "Wigl Bug" (Crescent Dental Co., Inc., Chicago, Illinois) with a tungsten carbide capsule of 6 ml effective volume.

Materials

Iron, magnetite, copper, copper(II) oxide, calcium carbonate, sulphur, silicon dioxide and aluminium oxide powders were used as standards and for the preparation of binary mixtures. The mixtures were prepared in the "Wigl Bug" by 2 min grinding and mixing. The copper-intermediate specimens were the usual daily samples. To assay the individual elements the following "wet" methods were used: cerimetric potentiometric titration of iron, electrolytic gravimetry for copper, permanganate titration for calcium, barium sulphate gravimetry for sulphur, silicon dioxide gravimetry for silicon and aluminium phosphate gravimetry for aluminium.[2] All chemicals used were Baker analysed reagents.

Measurement

Plastic cups of 7 ml effective volume with a 1-mm hole in the bottom (for measurements in vacuum) were used. About 2 g of specimen were placed in each cup, covered with Spex-Film (Spex Industries, Inc., Metuchen, New Jersey), inserted into the metallic holder, tapped gently on a bakelite plate and inserted into the spectrometer. The parameters of measurement for individual elements are listed in Table 1.

THEORETICAL

Lachance–Traill equation

If R_A is the relative X-ray fluorescence intensity of an element A such that

$$R_A = (I_A - I_{Ab})/(I_{A1} - I_{A1b}) \qquad (1)$$

where I_A and I_{A1} are the intensities for A in the sample and a pure specimen respectively and I_{Ab} and I_{A1b} are the corresponding background intensities, the Lachance–Traill equation[3,4] has the form

$$c_A/R_A = 1 + \sum_{B}^{Z} \alpha_{AX} c_X \qquad (2)$$

where c_A and c_X are the concentrations of elements A and X, respectively (as weight fractions of the total specimen amount), and α_{AX} is the coefficient for the influence of element X on the intensity for element A. It is assumed that the specimen consists of elements A, B,...Z.

Equation (2) is a simplified Gillam–Heal[5] and Shiraiwa–Fujino[6] equation describing the general relationship between the relative fluorescent intensity of

an element and the concentrations of all elements present in the specimen. The application of that relationship to quantitative analysis is inconvenient, especially for multielement systems, because the mathematics is too complicated. There are many modifications of equation (2)[7] but the Lachance–Traill version is the most convenient for calculation.

The value of α_{AX} can either be determined experimentally from binary mixtures or calculated theoretically by means of the equation[3,4]

$$\alpha_{AX} = \frac{\mu_{X1}/\sin\theta_1 + \mu_{X2}/\sin\theta_2}{\mu_{A1}/\sin\theta_1 + \mu_{A2}/\sin\theta_2} - 1 \qquad (3)$$

where θ_1 is the angle at which radiation strikes the specimen and θ_2 is the angle of emergence of radiation. The mass-absorption coefficients μ_{A1}, μ_{X1} and μ_{A2}, μ_{X2} (for elements A and X) are measured at wavelengths of the absorption edge (subscripts 1) and characteristic line (subscripts 2) of element A. For the absorption edge an effective wavelength should be used:

$$\lambda_{E(\text{eff})} = \lambda_E - 0{\cdot}01 \qquad (4)$$

where λ_E is the value from tables. The correction is empirical and is connected with some losses of energy by scattering.[8]

Equation (3) is valid only for mixtures of pure elements since the values of the mass absorption coefficients were determined for those conditions. In practice, we often have mixtures of the oxides and carbonates. If the "dilution" by oxygen and carbon is the only effect we take into account, and the new mixture contains the elements A and X in the *same ratio* as the original mixture, then

$$R_A = R'_A \qquad (5)$$

where R'_A is the ratio of the net intensities of the new mixture and the new reference standard (*i.e.*, the corresponding oxide or carbonate).

For binary mixtures we obviously have

$$c_A = 1 - c_X \quad \text{and} \quad c'_A = 1 - c'_X \qquad (6)$$

and from equation (2)

$$(1 - c_X)/R_A = 1 + \alpha_{AX}c_X \qquad (7)$$

$$(1 - c'_X)/R'_A = 1 + \alpha'_{AX}c'_X. \qquad (8)$$

The combination of equations (5), (7) and (8) results in

$$(1 - c_X)/(1 + \alpha_{AX}c_X) = (1 - c'_X)/(1 + \alpha'_{AX}c'_X). \qquad (9)$$

If r_A represents the conversion factor from element A to its oxide (or carbonate), and r_X the corresponding factor for element X, we have

$$c'_X = c_Xr_X/[(1 - c_X)r_A + c_Xr_X]. \qquad (10)$$

Combining equations (9) and (10) we get

$$\alpha'_{AX} = r_A(1 + \alpha_{AX})/r_X - 1. \qquad (11)$$

Employing this equation we can calculate the influence-coefficient α'_{AX} of an oxide (or carbonate) mixture from the original coefficient α_{AX} calculated by means of equation (3), although this calculation is only approximate because of the simplifications made.

Structural and trace element effects

It is well known[9] that certain deviations sometimes occur if equation (2) is applied to multielement mixtures. Those deviations are explained by enhancement and polychromaticity effects and there have been attempts to correct them by expansion of the right-hand side of equation (2) to include terms with higher powers of the concentration.[7,10] In our opinion, this is completely justified only if the binary mixtures and sample specimens exhibit exactly the same distribution of atoms of the elements to be determined (microcosmic homogeneity). Unfortunately, the copper intermediates do not meet that condition. Both copper and iron are able to form with sulphur a great variety of compounds, the distribution of which in the test specimens is virtually unknown.[11] Since most of the bonds are covalent in character it is uncertain, even for pellets prepared by fusion, whether the condition of microcosmic homogeneity is met.

The uncertainty in the composition of the specimens (it also affects the system of iron and oxygen) leads to the fact that the equation

$$\sum_{A}^{Z} c_X = 1 \tag{12}$$

the validity of which is the necessary condition of equation (2), may not hold exactly, the sum coming to 0·90–0·95 instead of 1·00. Fortunately, the effect of those factors [microcosmic inhomogeneity plus failure of equation (12)] is relatively small and sometimes negligible; nevertheless, it requires the introduction of an additional distribution correction constant k_{dist} such that the final concentration of an element A is given by the equation

$$c_A^{\text{corr}} = k_{\text{dist}} c_A. \tag{13}$$

The values of k_{dist} can be calculated by measurement of a set of standards (concentrations c_A^{std}) and use of the equation

$$\sum c_A^{\text{std}} = k_{\text{dist}} \sum c_A. \tag{14}$$

The determination of c_A^{std} by "wet methods" must be performed with the greatest care and accuracy. Equation (14) is another approximation justified by the relatively constant composition of test specimens. A high value of k_{dist} can be due to incorrect values of α_{AX} and of the background.

RESULTS AND DISCUSSION

A typical dependence between the particle size and the fluorescence intensity is presented in Fig. 1. It shows that for particles finer than about 300 mesh the fluorescence intensity becomes independent of the particle size.

The behaviour of binary mixtures of the eight most common components of copper intermediates is illustrated in Fig. 2. The function of $c_A/R_A = f(c_A)$ shows very good agreement with the equation (2) so that no special treatment of the polychromaticity and enhancement effects is necessary. The values obtained for the influence coefficients α_{AX}, together with the theoretical values calculated by means of equations (3) and (11), are presented in Table 2. Taking into account the approximations in the theoretical calculation, there is reasonable agreement between the experimental and theoretical values. It should be kept in mind that the values can vary according to the geometry of the spectrometer.

Dependence $c_A/R_A = f(c_A)$ of binary mixtures. *a*: 1, $CaCO_3$–Fe; 1', Fe–$CaCO_3$; 2, $CaCO_3$–SiO_2; 2', SiO_2–$CaCO_3$; 3, $CaCO_3$–Fe_3O_4; 3', Fe_3O_4–$CaCO_3$; 4, S–CuO; 4', CuO–S; 5, S–Fe; 5', Fe–S; 6, Fe_3O_4–S; 6', S–Fe_3O_4. *b*: 1, Cu–Fe; 1', Fe–Cu; 2, $CaCO_3$–CuO; 2', CuO–$CaCO_3$; 3, $CaCO_3$–Al_2O_3; 3', Al_2O_3–$CaCO_3$; 4, S–Cu; 4', Cu–S; 5, S–SiO_2; 5', SiO_2–S; 6, S–Al_2O_3; 6', Al_2O_3–S. *c*: 1, SiO_2–Cu; 1', Cu–SiO_2; 2, Al_2O_3–Fe; 2', Fe–Al_2O_3; 3, SiO_2–Fe; 3'; Fe–SiO_2; 4, SiO_2–Fe_3O_4; 4', Fe_3O_4–SiO_2; 5, $CaCO_3$–Cu; 5', Cu–$CaCO_3$; 6, CuO–Fe_3O_4; 6', Fe_3O_4–CuO. *d*: 1, Al_2O_3–Cu; 1', Cu–Al_2O_3; 2, $CaCO_3$–S; 2', S–$CaCO_3$; 3, SiO_2–CuO; 3', CuO–SiO_2; 4, Al_2O_3–Fe_3O_4; 4', Fe_3O_4–Al_2O_3; 5, Al_2O_3–CuO; 5', CuO–Al_2O_3; 6, SiO_2–Al_2O_3; 6', Al_2O_3–SiO_2. The first component is A.

The estimated experimental values of α_{AX} were used in equation (2) for the assay of copper intermediates. The calculation was done by means of a general program for 3–6 components (machine model 1860, Monroe Co., Orange, New Jersey), which can be easily extended to any higher number of components. The results together with the results of "wet methods" are presented in Table 3. A relatively good agreement of both methods can be seen. Some higher deviations can be explained in terms of errors in both methods. The higher deviations of converter flux specimens are due to the low density. The instrumental drift was corrected by measurement of one standard. It is useful

Table 4. Some empirical methods investigated*

Reference	Equation	Comment
13	$c_A = k_A + I_A(k_{AA} + \sum_{B}^{Z} k_{AX} I_X)$	Poor results
12	$I_A = k_A + c_A(k_{AA} + \sum_{B}^{Z} k_{AX} I_X)$	Good for SiO_2 in converter flux
14	$c_A = k_A + \sum_{A}^{Z} k_{AX} I_X$	Good for narrow range of concentrations
12	$I_A = k_A + \sum_{A}^{Z} k_{AX} c_X$	Poor results

* For the meaning of individual symbols see the text; k_A, k_{AA}, k_{AX} are the empirical interdependent constants determined by least-squares method.

to repeat the standard measurement for each set of samples in the spectrometer.

The Rasberry–Heinrich[7] and Claisse–Quintin[10] methods give better results for copper intermediates than the Lachance–Traill method. However, even with those methods an additional correction for structural and trace-element effects is necessary. The iteration technique is the only mathematical approach by which those methods can be applied to multielement systems, which, together with the considerably higher number of correction constants, represents a drawback of those methods which is not always compensated by a better accuracy and precision.[12]

From the practical viewpoint of routine analysis, the present method and all methods employing true influence constants have one drawback. They require the intensity measurement of all components of a specimen to satisfy equation (12). That could sometimes be inconvenient, if the concentration of only one or two elements is of interest. In those cases, some workers prefer a solely empirical relationship between the concentrations of the given elements and their intensities (usually on the basis of a regression formula). That relationship is able to produce quite good results if the concentrations of all elements present are in a certain relatively narrow range. However, the trouble is that there is not sufficient evidence that that condition is obeyed. We have investigated several empirical regression methods. Their brief description and evaluation is given in Table 4.

The practical importance of the Lachance-Traill method was stressed recently by the fact that Norelco Corporation (Mount Vernon, New York) introduced it as a built-in method for their machines.

The computer program can be obtained upon request. It includes the counter dead-time, background, and instrumental-drift corrections.

TRACE ANALYSIS FOR CHLORINATED HYDROCARBONS IN AIR BY QUANTITATIVE COMBUSTION AND COULOMETRIC CHLORIDE DETERMINATION

APPLICATION TO STANDARDIZATION OF VINYL CHLORIDE PERMEATION TUBES

A. Cedergren and S. Å. Fredriksson

Department of Analytical Chemistry, University of Umeå, S-901 87 Umeå, Sweden

(*Received* 28 *April* 1975. *Accepted* 22 *May* 1975)

Summary—Methods for high-temperature combustion of vinyl chloride in air were studied theoretically and two types of gas mixtures were found to give 100% conversion into HCl. The chloride was determined by coulometric titration with silver, in 70% acetic acid. Good agreement between theoretical and experimental results was obtained. Permeation rates of vinyl chloride from fluorinated ethylene propylene permeation tubes were determined gravimetrically and with the coulometric method developed. The standard deviations of the methods were 0·002 and 0·001 μg/min respectively for permeation rates of 0·5 μg/min when the temperature was controlled to ± 0·02°. The coulometric mean value was 99·9% of the gravimetric mean; 1 ppm of vinyl chloride in air could be determined coulometrically with a standard deviation of about 0·002 ppm.

Vinyl chloride has been linked to several liver cancer deaths among production workers and the maximum concentration allowable in factories has consequently been decreased. Taking the U.S. as an example, from 1 January 1975, vinyl chloride in workplace air has to be reduced to 1 ppm (v/v), averaged over an 8-hr period.

Very few methods for the trace determination of vinyl chloride in air have been described in the literature. Vinyl chloride can be absorbed[1] on activated carbon and then converted into formaldehyde, which is measured spectrophotometrically at 594 nm. This method must be calibrated with a standard of vinyl chloride in air. However, no primary standard for vinyl chloride has yet been described in the literature as far as we know. A gas-chromatographic method[2] using the flame-ionization detector has recently been described. The detection limit is reported to be 0·05 ppm and the method is simple and rapid. However, the apparatus must be calibrated with standard samples of vinyl chloride in air. The standards used[2] were obtained by a dilution procedure which resulted in a precision of about 10% at the 1-ppm level. In a recent paper[3] the use of a vinyl chloride permeation tube for calibration of a gas-sampling valve for gas chromatography was described. However, no determinations of permeation rate were reported.

This paper reports the investigation of a permeation-tube gas standard for vinyl chloride in air. The permeation rate was determined by two independent methods; a gravimetric and a coulometric. The latter method required a high-temperature conversion step to convert the chlorine in vinyl chloride into hydrogen chloride. The chloride can be determined very accurately in the nanomole range with a coulometric procedure. The development of the coulometric method involved a theoretical study of the combustion conditions for quantitative conversion into hydrogen chloride. Of special interest with regard to the coulometric titration was the determination of combustion conditions for 100% recovery of hydrogen chloride with formation of a minimum amount of water.

Several coulometric methods for the determination of chlorinated hydrocarbons[4–6] have been described. The sample is combusted in oxygen and the HCl formed is titrated with silver ions. The most commonly used titration medium is a mixture of acetic acid and water. The main drawback of these coulometric methods is that the recovery of HCl is strongly dependent on the matrix. For a hydrocarbon sample containing traces of chlorine the recovery[6] is 100%, but for traces of chlorinated hydrocarbons in air the recovery is very dependent on the combustion conditions.[7] It has been observed that addition of water, *e.g.*, humidification of the combustion gases, increases the recovery.[7] The theoretical reasons for these variations are given below in this paper.

Permeation tube

From its boiling point and its vapour pressure at room temperature, vinyl chloride seems to have the fundamental physical properties required for the permeation-tube technique. The permeation rate F is affected by the temperature, T, according to

$$F = F_0 \exp(-E/RT) \qquad (1)$$

where E is the activation energy. The value of E is rather high (about 10 kcal/mole) for fluorinated ethylene propylene co-polymer (FEP), which means that the permeation rate is very temperature-sensitive.

High-temperature equilibria

The system investigated is given by reaction (2) which corresponds approximately to the combustion of 150 ml of air containing 1 ppm (v/v) of vinyl chloride. The primary aim was to determine the conditions for obtaining a 100% recovery of HCl; x and y represent varying additions of hydrogen and carbon monoxide respectively to the mixture.

$$120N_2 + 30O_2 + 1{\cdot}5 \times 10^{-4}CH_2{=}CHCl + xH_2 + yCO \rightarrow \text{Products} \quad (2)$$

Because of the great complexity of this system we chose to use the computer program SOLGAS[8] which is a general program for the determination of high-temperature equilibria in systems containing an ideal gas phase and condensed phases of invariant composition. This program uses the free-energy minimization principle which was introduced by White *et al.*[9] An introductory book on equilibrium calculations has been written by van Zeggeren and Storey.[10] Recently, a thorough discussion of the SOLGAS[8] computer program was given by Eriksson.[11]

In order to perform chemical equilibrium calculations it is necessary to ascertain that equilibrium in the system has been attained. Generally, the probability of reaching equilibrium increases with increasing temperature.

The system dealt with in this paper contains five elements: C, H, O, Cl and N. In our system [see equation (2)] the following gaseous products were considered at equilibrium and at a total pressure of 1 atm: CO, CO_2, H_2, O_2, H_2O, N_2, HCl, HClO, ClO, Cl, Cl_2, $COCl_2$, CCl_4, CH_2Cl_2 and $CHCl_3$. Substances like CH_4, NO and NO_2 which also are thought to be possible reaction products were cancelled because they were not present in such concentrations that they were able to affect the mass balances. The values of the Gibbs free energy of formation of HCl, H_2O, CO and CO_2 are in this case very important for the results. The thermodynamic data for these substances have been determined with very high accuracy and an estimation of the quality of the data is available in JANAF.[12] Provided equilibrium is attained the calculations are expected to give very precise results.

EXPERIMENTAL

Gravimetric procedure

Permeation tubes, FEP (fluorinated ethylene propylene), were prepared according to the procedure proposed by O'Keeffe and Ortman.[13] The tubes (0·25 cm i.d., 0·40 cm o.d., 3–5 cm in length) were sealed with steel balls. The tubes were stored in test-tubes and a low flow of nitrogen was flushed through the test-tubes, which were connected in series. The effluent nitrogen was passed through a bottle of paraffin oil to absorb the entrained vinyl chloride. The test-tubes, each containing one permeation tube, were immersed in a thermostat. The temperature constancy was 25·0 ± 0·1° during a period of three months. With careful

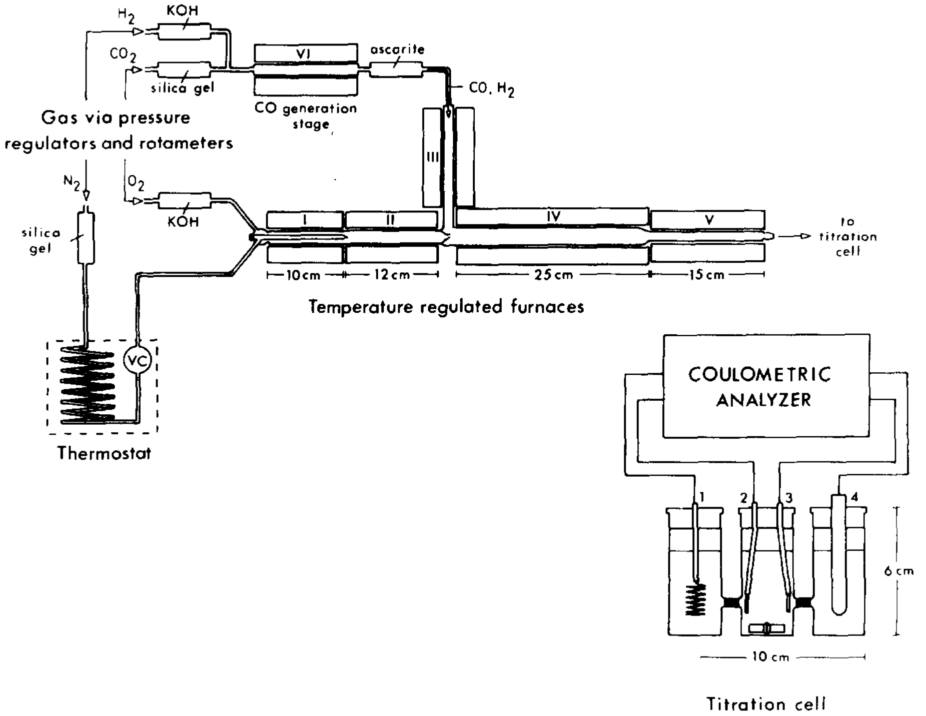

Fig. 1. Experimental arrangement. (1) Auxiliary electrode, (2) working electrode, (3) indicating electrode, (4) reference electrode, (VC) the vinyl chloride permeation tube.

adjustment of the heating and cooling, the temperature constancy within over an 8-hr period was 25·0 ± 0·02. The permeation tubes were normally weighed once a week.

Coulometric procedure

Six electrically heated ovens were arranged as shown in Fig. 1. The ovens I–V were provided with thermoelements connected to thermoregulators which kept the temperature constant within 10°. The combustion tube was made from quartz and its outlet tube was provided with a ground joint. The coulometric cell was placed very close to the outlet tube in order to eliminate the need for a heater. All gases were taken from high-pressure cylinders *via* reduction-valves, needle-valves and rotameters. The purity of the gases with respect to HCl and chlorinated hydrocarbons was examined. HCl was easily removed by absorption on solid potassium hydroxide and chlorinated hydrocarbons were pyrolysed to form HCl which was then absorbed on solid potassium hydroxide or "Ascarite". Normally this pyrolysis step was not needed. CO was produced at 1300 K by reaction between CO_2 and graphite according to the reaction $CO_2 + C \rightleftharpoons 2\,CO$. At 1300 K more than 99·9% of the CO_2 was transformed into CO. The amount of water in the gases as well as the water formed in the combustion was determined coulometrically according to a method developed earlier.[14] The rotameters were calibrated with soap-bubble flowmeters. The flow of hydrogen was also determined by coulometric determination of the amount of water formed. The agreement between these two methods was about 5% for a hydrogen flow of 1 ml/min.

A coulometric cell was made from glass with Teflon caps as shown in Fig. 1. It consisted of three chambers, one for the platinum auxiliary electrode, one for the generating silver wire (1 cm^2) electrode and the silver indicating electrode (diam. 1 mm, length 5 mm) and one for the Radiometer K 601 mercury–mercurous sulphate reference electrode. All compartments were filled with 15 ml of 70% (v/v) acetic acid (*p.a.*). Electrolytic contacts were made *via* asbestos-filled liquid junctions. Asbestos (Hopkin & Williams) was plugged tightly with a hard tool into the connecting glass tubes. The electrodes were cleaned once a day in concentrated nitric acid and rinsed carefully with distilled water. The generating electrode was placed close to the junction of the auxiliary electrode and the indicating electrode close to the reference electrode junction in order to minimize the interference from the generating electrode system with the indicating system. Further, the three compartments were arranged in line so that there should be geometric symmetry in the sample compartment. The sample compartment was provided with a gas-inlet tube and a magnetically-driven stirrer bar. The influence of light was minimized by wrapping the sample compartment with aluminium foil. The titration procedure was started by addition of at least 50×10^{-9} mole of chloride to ensure that solid silver chloride was always present in the sample compartment electrolyte.

The electrodes were connected to an LKB 16300 Coulometric Analyzer. This instrument contains a high-impedance voltmeter which measures the voltage between the indicator and the reference electrodes. This voltage is compared with a preset voltage and any deviation is amplified and used to control the current through the generating-electrode system. The gain and preselected indicator-electrode potential can be used to choose a suitable silver ion concentration during a continuous titration of chloride. A difference of 5–10 mV between the preselected potential and the indicator-electrode potential was found to be suitable. Normally the preselected potential was chosen to be −100 mV which corresponds to a potential value in the neighbourhood of the equivalence point of the titration. The amount of electricity required to titrate the chloride was recorded by an electronic integrator which could be read to 1×10^{-11} mole.

RESULTS

Gravimetric determinations

Weight losses for six permeation tubes are plotted *vs.* time in Fig. 2. The mean values and the standard deviations of the permeation rates during three months are given in Table 1 for 6 tubes. Only weight changes of more than 5 mg have been included in the calculations. A variation of 1% in the permeation rate corresponds to a temperature variation of 0·1°, which means that the temperature variation is the main factor influencing the standard deviations presented in the Table 1. The steel balls used to seal the permeation tubes were somewhat affected by corrosion. A precipitate, probably PVC, was formed inside the tube. The HCl formed in the polymerization process is known to catalyse the corrosion process. None of these products seemed to affect the permeation process. The assumed polymerization process can probably be reduced in extent by the use of stainless-steel balls.

Theoretical calculations

Case A. Flow of CO is zero. Figure 3 shows the recovery of HCl as a function of temperature and the amounts of H_2 added to 150 ml of air (120 ml of N_2 + 30 ml of O_2) containing 1 ppm (v/v) of vinyl chloride. The total pressure was assumed to be 1 atm. As can be seen in the figure there is a maximum on each curve between 900 and 1000 K. At such low temperatures the equilibrium is not expected

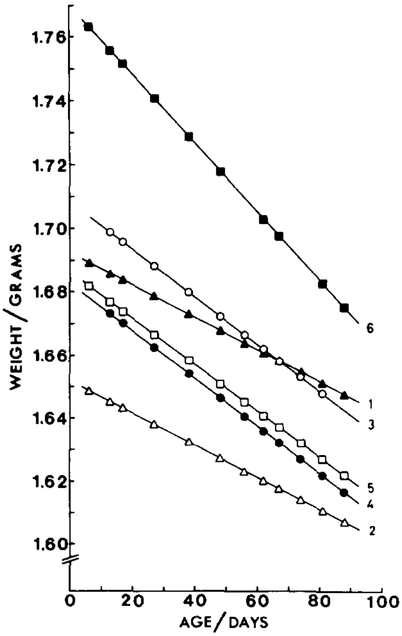

Fig. 2. Weight losses for six permeation tubes as a function of time. The mean value and standard deviation of the weight differences for the respective tube are given in Table 1.

Table 1. Gravimetric determinations of the permeation rate of vinyl chloride during a period of three months

Tube No.	Permeation rate mean value, *μg/min*	Number of determinations	Std. devn., *μg/min*	Rel. std. devn., %
1	0·352	11	0·0040	1·1
2	0·352	11	0·0085	2·4
3	0·514	10	0·0065	1·3
4	0·524	10	0·0075	1·4
5	0·509	11	0·0075	1·5
6	0·744	9	0·0079	1·1

to be reached rapidly enough, so it is perhaps more realistic to comment on this diagram for temperatures of the order of 1200 K. At this temperature about 50 ml of H_2 are needed to obtain 100·0% recovery of HCl: 50 ml of H_2 will, after reaction with O_2, give rise to about 37 mg of water, which causes a very unfavourable situation with respect to the coulometric detector, as will be shown later. It is thus necessary to add a rather large amount of H_2 to the air sample in order to obtain a high recovery of HCl. It is not necessary, however, to add H_2 in excess of O_2.

Case B. CO present. As is well known, in a combustion of an organic matrix it is not necessary to add H_2 when only traces of chlorine are present. This is so because H_2 is formed in the water-gas equilibrium (3) in sufficient amounts to yield 100% recovery.

$$CO(g) + H_2O(g) \rightleftharpoons CO_2(g) + H_2(g) \qquad (3)$$

This was explicitly shown in a recent paper by Cedergren.[15]

Consequently, we studied the influence of CO added to the gas mixture. Figure 4 shows the recovery of HCl at 1200 K as a function of H_2 and CO added to 150 ml of air containing 1 ppm (v/v) vinyl chloride.

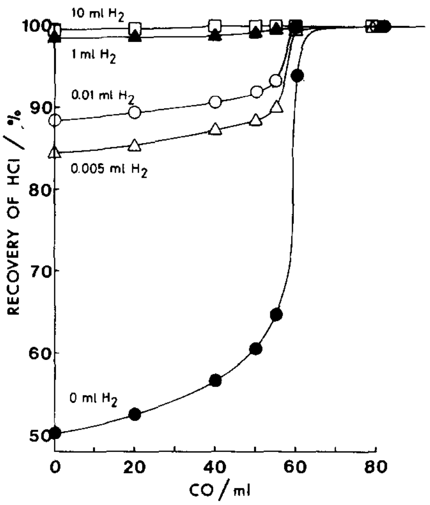

Fig. 4. The theoretical recovery of HCl at 1200 K as a function of H_2 and CO added to 150 ml of air (30 ml of O_2 + 120 ml of N_2) containing 1 ppm (v/v) vinyl chloride. The total pressure was 1 atm.

The smallest amount of H_2 for which a recovery of 100·0% is obtained is about 0·01 ml at CO = 60 ml. This amount of H_2 corresponds to a humidity of the air of about 67 ppm (v/v).

In Fig. 5 the recovery of HCl is given as a function of the amount of CO added to 150 ml of air containing 1 ml of H_2 and 1 ppm (v/v) vinyl chloride. The system was studied at 1100, 1200 and 1300 K. As can be seen, at least 60 ml of CO must be added in order to attain 100·0% recovery.

Figure 6 shows the distribution of other chlorine-containing compounds such as Cl(g), HClO(g), ClO(g), Cl_2(g) as a function of different volumes of CO added to the above-mentioned gas mixture at

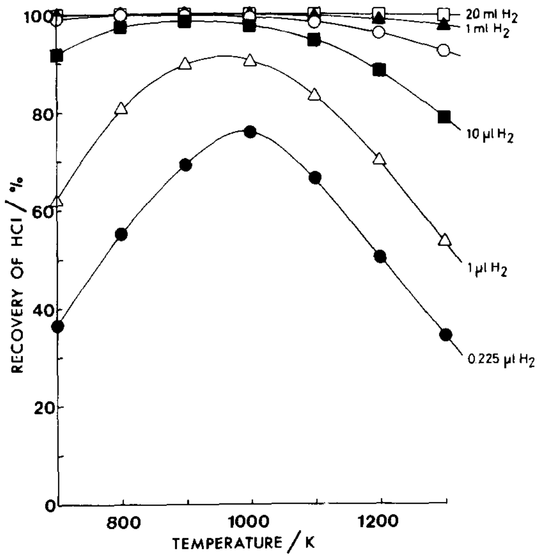

Fig. 3. The theoretical recovery of HCl as a function of temperature and the volume of H_2 added to 150 ml of air (30 ml of O_2 + 120 ml of N_2) containing 1 ppm (v/v) vinyl chloride at a total pressure of 1 atm.

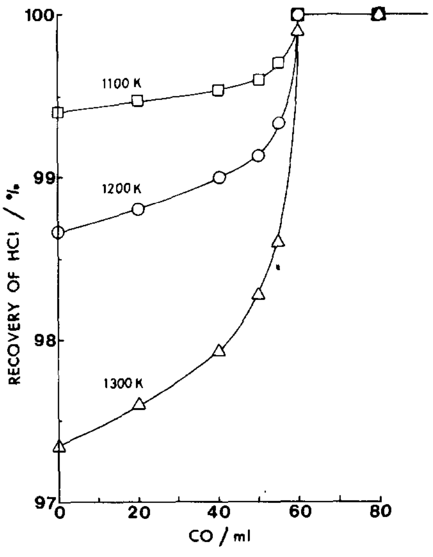

Fig. 5. The theoretical recovery of HCl at 1100 K, 1200 K and 1300 K as a function of CO added to 150 ml of air (30 ml of O_2 + 120 ml of N_2) containing 1 ppm vinyl chloride. The amount of H_2 added was 1 ml.

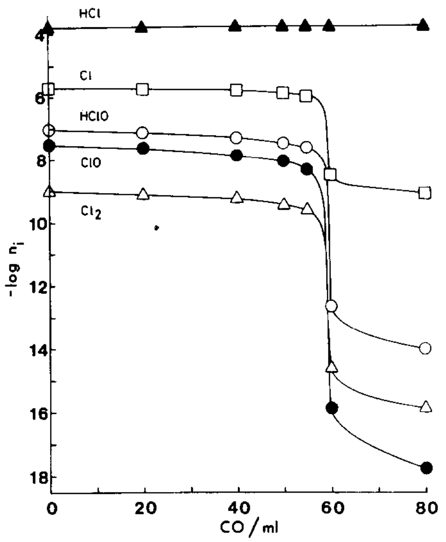

Fig. 6. Distribution of various chlorine-containing compounds at 1200 K as a function of various volumes of CO added to 150 ml of air containing 1 ppm (v/v) vinyl chloride. The amount of H_2 added was 1 ml. n_i is the number of moles of substance at equilibrium.

1200 K (1 ml of H_2 is also added). $COCl_2$, CCl_4, CH_2Cl_2 and $CHCl_3$, which were initially considered, are neglected in Fig. 6 because they were present in very small amounts.

Coulometric determinations

A coulometric determination of the permeation rate was made as shown in Fig. 1. Nitrogen was passed at 120 ml/min over a permeation tube containing vinyl chloride and into the combustion tube where it was mixed with oxygen flowing at a rate of 30 ml/min. The gas mixture was preheated in oven I to 800 K. The combustion occurs in oven II in an excess of oxygen. The temperature was kept between 1100 and 1200 K and was not critical. Dried CO_2 and H_2 were mixed and passed through a quartz tube filled with graphite, in oven VI which was kept at 1300 K. The carbon dioxide was converted into CO with almost 100% efficiency. H_2 passes this reactor unchanged. The gases were dried and preheated in oven III at 1200 K and mixed with the combustion products in oven IV. A preliminary investigation showed that this oven must be kept at 1200 K in order to reach equilibrium sufficiently quickly. If the gas mixture entering the titration cell is too hot, the evaporation will be high. Oven V was therefore kept at 1000 K, which also favours formation of HCl in the gas mixture, see Fig. 3. The gas was bubbled through the sample compartment of the titration cell, where it was titrated continuously with coulometrically generated silver ions.

Table 2 shows the recovery of HCl when the flows of CO and H_2 were varied. The results are also compared with recoveries calculated by the method discussed above and it can be seen that the agreement is good except for the first value. The discrepancy might depend on difficulties in measuring the very low flow of H_2. It should also be noted that the calculations were made for 1200 K in oven IV as the rate was too low at lower temperatures. The equilibria might change somewhat in oven V, resulting in a higher recovery of HCl than that calculated, compare Fig. 3.

Table 2. The recovery of HCl as a function of H_2 and CO at 1200 K. O_2 = 30 ml/min; N_2 = 120 ml/min; $CH_2{=}CHCl$ = 7·42 × 10^{-9} mole/min (mean value of gravimetric results)

H_2*, *ml/min*	CO, *ml/min*	HCl found† mean values, %	Rel. std. devn., %	Number of dtns.§	Theoretical recovery of HCl, %
0·01	0	92	1	3	88·3
0·1	20	97·7	—	2	96·3
1	0	98·6	0·1	3	98·7
1	20	99·0	0·1	10	98·8
1	60	99·9	0·1	10	100·0
0·6	80	99·8	0·2	3	100·0

* Determined as water after reaction with oxygen.

† The values are related to the gravimetric mean value: 7·42 ± 0·04 nmoles of vinyl chloride per min.

§ The time for each determination was 5–10 min.

There are several combinations of H_2 and CO which give high recovery of HCl. At 60 ml/min practically all CO is converted into CO_2 by the oxygen and it is desirable to limit the CO to this value as the excess is emitted to the air. Therefore the selected CO_2 gas flow was 30 ml/min which equals a CO flowrate of 60 ml/min after reaction with the graphite. The flow of H_2 required then becomes 1 ml/min or somewhat less.

By use of the optimum conditions deduced, the permeation rate of a tube was determined and the results are given in Table 3, which also contains the results of gravimetric determinations on the same tube. As can be seen, the coulometric method gives precise results which are in good agreement with the gravimetrically determined values. The coulometric results were corrected for a blank value which was about 1% of the sample value, *i.e.*, less than 10^{-10} mol of chloride per min. The variation in the blank was less

than 10%. The blank can be determined by by-passing the permeation tube.

The temperature-dependence of a permeation tube is represented in Fig. 7. The dotted line in Fig. 7 shows the temperature of the thermostat as a function of time. A change from 25·0 to 26·0° resulted in an increase of the permeation rate from 7·40 × 10^{-9} to 7·85 × 10^{-9} mole/min. About 4 min were needed to obtain a constant permeation rate when the temperature was changed from 25·0 to 26·0°, compared to about 10 min when the temperature was changed from 26·0 to 30·0°. A change in temperature of 0·1° will thus correspond to a change of approximately 1% in the permeation rate and this is about the same as for sulphur dioxide when FEP-tubes are used.[16]

DISCUSSION

The effect of water on the titration system

In a continuous titration using 1 ml of H_2 per min in the combustion there is formation of about 0·7 μl of H_2O per min. In 1 hr this will correspond to 42 μl of H_2O. The error due to the dilution effect of this volume of H_2O on 15 ml of 70% (v/v) acetic acid was negligible. On the contrary if only H_2 (or H_2O) had been used to obtain complete conversion into HCl it would have been necessary to add about 50 ml of H_2 per min. This would have resulted in the formation of 37 μl of H_2O per min or 2 ml in 1 hr. Figure 8 explains the effect of dilution of the titration medium. In this experiment 2 ml of H_2O were added to 15 ml of 70% (v/v) acetic acid. Two titrations were done; one for 15·0 ml of 70% acetic acid and one for 15·0 ml of 70% acetic acid + 2 ml of water. The figure shows explicitly the end-point displacement resulting from dilution of the solvent.

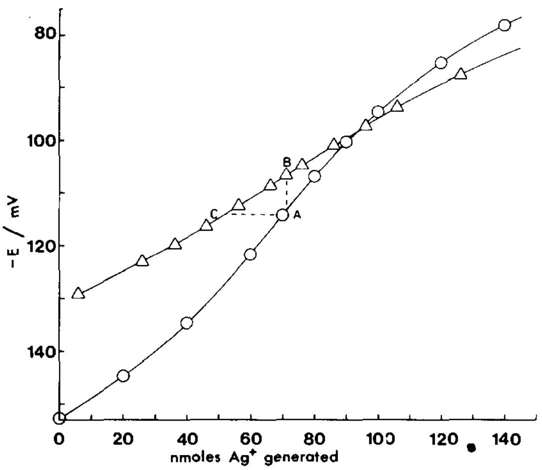

Fig. 8. The effect of diluting the titration medium with water. For the significance of A, B and C, see the text under "Discussion". (○) 15 ml of 70% HAc, (△) 15 ml of 70% HAc + 2 ml of H_2O.

The potential of point A in Fig. 8 is the equivalence point for use of the 70% (v/v) solvent. When this solvent is diluted the potential of the new system corresponds to point B because in both cases there must be equivalence between chloride and silver ions. As the coulometric analyser titrates to a predetermined potential it will titrate to point C. The error, which is negative in this case, will correspond to the marked difference CA on the abscissa. As shown earlier,[17] this water effect can be compensated for either by adding the equivalent of distance CA in Fig. 8 to the result read on the integrator or by selecting an end-point other than the equivalence point. However, the corrected result will be more uncertain than that determined by the present method in which this type of error is eliminated. For this reason conditions corresponding to Case B in the calculations, *i.e.*, addition of CO, were selected.

Comparison between the coulometric and the gravimetric methods

As was shown in Table 3, the results obtained by the coulometric and the gravimetric methods were not significantly different from each other. In fact the mean values of the coulometric results were about 99·9% of the gravimetric mean value. However, it is difficult to prove that the coulometric method is capable of giving a recovery of 100·0%, because of the relatively large standard deviation of the gravimetric method to which the coulometric mean value is referred. In order to obtain a precision of 1% by the use of the gravimetric method about three weeks were needed and during this time three weight differences of about 5 mg each could be obtained provided that the permeation rates were of the order of those presented in this paper. The coulometric method for standardizing the permeation tubes was very rapid. In less than 1 hr the permeation rate could be determined with a precision of about 0·1%. In this time about eight 5-min titrations plus a blank run could be performed.

The relative standard deviation of 0·2% which was obtained for determinations of 1 ppm of vinyl chloride in air on different occasions is equal to an uncertainty of about 0·002 ppm (v/v). This means that the coulometric method is capable of accurate and rapid standardization of test atmospheres in the range 0·1–100 ppm (v/v).

(*Received* 17 *March* 1975. *Accepted* 16 *June* 1975)

Summary—A method is presented for the determination of niobium, tantalum and tungsten in steel and non-ferrous alloys, based on hydrolysis with sulphurous acid followed by X-ray fluorescence measurements. The limit of determination is about 0·002% and the standard deviation is 0·002 at the 0·05% level. Results below 0·01% by this method are only semiquantitative.

A rapid chemical X-ray method is proposed for determining trace amounts of niobium, tantalum and tungsten in iron-base and non-ferrous alloys. Standard wet chemical procedures for these elements tend to be time-consuming and lack sufficient sensitivity for accurate analysis at levels less than 0·1%.[1] Direct instrumental methods (X-ray, atomic absorption and optical emission) are severely limited by the number and types of standards available as well as by a general lack of sensitivity at levels below 0·01%. For the method described in this report, the ease and speed of sample preparation together with the demonstrated accuracy and precision render it extremely useful for the determination of these elements at trace levels, a task which is becoming increasingly more important in alloy development programmes and is widely pursued at Crucible's Research Center for a number of traces, already reported.[2,3] The method utilizes the hydrolysis of niobium, tantalum and tungsten in the dissolved sample before their determination by X-ray fluorescence. All three elements are chemically characterized by a strong tendency to hydrolyse, enhanced by the use of sulphurous acid (H_2SO_3).[4,5] X-ray examination of hydrolysed niobium, tantalum and tungsten oxides on the same sample, showed constant and reproducible recoveries of the elements, thus offering a simple method for their determination without tedious separations and with no involved sample preparation.

EXPERIMENTAL

X-Ray apparatus

A Siemens X-ray fluorescence spectrograph, type "Crystalloflex IV", with an X-ray generator and control having a full-wave rectified power-supply voltage and current regulation up to 50 kV and 40 mA in air, and a high-purity gold target, was used.

Materials

Niobium, tantalum and tungsten solutions, 0·10 *mg/ml.* Dissolve 0·10 g of the appropriate metal in 20 ml of hydrofluoric acid–nitric acid mixture (1:1) and dilute with distilled water to 1000 ml.

Procedure

Weigh a sample containing between 0·20 and 1·0 mg of niobium, tantalum and tungsten and transfer it to a 600-ml beaker. Add 50 ml of water followed by 50 ml of concentrated hydrochloric acid. Heat gently and add 10 ml of concentrated nitric acid to complete the dissolution. Add 30 ml of 70% perchloric acid and evaporate to low volume (20–25 ml). Dilute to 200 ml with boiling water and add, while stirring, 30 ml of sulphurous acid (7·3% SO_2). Boil for 10 min and allow to stand for 10 min before filtering off on a 0·22-μm micropore membrane. Wash the precipitate with boiling water, air-dry for 1 min and mount the membrane in a suitable holder for X-ray analysis. Place the mounted membrane in the X-ray spectrograph and determine niobium, tantalum and tungsten sequentially, starting with niobium, according to the following conditions:

Primary voltage	50 kV
Primary current	40 mA
Detector	Scintillator
Detector voltage	500–700 V
Pulse-height analyser base-line	8 V
Pulse-height analyser channel-width	8 V
Preset time	24 sec
Crystal—lithium fluoride 1st order K_α radiation for niobium, 1st order L_β radiation for tantalum, L_α radiation for tungsten	
2θ values	Nb 21·41° Ta 38·47° W 43·00°

Measure the counts accumulated during a fixed time (24 sec), also the number of counts accumulated at a 100 V higher detector voltage for niobium and at 1° above the 2θ values for tantalum and tungsten; take the difference between the two counts for the element sought and divide it by the fixed time to calculate the count-rate.

Plot counts/sec against mg of niobium, tantalum and tungsten to construct calibration graphs, using a set of synthetic standards consisting of 1·0 g of pure iron containing 0·1–1·0 mg of the element of interest and treated according to the procedure. Calibration graphs constructed by the use of electrolytic iron dosed with niobium, tantalum and tungsten are linear over the range from 0·1% down to just below 0·02% of the element (Table 1).

RESULTS AND DISCUSSION

A number of individual samples of ferrous and non-ferrous materials, including certified standards, were analysed in order to evaluate the accuracy, precision and reproducibility of the method.

Table 1 shows that for both niobium and tungsten it appears that at 0·20 mg the method is operating at its limit of detection. For tantalum the detection of levels lower than 0·06 mg seems feasible although the accuracy below 0·20 mg is questionable.

To evaluate the accuracy, NBS stainless and low-alloy steel samples were analysed for the three elements. Results obtained by use of the original calibration graphs used for the data in Table 1 are given in Tables 2 and 3; duplicate results are reported. In general, agreement between duplicate analyses in Tables 2 and 3 is satisfactory. Agreement obtained with the values reported by NBS for niobium and tantalum is good in Table 2 and superior in Table 3. No significant improvement in the accuracy was obtained for tungsten by using either a 0·5 or a 1·0 g sample, while it is evident from Tables 2 and 3 that the use of a 1·0 g sample improves the accuracy and precision for niobium and tantalum by shifting the responses to areas where the method operates at its best. For tungsten our values are consistently lower than those reported by NBS but if corrected by a factor averaged out for NBS 363, NBS 442 and NBS 443 they would read 0·045, 0·070 and

Table 4 includes duplicate results obtained for the determination of tantalum in mischmetal, samarium and rare-earth–cobalt alloys.

Tantalum recoveries obtained for samples 6-1 to 6-4, used as background for an addition technique, were quite satisfactory. Again, at 0·055 mg the method is operating below optimum sensitivity levels, which explains the lack of agreement between tantalum found and added.

Tables 5, 6 and 7 include niobium, tantalum and tungsten results for high-temperature alloys. Such an analytical capability was needed because of a lack both of solid standards for direct X-ray techniques and wet chemical methods for the analysis of the desired traces.

The results in Tables 8 and 9 show satisfactory recoveries of all three elements down to the 0·05 mg level. Again, an addition technique was employed whereby the sample to be analysed was used as background for known additions of the three elements sought.

Efforts were made to determine lower levels of the three elements (0·001–0·01%) by the use of an addition technique; 0·40 mg of each element was introduced into a series of electrolytic iron samples which were subsequently dosed with 0·02–0·10 mg of niobium, tantalum and tungsten. The results were corrected for the 0·04% background, and as shown in Table 8 were reasonable for the range up to 0·01%.

Table 8 shows that the addition of 0·40 mg of each element seems beneficial in providing semi-quantitative analytical capability for all three elements below 0·01%. The reproducibility after the addition of 0·40 mg of each element falls within the statistical limits reported in Table 9. Attempts to increase sensitivities by using larger samples (5–10 g) were unsuccessful.

Reproducibility

The reproducibility of the method was evaluated by analysing ten 1-g samples of NBS 363. The results are given in Table 9.

X-Ray interferences

The 2θ lines used and background correction applied during the development of the method were chosen after careful testing with available X-ray instrumentation. To confirm the lack of any interference caused by tantalum L_α 44·41°, in the background read for tungsten L_α 43·00° at 1° above 2θ, a study was conducted on synthetic samples with and without tungsten and tantalum, as shown in Table 10.

Table 10. Data to show lack of interference between tantalum and tungsten background

Sample composition	Background for tungsten read at 44·00°, counts/24 sec
Iron + 0·80 mg Ta + 0·80 mg W	1670
Iron + 0·80 mg W	1674
Iron	1530

No other interferences were encountered or needed to be explored.

USE OF LONG-CHAIN ALKYLAMINES FOR PRECONCENTRATION AND DETERMINATION OF TRACES OF MOLYBDENUM, TUNGSTEN AND RHENIUM BY ATOMIC-ABSORPTION SPECTROSCOPY—II

MOLYBDENUM IN SOILS, SEDIMENTS AND NATURAL WATERS

(*Received* 18 *June* 1975. *Accepted* 30 *July* 1975)

Summary—Molybdenum is extracted as the thiocyanate complex with the quaternary long-chain aliphatic amine Aliquat 336 in chloroform, followed by evaporation of the solvent, dissolution in MIBK, and atomic-absorption spectroscopy. The method is simple, rapid and sensitive, with few interference problems for the determination of the Mo content of soils and sediments in the range 0·1–1·0 ppm with a relative standard deviation better than 5% when 1-g samples are used. Quantitative extraction from large volumes of aqueous solution has also been confirmed, allowing the determination of Mo in natural waters in the ppM range.

Methods based on solvent extraction of molybdenum complexes, with either spectrophotometric or atomic-absorption finishes, continue to be popular for the determination of traces of molybdenum in waters and geological, biological and industrial materials. Such methods have the advantages of sensitivity, selectivity and speed. Kim *et al.*[1] used solvent extraction of the molybdenum thiocyanate complex (Mo–SCN) with methyl isobutyl ketone (MIBK) for the determination of molybdenum in the range 1–500 ppm in soils and geological materials by atomic-absorption spectroscopy. The method had few interferences and the detection limit was 0·1 ppm with a relative standard deviation not exceeding 8% at the level of 1 ppm. Kim *et al.*[2] also showed that solvent extraction of the Mo–SCN complex with long chain alkylamines could form the basis of methods for the determination of Mo, W and Re with improved sensitivity. Haddad *et al.*[3] reported a versatile spectrophotometric or fluorometric method using the ternary complex formed by the reaction of the molybdenum oxypentathiocyanate ion with the dyestuff Rhodamine B for the determination of molybdenum in soils and plants with detection limits of 0·1 μg and 0·05 μg respectively for the absorption and fluorescence methods.

Other trace methods for molybdenum recently reported in the literature include: molybdenum in hard dental tissues by using ammonium pyrrolidinedithiocarbamate–MIBK with a detection limit of 0·2 ppm;[4] vanadium and molybdenum in uranium products and uranium minerals in the range from ppm to mg by using anion-exchange;[5] a spectrophotometric method for molybdenum in steels in the range 1–32 μg by using solvent extraction of the thiosulphate complex into isoamyl alcohol;[6] an enthalpimetric method with a sensitivity between 3×10^{-3} and 2×10^{-2} ppm;[7] molybdenum in high-purity tantalum by using proton-activation analysis with a reported detection limit of 0·2 ppm;[8] an automated catalytic method for molybdenum in plants, based on liberation of iodine from potassium iodide and hydrogen peroxide, applicable in the range 0·2–2·0 ppm;[9] a spectrophotometric method using the Mo–SCN complex with two different extractions with different reagents applicable to rocks in the range 0·3–5 μg/g;[10] a modification of the extraction of the dithiol complex of molybdenum with spectrophotometric finish, with sensitivities of 0·05 ppm for biological materials, 0·5 ppm for geological materials and 10 ppm for steels with relative standard deviations of ±7%;[11] and a spectrophotometric method for molybdenum(VI) in the range 0·75–8·5 μg/ml by extraction with 2-mercaptobenzo-γ-thiopyrone.[12] Nearly all of these methods[4–12] suffer from some interferences, time-consuming processing or lack of colour stability or sensitivity in the important range below 1 ppm.

We have developed and applied the procedure using solvent extraction of the Mo–SCN complex with long-chain alkylamines[2] for the determination of traces of molybdenum in soils, sediments and natural waters. The extraction is done with the quaternary long-chain aliphatic amine Aliquat 336 in chloroform followed by evaporation of the solvent, dissolution in MIBK, and atomic-absorption finish. The method offers significant advantages as a simple, rapid, sensitive procedure with very few interferences.

---

* Part I—*Talanta*, 1975, **22**, 739.

In addition, similar procedures can be used for the determination of tungsten and rhenium in related materials, with improved sensitivity.

EXPERIMENTAL

Reagents and apparatus

All reagents have been described previously.[2] The atomic-absorption spectrophotometer used was a Varian–Techtron AA5 instrument and instrumental settings have also been reported.[2]

Procedure

The general procedure for determination of molybdenum was extraction from aqueous medium of 1*M* hydrochloric acid, 1% potassium thiocyanate and 1% stannous chloride into a chloroform solution of a long-chain alkylamine, followed by evaporation of the chloroform and dissolution of the residue in MIBK. Molybdenum in the final MIBK solution was determined by atomic absorption. Complete details of this procedure have been published.[2]

This general procedure was modified as follows for determination of molybdenum in natural samples. Soil and sediment samples (1 g) were dissolved by the method of Kim *et al.*,[1] giving a final solution volume of 40 ml in 1*M* hydrochloric acid. To this solution were added 2 ml of 20% potassium thiocyanate solution and 2 ml of 20% stannous chloride solution. If required, more stannous chloride solution was added slowly with stirring until the red colour of ferric thiocyanate disappeared. Molybdenum was extracted with 10 ml of 0·2% Aliquat 336 in chloroform by shaking vigorously for 1 min. After phase separation, the organic phase was drained into a 25-ml weighing bottle. The aqueous phase was extracted with a further 10 ml of the organic solvent, which was separated from the aqueous phase and added to the initial organic solvent. After the chloroform had been evaporated off on a steam-bath, 1–10 ml of MIBK were added to the residue, depending on the quantity of molybdenum present (as judged from the colour of the extract). The residue was dissolved in the MIBK by brief warming in the stoppered bottle and, after cooling, the molybdenum atomic absorbance was determined, with MIBK as the blank.

Equilibration time for the complete reduction of Mo(VI) to Mo(V) by stannous chloride and complexation with thiocyanate in 1*M* hydrochloric acid was of the order of a few min. Tests for equilibration were carried out by measurement of extracted molybdenum at various times after the addition of potassium thiocyanate and stannous chloride solutions to the aqueous phase. After equilibration of the aqueous phase, 1 min of vigorous shaking was sufficient for complete extraction of 10 μg of molybdenum from 50 ml of aqueous solution with 10 ml of the organic extracting agent.

For the analysis of waters, samples were filtered through MA-MF Millipore filter paper (0·45 μm), diameter 47 mm, by use of Millipore all-glass filter apparatus, and stored for a short time in polyethylene containers. A sample volume of 100 ml was treated with 1 g of solid potassium thiocyanate and 10 ml of 10% stannous chloride in 10*M* hydrochloric acid, giving a final 1*M* hydrochloric acid solution. Molybdenum was extracted with 10 ml of 0·2% Aliquat 336 in chloroform followed by a 10-ml chloroform wash. The chloroform was evaporated from the organic extract and as before, MIBK [1·0 ml (or 2·0 ml for sea-water)] was added to the residue before measurement of the molybdenum absorbance.

RESULTS

In the previous work by Kim *et al.*,[2] optimization of reagent conditions and interference studies were carried out with Amberlite LA1 as a general extractant for molybdenum, tungsten and rhenium. However, Aliquat 336 in chloroform was shown to give optimum extraction of molybdenum over a wider range of hydrochloric acid concentration (from 1*M* to 5*M*) and wide range of thiocyanate and stannous chloride concentrations (1–5%). Maximum extractions were obtained from 1*M* or 2*M* hydrochloric acid with slight decreases above 2*M*, and 1*M* hydrochloric acid solution was chosen for routine applications. Aliquat 336 in chloroform was therefore used in this work for extraction of molybdenum from aqueous 1*M* hydrochloric acid solution containing 1% potassium thiocyanate and 1% stannous chloride.

Single extractions were carried out with 10 ml of 0·2% Aliquat 336 in chloroform. In order to recover the incompletely separated portion of organic phase, 10 ml of chloroform were used for washing the aqueous phase in the separating funnel and finally combined with the initial extract. After evaporation of the chloroform, the residue was dissolved in MIBK and made up to a final volume of 1–10 ml.

Effect of Aliquat 336 extraction

Data for the extraction of 10 μg of molybdenum with various concentrations of Aliquat 336 in chloroform are given in Table 1. Single extractions with 10 ml of 0·2% Aliquat 336 in chloroform were quantitative. High concentrations of Aliquat 336 in MIBK, up to 6%, were found to have no effect on the molybdenum absorbance, despite the high viscosity of the solutions. Furthermore, there was no background absorbance by 6% Aliquat 336 solution in MIBK, relative to pure MIBK. Accordingly, pure MIBK was used as a blank for zero absorbance setting. In practice, when 1 ml of MIBK was used for final residue dissolution after double extraction with 10 ml of 0·2% Aliquat 336 in chloroform, the concentration of Aliquat 336 in the final MIBK solution was 4% v/v.

Recovery of molybdenum from large volumes of aqueous phase

To establish the possibility of determining traces of molybdenum in waters, recovery from highly diluted aqueous solutions of large volume was determined, as shown in Table 2. Trace quantities of molybdenum (2·0–0·5 μg) were taken in 50–200 ml of 1*M* hydrochloric acid. For the extraction, the volume

2·0	100

Table 2. Recovery of molybdenum from large volumes of aqueous solution

Volume of aqueous phase *ml*	MIBK *ml*	No. of determinations	Mo taken, *μg*	Recovery, %
50	2	5	2·0	99·0–100
100	2	5	2·0	99·5–100
50	1	5	0·5	98·5–101
100	1	5	0·5	99·0–100
200	1	4	0·5	98·5–103

of 20% potassium thiocyanate and 20% stannous chloride solutions added to the aqueous phase was increased by 0·5 ml for every 50 ml of aqueous solution. Single extractions were carried out with 20 ml of 0·2% Aliquat 336 in chloroform.

The data in Table 2 show excellent recovery of molybdenum at 2·5–10·0 ppM levels from aqueous solutions and indicate the value of the present procedure for trace analysis of waters.

Interference studies

A detailed study of interference effects was made for cations and anions in amounts ranging up to 0·1 and 1 g respectively, with 10 μg of molybdenum. Among the cations tested, the only major interference was from rhenium, which was co-extracted with molybdenum as the thiocyanate complex. However, this element can be neglected in applications to soil analysis because of its rarity. Although some elements such as cobalt and palladium were also extracted with molybdenum as coloured complexes, no effect was observed on the atomic absorbance. Cu(II) was reduced to Cu(I) by stannous chloride and formed a white precipitate of CuSCN in the aqueous phase. Interference from large amounts of iron (up to 500 mg) was eliminated by reduction with an excess of stannous chloride.

Among the anions tested, nitrate was extracted and caused a slight negative error. EDTA complexed molybdenum and prevented complete extraction. Perchlorate gave a precipitate of potassium perchlorate after the addition of potassium thiocyanate. Therefore complete evaporation of perchloric acid was required in the dissolution procedure for geological samples.

Interference data are summarized in Tables 3 and 4.

Table 6. Determination of molybdenum in waters

Type	Location in Sydney Area	No. of detns.	Proposed method		Oxine-MIBK method[13]	
			Range, *ppm*	Mean, *ppm*	Range, *ppm*	Mean, *ppm*
Fresh	Cook's River	5	0·0014–0·0015	0·0014	0·0003–0·0008	0·0005
Estuarine	Parramatta River	5	0·0041–0·0043	0·0042	0·0042–0·0050	0·0044
Sea	North Bondi Beach	5	0·0108–0·0110	0·0110	0·0089–0·0120	0·0105

In view of the lack of serious interference, we conclude that the present extraction procedure is superior to direct MIBK extraction of the Mo–SCN complex, which suffered from some interference above the 1000-mg iron level (masking agent ascorbic acid) and above the 3-mg titanium level (masking agent sodium fluoride).[1]

Working curve

A standard solution of 2·5 ppm molybdenum in MIBK was prepared from an aqueous solution containing 250 μg of molybdenum. Three consecutive extractions were carried out with 10 ml of 1% Aliquat 336 in chloroform and, after evaporation, the residue was dissolved in MIBK and diluted to 100 ml. A linear calibration curve was obtained for the range 0·1–1·25 ppm molybdenum after appropriate dilution of the 2·5-ppm standard in MIBK. The absorbance values of the standards remained unchanged over a period of two months.

Analysis of molybdenum-deficient soils and sediments

Soils and sediments containing less than 5 ppm molybdenum were analysed by using the Aliquat 336 extraction procedures (Table 5). A 1-g sample was taken in each case and the results were compared with analytical data obtained previously by the direct MIBK extraction procedure.[1] Acceptable agreement between the two methods was obtained for samples containing above 1·0 ppm molybdenum, but the direct method gave poorer reproducibility and a wider spread of results than the Aliquat 336 method for samples with less than 1·0 ppm.

Analysis of natural waters

Samples of sea-water, fresh water and estuarine water were analysed for molybdenum content by the Aliquat 336 extraction method, using 100-ml samples. The results were compared with data obtained by the oxine–MIBK method,[13] reported recently. As shown in Table 6, the molybdenum content was in the ppM range for each sample. We obtained better precision with the proposed Aliquat 336 extraction method than with the oxine method, which gave inferior reproducibility in this concentration range.

CONCLUSIONS

Determination of molybdenum in the sub-ppm range has been demonstrated on samples of soils, sediments and natural waters at concentration levels difficult to determine by earlier methods. In particular, recently reported colorimetric methods[6,10–12] suffer from lack of sensitivity or from interferences. The proposed method offers significant advantages as a simple, rapid, sensitive procedure with few interferences.

It has been shown that the molybdenum content of soils and sediments can be determined in the range 0·1–1·0 ppm with a relative standard deviation better than ±5%, on 1-g samples. Extraction from large volumes of aqueous solution was found to be quantitative, allowing molybdenum determination in the ppM range in natural waters.

SEPARATION AND GRAVIMETRIC DETERMINATION OF RARE EARTHS WITH *N*-*m*-TOLYL-*m*-NITROBENZOHYDROXAMIC ACID

Y. K. AGRAWAL*
Department of Chemistry, Government Polytechnic Ujjain (M.P.), India,
H. L. KAPOOR
Department of Chemistry, Maulana Azad College of Technology, Bhopal (M.P.), India

(*Received* 8 *April* 1975. *Accepted* 8 *July* 1975)

N-*m*-Tolyl-*m*-nitrobenzohydroxamic acid (TNBHA) has been used[1] for the separation and gravimetric estimation of Ce^{4+} and La^{3+}. Its use is now extended to determination of Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+} and Gd^{3+} in presence of several other metal ions. The solid complexes formed are of definite composition $(C_{14}H_{11}N_2O_4)_3M$.

EXPERIMENTAL

Reagents

TNBHA was prepared as described elsewhere[2]. Stock solutions of the rare earths were prepared by dissolving weighed quantities of their nitrates, and standardized volumetrically[3]. Masking agents were used as their 1% aqueous solutions.

Procedure

The procedure was the same as that described for cerium (IV) and lanthanum(III)[1], except that the precipitates were digested for only 30 min instead of 2–3 hr.

RESULTS AND DISCUSSION

The pH of precipitation for tervalent rare-earth metals with TNBHA is given in Table 1.

Ag^{+}, Cu^{2+}, Pb^{2+}, Pd^{2+}, Mg^{2+}, Zn^{2+}, Cd^{2+}, Al^{3+}, Bi^{3+}, Fe^{3+} precipitate at pH $\leqslant$ 6·5; Ce^{4+}, Th^{4+} and U^{6+} precipitate at pH 3·8–4·8; Ga^{3+} gives no precipitate.

Ag^{+}, Cu^{2+}, Mn^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Fe^{3+} can be masked with cyanide; Pb^{2+}, Pd^{2+}, Be^{2+}, Sb^{3+}, Sn^{4+}, Bi^{3+}, Zr^{4+} and Ti^{4+} can be masked with citrate and oxalate; Al^{3+}, V^{5+} and Mo^{6+} with Mg–EDTA.

The precipitates are soluble in benzene, ethanol, dioxan and chloroform, but sparingly soluble in diethyl ether, acetone and carbon tetrachloride, and are decomposed by mineral acids.

Table 1. Optimum pH for the precipitation of rare earths with *N*-*m*-tolyl-*m*-nitrobenzohydroxamic acid

Metal	pH	Colour of precipitate
Ce^{3+}	6·0–6·8	Brownish white
La^{3+}	7·5–8·5	Canary
Pr^{3+}	8·6–9·2	Light green
Nd^{3+}	8·8–9·5	Light grey
Sm^{3+}	9·6–10·2	Light green
Gd^{3+}	10·3–10·5	Yellow

Separations can be achieved by selective precipitation at carefully controlled pH..The maximum error observed in determination of 1–30 mg amounts of the lanthanides tested (in the absence of other metal ions) was 0·03 mg. The maximum error for determination of 5–20 mg amounts of these lanthanides in presence of 60 mg each of silver, titanium and zirconium, 80 mg each of copper(II), zinc, cadmium, palladium(II), antimony(III), bismuth, gallium, arsenic(III) and aluminium, and 100 mg each of manganese(II), metal, mercury(II), vanadium(V), molybdenum(VI), uranium(VI), tin(IV), and other lanthanides, with selective precipitation and masking as outlined above, was 0·04 mg and the general error was 0·01 mg.

PROPERTIES OF 4-AMINO-4′-METHYLDIPHENYLAMINE AS A REDOX INDICATOR*

ADAM HULANICKI and STANISŁAW GŁAB
Institute of Fundamental Problems in Chemistry, University, Warsaw

(*Received* 20 *June* 1975. *Accepted* 28 *August* 1975)

The properties and structure of 4-amino-4′-methyldiphenylamine suggest its application as a redox indicator. Some preliminary studies of this compound were carried out by Erdey *et al.*,[1] but fuller characterization is desirable.[2] In this study appropriate constants have been measured and the usefulness of the indicator verified experimentally.

EXPERIMENTAL

Reagents

4-Amino-4′-methyldiphenylamine has been synthesized[3] and transformed into its hydrochloride with excess of hydrochloric acid. The compound was purified similarly to Variamine Blue.[4] Its aqueous solution, $5 \times 10^{-3}M$, was kept under nitrogen to prevent oxidation.

The chemicals used were of analytical grade.

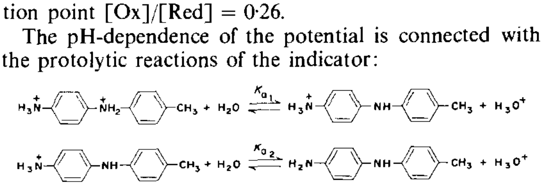
The standard solutions used in this work were prepared by the usual procedures.

RESULTS AND DISCUSSION

When applied in redox titrations in the pH range 1·5–5·5, the indicator exhibits a reversible colour change. In the course of potentiometric redox titrations of the indicator the hysteresis of the titration curve is insignificant, confirming its reversibility (Fig. 1). On the basis of such titrations the formal potentials of the indicator were determined at the half-oxidation point ($f = 0{\cdot}5$) for the pH range 1·5–5·0. The value of this potential may be described by the equation $E = 0{\cdot}735 - 0{\cdot}059\,\mathrm{pH}$. On this basis and from the stoichiometry of the reaction it follows that the oxidation is a two-electron process in which two protons are set free.

The transition potential, determined by titration of iron(II) with standard vanadate solution, is 0·54 V at pH 2·6–2·8. The indicator concentration was $8 \times 10^{-5}M$. This transition potential is about 0·035 V lower than the formal potential, determined above. This means that at the transition point [Ox]/[Red] = 0·26.

The pH-dependence of the potential is connected with the protolytic reactions of the indicator:



The absorbance of the indicator solution depends on pH, thus allowing determination of the dissociation constants. The most significant absorbance change is at $\lambda = 280$ nm (Fig. 2) in the acidity range from $H_0 = -1{\cdot}0$ to pH 6·0 and the constants determined have the values $\mathrm{p}K_{a_1} = -0{\cdot}08 \pm 0{\cdot}04$ and $\mathrm{p}K_{a_2} = 5{\cdot}15 \pm 0{\cdot}09$. The latter value is uncertain because in the pH region 4·5–6·0 the absorbance change is small. However, the potentiometric method[5] has confirmed the result, giving the value $\mathrm{p}K_{a_2} = 5{\cdot}09 \pm 0{\cdot}02$.

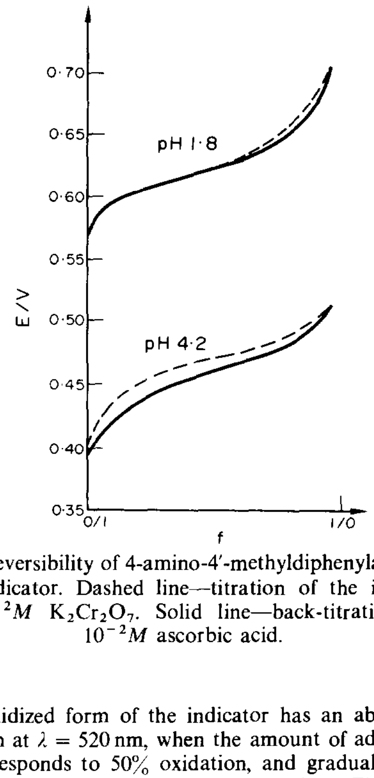


Fig. 1. Reversibility of 4-amino-4′-methyldiphenylamine as redox indicator. Dashed line—titration of the indicator with $10^{-2}M$ $K_2Cr_2O_7$. Solid line—back-titration with $10^{-2}M$ ascorbic acid.

The oxidized form of the indicator has an absorption maximum at $\lambda = 520$ nm, when the amount of added oxidant corresponds to 50% oxidation, and gradually shifts to 510 nm for larger amounts of the oxidant. The molar absorptivity is about 6×10^3 l.mole^{-1}.cm^{-1}, changing less then 10% in the pH range from 1·95 to 5·20. When the pH is greater that 5·5 the oxidized indicator turns from red-violet to yellow, as a result of deprotonation of the oxidized form. This limits the applicability of the indicator to use in the pH range below 5·5.

The oxidized form is not very stable in solution and decomposes at a rate depending on the acidity. The half-life ($\tau_{1/2}$), *i.e.*, the period necessary for decrease of the absorbance to half its initial value, for $10^{-4}M$ indicator solution is 15 min at pH 1·95, 21 min at pH 2·38, 40 min at pH 3·12, 90 min at pH 4·20 and 130 min at pH 5·10.

Thus, it can be concluded that the oxidation of the indicator proceeds according to the equation:

The change of the absorption spectrum in the absence of excess of oxidant probably indicates that in the one-electron process a radical may be formed.

The decomposition products of the oxidized form have been identified by using TLC on Silicagel $HF_{256-366}$, the developing medium being chloroform + diethyl ether (9 + 1). Among the products were found *p*-quinone and *p*-toluidine, confirmed by ultraviolet spectrophotometry. Thus the decomposition of the oxidized indicator should

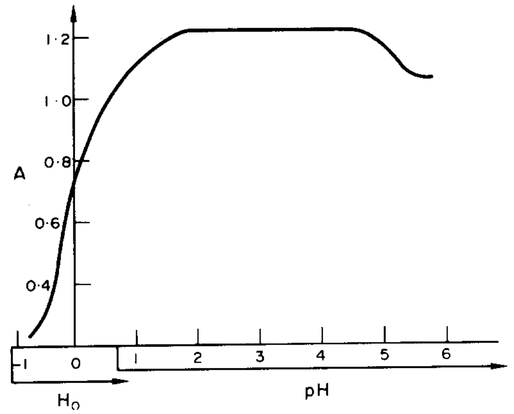

Fig. 2. Absorbance dependence on acidity of the solution for 4-amino-4′-methyldiphenylamine. $\lambda = 280$ nm. Acidity function H_0 determined in H_2SO_4 solutions.[6]

follow the reaction:

The p-toluidine formed may be further oxidized by a strong oxidant, *e.g.*, bromine.

The use of the indicator in titrations

The practical application of the indicator in titration has been confirmed in a standard system with suitable potential, *i.e.*, the titration of Fe(II) with vanadate in the presence of phosphoric acid. For this purpose to 10 ml of 0·1*M* Fe(II) solution, 14 g of sodium acetate and 15 ml of phosphoric acid were added and the sample was diluted to about 100 ml; 1·5 ml of 0·005*M* indicator were added, and the titration was carried out until a red-violet colour persisted. The results obtained, compared with those of potentiometric titrations, indicate that the error is not greater than 0·2%.

DETERMINATION OF VICINAL HYDROXYL GROUPS IN POLY(VINYL ALCOHOL) (PVA)*

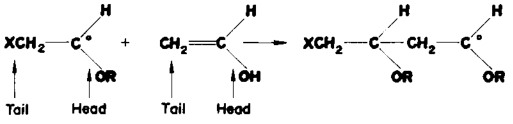
J. G. PRITCHARD and Y. L. LAN CHUN FUNG
Department of Chemistry, North East London Polytechnic, London E.15, England

(*Received* 5 *May* 1975. *Accepted* 10 *June* 1975)

The proportion of vicinal hydroxyl groups in PVA polymers and copolymers is one of the characteristics of molecular structure which can contribute to the physical properties of the material in bulk. In this paper we review an application of the Fleury–Lange periodate–arsenite method[1] for the determination of 1,2-diol groups in PVA.[2]

The normal 1,3-polyol structure of PVA arises from "head-to-tail" free-radical-initiated polymerization of vinyl ester or vinyl ether monomer:



X = initiating radical

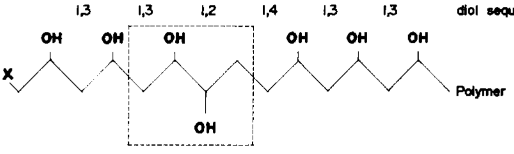
R = alkyl or acyl group

However, the occurrence of the energetically unfavoured head-to-head mode of polymerization produces a polymer

---

[*] Based on part of the report by Miss Y. L. Lan Chun Fung presented in part fulfilment of the requirements for the M.Sc. degree of the University of London in analytical chemistry, 1974.

with the occasional 1,2 and 1,4 sequences:[3]



I

The fraction of 1,2-diol units can be measured by two methods based on specific cleavage of the 1,2-diol by periodate. In the first, due to Flory and Leutner, the number of 1,2-diol two-carbon units is measured with respect to the total number of two-carbon units condensed in the polymer.[4] The increase in the number of molecules on cleavage is equal to the number of 1,2-diol units and is given by $(w/M_f) - (w/M_i)$ where M_i and M_f refer to the initial and final gram molecular weights and w is the weight of polymer. The total number of vinyl alcohol units condensed is $w/44{\cdot}05$ (atomic weight scale $0 = 16{\cdot}00$), so the fraction of 1,2-diol two-carbon units is $44{\cdot}05\ (1/M_f - 1/M_i)$. The fraction thus determined is about 0·013 for common PVA.[3]

In the titrimetric method, the weight of 1,2-diol units present in the polymer is referred to standard iodine solution through the following reactions:

$$IO_4^- + HAsO_3^{2-} \xrightarrow[\text{(Catalyst)}]{I^-} IO_3^- + HAsO_4^{2-}$$

$$HAsO_3^{2-} + I_2 + H_2O \longrightarrow HAsO_4^{2-} + 2HI$$

R and R′ are organic radicals or H in the case of a standard substance, or macromolecular chains in the case of polymer. The excess of periodate, or all of it in the absence of 1,2-diol, reacts with an excess of arsenious oxide, and the excess of this is titrated with standard iodine solution. The volumes (in litres) of xM I_2 solution consumed in the absence and presence of 1,2-diol can be termed V_0 and V, respectively. When the procedure refers to a pure, low-molecular-weight standard compound, *e.g.*, R = H, R′ = $C_6H_5CH_2$, the weight of standard present (in grams) is $(V - V_0)xW$, where W is the gram molecular weight of the standard, *e.g.*, 138·17. The purity of the standard is then $100\ (V - V_0)xW/$(weight of standard taken). In the case of the polymer, the number of moles of 1,2-diol segments present is $(V - V_0)x$, and the weight of 1,2-diol functional groups would be $(V - V_0)x \times 60{\cdot}05$, because the formula weight of CHOHCHOH is 60·05. However, in order to be consistent with the Flory and Leutner method, the weight must be referred to one-half of the formula weight of the four-carbon segment outlined in I. Thus, the weight of vinyl alcohol segments polymerized head-to-head to generate 1,2-diol groups is $(V - V_0)x \times 44{\cdot}05$, and the fraction of such two-carbon segments present is $100\ (V - V_0)x \times 44.05/$(weight of polymer taken)*.

EXPERIMENTAL

Materials

The PVA was a sample of Gelvatol 1–30, weight-average molecular weight $1{\cdot}40 \times 10^4$, degree of hydrolysis 98·5–100%. It was dissolved in water at 70–80°.

Styrene glycol (1,2-dihydroxy-2-phenylethane) was prepared by the hydration of styrene oxide (Merck). A solution of the oxide (10 g) in iso-octane (200 ml) was stirred vigorously with water (100 ml), at pH *ca.* 5, for 2 hr at *ca.* 50°. The crude product (9 g, m.p. 65–66°) was obtained by crystallization from water. Double sublimation gave an analytical sample of styrene glycol, m.p. 66–67° (m.p. 67–68° when recrystallized from ligroin[5]).

Table 1. Standardization check on periodate cleavage method with styrene glycol, and determination of fraction of 1,2-diol units in PVA

Substance	Weight, *g*	*V*, *ml*	1,2-Diol, %
Styrene glycol	0·0911	24·18*	100·0
Styrene glycol	0·0944	24·62*	99·7
Polyvinyl alcohol	2·4328	24·92†	1·28
Polyvinyl alcohol	2·4354	24·81†	1·27

* Iodine concentration $0{\cdot}04964M$; $V_0 = 10{\cdot}90$ ml.
† Iodine concentration $0{\cdot}05014M$; $V_0 = 10{\cdot}78$ ml.

Analytical-reagent grade arsenious oxide (primary standard, 2·4746 g) was dissolved in 40 ml of 10% w/v aqueous sodium hydroxide solution; the solution was neutralized and made up to give 500·0 ml of $0{\cdot}05005M$ arsenious acid solution. Starch (1 g) was boiled with water (100 ml) for 1 min, and 3 g of potassium iodide were added to the cooled solution to complete the indicator. Resublimed iodine (*ca.* 6 g) was dissolved in 20 ml of 50% w/v potassium iodide solution and made up to give 500 ml of approximately $0{\cdot}05M$ I_2 solution. This was standardized by using it to titrate, to a faint permanent blue colour, aliquots of the arsenious oxide solution (25·00 ml) plus water (15 ml), sodium bicarbonate (2 g) and starch solution (2 ml). A $0{\cdot}071M$ sodium periodate solution was made from the analytical-reagent grade reagent.

1,2-Diol cleavage reaction

A slight excess of the sodium periodate solution (10 ml) was added to the diol solution (*ca.* 2·5 g/350 ml) at room temperature, and the mixture was allowed to stand for 30 min to ensure completion of the cleavage reaction. Sodium bicarbonate (2 g) was added, followed by 25·00 ml of the standard arsenious oxide solution and 0·1 g of solid potassium iodide. The resulting solution was titrated with standard iodine solution (after addition of 2 ml of the starch indicator) to give the results (V) listed in Table 1.

RESULTS AND DISCUSSIONS

Table 1 gives typical results. The styrene glycol is close to 100% pure. It is crystalline and non-deliquescent at room temperature and serves to check our whole procedure. The cumulative (maximum) random errors in V_0 and V are 0·24% and 0·18%, respectively, which yields 0·46% for $(V - V_0)$, if the random error in each volume measurement is estimated as ±0·01 ml (a plausible minimum value for very careful work). There is an error of about ±0·1% in the weighing of the styrene glycol. The estimated maximum scatter in the results for the diol purity in this case could therefore be as large as ±0·6%. Some of the errors would usually cancel, but determinations should clearly be at least duplicated to guard against a freak result. When a much larger weight of PVA is substituted for the styrene glycol (Table 1) the estimated possible scatter is reduced to ±0·5% because the weighing error is no longer significant. Harris and Pritchard reported root-mean-square deviations in the range 2–4% for specimens of PVA from various sources.[2] However, in their work $(V - V_0)$ was less than 2 ml, which introduces a maximum scatter of ±5% on the basis of our estimate above. We therefore suggest the use of a value of $(V - V_0)$ in the range 15–20 ml to keep the error in this quantity to less than ±0·5%. We note that heterogeneity of the 1,2-diol content and gel-forming properties of the PVA could lead to a greater scatter of results.

---

* We note that the expression given by Harris and Pritchard[2] is in error by a statistical factor of 2, and by an additional factor of 1000 due to the expression of volume in ml.

The periodate method is reported to give results ranging in accuracy from 99 to 101% for the determination of several 1,2-glycols related to glycerol,[6] and we have found the procedure above useful for the estimation of glycerol α-monochlorohydrin (1-chloro-2,3-dihydroxypropane) in the commercial "monochlorohydrin", which also contains the β-isomer, 2-chloro-1,3-dihydroxypropane. More generally, the method should be used with caution: we have shown, for example, that dimethyl tartrate cannot be estimated, owing to slow non-stoichiometric oxidation by the periodate. Weiss gives a list of substances which do not contain the 1,2-diol group but react with periodate and can interfere if present.[6] The periodate–arsenate method has been applied with 95–98% accuracy to the determination of sugars[7] and is the generally preferred method in this field.[8]

NEW REDOX TITRANTS IN NON-AQUEOUS OR PARTIALLY AQUEOUS MEDIA—VI*

POTENTIOMETRIC DETERMINATIONS USING DIBROMAMINE-T AND SOME FURTHER APPLICATIONS OF DICHLORAMINE-T

C. G. R. NAIR and P. INDRASENAN
Department of Chemistry, University of Kerala, Trivandrum-695001, India

(*Received* 7 *April* 1975. *Accepted* 18 *July* 1975)

Despite a recent renewal of interest in non-aqueous redox titrimetry, the number of good oxidants available in this field continues to be very limited. As part of our programme for the development of new redox titrants in non-aqueous media,[1–5] we are introducing *N,N'*-dibromo-*p*-toluenesulphonamide ("Dibromamine-T", hereafter abbreviated as DBT) as an ideal oxidimetric titrant in acetic acid medium. This compound is closely related to Dichloramine-T, developed as an oxidimetric titrant by us earlier[1–3] and can be considered complementary to it in some ways. The results of the individual determinations of typical, yet diverse, reductants such as antimony(III), arsenic (III), thallium(I), ferrocyanide, iodide, ascorbic acid, hydroquinone, iron(II), hydrazine, aniline, phenol and oxine with this new redox titrant are presented in this communication.

In view of our observation that oxine may be readily determined by *direct* potentiometric titration with both DBT and DCT in partially non-aqueous media containing excess of bromide, it was considered worthwhile to examine whether metal oxinates could be similarly determined. The results of such a study proved to be most promising. Procedures for the *direct* potentiometric titrations, with DBT as well as DCT, of oxinates of six typical 3*d*-transition metals, [Mn(II), Fe(III), Co(II), Ni(II), Cu(II) and Zn(II)] are also described in this communication. These direct titration procedures are faster than the usual back-titration and have the further advantage that errors due to loss of bromine are eliminated.

EXPERIMENTAL

Apparatus

The apparatus and electrode assemblies described earlier[2] were used.

Reagents

Dibromamine-T. Prepared by the bromination of chloramine-T. Recrystallized chloramine-T (10 g) was dissolved in water (200 ml) and liquid bromine (2 ml) was added dropwise from a burette with constant stirring of the solution. The golden yellow precipitate of DBT was thoroughly washed with water, filtered under suction and dried in a vacuum desiccator for 24 hr. The dry sample was found to melt at 92–93° with decomposition. The purity of the sample was checked by elemental analysis for N, S and

The periodate method is reported to give results ranging in accuracy from 99 to 101% for the determination of several 1,2-glycols related to glycerol,[6] and we have found the procedure above useful for the estimation of glycerol α-monochlorohydrin (1-chloro-2,3-dihydroxypropane) in the commercial "monochlorohydrin", which also contains the β-isomer, 2-chloro-1,3-dihydroxypropane. More generally, the method should be used with caution: we have shown, for example, that dimethyl tartrate cannot be estimated, owing to slow non-stoichiometric oxidation by the periodate. Weiss gives a list of substances which do not contain the 1,2-diol group but react with periodate and can interfere if present.[6] The periodate–arsenate method has been applied with 95–98% accuracy to the determination of sugars[7] and is the generally preferred method in this field.[8]

NEW REDOX TITRANTS IN NON-AQUEOUS OR PARTIALLY AQUEOUS MEDIA—VI*

POTENTIOMETRIC DETERMINATIONS USING DIBROMAMINE-T AND SOME FURTHER APPLICATIONS OF DICHLORAMINE-T

C. G. R. Nair and P. Indrasenan
Department of Chemistry, University of Kerala, Trivandrum-695001, India

(*Received* 7 *April* 1975. *Accepted* 18 *July* 1975)

Despite a recent renewal of interest in non-aqueous redox titrimetry, the number of good oxidants available in this field continues to be very limited. As part of our programme for the development of new redox titrants in non-aqueous media,[1–5] we are introducing *N,N'*-dibromo-*p*-toluenesulphonamide ("Dibromamine-T", hereafter abbreviated as DBT) as an ideal oxidimetric titrant in acetic acid medium. This compound is closely related to Dichloramine-T, developed as an oxidimetric titrant by us earlier[1–3] and can be considered complementary to it in some ways. The results of the individual determinations of typical, yet diverse, reductants such as antimony(III), arsenic (III), thallium(I), ferrocyanide, iodide, ascorbic acid, hydroquinone, iron(II), hydrazine, aniline, phenol and oxine with this new redox titrant are presented in this communication.

In view of our observation that oxine may be readily determined by *direct* potentiometric titration with both DBT and DCT in partially non-aqueous media containing excess of bromide, it was considered worthwhile to examine whether metal oxinates could be similarly determined. The results of such a study proved to be most promising. Procedures for the *direct* potentiometric titrations, with DBT as well as DCT, of oxinates of six typical 3*d*-transition metals, [Mn(II), Fe(III), Co(II), Ni(II), Cu(II) and Zn(II)] are also described in this communication. These direct titration procedures are faster than the usual back-titration and have the further advantage that errors due to loss of bromine are eliminated.

EXPERIMENTAL

Apparatus

The apparatus and electrode assemblies described earlier[2] were used.

Reagents

Dibromamine-T. Prepared by the bromination of chloramine-T. Recrystallized chloramine-T (10 g) was dissolved in water (200 ml) and liquid bromine (2 ml) was added dropwise from a burette with constant stirring of the solution. The golden yellow precipitate of DBT was thoroughly washed with water, filtered under suction and dried in a vacuum desiccator for 24 hr. The dry sample was found to melt at 92–93° with decomposition. The purity of the sample was checked by elemental analysis for N, S and

---

* Part V: *Talanta*, 1975, **22**, 57.

Br (found: N, = 4·3%, S = 9·6%, Br = 48·5%; required: N = 4·26%, S = 9·73%, Br = 48·56%).

Dichloramine-T. Prepared as described earlier.[2]

Preparation and standardization of stock solutions

The solubility of DBT in acetic acid was determined and was found to be 38 g/l. at 30°. Approximately 0·05*M* (~ 0·2 *N*) solutions of DBT were prepared by dissolving 8·2 g of the sample in 500 ml of water-free acetic acid and were kept in amber-coloured bottles fitted with automatic microburettes and guard-tubes for the exclusion of moisture. These solutions were standardized by adding aqueous potassium iodide solution to aliquots and titrating the liberated iodine with thiosulphate as usual.[2] The stock solutions were found to be reasonably stable. The normality of a typical stock solution (kept as described above) over a period of 15 days is given below.

No. of days	0	1	2	3	5	9	15
Normality	0·2388	0·2388	0·2379	0·2362	0·2345	0·2328	0·2305

Stock solutions of DCT were prepared, stored and standardized as described earlier.[2]

Reductant solutions. Solutions of antimony(III), iodide, ferrocyanide, hydrazine, ascorbic acid, hydroquinone, aniline and phenol were prepared in distilled water. Arsenic(III) solutions were prepared by dissolving weighed quantities of As_2O_3 in 1*M* sodium hydroxide, neutralizing with 1*N* sulphuric acid and making up to a definite volume with distilled water. Solutions of iron(II) were prepared in 2*N* sulphuric acid. Solutions of thallium(I) and oxine were prepared in 50% aqueous acetic acid. The strengths of these solutions were all checked by standard methods.[7]

The oxinates of Mn(II), Fe(III), Co(II), Ni(II), Cu(II) and Zn(II) were prepared by standard procedures.[6] Standard solutions of these oxinates were prepared in 4*N* sulphuric acid and the strengths were checked by the bromate–bromide method.[6] All the reagents used were of analytical reagent quality.

Procedures for titrations

The potentiometric titrations were carried out as described earlier.[5] All the titrations were done at room temperature (28 ± 2°).

Normal, first derivative and second derivative curves were drawn. The equivalence points were obtained both graphically and numerically (employing the Hostetter–Roberts equation[8] or the Yan equation[9]).

RESULTS AND DISCUSSION

A statistical evaluation of results (standard deviations and coefficients of variance) is given in Tables 1 and 2.

Table 1. Potentiometric titrations of some common reductants with Dibromamine-T (6 replicates).

Reductant	Reductant taken, *mmole*	Standard deviation *μmole*	Coefficient of variance, %
Antimony(III)	0·3084	0·10	0·03
Arsenic(III) (As_2O_3)	0·2517	0·55	0·22
Thallium(I)	0·3445	0·18	0·05
Ferrocyanide	0·5442	0·99	0·18
Iodide	0·5331	0·88	0·17
Ascorbic acid	0·7379	1·62	0·22
Hydroquinone	0·5499	1·23	0·22
Iron(II)	0·5037	2·07	0·41
Hydrazine	0·1596	0·10	0·06
Aniline	0·2217	0·15	0·07
Phenol	0·1489	0·12	0·08
Oxine	0·2275	0·06	0·03

Table 2. Potentiometric titrations of metal oxinates with Dibromamine-T and Dichloramine-T (6 replicates)

Reductant	Reductant taken, *mmole*	Standard deviation, *μmole*	Coefficient of variance, %
	Dibromamine-T		
$Mn(C_9H_6ON)_2\ 2H_2O$	0·0875	0·37	0·42

In the case of antimony(III), arsenic(III), thallium(I), ferrocyanide, iodide, ascorbic acid and hydroquinone, simple direct titration against DBT was successful; there was no need to add potassium bromide or hydrochloric acid. [It may be noted that Tl(I) and ferrocyanide could be successfully titrated with DCT only in presence of added bromide.] For iron(II), addition of phosphoric acid was necessary to get a clear-cut potential break, by complexing the Fe^{3+} formed. Addition of hydrochloric acid was found to be necessary in the case of hydrazine; otherwise somewhat premature end-points were obtained. Addition of bromide (KBr) was essential in the case of aniline, phenol, oxine and the metal oxinates. The approximate potential jumps (in mV) at the equivalence points for the addition of 0·1 ml of 0·05*M* DBT were as follows: for antimony(III), 200; arsenic(III), 300; thallium(I), 200; ferrocyanide, 500; iodide, 100; ascorbic acid, 400; hydroquinone, 300; iron(II), 400; hydrazine, 250; aniline, 100; phenol, 150; oxine, 350. The potential breaks for the metal oxinates were ~ 300 mV for the addition of 0·1 ml of 0·05*M* solution of either DBT or DCT. In DBT titrations, the time required to attain the steady potentials near the end-point was in general small (< 1 min); in this respect, DBT has a clear advantage over DCT in many cases.

The oxidation half-reactions undergone by the different reductants are the same as those in the case of oxidation by iodobenzene diacetate.[5] In the case of aniline, phenol, oxine and the metal oxinates the actual oxidant is bromine produced *in situ* by the reaction of bromide with the oxidant. In all these cases, DBT is reduced to *p*-toluenesulphonamide in accordance with the half-reaction

$$RNBr_2 + 2H^+ + 4e^- \rightarrow RNH_2 + 2Br^-$$

(where R = $CH_3–C_6H_4–SO_2$).

The formal potential of the DBT–sulphonamide couple was determined at 25 ± 0·02° and found to be +1·28 V (mean of 9 experiments).

Summary—A new redox titrant, Dibromamine-T (*N,N'*-dibromo-*p*-toluenesulphonamide) is introduced for use in acetic acid media. Potentiometric titrations of Sb(III), As(III), Tl(I), Fe(II), ferrocyanide, iodide, ascorbic acid, hydroquinone, hydrazine, aniline, phenol and oxine are described. Direct potentiometric titrations of oxinates of Mn, Fe, Co, Ni, Cu and Zn with Dibromamine-T as well as with Dichloramine-T are also described.

INDICATORS IN NON-AQUEOUS CERIMETRIC TITRATIONS OF THIOUREAS AND XANTHATES

BALBIR CHAND VERMA[*] and SWATANTAR KUMAR
Department of Chemistry, H.P. University, Simla-171001, India

(*Received* 12 *June* 1975. *Accepted* 28 *August* 1975)

Non-aqueous solvents are important for redox determinations, especially of those compounds which are slightly soluble in water or react with it through hydrolysis or oxidation. However there is a lack of redox reagents of suitable stability for use in non-aqueous media. Acetonitrile, because of its high dielectric constant and resistance to oxidation or reduction has proved quite promising as a solvent[1] especially with stronger oxidants such as ammonium hexanitratocerate(IV). Rao and Murthy have used this oxidant in acetonitrile for the determination of hydroquinone,[2] potassium ethyl xanthate,[3] iron(II),[4] oxalic acid,[5] ascorbic acid[6] and potassium iodide.[7] Verma and Kumar[8] have recently described its use in the determination of thiourea and its derivatives.

The only attempt to use visual indicators in titrations with Ce(IV) in a non-aqueous medium appears to be due to Rao and Murthy[2] who used diphenylamine, ferroin, Methyl Red and Janus Green as indicators in titrations of hydroquinone. The present communication reports the use of some chemical indicators in titrations of thioureas and xanthates with ammonium hexanitratocerate in acetonitrile.

EXPERIMENTAL

Reagents

Acetonitrile. Distilled twice from phosphorus pentoxide (5 g/l.).

Ammonium hexanitratocerate, 0·05N *in acetonitrile.* Prepared by dissolving a little more than the calculated amount of dried analytical-grade oxidant in acetonitrile, and standardized by titration with ferrous ammonium sulphate in the presence of dilute sulphuric acid, with ferroin as indicator. The solution was stored in coloured glass-stoppered bottles and kept in a dry chamber.

Xanthates. Prepared by mixing equimolar quantities of the corresponding alcohols, potassium hydroxide (dissolved in minimum quantity of water) and carbon disulphide, at temperatures below 10°. The compounds were crystallized twice by dissolving in acetone and precipitating with petroleum ether (60–80°). The purity was checked by known methods.

Thiourea. Recrystallized from alcohol. The alkyl derivatives of thiourea were prepared from the corresponding isothiocyanates[9] by condensation with ammonia.

Indicator solutions. Fuchsin, Gentian Violet, Light Green, Methyl Red and quinalizarin indicators were prepared as 0·1% solutions in acetonitrile. Ferroin solution (0·025 *M*) was prepared by dissolving 1·485 g of *o*-phenanthroline and 0·695 g of analytical grade ferrous sulphate heptahydrate in 100 ml of acetonitrile. Diphenylamine was used as a 0·25% solution in acetonitrile.

Procedure

Aliquots of solutions of thiourea or potassium ethyl xanthate in acetonitrile were taken in dry conical flasks, and made up to 20 ml with acetonitrile; indicator solution (2 or 3 drops) was added. Each solution was cooled to room temperature (25°) and titrated with 0·05*M* ammonium hexanitratocerate from a microburette provided with guard-tube for the protection of oxidant solution from atmospheric moisture. During the titration, white cerous nitrate was precipitated. The titrations were repeated with substituted thioureas and xanthates. The results of titrations of thiourea and potassium ethyl xanthate, as representatives of substituted thioureas and xanthates with use of various indicators, are given in Table 1. The colour changes observed during the end-points are also given.

RESULTS AND DISCUSSION

Acetic acid and acetonitrile have been most used as media for non-aqueous redox titrations and electro-

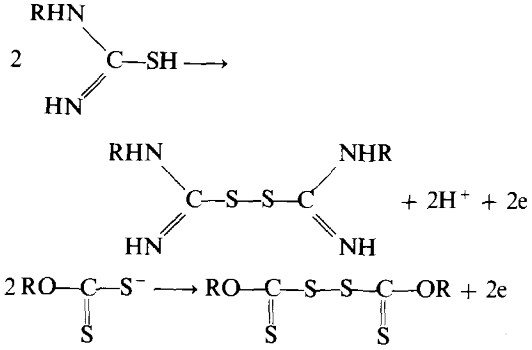
‡ 6 or 7 drops of indicator added.

chemical methods (mostly potentiometric) have been used to detect the end-point. Only limited efforts have been made to use visual indicators in non-aqueous redox titrations. This appears to be because the scale of potentials of different redox systems in various solvents, similar to those known in water, has not been developed. Verma and Bose[10] have described the use of quinalizarin as an indicator in the redox determination of phenyl thioureas with lead tetra-acetate in glacial acetic acid. Recently Braun and Stock[11] have employed some indicators in redox titrations in dimethylformamide medium.

The results of titrations of substituted thioureas and xanthates, performed similarly, agree closely with those listed in the table. The results indicate that thioureas and xanthates react with Ce(IV) in a 1 : 1 molar ratio. This corresponds to the oxidation of thioureas and xanthates to the corresponding disulphides and dixanthogens respectively.



The solutions of these indicators may also be prepared in acetic acid or acetic acid–acetonitrile mixtures, but these solutions are not recommended for use in the titrations of xanthates because of the risk of their decomposition with acetic acid.

DETERMINATION OF PEROXYDIPHOSPHATE IN ACID MEDIUM WITH OXALATE (*i*) WITH SILVER(I) AS CATALYST AND (*ii*) IN THE PRESENCE OF EXCESS OF MANGANESE(II)

L. M. Bharadwaj, D. N. Sharma and Y. K. Gupta
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 11 *June* 1975. *Accepted* 19 *June* 1975)

A study in this laboratory of the kinetics and mechanism of oxidations with peroxydiphosphate necessitated the development of titrimetric methods for determination of peroxydiphosphate suitable to a particular kinetics study. So far only two titrimetric methods for its determination have been reported, indirect cerimetric[1] and direct iodometric.[2] The interest in the present work arose on account of a well-known method for determination[3]

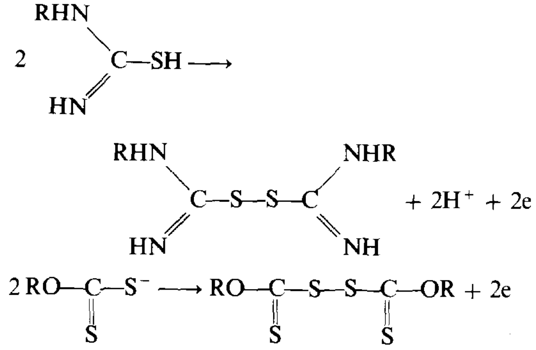
This corresponds to the oxidation of thioureas and xanthates to the corresponding disulphides and dixanthogens respectively.



$$2\,\mathrm{RO{-}\overset{\displaystyle S}{\overset{\|}{C}}{-}S^-} \longrightarrow \mathrm{RO{-}\overset{\displaystyle S}{\overset{\|}{C}}{-}S{-}S{-}\overset{\displaystyle S}{\overset{\|}{C}}{-}OR} + 2e$$

The solutions of these indicators may also be prepared in acetic acid or acetic acid–acetonitrile mixtures, but these solutions are not recommended for use in the titrations of xanthates because of the risk of their decomposition with acetic acid.

DETERMINATION OF PEROXYDIPHOSPHATE IN ACID MEDIUM WITH OXALATE (*i*) WITH SILVER(I) AS CATALYST AND (*ii*) IN THE PRESENCE OF EXCESS OF MANGANESE(II)

L. M. Bharadwaj, D. N. Sharma and Y. K. Gupta
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 11 *June* 1975. *Accepted* 19 *June* 1975)

A study in this laboratory of the kinetics and mechanism of oxidations with peroxydiphosphate necessitated the development of titrimetric methods for determination of peroxydiphosphate suitable to a particular kinetics study. So far only two titrimetric methods for its determination have been reported, indirect cerimetric[1] and direct iodometric.[2] The interest in the present work arose on account of a well-known method for determination[3] of peroxydisulphate which is isoelectronic and isostructural with peroxydiphosphate. The present communication describes two methods for the determination of peroxydiphosphate, (*a*) with silver(I) as a catalyst for the reaction between excess of oxalic acid and peroxydiphosphate, the excess of the oxalic acid being determined with standard permanganate, and (*b*) with excess of manganese(II) for reaction with a sample of peroxydiphosphate, yielding MnO_2 which is directly titrated with a standard solution of oxalic acid.

EXPERIMENTAL

Reagents

The potassium peroxydiphosphate was a gift sample from FMC corporation, New York, U.S.A. The solution of peroxydiphosphate was prepared by direct weighing and standardized[1] cerimetrically, with *N*-phenylanthranilic acid as indicator. A standard solution of oxalic acid was prepared by direct weighing. All solutions were made in doubly distilled water, permanganate being added before the second distillation.

Procedures

Silver(I) as catalyst. The sample of peroxydiphosphate, a known excess of oxalic acid solution, enough sulphuric acid to give a 2·5*N* solution, and silver nitrate to yield at least a $4 \times 10^{-3}M$ solution, were mixed and heated just to boiling. The unreacted oxalic acid was determined with standard permanganate solution

With excess of manganese(II). The sample of peroxydiphosphate, enough sulphuric or perchloric acid to yield a 0·25–1·0*N* solution and at least a 500% excess of manganese sulphate were mixed and boiled for about 2 min. The manganese dioxide produced was titrated with a standard solution of oxalic acid to a colourless end-point.

RESULTS AND DISCUSSION

Titration of 7–350 mg of peroxydiphosphate by the silver(I) method and of 3–70 mg by the manganese(II) method gave results within ± 0·3% of the cerimetric assay with only one exception (+ 0·9%). The methods are quick but have the drawback that heating is required.

The catalysis of peroxydiphosphate oxidations was recently found[4] in this laboratory during one of the kinetics studies. However, the reaction still does not become instantaneous at room temperature and heating is necessary to complete the reaction. The overall stoichiometry is given by equation (1)

$$H_4P_2O_8 + H_2C_2O_4 \rightarrow 2H_3PO_4 + 2CO_2 \qquad (1)$$

The catalysis by silver(I) probably operates through an Ag(I)/Ag(II) or Ag(I)/Ag(III) cycle as found in the silver(I)-catalysed oxidations by peroxydisulphate[5] and given below.

$$P_2O_8^{4-} + Ag^+ \rightarrow 2PO_4^{3-} + Ag^{3+} \qquad (2)$$

$$Ag^{3+} + C_2O_4^{2-} \rightarrow Ag^+ + 2CO_2 \qquad (3)$$

There is no definite view yet whether Ag(II) or Ag(III) is formed. There is still another view that probably both the higher oxidation states of silver exist in the system in equilibrium.[6]

The determination in the presence of manganese(II) depends on the fact that this is oxidized to MnO_2 or permanganate depending on the concentration of Mn(II) and the acidity of the medium. The Mn(II) is oxidized to Mn^{3+} which in the absence of complexing agents[8–10] and at low acidity disproportionates,[11] yielding MnO_2 and Mn(II).

$$P_2O_8^{4-} + 2\,Mn^{2+} \rightarrow 2PO_4^{3-} + 2Mn^{3+} \qquad (4)$$

$$2\,Mn^{3+} \rightleftharpoons Mn^{4+} + Mn^{2+};\ 2\,Mn^{3+} + 2H_2O = MnO_2 + Mn^{2+} + 4H^+ \qquad (5)$$

A large concentration of Mn(II) is employed to make the reaction of peroxydiphosphate and Mn(II) fast and to inhibit[10] the formation of MnO_2 as far as possible so that there is no difficulty in titration with oxalic acid. Reactions of oxalic acid with Mn^{3+} and MnO_2 are well known.[13,14]

Oxidation of Mn(II) to permanganate by peroxydiphosphate is also possible and thus a colorimetric determination can be made. However, for this the concentration of Mn(II) has to be sufficiently low (but larger than that of the peroxydiphosphate) and the acidity high, or otherwise permanganate will react[15,16] with Mn(II) yielding MnO_2 as in the present method.

Acknowledgements—We are thankful to FMC Corporation, New York, U.S.A., for the generous gift of a sample of potassium peroxydiphosphate. One of us (LMB) is thankful to C.S.I.R., India, for a research fellowship and a grant.

Summary—Peroxydiphosphate can be determined with oxalate in acid medium in the presence of silver(I). Excess of oxalic acid along with the sample and silver(I) is heated to boiling and the excess of oxalic acid is titrated against standard permanganate. Another method involves boiling for 2 min a mixture consisting of the sample and excess of manganese(II), followed by titration of the resulting Mn(III) or MnO_2 with standard oxalic acid solution.

SIMPLE SEMIQUANTITATIVE DETERMINATION OF TRACE METAL IONS BY USE OF REAGENT GEL COLUMNS—II

DETERMINATION OF ZINC WITH DITHIZONE GEL*

YONG KEUN LEE,† KYU JA WHANG‡ and KEIHEI UENO®
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812, Japan

(*Received* 3 *June* 1975. *Accepted* 20 *June* 1975)

By use of the principle previously described,[1] zinc(II) at the sub-ppm level in environmental water has been determined with an analytical column packed with dithizone gel beads. As zinc reacts with dithizone at pH 6–7, where many other heavy metal ions are similarly complexed, interfering cations have to be masked.

EXPERIMENTAL

Reagents

All reagents were of analytical grade. Dithizone was recrystallized from chloroform. Buffers, masking reagents and distilled water were treated beforehand with a 0·05% dithizone gel column[2] or shaken with 0·05% dithizone solution in chlorobenzene to remove traces of heavy metal ions. *N,N*-Bis(β-hydroxyethyl)dithiocarbamate[3] and β-dithiocarbaminopropionic acid[4] were prepared according to the literature.

Preparation of dithiozone gel beads

Styrene–divinylbenzene copolymer beads (2% divinylbenzene, particle size 70–100 mesh) were treated successively with 3% hydrochloric acid, distilled water and acetone, dried at 95–97°, then soaked in 0·01% dithizone solution in chlorobenzene for 15–17 hr at 5° in a dark place. The beads were separated by centrifugation, and immediately transferred into 0·1*M* acetate buffer solution (pH 5·6) containing sodium thiosulphate (0·1*M*) as a stabilizer. One gram of dry polymer accepted about 2·9 ml of chlorobenzene.

Preparation of analytical gel bead column

The column and packing procedure were essentially as before,[1] the downward packing being preferred, with the acetate buffer containing sodium thiosulphate as the suspension medium. The column was sealed, wrapped and stored as before.[1]

Procedure

A known amount of sample was placed in a 25-ml volumetric flask, to which acetate buffer solution (pH 6·2) and sodium thiosulphate solution were added to give a final 0·1*M* concentration of both. If interfering cations were present, appropriate masking agents were also added. Finally the whole was made up to volume.

A bead column was connected to a sample reservoir and the flow-rate was adjusted to 0·2 ml/min. As the sample solution flowed through the column, the green gel turned to pink from the upper end when zinc was complexed with dithizone. After passage of a measured volume of sample, the length of pink zone was measured and the amount of zinc was calculated from a (linear) calibration curve. A correction was necessary for the dilution of sample with reagent solutions.

RESULTS AND DISCUSSION

Gel beads and analytical column

Since the concentration of dithizone in the gel beads is directly related to the zone length of the zinc complex, stability of the dithizone is essential for an accurate result. However, dithizone decomposes so easily that gel beads of 0·01% or lower dithizone concentration could not be stored satisfactorily for more than 24 hr even in a dark cool place.

Dithizone gel beads stabilized by means of the zinc chelate, which were successfully used in mercury determination,[1] could not be used, because the regeneration of free dithizone by preliminary acid treatment always suffered interference from the trace of zinc which remained in the inner core of the gel beads. Thus, the green gel turned back to greenish pink when the pH was raised to 6·2.

Free dithizone gel beads were best stored in the 0·1*M* acetate buffer–0·1*M* sodium thiosulphate medium, the latter being added as a stabilizer for dithizone and also as a masking agent for interfering cations.[5] Columns filled with this medium could be stored in aluminium foil for 2·5 month at 5°.

The reaction of dithizone with heavy metal ions is so sensitive that even a slight touch of a metal surface such as a stainless-steel spatula to the green gel beads immediately causes the colour change to pink. Such coloured species tend to be localized in the gel beads, and the gel column gives a very sensitive colour spot-test for trace metal contamination. Incomplete pretreatment of polymer beads, porous plugs and other materials for the preparation of analytical columns with 3% hydrochloric acid often resulted in the appearance of pink spots on the gel column or on the interface between the gel and plugs.

Analytical procedure and colour reaction

The complexation of dithizone with zinc can be expressed as follows:

$$\underset{\text{green}}{2(\mathrm{H_2Dz})_o} + (\mathrm{Zn}^{2+})_w = \underset{\text{pink}}{(\mathrm{Zn(HDz)_2})_o} + 2(\mathrm{H}^+)_w$$

where o and w indicate the organic and aqueous phases respectively. The pH profile of the extraction of zinc dithizonate into chlorobenzene is shifted to slightly higher pH range than that for solvents such as chloroform,[6] reaching 100% extraction at around pH 6·0. On the other hand, free dithizone tends to distribute into the aqueous phase as

the dithizonate anion at above pH 7. Accordingly, the pH of the sample solution was adjusted to 6·2 with acetate buffer.

As dithizone complexes many heavy metal ions in the neutral pH range, all reagent solutions and the distilled water used have to be completely free from such ions. Therefore, all reagent solutions were previously shaken repeatedly with 0·05% dithizone solution in chlorobenzene until the organic layer remained clear green, or more conveniently were treated with a 0·05% dithizone gel column (11·3 mm bore and 250 mm long).[2]

Various masking agents were evaluated, in order to make the analytical column highly selective for zinc at the pH used. Poisonous reagents such as cyanide should be avoided, because the procedure may be used by non-chemists. Although sodium thiosulphate has been recommended for masking copper, bismuth, lead, cadmium and other interfering cations at pH 4–5·5,[5] this reagent alone was not so effective for moderate amounts of these ions at pH 6·2. *N,N*-Bis(β-hydroxyethyl)dithiocarbamate[3] effectively masked moderate amounts of metal ions such as silver, cadmium, cobalt(II), copper(II), lead and nickel. β-Dithiocarbaminopropionic acid[4] was effective for masking mercury(II) up to an amount equal to that of the zinc. Iron(III) could be masked as the non-extractable ferrous bipyridyl complex with α,α'-bipyridyl and hydroxylamine hydrochloride. With the combined use of these masking agents, the above-mentioned interfering cations could be masked. Tolerances and the amounts of masking agents necessary are summarized in Table 1.

Anions, with the exception of strong complexing agents such as EDTA or cyanide, did not interfere.

The rate of extraction of zinc into dithizone gel at pH 6·2 was found to be much slower than that of mercury(II) at pH 1. Accordingly, the flow-rate was kept at 0·2 ml/min in order to obtain a sharp colour boundary.

The sensitivity can be expressed by the weight of metal ion needed to give unit length of coloured zone. In the present procedure, with 0·01% dithizone gel, a 10-mm length of pink zone corresponded to 0·2 μg of zinc. Therefore, it was possible to determine down to 0·01 ppm of zinc with a 10-ml sample.

The accuracy of the results depends upon the sharpness of zone boundary, as well as the dithizone concentration in the gel beads. With a freshly prepared analytical column of 0·01% dithizone gel and at a flow-rate of 0·2 ml/min, the error is about ±10% at the 0·2–0·4 μg level and ±3% at the 2 μg level.

Under these conditions, the relation between the zone length and the volume of sample solution containing a given amount of zinc was linear, with slope dependent on the zinc concentration. Accordingly, the zinc concentration can be determined either by observing the zone length after passage of a known amount of sample solution, or by measuring the volume of sample solution needed for the coloured zone to reach a given point.

Table 1. Determination of zinc in the presence of some foreign metals (0·1 ppm zinc was taken in each determination)

EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF COBALT(II) WITH THIOBENZOYLACETONE AND SIMULTANEOUS DETERMINATION OF COBALT AND NICKEL

M. V. R. MURTI and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay-400 076, India

(*Received* 16 *May* 1975. *Accepted* 10 *June* 1975)

Thiobenzoylacetone (3-mercapto-1-phenylbut-2-en-1-one) has been used for the extractive photometric determination of nickel.[1] Further studies have revealed that cobalt can also be extracted as the orange–yellow complex at pH 8·4–9·1 and measured spectrophotometrically at 640 nm.

No systematic studies have been made on the solvent extraction of cobalt with benzoylacetone, dibenzoylmethane or furoyltrifluoroacetone.[2] Extraction with acetylacetone is generally incomplete[2] whereas extraction with 2-thenoyltrifluoroacetone in acetone–xylene mixture is quantitative. Thiothenoyltrifluoroacetone[3] has also been used but nickel shows strong interference. Thiodibenzoylmethane[4] has been used for the simultaneous spectrophotometric determination of cobalt and nickel with some advantage.

The method proposed in this paper is simple, rapid, selective and sensitive. It not only permits extractive spectrophotometric determination of cobalt at microgram concentrations but also makes it possible to determine cobalt and nickel simultaneously.

EXPERIMENTAL

Reagents

Thiobenzoylacetone (*SBA*). Synthesized from benzoyl acetone by the procedure described earlier.[1] An approximately 0·001*M* SBA solution in benzene was used. The reagent was preferably preserved in the refrigerator.

Cobalt nitrate solution. The hexahydrate (1·2 g) was dissolved in 250 ml of distilled water containing 1% nitric acid. The solution was standardized complexometrically[5] with EDTA, with Pyrocatechol Violet as indicator. The stock solution was diluted 100-fold (cobalt concentration 9·16 μg/ml).

General procedure

A 2-ml aliquot of the diluted cobalt nitrate solution (18·32 μg of Co) was diluted and its pH was adjusted to 8·4–9·1 with 0·01*M* nitric acid and 0·01*M* ammonia solution, in a total volume of 25 ml. It was then shaken for about 10 min with 10 ml of 0·001*M* thiobenzoylacetone in benzene. The layers were allowed to separate. The orange–yellow complex of cobalt(II) was measured spectrophotometrically at 460 nm against a reagent blank.

RESULTS AND DISCUSSION

Spectral properties

The absorption spectrum of the complex measured against a reagent blank had a maximum at 460 nm (Fig. 1). The reagent had an absorption maximum at 400 nm and the difference in absorbance between the complex and the excess of the reagent used was maximal at 460 nm. The molar absorptivity of the complex at 460 nm was $12{\cdot}7 \times 10^3$ $\text{l.mole}^{-1}.\text{cm}^{-1}$. The sensitivity of the method as defined by Sandell was 0·0046 μg/cm^2. Beer's law was obeyed at 460 nm in the concentration range 0·22–4·58 μg/ml in the extract. The absorbance of the complex remained constant for up to 144 hr.

Effect of pH

The extraction was studied over the pH range from 1·00 to 12·00 (Fig. 2). There was no extraction at pH < 6·0. The optimum pH was 8·4–9·1 and pH 8·8 was selected as being about in the middle of the range.

EXPERIMENTAL

Reagents

Thiobenzoylacetone (*SBA*). Synthesized from benzoyl acetone by the procedure described earlier.[1] An approximately 0·001*M* SBA solution in benzene was used. The reagent was preferably preserved in the refrigerator.

Cobalt nitrate solution. The hexahydrate (1·2 g) was dissolved in 250 ml of distilled water containing 1% nitric acid. The solution was standardized complexometrically[5] with EDTA, with Pyrocatechol Violet as indicator. The stock solution was diluted 100-fold (cobalt concentration 9·16 μg/ml).

General procedure

A 2-ml aliquot of the diluted cobalt nitrate solution (18·32 μg of Co) was diluted and its pH was adjusted to 8·4–9·1 with 0·01*M* nitric acid and 0·01*M* ammonia solution, in a total volume of 25 ml. It was then shaken for about 10 min with 10 ml of 0·001*M* thiobenzoylacetone in benzene. The layers were allowed to separate. The orange–yellow complex of cobalt(II) was measured spectrophotometrically at 460 nm against a reagent blank.

RESULTS AND DISCUSSION

Spectral properties

The absorption spectrum of the complex measured against a reagent blank had a maximum at 460 nm (Fig. 1). The reagent had an absorption maximum at 400 nm and the difference in absorbance between the complex and the excess of the reagent used was maximal at 460 nm. The molar absorptivity of the complex at 460 nm was $12{\cdot}7 \times 10^3$ $1.\text{mole}^{-1}.\text{cm}^{-1}$. The sensitivity of the method as defined by Sandell was 0·0046 μg/cm^2. Beer's law was obeyed at 460 nm in the concentration range 0·22–4·58 μg/ml in the extract. The absorbance of the complex remained constant for up to 144 hr.

Effect of pH

The extraction was studied over the pH range from 1·00 to 12·00 (Fig. 2). There was no extraction at pH < 6·0. The optimum pH was 8·4–9·1 and pH 8·8 was selected as being about in the middle of the range.

Selective extraction with (a) tributyl phosphate, (b) mesityloxide, (c) acetylacetone. Interference eliminated by masking with (d) thiourea, (e) fluoride.

Effect of reagent concentration

All other factors being kept constant, the concentration and volume of the reagent were varied. It was observed that the extraction of cobalt was complete with 10 ml of 0·001*M* SBA in benzene. The studies with 0·00025–0·002*M* reagent showed that the extraction was incomplete at lower concentration of the reagent, and no substantial increase in the extraction at higher reagent concentration. Varying the volume of 0·001*M* reagent from 2·5 to 20 ml showed that the extraction was quantitative even with 6 ml of reagent, but throughout 10 ml of reagent were used for the purpose of extraction.

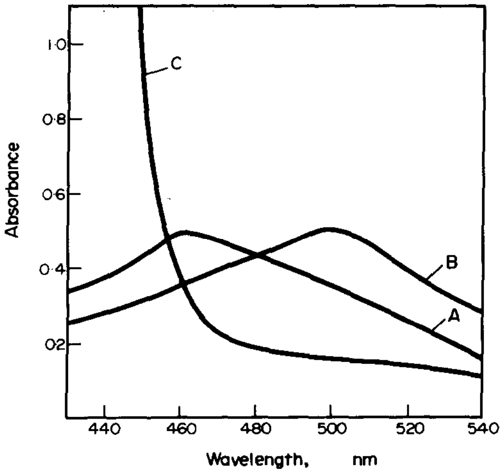

Fig. 1. Absorption spectra. A = Co(II)–SBA complex against reagent blank; B = Ni(II)–SBA complex against reagent blank; C = reagent blank against benzene. Co(II) = $3·886 \times 10^{-5}M$; Ni(II) = $8·396 \times 10^{-5}M$; SBA = 0·001*M* in benzene.

Period of equilibration

The period of equilibration was varied from 2 to 20 min. A wrist-action flask-shaker was used. The extraction was quantitative after 5 min of equilibration. It is therefore recommended to shake the mixture for at least 8–10 min.

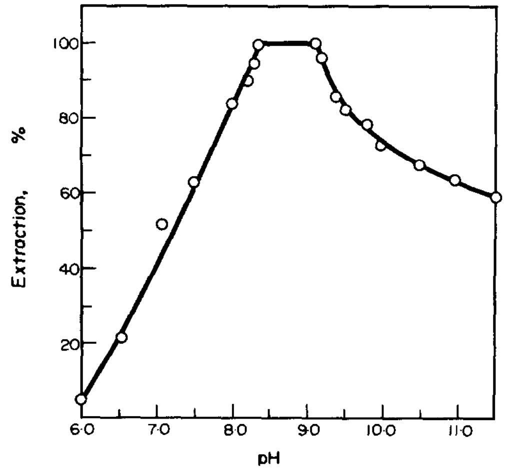

Fig. 2. Extraction of Co(II) as a function of pH. Co(II) = $3·109 \times 10^{-5}M$, 0·001*M* SBA in benzene.

Effect of salting-out agents

Ammonium, sodium, potassium, magnesium and calcium nitrates were tested as salting-out agents in the concentration range 1–4*M* but none enhanced the extraction.

Effect of diverse ions

Several ions were examined for their effect on the extraction of cobalt(II). The tolerance limit was taken as the amount of foreign ion required to cause ±2% error in the cobalt(II) recovery (Table 1). It was observed that many ions were tolerated in weight ratios (relative to cobalt) of 200:1 and 50:1. The ions showing interference were mercury(II), cyanide and EDTA. Several sequestering agents were tolerated at higher levels and hence they were used to eliminate the interference of some ions by forming negatively charged complexes which were not extracted along with cobalt(II), *e.g.*, silver and bismuth with thiourea, and aluminium, thorium and beryllium with fluoride. Mesityl oxide[2,6] was used to extract antimony, iron and chromium; tributylphosphate[2] was used for extraction of lead; acetylacetone[2] was used for copper and palladium. At the acidity used for the extraction of these ions cobalt(II) remained unextracted in the aqueous phase and could subsequently be extracted and determined with 0·001*M* SBA in benzene.

SIMULTANEOUS DETERMINATION OF COBALT AND NICKEL

Since the absorption maxima of the cobalt and nickel complexes are widely separated, these two metals were determined simultaneously by measurements at 460 and 500 nm (Fig. 1) and suitable spectrophotometric equations were applied.[7] Two conditions for use of these equations were satisfied, *viz.*, the absorbances of the complexes were additive at the wavelengths studied and Beer's law was obeyed by the complexes at both wavelengths. In Table 2 are given the molar absorptivities of the complexes for use in the calculations.[7]

$$C_{\text{Co}}(a_{\text{Co}})_{460} + C_{\text{Ni}}(a_{\text{Ni}})_{460} = A_{460} \qquad (1)$$

$$C_{\text{Co}}(a_{\text{Co}})_{500} + C_{\text{Ni}}(a_{\text{Ni}})_{500} = A_{500} \qquad (2)$$

where a = molar absorptivity and C = concentration of metal ion.

Table 2. Molar absorptivities of cobalt and nickel complexes, $l.mole^{-1}.cm^{-1}$

	460 *nm*	500 *nm*
Co(II)	$1{\cdot}27 \times 10^4$	$8{\cdot}84 \times 10^3$
Ni(II)	$4{\cdot}42 \times 10^3$	$5{\cdot}46 \times 10^3$

Table 3. Simultaneous determination of cobalt and nickel

Taken, μg $Co^{2+} + Ni^{2+}$	Found, μg $Co^{2+} + Ni^{2+}$	Error, % Co	 Ni
9·16 + 39·44	9·46 + 38·7	3·3	1·8
18·32 + 29·58	18·21 + 30·2	0·6	2·2
4·58 + 49·30	4·76 + 48·7	3·8	1·3
18·32 + 39·44	18·16 + 39·6	0·9	0·5
9·16 + 19·72	9·39 + 19·6	2·6	0·6
22·90 + 9·86	23·03 + 10·2	0·6	3·6

Procedure for simultaneous spectrophotometry

The mixture of cobalt and nickel was adjusted to pH 9·0 with 0·01*M* nitric acid and 0·01*M* ammonia solution. It was then extracted for 10 min with 10 ml of 0·001*M* SBA in benzene. The organic layer was separated and measured at 460 and 500 nm. The concentrations of cobalt and nickel were calculated by using the equations above. Results for various concentrations of cobalt and nickel are shown in Table 3.

Accuracy and precision

The proposed method possesses several advantages. The method is simple, selective, sensitive and applicable at tracer quantities. It is possible to extract quantitatively and determine spectrophotometrically cobalt and nickel in 30 min. As little as 0·2 μg/ml can be determined and the results are reproducible. The average recovery of cobalt in the absence of nickel is 99·9 ± 1%, relative standard deviation ±0·85%. The simultaneous determination of cobalt and nickel gives somewhat poorer accuracy (Table 3).

Summary—Thiobenzoylacetone in benzene is used for the extraction and spectrophotometric determination of cobalt at pH 8·4–9·1. The orange–yellow complex is measured at 460 nm. The system conforms to Beer's law over the range 0·20–4·58 μg/ml of extract. The colour of the complex is stable for at least 144 hr. Cobalt(II) is quantitatively extracted and determined in the presence of 200:1 (w/w ratios) of various ions. The method is made selective by using common sequestering agents such as thiourea or fluoride or by selective extraction with mesityl oxide, tributylphosphate and acetylacetone. It is possible to determine cobalt in the presence of nickel by simultaneous spectrophotometry. The method is rapid, simple, selective and sensitive.

OXIDATION WITH PERMANGANATE IN ACID MEDIUM CONTAINING FLUORIDE: DETERMINATION OF BISULPHITE

I. M. Issa, K. A. Idriss and M. M. Ghoneim
Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

(*Received* 9 *May* 1973. *Revised* 13 *June* 1975. *Accepted* 30 *June* 1975)

The reaction with alkaline permanganate has been applied by Issa *et al.*[1] for the determination of sulphite. The estimation of bisulphite has been the subject of a few investigations.[2–5] The reaction between HSO_3^- and MnO_4^- in acid medium is usually beset with difficulties owing to the precipitation of oxides of manganese. In the present method, this difficulty is overcome by oxidizing HSO_3^- with MnO_4^- in acid medium in the presence of fluoride.

EXPERIMENTAL

Solutions

Potassium permanganate solutions were prepared by a method similar to that of Stamm[6] and standardized with sodium oxalate.[7] Sodium bisulphite solutions were prepared and standardized according to a recommended procedure.[2] Other solutions included 2% sodium fluoride, 1*M* sulphuric acid and 0·25*M* copper sulphate. All solutions were prepared from analytical-grade reagents and twice-distilled water.

Apparatus

The emf of the titration cell was measured with a Radiometer millivoltmeter (Model pH M28 b). The cell used consisted of the titration half-cell and a calomel reference electrode. The platinum rod indicator electrode was always abraded with emery paper, etched with *aqua regia* and rinsed with twice-distilled water before use in each titration.

RESULTS AND DISCUSSION

The reaction proceeds rapidly but as the end-point is approached the electrode equilibration becomes rather sluggish, needing 5 min between additions of titrant. The potentiometric titration is not affected by addition of Cu(II), but this is essential for detection of the end-point in the visual titration (to mask the pink colour of the MnF_4^- complex).[8,9]

Titration of bisulphite with permanganate

From Tables 1 and 2, the reaction appears to proceed quantitatively in accordance with the equation

$$MnO_4^- + H^+ + 2HF_2^- + 3HSO_3^- \rightleftharpoons MnF_4^- + SO_4^{2-} + S_2O_6^{2-} + 3H_2O \quad (1)$$

The potentiometric titration curves have two inflections, the first due to formation of Mn(II) and the second to formation of Mn(III) (Fig. 1). This is confirmed by the absence of any absorption band for Mn(III)[10] in the spectrum of the reaction mixture at the first inflection and its presence in the spectrum of the solution at the second inflection.

The first inflection corresponds to:

$$4MnO_4^- + 7H^+ + 15HSO_3^- \rightleftharpoons 4Mn^{2+} + 5S_2O_6^{2-} + 5SO_4^{2-} + 11H_2O \quad (2)$$

and the second to the reaction

$$MnO_4^- + 10HF_2^- + 4Mn^{2+} \rightleftharpoons 5MnF_4^- + 2H^+ + 4H_2O \quad (3)$$

giving (1) as the overall reaction.

The formation of dithionate is confirmed by an absorption band at 242 nm, and by analysis by the method of Murthy.[12]

Effect of acidity. Tables 1 and 2 show that reasonable accuracy is obtained at acidities ranging from 0·01 to 0·02*M* sulphuric acid in presence of 0·24*M* sodium fluoride. At lower acidities the solution becomes yellowish brown owing to partial production of Mn(IV). At higher acidities the end-point occurs too early owing to the instability of bisulphite solution under such conditions.

Effect of fluoride concentration. Tables 1 and 2 indicate that the fluoride concentration can be varied from 0·24 to 0·38*M* at constant concentration of 0·02*M* sulphuric acid, without causing appreciable error. Although 0·12*M* sodium fluoride is sufficient for complexation of Mn(III),[9,11] a higher concentration is needed because of protonation of fluoride by the strong acid added, and for stabilization of the MnF_4^- complex.

Effect of $NaHSO_3$ concentration. The visual end-point method is suitable for 10–60 mg of bisulphite, and the potentiometric titration for amounts up to 100 mg (Table 3). With higher bisulphite concentrations the reaction becomes slow and the titration medium slightly turbid owing to hydrolysis of Mn(III) to Mn_2O_3.[9,11] The error is generally < 0·7%.

Titration of permanganate with bisulphite

The results indicate that the reaction proceeds quantitatively according to the equation

$$MnO_4^- + 2HF_2^- + 2HSO_3^- \rightleftharpoons MnF_4^- + 2SO_4^{2-} + 2H_2O \quad (4)$$

The titration curves have a single sharp inflection at the Mn(III) step, varying in height with acidity. Since all manganese(III) salts are strong oxidizing agents, a further reaction between the Mn(III) formed and more HSO_3^- to produce Mn(II) and SO_4^{2-} would be expected to occur, but it was found difficult to continue the titration to the Mn(II) reduction step owing to the sluggishness of the reaction.

Effect of acidity. Table 4 shows that good results are obtained at acidities ranging from 0·02 to 0·05*M* sulphuric acid, both in the visual and potentiometric titrations with use of 50 ml of 2% sodium fluoride solution but at the higher acidities, the end-point occurs later than expected, probably because of partial production of Mn(II).

Effect of fluoride concentration. In 0·24–0·38*M* sodium fluoride at the optimum acidity, the titration yields good results in both the visual and potentiometric methods (Table 4). With lower concentrations of sodium fluoride, late end-points were obtained [production of Mn(II)].

Amounts of permanganate corresponding to 3–16 mg of manganese could be titrated successfully under the optimum conditions (Table 5), the error being generally < 0·7%.

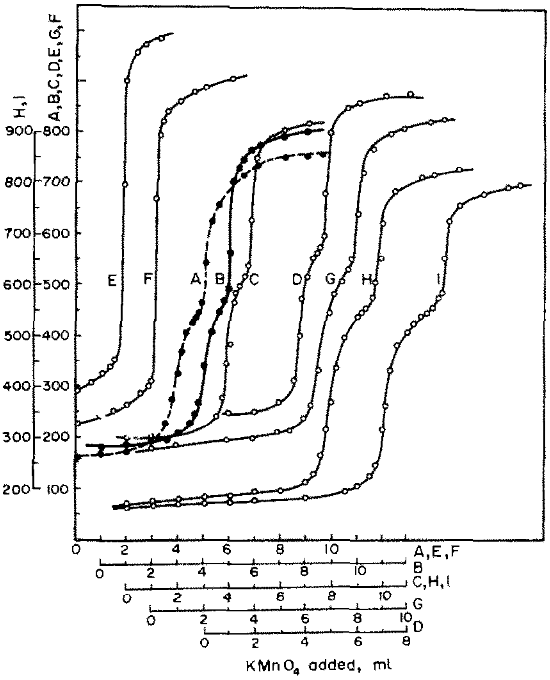

Fig. 1. Titration of 0·047*M* bisulphite with 0·0189*M* MnO_4^-. (A) 6 ml of HSO_3^-, 50 ml of 2% NaF and 1·0 ml of 1*M* H_2SO_4; (B) 6 ml HSO_3^-, 50 ml of 2% NaF and 2·0 ml of 1*M* H_2SO_4; (C) 6 ml of HSO_3^-, 50 ml of 2% NaF and 4·0 ml of 1*M* H_2SO_4; (D) 6 ml of HSO_3^-, 50 ml of 2% NaF and 9·0 ml of 1*M* H_2SO_4; (E) 6 ml of HSO_3^-, no sodium fluoride, 2·0 ml of 1*M* H_2SO_4; (F) 6 ml of HSO_3^-, 10 ml of 2% NaF and 2·0 ml of 1*M* H_2SO_4; (G) 10 ml of HSO_3^-, 50 ml of 2% NaF and 2·0 ml of 1*M* H_2SO_4; (H) 12 ml of HSO_3^-, 50 ml of 2% NaF and 2·0 ml of 1*M* H_2SO_4; (I) 15 ml of HSO_3^-, 50 ml of 2% NaF and 2·0 ml of 1*M* H_2SO_4.

General discussion

Oxidation of sulphur compounds with permanganate usually produces sulphate, especially when performed in

alkaline medium.[1,13,14] An exception is the oxidation of sulphide in presence of telluric acid which yields dithionate.[15] In acid medium, dithionate is often an intermediate stage in the oxidation of sulphide, sulphite and thiosulphate,[16] and this is apparently also the case when bisulphite is titrated with permanganate in presence of fluoride, though the reverse titration gives sulphate because the oxidant is always present in excess.

The pH of the reaction mixture under optimum conditions is 4–5·5. Since pK_1 for H_2SO_3 is 1·92 then practically no H_2SO_3 should be present and hence decomposition to yield SO_2 is not probable. This was confirmed experimentally by doing the titration with a closed system and testing the atmosphere above the titrated solution for SO_2; none was found.

Summary—The factors affecting the success of both visual and potentiometric end-point detection in titration of bisulphite with permanganate in the presence of fluoride are examined. The optimum conditions are 0·02*M* H_2SO_4 and 0·24–0·38*M* NaF. The oxidation product comprises dithionate and sulphate according to the overall reaction $MnO_4^- + H^+ + 2HF_2^- + 3HSO_3^- \rightleftharpoons MnF_4^- + S_2O_6^{2-} + SO_4^{2-} + 3H_2O$. The reverse titration is also satisfactory, but proceeds quantitatively according to $MnO_4^- + 2HF_2^- + 2HSO_3^- \rightleftharpoons MnF_4^- + 2SO_4^{2-} + 2H_2O$.

(*Received* 28 *February* 1975. *Accepted* 18 *June* 1975)

INTRODUCTION

The increased stability of mixed complexes of Cu(II), 2,2′-bipyridyl and ligands which have oxygen donor atoms[1] has been attributed to the entropy effect, π-bond formation between copper(II) and the bipyridyl, and, in minor measure, to the effect of the oxygen-donor ligand.[2] To test this hypothesis further, we decided to study a series of dicarboxylic acids in this reaction, first those which form six-membered chelate rings,[3–5] and now those which form seven-membered rings.

EXPERIMENTAL

Reagents

Maleic acid (MALE) and phthalic acid (PHT) were recrystallized several times; their purity was found to be >99·8% by potentiometric titration. Disodium maleate was obtained by adding a slight excess of sodium hydroxide to maleic acid, evaporating the solution to dryness, shaking the residue for 1–2 hr with ethanol to dissolve out the surplus alkali, filtering and drying. Other reagents were prepared as described earlier.[3,4] The copper perchlorate solutions contained a small amount of perchloric acid; this was allowed for in the calculations. All solutions were prepared with twice-distilled CO_2-free water.

Apparatus

The potentiometric equipment was that used earlier.[3] The cells were equipped with a capillary tube for deaeration of the solutions during measurement. All solutions were maintained at 25 ± 0·1° and constant ionic strength 0·1M ± 5% (perchlorate acid and sodium perchlorate).

Procedures

Determination of the ligand protonation constants. Solutions containing the ligand in concentrations from 10 to 1mM were titrated potentiometrically with sodium hydroxide. For maleic acid, which has a very low first pK_a, it was necessary to add an excess of protons (perchloric acid) to the initial solution so that $\bar{n}_H$ was significantly greater than 1.

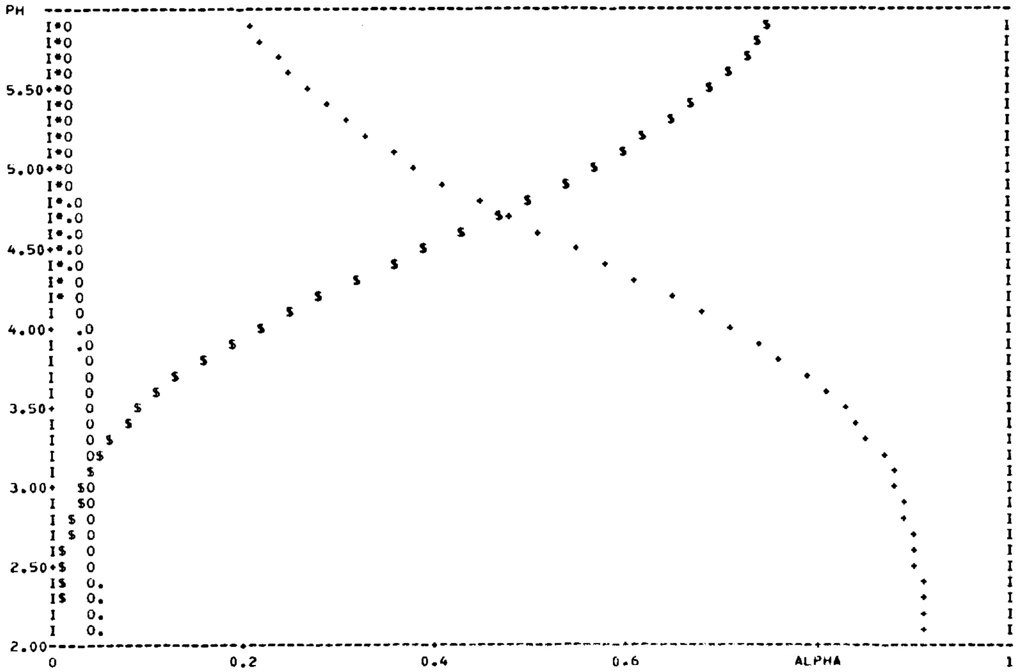

Fig. 1. Distribution diagram of the species present in aqueous solutions of Cu(II), 2,2′-bipyridyl and maleic acid (each 1 mM), calculated by the program DISDI.[7] \$—CubipMALE; +—Cubip; ○—Cubip$_2$; *—CuMALE; ·—Cu; ALPHA = degree of formation.

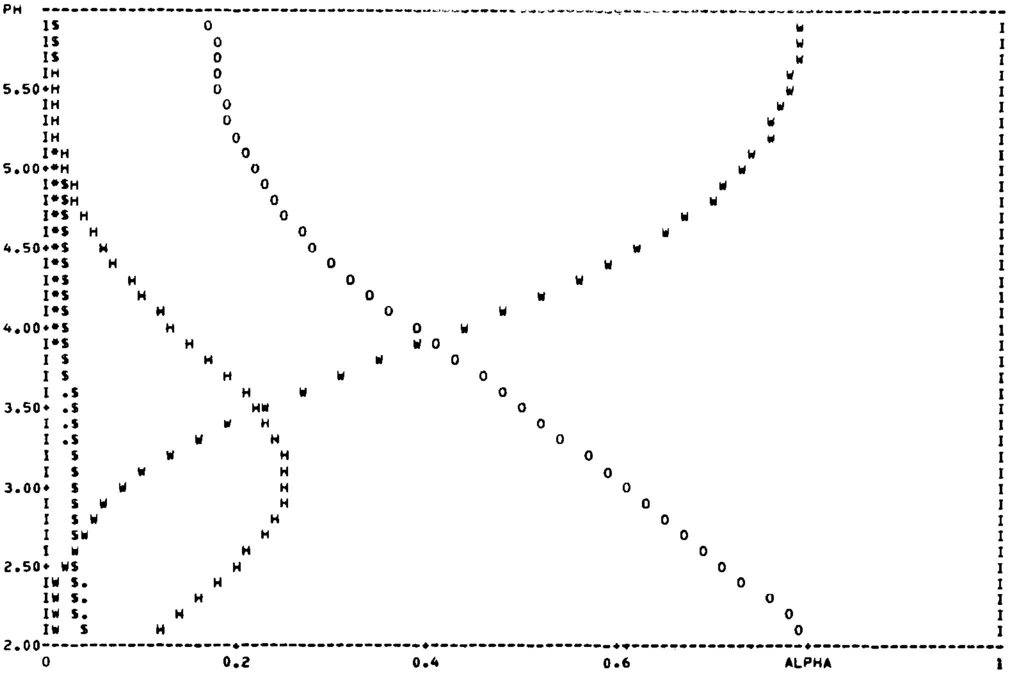

Fig. 2. Distribution diagram of the species present in aqueous solutions of Cu(II), 2,2′-bipyridyl and phthalic acid (each 1 mM), calculated by the program DISDI.[7] W—CubipPHT; O—Cubip; H—CubipHPHT; \$—Cubip$_2$; *—CuPHT; ·—Cu; ALPHA = degree of formation.

Determination of the formation constants of the Cu(II)–maleate and Cu(II)–phthalate complexes. Cupric perchlorate (*ca.* 1mM) solutions containing ligand in up to 6-fold ratio to copper were titrated with sodium hydroxide to a pH equal to pK_2 + 0·2. Solutions containing cupric perchlorate and perchloric acid were also titrated with disodium maleate.

Determination of the formation constants of the mixed complexes. Solutions containing copper, bipyridyl and phthalic acid in the ratios 1:1:1, 1:1:2, 1:1:3, 2:1:1, 3:1:1 (1mM bipyridyl) were titrated to pH 5·3 in the first three cases, and pH 4 in the last two. Solutions containing copper, bipyridyl and maleic acid in the ratios 1:1:1, 1:1:2, 1:1:3 (1mM bipyridyl) were titrated up to pH 6·1, and solutions containing copper and bipyridyl (1:1) and perchloric acid (1mM) were titrated with disodium maleate.

CALCULATIONS

The values of the protonation and formation constants[4,6] of the copper(II) with 2,2′-bipyridyl, for calculation of the constants relative to the ternary systems, were taken from the literature. The calculations were performed by means of the programs PMGZ and SCOGSB, as described earlier.[3,4]

RESULTS AND DISCUSSION

The values of the protonation constants of the acids and their formation constants with copper(II) are listed in Table 1. The stability constants of the ternary complexes are reported in Table 2. Distribution diagrams of the species present in solution are reported in Figs. 1 and 2, as they were printed by the computer.[7] By using the values listed in Tables 1 and 2, we calculated the data relative to the parameters log K_r and Δlog K,[8] defined as before.[3] The results are reported in Table 3, together with those for similar systems already studied, the log $\beta^{\mathrm{Cu}}_{\mathrm{CubipL}}$ values, and the differences between the first and the second stability constants of the complexes CuL and CuL$_2$ (Δ'log K = log $K^{\mathrm{Cu}}_{\mathrm{CuL}}$ − log $K^{\mathrm{Cu}}_{\mathrm{CuL_2}}$). From these values we can say that

these complexes are more stable than would be expected on statistical grounds (log $K_r > 0·6$) and show good discriminating properties (namely the complex Cubip^{2+} prefers to give the species CubipL rather than the cation Cubip$_2^{2+}$, in fact[1,2] Δlog $K > 0$). Because these systems have the same co-ordination number and type,[11] they can be used to assess the influence of the chelate-ring size and the ligand characteristics on the stability of the mixed complexes. Thus the complexes with five-membered rings are more stable than those with six-membered rings, which, in turn, are more stable than those with seven-membered ones; in contrast, the system CubipCPRD showed a different behaviour, as the conjugating effect of the alicyclic ligand[10,11] increased the chelation effect. Recently, Sigel and co-workers,[12] examining ternary complexes with five- or six-membered rings, and also with one five- and one six-membered ring, pointed out that great care is necessary in choosing the parameters for correct comparison of systems. In particular, the mixing constant log K_r, because it is strongly influenced by Δ′log K, can be used as a stabilization index only for series of systems in which Δ′log K is of the same order of magnitude. As in our systems Δ′log K ranges from 0·9 to 2·5, the use of Δlog K is a more realiable means of evaluating the stabilization of ternary complexes. This agrees with the opinion of others.[13] The final conclusions are: (*a*) ternary complexes with five-membered chelate rings are stabilized more than those with six- and seven-membered rings which have similar stabilizing power; (*b*) a ligand with conjugating and delocalizing properties increases the chelating effect, both with six- and seven-membered rings.

purity was confirmed by elemental analysis, m.p., and spectroscopy.

The stability constants were calculated as described earlier, and activity coefficient corrections were applied.

The concentrations of beryllium(II), ligand and nitric acid in the titration vessel were generally around 0·001, 0·01 and 0·001 M respectively. The nitric acid was added in the preparation of the beryllium nitrate solutions, to minimize hydrolysis.

RESULTS AND DISCUSSION

The thermodynamic stability constants are summarized in Table 1. The maximum scatter in log K_1 was ±0·15. The hydroxamic acids used are bidentate ligands. Beryllium(II) has a co-ordination number of 4 in its hydroxamic acid complexes.[8,9] The nature of the metal–ligand bond can be assessed from comparison of the pK_a of closely related ligands and log K_1 for the corresponding 1:1 beryllium complexes. Correlations between pK_a and log K_2 are less exact because other factors influence the complex formation.[10] This is in agreement with the values given in Table 1.

A graph of log K_1 *vs.* pK_a is linear; least squares calculations give the relation log K_1 = 1·44 pK_a − 6·99. Since the slope is greater than unity the nuclear substitution affects the stability of the complex more than that of the free acid.[11–13]

Table 1. Stability constants of beryllium(II) complexes

X	pK_a	log K_1	log K_2
OCH_3	11·13	9·05	8·03
CH_3	10·98*	8·85	7·46
H	10·96*	8·68	7·15
Cl	10·68	8·41	6·98
Br	10·65	8·24	6·89
NO_2	10·15	7·76	6·48

* Ref. 15.

Table 2. Comparison of log K_1 with ionization potential for bivalent metal complexes of *N*-phenylbenzohydroxamic acid

Ion	I.P., *eV*	log K_1[15]
Cu^{2+}	27·92	10·36
Be^{2+}	27·46	8·68*
Zn^{2+}	27·28	7·51
Ni^{2+}	25·76	7·00
Mn^{2+}	23·13	6·02

* This work.

It was found that the Hammett equation is applicable to the K_1 values for the beryllium complexes; a plot of log K_1 *vs.* σ being linear: log K_1 = 8·66 − 1·225 σ. The values of log K_1, log K_2, and pK_a decrease when the substituted acids are arranged in the order

$$CH_3OR > CH_3R > HR > ClR > BrR > NO_2R$$

where R represents $-C_6H_4.CO.NOH.C_6H_5$.

Comparison of the metal ionization potentials and K_1 *values*

It is observed that log K_1 of *N*-phenylbenzohydroxamic acid is linearly related to the ionization potential for Mn, Ni and Zn (Table 2) but the beryllium and copper complexes have higher stability. In the case of copper this may be attributed to the Jahn–Teller effect, and in that of beryllium to the small radius of the beryllium ion.

Summary—The thermodynamic stability constants of beryllium(II) complexes of *p*-substituted *N*-phenylbenzohydroxamic acids have been determined in 50% v/v aqueous dioxan at 35°. The effect of methoxy, methyl, chloro, bromo, and nitro groups as substituents is discussed. There is a linear relationship between log K_1 and pK_a, and the Hammett equation is applicable. The beryllium complexes have been compared with those of Cu, Zn, Ni and Mn.

ANALYTICAL PROPERTIES OF 1,3-CYCLOHEXANEDIONE BISTHIOSEMICARBAZONE MONOHYDROCHLORIDE

J. J. BERZAS NEVADO, J. A. MUÑOZ LEYVA and M. ROMAN CEBA
Department of Analytical Chemistry, Faculty of Sciences Badajoz, University of Extremadura, Spain

(*Received* 28 *April* 1975. *Accepted* 29 *May* 1975)

Thiosemicarbazones are interesting as analytical reagents. Monothiosemicarbazones with an electron-donating group in the α-position have been studied the most. In this paper the synthesis, properties and analytical possibilities of a β-thiosemicarbazone, *viz*. 1,3-cyclohexanedione bisthiosemicarbazone monohydrochloride (1,3-CHDT·HCl), are described for the first time.

EXPERIMENTAL

Preparation of the compound

A hot solution of 2·0 g of 1,3-cyclohexanedione in 6 ml of ethanol was added dropwise to a stirred solution of 3·26 g of thiosemicarbazide dissolved in 14 ml of water, 12 ml of ethanol and 3 ml of concentrated hydrochloric acid. A white product separated and was purified by washing with ethanol (m.p. 240–242°; yield, 75%). Found: C 32·7%, H 5·1%, N 28·5%. Calculated for $C_8H_{14}N_6S_2 \cdot HCl$: C 32·60%, H 5·09%, N 28·50%. The purity of the product was found to be 99·2% by direct titration with 0·05*M* sodium hydroxide with phenolphthalein as indicator.

To obtain the 1,3-cyclohexanedione bisthiosemicarbazone a hot saturated solution of 1,3-CHDT·HCl was neutralized with 5*M* sodium hydroxide. As the solution cooled a yellow product crystallized out (m.p. 175–177°, decomp.). The yield was poor. Found: C 37·5%, H 5·6%, N 31·9%, S 24·9%. Calculated for $C_8H_{14}N_6S_2$: C 37·21%, H 5·42%, N 32·55%, S 24·80%.

Properties

Some physicochemical properties of 1,3-CHDT·HCl are summarized in Table 1. The absorption spectra at various pH values are shown in Fig. 1. Dilute aqueous solutions of 1,3-CHDT·HCl ($7{\cdot}75 \times 10^{-5}M$) were not very stable, but 0·1% solutions in hydrochloric acid were stable for more than a month. The p*K* values were calculated from the absorption spectra of solutions of 1,3-CHDT·HCl at different pH values from 0·5 to 13·0.[1] The p*K* values shown in Table 1 are the arithmetic mean of the values obtained from measurements at four different wavelengths. The pK_1 value was also determined by potentiometry.

TGA shows a loss of ammonium chloride from 1,3-CHDT·HCl and loss of ammonia from 1,3-CHDT. As in the solutions, the compound is stabilized by protonation.

A peak at 5·7 ppm in the NMR spectrum of the compound dissolved in deuterium oxide indicates the presence of a vinyl proton.

pK_1 (potentiometric method)	4·75
pK_2 (photometric method)	10·5

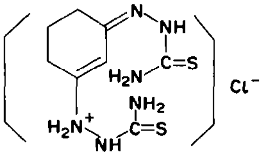
Reactions with cations and anions

The reactions of 40 cations and 13 anions with 1,3-CHDT·HCl were tested at different pH values. The samples were prepared in 50-ml volumetric flasks with 2 or 8 ppm of ion, 10 ml of 0·1% solution of 1,3-CHDT·HCl in 0·01*M* hydrochloric acid, 5 ml of dimethylformamide and 2 ml of 1*M* sodium hydroxide, buffer solution or 1*M* hydrochloric acid, and dilution to 50 ml with distilled water. The absorbance was measured at 350–700 nm against reagent blanks. The most important results are summarized in Table 2.

RESULTS AND DISCUSSION

1,3-Cyclohexanedione bisthiosemicarbazone monohydrochloride is as easily obtained by condensation in hydrochloric acid medium as the α-bis-thiosemicarbazones,[2] probably because it is stabilized as the hydrochloride. In general, the sythesis of β-bisthiosemicarbazones is more complicated[3] and produces thiazoles under the conditions of our synthesis.[4]

The presence of a vinyl proton and the fact that 1,3-CHDT·HCl is obtained as the monohydrochloride shows that there is a quaternary ammonium group. From these results we propose the following structure:



This structure is consistent with the loss (in the TGA) of ammonium chloride from 1,3-CHDT·HCl and ammonia from 1,3-CHDT to give the same product.

The bathochromic shift of a strong absorption band from 309 to 360 nm indicates that in solution, on increasing the pH, the acid is neutralized and the >C═S group is enolized and dissociated.[5]

In general, bisthiosemicarbazones are easily oxidized or reduced and in acid medium are easily hydrolysed. 1,3-CHDT·HCl is unstable towards strong redox agents but is not hydrolysed by acids, and can be used in acidic solutions.

The stability, solubility in water, absence of absorption in the visible region and the sensitive reactions with several ions to form intensely coloured compounds, show that 1,3-CHDT·HCl is an interesting analytical reagent.

ANNOTATION

THE EFFECT OF PLATINUM(IV) ON THE COULOMETRIC GENERATION OF TIN(II)

ADAM HULANICKI and WOJCIECH JEDRAL
Institute of Fundamental Problems in Chemistry, The University, Warsaw, Poland

(*Received* 19 *February* 1975. *Revised* 8 *May* 1975. *Accepted* 4 *July* 1975)

Most titrimetric methods for determination of platinum are based on the preliminary reduction of platinum(IV) to platinum(II); the excess of reducing agent is then determined or is destroyed and the platinum(II) titrated. This is the basis of the biamperometric method of platinum determination, which has been applied to analysis of several technical materials.[1,2] A simpler method would be direct reductometric titration of platinum(IV) but it is difficult to find a convenient titrant. A good reagent of this sort should be tin(II), but its solutions are unstable. Therefore electrogeneration of tin(II) should be considered.

Several authors have investigated electrolytic generation of tin(II) by reduction of tin(IV). Those studies indicate the difficulty of getting 100% current efficiency, which depends on the electrolyte composition and the type of electrode used. Because of competitive reduction of hydrogen ions, the choice is limited to electrodes which have a high overpotential for hydrogen evolution and electrolytes in which the formal potential of the Sn(IV)/Sn(II) system is as positive as possible. However, in some electrolytes tin(II) may be too weak a reducing agent for practical determinations.

Bard[3] has studied titration with electrogenerated tin(II) and its application to the determination of platinum. He used $4M$ NaBr/$0{\cdot}3M$ HCl/$0{\cdot}2M$ $SnCl_4$ as electrolyte with gold or platinum electrodes. In our experiments we failed to obtain satisfactory results by use of those conditions. Ginstrup[4] also used electrogenerated tin(II) for platinum(IV) reduction under those conditions, but the determination was completed by oxidation with bromine. He also mentioned difficulties in obtaining 100% efficiency of tin(II) generation. We have been trying to develop a coulometric titration for platinum and have investigated electrogeneration of tin(II) as the titrant. This paper described the difficulties encountered.

EXPERIMENTAL

Reagents

Platinum(IV) solution was obtained by dissolution of 99·99% pure platinum foil in *aqua regia*, evaporation three times with hydrochloric acid, and dilution to standard volume.

Sodium bromide, $4M$ solution; sodium chloride, $4M$ solution; calcium chloride, $5M$ solution; tin(IV) chloride, $2M$ solution; cadmium chloride, $0{\cdot}5M$ solution: all were prepared from analytical-grade reagents.

Apparatus

Coulometric analyser (Radelkis OH-404), pH-meter (N-512, Elpo-Poland), quartz clock (C-549, Elpo).

All measurements were carried out in a 150-ml cell.

RESULTS AND DISCUSSION

Coulometric generation of tin(II)

Tin(II) was generated in concentrated halide solutions, namely $6M$ hydrochloric acid, $3M$ sodium bromide, $3M$ sodium chloride, or $2M$ calcium chloride, the last three being acidified to be $0{\cdot}2M$ in hydrochloric acid. Gold, platinum, graphite, graphite impregnated with paraffin[5] and glassy carbon (surface area about 1 cm^2) were used as electrodes. A cadmium bar was used as the anode, in $0{\cdot}5M$ cadmium chloride, separated by a sintered-glass disc from the rest of the electrolytic cell.

The efficiency of generation was calculated on the basis of the voltammetric curves obtained for solutions with and without tin(IV) (Figs. 1 and 2). The potential of the electrode was potentiostatically controlled and varied at 0·05 V intervals in the range from 0 to $-1{\cdot}0$ V *vs.* SCE.

In all cases an increase of tin(II) generation was

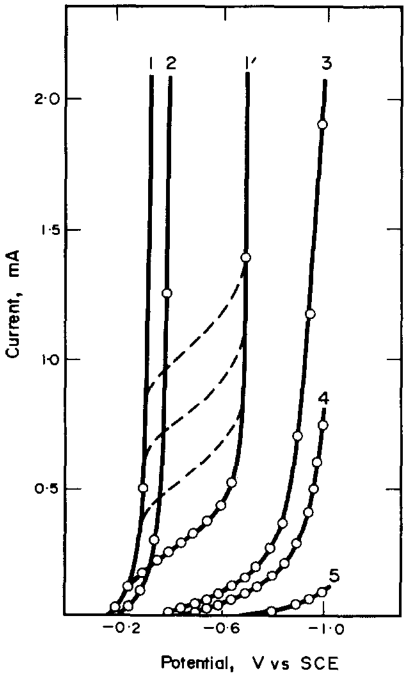

Fig. 1. Voltammetric curves obtained for various electrodes (approx. 1 cm^2 surface area) in $3M$ NaBr/$0{\cdot}2M$ HCl. 1—platinum, 2—gold, 3—graphite, 4—glassy carbon, 5—paraffin-impregnated graphite. The dashed lines indicate results for various degrees of passivation of the platinum electrode.

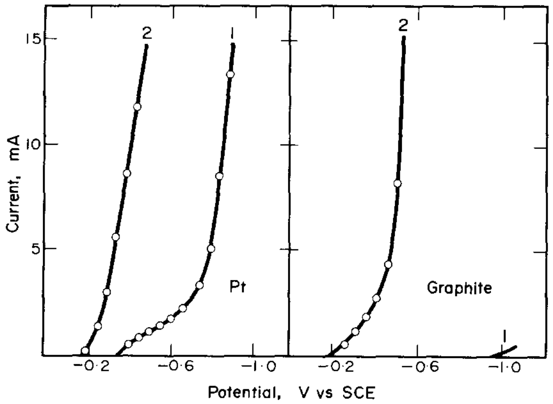

Fig. 2. Voltammetric curves for the platinum and paraffin-impregnated graphite in the following electrolytes: 1—3*M* NaBr/0·2*M* HCl, 2—3*M* NaBr/0·2*M* HCl/0·2*M* $SnCl_4$.

observed for current densities above 10 mA/cm^2, but at 20 mA/cm^2 reduction of tin(IV) to metal was observed (Fig. 3). However, this does not influence the efficiency of generation of the reducing agent, which remains constant at current densities up to 50 mA/cm^2.

The efficiency at metallic electrodes was lower than that at graphite electrodes, the highest being for the paraffin-impregnated graphite. With this electrode, for 0·2*M* tin(IV) chloride, the calculated efficiencies are

3*M* NaCl + 0·2*M* HCl	99·7–99·9%
3*M* NaBr + 0·2*M* HCl	99·7–99·9%
2*M* $CaCl_2$ + 0·2*M* HCl	99·9–99·98%
6*M* HCl	98–99%

In 6*M* hydrochloric acid, generation of tin(II) proceeded satisfactorily only at the graphite electrodes. In the other media the efficiency at the gold electrode was about 0·5% lower that at the impregnated graphite electrode. For the platinum electrode the results were still lower, and significantly dependent on the nature of the platinum surface. The results were especially poorly reproducible in sodium bromide. The passivated platinum electrode was found better than gold, but freshly cleaned platinum has an efficiency lower by several per cent. The current–potential curves for platinum electrodes passivated to various degrees are indicated by dashed lines in Fig. 1. Change of tin(IV) concentration from 0·02 to 4*M* increases the limiting current density at which tin(IV) is reduced to metal, causing the better efficiency of Sn(II) generation only up to 2 mA/cm^2. For greater current densities the concentration of Sn(IV) does not influence the efficiency of Sn(II) generation (Fig. 4).

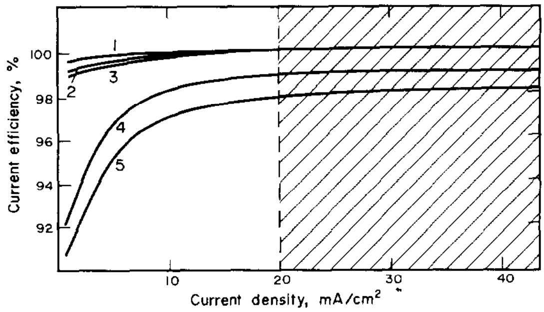

Fig. 3. Current efficiency of tin(II) generation at the various electrodes in 3*M* NaBr/0·2*M* HCl/0·2*M* $SnCl_4$: 1—paraffin-impregnated graphite, 2—graphite, 3—glassy carbon, 4—platinum, 5—gold. The shaded area corresponds to the range of current density where metallic tin is deposited on the electrode.

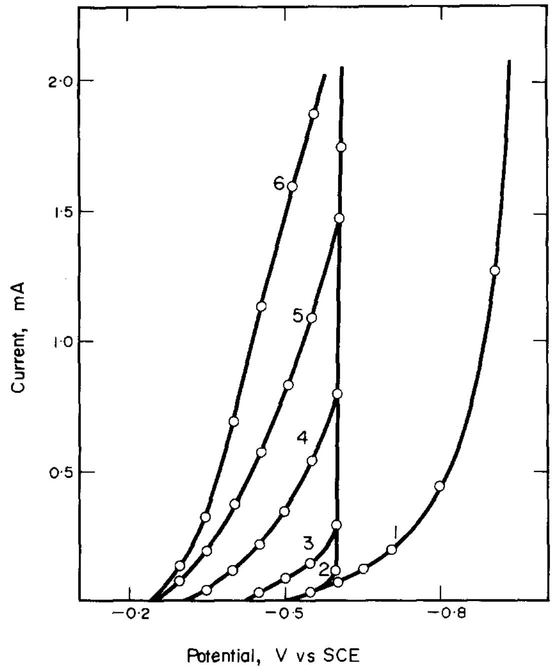

Fig. 4. Voltammetric curves for the paraffin-impregnated graphite electrode in 3*M* NaBr/0·2*M* HCl containing the following concentrations of $SnCl_4$: 1—0, 2—0·02*M*, 3—0·05*M*, 4—0·1*M*, 5—0·2*M*, 6—0·4*M*.

Titration of platinum

To obtain high current efficiency in the generation of tin(II) the current density should be at least 10 mA/cm^2, but too great an increase in current density may favour reduction to the metal, which prolongs the titration. Therefore intermediate current densities were used in the range from 10 to 20 mA/cm^2. Impregnated graphite or platinum were used for the working electrodes. Titrations were done in a nitrogen atmosphere with a working electrolyte volume of 100 ml, 1 ml of platinum solution being added as sample by microburette, thus enabling several titrations to be done in one solution. The end-point was determined potentiometrically, using a platinum indicator electrode. Titration of 1–10 mg of platinum in 3*M* sodium bromide medium proceeds slowly, as the result of a slow redox process as well as slow establishment of the potential of the indicator electrode. These conditions correspond to those used by Bard.[3] In subsequent titrations in the same electrolyte solution the potential end-point break systematically decreases. The results indicate insufficient titration efficiency (Table 1), contrary to the previously obtained efficiency data based on voltammetric curves. When several samples are titrated in the same solution, the titration efficiency systematically decreases, whichever electrode is used. This behaviour is more marked at higher current density.

The same effects were much more obvious in titrations in 3*M* sodium chloride medium. Under those conditions the presence of platinum(IV) has a catalytic effect on the electrolytic reduction of hydrogen ions. For platinum concentrations of 10 μg/ml the efficiency is only about 95%, and decreases with increasing platinum concentration; at the 100 μg/ml level the titration is completely impossible.

These processes can be explained and summarized as follows. In the presence of platinum(IV) the products of

Table 1. Titration of platinum with electrogenerated tin(II) (100 ml of electrolyte)

Electrolyte composition	Current density, mA/cm^2 (electrode)	Platinum, *mg*		Current efficiency, %

			8·12	65·7

Results for each weight of platinum shown as taken were obtained by successive titrations in the same electrolyte solution.

electrolytic reduction of tin(IV) react according to

$$Pt(IV) + Sn(II) \rightarrow Pt(II) + Sn(IV)$$

$$Pt(IV) + Sn(0) \rightarrow Pt(II) + Sn(II)$$

but at low current densities direct reduction of platinum to the metal is also possible:[2]

$$Pt(IV) + 4e \rightarrow Pt(0)$$

At high current densities the contribution of the catalysed hydrogen evolution significantly increases:

$$2H^+ + 2e \xrightarrow{Pt} H_2$$

When an electrode covered with metallic tin is immersed in tin(IV) solution, slow dissolution of the metal proceeds. If this solution also contains platinum(IV), hydrogen is vigorously evolved at the electrode surface immediately. This indicates that the reduction of hydrogen ions by metallic tin proceeds according to the equation:

$$Sn(0) + 2H^+ \xrightarrow{Pt} Sn(II) + H_2$$

The reduction of hydrogen in the absence of platinum compounds in the solution is very slow because of the high overpotential of hydrogen evolution in spite of thermodynamically favourable conditions. The addition of platinum(IV)—and to a smaller extent platinum(II), because of the less favourable kinetics in the latter case—produces platinum black at the electrode surface. This is responsible for the formation of the centres exhibiting a seriously diminished overpotential for hydrogen evolution.

The catalytic effects of platinum(IV), occurring at the electrode as well as in the chemical process, may also have a significant effect in coulometric titrations with reducing agents other than tin(II). The greater stability of the $PtBr_6^{2-}$ complex compared with $PtCl_6^{2-}$ is responsible for the somewhat better results in bromide solutions, where the catalytic activity of platinum is smaller.

Summary—The current efficiency of tin(II) generation has been measured for various electrolytes and electrodes. The best results (>99·9%) were obtained with the paraffin-impregnated graphite electrode in $2M$ $CaCl_2$ + $0{\cdot}2M$ HCl + $0{\cdot}2M$ $SnCl_4$. In titrations of platinum(IV) with electrogenerated tin(II) in an electrolyte containing chloride or bromide it was found that the presence of platinum(II) or (IV) interferes in the cathodic generation of tin(II). The platinum is reduced to the elemental state at the electrode and causes simultaneous generation of hydrogen which decreases the current efficiency. This effect is more pronounced in chloride media.

LETTER TO THE EDITOR

DERIVATION OF THE SAMPLING CONSTANT EQUATION

Sir:

In 1972, Ingamells and Switzer[1] published a general equation for the sampling constant of a two-mineral mixture of uniform grain size. Derivation of this equation was not given in detail, and a typographical error, undiscovered in proof, interchanged subscripts on two terms. The correct equation is

$$K_s = \left(\frac{Bd_B - Hd_H}{K}\right)^2 \cdot \frac{p_w q_w u^3 w}{d_B w_H + d_H w_B} \cdot 10^{-8} \text{ grams} \qquad (1)$$

[i.e., with $(d_B w_H + d_H w_B)$ in the denominator, not $(d_B w_B + d_H w_H]$. In this equation, B and H are the X-contents of the two constituent minerals, K is the X-content of the mixture, p_w and q_w are the weight proportions of the two minerals, w is the weight of a sample containing w_H grams of one mineral and w_B grams of the other, u is the linear dimension (grain size) in μm, and K_s is the sampling constant for the constituent of interest, X, (i.e., the weight of the mixture which must be taken to ensure a sampling error of no more than 1% with 68% confidence). This equation may be derived as follows.

If q and p are the volume proportions of the two minerals in the mixture, it is identically true that

$$\frac{q}{p} = \frac{d_H q_w}{d_B p_w}\ , \quad p_w + q_w = 1\ , \quad p + q = 1 \qquad (2)$$

where d_B and d_H are the densities of the two minerals in g/cm^3.

The total relative sampling error, R (%), is related to the relative sampling error R_H incurred in sampling the constituent with X-content H and the relative sampling error R_B incurred in sampling the constituent with X-content B:[2]

$$KR = \left| p_w H R_H - q_w B R_B \right| \qquad (3)$$

From Kleeman,[3] we have the binomial relationships

$$R_H = \frac{100}{\sqrt{n}}\sqrt{\frac{q}{p}} \quad \text{and} \quad R_B = \frac{100}{\sqrt{n}}\sqrt{\frac{p}{q}} \qquad (4)$$

Also, identically,

$$K = p_w H + q_w B \text{ and } q_w = \frac{w_B}{w}\ , \quad p_w = \frac{w_H}{w} \qquad (5)$$

Substituting (4) in (3) and squaring,

$$K^2R^2 = \frac{10^4}{n}\left(p_w H\sqrt{\frac{q}{p}} - q_w B\sqrt{\frac{p}{q}}\right)^2 \qquad (6)$$

Substituting (2) in (6),

$$K^2R^2 = \frac{10^4}{n}\left(H\sqrt{p_w q_w d_H/d_B} - B\sqrt{p_w q_w d_B/d_H}\right)^2 \qquad (7)$$

$$= \frac{10^4\ p_w q_w}{n}\left[\frac{(d_H H)^2 + (d_B B)^2 - 2\ BH d_B d_H}{d_B d_H}\right]$$

whence

$$R^2 = \frac{10^4 p_w q_w}{n d_B d_H}\left(\frac{Bd_B - Hd_H}{K}\right)^2 \qquad (9)$$

By definition,[1]

$$K_s = R^2 w \tag{10}$$

The number of equal-sized cubic grains in a sample of weight $w_H + w_B = w$ is

$$n = \frac{w_H}{d_H(10^{-4}u)^3} + \frac{w_B}{d_B(10^{-4}u)^3} \tag{11}$$

$$= \frac{d_B w_H + d_H w_B}{d_H d_B (10^{-4}u)^3} \tag{12}$$

Substituting (9), then (12), in (10) gives the correct equation (1). This equation may be put in several different forms by substituting the identities (2) and (5) and through the use of appropriate approximations: putting $p_w = w_H/w$, $q_w = w_B/w$, and $K = p_w H + q_w B$,

$$K_s = \left(\frac{Bd_B - Hd_H}{Bw_B + Hw_H}\right)^2 \cdot \frac{w_B w_H u^3 w}{d_B w_H + d_H w_B} \cdot 10^{-8} \text{ grams} \tag{13}$$

or, with $w_H = p_w w$ and $w_B = q_w w$

$$K_s = \left(\frac{Bd_B - Hd_H}{p_w H + q_w B}\right)^2 \cdot \frac{p_w q_w u^3}{p_w d_B + q_w d_H} \cdot 10^{-8} \text{ grams} \tag{14}$$

or, solving (2) and (5) to eliminate p_w and q_w, obtaining
$p_w = (B - K)/(B - H)$ and $q_w = (K - H)/(B - H)$,

$$K_s = \frac{(Bd_B - Hd_H)^2 (B - K)(K - H)u^3}{d_B(B - K)(B - H) + d_H(K - H)(B - H)} \cdot \frac{10^{-8}}{K^2} \text{ grams} \tag{15}$$

These equations involve no approximations. If the densities of the two component minerals are nearly the same,

$$K_{s(d_B \sim d_H)} \sim (B - K)(K - H)u^3 d_B \cdot \frac{10^{-8}}{K^2} \text{ grams} \tag{16}$$

If B is much larger than K (the common case in mineral exploration),

$$K_{s(B \gg K)} \sim (B - H)(K - H)u^3 d_B \cdot \frac{10^{-8}}{K^2} \text{ grams} \tag{17}$$

$$\sim B^2/K^2 \cdot p_w q_w u^3 d_B \cdot 10^{-8} \text{ grams} \tag{18}$$

Other forms are useful, depending on the application. The parameter u, which is rather artificial, may be replaced by an <u>effective</u> grain size, which may be estimated in a number of ways. In many real cases, the linear dimension of the mesh of the screen through which the material is passed is very close to the effective grain size.

Equation (17) may be derived in several ways: this is of interest because of its importance in mineral exploration and mine evaluation.[4] An alternative derivation has been published.[5]

INSTRUMENTS IN ANALYSIS – CRITICAL REVIEWS

THE MASS FILTER

JOHN MAJER
Chemistry Department, University of Birmingham, P.O. Box 363, Birmingham 15, U.K.

The analytical function of a mass spectrometer consists in converting atoms or molecules into ions and segregating these ions according to their mass-to-charge ratio (m/e). The mass of the ions is related to the nature of the original atom or molecule and their abundance to the concentration of the atom or molecule in the sample under examination.

The segregation in the past has been most commonly achieved by accelerating the ions in a potential gradient and subjecting them to the influence of a transverse magnetic field. The ions suffer a deflection in their flight path, the extent of this deflection being related to their velocity and their mass-to-charge ratio. Instruments based on this principle have been in an active state of development for the past fifty years and at the present time a considerable number of different designs of magnetic deflection instruments are commercially available.

More recently, however, alternative systems of mass segregation have been developed, the most successful being that embodied in the instrument now known as the mass filter.

Charged particles moving with constant velocity will also suffer a deflection if exposed to a transverse potential gradient. Furthermore, if the potential gradient changes rapidly in strength or direction, the ions are sufficiently light to be able to follow these oscillations with appropriate changes in the extent or direction of their deflections, provided that the mean free path of the ions is sufficiently long, i.e., they make no collisions with gas molecules. The concept of beams of ions oscillating between a pair of electrodes was exploited by Paul and von Zahn who considered the possibility of relating the extent or direction of the oscillations to the nature of the ion, more particularly its mass-to-charge ratio. In the most successful arrangement, beams of ions are allowed to pass along the axis of a field created by four electrodes, disposed symmetrically around the flight path. Theoretically the establishment of an axially symmetrical field requires electrodes of hyperbolic cross-section, but in practice for ease of fabrication, four rods of circular cross section are used. When the rods are connected in opposite pairs to the output of a radio-frequency oscillator, ions have unstable trajectories. If, however, upon the radiofrequency field there is superimposed a d.c. field, the applied voltage (U) being less than one-sixth of the peak amplitude of the RF voltage (V), so that if P_x and P_y are the instantaneous potentials on the opposite rod-pairs and $P_x = -P_y = U + V \cos \omega t$ (where ω is the frequency of oscillation), then some ions have stable trajectories. After injection, ions can traverse the longitudinal space between the rods and emerge from the opposite end in a manner defined by the relationships

$$U = 1.212\, m\, \omega^2 r_0{}^2$$

$$V = 7.219\, m\, \omega^2 r_0{}^2$$

where r_0 is the field radius (in cm), ω is the frequency in MHz and m is the mass of the ion (relative to C = 12). It has been found that for a given RF frequency and a given peak voltage on the rods, only those ions with a closely defined mass-to-charge ratio can escape from the quadrupole rod assembly. The arrangement thus constitutes a mass filter, for an ion-source producing a multi-ionic beam may be coupled to the rod assembly and an ion-detector mounted at the far end. The mass-to-charge ratio of the ion reaching the detector is then selected by adjusting either the frequency, or more conveniently, the amplitude, of the RF voltage applied to the rods. While some of the properties of this quadrupole system are shared by other electrode geometries involving the use of rings or single poles and grounded strips, it is the quadrupole electrode system which has been commercially exploited and forms the basis of a number of recently developed instruments.

The first commercial design was marketed by the Atlas Company in Germany in the early sixties and had a mass resolution of 100. In less than ten years other manufacturers have produced instruments having a performance better by an order of magnitude. Before considering the future possibilities of mass filters it is appropriate to examine the advantages of this type of mass segregation over the more conventional magnetic deflection and to describe how these advantages are embodied in recent commercial designs. The chief advantage which was exploited in the earliest designs was the small size and simplicity of the rod assembly, commonly about 20 cm in length and 5 cm in diameter (the individual rods being less than 1 cm in diameter). Further, the rate at which the spectrum can be scanned is high, scan-time being in the msec range. This is not as fast as the time-of-flight mass spectrometer, but faster than the magnetic deflection instruments and allows the spectrum to be displayed upon an ordinary rather than a long-persistence oscilloscope.

The mass-selection system is not very demanding upon the homogeneity of the ion-beam as regards its direction or its velocity, so that comparatively simple ion-sources may be used, most having only three plates, and finally, the ion-accelerating voltage must not be too high, otherwise the ion cannot undergo sufficient oscillations between the rods to reveal its identity. As a result, most ion-sources operate with accelerating voltages below 100 V and this makes them more accessible to external probes and auxiliary equipment. The problems associated with the high accelerating potentials of magnetic deflection instruments are thus avoided.

The instruments now commercially available may be divided into two classes, those with mass resolutions of 100 or less, which are most commonly designed for the monitoring of residual gases in vacuum systems, and those with resolutions of 250 and above, which are used as low-resolution general purpose mass spectrometers.

RESIDUAL GAS ANALYSERS

The total pressure in vacuum systems is normally measured by means of an ionization gauge which collects and measures the ion-currents produced by ionizing all the constituents of the residual gas in the system. As vacuum systems become more efficient and complex and are applied to a variety of production processes there emerges a demand for a partial-pressure gauge, which not only gives a measurement of the total residual gas pressure, but also provides an indication of the composition of the residual gas by measuring ion-currents representative of each constituent. Because of the comparative ease of manufacture of mass filters with resolutions below 100, quadrupole partial-pressure gauges which can monitor the air, carbon dioxide, water vapour and hydrocarbon constituents of residual gases have been marketed. Their chief defect is their inability, because of low resolution, to distinguish between carbon monoxide and nitrogen. In its simplest form the quadrupole partial-pressure gauge consists merely of an ion-source, an analyser and a detector, bolted directly into the vacuum system to be monitored. Centronics have produced devices of this type, the simplest being a disposable gauge head having multiple filaments and a mass resolution of about 30. A more highly developed version is the model Q806 with a resolution of 100 and a sensitivity of better than 10^{-12} mmHg for nitrogen.

Similar instruments have been marketed by VG-Quadrupoles Ltd. The Q4 provides a measurement of total pressure, or alternatively, a reading of ion-current at any *m/e* value up to 60. It can be used for leak detection with a suitable probe gas, such as helium. Scanning facilities are provided in the more complex model Q7 which has twice the resolution and mass range. It provides a reading of total and partial pressures, but may be combined with a suitable inlet system, enabling it to carry out simple analytical tasks such as the monitoring of respiratory gases.

These devices are in competition with partial-pressure gauges based upon small radius (2 cm) 180° magnetic deflection instruments. These use permanent magnets, and scan by altering the ion-accelerating potential. If the mass filter is pumped separately and provided with an inlet system it can be used for stable-isotope tracing for such isotopes as nitrogen-15, oxygen-18 and carbon-13.

The E.A.I. Company in the U.S.A. were the first to produce a satisfactory instrument with a resolution in excess of 250, but this performance is exceeded by a range of instruments produced by the VG-Quadrupoles Company. Using molybdenum rods of 18 mm diameter, they have produced units with a resolution of 700 and a mass range of 350 (Model Q50). By reduction of the rod diameter to 12 mm the range has been extended to 800 and the resolution to 1200 (Model Q40). The most advanced quadrupole mass filter is that marketed by Finnegan Instruments. This has a mass resolution of 2000 and a mass range of 1000. The model 3300F incorporates a programmable ion-source allowing injection of ions with a velocity appropriate to the mass, thus giving improved sensitivity.

The short mass scan-time (about 0.1 sec) and the ability of the analyser to perform at comparatively high pressures (up to 10^{-4} mmHg) make the mass filter eminently suitable as a monitor for the effluents from gas-chromatography columns. Mass spectra of components of mixtures issuing from the chromatographic column can be recorded on a *U/V* recorder, displayed upon an oscilloscope or processed in a data system using a small computer. In addition, advantage is taken of the fast response-speed and scan-time to allow continuous monitoring of a selected small number of mass peaks. Similar diversity is incorporated into the Dodecapole instrument marketed by Hewlett Packard. In this device advantage is taken of the linear relationship between rod voltages and the masses of the ions transmitted. Mass marking is achieved neatly by matching a mass-peak displayed on an oscilloscope, with a blip on a second trace, the position of which is determined by an adjustable reference voltage. This voltage is indicated on a digital voltmeter directly in terms of mass. The Dodecapole is a more complex instrument in which the shortcomings of the single quadrupole mass analyser are minimized by the use of additional rod systems. The resolution is thereby increased to as high as 3000.

Opponents of the quadrupole system of mass analysis have claimed that it is particularly susceptible to contamination and that rod performance declines with use. The rod alignment is critical and may be disturbed by baking. However, at the present time, the choice between a low-resolution magnetic sector instrument and a quadrupole of comparable performance is difficult to make. It is significant that the Vacuum Generators Group of Companies market both types.

FUTURE PROSPECTS

Today, the mass filter is approximately in the same state of development as the single-focusing magnetic deflection system was in the late fifties, before the advent of the double-focusing mass analyser. While it is not possible to speculate upon the introduction of some similar revolutionary improvements in the case of mass filters, sufficient evidence is forthcoming to provide a guide to the possible ultimate performance of a simple quadrupole analyser. There are three broad areas of improvement: the sensitivity, the mass range and the mass resolution. If we accept that no great change is going to occur in either the efficiency of ionization within the ion-source or the degree of particle multiplication at the detector, then any increase in sensitivity is likely to come from improvements in the transmission of the rod system. The aperture into the rod system is not the physical but the electric aperture imposed by the fields. At present many of the ions produced in the ion-source do not pass through this aperture. Some undergo unstable trajectories under the influence of the fringing fields at the ends of the rods. Marked improvements in sensitivity have been achieved by reducing the effects of these fields with the aid of a second rod assembly which experiences only the RF voltages and guides the ions into the electric aperture. This aperture is reduced by increased resolution so for high-performance instruments the ultimate limitation may be space charge. The mass range of a quadrupole is limited by the voltage which can be applied to the rods to make the ions oscillate. This in turn is limited by the power requirements imposed upon the oscillator as the voltage rises. The power required increases with increase in rod dimensions so that power is saved by smaller rods, but these tend to be less efficient as the ions perform fewer cycles with a small rod assembly. Raising the frequency would correct this, but would once again call for increased RF power. These limitations are summarized in the equation

$$\text{Power (in W)} = 6.5 \times 10^{-4} \frac{Cm^2 \omega^5 r_0{}^4}{Q}$$

where C is the capacity of the rod assembly (in pF) and Q is the figure of merit of the power circuit. Multiple-analyser assemblies will probably permit recording of masses in the 1–2000 region, allowing competition on this score with magnetic deflection instruments.

The resolution obtainable with a quadrupole mass filter depends upon a number of factors. Mass peaks tend to be trapezoid in shape rather than Gaussian and increasing the d.c. to RF voltage ratio (U/V) converts these into triangles before the transmission drops to zero. With a constant U/V ratio the resolution depends not only on the accuracy with which the voltages can be kept constant, but more critically upon the accuracy of alignment of the rods and the quality of their surfaces.

Fyte has calculated that a quadrupole assembly capable of providing a resolution of 5000 would require an accuracy of alignment of 1 part in 4×10^7. This would require prohibitively expensive engineering of the highest precision. Already the rod system in the mass filter marketed by Finnegan instruments involves a precision of 1 part in 10^6. There is, however, one feature of the mass resolution of a quadrupole which is not yet completely exploited and that is the ability to change the U/V ratio during scanning. This changes the resolution and the sensitivity so that low masses are recorded with high sensitivity and low resolution and only the resolution necessary at any point on the mass-scale is actually employed.

We may therefore expect a slow and steady improvement in mass-filter performance over the next decade, allowing the device to compete successfully with other systems of mass analysis. The development of high-resolution instruments capable of comparison with double-focusing mass spectrometers must await the appearance of a new principle.

TALANTA MINI-REVIEW*

RECENT APPLICATIONS OF QUANTITATIVE NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY IN PHARMACEUTICAL RESEARCH

DAVID M. RACKHAM
Lilly Research Centre Limited, Erl Wood Manor, Windlesham, Surrey, GU20 6PH, England

(*Received* 2 *September* 1975. *Accepted* 26 *September* 1975)

Summary—Increasing use is being made of N.M.R. spectroscopy as a quantitative analytical tool. Recent developments (1970–mid-1975) in methods and reagents are discussed with special regard to the role of Fourier-transform spectrometers, lanthanide-shift reagents and the choice of standard materials. Applications to quantitative analytical problems in pharmaceutical research are listed together with an indication of the advantages of the N.M.R. method over official analytical procedures.

A previous review written by this author in 1970[1] was concerned with the application of quantitative N.M.R. methods to a range of pharmaceutical materials. This article describes recently developed instruments, accessories, reagents and techniques, together with applications of N.M.R. to the quantitative problems encountered by analysts working in pharmaceutical research and control. It is designed to extend coverage to summer 1975.

BOOKS AND GENERAL REVIEW MATERIAL

A comprehensive book describing the quantitative uses of N.M.R. has appeared.[2] Practical methods are well discussed with a multitude of applications to functional group analysis and to problems in pharmacy and industrial chemistry. Reports have also appeared in French[3] and English[4] concerning quantitative measurement on non-pharmaceutical products and in German[5,6] and English[7] on the general application of the quantitative N.M.R. approach to pharmaceutical[5,6] and forensic[7] chemistry. The importance of peak areas, signal shapes and saturation effects in quantitative N.M.R. is clearly set out in a manufacturer's publication.[8]

EQUIPMENT, REAGENTS AND TECHNIQUES

Instrumentation

A few examples of the use of dedicated computers of average transients (CAT) to enhance the signals from small quantities of material have appeared, *e.g.*, for sub-milligram levels of barbiturates in brain autopsy material,[9] DDT in tissues[10] and 30–40 μg levels of potentially carcinogenic polynuclear hydrocarbons.[11] The disadvantages of CAT accessories lie in baseline instability, resolution limitation and the need for long accumulation times.

The approach to the proton N.M.R. spectra of small quantities and to low abundance nuclei (*e.g.*, ^{13}C) has been revolutionized by the advent of the Fourier-transform spectrometer. The high cost of this equipment has to be offset against the ease of obtaining good proton spectra on μg quantities within a few hours and the excellent resolution which can be achieved. A constant problem with this technique lies in the impurities present in commercial N.M.R. solvents. These may be insignificant when a conventional instrument is used but become very apparent, even at the μg level, on accumulation. It is helpful to store these solvents over a clean molecular sieve in glass- (not plastic-) stoppered bottles to minimize peaks due to water or leached plasticizer. Pre-washing of the N.M.R. tube with D_2O/MeOH-d_4 is also a help in reducing the water peak. Alternatively, and more satisfactorily when solubility permits, one can use capillary microcell inserts (*e.g.*, for the Varian XL-100[12]) with the sample material dissolved in only a few μl of solvent. Fourier-transform spectrometers are unlikely to come within the budget of the smaller control laboratory for several years but the analyst with occasional access to this equipment is in a position to resolve some hitherto insoluble problems.

Lanthanide-shift reagents (*LSR's*)

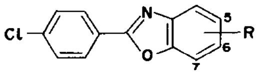
This family of organometallic reagents has achieved wide popularity amongst chemists and analysts for separating and simplifying the N.M.R. peaks of complicated molecules and of normally unresolved isomeric mixtures. In this respect, a low-cost instrument can sometimes match, or surpass, the performance of the most powerful superconducting-magnet systems. A recent review (1970–1973) lists nearly 500 papers but only a handful exploit the potential of LSR's for

---

* For reprints of this Mini-Review, see Publisher's announcement near the end of this issue TALMR3.

quantitative analysis.[13] Applications of LSR's to problems in pharmaceutical research and outside N.M.R. (*e.g.*, to gas chromatography[14] and infrared spectrophotometry[15]) are very scarce. The scope of LSR-assisted analysis is indicated below.

Positional isomers and homologous series. The anti-inflammatory compound, "Benoxaprofen" (**I**, R in the 5-position) has been analysed for possible impurities (R in the 6- or 7-positions).[16]



I, R is —CH(Me)CO_2H

All compounds were converted into their methyl esters. No separation of peaks was seen in $CDCl_3$ solution but addition of an LSR resolved the peaks of the methyl esters and the side-chain methyl groups, allowing assay of the impurities. With a 90-MHz Fourier-transform spectrometer, a minimum detection limit of 0·2% for the 6- or 7-isomers was achieved. On conventional instruments the detection limit was 3–4%. It has also been possible to determine the isomeric *o*-, *m*- and *p*-cresols in admixture[17,18] and analyse mixtures of homologous (C_1–C_6) alcohols[19] and carboxylic acids (C_1–C_8).[20]

Optical isomers (enantiometers). Optically active lanthanide-shift reagents form diastereoisomers with mixtures of optical isomers.[13,21] In favourable cases, the N.M.R. signals of the enantiomers are clearly distinguished and the enantiomer ratio can be calculated. This technique can be used[22] for detecting low levels of unwanted L(+) penicillamine in the D(−) enantiomer after a simple derivative-formation step. The limit of detection is 0·4% with a Fourier-transform spectrometer (see Fig. 1).

Separation of enantiomer peaks can sometimes be improved by using an LSR and an optically active solvent.[23] The N.M.R. method yields results which compare very favourably with enantiomer ratios based upon optical activity, but without the need to prepare an optically pure specimen of one enantiomer as calibration standard.[21,24]

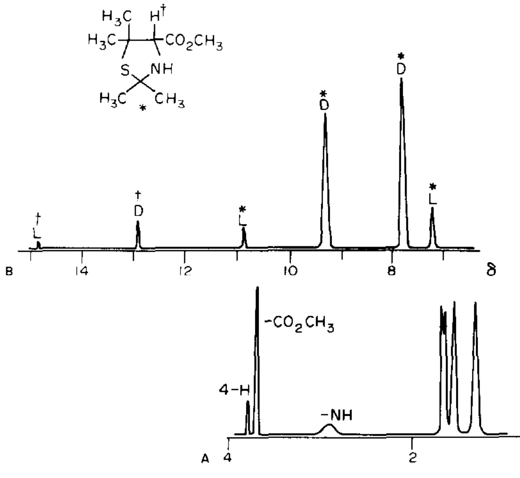


Fig. 1. A. Spectrum of acetone adduct of penicillamine (D : L isomer ratio = 92 : 8). B. Part spectrum of adduct after addition of 0·45 mole equivalents of optically active europium shift reagent.[22] (Reprinted by permission of the copyright owners).

Cis/trans *isomers and diastereoisomers.* The *cis/trans* ratio of oxime isomers can be readily determined with the aid of europium-shift reagents.[25] This method offers advantages over previous N.M.R. techniques using benzene solvent shifts. The same ratio can also be determined for vitamin A isomerization,[26] aminocyclohexylmethanes[27] and oleate/elaidate esters.[28] However, it is known that LSR's can themselves affect the ratio of *cis/trans* isomers in secondary amides[29] and this complication must be eliminated before reliance can be placed on assay figures.

A new isoxazolobenzoxazine anti-inflammatory agent consists of a pair of diastereoisomers, and a convenient method using a europium-shift reagent is available for their assay.[30] Similarly, the N.M.R. peaks for the diastereoisomeric tetrahydropyranyl ethers of cholestanes and cholestenes are clearly resolved when such a reagent is added.[31]

Other quantitative applications of LSR's. These include the analysis of mixtures of tocopheryl acetates,[32] glycerinformals,[33] steroidal enones and polyenones[34] and of polymers derived from chloroprene[35] and polyalkylene glycols.[36,37] Lanthanide reagents closely related to LSR's can also be used to distinguish between substrate molecules which are "inside" and "outside" a model cell membrane system.[38]

Use of nuclei other than the proton

Fourier-transform N.M.R. spectrometers allow one to obtain spectra for ^{13}C nuclei within a few hours (30–50 mg of material). The ^{13}C spectrum is often much simpler to interpret than the corresponding proton spectrum, because of extended chemical shifts. Serious drawbacks to ^{13}C N.M.R. quantitative analysis are the low inherent sensitivity and the lack of correspondence between peak areas and relative numbers of carbon atoms. This is due to unequal peak enhancements, attributable to varying nuclear Overhauser effects and relaxation times. Shoolery[39] has discussed methods of overcoming these problems by using gated decoupling or special shiftless relaxation reagents (preferring the latter for speed). He gives examples of the analysis of acenaphthenes and corn and crude oil samples. Good agreement is found between the ^{13}C and iodine-number assays. Other workers have assumed that chemically similar compounds in mixtures will show approximately the same relaxation and nuclear Overhauser effects and assumed exact equivalence of peak areas and carbon atom content, *e.g.*, for 2,4- and 2,6-isocyanatotoluenes,[40] n- and iso-paraffin oils[41] and *cis/trans* polypentenamers.[42]

N.M.R. spectra obtained for the ^{19}F nucleus are also characterized by larger chemical shift differences (and hence simpler spectra). In contrast to ^{13}C, the nucleus has 100% natural abundance and is of high inherent sensitivity. It is possible to convert μg quantities of hydroxysteroids into their trifluoroacetates and assay them by using the ^{19}F peaks.[43] Other examples include simple aliphatic alcohols[44,45] (with trifluoroacetic acid or hexafluoroacetone), xylenols,[46] terpenols,[47] amino-acids and peptides[48] and hydroxyl groups in polymers.[49]

Bowen and co-workers have reported the only relevant application of the ^{31}P nucleus, *i.e.*, the analysis of a sucrose/aqueous phosphorylcolamine formulation, with sodium triphosphate as added standard.[50]

N.M.R. analysis of liquid/solid components

The analysis of liquids in the presence of solid materials has been further exploited in the last five years. Most applications have been concerned with the liquid contents of fats,[51] meats[52] and cereal and oil seeds.[53] A pulsed N.M.R. spectrometer provides a particularly rapid means of analysing fats and margarines.[54]

Lawrenson has shown that a low-cost permanent-magnet spectrometer can be applied cryoscopically to a variety of problems, including the purity control of phenol, cyclohexanone and a pesticide.[55]

Computer simulation of spectra

This method may be of assistance in cases where the components to be determined possess N.M.R. peaks which overlap seriously (*e.g.*, closely similar aromatic compounds). Although a chromatographic method of analysis may often prove most suitable, it is still possible to proceed by N.M.R. A computer is programmed to accept the individual spectra of the components and an estimated weighting is put on these. The summed spectra are then calculated. The weightings can then be varied by an iterative procedure until the best fit of observed and calculated spectra is obtained. A drawback to this procedure arises from small variations in frequency with concentration and with intermolecular interactions, but a frequency shift of 2–3 times the peak width appears to be tolerable if a suitable line-broadening parameter is included. Quantitative analysis by this procedure has been mentioned briefly[8] and a full paper has recently appeared.[56]

Standards added for quantitative analysis

The criteria for internal standards for quantitative analysis are that they possess a sharp N.M.R. absorption in a clear region of the spectrum and are easily purified materials reacting with neither solvent nor analysed substance. The addition of an unrelated standard to the solution under test is preferred to the use of solutions of the pure material and separate analysis of their spectra. In the former, instrumental conditions (field homogeneity and integral response,) are identical and it is possible to assay without the necessity of preparing a very pure sample of the unknown.

In his book, Kasler[2] presents a comprehensive series of 128 likely internal standards. A choice can be made on the basis of an optimum "window" in the N.M.R. spectrum of the unknown. It is important to remember that some apparently well-suited standards may be precluded because they are unstable when strong acids or bases are to be analysed (*e.g.*, *sym*-tetrachloroethane with base) or because of molecular interactions (*e.g.*, donor–acceptor complexes with polynitrobenzenes) which can cause unacceptably large chemical shifts. Two groups[50,57] give a shorter selection of standards for non-polar solvents, including hexamethylcyclotrisiloxane, hexamethylbenzene, dimethylsulphoxide, t-butanol, methanol, malonic, maleic and succinic acids, *p*-benzoquinone, *p*-dichlorobenzene and 1,2,4,5-tetrachlorobenzene. We have found one of the standards hexamethylcyclotrisiloxane ($\delta = 0{\cdot}15$), trioxan ($\delta = 5{\cdot}10$) or pyrazine ($\delta = 8{\cdot}51$) suitable for any quantitative assay problem when using $CDCl_3$ or $CDCl_3/(CD_3)_2SO$ mixture. It may be advantageous to add two standards to improve the precision of the analysis and to detect any decomposition of one of these.[58] This "dual standard" approach has been used in a reverse manner to analyse mestranol by means of both the ethinyl and the methoxyl protons of the drug and a single added standard. The presence of starting material impurity was indicated by the discrepancy between the assay figures for the chosen mestranol protons[59] as well as by analysis using thin-layer chromatography.

Aqueous solutions are less frequently assayed.[50,57,60] Standards suitable for this medium are sodium acetate, maleic acid, succinic acid, sodium formate and t-butanol.

A Japanese group[61] recommends the use of coaxial N.M.R. tubes for quantitative work, with the standard material in the central tube and the unknown in the outer annulus. These can be particularly useful for containing solutions which are not miscible or are chemically reactive.

QUANTITATIVE PHARMACEUTICAL ANALYSIS

Applications

Within the past five years, more N.M.R. applications have been found for the quantitative analysis of drug formulations and products with a pharmaceutical background. The pioneering work carried out by Turczan and colleagues[57,62–73] represents a major attempt to establish N.M.R. as an alternative to USP and NF official analytical procedures. In Table 1 the compounds and formulations which have been analysed are collected according to their mode of clinical action. Quantitative methods for a further 20 compounds, including amphetamine, antipyrene, aspirin, bemegride, caffeine, mannitol, pentaerythritol tetranitrate and phenobarbital have also been briefly mentioned.[57,68] Collections of reference spectra are also available for sulphonamides,[64] amphetamines[89] and barbiturates.[90,91]

The N.M.R. method

N.M.R. offers a number of advantages over alternative analytical techniques for the analysis of pharmaceutical materials. It is often quicker than official USP or NF procedures and compares very favourably in accuracy (error usually <2%); thus thiotepa[83] involves a lengthy titrimetric or spectrophotometric USP method but can be analysed by N.M.R. in 10 min with a standard deviation of 0·6%. Indeed the first quantitative N.M.R. method in the NF (for amyl nitrite) has recently appeared.[92]

Further, little sample preparation is needed, and the method has been applied to tablets, capsules, syrups, injections, suspensions, creams and aerosol fluids. Interference from excipients (starch, lactose, gelatin and colouring agents) is rare.

Specific structural proof of the identity of the analysed material and of impurities can be obtained.

Table 1. Quantitative N.M.R. analysis of pharmaceuticals

Mode of action and name	Solvent	Standard	Standard deviation (*a*) or average error (*b*)	Ref.
Central Nervous System				
Meprobamate, carisoprodol mebutamate	$(CH_3)_2CO$	Malonic acid	*b*, 0·9%	62, 74

† originally used as an anti-viral agent.

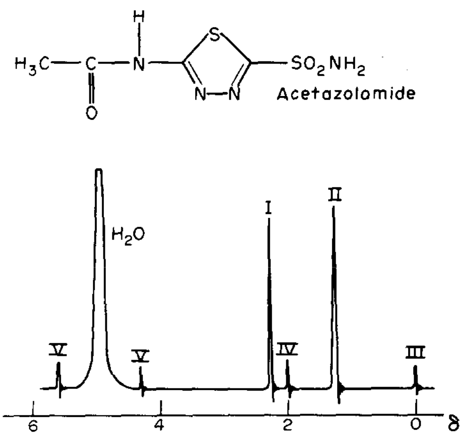

Fig. 2. N.M.R. spectrum of acetazolamide in 25% ammonia solution. (I) Acetazolamide; (II) t-butanol; (III) TMS Na salt; (IV) acetate decomposition product; (V) side-bands. (Reprinted by permission of the copyright owners).

Thus N.M.R. shows a specificity which is often absent in official spectrophotometric or titrimetric procedures. Chloral hydrate[65] can contain impurities, and acetazolamide[71] an acetate degradation product (Fig. 2) which are clearly identified and determined by N.M.R. but not by the official USP methods, where they behave analytically in the same way as the matrix.

Although the method is most suitable for high unit-dosage materials, it can be extended to the analysis of smaller (sub-milligram) quantities by using dedicated computer facilities and micro-sample containers.

Quantitative measurements are carried out by means of relative peak areas (or, rarely, peak heights). Thus an ultrapure sample of the determinand is not needed as a standard.

MISCELLANEOUS QUANTITATIVE ANALYSES USING N.M.R.

The analyst working in the pharmaceutical research laboratories of a multi-operational organization may very often be called upon to examine materials from affiliate disciplines, *e.g.*, biochemical metabolites and agricultural or veterinary formulations. Some applications of the quantitative N.M.R. procedure to such problems are listed below.

Determination of alcohols as their trimethylsilylethers.[93]

Estimation of keto-enol tautomers.[94]

Pesticides.[10,95]

Surfactants.[96,97]

Diglycerides,[98] wax esters and oils.[99]

Polyethylene glycols[100] and cellulose ethers.[101]

Modified starch.[102]

Peroxides[15] and hydroperoxides.[103]

Organo-magnesium, -lithium and -mercury reagents.[104]

Enzymatic dipeptide hydrolysis.[105]

Acknowledgements—My grateful thanks are due to Dr. J. W. Turczan (Food and Drug Administration, New York) and Mr. M. A. Pringuer (Laboratory of the Government Chemist, London) for reprints and for their helpful comments, also to several of my colleagues for their constructive and kindly criticism.

SPECTROPHOTOMETRIC AND FLUOROMETRIC DETERMINATION OF COBALT

P. R. Haddad,* P. W. Alexander and L. E. Smythe

Department of Analytical Chemistry, University of New South Wales, P.O. Box 1,
Kensington, N.S.W., Australia 2033

(*Received* 3 *September* 1975. *Accepted* 14 *October* 1975)

Summary—The reaction of Co(II), pyridine-2-aldehyde-2-pyridyl hydrazone (PAPHY) and eosin at pH 5·6 produces the ternary complex $Co(L)(HL)E_2$ (where HL represents the protonated form of the ligand and E represents the eosinate anion). This complex is extracted by a chloroform–acetone mixture to give a strongly coloured and highly fluorescent extract. Spectrophotometric and fluorometric methods for the determination of Co have been developed with detection limits of 0·017 and 0·008 ppm respectively. Cu(II), Ni, Fe(II), Pd(II) and Hg(II) interfere. The spectrophotometric method has been successfully applied to the analysis of steels, following ion-exchange separation of Co.

Ternary complexes, wherein a metal reacts with two separate ligands, have found increasing use over recent years, particularly in spectrophotometric analysis. The most common form of ternary complex is the ion-association type in which a metal ion reacts with a ligand to produce a charged binary complex; this complex then further reacts with an ion of the opposite charge, usually a dyestuff.

Almost all publications in this field relate to reaction of anionic binary complexes with cationic (or basic) dyes. Ion-association ternary complexes containing a cationic binary complex are quite rare and are generally of the type metal–1,10-phenantholine–substituted fluorescein. The element studied most in this way is silver, with selectivity being achieved by using EDTA as a mass masking agent.[1,2] Very little application to fluorometric analysis has been made using this type of ternary complex, although the methods for silver were examined fluorometrically and a brief survey of the fluorescence of other metal–phenanthrotine–eosin complexes has been conducted.[3]

Substituted hydrazones such as pyridine-2-aldehyde-2-pyridyl hydrazone (PAPHY) and pyridine-2-aldehyde-2-quinolyl hydrazone (PAQH) have been extensively investigated as terdentate chelating agents in both acidic and alkaline solution.[4–9] The structures of these compounds are shown in Fig. 1. In acid solution, they react with many metals to form mono or bis complexes which are cationic.[10] Thus, reaction with a bivalent metal M produces the complexes $M(HL)^{2+}$ or $M(HL)_2^{2+}$ where HL represents the protonated form of the ligand.

If the solution is made alkaline, the hydrogen atom marked with the asterisk in Fig. 1 is lost from the molecule. Deprotonation of the complexes above produces $M(L)^+$ for the mono complex and $M(HL)L^+$ or ML_2 for the bis complex. The uncharged complex ML_2 is generally readily extractable, and such behaviour has been observed for predominantly six-coordinate metals such as nickel, zinc, cadmium, iron and manganese.[10] The charged complexes can only be extracted as suitable ion-pairs, *e.g.*, palladium(II) has been extracted as the complex Pd(PAPY)Cl into chloroform.[11]

In this work, the reaction between cobalt(II), PAPHY and the dyestuff eosin at pH 5·6 has been used to form a ternary complex which is then extracted into a chloroform–acetone mixture. Here, a cationic binary complex is formed between cobalt-(II) and PAPHY, and eosinate acts as the counter-anion in the ion-association ternary complex.

EXPERIMENTAL

Apparatus

All absorption measurements were taken on a Perkin–Elmer PE 124 recording spectrophotometer, and fluorescence measurements were taken with a Hitachi Perkin–Elmer MPF-2A fluorescence spectrophotometer. Wavelengths used were 547 nm for absorption and 530 and

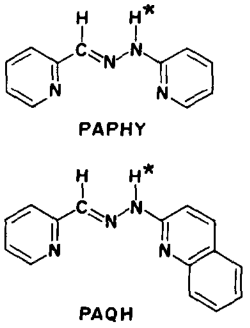

Fig. 1. Substituted hydrazone chelating agents.

558 nm for fluorescence excitation and emission, respectively.

Reagents

Eosin (*2,4,5,7-tetrabromofluorescein*), 0·1% aqueous solution.

Ion-exchange resin. Amberlite CG. 400 (100–200 mesh) anion-exchanger, prewashed with 10*M* hydrochloric acid and distilled water alternately.

PAPHY. Obtained from Aldrich Laboratories and used as a 0·1% solution prepared by dissolving 0·1 g in the minimum quantity (about 3 or 4 drops) of 5*M* hydrochloric acid and diluting to 100 ml with distilled water. The solution was kept for no more than one week.

Cobalt stock solution. A 1000-ppm Co(II) solution was prepared by dissolving the appropriate amount of analytical grade cobalt nitrate [$Co(NO_3)_2.6H_2O$] in 250 ml of distilled water and diluted as required to make standards of lower concentration.

All other reagents used were analytical grade.

Procedures

The effect of pH on the extraction of cobalt(II)–eosin–PAPHY was studied in the following way. An aliquot of cobalt(II) solution containing 10 μg of Co^{2+} was mixed with 0·5 ml of 0·1% PAPHY solution and 1 ml of 0·1% eosin solution and the pH adjusted to the required value with 0·1 *M* hydrochloric acid and 0·1 *M* ammonia. The final volume was about 20 ml. The solution was then transferred to a 125-ml separating-funnel and 10·0 ml of chloroform were added, after which the flask was shaken for 30 sec. The organic layer was drained off and centrifuged at moderate speed for 1 min before measurement of absorbance.

Calibration curves based on absorbance and fluorescence measurements were obtained by adding 0–4 and 0–2 μg of Co respectively to 125-ml separating-funnels. The following reagents were then added, in turn, 1 ml of citrate buffer (pH 5·6), 0·5 ml of 0·1% PAPHY solution and 0·5 ml of 0·1% eosin solution, before the final volume was made up to about 20 ml. A 30:70 v/v mixture of acetone and chloroform was prepared and 10·0 ml were added to each separating-funnel and shaken for 1 min. After the phases had separated, the organic layer was removed and centrifuged for 1 min at moderate speed. An aliquot of the organic layer was then transferred to a 1-cm quartz fluorometer cell and fluorescence and absorbance measurements taken.

Steel samples were analysed by weighing out an amount of steel containing about 20 μg of cobalt and dissolving it in 5 ml of *aqua regia*. The solution was evaporated to dryness and the residue dissolved in 5 ml of concentrated hydrochloric acid and made up to 50 ml with distilled water. This solution was then electrolysed at 0·5 A for 30 min, in a divided cell (this comprised a fritted glass tube cut just below the frit, containing one electrode and filled with saturated sodium sulphate solution: the second electrode was a platinum mesh electrode inserted in the sample solution in the usual way[12]). The electrolysis step was included to remove copper. Hydrogen peroxide (30%, 2 ml) was added to oxidize all iron(II) to iron(III) and the sample was evaporated to a volume of about 5 ml. This solution was transferred with 9*M* hydrochloric acid to a 15 × 2·5 cm anion-exchange column previously washed with 9*M* hydrochloric acid. The column was then eluted with two bed-volumes (about 80 ml) of 9*M* hydrochloric acid to remove nickel, and the cobalt was eluted with two bed-volumes of 4*M* hydrochloric acid. The cobalt eluate was placed on a hot-plate and evaporated to about 5 ml, then allowed to cool before quantitative transfer to a 25-ml volumetric flask and dilution to the mark with distilled water. If successive samples were to be run through the ion-exchange column, the adsorbed iron was removed by eluting with distilled water and the column rewashed with 9 *M* hydrochloric acid before the next sample was added. An aliquot of the evaporated eluate solution (prepared as above) corresponding to about 4 μg of cobalt was mixed with 0·5 ml of 0·1% PAPHY solution and the pH adjusted to about 5·6 with dilute ammonia solution, after which 1 ml of citrate buffer and 0·5 ml of 0·1% eosin solution were added, the final volume being 20 ml. This solution was then extracted and the fluorescence and absorbance were measured as described in the procedure for construction of a calibration curve. A reagent blank was also run through the entire procedure.

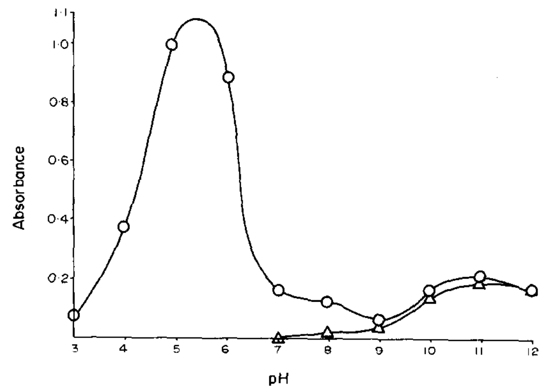

Fig. 2. Extraction of Co–PAPHY (△) and Co–PAPHY–eosin (○) at various pH values ([Co] = 10 μg/10 ml of solvent).

RESULTS

Effect of pH

Figure 2 shows the effect of pH on the extraction of Co-PAPHY into chloroform, in the presence and absence of eosin. The absorbance was used to estimate the degree of extraction since the chloroform extracts exhibited only a weak fluorescence. The absorption spectrum for Ci–PAPHY–eosin in chloroform is shown in Fig. 3.

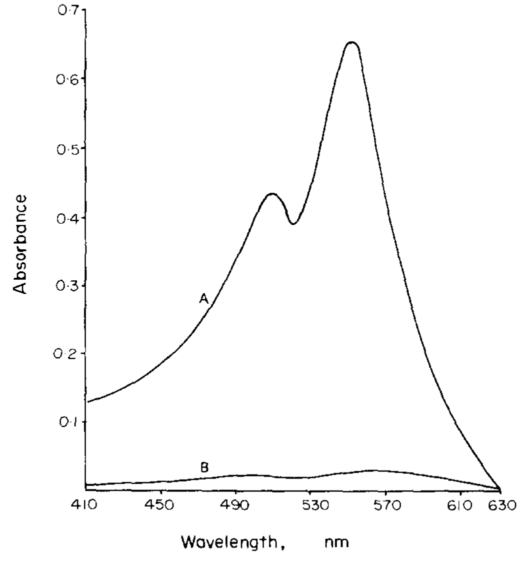

Fig. 3. Absorbance spectrum of Co–PAPHY–eosin ([CO] = 4 μg/10 ml of solvent). A. Co–PAPHY–eosin, B. Blank

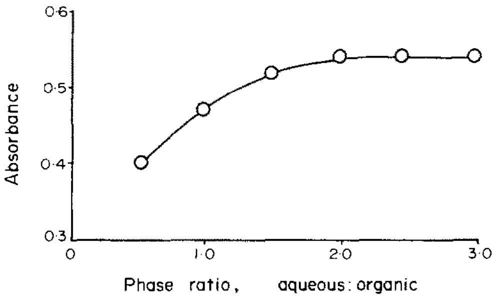

Fig. 4. Effect of phase ratio on extraction of Co–PAPHY–eosin. Conditions: 4 μg of Co/10 ml of solvent, 0·5 ml of 0·1% PAPHY, 1·0 ml of 0·1% eosin, 1 ml of citrate buffer, final volume varied.

The optimum acidity for extraction of the ternary complex was pH 5·4–5·8, and pH 5·6 was selected for further work. It will be noticed from Fig. 2 that this pH corresponds to a region of non-extraction of the Co-PAPHY complex.

In studies on the solvent extraction of complexes containing large organic dye molecules, it has frequently been noted that many buffer systems cause interference by promoting excessive extraction of the dye, presumably as a complex with the buffer components. This leads to unacceptably high blank levels and requires that any buffers used be examined for this type of interference.

Three buffer systems of pH 5·6 were investigated for possible interference; potassium hydrogen phthalate–sodium hydroxide, citric acid–sodium hydroxide and sodium acetate–acetic acid. Of these, the citrate buffer was found to produce the lowest level of extraction of eosin and was therefore used exclusively throughout this work.

Optimization of quantities of reagents

The effects of varying quantities of eosin, PAPHY and citrate buffer on the extraction of 4 μg of cobalt-(II) into 10 ml of chloroform were studied. In each case, the absorbance of the extract increased up to a constant value with increasing reagent concentration. It was observed that extraction of Co–PAPHY–eosin was dependent on the phase-volume ratio. Reduced extraction occurred if the ratio of aqueous:organic phase was less than 2:1. This effect is illustrated in Fig. 4.

The optimum conditions for extraction of Co–PAPHY–eosin into 10 ml of chloroform were found to be 0·5 ml of 0·1% PAPHY solution, 1·0 ml of 0·1% eosin solution, 1·0 ml of citrate buffer and a final aqueous phase volume of 20 ml.

Choice of solvent

Many solvents have been examined[13] for their efficiency in extracting ion-association complexes containing fluorescein derivatives. They are representative of most classes of organic compounds, including alcohols, ketones, esters, ethers, hydrocarbons, chlorinated hydrocarbons and aromatic hydrocarbons. In general, alcohols and ketones have been found to dissolve the dye itself, ethers and esters achieve slight extraction but cause the complexes to float on the interface, and extraction of the complex is only achieved with aromatic or chlorinated hydrocarbons, usually nitrobenzene or chloroform.

These two solvents were examined under conditions of optimum complex formation and extraction. Both extracted the complex, with nitrobenzene being the most efficient, but this solvent produced exceedingly high blank values which rendered it unsuitable. Chloroform gave acceptably low blank values but appeared to concentrate the colour of the complex

Table 1. Comparison of solvents for extraction of Co(II)–PAPHY–eosin complex

Solvent	Absorbance for 0·4 *ppm* Co soln.	Blank absorbance	Molar absorptivity, *l. mole*$^{-1}$ *cm*$^{-1}$	Remarks
Chloroform	0·612	0·052	$8{\cdot}26 \times 10^4$	Colour collection at interface
Nitrobenzene	1·34	0·560	$1{\cdot}15 \times 10^5$	High blank absorbance
Chloroform–acetone (7:3)	0·595	0·059	$7{\cdot}8 \times 10^{-4}$	Clean phase separation, high fluorescence

at the interface, a uniform colour being assumed only after 10 min standing time or centrifuging. Weak fluorescence was observed from the chloroform extract whereas the nitrobenzene extract showed no fluorescence.

The addition of acetone or alcohol to a chloroform extract of an eosin ion-association complex has been noted to increase fluorescence,[13,14] probably by increasing the solubility of the dye in the organic solvent. Mixed acetone–chloroform solutions* were therefore examined as extractants for the Co–PAPHY–eosin complex, particularly with regard to maximization of fluorescence. Mixtures containing 0–30% acetone were prepared and used to extract 4 μg of Co at optimal reagent concentrations. The results are shown in Fig. 5, and the fluorescence spectra of the complex in the mixed solvent appear in Fig. 6. The fluorescence increased only marginally with more than 15% acetone, but a 30% mixture was chosen as the most suitable because of rapid phase separation and uniform colour distribution of the complex throughout the organic extract. The problem of colour concentration at the interface, mentioned above, was completely eliminated by use of the mixed solvent. In addition, the fluorescence of the extract was increased at least 100-fold. The wavelength of maximum excitation is 537 nm; the proximity of this wavelength to the emission maximum at 558 nm necessitates use of an excitation wavelength of 530 nm, but this reduces the fluorescence emission by only 10%.

The study of solvents can be summarized as in Table 1.

Calibration curves

With the mixed solvent described above, linear calibration curves for both absorbance and fluorescence techniques were obtained in the ranges 0·04–0·4 and 0·02–0·2 ppm Co respectively. The maximum concentrations used in each case were chosen as the points where the calibration curves began to deviate from linearity by more than 5%. That is, beyond the maximum concentration indicated, curvature of the calibration plot occurred, owing either to incomplete extraction, or in the case of fluorescence, to self-absorption effects.

Precision studies

Precision was estimated by taking the standard deviation of the absorbance or fluorescence of seven replicate solutions. Precision of the fluorescence technique was estimated by setting the fluorescence of the first solution to 50 units on the fluorometer scale and comparing the remaining solutions with the first. Values for precision, expressed as the relative standard deviation of the seven replicates were 2·2% (at [Co] 0·4 ppm) for absorbance and 3·5% (at [Co] 0·2 ppm) and 6·1% (at [Co] 0·1 ppm) for fluorescence.

Detection limits were 0·017 and 0·008 ppm Co for absorbance and fluorescence methods, respectively.

Interference studies

The possible interference of a large number of cations and anions in the solvent extraction of 2 μg of Co(II) was examined. This level of cobalt was chosen to enable absorption and fluorescence measurements to be taken on the same sample. The results are summarized in Tables 2 and 3.

Cationic interferences included copper(II), nickel, iron(II), palladium(II) and to a lesser extent, mercury(II); anionic interferences were restricted to thiocyanate and perchlorate and to a very slight extent, silicate. The interference of mercury(II) was the most interesting, with a marked colour change from orange to pink-red occurring when mercury(II) was added to an aqueous solution containing PAPHY, buffer and eosin. This colour was transferred to the organic phase on shaking with the chloroform/acetone mixture, giving rise to positive interferences for fluorescence and absorbance measurements. The colour change observed in aqueous solution could not be detected spectrophotometrically, indicating that it originated from quenching of the orange-yellow fluorescence of eosin. This was confirmed by taking fluorescence spectra for solutions containing 0–150 μg of Hg(II) added to eosin, PAPHY and buffer in the same concentrations as used for formation of the Co–PAPHY–eosin complex, and diluted to 25 ml with distilled water. The fluorescence of these solutions decreased with increasing amounts of Hg(II).

The interference of copper(II), nickel, iron(II) and palladium(II) can be attributed to the fact that these

elements form strong, coloured PAPHY complexes which are extractable at pH 5·6. These species therefore caused increased absorbance of the organic phase and reduced fluorescence through scattering or absorption of fluorescence radiation. The anionic interferences were probably due to the interfering ions causing reduced extraction of the ternary complex, although the mechanism of this interference is not clear.

Thiourea was found to eliminate the interference of copper(II), presumably by its ability to reduce copper(II) to copper(I) under acid conditions. Unfortunately it could not be used in presence of iron(III) (which did not interfere), because it reduced it to iron(II) (which does). It was therefore necessary to remove copper from the solution. The likelihood of palladium being found in significant concentrations in natural samples is low, and because of this, palla-

dium can be disregarded as an interferent of major importance. Thus, to eliminate interferences, a method of separation of cobalt from excesses of copper, nickel and iron was required.

Removal of interferences

Of the separation techniques available in analytical chemistry, ion-exchange provided the best possibility for separation of cobalt from copper, nickel and iron. The ion-exchange separation of cobalt from many elements in hydrochloric acid media has been extensively studied,[12,15–17] the results showing that cobalt is adsorbed strongly onto an anion-exchange resin in 9*M* hydrochloric acid. The cobalt can then be eluted from the resin with 4*M* hydrochloric acid, since at this concentration, the distribution coefficient of cobalt is very low. Nickel, which forms no anionic chloride complex, is not adsorbed on the column at any acid concentration. Iron(III), however, is strongly adsorbed at most concentrations of hydrochloric acid and can only be eluted by very dilute acid (0·1*M*). Palladium shows appreciable adsorption at most acid concentrations, with maximal adsorption from 1*M* hydrochloric acid; this element is therefore likely to be retained to a large extent on the anion-exchange column. Copper is difficult to separate from cobalt by ion-exchange, although this can be achieved by use of long columns and judicious choice of flow-rates. It is considerably more expedient to separate the copper first, and this can be readily done by electro-deposition in a divided cell to prevent polarization of the electrodes by the iron in the sample.[11] After the removal of copper, the sample is passed through the anion-exchange column, nickel is eluted with 9*M* hydrochloric acid and then cobalt with 4*M* hydrochloric acid. This process was tested for recovery of cobalt, the results appearing in Table 4.

These recoveries were adequate for determination of cobalt at levels ranging from ppm to percentage levels, provided a suitable sample size was chosen.

Analysis of samples

Ideally, the proposed methods of analysis were suited to samples containing low levels of cobalt in a matrix with favourable ratios of cobalt to copper, iron, nickel and palladium. Samples which met these criteria were plants and some soils, the latter being suitable because of the non-interference of silicate and fluoride (since soil digestion is often done with hydrofluoric acid). Samples of this type were not available, so the determination of cobalt in steels was attempted. The results for four standard steels are shown in Table 5.

Good agreement was obtained for three of the four steels analysed, and no comment can be made on the 221/1 carbon steel result, because of the non-certification of the published analytical result. The highly unfavourable ratio of cobalt to iron necessitated repetition of the ion-exchange separation step to ensure complete removal of traces of iron and nickel remaining after the initial ion-exchange separation. The results shown in Table 5 were obtained by the absorbance method because of the relatively high amounts of cobalt present in the samples. Although lengthy (3 hr), the procedure has the advantage of being applicable to a wide range of cobalt contents, with a very low detection limit.

DISCUSSION

Cobalt(II) complexes of many ligands have shown anomolous extraction behaviour, and this has also been observed for PAPHY and PAQH where the complexes formed have been found to be non-extractable at high pH values.[6,10] It has been demonstrated that PAPHY-type compounds act as oxidizing agents towards cobalt(II),[18] and the Co–PAPHY binary complex has been confirmed to be 2:1 (ligand to metal), diamagnetic and containing cobalt in the +3 oxidation state. Similar properties have been observed for the Co–PAQH complex,[19] in which only one of the ligands in the complex is deprotonated. The reaction between cobalt(II), PAPHY and eosin may be represented by the reaction scheme

(1) $\mathrm{Co(II)} \xrightarrow{\text{PAPHY}} \mathrm{Co(III)}$

(2) $\mathrm{Co^{3+} + 2HL \rightleftharpoons Co(HL)_2^{3+}}$

(3) $\mathrm{Co(HL)_2^{3+} \rightleftharpoons Co(L)(HL)^{2+} + H^+}$

(4) $\mathrm{Co(L)(HL)^{2+} + 2E^- \rightleftharpoons Co(L)(HL)E_2}$

Table 5. Analysis of steels for cobalt

221/1	Carbon steel	3	0·042	0·018*
239/2	Carbon steel	3	0·024	0·02*
235/2	Ti-stabilized stainless steel	3	0·055	0·056*

* Result not given British Chemical Standard certification, owing to insufficient independent analyses.

where E^- represents the eosinate anion. An alternative formulation would involve the double deprotonation of Co–PAPHY before the reaction with eosinate:

$$(4)' \quad Co(L)(HL)^{2+} \rightleftharpoons CoL_2^+ + H^+$$
$$(5) \quad CoL_2^+ + E^- \rightleftharpoons CoL_2E$$

Attempts to elucidate the nature of the extracted ternary complex by Job's method and the mole-ratio method proved to be unsuccessful owing to the large excesses of eosin and PAPHY required for complete reaction and extraction of the complex. However, at the acidity used throughout this study (pH 5·6), it is likely that Co–PAPHY would exist as the singly deprotonated form, suggesting that the correct formula for the complex is $Co(L)(HL)E_2$ where HL represents the protonated form of the ligand.

DETERMINATION OF URANIUM IN MINERALS AND ROCKS

J. Korkisch and H. Hübner
Institute for Analytical Chemistry, Analysis of Nuclear Raw Materials Division, University of Vienna, Währingerstraße 38, A-1090 Vienna, Austria

(*Received* 16 *June* 1975. *Accepted* 18 *October* 1975)

Summary—A method is described for the determination of uranium in minerals and rocks by spectrophotometry and fluorimetry. After treatment of the sample with hydrochloric acid, uranium is separated from matrix elements by adsorption on a column of the strongly basic anion-exchange resin Dowex 1 X8 from an organic solvent system consisting of IBMK, tetrahydrofuran and 12*M* hydrochloric acid (1:8:1 v/v). Following removal of iron, molybdenum and co-adsorbed elements by washing first with the organic solvent system and then with 6*M* hydrochloric acid, the uranium is eluted with 1*M* hydrochloric acid. In the eluate, uranium is determined by means of the spectrophotometric arsenazo III method or fluorimetrically. The suitability of the method for the determination of both trace and larger amounts of uranium was tested by analysing numerous geochemical reference samples with uranium contents in the range 10^{-1}–10^4 ppm. In practically all cases very good agreement of results was obtained.

Spectrophotometric and fluorimetric methods are employed extensively for the determination of uranium in a variety of geological samples, including materials of very low uranium contents such as basaltic rocks, and of uranium-rich minerals, as for instance torbernite, carnotite, uraninite and pitchblende.[1] For the successful analysis of both types of uranium-bearing materials the very sensitive spectrophotometric method of uranium determination can be used, which is based on measurement of the absorbance of the green uranium(IV)–arsenazo III complex in moderately concentrated hydrochloric acid medium.[1] Interferences are caused by thorium, zirconium, titanium, rare earth elements, molybdenum, and iron, so it is necessary to separate uranium from these elements and also from other components such as the main constituents of minerals and rocks. For this purpose, methods based on liquid–liquid extraction and ion-exchange have found widespread application.[1]

In the present paper an application is described of a single separation step which is based on anion-exchange in an organic solvent system. Following this quantitative separation, uranium can be determined, free from interferences, by either the arsenazo III method or fluorimetrically.

EXPERIMENTAL

Reagents

Ion-exchanger. The strongly basic anion-exchanger Dowex 1 X8 (100–200 mesh; chloride form) was used. To purify the exchanger (which contained, *e.g.*, iron and zinc) 200 g of the resin were treated in succession with 2 litres of 1*M* nitric acid, 2 litres of 6*M* hydrochloric acid, 2 litres of 1*M* hydrochloric acid, 3 litres of distilled water and 1 litre of reagent grade methanol. This batch of resin was air-dried and 3 g of it were slurried in a few ml of the IBMK–THF–HCl mixture (see below) and transferred to an ion-exchange column, with the same mixture used as a rinse.

Standard uranium solutions. Aliquots of a stock solution containing 10 mg of uranium (as uranyl chloride) per ml of 12*M* hydrochloric acid were diluted with water to obtain standard solutions in 9*M*, 6*M* and 1*M* hydrochloric acid containing 0·1–10^4 ppm of uranium.

IBMK–THF–HCl mixture. A mixture of IBMK (isobutyl methyl ketone), THF (tetrahydrofuran) and 12*M* hydrochloric acid (1:8:1 v/v) was prepared several hours before use (in order to prevent the formation of air-bubbles in the resin bed). This solution can be stored for at least a week without loss of effectiveness.

Arsenazo III solution. Freshly prepared and filtered 0·1% aqueous solution.

Other reagents. "Fluorbase" (200 mg) pellets consisting of 95% sodium fluoride and 5% lithium fluoride (Nordrhein-Chemie, 41 Duisburg 12, West Germany), zinc metal (dust or finely granulated zinc), oxalic acid, 1·0, 6, 9 and 12*M* hydrochloric acid, 1*M* nitric acid, and reagent-grade methanol.

Apparatus

The ion-exchange separations of uranium were performed in columns of the type and dimensions described earlier.[2]

Determination of distribution coefficients

The distribution coefficients (K_d-values) of uranium and some of the more strongly adsorbed metal ions were determined by using the batch-equilibrium method, and the column technique was employed to measure the K_d-values of iron, molybdenum and other elements which are weakly retained by the resin.[3] The usually high distribution coefficients of uranium were determined after equilibration (for 4 hr) of 1 g of the resin with 20 ml of the organic solvent–hydrochloric acid mixture tested (see Table 1) containing 20 mg of uranium, followed by filtration, etc.[3] In the determinations of the batch and column distribution coefficients of the other elements only 1 mg each of the metal ions was used (see Table 2).

Procedures

Dissolution of samples. To 1·0 g of the thoroughly homogenized sample, in a 250-ml beaker, 100 ml of concentrated hydrochloric acid are added, the beaker is covered with a watch-glass, and the mixture is heated on a sand-bath until its volume has been reduced to about 30 ml. Subsequently the solution is evaporated to dryness under an infrared lamp, another 100 ml of concentrated hydrochloric acid are added and the solution is evaporated to dryness again under the heat-lamp. To the residue 30 ml of 6*M* hydrochloric acid are added, the mixture is heated under the lamp for several minutes and then let stand (preferably overnight). Afterwards, insoluble material (mainly silica) is removed by filtering off on a dense filter, 6*M* hydrochloric acid being used for washing the filter paper and residue free from iron. The filtrate is evaporated to dryness on a steam-bath and the residue is taken up in about 30 ml of the IBMK–THF–HCl mixture. If two phases are formed, more solvent mixture is added until a homogeneous solution is obtained* in which however, a portion of the solute (mainly silica) usually reappears as a suspension, owing to the decrease of solubility on addition of the IBMK–THF–HCl mixture. This insoluble material is filtered off on a dense filter, and washed with IBMK–THF–HCl solution. The filtrate (usually 50–100 ml) is the sorption solution for the ion-exchange separation.

Ion-exchange separation. The sorption solution is passed through the ion-exchange column containing 3 g of the resin (pretreated with 10 ml of the IBMK–THF–HCl mixture), at a flow-rate of about 0·8 ml/min. Iron and molybdenum are removed by washing the column with 50 ml of the IBMK–THF–HCl mixture, and copper, cobalt, *etc.* as well as organic solvents left in the resin bed are eluted with 100 ml of 6*M* hydrochloric acid. The adsorbed uranium is then eluted with 100 ml of 1*M* hydrochloric acid.

The resin column may be used for the isolation of uranium from further samples provided that 30 ml of the IBMK–THF–HCl mixture are used to pretreat it following the elution of uranium.

Quantitative determination of uranium. The uranium eluate is evaporated to dryness on a steam-bath or under an infrared lamp and the residue is dissolved in 9*M* hydrochloric acid and transferred to a 25-ml standard flask and diluted to volume with the acid. If this solution contains >1 ppm of uranium (*i.e.*, >25 μg of uranium) it is necessary to dilute it (or an aliquot) with the same acid to a suitable volume in which this concentration is not exceeded.

A. Spectrophotometric method. Ten ml of the 9*M* hydrochloric acid solution of the uranium are transferred to a 100-ml wide-neck Erlenmeyer flask, 0·3 g of oxalic acid and 1·10 g of zinc are added and the flask is covered loosely with a stopper. During the reduction the flask is shaken carefully until all the zinc has dissolved. Immediately afterwards 1·0 ml of the arsenazo III solution is added and the absorbance is measured at 665 nm against a reagent blank prepared in the same way. A calibration curve for the range 1–10 μg of uranium is constructed according to the reduction procedure described above. Beer's law is strictly obeyed up to 10 μg of uranium (absorbance 0·400). Higher amounts give strong positive deviations from linearity. The absorbance remains constant for at least 100 min. If less than 0·2 μg of uranium is present in the 10 ml of test solution ($<0·5$ ppm in the original sample) this method is less reliable (because of the low absorbance) than the fluorimetric procedure described below.

B. Fluorimetric method. A suitable volume (*e.g.*, 0·1 ml) of the uranium eluate or of the 25 ml of the 9*M* hydrochloric acid solution containing the uranium is evaporated in a small platinum dish[4] and after addition of a "Fluorbase" pellet, a melt is prepared under strictly controlled conditions.[1] The fluorescence intensity of the cold flux is measured and compared with the intensity of fluxes of known uranium concentrations.

RESULTS AND DISCUSSION

The dissolution procedure described, in which only hydrochloric acid is used, proved to be highly satisfactory for all of the samples analysed although it is in principle based on leaching only. Investigation of the completeness of dissolution showed that the portions insoluble in hydrochloric acid never retained more than about 0·1% of the total uranium content.

During filtration of the IBMK–THF–HCl mixture to remove the insolubles, some of the silica passes into the filtrate but this was found not to interfere with the subsequent anion-exchange separation of uranium. The silica passes right through the resin bed and hence does not block the column.

Investigations of the effect of varying the concentrations of IBMK, hydrochloric acid and of water-miscible organic solvents on the adsorption of uranium and iron on Dowex 1 gave the results presented in Table 1.

At high acid concentrations in the presence of IBMK, acetone or tetrahydrofuran, the K_d-values and elution volumes for iron are considerably lower than those for the other systems shown in Table 1. That is not surprising, because these media contain three CIESE-active components,[4–6] namely hydrochloric acid and IBMK mixed with either acetone or tetrahydrofuran so that iron(III) chloride shows practically no tendency to be adsorbed on the anion-exchanger. This is also true for molybdenum although to a lesser extent in most of the media; like iron, molybdenum is also readily extracted by IBMK or other ketones or ethers from hydrochloric acid solutions.[3] Investigations using molybdenum dissolved in the systems in which elution volumes for iron of 2 or 3 ml were measured (Table 1) have shown that for molybdenum similarly small elution volumes, which are necessary to effect complete removal of molybdenum, were obtained with only three media *i.e.*, in the 1:8:1, 4:5:1 and 8:1:1 v/v IBMK–THF–HCl mixtures. In all other mixtures the elution volumes for molybdenum were found to exceed 50 ml. As will later be shown in Table 3, the virtually complete removal (separation) of molybdenum and iron is essential for the accurate spectrophotometric determination of uranium.

From Table 1 it is also seen that uranium (as the anionic chloride complex) is strongly adsorbed from virtually all of the systems investigated—the smallest but still sufficiently high distribution coefficients being found in the media containing acetone or tetrahydro-

---

* If after addition of the organic solvent mixture a total volume of 100 ml should be reached without obtaining homogeneity, 1 ml of concentrated hydrochloric acid is added—this causes immediate disappearance of the two phases.

Zn(II)	200	Ti(IV)	2
Ni(II)	50	Zr(IV)	1
Cr(III)	1	Th(IV)	2

* The elution volume on a 1-g column of the resin is equivalent to 3 ml.

furan. From the latter media the 1:8:1 v/v mixture was selected as the most suitable for the separation of uranium from geological samples. In this system the distribution coefficient of uranium (550) is high enough to guarantee the complete adsorption of even mg-amounts of uranium and the K_d-values and elution volumes of iron and molybdenum are very low (see also Table 2), so they can be separated from uranium most effectively. An additional advantage of this medium stems from the fact that the tendency for formation of two phases on dissolution of the chloride residue in IBMK–THF–HCl mixtures decreases with increasing concentration of tetrahydrofuran in the mixtures.

Investigations of the adsorption behaviour of numerous elements on Dowex 1 from the selected IBMK–THF–HCl mixture gave the results presented in Table 2. Atomic-absorption spectrophotometry was used for the necessary analyses. From these distribution coefficients it is evident that during the sorption process not only uranium but also copper, cobalt, lead, manganese, cadmium and zinc will be adsorbed on the resin. Previous experience has shown however, that under the conditions of analysis, *i.e.*, in the presence of large amounts of chlorides as is the case after treatment of the geological samples with hydrochloric acid, some of these elements (and also those, *e.g.*, lead, for which the adsorption decreases with increase in the chloride concentration) are much less strongly adsorbed than their K_d-values would indicate (salt-effect).

The washing with IBMK–THF–HCl mixture immediately after passage of the sorption solution through the resin bed removes residual iron and molybdenum* so that these will not interfere with either the spectrophotometric or the fluorimetric procedure for uranium assay. Other elements which, if not separated from uranium, may cause interferences in either or both of these methods, are eluted subsequently with 6*M* hydrochloric acid. Thus, this eluent quantitatively eliminates from the resin all of the adsorbed elements listed in Table 2 except uranium, cadmium and zinc (The distribution coefficients in 6*M* hydrochloric acid are 283, >100 and >100 for uranium, cadmium and zinc respectively.) At the same time the residual organic solvents are also removed from the resin bed. On subsequent elution of uranium with 1*M* hydrochloric acid ($K_d \sim 1$), cadmium and zinc ($K_{d_{Cd}} \sim 10^3$; $K_{d_{Zn}} > 100$) are not co-eluted with it.

The ion-exchange separation method described was applied to the analysis of numerous geological speci-

Table 3. Effect of iron and molybdenum on the spectrophotometric determination of uranium with arsenazo III (5·0 μg of uranium taken)

mens (see later) and to test-solutions containing known amounts of uranium (1, 10 and 100 μg), molybdenum (5 mg), iron (100 mg) and cobalt (1 mg). Analyses of these mixtures showed that in the entire uranium eluate not more than 25 μg of iron were present (determined by atomic-absorption spectrophotometry) even if as much as 100 mg of this element were present in the sorption solution. Molybdenum and cobalt were completely separated, no detectable amounts being found in the uranium eluate.

The effect of iron and molybdenum on the spectrophotometric determination of uranium with arsenazo III was tested with various concentrations of these elements. From Table 3 it is seen that the tolerance limit for iron is relatively high, up to 150 μg of iron not interfering with the uranium determination. Thus, the method is much less sensitive to iron than the fluorimetric procedure in which much smaller quantities of iron cause an appreciable quenching of the uranium fluorescence.[1] On the other hand molybdenum has practically no influence on the fluorimetric method but interferes seriously when arsenazo III is used, giving a positive error when <75 μg are present and a large negative error when >100 μg are present in the solution measured (Table 3). In the presence of 200–500 μg of molybdenum no uranium was found. Interferences by iron and molybdenum are not to be expected to occur, however, after the ion-exchange

separation, because the amount of iron accompanying uranium in the eluate is always much lower than 150 μg and molybdenum is separated quantitatively. Furthermore, thorium, zirconium, titanium, rare-earth elements and phosphate, which also strongly interfere with the arsenazo III method,[1] will have no effect on the determination of uranium because they are completely separated by the anion-exchange. Thus, 100 mg of sodium phosphate gave no interference, and up to 100 mg of sulphate did not interfere with the ion-exchange separation of uranium.

The results of uranium determinations in numerous reference samples are shown in Tables 4–6. The spectrophotometric method gives somewhat higher results than fluorimetry when very iron-rich samples, *e.g.*, Biotite Mica-Fe (total Fe as Fe_2O_3 = 25·75%) and Bauxite BX-N (total Fe as Fe_2O_3 = 23·21%) (see Table 5) are analysed, because the amount of iron accompanying uranium into the eluate causes quenching of the uranium fluorescence. Apart from these few instances in which the fluorimetric procedure gives lower results, the uranium results are generally in reasonably good agreement with the results obtained in other laboratories, exceptions being Sediment-2 and Phlogopite Mica-Mg (see Table 5).

Because the method is based on separations on anion-exchange columns, which can be performed more or less automatically, it is possible to analyse numerous samples simultaneously, *i.e.*, the procedure is very well suited for the routine determination of uranium over a concentration range of about five orders of magnitude.

(*Received* 19 *June* 1975. *Accepted* 19 *October* 1975)

Summary—A method is described for the atomic-absorption determination of beryllium in liquid environmental samples after separation by solvent extraction and cation-exchange. The beryllium is first isolated from natural waters and beverages by chloroform extraction of its acetylacetonate from a solution at pH 7 and containing EDTA. The chloroform extract is then mixed in the ratio of 3:6:1 with tetrahydrofuran and methanol containing nitric acid, and passed through a column of Dowex 50 X8 (H^+-form). After removal of acetylacetone, chloroform and tetrahydrofuran by washing the resin bed with methanol-HNO_3, beryllium is eluted with 6*M* hydrochloric acid and determined by atomic-absorption spectroscopy. The method was successfully applied to determine beryllium in tap-, river- and sea-water samples, mineral waters and wines. Beryllium contents in the range from <0·01 to 2·3 μg/l. were found in these materials.

Determinations of trace quantities of beryllium in liquid environmental samples, *e.g.*, natural waters and beverages, are gaining increased importance with the growing interest in pollution of the environment with this toxic element. Analytical techniques based on atomic-absorption spectrophotometry,[1,2] emission spectroscopy,[3–10] fluorimetry[11–13] and spectrophotometry[14–20] can be employed. To avoid interference by matrix elements and to increase the sensitivity, suitable preconcentration techniques are often used to separate beryllium before its quantitative determination. Especially suitable for quantitative isolation of trace amounts of beryllium from natural waters are separation methods based on the chloroform (or carbon tetrachloride) extraction of beryllium acetylacetonate[3,13,18,19] or co-precipitation with suitable collectors such as the hydrous oxides of iron(III),[6,11,14–16,20] aluminium[15,16] and manganese,[20] or titanium phosphate.[17] Other techniques are based on the adsorption of beryllium on various sorbents such as a 1:1 mixture of activated charcoal and chlorinated lignin,[7] silica gel[12] and the strong-acid cation-exchanger Dowex 50 X8 (in the Fe^{3+} or Mn^{2+} form and treated with excess of ammonia solution).[20] Combinations of these methods may also be employed, *e.g.*, co-precipitation of beryllium with ferric hydroxide and subsequent separation by anion-exchange.[15]

In the present paper, a combination of separation techniques is described, which utilizes chloroform extraction of beryllium acetylacetonate[21,22] as the first preconcentration step, followed by cation-exchange enrichment of beryllium directly from the organic extract.

EXPERIMENTAL

Solutions and reagents

Ion-exchange resin. Dowex 50 X8 (100–200 mesh; H^+-form) was used. For purification, 500 g of the resin were treated successively with 2 litres of 6*M* nitric acid, 500 ml of 0·1*M* nitric acid, 2 litres of distilled water and 500 ml of reagent-grade methanol. The purified resin was air-dried. Before use 4 g of the cation-exchanger were slurried with a few ml of $CHCl_3$–THF–MeOH solution and transferred to the ion-exchange column as completely as possible with the same solution.

Standard beryllium solutions. An exactly weighed amount of beryllium nitrate tetrahydrate was dissolved in 1*M* nitric acid to obtain a stock solution containing 630 ppm of beryllium. From this solution, standard solutions 0·1*M* in nitric acid and 0·6*M* in hydrochloric acid were prepared, which contained from 0·006 to 630 ppm and from 0·003 to 630 ppm of beryllium respectively.

$CHCl_3$-THF-MeOH solution. This solution, of 0·1*M* overall acidity, is prepared by mixing 30 ml of chloroform with 60 ml of tetrahydrofuran (THF) and 10 ml of MeOH–HNO_3 mixture (of 1*M* overall acidity).

MeOH–HNO_3 mixture. A mixture with 1*M* overall acidity is prepared by dilution of 69 ml of concentrated nitric acid to 1 litre with methanol. To obtain the MeOH–HNO_3 mixture of 0·1*M* overall acidity which is used for the ion-exchange separation of beryllium, 10 ml of this solution are diluted to 100 ml with methanol.

THF–MeOH solution. This consists of a 9:1 v/v mixture of tetrahydrofuran and MeOH–HNO_3 mixture (of 1*M* overall acidity). The overall acidity of this THF–MeOH solution is 0·1*M*.

Other reagents. Acetylacetone, 5% aqueous acetylacetone solution, chloroform, solid EDTA (disodium salt), 10% and 0·1*M* aqueous EDTA solutions, 5% and 20% solutions of sodium hydroxide, 0·1*M*, 0·6*M*, 6*M* and concentrated hydrochloric acid, 1% methanolic solution of arsenazo I, 2*M* sodium acetate, tetrahydrofuran, methanol and concentrated nitric, sulphuric, perchloric, and hydrobromic acids. The reagents used were all stable for at least 6 months

Apparatus and operating conditions

A Perkin–Elmer 303 atomic-absorption spectrophotometer (equipped with a Hitachi–Perkin–Elmer Recorder 56 connected to a read-out accessory) was used with the following instrumental settings.

Grating:	ultraviolet
Wavelength:	234·9 nm
Scale expansion:	up to 30X
Slit:	5 (3 mm; 2 nm bandpass)
Source:	beryllium hollow-cathode lamp
Lamp current:	30 mA
Burner:	one-slit burner for the acetylene–nitrous oxide flame
Acetylene pressure:	8 psig; 14 on flowmeter (arbitrary scale)
Nitrous oxide-pressure:	30 psig; 6 on flowmeter (arbitrary scale)
Noise suppression:	up to 5

Under these conditions the sensitivity for 1% absorption was found to be 0·015 ppm of beryllium in 0·6*M* hydrochloric acid. The detection limit for beryllium was 0·001 ppm. The calibration curve was linear up to 0.5 μg of beryllium per ml.

The spectrophotometric calibration curve (Beckman DB-GT instrument, 1 cm cells) was linear up to a beryllium concentration of 1·0 μg/ml.

The separations of beryllium were performed in ion-exchange columns of the type and dimensions described earlier.[23]

Determination of distribution coefficients

The weight distribution coefficients (K_d-values on Dowex 50) of beryllium were determined by using the batch equilibrium method.[22]

Pretreatment of samples and solvent extraction of beryllium

Natural waters and mineral waters. To 1 litre of the water sample (saline or non-saline), in the polyethylene bottle in which it was collected, 10 ml of concentrated hydrochloric acid are added and after filtration the sample is let stand for about 24 hr (degassing of the sample; mainly for removal of CO_2). Then 3 g of EDTA are added and dissolved, the pH is adjusted to about 7 with 20% sodium hydroxide solution (about 20–25 ml are required) and after addition of 2 ml of acetylacetone the mixture is shaken thoroughly until complete homogeneity is attained. Finally the pH of the solution is adjusted to 7 by careful addition of 20% and 5% sodium hydroxide solutions and let stand for at least 2 hr (preferably overnight) so that beryllium can react quantitatively with the acetylacetone. Then the sample solution is transferred to a 2-litre separatory funnel, 20 ml of chloroform are added and beryllium acetylacetonate is extracted by vigorous shaking for 1 min. After phase separation the organic extract is passed through a dry filter paper to remove aqueous droplets adhering to the organic layer. The extraction of the sample solution is repeated twice with 10 ml of chloroform each time and a shaking period of 30 sec. After filtration through dry filter paper these last two extracts are combined with the first and thus about 30 ml of chloroform–acetylacetone solution are obtained ("beryllium extract"). From this organic mixture beryllium is isolated by the cation-exchange procedure described below.

Wines. To the wine sample (1 litre) concentrated hydrochloric acid is added to make it 0·6*M* in this acid and after about 24 hr the acidified wine is filtered and 250 ml of it, in a 600-ml beaker, are evaporated to about one-third of the original volume. Subsequently 50 ml of concentrated nitric acid are added (preferably after the concentrated wine sample has been allowed to cool to room temperature) and the mixture is evaporated to dryness on a steam-bath. The residue is taken up in 100 ml of a 3:1:1 mixture of concentrated nitric, sulphuric and perchloric acids and the solution is first heated on a steam-bath (until its volume is reduced to about 50 ml) and then evaporated to dryness on a sand-bath. To destroy perchlorate, 25 ml of concentrated hydrobromic acid are added and after evaporation of the solution to dryness on the steam-bath the residue is dissolved in about 20 ml of 0·1*M* hydrochloric acid or water. Then 20 ml of 10% EDTA solution are added, the pH is adjusted to about 7 with sodium hydroxide, 2 ml of 5% aqueous acetylacetone solution are added, and then the same extraction procedure is followed as described above for the analysis of waters except that only half the volume of chloroform is used, *i.e.*, 10 ml for the first and 5 ml each for the two subsequent extractions.

Ion-exchange separation

The beryllium extract (about 30 ml)* is mixed with 60 ml of tetrahydrofuran and 10 ml of MeOH–HNO_3 mixture (overall acidity 1*M*) and the resulting solution (the sorption solution, overall acidity 0·1*M*) is passed through a 4-g column of the cation-exchanger (pretreated with 10 ml of $CHCl_3$–THF–MeOH solution) at a flowrate of about 60 ml/hr. The resin bed is then washed with about 5 ml of THF–MeOH solution, followed by about 10 ml of MeOH–HNO_3 mixture (overall acidity 0·1*M*) and finally beryllium is eluted with 50 ml of 6*M* hydrochloric acid (beryllium eluate).

Quantitative determination of beryllium

Atomic-absorption spectroscopy. The beryllium eluate is evaporated under an infrared lamp, the residue is dissolved in 1 ml of 6*M* hydrochloric acid, and after dilution with water to 10 ml the solution is aspirated into the acetylene–nitrous oxide flame. A calibration curve is constructed by aspirating suitable beryllium standard solutions before and after each batch of samples.

A reagent blank is run through the whole procedure (starting with addition of the first reagent) and finally deducted from the beryllium found in the sample.

Spectrophotometry. The beryllium eluate is evaporated and the residue is taken up in 1 ml of 6*M* hydrochloric acid; then 1 ml of arsenazo I solution and 1 ml of 0·1*M* EDTA solution are added, and the solution is diluted to 10 ml with 2*M* sodium acetate. The absorbance is measured at 580 nm against a reagent blank. The absorbance is 0·350 for 1 ppm of beryllium in the solution measured.

RESULTS AND DISCUSSION

Acidification of the samples with concentrated hydrochloric acid prevents the adsorption of beryllium on the walls of the sample container and co-precipitation of beryllium with hydroxides and phosphates of iron *etc.* which may occasionally be present in relatively large amounts, e.g., in some mineral waters and especially in wine samples.

The chloroform extraction of beryllium acetylacetonate is carried out in the presence of EDTA to prevent the co-extraction of most of the main and trace constituents of liquid environmental samples. Thus, a beryllium extract is obtained which is virtually free from elements interfering with the assay of beryllium.

---

* To prepare the sorption solution from the beryllium extract (about 20 ml) obtained from a wine sample, mix the extract with about 40 ml of tetrahydrofuran and 7 ml of MeOH–HNO_3 mixture (overall acidity 1*M*).

Unfortunately the assay cannot be done directly on the chloroform extract by atomic-absorption spectroscopy. Therefore, an attempt was made to determine beryllium in aqueous medium after removal of chloroform by evaporation. However, the volatility of beryllium acetylacetonate caused considerable losses of the element (especially when only submicrogram amounts were present) even when the evaporation was carried out at very low heat and with 4–5 ml of concentrated hydrochloric acid and 25 ml of methanol added to the chloroform extract. The hydrochloric acid was added to liberate beryllium from its acetylacetone chelate and methanol was added to obtain a homogeneous mixture with the chloroform.

Therefore a means was sought for separating beryllium from both the chelating agent and the chloroform without the application of heat. As a result, the cation-exchange method utilizing adsorption of beryllium on Dowex 50 from the mixed $CHCl_3$–THF–MeOH medium containing nitric acid was developed. In this mixture the presence of tetrahydrofuran is necessary to obtain a homogeneous solution, and the methanol is the component regulating the flow-rate through the ion-exchange column. In the absence of methanol the viscosity of the sorption solution is extremely low, so that a flow-rate is attained at which complete adsorption of beryllium is not guaranteed. Nitric acid has to be present in the mixture so that beryllium is in the ionic form which is adsorbed on the cation-exchanger during the sorption process, after which residual chloroform and acetylacetone are removed by washing the resin bed with THF–MeOH solution and MeOH–HNO_3 mixture. Thus, after the elution of beryllium with 6*M* hydrochloric acid an eluate is obtained which does not contain organic substances which could give rise to the formation of beryllium compounds that are volatile during evaporation of the eluate.

Through the combination of this ion-exchange separation step with the extraction of beryllium acetylacetonate from the water sample it is possible to isolate submicrogram and microgram amounts of this element from both saline and non-saline waters. Table 1 shows that beryllium recoveries are in the range 93–103%.

That the separation of beryllium is not affected by large quantities of foreign ions (which are usually only trace constituents of natural waters) is demonstrated by the results presented in Table 2.

The only two elements which are co-extracted with beryllium to a considerable extent are iron and copper, and then only from sea-water (see footnote to Table 2) because the dissolved salts act as salting-out agents during the extraction. In the cation-exchange separation of beryllium these co-extracted elements are co-adsorbed with the beryllium irrespective of the acidity used (the beryllium adsorption was found to decrease only slightly with increasing nitric acid concentration in the $CHCl_3$–THF–MeOH–HNO_3 mixture (Table 3).

In the absence of the organic solvents, distribution coefficients for beryllium of 255 and 900 were measured in 0·1*M* hydrochloric and 0·1*M* nitric acid media respectively. Under the conditions of elution, *i.e.*, in 6*M* hydrochloric acid, the distribution coefficient for beryllium was <1. Iron and copper are co-eluted with the beryllium but do not interfere with the atomic-absorption determination nor with the spectrophotometric method (because of the masking action of the EDTA added). However, the spectrophotometric results often showed a positive bias of about 3–5%; this is most probably due to the effect of small amounts of coloured organic matter in the residue obtained after evaporation of the beryllium eluate. Another disadvantage of the spectrophotometric method is its low sensitivity: beryllium concentrations below 0·06 μg/ml in the final solution measured cannot be determined with sufficient accuracy. Since this concentration is rarely reached in beryllium eluates obtained from 1-litre samples, the arsenazo I method was not used for most of the liquid environmental samples. The much more sensitive atomic-absorption spectroscopy technique (in which, contrary to recent information,[1] sodium was not

found to interfere) being preferred. Sometimes even the atomic-absorption method is not sensitive enough to determine beryllium accurately. Thus, in certain samples it was possible to detect beryllium (detection limit = 0.001 ppm) but the signals were not sufficiently strong to give reliable results.

Numerous samples of Austrian waters were analysed by the methods described above. Good agreement was obtained between results for spiked and unspiked samples. For sea-water (Adriatic Sea and Pacific Ocean) results ranging from <0·01 to 0·02 μg/l. were obtained, in agreement with the range of 0·001–0·03 μg/l. quoted in the literature.[24]

In most of the natural non-saline surface waters investigated, only very low beryllium contents were found (0·01–0·03 μg/l.); this is due to the relative insolubility of the oxide and hydroxide of beryllium at the normal pH range for these waters. Also, in the weathering process beryllium is concentrated in hydrolysates, and like aluminium does not go into solution to any appreciable degree.

On the other hand, some mineralwaters were found to have beryllium concentrations higher by several orders of magnitude than those found for most saline and non-saline waters (Table 4). Measurements of the pH-values and calcium contents (as a

measure of the carbonate concentrations) showed that the mineral waters with extremely high beryllium contents are considerably more alkaline than the others in which the beryllium levels are comparable to those of the non-saline waters. For instance, the calcium concentration in the Thalheimer and Preblauer samples was 450 and 340 mg/l. respectively, while in the samples of Vöslauer and Römerquelle it was 100 and 140 mg/l. The pH-values for the last two mineral waters were found to be lower by about 2 and 3·5 pH units than those of Thalheimer and Preblauer respectively.

In an oil-field water from a deep oil-well, (Litzelsdorf 1) containing appreciable amounts of dissolved carbonates, a beryllium content of about 0·10 μg/l. was found. Because of the presence of large quantities of organic substances the isolation of beryllium from this oil-field water was most probably not quite quantitative (it was very difficult to obtain two distinct phases during the extraction of beryllium acetylacetonate with chloroform) so the beryllium concentration may actually be higher.

According to previous experience[25] beryllium is regarded as one of the trace elements which is either not contained in wines under normal conditions or cannot be detected with certainty. That this is not the case, however, is illustrated by the results shown in Table 5 from which it is seen that in only one out of ten different wine samples (collected at random) was the beryllium content below the limit for accurate determination. It is also evident that wines originating from the same locality contain very similar beryllium concentrations. Before separation of beryllium the wine samples have to be wet-ashed by the method described. Direct extraction of beryllium from wine is not possible because of the presence of the alcohol.

In conclusion it should be mentioned that in place of the solvent extraction procedure beryllium can also be concentrated quantitatively on a 4-g column of the cation-exchanger Dowex 50 from one litre of non-saline water which is 0·1*M* in nitric acid. However, this cation-exchange method was abandoned in favour of the extraction method because the latter can be performed much more rapidly and is also applicable to natural waters of high salinity such as sea-water and mineral-waters.

APPLICATION OF ION-EXCHANGE SEPARATIONS TO DETERMINATION OF TRACE ELEMENTS IN NATURAL WATERS—IX

SIMULTANEOUS ISOLATION AND DETERMINATION OF URANIUM AND THORIUM

J. Korkisch and H. Krivanec

Institute for Analytical Chemistry, Analysis of Nuclear Raw Materials Division, University of Vienna,
Währingerstraße 38, A-1090 Vienna, Austria

(*Received* 27 *June* 1975, *Accepted* 19 *October* 1975)

Summary—A method is described for the determination of uranium and thorium in samples of natural waters. After acidification with citric acid the water sample is filtered and sodium citrate and ascorbic acid are added. The resulting solution of pH 3 is passed through a 4-g column of Dowex 1 X8 (citrate form) on which both uranium and thorium are adsorbed as anionic citrate complexes. Thorium is eluted with 8*M* hydrochloric acid and separated from co-eluted substances by anion-exchange in 8*M* nitric acid medium on a separate 2-g column of the same resin in the nitrate form. After complete removal of iron by washing with a mixture consisting of IBMK, acetone and 1*M* hydrochloric acid (1:8:1 v/v) and treatment of the resin with 6*M* hydrochloric acid, the uranium is eluted from the 4-g column with 1*M* hydrochloric acid. In the eluate thorium is determined spectrophotometrically (arsenazo III method) while fluorimetry is employed for the assay of uranium. The procedure was used for the determination of uranium and thorium in numerous water samples collected in Austria, including samples of mineral-waters. The results indicate that a simple relationship exists between the uranium and thorium contents of waters which makes it possible to calculate the approximate thorium content of a sample on the basis of its uranium concentration and *vice versa*.

Investigations of the isolation of trace quantities of uranium and thorium from natural waters have shown that, except for a method described by Korkisch *et al.*,[1] anion-exchange procedures are not available by means of which both elements can be separated simultaneously from a single water sample without its preliminary evaporation. In that method, the anionic ascorbate complexes of uranium, thorium and some other elements such as molybdenum, vanadium and titanium are first adsorbed on Amberlite IRA-400 or Dowex 1 (in the ascorbate form) from the water sample containing ascorbic acid and adjusted to a pH of 4–4·5. Thorium and uranium are eluted with 0·1*M* hydrochloric acid directly into a small column of Dowex 50, on which both elements are adsorbed. From this resin uranium is eluted with 1*M* hydrochloric acid and determined polarographically by means of the catalytic nitrate wave. Subsequently thorium is eluted with 3*M* sulphuric acid and determined spectrophotometrically by the Thoronol method. Disadvantages of the technique are that molybdenum, vanadium and titanium are co-adsorbed and co-eluted with uranium and thorium and interfere seriously with their determination. Furthermore, the volume of water sample from which uranium and thorium can be adsorbed on the anion-exchanger is rather critical; the effect of the principal anions in waters, especially sulphate, on the adsorbability of ascorbate complexes is most pronounced.

Although the effect of anions on the adsorption of thorium from samples of high salinity cannot be completely eliminated, the present method has the additional advantage of speed over a previous method of thorium isolation, based on evaporation of the water sample and anion-exchange in 7*M* nitric acid.[2] For uranium isolation the present method is of about the same efficiency but greater versatility than the thiocyanate method described in a previous paper,[3] because thorium is isolated quantitatively at the same time.

EXPERIMENTAL

Reagents

Ion-exchange resin. Dowex 1 (Bio-Rad AGl, X8; 100–200 mesh; chloride form) was used. To prepare the citrate form, 4 g of the resin were slurried with a few ml of 6*M* hydrochloric acid and after about 30 min transferred to the ion-exchange column as completely as possible with the same acid. Subsequently the resin bed was washed successively with 20 ml of water, 50 ml of 10% aqueous sodium citrate solution and 30 ml of wash-solution. The nitrate form of the resin was prepared as described earlier.[2]

Standard solutions. Aliquots of stock solutions of thorium (5 mg/ml) and uranium (1 mg/ml) (both as chlorides) in 6*M* hydrochloric acid were diluted with 1*M* hydrochloric acid to obtain standard solutions containing from 1 to 10 ppm of thorium and uranium.

Wash-solution. Ten g of citric acid, 3 g of sodium citrate and 2 g of ascorbic acid were dissolved in distilled water and the solution was diluted with water to 1 litre (this solution has a pH of 3).

IBMK–acetone–1M HCl solution. A mixture of isobutyl methyl ketone (IBMK), acetone and 1*M* hydrochloric acid (1:8:1 v/v). It is not recommended to use the freshly prepared mixture, because bubbles may form in the resin bed. Solutions more than about one week old should also not be used (polymerization of acetone by the action of hydrochloric acid). Ideally the mixture should be prepared 12–24 hr before use.

Other reagents. Citric acid, trisodium citrate dihydrate (solid and as 10% aqueous solution), ascorbic acid, 0·2% arsenazo III solution (freshly prepared and filtered), 2% potassium permanganate solution, concentrated formic acid, 1*M*, 6*M*, 8*M*, and concentrated hydrochloric acid, 8*M* nitric acid.

Apparatus

The separations of uranium and thorium were performed in ion-exchange columns of the type and dimensions described earlier.[4]

Determination of distribution coefficients

The weight distribution coefficients (K_d-values) of uranium, thorium and other elements were determined by the batch equilibrium method.[5]

Pretreatment of samples

As soon as possible after the water sample is taken (in a plastic bottle), 1 litre of it is acidified with 10 g of citric acid. After complete dissolution of this acid the sample is filtered through a dense filter and to the filtrate 3 g of sodium citrate and 2 g of ascorbic acid are added and the solution* (sorption solution) is shaken until these reagents are dissolved completely. It a larger or smaller volume of sample is required for analysis the amounts of all reagents added are varied accordingly.

Ion-exchange separation

Adsorption of uranium and thorium. About 12 hr after preparation the sorption solution is passed through a 4-g column of the anion-exchanger (citrate form, pretreated with 30 ml of the wash-solution) at a flow-rate of about 50 ml/hr, then the resin is washed with 100 ml of the wash-solution.

Separation of thorium. The adsorbed thorium is eluted with 50 ml of 8*M* hydrochloric acid and the eluate is evaporated under an infrared lamp until the co-eluted organic acids (mainly citric acid) start to decompose. At this point 10 ml of 8*M* nitric acid are added, the solution is evaporated once more and the residue of decomposed citric acid containing the thorium is dissolved in 50 ml of 8*M* nitric acid. The resulting solution (usually brown) is passed through a column containing 2 g of the anion-exchanger (nitrate form, pretreated with 50 ml of 8*M* nitric acid) at a flow-rate of about 50 ml/hr, the resin is washed with 50 ml of 8*M* nitric acid and thorium is eluted with 50 ml of 6*M* hydrochloric acid (thorium eluate).

Separation of uranium. After the elution of thorium from the 4-g column, the resin is washed with 100 ml of IBMK–acetone–1*M* HCl solution to remove all of the iron, then with 100 ml of 6*M* hydrochloric acid, and finally uranium is eluted† with 100 ml of 1*M* hydrochloric acid (uranium eluate).

Quantitative determinations

Thorium. The thorium eluate is evaporated to dryness on a steam-bath and the residue is taken up in 10 ml of 1*M* hydrochloric acid. Then 5 ml of 2% potassium permanganate solution are added and the solution is again evaporated to dryness (oxidation of organic matter from the resin). The residue is dissolved in 10 ml of 6*M* hydrochloric acid and after addition of 2 ml of concentrated formic acid the solution is evaporated to dryness on a steam-bath (destruction of residual nitrate). The residue is dissolved in 5 ml of concentrated hydrochloric acid and transferred to a 10-ml standard flask to which 1 ml of arsenazo III solution (filtered immediately before use) is added, followed by water to dilute the solution to 10 ml. The absorbance of the resulting solution is measured at 660 nm against a reagent blank and its thorium content determined from a calibration curve constructed in the same way. Beer's law is obeyed in the thorium range 0–1·5 μg/ml. An absorbance of 0·560 corresponds to 1·0 μg/ml.

Uranium, fluorimetric method. The uranium eluate is evaporated to dryness on a steam-bath or under an infrared lamp and the residue is dissolved in 2 ml of 6*M* hydrochloric acid. A suitable volume of this solution (*e.g.*, 0·1 ml) is evaporated in a small platinum dish[6,7] and after the addition of a "Fluorbase" pellet,[8] a melt is prepared under strictly controlled conditions.[6,7] The fluorescence intensity of the cold flux is measured and compared with the intensity of fluxes of known uranium concentrations.

Uranium, spectrophotometric method. If the 2 ml of 6*M* hydrochloric acid (see fluorimetric method above) contain more than about 0·5 μg of uranium the spectrophotometric arsenazo III method[8] can be used.

RESULTS AND DISCUSSION

Previous investigations by Korkisch and Hazan[9] have shown that the anionic citrate complexes of uranium and thorium are adsorbable on strongly basic resins from both aqueous and organic solvent systems. This fact has been utilized for the simultaneous enrichment of these two elements directly from samples of natural waters, as described above.

Studies on the effect of concentration of citric acid on the recovery of uranium and thorium gave the results presented in Table 1.

At citric acid concentrations below 1% the two elements are not completely retained by the anion-exchanger. On the other hand recovery of uranium and

Cu(II) 1	0·18	1·7
Zn(II) 1	0·15	1·6
Cd(II) 1	0·18	1·6
— —	0·20	1·6

* These results were obtained after deduction of known amounts of uranium (1·0 μg) and thorium (5·0 μg) added to the water samples before passing them through the 4-g anion-exchange columns.

thorium is quantitative at 1–3% citric acid concentration, and at the 1% citric acid level is not affected by the simultaneous presence of 3 g of sodium citrate and 2 g of ascorbic acid per litre. Under these conditions the pH of the sorption solution is very nearly 3, which according to Table 2 guarantees complete adsorption of uranium and thorium. These two elements are also quantitatively retained at pH 4 but not at lower acidities (see Table 2).

The ascorbic acid in the sorption solution reduces iron(III) to iron(II), which according to Table 3 is much less strongly retained than iron(III) by the anion-exchanger. Thus, if the concentration of iron(II) is about 1000 μg/l., less than about 5% of it is adsorbed on the resin under the conditions used, and about 50% of this is removed by passing the wash-solution through the resin bed. Another 25% of the adsorbed iron(II) is eluted together with thorium by the 8*M* hydrochloric acid while the residual 25% of iron is removed by elution with the IBMK–acetone–1*M* HCl solution (in this medium the K_d-values of iron and uranium are 1 and 1050 respectively).[8] Thus, it is possible to separate uranium completely from iron, which interferes with the fluorimetric assay of uranium by quenching its fluorescence.

In the elution of thorium with 8*M* hydrochloric acid ($K_d < 1$), which separates it from uranium, not only citric acid is co-eluted (displaced from the resin by the hydrochloric acid) but also several of the metal ions such as aluminium, titanium, zirconium, chromium, nickel and vanadium which are co-adsorbed with uranium and thorium during the sorption process. Not contained in this thorium eluate are uranium [both uranium(VI), $K_d \simeq 10^3$ and also uranium(IV) $K_d \simeq 50$ are retained by the resin at this acidity],[5] cobalt, copper, molybdenum and zinc (as well as traces of cadmium and manganese). Many of these elements are relatively strongly retained by the resin from the sorption solution (see distribution coefficients listed in Table 3). The effect of these elements as well as that of vanadium was therefore studied with respect to the separation and determination of uranium and thorium. From Table 4 it is seen that they did not affect the recoveries of uranium and thorium.* Vanadium, aluminium, titanium *etc.* (see above) are co-eluted with thorium and thus separated

Table 3. Distribution coefficients of metal ions in the sorption solution (in each case 1 mg of the metal ion was dissolved in 20 ml of the solution and equilibrated with 1 g of Dowex 1 X8, citrate form).

Metal ion	Distribution coefficient	Metal ion	Distribution coefficient
UO_2(II)	$4·0 \times 10^4$	Fe(II)*	100
Th(IV)	$1·6 \times 10^4$	Ni(II)	80
Ti(IV)	5×10^4	Co(II)	70
Zr(IV)	4×10^4	Cr(III)	40
Al(III)	$3·3 \times 10^3$	Zn(II)	25
V(V)	$\gg 10^4$	Pb(II)	10
Mo(VI)	$\gg 10^4$	Cd(II)	2
W(VI)	$3·3 \times 10^3$	Mn(II)	1
Cu(II)	195	Tl(I)	1

* For iron(III) a distribution coefficient of $1·2 \times 10^3$ was measured in the absence of ascorbic acid.

---

* Since the main cationic constituents of natural waters, *i.e.*, calcium, magnesium and the alkali metals, are not retained under the conditions of uranium and thorium adsorption their effect on the recovery of these two elements was not investigated.

Table 5. Effect of citric acid concentration on the spectrophotometric determination of thorium by the arsenazo III method

Citric acid concentration in measured solution, *mg/ml*	Absorbance* of 10-*ml* measured solution containing 0 *μg* of thorium	2	4	10
0	0·0	0·110	0·225	0·560

40	0·04	0·04	0·100	0·330

* At 660 nm, 1-cm cells.

from uranium by the 8*M* hydrochloric acid. Cobalt, copper *etc.* are separated from uranium by elution with 6*M* hydrochloric acid; at this acid concentration the K_d-value of uranium is 283.[7] On subsequent elution of uranium with 1*M* hydrochloric acid an eluate is obtained which contains only uranium and molybdenum because co-adsorbed zinc and cadmium are not eluted under these conditions.

For the separation of thorium from citric acid, which strongly interferes with the spectrophotometric thorium determination (see Table 5), a second anion-exchange procedure is employed, utilizing adsorption of the anionic nitrate complex of thorium[2] on Dowex 1 from 8*M* nitric acid. This separation is less time-consuming than wet-ashing procedures for removal of citric acid. An additional advantage is that all elements co-eluted with thorium by 8*M* hydrochloric acid (including titanium and zirconium, which strongly interfere with the arsenazo III method) are separated quantitatively from the thorium, so the thorium can be determined spectrophotometrically free from interferences.

On acidification of a natural non-saline water with citric acid the bicarbonates and carbonates of calcium, magnesium, *etc.* are transformed into citrates so that only sulphate will be present as a major foreign anion during the adsorption of uranium and thorium on the anion-exchanger (citrate form). That this anion has a decided influence on the recovery of thorium from water samples is evident from the results presented in Table 6 from which it is seen that quantitative isolation of thorium is possible from up to 2 litres of sample but not from 5 litres, although the distribution coefficient of $1{\cdot}6 \times 10^4$ indicates that thorium is adsorbable to practically the same extent as uranium ($K_d = 4 \times 10^4$, Table 3). The reason for this anomalous behaviour is that in contrast to thorium, uranium forms a very stable anionic sulphate complex at low acidities[5] so that the continuous displacement of citrate by sulphate during the sorption process does not affect the uranium adsorption. Consequently uranium is adsorbed quantitatively (as anionic citrate and sulphate complexes) from 5 litres of tap water while less than 10% of the thorium is retained by the resin, which after passage of 5 litres of sorption solution has been transformed into a resin which is no longer exclusively (or even principally) in the citrate form, but rather in the sulphate form owing to the adsorption of sulphate in course of the sorption process, this causing continuous displacement of thorium from the resin bed. This effect of sulphate becomes most pronounced when analysing mineral-waters. Thus, from the results shown in Table 7 it is seen that considerable losses of thorium but not of uranium are observed in the presence of large amounts of sulphate. For instance, the most significant loss of thorium was observed with Thalheimer, which contains 590 mg of sulphate per litre, whereas there was no loss of thorium from Preblauer, which contains only 30 mg of sulphate per litre. This strong influence of sulphate and also of chloride (which has a similar but smaller effect) on thorium adsorption makes it impossible to apply the present method to the analysis of natural waters of high salinity, including sea-water and oil-field waters. However, for the analysis of non-saline waters of normal hardness the method can be used most successfully, as can be seen from the results of water analyses presented in Tables 6 and 8.

In a series of analyses of Austrian water samples from the Salzburg area, the results for uranium and thorium were in excellent agreement for spiked and unspiked samples, showing quantitative recovery for both elements. The range of concentrations was 0·1–3 *μg/l.* for uranium and 0·8–4 *μg/l.* for thorium.

Table 6. Effect of the volume of water sample on determinations of uranium and thorium in Vienna tap-water

Volume of water,* *l.*	Contents found, *μg/l.* Uranium A	B	Thorium A	B
0·5	0·20	0·17	2·0	1·9
1·0	0·19	0·18	1·9	2·0
2·0	0·18	0·17	1·9	1·8
5·0	0·19	0·20	<0·2	<0·2

A = Results without a spike.

B = After deduction of 1 *μg* of uranium and 10 *μg* of thorium added to the water samples before passing them through the 4-g anion-exchange columns.

* On 8 February 1975 the water sample was taken in the Institute for Analytical Chemistry, 20 min after opening the tap.

Table 7. Results of determinations of uranium and thorium in samples of bottled mineral waters

	Contents found, *μg/l.*				
	Uranium		Thorium		
Trade name and geographical origin of sample	A	B	A	C	D
Gleichenberger Johannisbrunnen, Bad Gleichenberg, Styria	<0·01	<0·01	0·80	1·36 (1·0)	−24%

Thalheimer, Thalheim/Judenburg, Styria	4·31	4·40	0·85	0·70 (1·0)	−62%

A = Results without a spike (uranium determined fluorimetrically and thorium spectrophotometrically).

B = After deduction of comparable known amounts of uranium added to the samples before passing them through the 4-g anion-exchange columns.

C = After addition of the spike shown in parentheses.

D = Thorium lost during passage of the sorption solution (1 litre of mineral water) through the 4-g anion-exchange column.

An interesting correlation was found between the weight ratio of uranium to thorium and the uranium concentration (Fig. 1). It appears that high uranium contents are always accompanied by large U:Th ratios (*i.e.*, relatively low thorium contents) while the opposite is true for samples with small uranium concentrations. Since the results of 19 out of 20 samples analysed followed this pattern rather closely, this curve may be used to determine the approximate thorium contents of samples of which the uranium concentrations are known, and *vice versa*. Thus, taking the uranium content of Vienna tap-water (0·18 μg/l.) as an example, this corresponds to a U:Th ratio of about 1:10 which is equivalent to a thorium content of 0·18 × 10 = 1·80 μg. This value comes very close to the actual thorium contents measured in tap-water (Tables 1, 2, 4, 6).

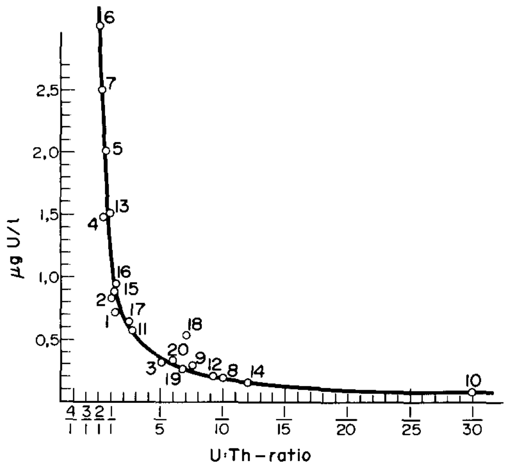

Fig. 1. Plot of uranium concentration *vs.* U:Th w/w ratio for 20 natural waters. (Salzburg area).

Table 8. Comparison of results of uranium determinations obtained by two different methods

	Uranium contents, *μg/l.*		
	This method		Thiocyanate method[3]
Water sample no. (see Fig. 1)	A	B	C
6	3·05	2·93	2·70
7	2·52	2·46	2·54
10	—	0·10	0·10*
13	1·60	1·46	1·40
18	0·50	0·50	0·50

A = Arsenazo III method.

B = Fluorimetric method.

C = Arsenazo III determination.

* Fluorimetric determination.

It remains to be seen, whether this is a universal principle that can be applied to all non-saline waters.* It does not apply to sea-water, for which it predicts a thorium content of 1·7 μg/l., whereas the actual content is less than 5 × 10^{-4} μg/l.[10]

The relatively large deviation from the curve shown by the results for sample 18 is most probably due to the presence of large quantities of finely dispersed brown particulate matter in this sample, which dissolved to some extent on acidification. This sample also had exceptionally high beryllium contents.

Since the ion-exchange separations described in the present paper can be performed more or less automatically, numerous samples can be analysed simultaneously and thus the method is suitable for the routine determination of uranium and thorium in natural water.

(*Eingegangen am* 9. *Mai* 1975. *Angenommen am* 30. *September* 1975)

Zusammenfassung—Bei der Pyrolyse–Massenspektrometrie von Ionenaustauschern auf Kunstharzbasis erhält man in 5 s Fingerprint-Spektren, deren Aussagen mit denen der Pyrolyse–Gaschromatogramme vergleichbar sind. Diese schnelle Aufnahmezeit wird durch den Verzicht auf die gaschromatographische Auftrennung der Pyrolyseprodukte, die *ca.* 60 min beträgt, ermöglicht. Aufgrund der geringen Elektronenenergie von 16 eV werden im Massenspektrum weitgehend nur die Molekülbanden der einzelnen Verbindungen des Pyrolysats wiedergegeben. Diese mit Hilfe der Pyrolyse–Gaschromatographie zugeordneten Verbindungen lassen Rückschlüsse auf den Aufbau des Austauschers zu: Bau der Matrix, Vernetzer, funktionelle Gruppe und deren Verknüpfungsstelle mit der Matrix sowie Beladungszustand.

Zur Identifizierung und Strukturaufklärung von Aüstauschern auf Kunstharzbasis durch die Pyrolyse–Gaschromatographie werden diese bei 800° thermisch fragmentiert, die entstehenden Pyrolyseprodukte gaschromatographisch getrennt und die Pyrolyse–Gaschromatogramme ausgewertet.[1–4]

In der vorliegenden Arbeit wird die Pyrolyse–Massenspektrometrie als neue Untersuchungsmethode für Austauscher auf Kunstharzbasis eingeführt. Hierbei werden die Pyrolyseprodukte nicht mehr gaschromatographisch getrennt, sondern gelangen direkt in die Ionenquelle eines Massenspektrometers. Die Identifizierung der Molekülbanden erfolgt nach qualitativer Analyse mittels Pyrolyse–Gaschromatographie. Durch die Kürze der Analysenzeit und die Aussagekraft der Pyrolyse–Massenspektren stellt somit die Pyrolyse–Massenspektrometrie eine wertvolle Ergänzung der oben zitierten Untersuchungen zur Charakterisierung der Ionenaustauscher auf Kunstharzbasis durch die Pyrolyse–Gaschromatographie dar.

Mit Hilfe der Pyrolyse-Massenspektrometrie werden Biopolymere und Bakterien[5,6] unter Verwendung von Quadrupol-Massenspektrometern und Kunststoffe mit Sektorfeld-Geräten[7] untersucht. Eine bessere Identifizierung der Pyrolysate gelingt mit dem Feldionisations-Massenspektrometer.[8] Zur Untersuchung gelangen die in den Veröffentlichungen[1–4] beschriebenen Ionenaustauscher auf Kunstharzbasis und Dowex A 1 Chelating Resin.

EXPERIMENTELLER TEIL

Geräte und Chemikalien

Massenspektrometer, Pyrolysegerät;[1] Schreiber Oscilloport, Siemens/Erlangen; Pyren *p.a.*, Merck/Darmstadt; Dowex A 1 Chelating Resin, Serva/Heidelberg; weiteres Ionenaustauschermaterial und Probenvorbereitung.[1–4]

Arbeitsbedingungen

Um eine zweite Fragmentierung in der Ionenquelle zu vermeiden, muß deren Elektronenenergie von 80 auf 16 eV gesenkt werden. Somit erhält man weitgehend nur die Molekülbanden der eingeschleusten Verbindung. Die gewählte Elektronenenergie wird von dem höchsten Energiepotential der Pyrolyseprodukte bestimmt. Dieses beträgt für CO_2 13,9 eV. Aus apparativen Gründen ist es günstiger, mit 16 eV und daher mit 150 μA Elektronenstrom zu arbeiten, wodurch eine größere Empfindlichkeit erzielt wird.

Die genaue Einstellung des Massenspektrometers, die mehrmals täglich überprüft wird, erfolgt bei einer Elektronenenergie von 80 eV mit Pyren, das mit Hilfe des Festkörpereinlasses in die Ionenquelle eingebracht wird. Die Elektronenenergie wird dann schrittweise unter ständigem Nachfokussieren auf 16 eV gesenkt.

Um gute Reproduzierbarkeit der Ergebnisse zu erhalten, wird ein elektronischer Schalter verwendet, der die manuelle Auslösung der Spektrenaufnahme automatisiert. Das Pyrolysat gelangt durch ein Kupferrohr im Ofen des Gaschromatographen und die Einlaßleitung direkt in die Ionenquelle des Massenspektrometers. In dieser registriert der EID (Electron Impact Detector) die Ankunft der Pyrolyseprodukte und leitet das Signal zum GC-Schreiber weiter. Hat die Schreibfeder eine bestimmte Höhe erreicht, wird durch den Schalter die Aufnahme des Massenspektrums ausgelöst. Der Einschaltpunkt läßt sich am GC-Schreiber kontinuierlich einstellen. Abbildung 1 zeigt schematisch die Wirkungsweise des Schalters. Die automatische Einschaltung des Massenspektrometers erlaubt es, bei der Aufnahme der Massenspektren die Spitze des Totalionenstromes zu erfassen.

Das parallel zum Massendurchlauf aufgenommene EID-Gaschromatogramm, das auch als Registrierung des Totalionenstromes angesehen werden kann, gibt den Zeitverlauf der Pyrolyse und die Einschleusung der Pyrolyseprodukte in die Ionenquelle wieder. Abbildung 2 zeigt die Registrierung des Totalionenstromes.

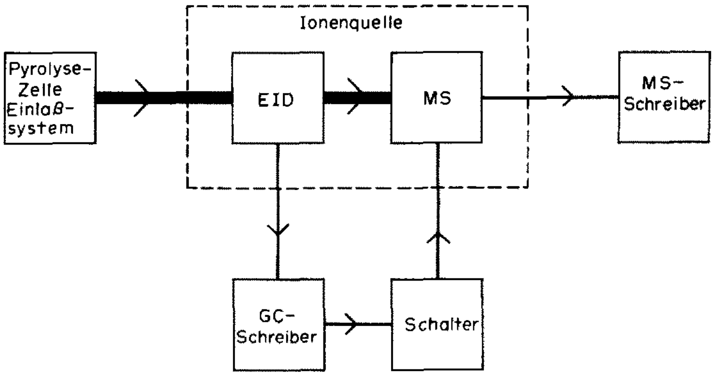

Abb. 1. Wirkungsweise des automatischen Schalters.

Da die Pyrolyse 2 s dauert, nach 1 s der maximale Totalionenstrom erreicht ist und der Massendurchlauf in 2 s erfolgt, erhält man nach 5 s das Fingerprint-Pyrolyse-Massenspektrum. Alle Arbeitsbedingungen zur Aufnahme der Pyrolyse-Massenspektren sind in Tab. 1 zusammengefaßt.

PYROLYSE-MASSENSPEKTREN

Abbildung 3 gibt das Pyrolyse-Massenspektrum von Dowex 50 W X10, H^+-Form in Abhängigkeit von der Elektronenenergie wieder.

Das obere Spektrum ist wesentlich bandenreicher und somit schwieriger zu deuten, wohingegen bei dem unteren fast nur die reinen Molekülpeaks auftreten.

Zur Messung der Reproduzierbarkeit werden an verschiedenen Tagen zehnmal die Pyrolyse-Massenspektren von Dowex 1 X4, Cl^--Form aufgenommen. Das Massenspektrometer wird vor jeder Aufnahme vollständig neu eingestellt. Tabelle 2 enthält die Intensitäten der zwölf stärksten Banden des Dowex 1 X4. Es sind die Mittelwerte und Standardabweichungen von zehn Messungen aufgeführt.[4] Die stärkste Bande ist auf 100% Intensität gesetzt, die anderen prozentual umgerechnet.

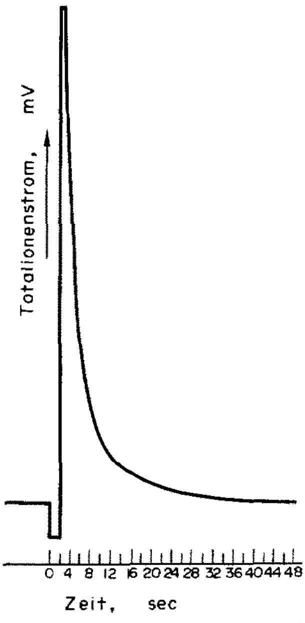

Abb. 2. Totalionenstrom bei der Pyrolyse-Massenspektrometrie.

Die Abb. 4–7 zeigen die Pyrolyse-Massenspektren von Dowex 1 X4, Dowex 2 X8, Amberlite IR-4B jeweils in der Cl^--Form und Amberlite IRC-50, H^+-Form.

Tabelle 3 gibt die charakteristischen Banden und deren Herkunft wieder. Außerdem ist die relative Intensität (% *B*) der Banden zu entnehmen.

In Tab. 4 und 5 sind die Ergebnisse, die bei verschiedenen Beladungszuständen von zwei Anionenaustauschern erhalten werden, zusammengestellt. Die Pyrolysetemperatur beträgt hier 400°.

DISKUSSION

Die an verschiedenen Tagen mit jeweils neuer Einstellung des Massenspektrometers aufgenommenen Spektren zeigen gute Reproduzierbarkeit. Die Zahl der Banden bleibt konstant. Geringe Intensitätsänderungen lassen sich dadurch erklären, daß die Menge des auf die Pyrolyse-Wendel aufgetragenen Austauschermaterials in geringen Grenzen schwankt. Außer-

dem kommt es bei einer dickeren Austauscherschicht infolge der schlechten Wärmeleitfähigkeit des Austauschers in der oberen Schicht zu einer etwas anderen Fragmentierung. Die Intensitätsschwankungen lassen sich durch gleichmäßiges Auftragen des Austauschers auf die Pyrolyse-Wendel in engen Grenzen halten. Die Einführung eines Schalters zur automatischen Auslösung des Massenspektrums erhöht die Reproduzierbarkeit sehr. Zudem erleichtert er die Aufnahme der Spektren.

Mit Hilfe der Pyrolyse-Massenspektren kann man auch Anionenaustauscher identifizieren, die sich nur durch den Ersatz einer CH_3-Gruppe durch eine C_2H_4OH-Gruppe in der Ankergruppe unterscheiden.

Bei den Anionenaustauschern auf Styrol-DVB-Basis und Dowex A 1 Chelating Resin ist die Basisbande *m/e* = 118 (*m*- und *p*-Methylstyrol), da die Ankergruppen über Methylenbrücken an die Benzolkerne gebunden sind. Dagegen wird bei dem kernsubstituierten Kationenaustauscher Dowex 50 W *m/e* = 104 (Styrol) zur Basisbande. Bei Amberlite IR-4B ist das Auftreten der Banden *m/e* = 94 und 108 (Phenol bzw. *o*/*p*-Kresol) charakteristisch. Aliphatische Kohlenwasserstoffe und DVB treten vorwiegend bei Amberlite IRC-50 und IRA-68 auf, da hier eine Acryl-DVB-Matrix vorliegt. Bei Dowex 44 lassen sich Grundkörper und Vernetzer nicht unterscheiden.

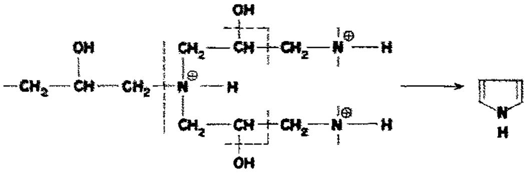
Durch Zerschlagung des Austauschergerüstes und Bindungsneubildungen entstehen verschiedene stickstoffhaltige Verbindungen, wie z.B. Pyrrole. Die Entstehungsmöglichkeit dieser Verbindungen ergibt sich aus dem folgenden Schema:



Man findet sehr viel Methylchlorid, bedingt durch die Cl^--Form des Austauschers.

Zur Ermittlung der Beladungszustände führt man die Pyrolyse bei 400° durch, da bei dieser Temperatur vorwiegend die Ankergruppen zersetzt werden. Als charakteristische Pyrolyseprodukte sind die entsprechenden Methylester bzw. deren Zersetzungsprodukte nachzuweisen.

DIRECT DETERMINATION OF CADMIUM IN BLOOD WITH A TEMPERATURE-CONTROLLED HEATED GRAPHITE-TUBE ATOMIZER

GILLIS LUNDGREN*
Department of Analytical Chemistry, University of Umeå, 901 87 Umeå, Sweden

(*Received* 20 *February* 1975. *Revised* 23 *September* 1975. *Accepted* 4 *October* 1975)

Summary—By temperature-controlled heating during the atomization step a selective vaporization between Cd and the matrix is achieved. A final temperature of 830° gives an optimized signal for Cd without too high a background absorption. The sensitivity is 0·1 μg/l. (0·01 μg of Cd/100 ml of blood) with a detection limit of 0·6 μg/l. (0·06 μg/100 ml of blood).

Atomic-absorption spectroscopy has become the most commonly used technique for the determination of cadmium in biological materials. Other techniques for cadmium determination are neutron-activation analysis and emission spectrography. The biological effects of cadmium have been reviewed by Friberg *et al.*[1] For determination in whole blood an extraction procedure is necessary to increase the sensitivity of the method. For a direct determination of cadmium in blood, flameless atomizers must be used. A problem will immediately arise when carrying out a direct determination on a biological fluid. The bulk of the sample will, in most cases, vaporize in the same temperature region as the metal. Several commercial instruments have background correctors for automatic subtraction of the non-specific absorption. In general, these correctors cannot subtract more than 0·4–0·8 absorbance units. To fulfil this requirement the two beams in the spectrophotometer, *i.e.*, from the hollow-cathode lamp and the deuterium or hydrogen lamp, have to be aligned exactly in the graphite tube. If not, a false correction may be achieved. This might become a serious source of error because the non-specific absorption is in most cases not reproducible. To improve the accuracy of the cadmium absorbance signal the cadmium peak and the non-specific peak should be separated in time when registered on a chart-recorder, and the non-specific absorbance should not exceed the stipulated maximum correction of the instrument. This will imply that a slow heating rate must be used to obtain a time-resolution. As the sensitivity for a metal is directly correlated to the heating rate of the atomizer, the improvements in time-resolution between metal and matrix absorbance caused by lowering the heating rate will be offset by the decreased sensitivity.

Attempts to attain selective vaporization of cadmium from the bulk of a biological matrix have been made by Ross and Gonzalez.[2] They used a Perkin–Elmer HGA-2000 with a background corrector. For resolution of the cadmium and the non-specific absorption when analysing urine samples, the final temperature had to be 1300°. In this way they were able to determine cadmium in 20-μl samples of urine and 20% solutions of serum with reproducibilities of the order of 5%. The sensitivity was 0·25 ppM† (1% absorption) in a 20-μl sample or 5 pg absolute.

Cruz and van Loon[3] have made a critical study of the possibilities of using graphite furnaces for trace element determinations in complex heavy-matrix solutions. They used a Perkin-Elmer HGA-70 as well as the newer model HGA-2000. They tested only for lead in blood but found that cadmium, among other elements, was almost impossible to vaporize without causing co-volatilization of the matrix when inorganic materials containing large amounts of sodium and potassium salts were analysed. Some separation was achieved when the final temperature was lowered, but at the expense of a lowered analytical response for cadmium. Similarly Segar and Gonzalez[4] were unsuccessful in determining cadmium in sea-water.

Just recently a procedure for the determination of cadmium in biological materials by using the I.L. tantalum-strip atomizer has been presented by Ulluci and Hwang.[5] For blood, instead of a direct determination they used a micro-extraction procedure with the APDC–MIBK system. The advantage lies in the fact that very small samples, *e.g.*, from finger punctures, can be used. If sample size is not a limiting factor, little advantage is achieved compared to a flame determination on the organic phase.

In this paper a simple technique using a temperature-controlled graphite-tube atomizer is described. The temperature control permits a selective vaporization of metal and matrix at a high heating rate, thus yielding very good sensitivity.

† Parts per milliard

EXPERIMENTAL

Apparatus

A graphite furnace with a 10-cm graphite tube (Ringsdorff RWO spectrographic graphite) was used. The furnace is gas-tight and has a large dead volume. The gas is not flushed through the tube, but fills the whole volume. The construction has been presented in detail elsewhere.[6] The spectrophotometer is mounted on an optical rail with quartz lenses and with a Heath Scanning Monochromator 700 E with a spectral dispersion of 20 Å/mm at the exit slit. A Hamamatsu photomultiplier was used. The spectrometer is supplied with a hydrogen background-corrector. The amplifier is a sample-and-hold amplifier with absorbance outputs for metal lamp, hydrogen lamp or the corrected absorbance outputs for metal lamp, hydrogen lamp or the corrected absorbance. The three different signals can be monitored simultaneously if required. The metal lamp and the hydrogen lamp are electrically modulated at 100 Hz. Subtraction of the background is made in a circuit with time constants of 20, 50, 100, 200, or 500 msec.

The graphite furnace is supplied with a temperature-controlled heating (TCH) unit which has been described in detail.[7] The temperature of the centre of the graphite tube is measured with a photo-diode. The output from the diode is compared with a preset value on the TCH-unit. Heating of the tube proceeds with maximum power supplied to the furnace up to the desired temperature. Thereafter the power is decreased, keeping the temperature constant at the required temperature. This construction enables the atomizer to be heated at a maximum rate, independent of the final temperature setting. The instrumental parameters are given in Table 1.

Sample preparation

The blood samples were diluted with water: 0·1 ml of whole blood (heparinized) was diluted with 0·9 ml of distilled water with a pneumatic diluter (AutoChem Instrument AB, Sweden). To the samples were added 20 μl of heparin and 20 μl of 2% Triton X-100. The sample was mixed thoroughly in a mechanical shaker (Shiltern). Standards were made from a 1000-ppm solution of $CdCl_2$ and a calibration curve was obtained by standard addition to the blood sample.

RESULTS AND DISCUSSION

Matrix effects

If a temperature-controlled atomizer is used, the problems with time-resolution of the metal and non-specific absorption are almost negligible, as will be seen in Fig. 1. When a blood sample containing cadmium is atomized, with different final temperatures, the signal increases with temperature up to that at which the vapour pressure of the element is sufficiently high to give a rapid atomization. For cadmium an optimized signal is achieved at 830°. A further temperature rise will not increase the absorbance peak. If, on the other hand, the non-specific absorption is registered by means of a hydrogen lamp, the background absorption will increase with the final temperature. At 950° the amount of non-specific absorption is large enough to create problems in automatic background correction. The useful temperature region is very small as the temperature must reach 750° but not exceed 950°. If an automatic background corrector is used, the final temperature can be chosen between 830° and 900°, where an optimized analytical response is obtained. If an instrument without background corrector is used, an even lower final temperature must be set, to make the non-specific absorption as small as possible. From this figure it can be seen why difficulties have arisen when using a commercial furnace for this determination. In that case, a final temperature of at least 1300° must be chosen to obtain a sufficiently good response, as a higher final temperature implies a better sensitivity. The atomic vapour is formed between 700° and 900° but the non-specific absorption starts to form at 850°. The possibilities of time-separating these two absorption sources is a function of the rate at which this temperature region is traversed. The advantage of TCH over commercial atomizers is obvious, as the final temperature can be set independently of the heating rate. A fast heating rate can be chosen to obtain an optimized sensitivity even if the final temperature is set as low as 830°. One does not have to compromise between sensitivity and time-separation of metal and background absorption.

Table 1. Instrumental parameters

Graphite atomizer	
Inert gas	Nitrogen
Dry sequence	100°, 60 sec
Ash sequence	600°,60 sec
Atomize sequence	830°

Operating mode	Background correction
Metal lamp (Varian) current	3 mA
Hydrogen lamp (Varian) current	20 mA
Photomultiplier voltage	800 V
Slit-width	200 μm (S.B.W. = 0·4 nm)
Wavelength	228·8 nm

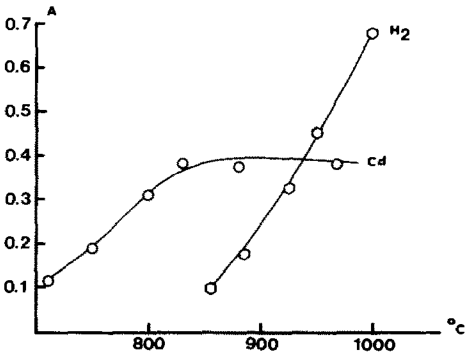

Fig. 1. Determination of optimized absorbance for Cd in blood and of non-specific absorption as a function of final temperature in the atomization step (3 μl of diluted blood with 6·5 ppM of added Cd).

The non-specific absorption would be expected to be irreproducible. This would make it very difficult to obtain reproducible results if an instrument without automatic background correction were used. In Fig. 2 is shown an example of the variations in non-specific absorption for different sample volumes.

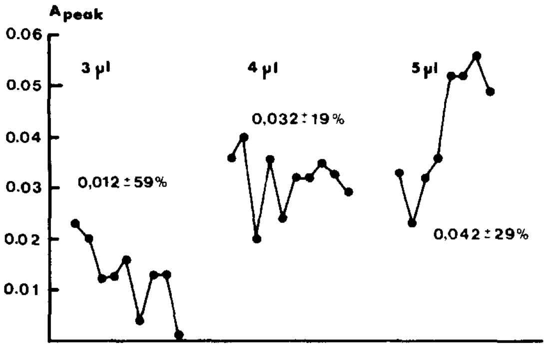

Fig. 2. Variation of non-specific absorption for different sample volumes (average and range are shown).

Table 2. Comparison between direct determination of Cd and an extraction procedure

Sample no.	No. of detns.	Mean value ± 1 std. devn., *μg/100 ml*	Lab A (APDC–MIBK), *μg/100 ml*
1688	5	3·4 ± 0·60	3·9
500	8	1·1 ± 0·35	1·0
503	7	1·5 ± 0·04	1·4
557	2	1·5 ± 0·15	1·3
640	11	2·4 ± 0·30	2·6
605	1	2·5	2·9
536	3	1·6 ± 0·18	1·2
558	3	3·0 ± 0·26	3·0
518	7	1·3 ± 0·20	0·9
604	4	2·3 ± 0·17	2·5

Diluted blood samples were atomized with a final temperature of 830° (TCH). The amount of non-specific absorption, measured with the aid of a hydrogen lamp, was registered on a chart-recorder. The samples were ashed at 600° before atomization. It is seen that the amount of background increases with sample volume.

The major analytical problem is that this variation is very high. If an instrument without background corrector is used, the normal method is first to run a sample with the metal lamp and then to change to a hydrogen lamp and run a sample to get the amount of non-specific absorption. Even if a large number of background determinations are performed, a rather uncertain correction is achieved and the procedure is very time-consuming. For a 4-μl sample the amount of non-specific absorption corresponds to a Cd-value of 0·3 μg/100 ml of blood.

Gas parameters

The graphite furnace that was used has quite large dimensions, so the tube is surrounded by a dead volume several times larger than the volume occupied by the graphite tube itself. When gas is flushed through the system it is not directed through the tube as in the new Perkin–Elmer HGA-74. This large dead volume will absorb the expansion of the gas inside the tube when it is heated. The effect of different gas parameters was tested on an aqueous cadmium solution: 8 pg of cadmium were atomized under argon or nitrogen atmospheres. No significant difference was observed whether the gas flowed during the atomization cycle or not. This is because the gas is not directed through the tube. Furthermore, no effect on the analytical response was observed if argon was replaced by nitrogen.

In the ashing cycle the choice of gas is very important for effectiveness of ashing. In Fig. 1 it was seen that with a nitrogen atmosphere the ashing was effective enough to keep the amount of background absorption sufficiently low to be properly corrected for. If argon was used, the matrix produced a much higher background adsorption. Mixing the argon with oxygen or hydrogen during the drying and ashing cycle did not improve the ashing effectiveness. Nitrogen seemed to be the most effective gas for a complete ashing of the blood matrix. The reasons for the differences between argon and nitrogen have not been examined yet.

Calibration and results

No interferences were observed when blood was compared with a pure water solution. Tests on known additions of a water standard to a blood sample gave 100% recovery within experimental error, hence normally the calibration is best carried out by making standard additions to one blood sample and using the slope of the curve as the calibration factor for the rest of the blood samples.

A series of blood samples was analysed by the procedure described and compared with results from another laboratory, Table 2. Laboratory A used the conventional extraction procedure as for lead[8] but with a final determination of cadmium in the MIBK-phase by using a Perkin-Elmer HGA-72. The agreement between direct determination and the extraction procedure is quite good. The reproducibility is about 10%. In the determinations, differently diluted samples were analyzed.

Different sample volumes were used in the range 1–5 μl. No difference was observed in the cadmium values when the volume was changed. It is, however, better to use a large sample volume to obtain a bigger signal height; 3 or 4 μl were used in the experiments. Larger volumes gave residues in the graphite tube after the atomization.

Direct determination of Cd in undiluted blood was also tried. The blood sample was haemolysed by addition of 0·1 ml of Triton X-100 to 5 ml of whole blood. The blood sample was then shaken vigorously, and 1 μl was inserted into the graphite tube. In Table 3 are shown results for determinations in triplicate. The columns at the right show the peak absorbance values. The reproducibilities are about the same as for diluted blood samples. A disadvantage is, however, that residues are formed in the graphite tube after a few determinations.

Table 3. Determination of Cd in undiluted blood (1 μl).

Sample	$\mu g/100\ ml$			Peak absorbance
A	0·66	0·72	0·71	0·28
B	1·41	1·62	1·50	0·55
C	1·47	2·04	1·68	0·60
D	1·98	1·78	2·15	0·66

Sensitivity

The sensitivity for diluted blood is 0·01 μg/100 ml (1% absorption) or $2{\cdot}5 \times 10^{-13}$ g for a 4-μl sample. The detection limit, defined as a signal that is twice the standard deviation in blank runs (10 determinations on blood with very low cadmium content), is 0·06 μg/100 ml.

The cadmium values in blood, for normally exposed persons, are a few tenths of a microgram per 100 ml (a few ppM). The sensitivity for a direct determination is sufficient to detect normal values. Reproducibility can vary a lot depending on the homogeneity of the blood sample. In order to get a representative sample the blood must be totally haemolysed. If so, the direct determination procedure gives a rapid determination of cadmium in blood, with a typical error of 10%.

DETERMINATION OF SHORT-LIVED RADIONUCLIDES IN FRESH FALL-OUT DEBRIS FOR IDENTIFICATION OF NUCLEAR WEAPON TESTS

S. B. HINGORANI, R. N. KHANDEKAR and S. J. S. ANAND
Air Monitoring Section, Bhabha Atomic Research Centre, Trombay, Bombay–400085, India

(*Received* 7 *April* 1975. *Accepted* 9 *September* 1975)

Summary—Radiochemical procedures for the assay of short-lived fission and activation products are described. They are rapid and quantitative and the radionuclides separated are radiochemically pure. Ratios of some of the short-lived radionuclides obtained by these measurements for selected Chinese and French nuclear tests are given and provide information about the fissile material used in the tests.

The programmes of nuclear weapon testing by China and France contribute considerable quantities of short-lived radionuclides to the atmosphere. The measurement of this short-lived activity by γ-ray spectrometry alone is not sufficient for the identification of a weapon test, so a chemical separation of the fission and induced products is necessary. The chemical methods selected must take into account the complicated composition of the sample, be rapid and quantitative and have high chemical yield. The methods presented in this paper meet these criteria and also permit joint assay of various radionuclides from a single sample.

The sample material is a swab collected by rubbing the surface of commercial aircraft with cotton soaked in organic solvent. These samples are routinely collected on arrival of the aircraft at Bombay to estimate the background levels of the atmosphere before and after nuclear tests. The results are used to get information about detonation, *e.g.*, fissile material used, mode of detonation *etc.*, by comparison of the activity ratios of selected fission products such as ^{89}Sr, ^{111}Ag, ^{132}Te and ^{99}Mo. These fission products, being short-lived, do not suffer interference by products from earlier tests.

There are two important activation products which help in deciding whether the test was with a conventional H-bomb using a three-stage device with ^{238}U in the third stage. These are neptunium-239 and uranium-237 which are produced from ^{238}U by (n, γ) and (n, 2n) reactions respectively. ^{237}U, in a nuclear weapon, is also produced from ^{235}U by double neutron capture but its production by this reaction is very small compared with that from the (n, 2n) reaction in a conventional H-bomb test. Other activation products also help in determining parameters of the weapon test. However, the samples collected for our studies gave hardly any measurable quantities of these activation products and therefore only ^{237}U and ^{239}Np are discussed in this paper.

EXPERIMENTAL

Sample preparation

The sampling method collects considerable quantities of insoluble silica, iron, sulphate and phosphate compounds. Because of the difficulty with which these compounds dissolve, a leaching procedure for the dissolution of the sample is used.[1] The cotton swab is digested with a mixture of 3*M* hydrochloric acid and 0·1*M* hydrofluoric acid in the presence of known amounts of carriers. The heating time is reduced to a minimum to reduce the attack on the glassware. The solution is filtered through a Whatman No. 54 paper on a Büchner funnel. This process is repeated 3 or 4 times and finally the residue is leached with 6*M* nitric acid and filtered off. It is found that more than 95% of the total activity is leached out by this process. All parts of the filtrate are then pooled and a suitable aliquot is taken for the determination of each individual nuclide.

Chemical procedures

The chemical procedures developed in our laboratory are described below. Barium-140 is usually determined directly from the gamma-ray spectrum through its daughter ^{140}La. For this a known fraction of the leach solution (usually a tenth of the total volume) is evaporated in a beaker to minimum volume and transferred to a 5·0-cm diameter "Perspex" planchette which, after drying, is sealed and counted by a 256-channel pulse-height analyser, using a Ge(Li) detector. In general, the final isolation of the precipitate is carried out by filtration with a special filter funnel using a 1-in. Whatman No. 542 paper and the chemical yield is obtained by weighing the precipitate. The sample is then mounted on a planchette and counted conventionally. The filter funnel is made of "Perspex", and has a threaded base, a 2·5-cm diameter circular perforated disc and a vertical reservoir 2·4 cm i.d. and 12 cm in height.

Separation of strontium and barium.[2] A known volume of the leach solution with known quantities of carriers (150 mg of Sr + 100 mg of Ba) is placed in a beaker. The solution is warmed and anhydrous sodium carbonate added. The insoluble carbonates are filtered off (Whatman No. 540 paper) and redissolved in 6*M* nitric acid.

The volume of the solution is reduced to 40 ml by evaporation and 65 ml of fuming nitric acid (s.g. 1·52) are added slowly to the ice-cooled solution. The crystals of barium and strontium nitrates are allowed to settle. The supernatant liquid is decanted and the crystals are dissolved in distilled water. The volume of the solution is again brought to 40 ml and the nitrate precipitation repeated twice with 60 ml of fuming nitric acid. The nitrate crystals are then dissolved in water and strontium and barium precipitated by addition of ammonium carbonate. The solution is warmed for about 10 min to coagulate the carbonates and finally filtered.

The precipitate is dissolved in $6M$ hydrochloric acid and barium is precipitated as chromate by addition of 10 ml of $1{\cdot}5M$ sodium chromate and adjustment of the pH to 3·5–4. The chemical yield and activity are then measured.

The filtrate from the chromate separation is warmed and ammonium carbonate added to precipitate strontium. The precipitate is filtered off (Whatman No. 540 paper) and dissolved in $6M$ hydrochloric acid. The solution is warmed with absolute alcohol (2 or 3 drops) to reduce any chromate. Twenty mg of yttrium carrier are added and the yttrium is precipitated by slow addition of freshly prepared ammonia solution to remove yttrium-90 and other rare-earth activity. The solution is warmed, cooled and filtered and the time noted. Ammonium carbonate (2–3 g) is added to the filtrate, the solution is warmed and the strontium carbonate allowed to settle. The activity is then determined after filtration.

After the counting of ^{89}Sr and ^{90}Sr activity, the precipitate is ignited to constant weight in a platinum crucible to obtain the chemical yield. The residue is dissolved in $3M$ hydrochloric acid and stored with 20 mg of yttrium carrier for equilibration and subsequent milkings.

Separation of silver and molybdenum.[3] A known volume of the leach solution, with known amounts of carriers, is placed in a beaker and evaporated almost to dryness. To the residue are added 2 ml of conc. nitric acid and 2 ml of bromine water, and the resultant solution is slowly heated to oxidize tin and molybdenum. The solution is cooled and diluted and a few drops of $6M$ hydrochloric acid are added, with constant stirring, to precipitate insoluble chlorides. The precipitate is centrifuged, washed with distilled water and dissolved in ammonia solution. Ten mg of iron carrier are added to the solution and iron hydroxide scavenging is carried out to remove impurities such as Sr and Ce. To the filtrate are added 10 ml of saturated thioacetamide solution and silver sulphide is precipitated on gentle heating. The precipitate is centrifuged, dissolved in 5 ml of conc. nitric acid and boiled to remove sulphur completely. The solution is then cooled. The scavenging cycle with iron hydroxide and precipitation as silver sulphide is repeated. The filtrate is finally adjusted to pH 3·5 with $6M$ hydrochloric acid. The precipitate is digested by gentle heating and allowed to settle. It is then filtered off and the chemical yield and activity are measured.

The filtrate from the precipitation of silver chloride is adjusted to pH 8·5 with ammonia solution. To the solution are added 10 mg of iron carrier and hydroxide scavenging is carried out to remove Cr and Nb impurities. The filtrate is adjusted to pH 3·5 with $6M$ nitric acid and 10 ml of 4% α-benzoinoxime solution in ethanol are added. The precipitate is centrifuged and dissolved in a mixture of 10 ml of fuming nitric and 3 ml of perchloric acid and the solution evaporated slowly to dryness. Iron hydroxide scavenging is once again carried out to remove Zr, Nb, I_2 *etc.* The filtrate is finally adjusted to pH 3 with $6M$ nitric acid. Three ml of saturated lead nitrate solution are added to the solution, which is then gently heated to precipitate lead molybdate, which is collected, weighed and counted.

Separation of tellurium. A known fraction of the leach solution with 40 mg of tellurium carrier is evaporated to dryness. The residue is taken up in a small quantity of hydrochloric acid and evaporated again to dryness. This is repeated 2 or 3 times to bring the residue into the chloride form. The residue is then taken up in $3M$ hydrochloric acid and freshly prepared sulphur dioxide is passed through it. Elemental tellurium is precipitated. It is then dissolved in *aqua regia*, reprecipitated and redissolved in *aqua regia*. Ten mg of iron carrier are added to the solution and pure tellurium is precipitated, dried, weighed and counted.

Separation of neptunium and uranium.[4] A measured fraction of the leach solution with known amounts of ^{233}U, ^{237}Np and ^{236}Pu tracers is taken in a beaker along with 1 mg of iron carrier, 1 g of hydroxylamine hydrochloride and 10 ml, for every 100 ml of leach solution, of a 4:1 v/v mixture of saturated boric acid solution and conc. nitric acid. The solution is warmed and ammonia solution added slowly to precipitate hydroxides. The precipitate is filtered off, washed and dissolved in $6M$ nitric acid and the solution evaporated almost to dryness. The residue is taken up in 15 ml of $1M$ nitric acid and neptunium is converted into oxidation state IV by addition of 1 ml of 15% hydroxylamine hydrochloride solution and 0·3 ml of $3M$ ferrous sulphamate. Neptunium is twice extracted with $0{\cdot}5M$ thenoyotrifluoroacetone in xylene by shaking for about 10 min in a 100-ml separating funnel. The organic phase is washed with an equal volume of $1M$ nitric acid and the washings are added to the aqueous phase. Neptunium is stripped from the organic phase with an equal volume of $8M$ nitric acid, which is then evaporated to dryness with $1M$ hydrochloric acid and the residue taken up with two 3-ml portions of electrolyte solution ($1M$ ammonium chloride, $0{\cdot}01M$ oxalic acid) and placed in an electrolysis cell. Neptunium is deposited on a 2·5-cm diameter stainless-steel disc for 20 min at a current density of 1–1·2 A.

The aqueous phase left after the neptunium extraction is three times evaporated to dryness with a little nitric acid and the residue is finally taken up in 10 ml of $1M$ nitric acid. Ten g of aluminium nitrate, 3 or 4 drops of cerium carrier (10 mg of Ce^{4+}/ml) and 10–15 drops of hydrogen peroxide are added to the solution and uranium is extracted by shaking with an equal volume of ethyl acetate for 1 min. The organic phase is slowly evaporated on a hot-plate. The residue is taken up in 10 ml of $1M$ nitric acid and the uranium extraction with ethyl acetate is repeated twice more. Finally the uranium is electroplated on a stainless-steel disc similarly to neptunium.

RESULTS AND DISCUSSION

The chemical procedures described above are rapid and quantitative and the radionuclides separated are free from contamination by other fission products. The β-emitting isotopes are counted in a low-background assembly using an end-window GM counter with a lower thickness of the sample. The necessary corrections for the loss due to self-absorption *etc.* are made and the final count-rate is used to estimate the concentration of each nuclide. The purity of each separated nuclide is checked by following the radioactive decay and in the case of β-emitting nuclides by using appropriate aluminium absorbers.

The chemical yields of uranium and neptunium are determined radiometrically by adding ^{233}U and ^{237}Np tracers and in the case of fission products the yields are determined gravimetrically by adding an appropriate inactive carrier. The chemical yields of separated radionuclides are 65–80% for strontium and barium, 85–90% for silver, 50–55% for molybdenum, 70–80% for tellurium, 82–85% for neptunium and 55–60% for uranium. The overall errors in the estimation of these nuclides are within 10%. The time taken for the entire analysis is 5–10 hr.

Table 1. Expected activity ratios of selected fission products at the time of fission[5]

Isotope ratio	Fission-spectrum neutron fission of			14-MeV neutron fission of

	4·1	11.9.66	A-bomb using ^{239}Pu

The expected activity ratios of selected nuclides at the time of fission are given in Table 1. Tables 2 and 3 give the observed ratios from some Chinese and French tests. The fission product ratios measured correspond with those expected. Furthermore, the mode of detonation and the fissile material used in the weapon are also determined by comparing these measured ratios with the expected activity ratios given in Table 1. The most sensitive ratio for the determination of fissile material is $^{111}Ag/^{89}Sr$, as ^{235}U and ^{239}Pu fission in A-bomb tests give ratios which differ by a factor of 29. A thermonuclear reaction is identified by comparing the observed ratios with corresponding ^{238}U 14-MeV fission ratios, though more significant are the ratios of ^{237}U and ^{239}Np to ^{140}Ba. This is because the $^{237}U/^{140}Ba$ value varies between 0·02 and 0·2 for purely fission devices, depending on whether ^{239}Pu or ^{235}U is used as fissile material, and for thermonuclear devices it is usually higher than 2·0. Similarly the $^{239}Np/^{140}Ba$ value is higher for H-bombs as the amount of ^{238}U is much larger and the number of neutrons liberated in the reaction is also about 10 times that for an A-bomb of the same energy.[4]

Some variations in the ratios are observed. For example, the expected ratio for $^{111}Ag/^{140}Ba$ for the fission-spectrum neutron fission of ^{235}U is 0·018,[5] while for the second and third Chinese A-bomb tests these values are 0·01 and 0·045 respectively. Similarly the $^{111}Ag/^{140}Ba$ values for the sixth and eighth Chinese tests are 0·23 and 0·16 respectively, compared with the value of 0·40 for 14-MeV fission of ^{238}U.[5] These variations could be due to a difference in neutron energies at the time of detonation.

If the tests are held close together, the activity collected will contain short-lived isotopes from earlier tests, thus making it difficult to make detailed measurements of the sample. In such cases the fission products ^{99}Mo and ^{132}Te ($t_{1/2} = 67$ and 77 hr respectively) are used to express activity ratios relative to other fission products.

Thermal vaporization devices have proved to be useful for introduction of the analyte into microwave-induced plasmas and several applications have recently been reported.[1–5] Nixon *et al.* utilized a tantalum-strip vaporization assembly for analyte introduction into an inductively-coupled plasma.[6] This report describes a similar tantalum-strip assembly coupled to a microwave-induced argon plasma and an application of this system in the analysis of samples with complex matrices.

The bomb technique[7] was used to destroy the organic matrix and a modification of the extraction procedure developed by Kinrade and Van Loon[8] using ammonium pyrrolidinedithiocarbamate (APDC) and sodium diethyldithiocarbamate (DDC) was used to separate the trace elements from the alkali and alkaline-earth metal salts. The quantitative recovery of both volatile and non-volatile trace elements was investigated through standard-addition studies on Se, Cd, Pb and Cu in various matrices. In addition, Cu was determined in various biological samples, in order to compare the results with those of a flameless atomic-absorption study carried out in these laboratories, for which the same samples were used.

EXPERIMENTAL

Apparatus

The instrumentation utilized in this study is listed in Table 1. Figure 1 is a block diagram of the experimental arrangement. The tantalum vaporization assembly and its operation are similar to that described by Nixon *et al.*[6]

Decomposition bombs. A drawing of the cross-section of the decomposition bomb is shown in Fig. 2.* This bomb is a modification of the design suggested by Krogh.[10] The modifications are as follows: the Teflon cup has been redesigned so that the inner pressure causes formation of a tight seal between the Teflon cap and body, a spring has been installed to keep the bomb tightly sealed during the cooling process and the Teflon sleeve has been omitted.

* A more detailed drawing of the decomposition bomb is available upon request.

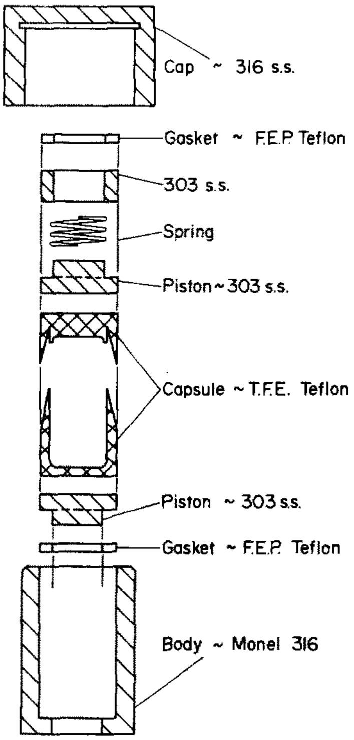

Fig. 2. Drawing of decomposition bomb.

Two different types of steel were required in the construction of the cap and body to prevent stripping of the threads.

Reagents

Stock solutions were prepared from Fisher atomic-absorption standards or alternatively by dissolving pure metals or reagent grade salts in acid diluted with demineralized water.

Nitric acid. Redistilled.

Chloroform. Reagent grade washed with demineralized water.

APDC–DDC. The reagents, 500 mg of each, were placed in a 50-ml flask, treated with demineralized water, and the solution was filtered through glass wool and extracted with three 10-ml portions of chloroform and then centrifuged.

Potassium hydrogen phthalate buffer pH 5·5. Sodium hydroxide solution (36·6 ml, 0·1*M*) was added to potassium hydrogen phthalate solution (50·0 ml, 0·1*M*).

Argon. Commercial grade, purified by passage through a train of concentrated sulphuric acid, Anhydrone, Ascarite and glass wool.

Procedure

Sample preparation. To illustrate the applicability to tissue, a fish sample (Northern Pike) was filleted and all bones removed. It was then blended (Osterizer Model 403) to produce a homogeneous composite. Lettuce was also blended to produce a homogeneous composite. The baby-food pears were taken directly out of the jar. Samples (3–5 g) were then weighed into the Teflon cup of the bomb.

From 0·28 to 0·35 g of bovine liver samples were obtained by carefully removing a section of the hepatic membrane and taking 1 cm^2 of undisturbed tissue. The samples were then ground in an agate mortar and weighed into the bombs. Only a small fraction of the total liver was sampled.

Human serum was prepared by taking fresh blood from a donor and allowing it to clot. It was then centrifuged for 10 min at 2500 rpm, and 1·0 ml of serum was taken for analysis.

Human ceruloplasmin, type III, was obtained from Sigma Chemical as a 5% solution in 0·25 *M* sodium chloride–0·05 *M* sodium acetate at pH 7. It was desalted by passage through a Sephadex G-25 desalting column equilibrated with 0·2 *M* ammonium acetate/acetic acid solution. The middle fraction was collected.

Sample digestion. After insertion of the sample into the bomb 3·0 ml of nitric acid was added and the bomb sealed and placed in an oven at 140° for 2 hr. The bomb was cooled with a stream of air for about 30 min.

Extraction. The Teflon cup was removed from the bomb and placed in a small ice-bath. The pH of the solution in the cup was adjusted (Fisher micro combination electrode) to pH 5·5, by adding dropwise 50% sodium hydroxide solution to reach pH 2 and then 1 *M* sodium hydroxide to reach the final pH. This solution was then transferred quantitatively to a 60-ml separatory funnel; 5·0 ml of the potassium hydrogen phthalate pH 5·5 buffer were added and mixed, followed by 10·0 ml of chloroform and 5·0 ml of the APDC–DDC solution. The mixture was shaken for 2 min and then shaken by mechanical shaker for 13 min. The separatory funnel was centrifuged and the chloroform drained into a glass-stoppered flask.

Specroscopic analysis. After the argon flow-rate was set at 900 ml/min, the plasma was initiated with a Tesla coil and the microwave power was adjusted to 45 W. The alignment of the argon plasma with the monochromator was optimized by maximizing the intensity of the 3093·41-Å argon line. Radiation from the appropriate hollow-cathode lamp was reflected into the monochromator with a removable mirror for optimization of the analytical response for a given element. A 5·0 μl portion of the chloroform solution was pipetted (Drummond Wiretrol 5-μl pipette) onto the tantalum strip. The solvent was evaporated by drying without heat for 40 sec with the injection port open. The port was closed and the tantalum strip heated (approximately 150–200°) for 80 sec. at a low current setting. After this drying sequence, the strip was fired for 1 sec at a high current setting (i.e., at approximately 1800°) and the peak height of the resulting emission signal was recorded on a strip-chart recorder. Standards bracketing the sample were run through the procedure. The sample and standard peak heights, corrected for reagent blank, were compared to determine the element concentration.

Standard recoveries. A 5·0-ml portion of demineralized water was pipetted into the Teflon cup. The desired amount of the element was added from a microlitre pipette (MLA precision pipette), then 3·0 ml of nitric acid were added and the procedure above, starting with the sample digestion, was used to determine the recoveries.

Spiked samples After the sample had been weighed into the Teflon cup, the desired amount of an element was added with a microlitre pipette (MLA precision pipette) followed by 3·0 ml of nitric acid and the procedure was used to determine the recovery.

RESULTS AND DISCUSSION

The decomposition bomb shown in Fig. 2 provided a seal that did not show visible signs of leaking when 0·5–0·9 g (dry weight) of sample was decomposed, even after 30 such decompositions. Attempts to analyse the nitric acid digest of most samples directly for trace elements did not succeed because there were severe matrix effects and spectral interferences from the large amount of alkali and alkaline earth metal salts present, several elements formed volatile nitrosyl compounds and consequently were lost during the drying stage, and nitric acid attacked the tantalum strip, causing it to oxidize rapidly. Therefore, the chelate

* Sample volume 5 μl.

extraction procedure was developed, with chloroform chosen as the solvent since it evaporated very rapidly from the tantalum surface, extracted the chelate quantitatively, formed only a slight emulsion and could be drained directly from the separatory funnel after centrifugation.

A disadvantage of this procedure is that it does not extract As and Be, two toxic elements which would have been of interest in this study.

The characteristics of the microwave-induced plasma have already been discussed.[1] The position of the plasma tended to wander within the tube. In order to stabilize it, a small metal bar was placed against the quartz tube near the lower portion of the plasma. Since the plasma was attracted to the metal bar, it remained fixed at the front wall of the tube. The emission from the elements was viewed just below the centre of the plasma, as this position appeared to give the best response for most of the elements.

The injection port was left open during the evaporation of the chloroform so that a large amount of chloroform would not enter the quartz tube, possibly extinguishing the plasma or causing the plasma to be concentrated and to etch the tube.

The detection limits for the system are shown in Table 2. These values were determined by measuring the signal-to-noise ratio at a sample level approximately ten times the detection limit and calculating the sample level which would have generated a signal-to-noise ratio of 2. Co and Ni were not determined owing to reaction of these elements with the tantalum strip.[11]

As an example of the precision of the system, relative standard deviations for 5 replicate determinations of 1·25, 1·67 and 2·50 ng of Cu (aqueous standards) were 1·4, 1·1 and 0·87%, respectively.

Standards alone and standards added to the samples (spiked samples) were taken through the entire procedure and the results are shown in Tables 3 and 4. Each recovery shown is an average of 4 separate determinations with 5 emission signals recorded for each determination. The spike levels were chosen to indicate that recovery of both volatile and non-volatile elements by the bomb digestion–solvent extraction procedure was quantitative. They do not indicate the lower or upper limits of the method.

A background correction was made for selenium, by using the 1965·0 Å line. This background is due to traces of organic compounds left in the nitric acid digest, causing an emission continuum.

Table 3. Standard recoveries

† 3 g sample taken (Northern Pike).
‡ 5 g sample taken.

The results for the portion of bovine liver sampled yielded for Cu an average of 23 $\mu g/g$ with an average deviation of ± 3 μg. These results compare favourably with those of the flameless atomic-absorption (FAA study[12] which gave an average of 28·9 $\mu g/g$. The human serum study gave an average Cu value of 102 $\mu g/100$ ml with an average deviation of ± 5 μg. (FAA[12] gave 98 $\mu g/100$ ml). The generally accepted value for copper in human serum is 100 $\mu g/100$ ml. The sensitivity is high enough for the sample sizes to be reduced at least tenfold, an important factor in pediatric screening or when working with small animals.

The desalted human ceruloplasmin yielded a copper content of 5·5 ppm, *ca.* 20% higher than that obtained by FAA,[12] but no ashing or extraction was required. The copper content of the ceruloplasmin (0·32%) is high enough to allow the sample to be highly diluted so that the organic matrix is destroyed in the plasma without interference. The desalting eliminates any alkali or alkaline earth metal interference and hence extraction is unnecessary. Ceruloplasmin was the only sample in this study for which ashing and extraction were unnecessary.

In view of these results, it can be concluded that the tantalum-strip vaporization assembly/microwave-induced plasma system (if necessary, combined with bomb decomposition and chelate extraction) offers a sensitive technique for the determination of some trace elements in samples with complex matrices.

The major advantage of this system over non-flame atomic absorption is the potential capability for multielement trace analysis. A study[13] in which a similar system was coupled to a vidicon detector has been completed which demonstrates this advantage.

LINEAR TITRATION PLOTS FOR POLYFUNCTIONAL WEAK ACIDS AND BASES

D. MIDGLEY

Central Electricity Research Laboratories, Kelvin Avenue, Leatherhead, Surrey

C. McCALLUM

Department of Chemistry, The University, Southampton, England

(*Received* 8 *July* 1975. *Accepted* 5 *October* 1975)

Requests for a Fortran version of an Algol program for calculating linear plots for the potentiometric titration of a number of weak acid systems[1] have led us to develop the program in additional directions. The plot for the titration of a dibasic weak acid with a strong base has been extended to cover polybasic weak acids with up to six functional groups and a corresponding plot has been devised for the titration of a polyacidic weak base with a strong acid. The plots can be used to give a graphical solution, or the equivalence volumes can be obtained from a least-squares fit of the function. Activity coefficient corrections can be made through an iterative process. Copies of the program are available on request.

THEORY

For convenience, charges have been omitted from ionic symbols; f_i is the activity coefficient of the ith protonated

LINEAR TITRATION PLOTS FOR POLYFUNCTIONAL WEAK ACIDS AND BASES

D. MIDGLEY

Central Electricity Research Laboratories, Kelvin Avenue, Leatherhead, Surrey

C. MCCALLUM

Department of Chemistry, The University, Southampton, England

(*Received* 8 *July* 1975. *Accepted* 5 *October* 1975)

Requests for a Fortran version of an Algol program for calculating linear plots for the potentiometric titration of a number of weak acid systems[1] have led us to develop the program in additional directions. The plot for the titration of a dibasic weak acid with a strong base has been extended to cover polybasic weak acids with up to six functional groups and a corresponding plot has been devised for the titration of a polyacidic weak base with a strong acid. The plots can be used to give a graphical solution, or the equivalence volumes can be obtained from a least-squares fit of the function. Activity coefficient corrections can be made through an iterative process. Copies of the program are available on request.

THEORY

For convenience, charges have been omitted from ionic symbols; f_i is the activity coefficient of the ith protonated species, f_A the activity coefficient of the unprotonated form of the acid or base, V_e the equivalence volume of titrant and V the volume of titrant added. K_w is the thermodynamic autoprotolysis constant of water and, assuming $f_H = f_{OH} = f_\pm$, [OH] is given by $K_w/\{H\}f_\pm$, $\{H\}$ being the hydrogen-ion activity.

Weak acid titrations

V_0 ml of a solution of a weak acid, H_hAP_q, with k acidic functional groups, are titrated with a strong base, BOH, of molar concentration m. P is a univalent ion with the charge-sign necessary to maintain electrical neutrality, h is the number of protons per molecule removable by titration, a is the negative charge on A and $q = |h - a|$. If charge p is assigned to P and $K_i = [H_iA]f_i/(\{H\}^i[A]f_A)$ is the ith association constant of the weak acid, the mass-balance equations are:

$$\begin{aligned} T_A &= [A] + [HA] + \cdots + [H_iA] + \cdots + [H_kA] \\ &= [A]\left(1 + \sum_{i=1}^{k} K_i\{H\}^i f_A/f_i\right) \\ &= \frac{mV_e}{h(V_0 + V)} \end{aligned} \tag{1}$$

$$p[P] = -(h - a)T_A \tag{2}$$

$$[B] = T_B = mV/(V_0 + V). \tag{3}$$

The charge-balance equation is

$$\begin{aligned} [B] + [H] + p[P] = [OH] + a[A] + (a-1)[HA] + \cdots \\ + (a-i)[H_iA] + \cdots \\ + (a-k)[H_kA] \end{aligned} \tag{4}$$

Substituting from equations (1), (2) and (3) in equation (4), we obtain

$$\begin{aligned} T_B + [H] - (h - a)T_A \\ = [OH] + a.T_A - [A]\sum_{i=1}^{k} iK_i\{H\}^i f_A/f_i. \end{aligned}$$

On rearrangement and further substitution in terms of the measured quantities $\{H\}$, V and V_0, we obtain:

$$\frac{mV}{V_0 + V} + \frac{\{H\}}{f_\pm} - \frac{K_w}{\{H\}f_\pm} = \frac{mV_e}{h(V_0 + V)}\left\{h - \frac{\alpha}{1 + \beta}\right\}.$$

Hence

$$\begin{aligned} \{h(V_0 + V)(\{H\} - K_w/\{H\})/f_\pm \\ + mV\alpha/(1 + \beta)\}/\{h - \alpha/(1 + \beta)\} = m(V_e - V) = F_{PA} \end{aligned} \tag{5}$$

In equation (5)

$$\alpha = \sum_{i=1}^{k} iK_i\{H\}^i f_A/f_i \quad \text{and} \quad \beta = \sum_{i=1}^{k} K_i\{H\}^i f_A/f_i.$$

A plot of F_{PA} against V is linear and intercepts the V-axis at $V = V_e$.

Weak base titrations

V_0 ml of a weak base, H_hAP_q, with k basic functional groups are titrated with a strong acid, HX, of molar concentration m; $k - h$ protons can be added to each molecule. P, p, q, a, K_i, α and β are defined as above. The mass- and charge-balance equations may be written:

$$T_A = [A](1 + \beta) = \frac{mV_e}{(k - h)(V_0 + V)} \tag{6}$$

$$p[P] = -(h - a)T_A \tag{7}$$

$$[X] = mV/(V_0 + V) \tag{8}$$

$$\begin{aligned} [H] + p[P] = [OH] + [X] + a[A] + \cdots \\ + (a - i)[H_iA] + \cdots + (a - k)[H_kA] \end{aligned} \tag{9}$$

Substituting and rearranging as before, we obtain

$$\begin{aligned} \{(k - h)(V_0 + V)(\{H\} - K_w/\{H\})/f_\pm \\ + mV(\alpha/(1 + \beta) - k)\}/\{h - \alpha/(1 + \beta)\} = m(V_e - V) = F_{PB} \end{aligned}$$

A plot of F_{PB} against V is linear and intercepts the V-axis at $V = V_e$.

Effect of an error in the association constant

The extent of the deviation from the true function produced by an inaccurate value of the association constant has already been discussed,[1] but the apparent equivalence volume indicated by the intercept of the inaccurate function on the V-axis was not considered. For a monobasic weak acid of concentration c, the function F_{PA} reduces to

$$F_{PA} = (1 + K_1\{H\}f_A/f_i)(V_0 + V)\theta + mVK_1\{H\}f_A/f_i,$$

where $\theta = (\{H\} - K_w/\{H\})/f_\pm$. If the function calculated with an inaccurate constant $K_1' = rK_1$ is designated Φ_{PA}, we have:

$$\Phi_{PA} = (1 + K_1'\{H\}f_A/f_i)(V_0 + V)\theta + mVK_1'\{H\}f_A/f_i.$$

Therefore,

$$F_{PA} - \Phi_{PA}/r = (1 - r^{-1})(V_0 + V)\theta \tag{10}$$

Φ_{PA} intercepts the V-axis at $V = V_e'$, the apparent equivalence volume and the value of θ at this point is θ_e'. By definition the error in V_e is $\Delta V_e = V_e' - V_e$.

Since at $V = V_e'$, $\Phi_{PA} = 0$, we have from equation (10)

$$F_{PA} = (1 - r^{-1})(V_0 + V_e')\theta_e'$$

and from equation (5)

$$F_{PA} = m(V_e - V_e') = m\Delta V_e$$

Hence

$$\Delta V_e = \frac{(r^{-1} - 1)(V_0 + V_e)\theta_e'}{m - (r^{-1} - 1)\theta_e'}$$

and the relative error is

$$\frac{\Delta V_e}{V_e} = \frac{(1 + m/c)(r^{-1} - 1)}{1 - r^{-1} + m/\theta_e'} \tag{11}$$

For a monoacidic weak base, we obtain by a similar process

$$F_{PB} = \frac{(1 + K_1\{H\}f_A/f_i)(V_0 + V)\theta - mV}{-K_1\{H\}f_A/f_i}$$

$$\Phi_{PB} = \frac{(1 + K_1'\{H\}f_A/f_i)(V_0 + V)\theta - mV}{-K_1'\{H\}f_A/f_i}$$

$$F_{PB} - r\Phi_{PB} = (r - 1)(V_0 + V)\theta$$

When

$$\Phi_{PB} = 0,\ V = V_e' = V_e + \Delta V_e \quad \text{and} \quad \theta = \theta_e',$$

hence

$$F_{PB} = (r - 1)(V_0 + V_e + \Delta V_e)\theta_e' = -m\,\Delta V_e,$$

$$\Delta V_e = \frac{(1 - r)(V_0 + V_e)\theta_e'}{m + (r - 1)\theta_e'}$$

$$\frac{\Delta V_e}{V_e} = \frac{(1 - r)(1 + m/c)}{r - 1 + m/\theta_e'}$$

If $r > 1$, Φ_{PA} results in an overestimate of V_e, and Φ_{PB} in an underestimate, and conversely for $r < 1$. The magnitude of the error produced by a given value of r depends principally on θ_e'. The stronger the acid or base, and

the lower its concentration, the smaller θ'_e, and hence the error, becomes.

CALCULATION

A Fortran program has been written to carry out the calculations. The value of the function F_{PA} or F_{PB} for each addition, V, of titrant is calculated by a subroutine ALLONE and the best straight line through the points (V, F_{PA}) or (V, F_{PB}) is determined by an unweighted least-squares fit using a subroutine LEAST. If the ionic strength changes in the course of the titration, activity coefficients can be calculated iteratively by a subroutine ACTCO, which uses the equation

$$-\log f_z = A.z^2\{I^{1/2}/(1 + BaI^{1/2}) - bI\}$$

where A and B are the Debye–Hückel parameters, a and b are adjustable parameters supplied to the program and z is the charge on the ion. The ionic strength, I, is calculated by a function subroutine MU. Iteration in the cycle ALLONE–V_e–MU–ACTCO–ALLONE proceeds until successive values of V_e agree within 0·01%. The subroutines LEAST and ACTCO can be used with another program dealing with mixtures of acids.[2] The use of ACTCO is not contingent on the particular equation used and it should be possible to accommodate any other method of calculating activity coefficients.

The equivalence volume, V_e, and the slope of the plot, BCALC, are printed with their respective standard deviations. Systematic errors can cause curved plots (evident from the large standard deviations), but usually a good graphical solution can be obtained and the co-ordinates of the plot are therefore also printed. BCALC provides a check on the calculations, since errors, whether resulting in curvature or not, cause BCALC to differ from its theoretical value, m, the concentration of the titrant.

Scope of the method

The program allows for up to six acidic or basic functional groups per molecule, but it has not been tested with more than three. All forms of acids or bases are covered, *e.g.*, citric acid, $k = h = a = 3$; trisodium citrate, $k = a = 3$, $h = 0$; glycine, $k = 2$, $h = a = 1$; glycine hydrochloride, $k = h = 2$, $a = 1$; ammonia, $k = 1$, $h = a = 0$. The acids or bases may be very weak and may have overlapping dissociation steps. The limitations due to the neglect of activity coefficients and, in part, to errors in the association constants have been discussed before,[1] together with a comparison with Gran's method.[3]

The greatest accuracy would be achieved if the association constants of an acid or base were determined with the same apparatus before any analytical titrations were carried out, but a practicable method should be capable of producing accurate results with literature values for the constants and independently obtained pH readings. The results of some calculations with published titration data are given in Table 1.

The agreement between theoretical and observed results is reasonable, given the unfavourable conditions. In the case of the glycine–hydrochloric acid titration the plot was scattered more than usual and the few titration points were badly distributed for our purposes. Other results have been reported earlier.[1]

Summary—Procedures are derived for obtaining the equivalence volumes in the potentiometric titrations of polyfunctional weak acids and weak bases by a linear titration plot method. The effect of errors in the equilibrium constants on the accuracy is considered. A Fortran program is available to do the calculations.

ION-EXCHANGE BEHAVIOUR OF PYRIDINIUM TUNGSTOARSENATE

W. U. MALIK, S. K. SRIVASTAVA and SATISH KUMAR
Department of Chemistry, University of Roorkee, Roorkee, India

(*Received* 14 *May* 1975. *Accepted* 19 *August* 1975)

The cation-exchange behaviour of salts of heteropoly acids is well established. Smit *et al.*,[1] while investigating the properties of the ammonium salts of heteropoly acids observed that ammonium tungstoarsenate and tungstophosphate become colloidally dispersed and cannot be used as cation-exchangers. We have replaced the ammonium ion in the tungstoarsenate salt with organic bases and have found that pyridinium tungstoarsenate is chemically and thermally stable and possesses promising exchange properties, comparable to those of the ammonium salt.

The work described in this paper is concerned with the sorption of some univalent and bivalent cations on the exchanger, evaluation of the constants and an interpretation of the mechanism.

EXPERIMENTAL

Sodium tungstate and arsenic pentoxide, used in these studies, were reagent grade chemicals. The salts of sodium, potassium and lithium were of analytical reagent quality. Their solutions were prepared in doubly distilled water.

Pyridinium nitrate was obtained as a white crystalline compound, by mixing nitric acid and distilled pyridine in equimolar quantities. It was crystallized from water and alcohol and dried in a vacuum desiccator, Pyridinium tungstoarsenate was obtained as follows.

Arsenic pentoxide (4·6 g), dissolved in concentrated sodium hydroxide solution and diluted to 140 ml, was added slowly with constant stirring to a solution of sodium tungstate (105·6 g dissolved in 180 ml of water). The mixture was then acidified with concentrated hydrochloric acid and 40 g of pyridinium nitrate were added in small amounts with constant stirring. The mixture was heated over a water-bath for 30 min, then left for 24 hr and filtered. The product was washed with dilute acid and distilled water and dried at 90°.

The pyridinium tungstoarsenate was then analysed. Tungsten was determined as the thiocyanate complex. Pyridine was determined spectrophotometrically at 256 nm. Arsenic was determined by dissolving a known amount of the product in 0·1*N* sodium hydroxide and back-titrating the excess of alkali.

The exchange isotherms with various cations were obtained by estimating spectrophotometrically the amount of pyridinium ion liberated by different concentrations of a particular cation in presence of 0·001*M* pyridinium nitrate. The amount of exchanger (0·1 g), the total volume of the solution (20 ml) and the acidity of the medium (0·01*M* nitric acid) were the same in all cases.

In order to ascertain the stoichiometry of the exchange reactions both the solid and liquid phases were analysed after exchange. The experiments were carried out at 32°.

RESULTS AND DISCUSSION

The values obtained for pyridine, tungsten and arsenic in the compound pyridinium tungstoarsenate are given below and compared with the theoretical values calculated on the bases of the formula $(C_5H_5NH)_3W_{12}AsO_{40}$. [Found: C_5H_5N, 7·6%; As, 2·0%; W, 69·9%; $(C_5H_5NH)_3W_{12}AsO_{40}$ requires C_5H_5N, 7·6%; As, 2·3%; W, 70·4%]. The analysis shows that the salt is anhydrous, and this is confirmed by the thermogravimetric analysis (Fig. 1) which reveals only the thermal decomposition of the product at 480°.

The pyridinium ion in this compound is exchangeable and the exchange reaction is found to be stoichiometric. The exchange isotherms are plotted in Figs. 2–4.

The order of adsorption on the exchanger is $Cs^+ > Rb^+ > Na^+ > Li^+ > K^+ > NH_4^+$ and $Cu^{2+} > Sr^{2+} > Ba^{2+}$. The compound seems to be highly specific towards Cs^+, Ag^+ and Tl^+, and an almost complete replacement of pyridinium ion occurs with silver and caesium. The slopes of the isotherms are quite different, showing that the exchanger can be used for the separation of these cations.

The sequence of cationic uptake is not the same as reported by other workers for heteropoly salts.[2,3] The adsorption seems to decrease with increasing atomic number or size of bivalent cations *viz.* Cu^{2+}, Sr^{2+} and Ba^{2+}. In the case of univalent cations no regular order is observed with respect to the size of the ion or the volume of the hydrated ion. On the other hand their sequence seems to follow the lyotropic number, which according to Bruins[4] and Voet,[5] holds true for ion-exchange processes, the species with a lower lyotropic number being adsorbed more strongly. Steric effects sometimes influence the selectivity order of adsorption of alkali metal ions and a reverse behaviour for alkaline earth cations has also been reported by Lefebvre and Gaymard.[6]

The X-ray studies of the heteropoly acids and their salts (summarized by Wells[7]) have shown that in such crystals

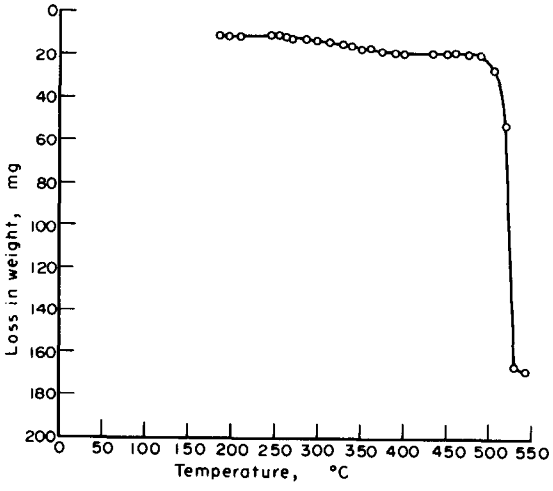

Fig. 1. TGA of pyridinium tungstoarsenate.

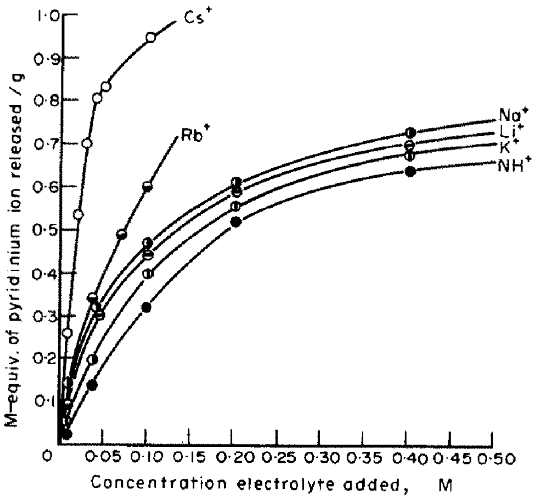

Fig. 2. Exchange isotherms of alkali metal ions and NH_4^+.

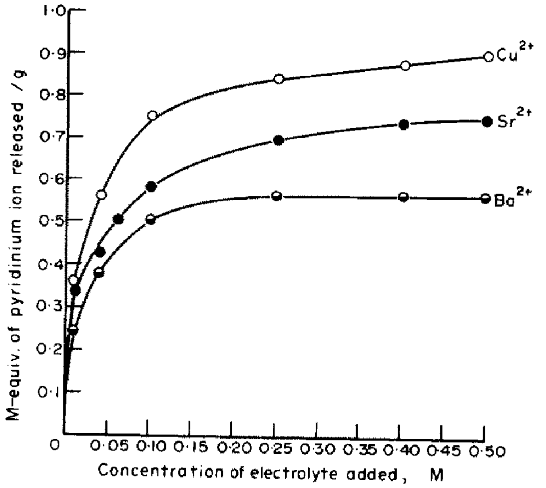

Fig. 4. Exchange isotherms of Cu^{2+}, Sr^{2+} and Ba^{2+}.

the cations with associated water molecules are fitted in between the large negative ions. Comparatively large cavities exist between these negative ions, allowing the accommodation of larger cations, even those of organic bases. Univalent cations such as Rb^+, Cs^+, Tl^+, Ag^+ and K^+, can be packed stably into the structure and lower the crystal energy sufficiently to give salts insoluble in water. In other cases, *e.g.*, lithium or sodium pyridinium heteropoly salts, their peculiar behaviour may be due to their solubility in the medium.

For the alkali metal ions and also for thallium and silver the logarithm of the selectivity coefficient (K') varies linearly with the saturation of the exchanger (Fig. 5) thus conforming to the empirical Kielland equation[8] established on theoretical grounds by Barrer and Falconer.[9]

$$\log K' = \log K + C(1 - 2\overline{X}_M)$$

where K' is the selectivity coefficient, K the thermodynamic equilibrium constant, $\overline{X}_M$ the fraction of exchanging sites occupied by the exchanging ion and

$$C = -\frac{E_\omega}{2{\cdot}303\,kT}\cdot\frac{N_A + N_B}{N}$$

N_A and N_B are the number of ions of the type A and B in the exchanger, N is the total number of available sites and E_ω is the interaction energy or the energy change in the crystal associated with pair formation, when two ions occupy adjacent sites.

Figure 5 shows the plot of log K' *vs.* $(1 - 2\overline{X}_M)$. The values of the thermodynamic equilibrium constant, K, free energy change, ΔG° and the energy of interaction between the adjacent ions on the surface, E_ω, are given in Table 1.

The smaller magnitude of E_ω suggests that the neighbouring ions on the exchanger surface are very little affected by adjacent ions. These values also indicate a

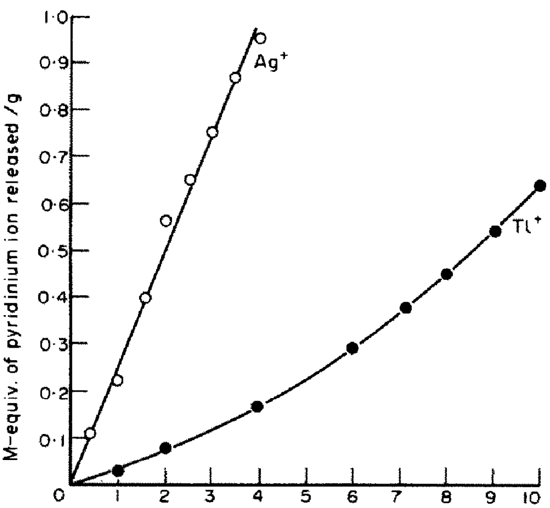

Fig. 3. Exchange isotherms of Ag^+ and Tl^+.

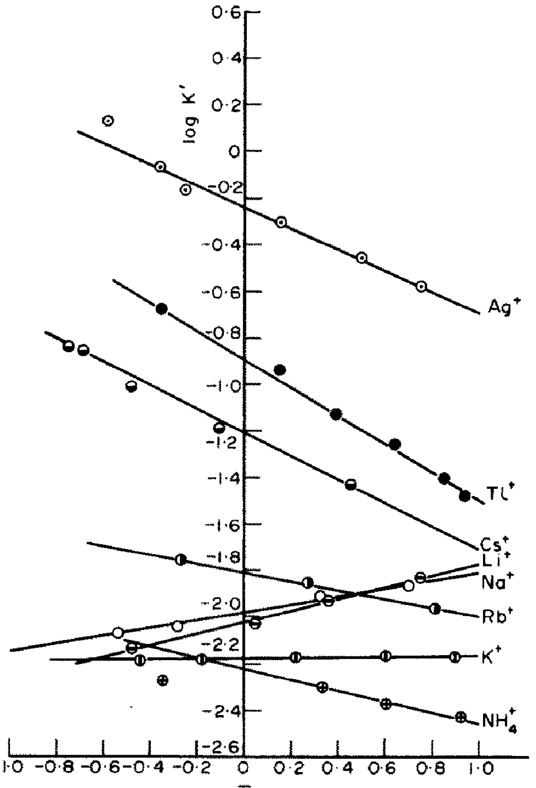

Fig. 5. Plot of logarithm of selectivity coefficients *vs.* $(1 - 2\overline{X}_M)$.

Table 1.

	Thermodynamic equilibrium constant	ΔG°, *kcal/mole*	E_ω, *kcal/mole*
K_{Py}^{Li}	0·0095	$2{\cdot}7_7$	−0·36
K_{Py}^{Na}	0·0104	$2{\cdot}7_2$	−0·23
$K_{Py}^{NH_4}$	0·0060	$3{\cdot}0_4$	0·29
K_{Py}^{K}	0·0067	$2{\cdot}9_8$	0·027
K_{Py}^{Rb}	0·0159	$2{\cdot}4_7$	0·28
K_{Py}^{Cs}	0·069	$1{\cdot}6_6$	0·69
K_{Py}^{Ag}	0·575	0·33	0·62
K_{Py}^{Tl}	0·129	1·22	0·83

strong preference for silver and the following affinity series can be written for this exchanger:

$$Ag^+ > Tl^+ > Cs^+ > Rb^+ > Na^+ > Li^+ > K^+ > NH_4^+$$

The magnitude of E_ω for various cations reflects that more work has to be done by Ag^+, Cs^+ and Tl^+ to occupy adjacent sites than by Rb^+ and K^+. On the other hand, it has been observed that it is easier to saturate the lattice with these three cations and these findings cannot be reconciled unless the exchange mechanism approaches very closely a chemical reaction between the almost dehydrated Cs^+, Ag^+, Tl^+ and pyridinium ions. Similar findings have been reported for ammonium molybdophosphate and phosphotungstate compounds.[10]

The replacement of the pyridinium ion of this salt with other organic cations *viz.* methylammonium, dimethylammonium and trimethylammonium has also been investigated. The studies show that the uptake of the ions is directly proportional to their size in the case of the first two compounds. The uptake of trimethylammonium ion is the least. The crystal lattice in pyridinium tungstoarsenate is perhaps too compact to allow the entry of the large trimethylammonium cation, but loose enough to permit the exchange of mono- and dimethylammonium ions.

Lapachol is a yellow crystalline solid, m.p. 139–140°. It gives a violet-red colour with ferric chloride and a red colour with magnesium acetate. It dissolves in aqueous sodium hydroxide, giving a deep red solution which turns light yellow on addition of sodium dithionite, and the red colour can be restored on shaking for some time in air.

EXPERIMENTAL

Since it gave a blood-red colour with aqueous alkalies, we thought it worthwhile to examine its utility as an acid-base indicator. It gives no colour in acidic medium, probably because of protonation of the quinonoid oxygen atom suppressing its quinonoid nature, but has a red colour in alkaline medium, owing to its resonating forms.

The transition interval was determined by adding the indicator to a series of suitable buffers in test-tubes of equal colour and diameter, and found to be pH 4·8–5·8 when the indicator concentration is $10^{-3}\%$ in the test solution. The first perceptible colour is at pH 4·8, and the colour ceases to change at pH 5·8.

Lapachol is thus a suitable one-colour indicator for the titration of strong acids with strong or weak bases. The colour is fairly stable.

DETERMINATION OF SULPHIDE, SULPHITE AND THIOSULPHATE WITH THALLIC PERCHLORATE OR SULPHATE

D. N. Sharma, P. D. Sharma and Y. K. Gupta
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 8 *July* 1975. *Accepted* 4 *September* 1975)

Recently a review[1] describing analytical determinations of sulphide, sulphite and thiosulphate has appeared. It seems that there are contradictory reports about the iodimetric determination of sulphide. Kolthoff[2] has reported only partial oxidation of sulphide to sulphate in alkaline medium. Bethge[3] has reported that the iodimetric determination is not free from errors. Similarly difficulty has been encountered in the iodimetric determination of sulphite, particularly in alkaline medium, owing to air oxidation which can, however, be checked by addition of inhibitors.[4–6] Thiosulphate can, however, be determined[7,8] accurately iodimetrically both in acid and alkaline media.

The present paper describes the iodimetric determination of these substances with thallic perchlorate or sulphate and potassium iodide. The method is essentially a combination of iodometry and iodimetry. Thallium(III) liberates iodine from potassium and this iodine is subsequently used up by sulphide, sulphite or thiosulphate. The main advantage of the method is that it dispenses with the preparation of iodine solution (which does not have a constant titre) whereas thallic perchlorate or sulphate gives a standard solution stable over months and unaffected by air and light. Thallium(III) has already been used for the determination of thiourea, sulphite and thiosulphate, with *p*-ethoxychrysodine as indicator.[9] Apart from iodimetry, the present paper describes the use of indigo carmine indicator for the determination of sulphide, sulphite and thiosulphate.

EXPERIMENTAL

Reagents

Thallic oxide is added gradually to heated $\sim 5M$ perchloric or sulphuric acid until no more will dissolve. The solution is left overnight and then filtered. Alkali is added to the filtrate to precipitate thallic hydroxide, which is filtered off, washed, and dissolved in the appropriate acid. It is necessary to maintain about $0·5\,M$ acid concentration in the reaction mixtures and hence the acidity of the thallium(III) solutions is also determined by titration with caustic soda solution to the phenolphthalein end-point; it is necessary to add potassium bromide to complex thallium(III) to check its interference in the acid–base titration.

Solutions of sodium sulphide, sodium sulphite and sodium thiosulphate were prepared in doubly distilled water and standardized against an iodine solution. A 0·1% aqueous solution of indigo carmine was prepared.

Procedure

For iodimetric determination, a known quantity of sulphide, sulphite or thiosulphate was taken in an Erlenmeyer

DETERMINATION OF SULPHIDE, SULPHITE AND THIOSULPHATE WITH THALLIC PERCHLORATE OR SULPHATE

D. N. Sharma, P. D. Sharma and Y. K. Gupta
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 8 *July* 1975. *Accepted* 4 *September* 1975)

Recently a review[1] describing analytical determinations of sulphide, sulphite and thiosulphate has appeared. It seems that there are contradictory reports about the iodimetric determination of sulphide. Kolthoff[2] has reported only partial oxidation of sulphide to sulphate in alkaline medium. Bethge[3] has reported that the iodimetric determination is not free from errors. Similarly difficulty has been encountered in the iodimetric determination of sulphite, particularly in alkaline medium, owing to air oxidation which can, however, be checked by addition of inhibitors.[4–6] Thiosulphate can, however, be determined[7,8] accurately iodimetrically both in acid and alkaline media.

The present paper describes the iodimetric determination of these substances with thallic perchlorate or sulphate and potassium iodide. The method is essentially a combination of iodometry and iodimetry. Thallium(III) liberates iodine from potassium and this iodine is subsequently used up by sulphide, sulphite or thiosulphate. The main advantage of the method is that it dispenses with the preparation of iodine solution (which does not have a constant titre) whereas thallic perchlorate or sulphate gives a standard solution stable over months and unaffected by air and light. Thallium(III) has already been used for the determination of thiourea, sulphite and thiosulphate, with *p*-ethoxychrysodine as indicator.[9] Apart from iodimetry, the present paper describes the use of indigo carmine indicator for the determination of sulphide, sulphite and thiosulphate.

EXPERIMENTAL

Reagents

Thallic oxide is added gradually to heated ~5*M* perchloric or sulphuric acid until no more will dissolve. The solution is left overnight and then filtered. Alkali is added to the filtrate to precipitate thallic hydroxide, which is filtered off, washed, and dissolved in the appropriate acid. It is necessary to maintain about 0·5 *M* acid concentration in the reaction mixtures and hence the acidity of the thallium(III) solutions is also determined by titration with caustic soda solution to the phenolphthalein end-point; it is necessary to add potassium bromide to complex thallium(III) to check its interference in the acid–base titration.

Solutions of sodium sulphide, sodium sulphite and sodium thiosulphate were prepared in doubly distilled water and standardized against an iodine solution. A 0·1% aqueous solution of indigo carmine was prepared.

Procedure

For iodimetric determination, a known quantity of sulphide, sulphite or thiosulphate was taken in an Erlenmeyer flask and rendered about 0·5 M in acid with perchloric or sulphuric acid. For sulphide determination the acid concentration should not be less than 0·5M. Then 5 ml of 0·05M potassium iodide and some starch solution were added, and the solution titrated with thallium(III) solution with vigorous swirling. The titrant was added dropwise at intervals of 10–15 sec near the end-point.

In the direct determination using indigo carmine indicator, the end-point was marked by a colour change from blue to light green. Vigorous shaking is required in this case too. The end-point can be made sharper by the use of cobalt(II) sulphate along with the indicator. The colour change is then from blue to pink.

Results are given in Tables 1, 2 and 3.

Limitations

The method failed for amounts of sulphide larger than 10 mg, probably because hydrogen sulphide is formed in acid solutions and part of it escapes to the atmosphere. Cobalt(II) sulphate was not used in the case of sulphite because the colour of the indicator disappears within 2–5 min in its presence. Since sulphite solutions are known to decompose, the determinations were carried out also with solutions stabilized[12–15] by glycerol, sucrose and ethanol. The results were similar to those obtained without stabilization.

Determination of sulphide, sulphite and thiosulphate in admixture

Kurtenacker and Wollak[16] have carried out an iodimetric determination of the three in a mixture and the same method can be applied here, with thallium(III) solution substituted for iodine solution.Both iodimetric and indigo carmine methods are applicable for the mixtures. The results are given in Table 4.

4·15	7·55	8·67	4·10	7·51	8·56

DISCUSSION

The results of Tables 1, 2 and 3 are reasonable, the error being generally $< 1\%$. The errors are larger in the case of mixtures (Table 4), obviously because the determinations involve two operations, precipitation with $ZnCO_3$ and complexing with formadehyde.

The reactions of thallium(III) with sulphide, sulphite and thiosulphate are very fast in acid medium, that with sulphide being

$$\mathrm{Tl(III)} + \mathrm{H_2S} \rightarrow \mathrm{Tl(I)} + 2\mathrm{H}^+ + \mathrm{S}$$

The reaction of thallium(III) with iodide is still faster and the iodine so liberated reacts with sulphide, sulphite or thiosulphate, yielding iodide, and thus iodide acts as a catalyst through the operation of the I^0/I^- cycle. Although iodide may be regarded as a catalyst, it is not effective at lower concentrations because thallous iodide is precipitated and thus iodide is gradually removed from the solution during the titration. This thallous iodide adsorbs iodine, forming[11] $TlI.I_2$ and the bound iodine can be titrated only with difficulty and hence vigorous swirling is necessary.

Interferences

Mn^{2+}, Ni^{2+}, Co^{2+} and Zn^{2+} do not interfere in the iodimetric method, but Co^{2+} and Ni^{2+} interfere in the indicator method. Cu^{2+}, Fe^{3+}, As(III), As(V), Sb(III) and Sb(V) interfere in both the iodimetric and the indicator methods. Cl^-, Br^-, SO_4^{2-} and NO_3^- do not interfere.

Summary—Sulphide, sulphite and thiosulphate can be determined separately or in admixture, with thallic perchlorate or sulphate in acid medium. A sample solution is rendered ~0·5*M* in acid, 5 ml of 0·05*M* KI are added and the solution is titrated to a starch end-point with thallium(III) solution. In another method an acid sample solution is titrated with thallium(III) or iodine solution in the presence of indigo carmine indicator. The end-point is improved in the presence of Co(II).

DETERMINATION OF AZO COMPOUNDS WITH *N*-BROMOSUCCINIMIDE IN ACETIC ACID MEDIUM

Umesh C. Pande and Madhuban Gopal
Department of Chemistry, University of Allahabad, Allahabad-211002, India

(*Received* 10 *April* 1975. *Revised* 20 *September* 1975. *Accepted* 7 *October* 1975)

Azo compounds have been determined quantitatively with reducing agents, *e.g.*, chromium(II),[1] tin(II),[2] titanium(III),[3] but these reagents readily undergo aerial oxidation, and the steps needed to prevent this are cumbersome. The reduction processes are slow at normal temperature and heating is required to complete the reaction. This paper describes the study of the reaction of *N*-bromosuccinimide with azo compounds and its analytical application to their determination. A 2–10 mg sample is reacted with a measured excessive volume of *N*-bromosuccinimide at room temperature and the excess of reagent is back-titrated iodometrically, The results generally show ±1% maximum deviation from the theoretical value.

STOICHIOMETRIC STUDY

The reaction of chrysoidine with *N*-bromosuccinimide has been studied as a representative reaction. Different known quantities of chrysoidine were reacted with excess of *N*-bromosuccinimide and the stoichiometry was calculated from the amount of *N*-bromosuccinimide consumed, and found to be 1:2 with respect to chrysoidine and *N*-bromosuccinimide.

A similar procedure has been followed for determination of the stoichiometry of reaction of other compounds with *N*-bromosuccinimide (Table 1).

The reaction mixtures were analysed for the end-products after the reaction was over. Succinimide has been isolated from the reaction mixture and identified from its melting point and mixed melting point. Different bromo-derivatives have also been isolated and similarly identified.

EXPERIMENTAL

Reagents

N-*Bromosuccinimide solution*, ca. 0·02*M*. *N*-Bromosuccinimide (0·3560 g) was dissolved in the minimum amount of lukewarm water and the solution diluted to the mark with cold distilled water in a 100-ml volumetric flask and standardized iodometrically.[4] The solution was prepared fresh before use.

Sample solutions. Stock solution of each sample (re-crystallized if necessary) was prepared by dissolving an accurately weighed amount in 15 ml of glacial acetic acid, except for the sodium salts of Congo Red and Methyl Orange, which were dissolved in water. The solutions were made up to volume with water in 100-ml volumetric flasks. Portions of the stock solution to give 2–10 mg of sample were used for each determination.

Potassium iodide solution, 15%.

Starch solution, 1%.

Sodium thiosulphate solution, ca. 0·02*M*. Standardized with a standard solution of copper sulphate.

Table 1. Stoichiometric ratio of azo compounds and *N*-bromosuccinimide

Compound	Observed molar ratio		
Chrysoidine G	2·004	2·031	1·988
Butter Yellow	2·004	1·986	1·992
Congo Red	2·014	2·014	1·973
Chrysamine G	4·027	3·983	3·999
Methyl Orange	5·001	4·985	5·018
Methyl Red	5·001	4·984	4·987

Procedure

A portion of solution containing 2–10 mg of the sample was placed in a 100-ml iodine flask, 5 ml of glacial acetic acid and 10 ml of *N*-bromosuccinimide solution were added, the flask was stoppered, and the reaction was allowed to proceed for 10 min at room temperature. After the reaction was complete, 5 ml of potassium iodide solution were added and the liberated iodine was titrated with standard sodium thiosulphate solution, with starch as indicator. A blank experiment was run under identical experimental conditions.

The amount of azo compound was calculated by means of the expression

Amount of azo compound

$$= [(B - A) \times M \times \text{M.W.}]/[2000n]$$

where B = ml of thiosulphate (0·02*M*) used for blank, A = ml of thiosulphate (0·02*M*) used for sample, M.W. = molecular weight of the sample, M = molarity of thiosulphate solution, n = stoichiometric ratio of *N*-bromosuccinimide to sample compound.

RESULTS AND DISCUSSION

Chrysoidine G was chosen as the model compound and was found to react quantitatively with *N*-bromosuccinimide (error generally < 0·5%). The method was also applied to Butter Yellow, Congo Red, Chrysamine G, Methyl Orange and Methyl Red. The error is generally <1%.

Chrysoidine G and *N*-bromosuccinimide react in 1:2 molecular ratio. This can be explained in terms of the two amino-groups strongly activating the benzene ring in the molecule of Chrysoidine G. The *ortho-para* directing effect of the amino-groups causes the incoming bromine cations to substitute on the third and fifth carbon atoms of nucleus A while nucleus B remains deactivated and no substitution occurs.

Summary—Sulphide, sulphite and thiosulphate can be determined separately or in admixture, with thallic perchlorate or sulphate in acid medium. A sample solution is rendered ~0·5M in acid, 5 ml of 0·05M KI are added and the solution is titrated to a starch end-point with thallium(III) solution. In another method an acid sample solution is titrated with thallium(III) or iodine solution in the presence of indigo carmine indicator. The end-point is improved in the presence of Co(II).

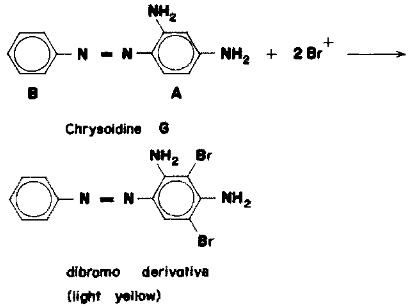
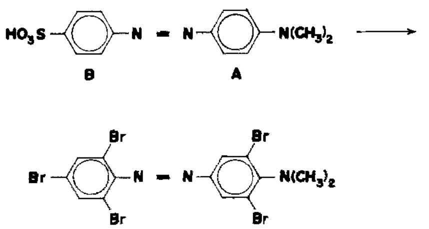
RESULTS AND DISCUSSION

Chrysoidine G was chosen as the model compound and was found to react quantitatively with *N*-bromosuccinimide (error generally < 0·5%). The method was also applied to Butter Yellow, Congo Red, Chrysamine G, Methyl Orange and Methyl Red. The error is generally <1%.

Chrysoidine G and *N*-bromosuccinimide react in 1:2 molecular ratio. This can be explained in terms of the two amino-groups strongly activating the benzene ring in the molecule of Chrysoidine G. The *ortho-para* directing effect of the amino-groups causes the incoming bromine cations to substitute on the third and fifth carbon atoms of nucleus A while nucleus B remains deactivated and no substitution occurs.



Hypotheses can also be advanced to account for the stoichiometry observed for the other reactions. For Methyl Orange, for example, the bromination proposed is



The *o*- and *p*-positions of nucleus A are activated by the $-N(CH_3)_2$ group and 2 atoms of bromine substitute at the free *ortho* positions. The nucleus B bears the electron-attracting $-SO_3H$ group and the electron density at positions *meta* to the $-SO_3H$ group increases, which facilitates the substitution at these two positions. Finally the $-SO_3H$ group is replaced by bromine. The pentabromo-derivative of Methyl Orange has been isolated and its structure identified and confirmed by infrared and NMR spectra.

Azo compounds are coloured but no difficulty has been experienced in detecting the end-point. However, it has been observed that azobenzene is not brominated with *N*-bromosuccinimide under the experimental conditions.

Because of the non-selectivity of the reagent, hydrazine, unsaturated compounds, amines, phenols, ascorbic acid, other azo compounds, *etc.* must be absent.

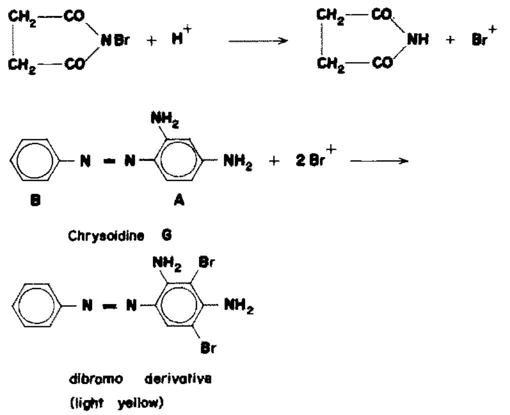
(*Received* 2 *September* 1975. *Accepted* 12 *September* 1975)

In the present paper we describe a new method for the determination of alkyl-1-biguanide, based on the use of a liquid-state Cu^{2+}-sensitive electrode. The construction and characteristics of the electrode have been described previously.[1–3] The method is based on the formation of complexes of the type $[Cu(Big)_2]X_2$ by the reaction between copper(II) ammine complexes with biguanides.[4]

There are a number of ways in which this method can be used for the determination of biguanides:

(*a*) use of an excess of copper(II) ammine in order to precipitate $[Cu(Big)_2]X_2$ and subsequent determination of the excess of Cu(II) in solution by potentiometric titration in presence of the Cu^{2+}-sensitive electrode;

(*b*) transformation of the biguanide salt into the free



Hypotheses can also be advanced to account for the stoichiometry observed for the other reactions. For Methyl Orange, for example, the bromination proposed is

(*Received* 2 *September* 1975. *Accepted* 12 *September* 1975)

In the present paper we describe a new method for the determination of alkyl-1-biguanide, based on the use of a liquid-state Cu^{2+}-sensitive electrode. The construction and characteristics of the electrode have been described previously.[1–3] The method is based on the formation of complexes of the type $[Cu(Big)_2]X_2$ by the reaction between copper(II) ammine complexes with biguanides.[4]

There are a number of ways in which this method can be used for the determination of biguanides:

(*a*) use of an excess of copper(II) ammine in order to precipitate $[Cu(Big)_2]X_2$ and subsequent determination of the excess of Cu(II) in solution by potentiometric titration in presence of the Cu^{2+}-sensitive electrode;

(*b*) transformation of the biguanide salt into the free

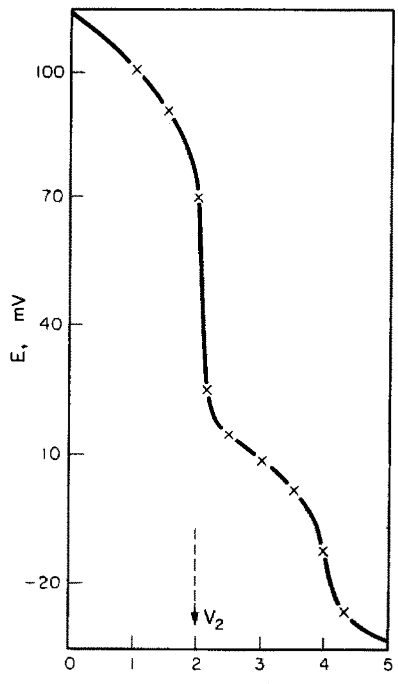

Fig. 1. Potentiometric titration curve of the ammoniacal mixture $[Cu(Big)_2]SO_4 + CuSO_4$ method (*a*).

base, which is then determined by direct potentiometric titration with an aqueous solution of $CuSO_4$, and use of the Cu^{2+}-sensitive electrode;

(*c*) separation of the water-insoluble complex and dissolution of a precisely known quantity in a suitable solvent and subsequent determination of Cu^{2+} in the solution by a convenient method.

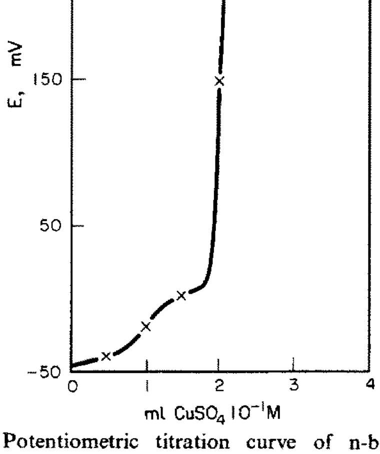

Fig. 2. Potentiometric titration curve of n-butyl-1-biguanide, method (*b*)

Table 1. Potentiometric determination of n-butyl-1-biguanide monohydrochloride

Taken, *mg*	Found, *mg*	Error, %
31·23	31·4	0·4
52·06	51·7	0·7
62·47	62·3	0·3
72·88	72·5	0·5
83·29	84·0	0·8
93·70	93·7	0·0
104·11	104·0	0·1

Methods (*b*) and (*c*) are more lengthy because a very accurate conversion of the biguanide salt into free base is needed. Also the filtration and drying are time-consuming and succeptible to errors.

In method (*a*) the $[Cu(Big)_2]SO_4$ complex is formed by adding an excess of ammoniacal $CuSO_4$ solution (with known titre) to an aqueous solution containing 30–100 mg of biguanide hydrochloride. The excess of Cu^{2+} is then determined by potentiometric titration with 0·1*M* EDTA, using the liquid-state Cu^{2+}-sensitive electrode.

We have studied the hydrochloride of n-butyl-1-biguanide which is the active component of the drug "Buformin". On the titration curve in Fig. 1 two potential jumps can be seen. They correspond to the excess of $CuSO_4$ and the complexed copper respectively. The quantity of n-butyl-l-biguanide monohydrochloride is given by

$$\text{n-butyl-1-biguanide.HCl} = 0{\cdot}03874(V_1f_1—V_2f_2)\text{g}$$

where V_1 is the total volume of 0·1*M* $CuSO_4$ solution added to precipitate $[Cu(Big)_2]SO_4$, f_1 is the factor of this solution, V_2 is the volume of 0·1*M* EDTA corresponding to the first potential jump (Fig. 1) and f_2 is the factor of this solution.

The application of the second method implies the quantitative conversion of n-butyl-1-biguanide hydrochloride into free base, by treatment with 0·1*M* NaOH of known titre; the n-butyl-1-biguanide is titrated potentiometrically with 0·1*M* $CuSO_4$. The potentiometric titration curve (Fig. 2) also shows two potential jumps.

The first of these is much smaller than the second, and corresponds to the formation of the 1: 1 soluble complex. The second jump ($\simeq$ 250 mV) is due to the formation of the insoluble complex $[Cu(Big)_2]SO_4$; 1 ml of 0·1*M* $CuSO_4$ corresponds to 0·03145 g of n-butyl-1-biguanide.

Tables 1 and 2 give the results of determinations by methods (*a*) and (b) respectively. The use of method (*a*) would have the advantage that the residual impurities remaining from the synthesis of the biguanide, such as dicyandiamide, n-butylguanidine, amines, *etc.* do not interfere in the determination.

The selectivity of the method has made possible the use of the electrode for the control of the synthesis of n-butyl-1-biguanide by following the concentration of the biguanide formed, directly in the reaction medium.

Table 2. Potentiometric determination of n-butyl-1-biguanide (free base)

Taken, *mg*	Found, *mg*	Error %
25·36	25·5	0·5
34·59	34·3	0·9
42·26	42·5	0·6
50·71	50·6	0·2
59·16	59·1	0·1
76·07	75·5	0·8

SPECTROPHOTOMETRIC DETERMINATION OF IMINODIACETIC ACID IN PRESENCE OF PRIMARY AMINO-ACIDS

S. N. BHATTACHARYYA and N. C. SAHA

Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 92 Acharya Prafulla Chandra Road,
Calcutta-700009, India

(*Received* 13 *June* 1975. *Accepted* 19 *September* 1975)

Several spectrophotometric and other methods[1–3] have been reported for the determination of amino-acids. None of them is, however, applicable to iminodiacetic acid, IDA, in presence of glycine and other primary amino-acids. The method proposed here is based on complex formation between IDA and ferric ions. Glycine also complexes ferric ion, but its interference can be eliminated by proper choice of pH and wavelength. Other primary amino-acids do not interfere.

EXPERIMENTAL

Reagents

Ferric alum was reagent grade. IDA was recrystallized from doubly distilled water. Fe(III)–IDA was prepared by mixing the requisite amounts of ferric alum and IDA, precipitated with alcohol and then recrystallized twice from doubly distilled water.

Procedure

To an aliquot of an unknown IDA solution, add a measured amount of ferric alum solution and dilute the solution to give a ferric alum concentration of $\sim 2{\cdot}5$–$3{\cdot}0 \times 10^{-4}M$, and an IDA concentration of ~ 1–$9 \times 10^{-5}M$ at pH 3·0–3·5. Measure the absorbance at 250 and 300 nm. The concentrations of iron(III) and IDA are chosen to give absorbances in the range 0·5–0·7.

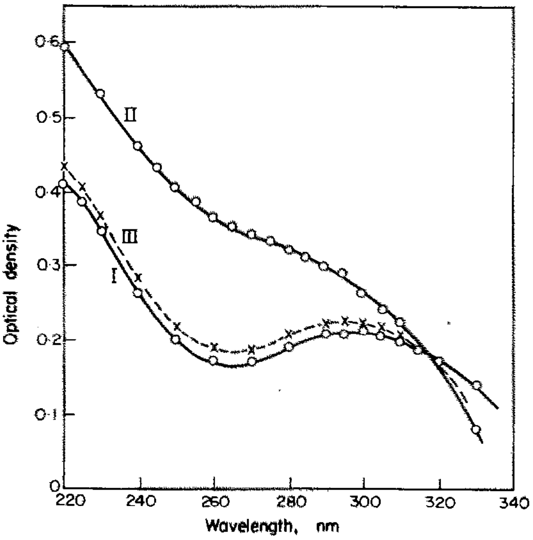

Fig. 1. Absorption spectra of (I), ferric alum; (II), (1:1) Fe(III)–IDA; and (III), (1:3) Fe(III)–GLY. pH = 3·0–3·5; $[Fe^{+3}] = 1 \times 10^{-4}M$.

RESULTS AND DISCUSSION

Figure 1 shows the absorption spectra of ferric alum, Fe(III)–IDA and Fe(III)–glycine complexes at pH 3·0–3·5. The ferric alum spectrum is characterized by a maximum at 300 nm and an identical absorbance at 250 nm. Fe(III)–glycine (1:3) also gives a similar, slightly more intense absorption spectrum. The spectrum of the Fe(III)–IDA (1:1) complex has no maximum but the absorbance at 250 nm is much higher than that at 300 nm.

All three systems obey Beer's law at the two selected wavelengths. Hence, if ϵ_1 and ϵ_2 are the molar absorptivities of Fe(III)–IDA at 250 and 300 nm respectively and A_{250} and A_{300} are the absorbances at 250 and 300 nm,

$$A_{250} - A_{300} = \Delta A = (\epsilon_1 - \epsilon_2)[\text{Fe–IDA}] = K[\text{IDA}] \qquad (1)$$

Thus a plot of ΔA *vs.* [IDA] serves as a calibration curve. K was found to be $1{\cdot}61 \times 10^3$ l. mole^{-1}. cm^{-1}. An IDA concentration as low as $\sim 10^{-5}M$ can be determined with a fair degree of accuracy.

The pH has an effect in the system, being optimum over the range 3·0–3·5. At pH greater than 3·5, the excess of iron(III) hydrolyses and at pH less than 3·0, ΔA for Fe(III)–IDA diminishes slightly. The accuracy of the method is further dependent upon the correct selection of the shorter wavelength such that there is automatic correction for the

$$\begin{aligned} A_{250} - A_{300} &= \Delta A = (\epsilon_1 - \epsilon_2)[\text{Fe–IDA}] \qquad (1) \\ &= K\,[\text{IDA}]. \end{aligned}$$

Thus a plot of ΔA *vs.* [IDA] serves as a calibration curve. K was found to be $1\cdot61 \times 10^3$ l. mole^{-1}, cm^{-1}. An IDA concentration as low as $\sim 10^{-5}M$ can be determined with a fair degree of accuracy.

The pH has an effect in the system, being optimum over the range 3·0–3·5. At pH greater than 3·5, the excess of iron(III) hydrolyses and at pH less than 3·0, ΔA for Fe(III)–IDA diminishes slightly. The accuracy of the method is further dependent upon the correct selection of the shorter wavelength such that there is automatic correction for the

Ni(II)	1:2	80·0	81·0	+1·3
Cr(III)	1:3	90·0	91·5	+1·7
Cr(III)	1:2	80·0	80·5	+0·6

absorbance of the excess of iron(III) and of the iron(III)–glycine complex. This shorter wavelength was found to lie in the range 250 ± 2 nm. It should therefore be separately determined for each experimental arrangement.

Table 1 shows the effect of primary amino-acids, *e.g.*, glycine and alanine. The amino-acid:IDA mole ratio was varied from 1:4 to 1:1. It is evident from the results that the method is very promising in these cases too. Probably the metal complexes of the primary amino-acids are not stable at pH 3–3·5 or else ΔA then is negligible.

It is sometimes necessary to determine IDA in the presence of metal ions, so the effect of some chosen metal ions was also studied. Metal ion complexes of IDA which are not stable at the pH range used or from which the metal ion can be easily displaced by ferric ion, do not interfere. Table 2 shows some typical results; it is evident that the metal ions under study do not interfere seriously.

It can be claimed that the method is very simple, reproducible and is easily adaptable.

Acknowledgement—The authors are grateful to Professor A. K. Saha for his kind encouragement.

ANALYTICAL CHEMISTRY OF UNUSUAL OXIDATION STATES: THE POLAROGRAPHY OF VANADIUM(IV) IN CYANIDE MEDIUM

J. Hernandez Mendez, A. Sanchez Misiego and F. Lucena Conde

Department of Analytical Chemistry, Faculty of Science, Analytical Chemistry Section of the Consejo Superior de Investigaciones Cientificas (C.S.I.C.) Salamanca, Spain

(*Received* 28 *September* 1973. *Revised* 28 *June* 1975, *Accepted* 3 *September* 1975)

This paper, which reports the results of a continued investigation of the analytical chemistry of some unusual oxidation states,[1] is concerned with the polarography of vanadium(IV) in cyanide medium. Irreversible oxidative and reductive waves have been reported for vanadium(IV) in strongly alkaline medium.[2–4] Lingane and Meites[5] studied the polarography of several oxidation states of vanadium in a number of supporting electrolytes, and at different pH's. Vanadium(III) was found to give two rather poorly shaped waves with $E_{\frac{1}{2}}$ at −1·17 and −1·77 V *vs.* SCE, being reduced to an unknown species of vanadium(II). There are no previous reports of the polarography of vanadium(IV) in cyanide medium.

EXPERIMENTAL

Apparatus

A Sargent Model XVI polarograph was used together with a dropping mercury electrode (DME) and a saturated calomel electrode (SCE) in the measurement cell. The characteristics of the capillary were: $m = 2{\cdot}83$ mg/sec, $t = 3{\cdot}2$ sec, at 25° in 1*M* potassium cyanide with ionic strength adjusted to 3·0 by addition of sodium sulphate, and with height of column = 58 cm. Nitrogen was bubbled first through a solution of vanadium(II) to remove oxygen, then through a phosphate-buffered cyanide solution to saturate it with hydrogen cyanide in equilibrium with that pH, then through the solution under investigation.

Procedure

A stock solution of vanadium(IV) was prepared by dissolving $VOSO_4.5H_2O$ in 0·09*N* sulphuric acid. A suitable volume of this was taken, potassium cyanide was added, first to neutralize the acidity and then to give the desired cyanide concentration for the experiment. Sodium sulphate was added to adjust the ionic strength to 3·0 (or other value as required) and a drop of 1% gelatin solution to suppress a small maximum. Nitrogen was bubbled through the solution, and after 15–20 min the polarogram was recorded, with the polarograph and a potentiometer.

RESULTS

Effect of the vanadium concentration

Over the range 8×10^{-5}–$1{\cdot}5 \times 10^{-2}M$ for vanadium, the wave-height is strictly proportional to concentration, with a slope of 7·36 μA.l.mmole^{-1} (standard deviation 4%). The temperature coefficient is about 1%/deg. The proportionality to the square-root of the height of the mercury column confirmed that the electrode process was diffusion-controlled.

These results and their reproducibility, together with the good development of the waves and their broad diffusion range, allow us to propose a new polarographic method for the determination of vanadium, the recommended procedure being that used in this paper. The precision and accuracy are within the usual limits for classical polarography, and minimal for 10^{-5}–$10^{-2}M$ vanadium in >0·5*M* cyanide medium at 10–50°, the polarography being performed within an hour of the addition of cyanide. It is necessary to work at constant ionic strength.

An experiment involving coulometric reduction of the vanadium with repeated scanning of the polarograms between electrolyses revealed that two electrons were involved in the reduction. From this figure, and the capillary parameters already mentioned, the diffusion constant *D* in the Ilkovič equation was calculated to be $6{\cdot}2 \times 10^{-6}$ cm^2/sec.

Effect of the cyanide concentration

A $2 \times 10^{-3}M$ vanadium(IV) solution gave a wave-height increasing steadily from 14 μA in 0·5*M* cyanide to 15 μA in 1·5*M* cyanide, thereafter remaining constant (Table 1). In 0·2*M* cyanide the polarogram was ill-defined, and in 0·4*M* the wave-height was 11 μA. As the pH is quite high (10–11) it is likely that the vanadium(IV) is partially oxidized before the nitrogen is passed, when there is not much cyanide present, and in some of these solutions a turbidity suggested that the vanadium was precipitating.

The half-wave potential

Logarithmic plots of log $i/(i_d\text{-}i)$ against potential gave straight lines with slopes of about 90 mV, and $E_{\frac{1}{2}}$ values varying from −1·15 V in 0·5*M* cyanide to −1·10 V in 2·86*M* cyanide. Experimental values are tabulated in Table 2. The slopes suggested that the reduction was irreversible. Matsuda and Ayabe have deduced a general expression for the current–voltage curve for all reactions, reversible and irreversible,[6] and have shown how it can be used for the analysis of polarograms.[7] Over most of the wave, their expression simplifies to

$$E = (E_{\frac{1}{2}})_{\mathrm{irr}} - 2{\cdot}3\,\frac{RT}{\alpha nF}.\log\frac{i}{i_1 - i} \tag{1}$$

The factor α is termed the transfer coefficient for an irreversible electrode reaction. The variation of $(E_{\frac{1}{2}})_{\mathrm{irr}}$ with ligand concentration is given by

$$(E_{\frac{1}{2}})_{\mathrm{irr}} = 2{\cdot}3\,\frac{RT}{\alpha nF}\left[\log\frac{(k_f^0)f_N}{D_N} + \tfrac{1}{2}\log t - 0{\cdot}053 - \log\left(\frac{i_1}{i_d}\right) - (N - p)\log(f_X C_X)\right] \tag{2}$$

where (k_f^0) is the rate constant for the slow reaction at the electrode, *N* is the number of ligands bound to the

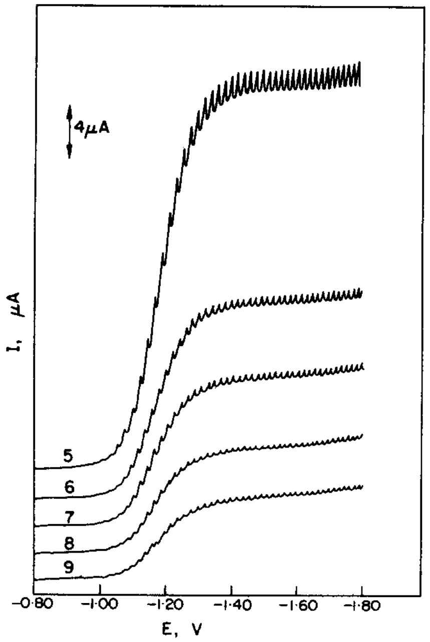

Fig. 1. Polarograms of $V^{(IV)}$ in cyanide 1·0*M* temperature 25°C, gelatine 0·05%, $V^{(IV)}$ concentration: (5)—$4 \times 10^{-3}M$; (6)—$2 \times 10^{-3}M$; (7)—$1{\cdot}5 \times 10^{-3}M$; (8)—$10^{-3}M$; (9)—$0{\cdot}8 \times 10^{-3}M$.

central ion in the species predominating in the solution and p the number in the species undergoing reduction after the dissociation step, f_N and D_N are the activity coefficient and diffusion coefficient respectively of the species MX_N and f_X and C_X are the activity coefficient and bulk concentration of the ligand X. The drop-time is denoted by t. As the limiting current is strictly diffusion-controlled in this case the term i_l/i_d becomes unity and its logarithm zero. From equation (1), assuming $n = 2$, we can solve to find α, which in this case is around 0·3 (see Table 2).

By combining equations (1) and (2) we get the simple relationship

$$N - p = \frac{\Delta \log \dfrac{i}{i_d - i}}{\Delta \log(f_X C_X)} \qquad (3)$$

Values for $(N - p)$ obtained by using this equation are also presented in Table 2. The considerable variation in these values makes it hard to come to any conclusion regarding the species involved in the reactions, though the figures do suggest that one cyanide ion is added to the complex species when reduction takes place in about 2*M* potassium cyanide solution.

* Arithmetical mean of three measurements.

The rate constant k_f^0 for the reduction step can be found from equation (2), and takes the value $10^{-14{\cdot}2}$ cm/sec for 2*M* cyanide solution.

Two simple experiments were carried out to determine the formal potential $(E^0)_B$ for the V(IV)/V(II) system in cyanide solution. In the first, the potential was measured after mixing equal volumes of equimolar vanadium(II) and vanadium(IV) solutions in the presence of 2*M* cyanide, and in the second, vanadium(II) in 2*M* cyanide solution was titrated potentiometrically with hexacyanoferrate(III) solution. In both experiments, the formal potential was found to be −0·70 V *vs.* SCE. The difference between this and the $(E_{\frac{1}{2}})_{irr}$ of −1·1 V certainly indicates the highly irreversible nature of this reduction.

The rate constant $(k_O)_B$ of the overall process is given by

$$(K_G)_B = (k_f^0)_B \exp\left[-\frac{\alpha n F}{RT}(E^0)_B\right]$$

and has the value $10^{-6{\cdot}87}$ cm/sec, positive proof that the reduction is irreversible.

The literature on cyanide complexes of vanadium is not very extensive, and what there is contains many contradictions. Virtually all the facts relate to solid species, usually produced by precipitation from non-aqueous media, and statements concerning ionic species are largely hypothesis. So much faith is placed in spectroscopic observation and prediction, in spite of lack of confirmation by analytical data[8] that it has taken X-ray structure analysis in one case[9] to prove that the complex cyanide of vanadium(III) is in fact $V(CN)_7^{4-}$. Solid potassium hexacyanovanadate(II) $K_4V(CN)_6$ is well characterized[10] but reacts with water to give a brown precipitate. The heat of formation of a soluble vanadium(II) cyanide complex has been reported[11] but without any proof of the constitution of the species.

Rivenq found that a solution of vanadium(IV) titrated with cyanide gave a precipitate, with a cyanide to vanadium ratio of 2:1, which subsequently dissolved in an excess of cyanide.[12] He suggested the formula $VO(CN)_6^{4-}$ for this species, but this does not lie up with the formula $Cs_3VO(CN)_5$ reported for a blue crystalline salt described by Bennett and Nicholls.[13]

If the $N - p$ value of −1 means anything, it would fit the requirements for the reaction

$$VO(CN)_5^{3-} + 2e + H^+ \rightarrow V(CN)_6^{4-} + OH^-$$

between hypothetical ions predicted on the basis of two known solid compounds. A reduction of an oxo-species to a simple metal complex would be expected to be irreversible. But there is nothing to suggest why reduction should be to vanadium(II) instead of to vanadium(III).

Summary—The polarographic reduction wave for vanadium(IV) in cyanide medium has been studied and the effect of cyanide concentration on the diffusion current and half-wave potential has been interpreted, using the theory of irreversible but diffusion-controlled reduction. Coulometric experiments suggest a two-electron transfer, and the shift of half-wave potential corresponds to the addition of one cyanide ion during the reduction step. The proportionality of wave-height to vanadium concentration in the used alkaline cyanide medium indicates a possible analytical unity. The half-wave potential is about −1·1 V.

A REFINED CHEMICAL ANALYSIS OF $SnF_2.AsF_5$

B. SEDEJ

J. Stefan Institute, University of Ljubljana, Ljubljana, Yugoslavia

(*Received* 20 *August* 1975. *Accepted* 12 *September* 1975)

Studies of the systems MF_2–AsF_5–HF, where M is any bivalent metal, carried out in this laboratory, have resulted in the isolation of a number of compounds of the type $MF_2.AsF_5$. Compounds of this particular composition might be discussed either in terms of ionic formulations such as $M^{2+}F^-AsF_6^-$, $MF^+AsF_6^-$ or in terms of covalent, fluorine-bridged structures $FMF.AsF_5$. The true nature of the compounds can only ultimately be determined by a crystal structure investigation but so far, it has not been possible to isolate crystals suitable for crystallographic work.

However, by chemical analysis simple direct evidence for the presence of free fluoride on the one hand and hexafluoroarsenate on the other can be obtained, since both can be determined separately. Known methods of analysis are not directly applicable to this problem and we describe here the modifications made to the methods for chemical analysis of $SnF_2.AsF_5$, which was taken as the first test compound since on the basis of its vibrational spectra it was formulated as a salt of the fluorine-bridged polycation $(Sn–F)_n^{n+}$ with the AsF_6^- anion,[2] and more recently as $[Sn–F]^+[AsF_6]^-$.[1]

EXPERIMENTAL

Reagents and apparatus

Tetraphenylarsonium chloride solution, 6·7% *w/v*.
Cupferron solution, 5%.
Sodium hydroxide solution.
Ammonia solution.
Sulphuric acid, 75% *v/v*.
Thorium nitrate standard solution, 0·0125*M*.
Methylthymol Blue, 0·2% *solution in* 75% *methanol.*
TISAB buffer.
CBS buffer.

All reagents and standard solutions were of analytical-reagent grade. The fluoride content was also determined with a fluoride ion-selective electrode (Orion No. 94–09) in conjunction with a reference electrode (Orion No. 90–01) and digital pH-meter (Orion Model 801). The analytical methods employed were all checked against official standards.

Procedures

$SnF_2.AsF_5$ is a very sensitive material and rapidly hydrolyses in moist air. Samples were therefore weighed into air-tight Teflon containers in a dry-box. Before the hydrolysis in alkaline solution these were cooled to liquid-nitrogen temperature in order to moderate the violent reaction with water.

Total fluorine in the solution of the hydrolysed sample was determined by a modified distillation method.[3–5] The sample was decomposed by 75% sulphuric acid in the presence of silica sand within 6 hr in a distillation apparatus which permitted recycling of water vapour. The distillate containing sodium hexafluorosilicate was titrated with 0·0125*M* thorium nitrate in the presence of Methylthymol Blue indicator. The results obtained in several parallel determinations were within the permitted experimental error (see Table 1).

to a simple metal complex would be expected to be irreversible. But there is nothing to suggest why reduction should be to vanadium(II) instead of to vanadium(III).

All reagents and standard solutions were of analytical-reagent grade. The fluoride content was also determined with a fluoride ion-selective electrode (Orion No. 94–09) in conjunction with a reference electrode (Orion No. 90–01) and digital pH-meter (Orion Model 801). The analytical methods employed were all checked against official standards.

Procedures

$SnF_2.AsF_5$ is a very sensitive material and rapidly hydrolyses in moist air. Samples were therefore weighed into air-tight Teflon containers in a dry-box. Before the hydrolysis in alkaline solution these were cooled to liquid-nitrogen temperature in order to moderate the violent reaction with water.

Total fluorine in the solution of the hydrolysed sample was determined by a modified distillation method.[3–5] The sample was decomposed by 75% sulphuric acid in the presence of silica sand within 6 hr in a distillation apparatus which permitted recycling of water vapour. The distillate containing sodium hexafluorosilicate was titrated with 0·0125*M* thorium nitrate in the presence of Methylthymol Blue indicator. The results obtained in several parallel determinations were within the permitted experimental error (see Table 1).

It was found that the distillation residue could not be used for the determination of tin or arsenic because metastannic acid precipitated out of the solution during the distillation.

On a separate sample, hydrolysed in dilute sulphuric acid, AsF_6^- was precipitated by tetraphenylarsonium chloride.[6] The results obtained, however, were too high because tin was co-precipitated under these conditions. Attempts to mask tin with many of the known agents for tin[7] were not successful.

We found, however, that tin could be masked by using a mixture of sodium citrate and EDTA at pH 5–5·5. The results obtained were checked against determinations of AsF_6^- in the filtrates obtained after tin had been precipitated by ammonia. The AsF_6^- content in samples determined either way corresponded well with calculated values for $SnFAsF_6$.

Tin was determined gravimetrically by precipitation with both ammonia and cupferron.[8] As expected, the results of this standard method agreed well with the calculated value. In order to check whether the precipitation of tin is quantitative in the presence of fluoride and hexafluoroarsenate, a standard solution containing tin, potassium hexafluoroarsenate and ammonium fluoride was made. The determinations of tin content in this solution by the methods above gave results which were within the limits of experimental error.

Since the gravimetric method is rather time-consuming a considerable effort was applied to investigation of the applicability of complexometric determination of tin.[9–12] The results were discouraging. The presence of fluoride and perhaps also of hexafluoroarsenate interfered with the titration. If fluoride was removed by fuming with sulphuric acid, either deposits of metastannic acid were formed or tin was partly lost by volatilization.

In order to determine the free fluoride ion or fluoride bound as SnF^+ species in our samples, limiting cases were first examined. A number of standard solutions of suitable concentrations were made. One was a solution of tin difluoride in which the fluoride content was determined both by the distillation method and by ion-selective electrode.[13,14] In both cases the results were comparable. However, in a solution of potassium hexafluoroarsenate the ion-selective electrode could not detect free fluoride, whereas the distillation method gave the theoretical results. The hexafluoroarsenate ion is therefore stable and does not dissociate under the conditions of the measurement. Consequently, free fluoride can be determined quite easily in the presence of the hexafluoroarsenate species.

In the solutions of $SnF_2.AsF_5$ we were able to determine free fluoride with the ion-selective electrode and total fluorine content by the distillation method. The results of the analyses are presented for comparison in Table 1.

It is concluded that, in solution, the adduct $SnF_2.AsF_5$ should be regarded as either $[Sn]^{2+}[F]^-[AsF_6]^-$ or $[SnF]^+[AsF_6]^-$. This analytical information, in conjunction with vibrational spectroscopic data for the solid[1] suggests that the latter is the more likely formulation.

Acknowledgement—The samples of $SnF_2.AsF_5$ were kindly prepared by Mrs. D. Gantar. The author is indebted to Dr. B. Frlec for useful discussion and support. This work was financed through the Boris Kidrič Foundation.

Summary—Combination of analyses using an ion-selective electrode and a distillation method make it possible to determine free fluoride in the presence of AsF_6^- in an adduct such as $SnF_2.AsF_5$, thus contributing to the structural information about the compound in solution. Other methods for the total analysis of the compound are described.

(*Received* 11 *June* 1975. *Accepted* 4 *September* 1975)

A large number of reagents have been proposed for the determination of palladium(II).[1–3] This study shows that 1-substituted-4,4,6-trimethyl-(1H,4H)-2-pyrimidinethiols (**I–VI**) are highly selective for Pd(II). In the presence of strong acids, the Pd(II) complexes are extractable into non-polar solvents without interference from large concentrations of other platinum-group metals. For simplicity and selectivity combined, the proposed method for determination of Pd(II) seems to be better than any other spectrophotometric procedure, but it does lack sensitivity.

(**I**) R = H
(**II**) R = C_2H_5
(**III**) R = n-C_4H_9
(**IV**) R = C_6H_5
(**V**) R = $C_6H_4OCH_3$(anisyl)
(**VI**) R = *p*-$C_6H_4NO_2$

EXPERIMENTAL

Reagents

2-Pyrimidinethiols were prepared by the method of Mathes.[4] Their standard solutions (0·01M) were prepared by dissolving appropriate amounts in chloroform. Anhydrous $PdCl_2$ (Johnson Matthey) was dissolved in 1·0N hydrochloric acid and standardized gravimetrically. All other solutions were prepared with analytical grade reagents. Doubly distilled water was used throughout the work.

Spectral characteristics

Solutions of all the pyrimidinethiols except (**VI**) are virtually colourless. That of (**VI**) is light yellow. When a few drops of pyrimidinethiol solution (in any non-polar solvent such as chloroform, benzene or carbon tetrachloride) are added to acidic Pd(II) solution, an extractable yellow complex is formed. All the complexes have λ_{max} at 430 nm. At least a 20-fold molar excess of pyrimidinethiol is required for complete development of the colour (Figs. 1 and 2). The other characteristics of the complexes are summarized in Table 1. The data show that there is a slight increase in sensitivity with increase in molecular weight of the ligand in alkyl (**I–III**) or aryl (**IV–VI**) substituted compounds.

* Of the absorbance for 10·7 ppm palladium.

Composition

The molar composition of the complexes was established by the methods of continuous variations and mole ratio. All the complexes contain palladium and pyrimidinethiol in a 1:4 ratio. This indicates that the ligands are probably acting as monodentate by complexation through the sulphur atom of the thiol group. The poor sensitivity of the ligands (Table 1) may also thus be explained.

Procedure

To a suitable aliquot of Pd(II) solution (Table 1), add 3–4 ml of 10*N* hydrochloric acid, dilute to 10 ml, add 10·0 ml of pyrimidinethiol solution (0·01*M* in chloroform) and shake for about 20 min. Allow to settle and remove the organic layer. Measure its absorbance at 430 nm against a reagent blank and calculate the metal concentration by comparing with a calibration graph.

Interferences

In determination of 10·7 ppm of Pd(II) with these thiols, at least 10^4 ppm of the following ions did not interfere: F^-, Cl^-, Br^-, NO_3^-, ClO_4^-, SCN^-, CH_3COO^-, SO_4^{2-}, $C_2O_4^{2-}$, tartrate, EDTA, BO_3^{3-}, PO_4^{3-}, citrate, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}, Al^{3+}, Fe^{2+} or Fe^{3+}. The presence of 5000 ppm each of Zn^{2+}, Cd^{2+}, Hg^{2+}, Sn^{4+}, V^{4+}, Mo^{6+}, Co^{2+} and Ni^{2+} could also be tolerated. Other platinum-group metals which could be tolerated are Ru^{3+}, Rh^{3+}, Ir^{3+} and Pt^{4+} (1100–1500 ppm) and Os^{8+} (100 ppm). Also 4000 ppm Cu^{2+}, 5 ppm Ag^+, 10 ppm Au^{3+} and 200 ppm NO_2^- were without interference. However, the anions I^-, CN^- and $S_2O_3^{2-}$ and also thiourea should be absent.

PRELIMINARY COMMUNICATION

DYNAMIC SURFACE TENSION MEASUREMENTS FOR THE ASSESSMENT OF POTABLE WATER QUALITY

G. Loglio , U. Tesei, A. Ficalbi and R. Cini

Institute of Physical Chemistry, University of Florence, Via Gino Capponi 9,
50121 Florence, Italy

(*Received* 28 *January* 1976. *Accepted* 11 *February* 1976)

The separation and identification of all individual surfactants is a difficult problem in water analysis.[1] Normally, pollution due to such materials is stated in terms of the equivalent concentration of a standard reference substance, which may differ chemically considerably from those substances actually present. On the other hand, it is important to note that different surfactants, at the same concentration, can affect the surface properties of water to a varying degree (even hundredfold differences are encountered). In our opinion this fact, which has heretofore been neglected in environmental studies, should be considered. In particular, we feel that the surface activity of substances present in water (that is, their capacity to change the excess surface free energy) can be a significant physical quantity in the assessment of the quality of water, in addition to the other chemical and physical quantities usually considered.

In this paper we have two aims: 1) to propose a parameter correlated with surface activity, which can be of practical use for the routine examination of potable water; 2) to reveal the significance of the surface activity in studies concerning pollution by surfactants.

EXPERIMENTAL

The concentration of anionic surfactants was determined according to the method of Longwell and Maniece,[2] of non-ionic surfactants according to the method of Greff et al.[3]

The dynamic surface tension of potable water samples was measured by a Langmuir apparatus with a recording electrobalance, following a procedure already described. Care was taken to avoid mistakes due to adsorption on the walls of the sample vessel.

RESULTS AND DISCUSSION

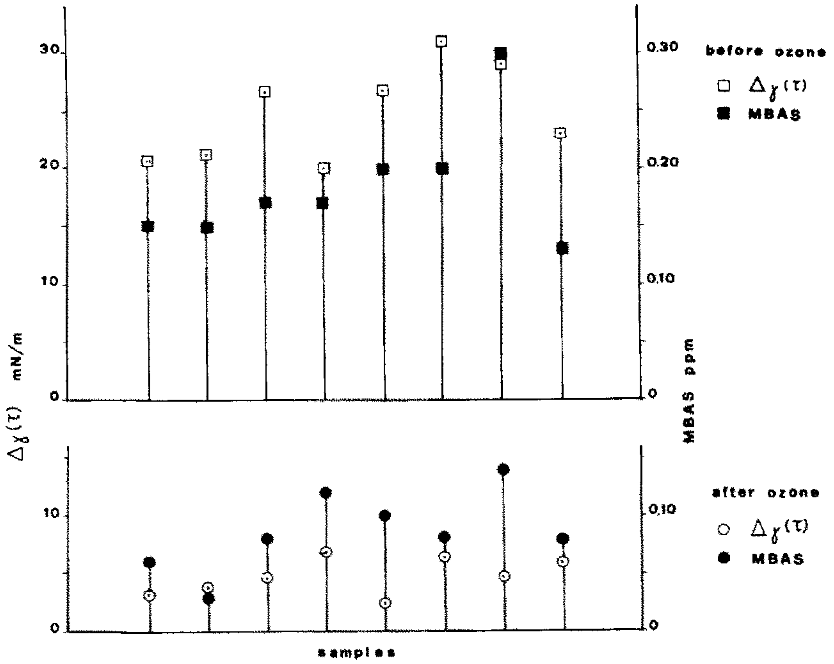
Parameter related to surface activity. The surface activity of a substance dissolved in water, defined as $-\lim d\gamma / dc$,[5] can be approximately determined for dilute solutions by the ratio $\Delta\gamma / c$, between the difference of the surface tension of the solution with respect to pure water and the concentration. The static surface tension is the appropriate quantity involved in this determination. However for potable water, in which the concentration of surfactants is normally very low ($c < 0.5$ ppm), the measurement of $\Delta\gamma$ (static) is not practical (a rigorous experimental procedure is required to obtain reproducibility and accuracy). Having in mind the importance of practicability in routine analysis, we take into consideration the dynamic surface tension, rather than the static one, for the investigation of the surface activity of substances present in water at very low concentratio levels. When the surface area of a solution of surfactants is decreased rapidly, there is a concomitant decrease of the surface tension, $\Delta\gamma$.[6] Following such a process, the value of $\Delta\gamma$ changes as a function of time. This function contains, among other quantities, the concentration and the surface activity.[7] Actually, for a given substance at various concentrations, the value of $\Delta\gamma(\tau)$, taken at a certain instant τ, increases roughly proportionally to c. Moreover, for different substances at the same concentration, the value of $\Delta\gamma(\tau)$ is a monotonically increasing function of the surface activity. Thus, we can take the ratio $\Delta\gamma(\tau)/\sum c_i$ as a parameter related to surface activity (SA), even if the latter cannot be determined from such a ratio. The most surface active substances are the predominant contributors to the value of SA, whereas those which are less so give negligible contributions.

Reproducibility of $\Delta\gamma(\tau)$ values is satisfactorily attained by standardization of sampling and measuring procedures.

Surface activity of substances in potable water. The figure shows values of $\Delta\gamma(\tau)$ and of MBAS (Methylene Blue Active Substances) relative to eight pairs of samples of potable water taken on different days from a municipal water treatment plant (fed from a river). Placing the respective segments on the same line, the figure also allows the visualization of the value of SA, that is, the parameter of surface activity (all samples were found to be free of non-ionic surfactants; therefore the value of MBAS was taken as the value of $\sum c_i$). The upper (lower) diagram concerns samples taken before (after) continuous flow treatment of the water with ozone.

As can be seen in both diagrams, for samples which have equal, or almost equal, MBAS values, the SA parameter can have values which are equal in some cases or very different in other cases (the differences quite exceed measurement errors). This means that, whereas the overall molar concentration of the surfactants is the same, the nature of the substances present, or, at least, the percentage concentration of each of them, varies

A comparison of the two diagrams shows that the MBAS values decrease by about 50 % following ozone treatment. If the nature of the substances remained the same, even though the concentration was halved, the same SA values would be expected before and after



ozone treatment. On the contrary, the SA values are drastically reduced. Thus ozone treatment, while reducing the molar concentration of the substances present, probably also changes to a large degree their chemical nature.

The above experimental results show that the SA parameter gives information concerning the nature of the substances present in water. Such information is additional to that given by the MBAS concentration parameter. On the basis of this consideration, we can conclude that the surface activity (or a parameter with relation to it) is a significant physical quantity in environmental studies. Moreover, pollution by surfactants can be more conveniently defined in terms of both the concentration and the peculiar property of these materials of modifying the excess surface free energy of water.

DETERMINATION OF LANTHANIDES AND YTTRIUM IN ROCKS AND MINERALS BY ATOMIC-ABSORPTION AND FLAME-EMISSION SPECTROMETRY*

J. G. SEN GUPTA
Geological Survey of Canada, Ottawa, Ontario K1A OE8, Canada

(*Received* 1 *April* 1975. *Accepted* 14 *August* 1975)

Summary—The sensitivity of atomic-absorption and flame-emission determination of lanthanides and yttrium is improved by a factor of 2–5 when an absolute ethanol solution of the perchlorate of the metal (instead of an aqueous solution) is aspirated into a nitrous oxide–acetylene flame. Based on this, a method has been developed for accurate determination of small amounts of certain rare earths and yttrium. Lanthanum (1%) is used as a spectroscopic buffer to eliminate interferences and to enhance the sensitivities in certain determinations. Where the use of lanthanum is not practicable because of interferences (such as in the determination of praseodymium and samarium by flame emission), sodium (2000 ppm) is used as the spectroscopic buffer. Studies with synthetic solutions indicate that yttrium and most lanthanides can be directly determined in minerals without any chemical separation. With rock samples it is necessary to preconcentrate the traces of the rare earths by fluoride or oxalate precipitation with calcium as the carrier, followed by removal of calcium by hydroxide precipitation using mg amounts of iron as the carrier. The method developed has been applied to the determination of certain lanthanides and yttrium in a variety of rocks, including the Canadian reference rocks, syenites SY-1, SY-2 and SY-3, and some minerals such as britholite, cenosite, chevkinite, allanite, apatite and sphene.

Studies on the geochemistry of the rare earths by the Geological Survey of Canada required the determination of these elements in a variety of rocks and minerals. Owing to the similarity of chemical properties of the rare earths, separation of the individual elements before determination is very difficult and time-consuming. For this reason the trend in the determination of rare earths during the past two decades had been to separate them *en masse* by ion-exchange or co-precipitation with a carrier such as calcium, aluminium of iron before determination by emission spectrography[1–4] or X-ray fluorescence.[5–7] In neutron-activation analysis a post-irradiation ion-exchange separation of the rare earths is favoured.[8–10] Recently, when the usefulness of the nitrous oxide–acetylene flame in atomic-absorption and flame-emission determination of the refractory elements was discovered, the detection limits for various rare earths in these flames were studied and recorded.[11–16] Among others, the work of Hingle *et al.*,[14] which involved flame-emission studies of the perchlorates of the rare earths in ethanolic solution in a separated nitrous oxide–acetylene flame, appeared promising because of its ability to detect very low levels of the rare earths. But since the full potentiality of this method had not been explored, by use of atomic absorption, and no mention of its application to the analysis of rocks and minerals was found in the work of Hingle *et al.*, it was thought worthwhile to investigate this method. The present paper is the result of such an investigation.

Thus a method has been developed which allows the determination of ppm levels of most lanthanides and yttrium in rocks. Also the concentration of most rare earths in minerals can be determined by this method directly on the sample solution, obviating the necessity of separation from other common elements and from each other.

EXPERIMENTAL

Apparatus

A modified Yechtron AA-3 atomic-absorption spectrophotometer, equipped with an IM-5 amplifier–read-out unit, a Hamamatsu R-213 photomultiplier tube, a variable-flow nebulizer and a Teflon spray-chamber, was used. An uptake rate of 4 ml/min was maintained throughout the work. A Goguel-type[17,18] water-cooled ridge-slot burner head (slot length 7·4 cm) mounted on a Techtron AA-5 burner mounting was employed. For flame-emission measurements, a 285-Hz chopper was installed between the second lens and the monochromator slit, and a six-speed wavelength-scanning system was attached to the monochromator. All measurements were recorded on a photovolt Varicord Linear/Log Model 43 recorder. ASL and Westinghouse shielded hollow-cathode lamps were used for atomic-absorption measurements. A nitrous oxide–acetylene flame was used in both atomic-absorption and flame-emission studies. The nitrous oxide pressure was kept at 15 psig and the acetylene pressure and the burner position were varied to provide maximum signal (the "red feather" was never allowed to disappear from the flame).

‡ Not determined.

Operating parameters and sensitivities

Instrumental parameters and sensitivities for the rare earths are recorded in Table 1. The sensitivity data were obtained by spraying into the nitrous oxide–acetylene flame a perchlorate solution of the rare earth in absolute ethanol, the solution being buffered by 1% lanthanum. A comparison with other published sensitivity values (see Table 1) reveals the superiority of the present method. After this work was completed, a paper by Ooghe and Verbeek[19] came to the author's notice in which they reported spraying an 80% methanol solution of the rare earth chlorides (buffered with sodium or potassium) into the nitrous oxide–acetylene flame and obtaining much higher sensitivities than those reported by Jaworowski *et al.*[11] who used similar solutions without any spectroscopic buffer.

Reagents

Rare earth stock solutions. Dissolve an accurately weighed quantity of a spectroscopically pure rare earth oxide in dilute nitric acid and evaporate the solution to dryness on the steam-bath. Add a small quantity of perchloric acid and evaporate again to a moist residue. Cool in a desiccator charged with silica gel, dissolve the residue in absolute ethanol and dilute to a suitable volume. Transfer 1–2 ml of the stock solution, containing not more than 5 mg of rare earth oxide per ml, to a 10-ml weighed platinum crucible and leave at room temperature till evaporated to a moist residue. Carefully heat the bottom of the crucible with a small flame until the perchloric acid vapour is completely expelled. Ignite at 1000°, cool and weigh on a microbalance, using a similar platinum crucible as the tare Dilute an aliquot of the standardized stock solution to a definite volume with absolute ethanol so that the rare earth concentration in μg/ml is an integral number.

Lanthanum buffer. Dissolve, by heating, a sufficient quantity of lanthanum oxide (purity 5–9 s) in dilute hydrochloric acid to give an equivalent of 5·85 g of La_2O_3 per 100 ml of total final volume. Evaporate the solution to small volume, add 10 ml of 60% perchloric acid and evaporate to a moist residue. Cool, add 25 ml of absolute ethanol, break up the lumps with a glass rod to a fine powder and dissolve by stirring. Filter, if necessary, through a Whatman No. 40 filter paper and wash with absolute ethanol. Dilute to volume (100 ml for 5·85 g of La_2O_3) with absolute ethanol. Take a small aliquot in an ignited and weighed platinum crucible, evaporate and ignite to constant weight at 1000° to establish a correction factor for water and carbon dioxide, if any.

Sodium (10000 ppm) buffer. Dissolve $NaClO_4 \cdot H_2O$/ (6–12 g) in 100 ml of absolute ethanol and store in a polyethylene bottle.

Interference studies

Inter-element effects of the lanthanides and yttrium amongst themselves and in different matrices, as encountered in rare earth minerals, were studied by preparing synthetic solutions approximating the composition of some minerals such as britholite, cenosite, allanite and chevkinite. The synthetic solutions were prepared by mixing salt solutions of the common and the rare earth elements in such a way as to contain the equivalent of 100 mg of the mineral sample. The solutions were evaporated with

* Plus specified amounts of rare earths.

† Determined by atomic absorption in 1% lanthanum buffer.

‡ Determined by flame emission in 2000 ppm sodium buffer (no buffer used in the case of lanthanum).

60% perchloric acid to a moist residue in order to convert the salts into perchlorates. After cooling in a desiccator, the salts were dissolved in absolute ethanol and the solution was diluted to 25 ml. From this stock solution three sets of solutions were prepared, all in absolute ethanol and containing 1 mg of sample/ml, the first having no spectroscopic buffer, the second containing 1% lanthanum and the third 2000 ppm of sodium as spectroscopic buffers. The rare earths and yttrium were determined in these solutions by atomic-absorption and flame-emission spectrometry. In order to test the recovery the calibration curves were prepared by use of mixtures of pure rare earth perchlorates in absolute ethanol and containing the spectroscopic buffer, where necessary. The results are given in Table 2.

Lanthanum was determined by flame emission from the first solution containing no spectroscopic buffer since sodium (2000 ppm) interfered at the most sensitive lanthanum line (550·13 nm). The use of strontium perchlorate buffer did not improve the sensitivity for lanthanum. Lanthanum (1%) buffer was found to interfere at the most sensitive lines of samarium (429·67 nm) and praseodymium (495·14 nm) during their flame-emission determinations. Therefore, the flame-emission determination of these two elements was completed in the sodium buffer medium. The results in Table 2 indicate that the lanthanides and yttrium can be directly determined in the mineral sample solutions without any chemical separation.

As most rocks contain minor or trace amounts of the rare earths, it is not possible to determine them without preliminary concentration. The bulk amount of the matrix elements such as calcium, iron, aluminium, titanium and magnesium (from a 2–10 g sample) must also be removed to reduce the salt concentration in the final small volume of solutions to be used for atomic-absorption and flame-emission determination of the rare earths. The disadvantage of ion-exchange separation of the bulk of the common elements from 5–10 g rock samples is the need to use big columns, a large volume of wash solutions and subsequent time-consuming evaporation steps. Separation of major amounts of iron by mercury cathode electrolysis from samples such as magnetite and limonite gossan before rare earths determination has been used with success in this laboratory. Tests also showed that if a sample contained a small amount of calcium, hydrofluoric acid attack would co-precipitate small amounts of rare earths with calcium fluoride; these could be converted into perchlorates, dissolved in ethanol and quantitatively determined by the method above. However, in the presence of large amounts of calcium, the separation of the rare earths with calcium as the oxalates, followed by removal of calcium by precipitation of the rare earth hydroxides in the presence of a small amount of aluminium hydroxide or ferric hydroxide as the carrier is generally favoured. Since the final rare earth concentrate obtained by this method contains aluminium or iron as the carrier element, it was necessary to investigate the effect of these two elements on the atomic-absorption and flame-emission determination of the lanthanides and yttrium. The results of this investigation, as given in Table 3, show that the rare earths can tolerate a concentration of 0·8 mg of Fe_2O_3 per ml in the sample solution. The presence of the aluminium carrier causes slightly lower results (*cf.* Table 3). Therefore, ferric hydroxide carrier was used in this work in the co-precipitation of small amounts of the rare earths.

Recommended procedures

Flow-sheets outlining the analytical schemes are given in Figs. 1 and 2.

Determination of lanthanides and yttrium in rare earth minerals (Fig. 1). Take the sample (0·1–0·2 g) in a 50-ml platinum dish and heat gently to drive off moisture and any carbonaceous material. Treat with 5 ml of hydrofluoric acid and 10 ml of nitric acid, cover and digest on the steam-bath. Add more hydrofluoric acid, if necessary, to complete the decomposition.

If the sample does not contain phosphate, evaporate the solution to dryness on the steam-bath, add 5 ml of nitric acid and evaporate to dryness again. Add 5 ml of 60% perchloric acid and evaporate to a moist residue.

If the sample contains major amount of phosphate (as in britholite, monazite, *etc.*), evaporate the solution to dryness on the steam-bath. Add 25 ml of hydrofluoric acid to the residue and heat on the steam-bath for 1 hr with occasional stirring. The fluorides of rare earths and calcium are completely precipitated. Allow the precipitate to settle, filter it off on a Whatman No. 40 filter paper and wash with hot water. Transfer the precipitate to the original platinum dish and decompose the paper with nitric acid (steam-bath). Evaporate to dryness, add 5 ml of perchloric acid (60%) and evaporate to a moist residue.

After cooling in a desiccator, dissolve the residue in absolute ethanol and dilute to 25 ml (volumetric flask) with the same solvent. Transfer aliquots of this stock solution into two volumetric flasks to prepare solutions containing 1 and 3 mg of sample per ml, respectively. Add sufficient lanthanum buffer to have a final 1% lanthanum concentration and dilute to volume with absolute ethanol. Determine, by atomic-absorption, the major rare earths with the 1-mg/ml solution and the minor rare earths with the 3-mg/ml solution. Determine lanthanum by flame-emission from a 2-mg/ml sample solution in absolute ethanol (no spectroscopic buffer). Prepare calibration curves by aspirating the blank (1% La) and standard solutions of the rare earths (containing 1% La) into the flame immediately before and after the sample solutions.

Determination of lanthanides and yttrium in rocks and other minerals containing small amounts of these elements (Fig. 2). Depending on the rare earth content, take 2–10 g of sample in a 100-ml platinum dish, add 30 ml of hydrofluoric acid, cover and heat on the steam-bath with occasional stirring with a platinum rod. After decomposition is complete, evaporate the solution to dryness on the steam-bath. Add 40–50 ml of hydrofluoric acid, break the lumps with the platinum rod, cover and digest on the steam-bath for 1 hr. Allow the precipitate to settle and filter it off on a Whatman No. 40 filter paper in a polyethy-

Determine La by flame-emission from an aliquot (no buffer) or after diluting it with absolute ethanol.

Transfer aliquots to 3-, 5-, and 10-ml vol flasks, add lanthanum buffer (1% La in the final vol), and dilute to vol. with absolute ethanol Determine Y, Nd, Sm, Eu, Dy, Ho, Er, Tm and Yb by AAS.

Fig. 2.

of Carron *et al.*,[22] using ammonia instead of sodium hydroxide for adjusting the pH to 3·8. Filter and wash the precipitate with 0·1% ammonium oxalate. Combine the two oxalate precipitates and decompose them by heating with 25 ml of concentrated nitric acid. Evaporate to a moist residue after adding 5 ml of perchloric acid. Dissolve the residue in water and dilute to 50 ml. Repeat the oxalate precipitation, followed by filtration and destruction of the filter paper and oxalates by nitric acid and perchloric acid as above. Dissolve the perchlorate residue in a solution containing 10% nitric acid and 5% hydrogen peroxide. Add a measured quantity of ferric chloride or nitrate solution to give the equivalent of 6 mg of Fe_2O_3, and 2 g of hydroxylamine hydrochloride, and precipitate the rate earth hydroxides and ferric hydroxide by adding enough ammonia to raise the pH to > 10 (pH paper). Filter off, and destroy the paper by nitric and perchloric acids as usual. After transferring the solution to a 10- or 20-ml beaker, evaporate to a moist residue of the perchlorates. Cool in a desiccator, dissolve in absolute ethanol and dilute to 5 or 10 ml in a volumetric flask (stock solution). According to the concentration of yttrium and the lanthanides expected, transfer aliquots of this stock solution to 3-, 5- and 10-ml volumetric flasks, add the required quantity of lanthanum buffer to each flask to yield 1% La in the final solution, and dilute to volume with absolute ethanol. Determine Y, Nd, Sm, Eu, Dy, Ho, Er, Tm and Yb in these lanthanum buffered solutions by atomic-absorption, using scale expansion up to 12·5 ×, if necessary. Determined lanthanum by flame-emission from the original stock solution, or from a diluted solution (no buffer). Determine the concentration of the unknown elements from the calibration curves prepared by aspirating the blank (1% La) and standard solutions of the rare earths (containing 1% La) in the flame immediately before and after the sample solutions. Although Table 3 shows that the determination of yttrium and lanthanides in the presence of 0·8 mg of Fe_2O_3 per ml is possible, it is perhaps better to add to the standards the amount of iron (as perchlorate in absolute ethanol) expected in the unknown sample solution, to increase the precision and accuracy.

RESULTS AND DISCUSSION

In order to test the effectiveness of the proposed method in actual sample analysis, two previously analysed rare earth minerals, britholite and cenosite, and three syenite reference samples, SY-1, SY-2 and SY-3 from the Canadian Certified Reference Materials project, were chosen. The results of analysis of britholite and cenosite as well as two other minerals, allanite and chevkinite, by the proposed method are given in Table 4. The X-ray fluorescence analyses of the rare earth concentrates from britholite and cenosite are also included in Table 4 for comparison.

* Directly determined after phosphate separation.

† Determined after separation by oxalate and hydroxide precipitation (without any carrier).

‡ Determined after separation by oxalate and hydroxide precipitation (with iron carrier).

The cenosite specimen (from Bancroft, Ontario) analysed in this work was not exactly the same as that analysed by Pouliot *et al.*[6] The grains were handpicked under a microscope by the donor at a different time. Consequently there is a possibility of slight variation in the composition. This may be the reason for small differences in the results for yttrium and erbium obtained by the two methods, although the agreement between the results for other rare earths is good (see Table 4).

As the X-ray fluorescence data for the minor rare earth contents of britholite are not available, the comparison is restricted to the values reported.[5] There is a minor difference in the neodymium values, but the results for yttrium, lanthanum and samarium are comparable. The advantage of the atomic-absorption method is shown by its ability to determine small amounts of Eu, Dy, Ho, Er, Tm and Yb in britholite. The results of replicate determinations of the minor rare earths in britholite are included in Table 5, which also gives comparative data on three ways of determination, *viz.* direct determination after phosphate separation, determination after separation by oxalate and hydroxide precipitation without using any carrier, and determination after separation by oxalate and hydroxide precipitation using iron as a carrier.

The rare earth values obtained by the proposed method on the reference rocks SY-1, SY-2 and SY-3, and three other samples (limonite gossan, apatite and

sphene) are given in Table 6. In the case of the syenite rocks the results are found to be close to other reported values or their medians, obtained by spectrographic or neutron-activation methods. Although the author was able to determine Ho, Er and Tm in SY-2 and SY-3 by the present method, no other laboratory has yet reported data for these elements.

Table 2 shows that the determination of praseodymium is possible by flame-emission. However, no praseodymium was detected in the samples reported on in Tables 4 and 6. Cerium, thorium and gadolinium were found to be very insensitive in both flame atomic-absorption and flame-emission. Perhaps flameless atomic-absorption should be tried for these elements to increase the sensitivity. Otherwise, in a composite scheme of analysis, these elements can be determined in a fraction of the concentrate by other methods[26] such as emission spectrography, X-ray fluorescence, colorimetry and titrimetry.

Acknowledgements—I am grateful to Mrs. A. M. Szaplonczay of Bell Canada Northern Electric Research Ltd. for the loan of yttrium, thulium and holmium lamps, and to G. A. Hunt of Canada Centre for Mineral and Energy Technology for loaning the remaining rare earth lamps used in this work. I also wish to thank H. R. Steacy for providing the britholite and cenosite specimens.

ON THE OPTIMUM CONDITIONS FOR THE REDUCTION OF NITRATE TO NITRITE BY CADMIUM

FOLKE NYDAHL
Department of Analytical Chemistry, University of Uppsala, Box 531, S-751 21 Uppsala, Sweden

(*Received 2 July* 1975. *Accepted 7 September* 1975)

Summary—The variables of direct importance in the reduction of nitrate to nitrite by a metallic reductant such as cadmium used in a reductor column are discussed with special reference to the determination of nitrate as nitrite in very dilute solutions, *e.g.*, natural waters. As a result of these considerations the effect of flow-rate (expressed as bed-volumes/min), pH, temperature, chloride concentration and various types of reductor cadmium on the yield of nitrite is investigated. The effect of dissolved oxygen in the sample solution on pH and cadmium concentration in the reduced solution is demonstrated. At constant pH a maximum yield of nitrite is obtained at a certain flow-rate, which is explained as the result of a rapid formation and simultaneously proceeding slow reduction of nitrite. With increasing pH this maximum is shifted to lower flow-rates, and grows broader whilst the yield at maximum approaches 100%; at pH 9·5 a yield of 99·9 ± 0·1% is obtained. The temperature has little effect on the reduction rate in the interval 20–30° but at 10° the reduction is noticeably slower. Chloride ions have a strongly retarding effect on the reduction rate but the yield at maximum is not affected. Electrolytically precipitated cadmium, filings of pure cadmium or amalgamated pure cadmium all give practically the same yield at maximum though some differences in reduction rate are observed. Impure cadmium or copper–cadmium and silver–cadmium, owing to the formation of galvanic cells with higher reducing power, give a high reduction rate, which also applies to nitrite, causing a poorer yield at maximum. The practical consequences of the results are thoroughly discussed.

For the determination of nitrate at very low concentrations, for instance in natural waters, it has for some time been customary to make use of the reaction

$$NO_3^- + 2H^+ + 2e^- = NO_2^- + H_2O$$

followed by determination of nitrite according to one of the many modifications of the Griess-Ilosvay reaction. If the sample contains nitrite as well as nitrate the former is directly determined by the same colour reaction and deducted from the sum. The determination of nitrite seems at present to be a satisfactory procedure. The reduction step, however, has obviously presented difficulties, which often originate from a tendency to over-reduction. Reducing agents in solution, as well as metallic reductants, have been used. The most promising results have been obtained by using cadmium,[1–4] amalgamated cadmium[5–7] or copper–cadmium[8,9] as reductants. The present state concerning the use of these reductants is summarized in the following quotation:[10] "However, which kind of reductor to use and how to prepare it, as well as how to control the different conditions governing the reduction process, are matters of very different opinion. What seems to be a suitable procedure in one laboratory does not always function in another. For these reasons it seems for the present impossible to distinguish one recommendable method from the great number of existing modifications."

This situation is due to the fact that the factors governing the reduction process and their interdependence have in no case been systematically studied. The aim of the present paper is to remedy this lack of knowledge to some extent and so facilitate the selection of a method. The aim is not to present a method ready for use on different kinds of samples; it must always be the province of the analytical chemist responsible to adapt a method to a particular kind of sample. To do that it is, however, indispensable to know how the method functions in its basic form, that is in absence of substances not essential for the reaction.

PRELIMINARY CONSIDERATIONS

Variables of obvious importance in the reduction of nitrate to nitrite by a metallic reductant used in a reductor column relate partly to such properties of the reductant as the reduction potential and the surface area per unit of volume, and partly to such properties of the solution as the pH and presence of substances influencing the reaction. If over-reduction can occur these combined properties would result in a certain optimum time of contact which might also be dependent on the temperature. Quite apart from the study of how these parameters affect the yield, some existing nitrite determination method must be adapted to the properties of the reduced solution. The investigation reported here has been guided by the following considerations.

The reduction potential

The standard reduction potential for the Cd/Cd^{2+} couple is $-0{\cdot}403$ V. If the cadmium contains metals of lower reduction potential, its reduction power will increase. This may, however, also occur through formation of local cells if the metallic impurities have a positive reduction potential. This effect has been artificially brought about by treatment of cadmium preparations with a copper sulphate solution;[8] copper is precipitated and partly adheres to the cadmium as a porous layer. A galvanic cell is produced with the copper as the cathode. As the standard reduction potential of the Cu/Cu^{2+} couple is $+0{\cdot}337$ V the emf of the cell under standard conditions will be 0·740 V and its reducing power much higher than that of cadmium alone.

It has also been proposed to amalgamate the cadmium by treatment with a mercuric chloride solution.[5] The surface layer of the cadmium particles will then be covered by a layer of solid cadmium amalgam and a small decrease of the reduction power may be expected.

Whether "copperizing" or amalgamation is used, a change of the active surface area may also occur. The influence of the specific surface area will be discussed in connection with the time of contact.

The properties of the solution

From the equations

$$NO_3^- + 2H^+ + 2e^- = NO_2^- + H_2O$$

$$HNO_2 + 5H^+ + 4e^- = NH_3OH^+ + H_2O$$

$$HNO_2 + 7H^+ + 6e^- = NH_4^+ + 2H_2O$$

it is evident that the hydrogen-ion concentration has a strong influence on the reduction process. A certain hydrogen-ion concentration is necessary for the quantitative reduction of nitrate to nitrite; too high a concentration will cause a further reduction of the nitrite formed. Most earlier authors have probably been aware of this fact but no systematic experiments at different pH-values have been published and statements on the proper pH to use are sometimes contradictory. Thus, for instance, several authors (*cf.* Elliott and Porter)[4] recommend a pH of 9·6. Grasshof[6] states, "Die quantitative Reduktion zur Stufe des Nitrites ist von der Einhaltung eines bestimmten pH-Wertes abhängig, der etwas unterhalb des Neutralpunktes liegt. Steigender pH bewirkt eine unvollständige, fallender eine weitergehende Reduktion." but uses an ammonium–ammonia buffer having a pH which can be calculated to be about 8·1. Henriksen and Selmer-Olsen,[9] using a buffer of pH 8·6, state, "The pH of the ammonium chloride buffer used could be varied between 5·0 and 10·0 without effect on the reduction of nitrate to nitrite.".

A second requirement for the solution is that it must prevent precipitation of cadmium hydroxide on the surface of the cadmium particles, which would seriously lower the efficiency of the reductor. Several authors have considered this problem but no one seems to have been aware of the fact that the production of cadmium ions in the reductor is very much larger than that caused by the nitrate reduction alone. As earlier established,[11] dissolved oxygen is very rapidly and quantitatively reduced according to

$$2Cd + O_2 + 4H^+ = 2Cd^{2+} + 2H_2O$$

thus producing an equivalent amount of cadmium ions. Around the neutral point only insignificant amounts of cadmium ions are produced by reduction of hydrogen ions. Dilute water solutions in equilibrium with air contain about 0·5 mg-atm of oxygen per litre corresponding to a cadmium concentration of about 0·5 m*M*. This concentration is further increased by the nitrate reduction but only by an amount of a lower order of magnitude. The solubility of cadmium hydroxide in pure water is about 0·01 m*M* and its solubility product about 6×10^{-15}. At a cadmium-ion concentration of 0·5m*M* precipitation of hydroxide is calculated to begin at about pH 8·5 if no ionic strength or complexing effects are considered. The risk of precipitation should be higher in fresh water than in sea-water, in which the complexing effect of chloride ions should be noticeable.

As seen from the reaction equation the reduction of oxygen will remove two hydrogen ions for every atom of oxygen. This corresponds to addition of 1 meq of base per litre of solution: a considerable increase of pH in unbuffered solutions will therefore occur.

From these considerations the following conclusions may be drawn. An investigation of the pH-dependence of the reduction is necessary. The buffer solutions to be used should have capacity enough to allow the addition of 1 meq of base per litre without a greater change of pH than a few tenths of a unit; they should if possible be used at their maximum buffer capacity. At higher pH-values the buffer solutions should contain a substance, preferably the buffer substance itself, able to form soluble complexes with cadmium ions, sufficiently stable to prevent precipitation of cadmium hydroxide at the pH of the buffer.

The time of contact

The reduction of nitrate and a simultaneously proceeding slow reduction of the nitrite formed would result in an optimal time of contact between metal and solution for a maximum yield of nitrite. Though the process may be performed by shaking the finely divided metal with the solution,[4] only the reduction in a reductor column is considered here as the generally most practical method. The optimal time of contact is a function of the surface area of the metal per unit of volume, its bed volume in the reductor and the flow-rate, as well as of the properties of the solution and the reduction potential of the metal previously discussed. If the flow-rate is expressed in bed-volumes/min (henceforth abbreviated bv/min), for roughly equal bed-diameters the optimal time of contact for a certain cadmium preparation and solution would be determined by the flow-rate only. The usual procedure for manual analysis has been to use an open reductor with a reservoir for the solution at its upper end, and an adjustment of the flow-rate with a stop-cock. This does not give rise to a constant flow-rate, but only a constant time for passage of a certain added volume. It therefore seems to be a better procedure, even for manual analyses, to use closed reductors and to pump the solution through them at a constant flow-rate, as is done in the flow systems for automatic analysis.

The nitrite determination

The most promising method for the determination of nitrite seems to be Bendschneider and Robinson's[12] modification of the method proposed by Shinn.[13] The nitrite is made to react with sulphanilamide, forming a diazonium salt which is coupled to *N*-(1-naphthyl)ethylenediamine. The resulting aminoazo compound has a molar absorptivity of about $5 \times 10^4\,\text{l.mole}^{-1}.\text{cm}^{-1}$ at 543 nm, the wavelength of its absorption maximum. Though the method seems to be fairly free from interferences the following precautionary measures should be taken when trying to utilize its full intrinsic precision. To avoid errors on account of minute variations of the absorptivity due to variations of, *e.g.*, temperature and composition of the solution, the nitrite standard should be made up to the same concentration as the sample as regards the buffer, added salts *etc.* and be processed simultaneously with the sample. The neutralizing effect of the buffer on the diazotizing reagent should be considered. Rather than measurement of the absorbance, its deviation from that of a nitrite standard corresponding to a 100% yield of nitrite should be determined by differential spectrophotometry.

EXPERIMENTAL

Equipment

To obtain a constant and adjustable flow-rate a peristaltic pump (Gilson "Minipuls II") with 2·6 mm i.d. Tygon tubing was used. With this dimension the maximum flow-rate was 10 ml/min. By use of two tubes connected to a T-tube before the reductor, the flow-rate could be doubled.

The reductor tubes were straight glass tubes of 1·0 cm^2 inner cross section, at the inlet end narrowed down to 4 mm o.d., at the outlet end closed with a ground joint or a rubber stopper with an outlet tube of 4 mm o.d. The cadmium bed (for bed length, see the tables) was enclosed between Pyrex wool plugs. To fill the reductors, the inlet end was connected to the pump, allowing buffer solution of pH 6·9 (see later on) to be pumped into the tube and the level of the solution to be raised or lowered at will. The cadmium was introduced in portions, the tube being continuously tapped to facilitate packing, and solution being kept above the cadmium level to avoid entrapped air. Small stray air bubbles are without consequence but can easily be removed by slowly pumping deaerated buffer solution through the reductor. The reductor was used in the vertical position with the inlet end at the bottom. Each day before the first series of reductions 25 ml of 0·05*M* sulphuric acid were passed through to remove any cadmium hydroxide which might possibly have formed, followed by buffer solution of pH 6·9 until the effluent was neutral. When not in use the reductors were kept filled with the buffer solution, and the inlet and outlet tubes closed with glass rods.

Cadmium preparations

Electrolytically precipitated cadmium (abbreviated e.p. cadmium). Prepared as described in an earlier paper;[11] the suggested method of storage, *i.e.*, keeping the cadmium crystals in the dry state, was employed. The material consists of fine dendritic needles and is fairly voluminous. About 11·5 g are needed to form a 10-cm^3 bed, the interstitial volume thus being about 85% of the total. Due to the method of preparation the percentage of foreign metals should be low.

Cadmium filings. The starting material was "Cadmium Sticks Reagent" from Matheson, Coleman & Bell with stated maxima of Cu 0·005, Fe 0·001, Pb 0·02 and Zn 0·1%. The burrs were removed from a brand-new rasp by rasping 20–30 g of cadmium. The filings thereafter obtained were washed with acetone, 2*M* hydrochloric acid, water and methanol, dried *in vacuo* and kept over silica gel in a desiccator. About 23 g are needed for a 10-cm^3 bed; the interstitial volume is about 74% of the total.

From these filings *"copperized" cadmium* was prepared by shaking 10 g with 25 ml of 0·08*M* copper sulphate. The product was washed with buffer solution of pH 6·9 and directly used for filling the reductor. In an analogous way *"silverized" cadmium* was prepared from 10 g of filings and 40 ml of 0·05*M* silver nitrate. In both cases precipitated copper or silver not adhering to the cadmium particles was removed by the washing. *Amalgamated cadmium* filings were prepared by shaking the filings with a solution of mercuric chloride in 0·1*M* hydrochloric acid, calculated to give amalgams of 1, 2 or 4% of mercury. The amalgams were treated as above.

Granulated cadmium. Merck's "Cadmium grob gepulvert, zur Füllung von Reduktoren" was passed through sieves and the 0·5–1 mm fraction washed and dried as described for the filings. About 10 g are needed for a 2-cm^3 bed, the interstitial volume being about 55% of the total.

Solutions

Buffer solutions were prepared from reagent grade chemicals in the concentrations given in Table 1. The imidazole in the pH 9·3 buffer was added as a complexing agent for cadmium ions ($\beta_4 \sim 7{\cdot}5$). Its complexing effect is not significantly influenced by an excess of calcium or magnesium ions. The solubility of cadmium hydroxide in the buffer solutions of pH 8·0 and 9·3 was determined. A small amount of e.p. cadmium was added to the solution and the mixture stirred in the presence of air until turbid from the precipitation of cadmium hydroxide. After filtration, and removal of the chlorides by evaporation with a small excess of sulphuric acid, the cadmium concentration was determined by potentiometric titration with EDTA.[11] The

Table 1. Buffer solutions used

Buffer *pH*	Moles of constituents used to make up 1 litre of stock solution	Dilution for use
5·4	0·150 tris(hydroxymethyl)aminomethane, 0·100 succinic acid	1:10
5·7	1·00 imidazole, 0·95 HCl	1:100
6·9	1·00 imidazole, 0·50 HCl	1:100
8·0	1·00 tris(hydroxymethyl)aminomethane, 0·50 HCl	1:100
9·3	1·00 NH_3, 1·00 NH_4Cl, 1·00 imidazole	1:100
5·1	1·00 NH_4Cl	1:10

solubility found in buffer of pH 8·0 was 1·22m*M*, in buffer of pH 9·3 1·18m*M*. The latter buffer without imidazole gave a solubility of only 0·56m*M* which was considered too close to the calculated minimum permissible value of 0·5m*M*. In this connection it may be mentioned that the solubility in a synthetic ocean-water of 3·5% salinity was found to be 0·48m*M*.

Standard solutions of 0·02*M* potassium and sodium nitrates were prepared from reagent grade chemicals dried at 110°. The solutions were stored in dark brown bottles. The nitrogen contents of both preparations were determined by reduction to ammonia with Devarda's alloy, distillation and titration.[14] No difference >0·05% relative was established. Dilutions of these solutions to 20µ*M*, containing buffer and other additions if any, were freshly prepared each day.

The diazotizing reagent. Sulphanilamide (2·50 g) and 50 ml of hydrochloric acid (1 + 1) were dissolved in water and diluted to 250 ml. For use in solutions with an excess of base >0·01*M*, the acid concentration was appropriately increased.

The colour developer. N-(1-Naphthyl)ethylenediamine dihydrochloride (0·250 g) was dissolved in water and diluted to 250 ml. The solution was kept in the dark in a refrigerator. Small portions were withdrawn and brought to room temperature before use.

Procedure

If not otherwise stated, the experiments were carried out at room temperature (20–23°).

In each series of experiments the flow-rate was varied and a sample taken for each flow-rate for the determination of nitrite. To minimize increases in concentration by evaporation at low flow-rates it was necessary to seal the vessels connected to the pump and reductor with rubber stoppers with capillary holes for equalizing the pressure. Before each series of experiments about 25 ml of 0·05*M* sulphuric acid were pumped through the reductor at the maximum flow-rate, followed by buffer solution of pH 6·9 until the effluent was neutral. The flow-rate was then adjusted to the highest value intended, the intake of the pump connected to the solution to be reduced, and a volume of about 4 times the free volume in the tubing and reductor pumped through the system. A sample allowing 10 ml to be pipetted out was then collected in a test-tube which was immediately thereafter sealed with a rubber stopper. Without the pump being stopped, the flow-rate was adjusted to the next value and a volume of about 1·5 times the free volume of the system was passed through before the next sample was collected, and so forth. On conclusion of the reductions the system was washed out and filled with buffer solution of pH 6·9.

Without undue delay, 10-ml portions of the collected samples as well as of a nitrite standard having the same concentration as the nitrate solution (even with regard to buffer and other additions if any), were pipetted into long-necked 25-ml flasks. With an "Oxford sampler" 200 µl of the diazotizing reagent were added and mixed by swirling, and after 5 min 200 µl of the colour developer were added in the same way. After a further 15 min the difference in absorbance at 543 nm of sample and nitrate standard was determined in a Beckman B spectrophotometer connected to a stabilized power supply, 1-cm cells being used, with the sample solution as zero.

The validity of Beer's law was confirmed. For each nitrite standard differing in composition, the absorbance was determined by using the same solution, without nitrite, as blank. The absorbance showed only minute variations for different buffers. The absorbance obtained from the 20 µ*M* nitrite solution used was ~0·97. Thus a deviation of 0·001 in absorbance corresponds to ~0·1% in yield of nitrite. The reproducibility of measurement of simultaneously developed 20 µ*M* standard solutions was better than 0·001 absorbance units.

As the same buffer *etc.* were used in both the nitrate and the nitrite standards, a blank caused by nitrite in the buffer *etc.* will cancel out if nitrite is not decomposed in the process. A blank caused by nitrate will, however, show and this was determined by reducing a solution containing only buffer *etc.* at the flow-rate found as optimum and measuring it against the unreduced solution. The absorbance of this blank, usually <0·001 and never >0·005, was applied as a correction.

RESULTS

The pH-dependence of the nitrite yield

In strongly acidic solution, ~5*M* sulphuric acid, nitrate is quantitatively reduced to ammonia by iron ($E^\circ = -0{\cdot}44$ V). On the other hand, the same reduction can be carried out in strongly alkaline solution by using a powerful reducing agent such as Devarda's alloy (Cu, Al, Zn). According to the author's experiments, the details of which will not be described in this paper, nitrate is rapidly reduced by cadmium at low pH (1–3) to hydroxylamine and small amounts of ammonia. In the pH interval 3–5 the velocity of this reaction decreases fairly rapidly and the reduction tends to stop at the formation of nitrite. The following experiments were intended to determine the yield of nitrite in the pH interval 5·4–9·3.

Solutions 20µ*M* in regard to KNO_3 and containing buffers in the dilutions given in Table 1 were reduced at different flow-rates in a reductor containing e.p. cadmium. This material was preferred as a representative of pure cadmium on account of the satisfying results obtained with it for other purposes, *cf.* Nydahl.[11] In this connection a study was also made of any simultaneously proceeding reduction of nitrite, starting with buffered 20µ*M* $NaNO_2$ solutions. Further details and the results are given in Tables 2 and 3.

As far as the increase in pH during the reduction is concerned, the following observation can be made. On reduction of the dissolved oxygen the concentration of base is increased by about 1 meq/l. while, in the present case, the reduction of nitrate contributes only about 0·04 meq/l., an amount which may be neglected in the following discussion. In the buffers

of pH 6·9 and 8·0, 0·005*M* in regard to base and corresponding acid, used at their maximum buffer capacity, the increase of pH was about 0·3, and in the twice as concentrated buffer of pH 9·3, half that amount.

According to an earlier paper[11] the reduction of the dissolved oxygen proceeds very rapidly. Even at a flow-rate of 33 bv/min, 98·5% of the oxygen is reduced. As the reduction of nitrate seems to proceed at less than 1/30 of this rate it is obviously the pH determined in the reduced solution that has been predominant during the reduction and that consequently has determined the course of the reaction. This is clearly evident in the series of experiments with the unbuffered 0·1*M* NH_4Cl which shows an increase of pH from 5·1 to 7·5 but a yield of nitrite intermediate between those obtained in solutions of final pH 7·2 and 8·3. This series, moreover, shows the influence of the chloride concentration, which will be discussed in a later section, and is therefore not discussed in the following.

If the pH is kept constant during the reduction of nitrate, a maximum yield of nitrite is obtained at a certain flow-rate. At flow-rates higher than the optimal the reduction is incomplete, at lower flow-rates the yields closely follow the recoveries obtained by the direct reduction of nitrite. This is particularly evident at a flow-rate of 0·2 bv/min.

With increasing pH the maximum is shifted to lower flow-rates, and grows broader whilst the yield approaches but does not reach 100%. Even at a final pH of 9·5 a slight reduction of nitrite occurs.

In its initial stage the reduction of nitrite at a constant pH increases almost linearly with the residence time in the reductor, as illustrated in Fig. 1, where the loss in recovery is plotted against the inverse of the flow-rate. Accordingly, the product *K* of loss (%) and flow-rate (bv/min), signifying the loss of nitrite at a flow-rate of 1 bv/min when reducing a nitrite solution, is nearly constant and, *ceteris paribus*, a measure of the reduction rate at the selected pH. Thus *K* is ~7 at a final pH of 5·6 and ~0·01 at a final pH of 9·5.

Table 4. Effect of temperature on the reduction of 20μM KNO_3 solutions by e.p. cadmium. Buffer of pH 8·0. Bed dimensions: 5·2 cm × 0·96 cm^2 = 5·0 cm^3. The approximate values of *K* are calculated from the losses at the flow-rate of 0·1 bv/min

Temp., °C	Yield of nitrite, %, at a flow-rate, *bv/min*, of						*K*, approx.
	2	1	0·5	0·2	0·1	0·05	
30·0	97·5	99·4	99·7	99·5	99·0	—	0·1
20·0	96·6	99·5	99·7	99·5	99·4	99·0	0·06
10·0	93·6	98·0	99·6	99·8	99·7	99·6	0·03

No specific influence of the different buffers can be gathered from these results.

The investigation was not extended to pH values above 9·5 on account of the expected difficulty of avoiding precipitation of cadmium hydroxide and also hydroxides or carbonates of other metals possibly present, when using the method in practice. From the latter point of view the buffer of pH 8·0 may well be preferred though the yield is slightly lower than that obtained with buffer of pH 9·3. On this account most of the following experiments were performed with use of the buffer of pH 8·0. An additional reason was that tendencies to deviations of the yield are larger and thus more easily observed than at a higher pH.

The effect of temperature on the rate of reduction

Reductions were performed with reductor and inlet tubing immersed in a thermostat. Further details and results are given in Table 4. In the interval 20–30° the temperature has little effect on the rate of reduction of nitrate. At 10° the reduction is noticeably slower, causing a shift of the maximum to the next lower flow-rate. As is evident from the values of *K*, the rate of reduction of nitrite is approximately doubled for a 10° increase of temperature. However, owing to the low values of *K*, the yields at the maxima vary only within experimental error.

Effect of salt concentration

For the determination of nitrate in sea-water it is of obvious interest to investigate the effect of the sodium chloride concentration on the yield. The results

of such experiments are given in Table 5. The concentration of 0·5M NaCl approximately corresponds to that of ocean-water while 0·1M NaCl may be considered as equivalent to Baltic sea-water.

Sodium chloride has a strongly retarding effect on the rate of the nitrate reduction, an effect which increases with the chloride concentration and causes the maxima to be shifted to lower flow-rates. The reduction rate of nitrite is also retarded though the effect is not so drastically noticeable as in the case of nitrate. The maximum yield remains unchanged within experimental error.

For comparison a few experiments were carried out in the presence of sodium sulphate. It was found that the dye formed by the colour reaction was not sufficiently soluble at the sulphate concentrations used but began to precipitate before the measurement was ended. The reduced solution was therefore diluted 5 times before the colour development and the absorbance determined in a 5-cm cell. A comparison of these results with those obtained in the presence of sodium chloride shows that the retardation is mainly caused by the chloride ions. Considering the reaction equation for the reduction, the reducing power of cadmium should increase when the concentration of cadmium ions decreases, in this case by complex formation with the chloride ions, and the reduction should be accelerated instead of retarded. However, the chloride ions might in some way interfere with the reaction mechanism.

The results obtained with the 0·1M NH_4Cl solution previously mentioned (Table 3) show about the same retardation as obtained with a 0·1M NaCl solution.

Effect of various cadmium and metal–cadmium preparations

Reduction experiments were carried out in the same way as before, using various commercial forms of cadmium, with or without copper treatment, or treatment with silver or mercury solutions. The results are given in Table 6. The different reduction properties are characterized by stating the maximum yield, the flow-rate at the maximum and the approximate value of K.

‡ In 0·5M NaCl solution.

Filings obtained by rasping pure cadmium gave, within experimental error, the same yield as e.p. cadmium but at a quarter the flow-rate, which may be ascribed to some form of passivity or, simply, a considerably smaller specific surface area. In this connection it may be mentioned that the first 20–30 g of filings obtained by using a brand-new rasp gave a higher reduction rate, probably on account of contamination by burrs from the rasp.

The granulated cadmium had an unexpectedly high rate of reduction, also with respect to nitrite, and consequently with a poorer yield at the maximum. Analysis of this material indicated Cu < 2 ppm, Zn ~ 10 ppm but also a residue, insoluble in HCl or HNO_3, of 0·1%, at least partly consisting of graphite. By forming local cells this residue is probably the cause of the increased reduction power.

Copperizing the filings brought about, as expected, an appreciable increase of the reducing power. The rate of reduction of nitrite is high, and the yield at maximum poor. If the reduction is carried out in 0·5M NaCl solution the retarding effect of the chloride ions will cause a somewhat better yield. These series of experiments are also illustrated by the curves of Fig. 2 showing the possibility of errors when using copperized cadmium without due attention to chloride contents and flow-rate.

Silverizing the cadmium brought about approximately the same results as copperizing.

Amalgamation of the cadmium filings brought about a considerable increase of the reduction rate, whilst retaining the same yield as that obtained with untreated filings or with e.p. cadmium. This fact indicates that the reduction potential has remained practically constant whereas a hypothetic passivity might have been removed or the specific surface area increased. Actually, the amalgamated filings under the microscope at 100× magnification showed a rough, grainy surface unlike the bright one of the untreated

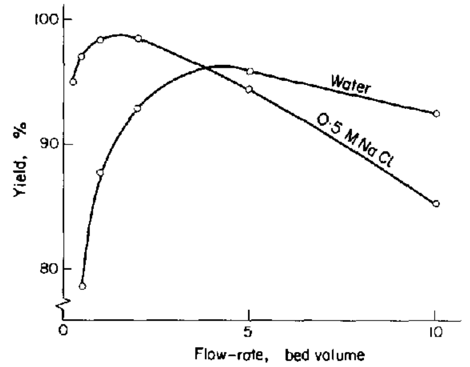

Fig. 2. Reduction of nitrate by copperized cadmium. Effect of chloride ions on the rate of reduction. Buffer pH 8·0.

filings. Varying the percentage of mercury brought about only minor variations of the reduction properties. Amalgamation of the granulated cadmium had little influence on the effect of its impurities. Amalgamation of e.p. cadmium led to a breakdown of its dendritic structure with the formation of lumps, causing difficulties in producing a homogeneous reductor bed. These experiments were therefore not pursued.

DISCUSSION AND CONCLUSIONS

The reductor cadmium

Every new sample of cadmium or metal–cadmium should be tested for its reducing power under the proper conditions by determining the yield of nitrite at the optimum flow-rate as previously described. Provided that these parameters are known it seems obvious that each type of reductor filling might be used for the determination of nitrate if allowance is made for the reduction of the nitrite formed as well as of that which might be originally present in the sample, depending on the error which can be tolerated.

A high rate of reduction of nitrite, as for instance with copper–cadmium in the reductor, results in a narrow optimum range of flow-rate, the location of which varies with the chloride concentration and probably also with the temperature. The correction for nitrite reduction (when copper–cadmium is used, amounting to 1·5–4% of the expected yield, depending on the chloride concentration) will therefore suffer from larger errors than at a low reduction rate. From this point of view the use of pure cadmium or amalgamated pure cadmium is to be preferred. The nitrite correction then amounts to only a few tenths of 1%, and at pH 9·5 to about 0·1%, within a far broader range of flow-rate. If, however, larger errors may be tolerated, the copper–cadmium, or an impure form of cadmium such as the granulated cadmium tested in this paper, can be used to advantage, as the time for reduction is considerably shortened. This gain of time should be especially valuable for the analysis of sea-water since it counteracts the retarding effect of the chlorides. Another advantage is that the purity of the cadmium used as starting material is of little or no consequence.

The special procedure, unsupported by experimental evidence, used by Wood *et al.*[8] for the preparation of copper–cadmium in order to avoid contact with air, seems not to serve any useful purpose since the metal is still allowed to react with the oxygen contained in the washing solution. Incidentally, the same observation applies to the procedure used by Koroleff[7] for the preparation of amalgamated cadmium.

The amount of copper remaining on the filings after the washing may be significant for the reduction rate as the copper functions as a cathode and its surface area consequently should have an influence on the time of contact.

E.p. cadmium and amalgamated pure cadmium filings both give a very low rate of reduction of nitrite. Which reductor filling to use is partly a matter of availability. If cadmium filings or granulated cadmium of sufficient purity and proper size were commercially available their use would be convenient since the amalgamation is easily carried out. It might also be possible to use these reductor metals without amalgamation after depassivation or enlargement of the surface area by etching. The manual tooling of a cadmium stick with a rasp is laborious and involves the risk of contamination. E.p. cadmium is easily prepared, and since nobler metals are removed with the anodic slime there is no risk of the formation of local cells. Precipitation of cadmium from a cadmium sulphate solution by zinc[1] is said to give easily clogged columns,[4] and also involves risk of formation of local cells by the nobler metals which might be present in the zinc and in this case are not removed.

If a reductor contains particles of different sizes, the smallest ones, at least partly packed in the interstices between the larger particles, are used up first and the surface area of the reductor bed is consequently lowered. This may have been a contributory cause of the gradually decreasing efficiency of the reductor observed by several authors. Another cause, and probably the main one, may have been the precipitation on the cadmium particles of hydroxides *etc.* as previously mentioned, or of such substances as humic matter, soil colloids or micro-organisms. This source of error should not be neglected but the reductor checked as to its reduction power at appropriate intervals. Concerning the e.p. cadmium used for the experiments on pure solutions in this paper, no decrease in efficiency in the optimum range has been observed. In this connection, and as a conceivable remedy against precipitated matter, it may be mentioned that amalgamated pure cadmium as well as e.p. cadmium can be washed with hydrochloric acid of 4*M* or even higher concentration without appreciable hydrogen evolution or change of efficiency at the optimum flow-rate.

Samples containing metals precipitated by cadmium will contaminate the reductor with these metals and, depending on the degree of contamination, have an effect on its reducing power. Thus a blackening was observed on the inlet end of the cadmium bed after the passage of several litres of solution through the reductor. This blackening was caused by the copper content of the distilled water, about 30 μg/l., but has so far not caused any significant increase in efficiency. The proposed use of copper wool[7,10] for enclosing the reductor bed should, however, be avoided. Probably a copper–cadmium reductor might be used to advantage for samples containing significant amounts of precipitable metals.

pH and buffer solutions

The higher the pH, the lower is the nitrite correction and the broader the optimum range of flow-rate. A lower pH than that necessary to avoid precipitation in the reductor should therefore not be used. A pH below 8 should rarely be needed. If larger errors are tolerated the demand for a predetermined and constant pH naturally decreases. Thus Table 3 shows that at a flow-rate of 0·5 bv/min a final pH varying between 6·3 and 9·5 causes the yield of nitrite to vary between 97 and 99%. The following discussion, however, presupposes a striving for minimal errors.

The buffer concentrations used in the present investigation appear sufficient for unbuffered sample solutions. However, the pH and buffer capacity of a sample solution may be such that addition of acid or base or the use of a more concentrated buffer solution is needed. This must be considered in each individual case.

The introduction of imidazole into the buffer of pH 9·3 might be avoided by using the buffer at a higher concentration. Its ability to complex cadmium ions is then increased and a higher buffer capacity is gained. To avoid higher chloride concentration the ammonium chloride might be replaced by ammonium acetate.

The use of an unbuffered ammonium chloride solution will cause a pH which varies with the actual oxygen content, pH and buffer capacity of the sample. The use of the tetrasodium salt of EDTA (2m*M*) as complexing agent for cadmium ions without addition of any buffer[8] will also cause pH variations depending on the actual composition of the sample solution.

Any significant increase of the buffer concentration should be compensated for by a corresponding increase of the concentration of hydrochloric acid in the diazotizing reagent in order to keep the pH constant during diazotation and colour development.

Reduction and nitrite determination

The use of a peristaltic pump in order to facilitate the attainment of a sufficiently constant flow-rate is a prerequisite. Such pumps designed for the simultaneous running of several samples are commercially available.

In the present investigation the absorbance was determined in a 1-cm cell and a sample volume of 10 ml was sufficient for rinsing and measurement. In practice, on account of low concentrations, it will sometimes be necessary to determine the absorbance in 5- or 10-cm cells requiring a sample volume up to 50 ml. When several successive reductions are run, and assuming that the system is to be rinsed with two times its free volume between samples, the time, *t*, in minutes, required for each sample, is obtained from the equation

$$t = (1/F)(V_s/V_b + 2V_f/V_b)$$

where F is the flow-rate in bv/min, V_s the sample volume, V_b the bed volume and V_f the free volume of the system. The approximate flow-rate to use being known, the appropriate bed volume in relation to the required sample volume can be estimated, as well as the required pump capacity.

The effect or removal of interfering substances is not considered in this paper because this will be a problem particular for every new kind of sample. The vital point is of course to reveal such interferences by appropriate experiments and then do something about it.

If a high degree of accuracy is desired, as for instance in determination of nitrate in commercial fertilizers, the differential spectrophotometric method is recommended. In that case the sample concentration can usually be chosen sufficiently high and near that of the standard solution. Regarding samples of natural waters, the demand for accuracy is considerably lower and their nitrate contents so widely varied and sometimes so low that differential spectrophotometry does not present any significant advantages. A calibration curve may then be applied in the usual way. In principle the calibration should be run with the same composition, temperature *etc.* in the standard nitrite solutions as for the sample. Sufficient experience will show to what extent deviations from this rule may be permitted.

The question may arise whether the analysis might not be performed in a wholly empirical way by establishing the relation between nitrate concentration and absorbance, thus omitting the calibration with nitrite standard solutions. This is, of course, possible if nitrite is absent from the sample or present only in such amounts that the correction for its decomposition is insignificant. Yet the need for checking this relation at appropriate intervals remains.

The running of reagent blanks as well as frequent checking of the cell correction is, of course, the more important the lower the concentrations to be determined.

AN INTERLABORATORY STUDY OF POTASSIUM DETERMINATION IN ROCKS AND MINERALS*

T. D. RICE
Chemical Laboratory, New South Wales Department of Mines,
36 George Street North, Sydney 2000, Australia

(*Received* 7 *July* 1975, *Accepted* 24 *October* 1975)

Summary—Seven laboratories took part in this interlaboratory study which was part of an investigation of the flame-spectrometric determination of potassium in rocks and minerals suitable for potassium–argon age-measurement. Three of these laboratories determined potassium in the following five international reference rocks: tonalite T-1, basalt BCR-1, andesite AGV-1, granite G-2, and granodiorite GSP-1. The other five samples (with the number of laboratories analysing them in parentheses) were: a chlorite rock (7), an altered basic igneous rock (5), an altered basaltic andesite (5), a biotite (6) and a potassium feldspar (7). Details of sample preparation and methods of analysis are given; no laboratory used exactly the same method as any of the other six laboratories. Results have been examined by analysis of variance; larger relative between- and within-laboratory variations occurred for the two samples containing less than 0.1% potassium than for seven of the eight other (higher potassium) samples; between-laboratory variations for the basalt BCR-1 and, to a lesser extent, the andesite AGV-1, were high and of similar magnitude to those for the samples containing less than 0.1% potassium. The causes of any poor interlaboratory agreement in the present study are considered.

This interlaboratory study was part of an investigation[1] of the flame-spectrometric determination of potassium in the many types of rocks and minerals[2] suitable for potassium–argon age-determination. The whole investigation was aimed at improving the reliability of potassium–argon age-determinations, by minimizing errors in the flame-spectrometric determination of potassium. The poor interlaboratory agreement of potassium results for the biotite B-3203 has been discussed by Pinson[3] who considered it to be "one of the great curiosities of modern analytical chemistry that it is possible to analyse for argon, which occurs to the extent of about 0.01 to 0.001 cc of gas per gram in a sample, to a much greater accuracy and with more confidence than it is possible to analyse for one of the major elements, namely potassium". The great majority of results reported for the biotite B-3203 involved flame emission measurement of the sample solution.

Results of previous interlaboratory studies of potassium determination are summarized in Table 1. The best interlaboratory agreement in Table 1 was obtained for the muscovite P-207: in this sample the between-laboratory relative standard deviations of results for potassium and potassium–argon age were 1.3 and 2.6% respectively.[7] Such agreement, while adequate for many age-determinations, is not adequate in many stratigraphic studies where, according to Cooper,[5] the total relative analytical error in a potassium–argon age-determination should not exceed 0.5%.

Ingamells[14] has found that poor interlaboratory agreement for the biotite B-3203 and the muscovite P-207 is largely due to sample inhomogeneity. It is very likely that sampling errors were eliminated in the present study by fine grinding as described later in this paper. Thus the variation of results observed in the present study can be confidently regarded as due to analytical errors as distinct from sampling errors.

The aims of the present interlaboratory study were:

(*i*) to compare between-laboratory variations with those in previous studies (Table 1);

(*ii*) to see whether between-laboratory variations are significantly greater than within-laboratory variations, and thus to indicate systematic errors in the methods of at least some of the participating laboratories.

As shown in Table 2, three laboratories in Australia and one in each of New Zealand, Russia, South Africa and U.S.A. took part in this study. These laboratories are all engaged in rock and mineral analysis and five of them in potassium–argon age-determination. Henceforth in this paper, the laboratories are identified by letters of the alphabet.

All participating laboratories were requested to:

· (*i*) determine potassium twice in each sample and not to do the second analysis concurrently with the first;

(*ii*) determine hygroscopic moisture in each sample at the time of each analysis;

(*iii*) check the accuracy of standard potassium solutions;

(*iv*) report the potassium content in the sample, as received, to 3 or 4 significant figures, to give an apparent precision of 0.1%;

(*v*) give details of standard compound used;

(*vi*) give details of dissolution and flame methods used.

Ten samples, with potassium contents between 0.05 and 10%, were used in this study. These samples were numbered from NSWMD-1 to NSWMD-10 in order of increasing potassium content. Five of the samples were international reference rocks, namely the tonalite T-1 from Tanzania,[12] and the basalt BCR-1, the andesite AGV-1, the granite G-2 and the granodiorite GSP-1 from the United States Geological Survey.[15] The other five samples were from New South Wales and had previously been analysed at this laboratory; these samples were as follows.

NSWMD-1. Foliated chlorite rock containing minor amounts of talc, quartz and albite; from Cow Flat Talc Mine *via* Bathurst, New South Wales; University of Sydney Geology Department Catalogue No. 46264; collected by Dr. B. J. Barron, New South Wales Department of Mines.

NSWMD-2. Medium-grained, altered basic igneous rock containing relict diopside, and a suite of alteration minerals including chlorite, tremolite and pla-

Table 3. Methods used in the present study

Laboratory	Summary of method	Standard K compound
A	HF–H_2SO_4 decomp. in Pt dishes. Na buffered, Li int. std. FE measurement on Baird Atomic instrument in propane–air flame. For samples NSWMD-1, -2, -3, prelim. IE sepn. similar to that of Lab. E.	K_2SO_4, Analar, Hopkin and Williams, Batch 20676, heated to constant weight at 500°
B	HF–H_2SO_4 decomp. in Pt dishes. Aliquots buffered with Merck Suprapur Cs_2SO_4 and K measured by AAS (Varian Techtron AA-5 instrument) in acetylene–air flame.	$KHC_8H_4O_4$ dried at 120° for 24 hr
C	Subsamples (100.0 mg) fused with $LiBO_2$ (700.0 mg) in graphite crucibles at 950° for 15 minutes and dissolved in 100.00 ml of 4% v/v HNO_3. A 1:10 dilution was made before aspirating into a direct reading (Li int. std.) IL 343 flame photometer with propane–air flame.	(Note 1)
D	100-mg subsamples decomp. in Pt dishes with HF–$HClO_4$. After addn. of 2.5 g of pure $MgCl_2$ (as buffer), solutions diluted to 50.00 g with water. FE measurement on a "high sensitivity diffraction grating flame spectrophotometer built in the laboratory", in gas (mostly methane)–air flame.	KCl dried at 105°
E	HF–HNO_3 decomp. and ultrasonic dispersion of solid particles in 100-ml Teflon beakers. Evapn. to dryness on water bath. Further HF–HNO_3 treatment and evapn. to dryness. Residue dissolved by adding 0.5 ml of HNO_3 and 10 ml of satd. H_3BO_3, warming and dilg. with H_2O to about 60 ml. K in this solution sepd. by IE on Dowex 50W-X12 resin, 200–400 mesh. K eluted with 0.75*M* HNO_3 collected in weighed glass flask, and measured by FE (propane–air flame and water-cooled burner).	$KHC_8H_4O_4$, Analar, BDH, dried at 120°
F	HF–HCl–$HClO_4$ decomp. in 100-ml Teflon beakers. After heating to $HClO_4$ fumes, contents of beaker dissolved in 10 ml of 1*M* HCl and transf. to a 150-ml Pyrex beaker to be diluted to about 0.2*M* in acid. After addition of 0.10% H_2O_2, K sepd. by IE on Bio-Rad AG 50W-X8 resin, 200–400 mesh. K measured by AAS (Perkin-Elmer 303 instrument, propane–butane–air flame and specially designed flat water-cooled burner).	KCl, Merck "*pro analysi*", dried at 150°
G	$LiBO_2$ fusion of 500-mg subsamples in 30-ml Pt crucibles for 15 min at 900°. Melt dissolved in dilute HNO_3 and an aliquot diluted gravimetrically and buffered with 1.20 mg of Merck Suprapur CsCl per g. K separated from another aliquot by IE on Dowex 50W-X8 resin, 100–200 mesh; K fraction (containing some Na) buffered with Cs as above. Polyethylene-ware used exclusively. K measured by AAS (Varian Techtron AA-5 instrument with digital read-out) in acetylene–air flame. Reported	KCl, "Specpure", heated at 550° for 4 hr

Table 3—continued

Laboratory	Summary of method	Standard K compound
	results are means for both types of measurement solution; individual results are given in Table 9.	

Notes. 1. Laboratory C used analysed samples (of well-established K contents and proven homogeneity) as standards. These were prepared by the same technique as the other samples. Sierra quartz was used for setting instrument to zero; the French biotite BIO-R (7.305% K) and an amphibole (0.758% K) were used to calibrate the instrument.

2. Int std. = internal standard; FE = flame-emission spectrometry; AAS = atomic-absorption spectrometry; IE = cation-exchange chromatography.

gioclase; from Woods Reef *via* Barraba, New South Wales; University of Sydney Geology Department Catalogue No. 47624; collected by Mr. R. Glen, New South Wales Department of Mines.

NSWMD-3. Porphyritic clinopyroxene-rich, altered basaltic andesite also containing phenocrysts (which were probably olivine but have been altered to chlorite) in a matrix of chlorite, carbonate, albite, epidote and sphene; from breccia pipe at Sofala, New South Wales; University of Sydney Geology Department Catalogue No. 46120; collected by Dr. B. J. Barron, New South Wales Department of Mines.

NSWMD-9. Biotite separated manually from host rock which also contained quartz, fluorite and minor amounts of sphalerite; from Torrington, New South Wales; supplied by Mr. D. R. Pinkstone, New South Wales Department of Mines.

NSWMD-10. Impure potassium feldspar containing microcline, some albite and a small amount of quartz; from 13 km SE of Broken Hill, New South Wales.

Because of scarcity of several samples, there was enough of only two samples to be sent to all seven laboratories; the potassium feldspar NSWMD-10 is the only sample of which an appreciable amount (8 vials) remains for distribution to other interested laboratories.

EXPERIMENTAL

Preparation of samples

In order to overcome sampling errors and errors due to segregation of particles on storage,[16] the five samples from New South Wales were ground to pass a 200-mesh sieve; these samples were ground in a 50-ml capacity Siebtechnik tungsten carbide mill. Since the possibility of contamination of low-potassium samples with minerals high in potassium is best avoided,[17] samples were crushed and sieved in order of increasing potassium content.

One jar of each of the five international reference rocks was available. These samples were not further ground or sieved because they were already at least 98% 200-mesh.[15]

Samples were distributed in clear polystyrene vials with polyethylene snap-on caps. These containers, from new stock, were initially washed with tap-water and a brush, followed by washing with demineralized water and drying at 60°C for 24 hr.

Vials to hold a particular sample were numbered and placed, in numerical order, in a row. The sample was thoroughly mixed by being rolled in a large polystyrene jar for 30 min on a rolling machine, and was then added in equal increments, by means of a small nickel spatula, to each vial in turn. This was continued until each vial had its full complement of sample–ranging from 2.7 g for sample NSWMD-7 to 9.0 g for sample NSWMD-10.

Methods used

Table 3 summarizes the methods used and gives details of the standard compounds used. No laboratory used exactly the same method as any of the other six laboratories. All laboratories brought the samples into solution by either hydrofluoric acid attack or lithium metaborate fusion, and subsequently measured potassium concentration by either flame emission or atomic-absorption spectrometry.

Three laboratories (E, F and G) separated potassium by cation-exchange chromatography. Laboratory A did so only for the low-potassium samples, NSWMD-1, NSWMD-2 and NSWMD-3.

Laboratory F filtered off the residues of samples NSWMD-1 and NSWMD-2 after the acid treatment (described in Table 3) and dissolved them with a mixture of phosphoric, perchloric and hydrofluoric acids.[18]

RESULTS AND DISCUSSION

Table 4 summarizes the results for the international reference rocks and also lists the "usable values" of Abbey[19] and, except for the tonalite T-1, results[20] obtained by Laboratory E on initial lots of samples (from United States Geological Survey) different from those used in this study. The right-hand double column of Table 4 summarizes the results of analysis of variance for each sample.

Analysis of variance showed that the results of Laboratories A, D and G in Table 4 agreed well with one another only for the granite G-2. The agreement between the results of these three laboratories was worst for the basalt BCR-1, although the overall mean for this sample agreed very well with the result of Laboratory E—which could indicate that the "usable value" for the basalt BCR-1 is low by about 1.7% relative. For the remaining three international reference rocks, one laboratory reported results consistently lower than those of the other two laboratories.

Results reported in Table 4 for the tonalite T-1 indicate that its "usable value" is high by 1.5–2% relative.

Table 4. Results for international reference rocks

	% K (dry basis)			% Rel. std. devn. of mean of duplicate[a] results of labs. A, D and G	
Sample	"Usable value"	Lab. E[e]	Labs. A, D and G overall mean	Between-lab.	Within lab.
MRT Tonalite T-1	1.03[f]	—	1.008 (0.998–1.014)[b] (0.04–0.15)	0.86[d]	0.62
USGS Basalt BCR-1	1.40	1.429 ± 0.005	1.426 (1.399–1.457) (0.75–1.02) (80/9)	2.02[c]	0.17
USGS Andesite AGV-1	2.43	2.456 ± 0.003	2.430 (2.383–2.458) (0.70–1.35) (11/4)	1.71[c]	0.13
USGS Granite G-2	3.75	3.760 ± 0.013	3.732 (3.725–3.743) (0.11–0.32) (23/21)	0.25	0.28
USGS Granodiorite GSP-1	4.59	4.630 ± 0.015	4.575 (4.541–4.594) (0.05–0.18) (18/12)	0.64[d]	0.28

[a] Labs. A, D and G each reported the results of two separate determinations (carried out at least six days apart) per sample.

[b] The top set of figures in brackets for each sample gives the range of laboratory mean results for potassium; the set below this gives the range of laboratory mean results for hygroscopic moisture; in the lowest brackets for the USGS samples are the Split/Position numbers.

[c] Greater than within-laboratory standard deviation at 99% confidence level.

[d] Not greater than within-laboratory standard deviation at 95% confidence level.

[e] On initial lot of sample different from that analysed by Labs. A, D and G. Each result of Lab. E is the mean of 12 complete determinations ± the 99% confidence limit of the mean.

[f] This "usable value" and subsequent ones are as reported by Abbey.[19].

The result in Table 4 from Laboratory E for a different initial jar of the granodiorite GSP-1 is appreciably higher (by 1.2% relative) than the overall mean result in Table 4; this is probably due to the inhomogeneity of sample GSP-1 which has been noted by Ingamells and Switzer.[17]

Table 5 is rather similar in structure to Table 4 but concerns the five samples from New South Wales. Instances of poor agreement between duplicate analyses can be isolated by examination of tables of individual results for these samples. (Tables of individual results for all samples in the present study can be supplied on request.)

Table 6 gives results of analysis of variance when such instances are excluded. Exclusion of poorly agreeing duplicate analyses before analysis of variance is justified by the fact that, where more than two laboratories have analysed a given sample (as in the present study), the methods of all laboratories must be of the same precision for the conclusions from analysis of variance to be strictly valid.[21]

Low within-laboratory standard deviations in Table 6 of between 0.1 and 0.2% relative indicate the best precision attainable with flame-spectrometric instrumentation; such precision has been well documented elsewhere.[17] However, multiple instrumental readings of sample and standard solutions are necessary for such good precision; the methods of all laboratories in the present study involved such multiple readings. The attainment of flame-spectrometric precision of 0.1–0.2% relative standard deviation, by taking fewer than six sets of individual readings of a given sample solution and appropriate pair of standard solutions, awaits further improvements in nebulizer-burner and gas-control systems.[1]

The emphasis of the remaining discussion in this paper is on problems of accuracy of flame methods for determining potassium in rocks and minerals, rather than precision.

Results of previous interlaboratory studies

Comparison of between-laboratory relative standard deviations in Tables 4 and 5 with those of previous studies in Table 1 shows that only for the basalt BCR-1, the andesite AGV-1, and the low-potassium samples NSWMD-1 and NSWMD-2 does the between-laboratory relative standard deviation exceed 1.3%, which was obtained[7] for the muscovite P-207 and is the lowest figure in Table 1.

Table 5. Results for samples from New South Wales

Sample	No. of labs.	Overall mean % K (dry basis)	% Rel. std. devn. of mean of duplicate[a] results	
			Between-lab.	Within-lab.
Chlorite rock NSWMD-1	7	0.0570 (0.0553–0.0611)[b] (0.14–0.37)	3.59[c]	1.57
Altered basic rock NSWMD-2	5	0.0739 (0.0722–0.0760) (0.19–0.47)	1.89	1.91
Altered andesite NSWMD-3	5	0.3002 (0.297–0.303) (0.40–0.90)	0.86[c]	0.36
Biotite NSWMD-9	6	7.603 (7.48–7.67) (0.15–0.59)	0.89[c]	0.32
Feldspar NSWMD-10	7	9.794 (9.71–9.90) (0.12–0.53)	0.67[c]	0.26

(Analysis by the author of the low-potassium samples gave: %SiO_2 26.5, 55.5, 45.0; Al_2O_3 20.3, 14.5, 9.17; TiO_2 0.17, 0.46, 0.71; ZrO_2 0.02, 0.02, 0.01; Fe_2O_3 3.11, 0.32, 1.61; FeO 22.6, 8.48, 9.31; MnO 0.58, 0.12, 0.26; MgO 15.2, 4.18, 15.0; CaO 0.22, 7.68, 9.84; SrO 0.005, 0.05, <0.005; BaO 0.01, <0.01, 0.01; Na_2O 0.02, 5.93, 1.27; K_2O 0.06, 0.09, 0.36; P_2O_5 0.06, 0.06, 0.19; H_2O (+105°C) 11.0, 2.19, 4.58; H_2O (−105°C) 0.18, 0.16, 0.60; CO_2 0.09, 0.32, 1.68; S 0.01, <0.01, 0.04; Total 100.1, 100.1 and 99.6 for samples NSWMD-1, NSWMD-2 and NSWMD-3 respectively.)

[a] Each laboratory reported the results of two separate determinations (carried out at least six days apart) per sample.

[b] The upper set of figures in brackets for each sample gives the range of laboratory mean results for potassium; the lower set gives the range of laboratory mean results for hygroscopic moisture.

[c] Greater than within-laboratory standard deviation at 95% confidence level.

Sampling problems

The suitability of the procedure used in the present study for allocating samples to vials has been confirmed[1] by analysing replicate 500-mg subsamples from three vials of sample NSWMD-1 and replicate 100-mg subsamples from four vials of sample NSWMD-10. The potassium contents of NSWMD-1 and NSWMD-10 were found to be 0.0560 ± 0.0002 and 9.81 ± 0.02% respectively, in all vials studied. Hence it is reasonable to assume that the observed potassium content of a given sample in the present study is independent of the particular vial used.

Results for hygroscopic moisture, $H_2O(-105°)$

As indicated in Tables 4 and 5, there were frequent instances of poor interlaboratory agreement of hygroscopic moisture results. In the foregoing statistical study of potassium results converted onto a dry basis

Table 6. Results of analysis of variance before and after exclusion of instances of poor within-laboratory agreement

Sample	No. of labs.	Overall mean % K (dry basis)	% Rel. std. devn. of mean of duplicate results		Is between-lab std. dev. greater than within-lab std. dev. at 95% confidence level?
			Between-lab.	Within-lab.	
NSWMD-2	5	0.07391	1.89	1.91	No
	4	0.07383	2.17	0.78	Yes
	3[a]	0.07395	2.62	0.09	Yes[b]
NSWMD-9	6	7.603	0.89	0.32	Yes
	5	7.627	0.47	0.18	Yes
NSWMD-10	7	9.794	0.67	0.26	Yes
	4	9.799	0.50	0.09	Yes[b]

[a] Labs. E, F and G.

[b] Also at 99% confidence level.

(as recommended[19]), interlaboratory variations of hygroscopic moisture results have been assumed to be due to differences in geographical location of the laboratories, and not due to major inaccuracies in some laboratories' methods for hygroscopic moisture.

Methods of sample dissolution

Work reported elsewhere[1] has shown that, for samples NSWMD-1 and BCR-1, solutions prepared after fusion with lithium metaborate for 15 min at 900° give the same potassium results as solutions prepared by hydrofluoric acid attack in both open and sealed vessels. Hence it is reasonable to assume that errors in the various dissolution procedures listed in Table 3 are negligible provided sufficient care is taken to avoid contamination and mechanical losses.

Choice of standard compound

Analytical-reagent grade potassium chloride, potassium hydrogen phthalate and bisulphate-free potassium sulphate have been found[1] to be suitable standard compounds; *i.e.*, readily obtainable at least 99.8% pure after appropriate heating. Any significant systematic error from this source is therefore very unlikely.

Accuracy of standard solutions

Accuracy of standard solutions, besides depending upon the use of a suitable standard compound, also depends upon other factors such as calibration of balances (and of volumetric glassware if this is used instead of gravimetric dilution) and freedom of interaction of the potassium in the standard solutions with container walls. It was impossible to establish whether these factors were sufficiently considered by all laboratories in the present study. Therefore inaccurate standard solutions could have made a significant contribution to the lack of interlaboratory agreement in some instances in the present study.

Contamination from glassware

High between-laboratory variations for the low-potassium samples NSWMD-1, -2 and -3 are at least partly due to contamination from reagents, surroundings, or vessels. As shown in Table 6 except for sample NSWMD-2, Laboratories E, F and G obtained very good within-laboratory agreement for these samples; this suggests that contamination from glassware (not accounted for by blank runs) or adsorption onto walls of polyethylene vessels (Laboratory G) occurred. The latter possibility has been excluded by the finding[1] that the polyethylene vessels used by Laboratory G do not adsorb potassium from acidified solutions.

It is worth noting that the glassware of Laboratories E and F was preconditioned by soaking in 0.75*M* nitric acid and in hot 1:1 nitric acid, respectively. Such treatment has been stated[22] to be likely to sensitize the glass surface so that it will retain adsorbed ionic films. This is presumably because of replacement, by hydrogen ions, of cations such as calcium, sodium and potassium previously bound to the surface of the glass. The acid-treated glass surface, when attacked by very dilute hydrofluoric acid resulting from hydrolysis of complex fluorides[23] in the sample solutions of Laboratories E and F, would thus cause less contamination by potassium than a glass surface not acid-treated. (However such contamination by potassium from acid-treated glassware would not occur if, after nitric acid treatment, no potassium remained on or near the surface in sites accessible to attack by very dilute hydrofluoric acid; negative errors could then arise because of adsorption

Table 7. Comparison of results of Laboratories E, F and G for low-potassium samples

		Mean K *ppm*			Between-lab. difference, K *ppm*		
Sample	Ca, %	Lab. E	Lab. F	Lab. G	E − F	E − G	F − G
PCC-1	0.38	13.2 (±1.2)	30.9 (±0.8)	—	−18	—	—
DTS-1	0.1	10.5 (±1.0)	14.0 (±1.9)	—	−3	—	—
NSWMD-1	0.16	565	583	560	−18	+5	+23
NSWMD-2	5.49	737	760	722	−23	+15	+38
NSWMD-3	7.03	3025	—	3001	—	+24	—

Notes. 1. Laboratory E made 10 and 9 complete determinations on samples PCC-1 and DTS-1, respectively.[20] Laboratory F made 4 complete determinations on these two samples.[24]

2. Results of Laboratories E and F for samples PCC-1 and DTS-1 are ± the standard deviation of a single determination.

3. In Reference 10, three laboratories obtained the following potassium results (on the USGS samples) by neutron activation analysis:

Sample PCC-1; 11.5, 11, 9.0 ppm K
Sample DTS-1; 8.8, 9, 7.9 ppm K

4. Laboratory C has reported 9 ± 2 ppm K for sample DTS-1.[17] This is the mean of six complete determinations ± the standard deviation of a single determination and agrees well with the neutron activation results.

by acid-treated glassware of potassium in sample solutions.)

Table 7 gives results of Laboratories E, F and G for low-potassium samples in the present study; results[20,24] of Laboratories E and F for the USGS reference rocks, PCC-1 and DTS-1, are also included. Note 3 of Table 7 gives results of three other laboratories[10] which have analysed samples PCC-1 and DTS-1 by neutron activation; these results are appreciably lower than the flame-spectrometric results of Laboratories E and F. The good agreement of the result of Laboratory C for sample DTS-1 (Note 4, Table 7) with the neutron-activation results, indicates that contamination from glassware is less likely when solutions are prepared by lithium metaborate fusion rather than by hydrofluoric acid treatment.

Interlaboratory differences in Table 7 vary from sample to sample, and are more pronounced for samples with higher calcium contents (also given in Table 7). The question of the possibe effect of calcium upon the extent of potassium contamination from glassware arises because calcium has the widest range of composition of all the major elements in the five samples in Table 7.

When samples high in potassium are analysed by the methods of Laboratories E and F, the results in Table 7 show that contamination from glassware does not cause an appreciable error; an absolute positive error not exceeding 0.004% potassium (38 ppm) is indicated; this represents a relative error of 7% for sample NSWMD-1, and of only 0.04% for sample NSWMD-10 which contains 9.8% potassium.

The occurrence of contamination from glassware, during analysis of samples low in potassium, requires further investigation.

Flame-spectrometric method and technique

Procedures involving flame measurement are susceptible to small systematic errors due to any of the following: (*a*) inaccurately diluted standard and sample solutions, (*b*) contamination by airborne potassium (*e.g.*, in smoke), (*c*) failure to maintain standard and sample measurement solutions at the same temperature, (*d*) large variations in hydrostatic head between sample and standard measurement solutions,[25] and (*e*) slight non-linearity of instrument response. It has been shown[1] that such errors can be avoided.

Table 8. Results of Laboratory A for samples NSWMD-1 to NSWMD-3, with and without cation-exchange separation of potassium

	% K (dry basis)	
Sample	With separation	Without separation[a]
NSWMD-1	0.0548	0.0737
	0.0557	0.0671
		0.0707
		0.0701
NSWMD-2	0.0772	0.0819
	0.0713	0.0745
		0.0821
		0.0822
NSWMD-3	0.2989	0.3127
	0.2976	0.3135

[a] No correction made for bias[26] due to iron.

Table 9. Results of Laboratory G with and without cation-exchange separation of potassium

		% K (dry basis) Type of AAS measurement solution[b]		
Sample	Run[a]	NO	Cs	IE
NSWMD-1	1	0.0555	0.0556	0.0569
	2	0.0553	0.0554	0.0559
NSWMD-2	1	0.0752[c]	0.0721	0.0720
	2	0.0749	0.0720	0.0724
NSWMD-3	1	0.2998	0.2991	0.2999
	2	0.3021	0.3012	0.2999
T-1	1	1.011	1.011	1.021
	2	1.013	1.009	1.013
BCR-1	1	1.444	1.426	1.424
	2	1.433	1.418	1.423
AGV-1	1	2.468	2.458	2.460
	2	2.502	2.459	2.455
G-2	1	3.773	3.738	3.715
	2	3.724	3.713	3.732
GSP-1	1	4.594	4.610	4.600
	2	4.590	4.579	4.587
NSWMD-9	1	7.59	7.61	7.59
	2	7.60	7.58	7.58
NSWMD-10	1	9.86	9.84	9.77
	2	9.86	9.80	9.82

[a] Run 2 was done about 2 months after run 1.

[b] NO = no buffer other than lithium from flux. Cs = buffered with 1.20 mg of CsCl per g. IE = K fraction from ion-exchange separation, buffered with 1.20 mg of CsCl per g.

[c] High probably because of ionization interference by large excess of sodium over potassium in sample NSWMD-2.

The need to separate potassium from other constituents in the sample before flame measurement seems to depend upon the type of flame measurement: the lithium internal-standard, propane–air flame emission method of Laboratory A gave high results for the low-potassium, ferromagnesian samples NSWMD-1, -2 and -3 when potassium was not separated (Table 8); however, the atomic-absorption, acetylene–air flame method of Laboratory G for unseparated solutions buffered with caesium always gave results which agreed well with results for separated solutions (Table 9).

CONCLUSIONS

The results of the present interlaboratory study are good enough to support the conclusion[1] that—provided sampling errors are overcome and sufficient attention is paid to detail at all stages of the analytical procedure—a between-laboratory variation in flame-spectrometric potassium results of less than 0.5% relative standard deviation is attainable. Greater precautions to avoid losses and contamination during preparation of sample solutions, and stricter measures to avoid interferences and other errors in the flame measurement step would yield better interlaboratory agreement than that observed in some instances in the present study.

RELATIVE SENSITIVITY COEFFICIENTS FOR THE ANALYSIS OF STEEL BY SPARK-SOURCE MASS-SPECTROMETRY

E. VAN HOYE, R. GIJBELS and F. ADAMS
Department of Chemistry, Universitaire Instelling Antwerpen, Universiteitsplein 1, B-2610 Wilrijk, Belgium

(*Received* 7 *October* 1975. *Accepted* 16 *October* 1975)

Summary—Quantitative analysis by spark-source mass-spectrometry requires the knowledge of so-called sensitivity coefficients for the elements being determined. Five series of analyses have been carried out on five different steel standard reference materials (NBS-SRM 661–665), using photoplate detection. The relative sensitivity coefficients (S_R) of Ti, V, Cr, Mn, Co, Ni, Cu, As, Zr, Nb, Mo, Sn, Sb, La, Ta and W were determined *vs.* iron as an internal standard. The S_R values were independent of the elemental concentration. A relative standard deviation of about 15% was obtained. The accuracy as confirmed by comparing the results for a pure iron sample with those obtained by neutron-activation analysis was within the same limits.

Spark-source mass-spectrometry is increasingly being used for trace analysis in metals and alloys. This technique has the advantage of being capable of determining almost all elements at the sub-ppm level, and down to the ppM (parts per milliard) level in favourable conditions, but suffers from poor precision with a coefficient of variation of 20–30%.[1,2] When the method is used on an absolute basis, *i.e.*, without standards, inaccurate results are obtained. The mass-resolved ion-beams reaching the detector are not representative of the true composition of the sample, as a result of selective evaporation, non-uniform ionization efficiency and selective transmission through the analyser.[3,4] For each element a concentration level is measured which differs from the true concentration, and the ratio of these values is called the sensitivity coefficient or sensitivity factor.

Honig[4] defined the "absolute overall yield" $Y_0(x)$ of component x as

$$Y_0(x) = I_d(x)/A(x) = Y_s(x).f_t(x).f_d(x)$$

where

$I_d(x)$ = number of ions detected
$A(x)$ = number of sample atoms vaporized
$Y_s(x) = I_s(x)/A(x)$, "source yield" or the ratio of number of ions produced to the number of sample atoms vaporized
$f_t(x)$ = instrumental transmission factor
$f_d(x)$ = detector response factor.

In a typical double-focusing mass spectrometer $Y_0(x)$ lies between 10^{-7} and 10^{-8}.

In practical quantitative analysis the most important parameter is the ratio $Y_0(x)/Y_0(y)$ where y represents the matrix element, or more generally, an element, present in the sample at known concentration, which is used as an internal standard. This parameter is called the relative sensitivity coefficient of component x.

In the literature various kinds of "sensitivity factors" or "sensitivity coefficients" are frequently encountered. In this paper the relative sensitivity coefficient (S_R) for element x is defined as $S_R\,(x/y)_z$ = ratio of the concentrations of elements x and y in the matrix material z as determined by mass spectrometry, divided by the ratio of the true concentrations of elements x and y. This can be expressed as

$$S_R(x/y)_z = [(C_x/C_y)_{\text{determined}}/(C_x/C_y)_{\text{true}}]_z. \quad (1)$$

Only singly-charged ions are considered and corrections are made for variation in background and line-width. The definition proposed by Farrar[5] includes a correction for the influence of the ion-mass on the detector response. This correction is not made in this work, since there is no unanimity in the literature about the exact value of this correction factor,[6] which depends on the nature of the ion-sensitive plate.

From the definition of S_R it is obvious that all values are calculated with respect to an element y having an arbitrary value of unity. In the steel standards analysed in this work, the sensitivity coefficient of iron is set equal to unity thus: $S_R(\text{Fe/Fe})_{\text{steel}} = 1$.

For the experimental determination of sensitivity coefficients, standard reference materials are required. A large number of experimentally measured sensitivity coefficients can be found in the literature,[5,7–9] but agreement is rather poor. The data are often difficult to compare because of differences in the definition of S_R or because they are calculated with respect to different elements. In addition, the sensitivity coefficients may depend on the characteristics of the instrument used and on a number of experimental parameters, such as spark conditions, spark geometry with respect to entrance slit, width of various slits, and accelerating voltage. Several authors have observed matrix effects.

Another approach is to calculate relative sensitivities of elements in a radiofrequency spark, from their physical and chemical properties.[3,5] For analytical work, such calculated values may be of interest when no suitable standards are available.

The purpose of the present work is to determine the relative sensitivity coefficients of a number of elements in steel under well-specified experimental conditions. The effect of varying various experimental parameters is reported.

EXPERIMENTAL

Apparatus

The experiments were performed with a double-focusing instrument with Mattauch–Herzog geometry (JMS-01 BM-2, JEOL, Tokyo). The instrument incorporates a spherical electric field to reduce the beam spread in the *z*-direction, and is equipped with a radiofrequency spark source. Ilford Q-2 ion-sensitive plates were used as the detector. These plates were read with a scanning microdensitometer JEOL JMD-2C interfaced to a JEOL JEC-6 computer (8K, 16-bit words; magnetic drum memory of 8K). The computer program (JEOL JMA-1340) has been discussed in a recent paper.[10]

Samples

Four low-alloy steels and one electrolytic iron, available from the National Bureau of Standards, Washington, D.C. (NBS-SRM 661–665) were chosen as standard reference materials covering a large concentration range for as many elements as possible. These materials have the reputation of excellent homogeneity.

Table 1 lists the certified concentrations for a number of elements; the only elements indicated are those for which a certified concentration is available for at least 4 standards and with interference-free mass-lines. According to the certificate, these values are not expected to deviate from the "true" concentration by more than ±1 in the last significant figure reported; for a subscript figure, the deviation is not expected to be more than ±5 The values in brackets were obtained by a single method of analysis

In addition, a so-called high-purity iron sample, prepared for the "Verein Deutscher Eisenhüttenleute" was analysed. The analysis of this sample by neutron activation has been studied exhaustively.[11]

Sample preparation

As the standards were in rod form (diam. 3·2 mm), they were cut to the proper length. The sparking surfaces were ground flat to minimize changes in interelectrode self-shielding. After etching with nitric acid of *pro analysi* quality the electrodes were mounted in the sample holders in such a way that sparking would occur preferentially between the flattened portions of the electrodes.

Mass spectrometric procedure

The electrodes were positioned as shown in Fig. 1 in order to minimize the effects of irreproducible spark position[12] and were aligned so as to obtain maximum transmission

The width of the slits was as follows, object slit 30 μm, α slit (in front of the electrostatic field) 0·7 mm and β slit (energy-defining slit—behind the electrostatic field) 1·0 mm.

The "Variac" setting which controlled the input to the radiofrequency oscillator was set at 4 kV, this corresponds to a spark-source voltage of about 65 kV. The other spark conditions were as follows, pulse length 20 μsec, repetition frequency from 10 to 3000/sec, and ion-accelerating voltage 30 kV.

A series of graded exposures was made on each plate, ranging from 3×10^{-13} to 2×10^{-7} C in steps of about $10^{1/2}$. All samples were pre-sparked for at least 5 min

RESULTS AND DISCUSSION

Reproducibility of experimental sensitivity coefficients for standard NBS-SRM 661

Standard sample NBS-SRM 661 was analysed eight times in sequence. The average value of the experimentally determined concentrations is indicated in

Table 1. Composition of standard samples, % w/w

* By difference

† Approximate value

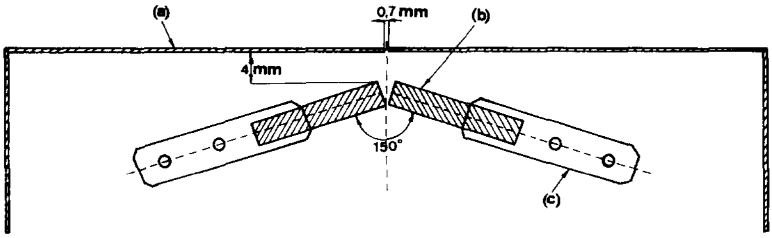

Fig. 1. Electrode position. (a) Accelerating slit (tantalum), (b) sample electrode, (c) sample holder (tantalum).

column 3 of Table 2, iron being used as the internal standard. The relative standard deviation, shown in column 4, is defined as

$$s_{\%} = \frac{100}{\bar{C}}\sqrt{\frac{(C_i - \bar{C})^2}{n-1}} \qquad (2)$$

where C_i is an individual concentration, $\bar{C}$ is the mean concentration and n is the number of analyses.

The average value of $s_{\%}$ for all elements is 15%. The relative sensitivity coefficient S_R (column 5 of Table 2) is in accordance with equation (1), where $S_R(\mathrm{Fe/Fe})_{\mathrm{steel}} = 1{\cdot}00$ and can be calculated by using the data in Table 1 (column 2). Significant differences can be observed among the tabulated S_R values and there is a correlation between these values and the properties of the elements concerned.

Sensitivity coefficients as a function of concentration: analysis of standards NBS-SRM 661–665

From the analytical point of view it is important to show whether the S_R values vary with the concentration of the element in a given matrix. This information can be extracted from a study of all the available steel standards, since the elemental concentrations span one or more orders of magnitude. Therefore the standards NBS-SRM 662–665 were analysed five times and the average concentrations were used to calculate the S_R values given in Table 3.

The errors of the certified values (Table 1) differ widely, and the specified uncertainty was interpreted as being twice the standard deviation. The standard deviation indicated with each relative sensitivity coefficient in Table 3 was obtained from

$$s = \frac{a}{b}\sqrt{\left(\frac{s_a}{a}\right)^2 + \left(\frac{s_b}{b}\right)^2}$$

where a refers to the concentration determined by mass spectrometry and b to the certified concentration.

Table 3 also gives the weighted average of the S_R values derived from all the standards and its relative standard deviation calculated from

$$\bar{S}_R = \frac{\Sigma(S_{R_i}/s_i^2)}{\Sigma(1/s_i^2)}; \quad s_{\%} = \frac{100}{\bar{S}_R}\cdot\frac{\sqrt{N}}{\Sigma(1/s_i^2)}$$

* Interference of $^{118}Sn^{2+}$

The overall mean relative standard deviation of 15% is to be compared with the corresponding standard deviation for the NBS 661 sample, which is 16%. It can thus be concluded that over the impurity concentration range studied there is no evidence that S_R is a function of the composition. Figure 2 shows the S_R values measured for chromium, vanadium, cobalt, nickel, molybdenum and tantalum, plotted as a function of concentration. It is possible, by linear regression analysis, to calculate the slopes of the straight lines and their uncertainty. A systematic survey for all the elements studied shows no evidence that the slope differs significantly from zero, as is apparent from Table 4.

Precision and accuracy

From Tables 2 and 3 it is apparent that the precision of the experimentally determined S_R values is of the order of 15%. This can be compared with the corresponding figures obtained by other authors, which are summarized in Table 5.

This precision gives an indication of the accuracy with which similar steel samples can, in principle, be analysed, relying on the experimentally determined S_R

* The values from a single method of analysis are excluded.

values. To confirm this the high-purity iron sample was analysed and the results are compared with those obtained by neutron-activation analysis,[11] in Table 6.

Various experimental parameters control the precision. *High frequency spark.* Systematic fluctuations in the spark plasma are now considered to be insignificant in comparison with random variations.[15] These variations are averaged out to some extent. *Densitometer and photoplate.* The errors originate from nonuniformities of the emulsion and also from the measurement of the line and background optical densities. We have found that with the automated densitometer the precision of the measurements is 2–5%.[10] This is consistent with results obtained by Franzen and Schuy[16] and Skogerboe, Kashuba and Morrison.[15] *Exposure measurements.* The accurate measurement of very low exposures is difficult.[17] This leads to imprecise results, especially when the matrix lines are used as internal standard. To assess this effect 5 photoplates were taken, each containing 15 identical exposures varying from 3×10^{-9} to 10^{-12} C. A number of lines of roughly equal transmission were measured and the integrated intensities were averaged. The results are indicated in Table 7, column 3. As the precision of the optical density measurement can be assumed to remain constant, the monitor readings become much more unreliable for low exposure values. Care was taken to measure matrix or major element lines at the lowest exposures to eliminate effects due to inhomogeneity.

Sample. Apart from the instrumental parameters considered above, the sample itself may be a source of errors due to inhomogeneities, inaccurate certification and spectral interferences. The reference standard materials NBS 661–665 are often used for the evaluation of the precision of spark-source mass-spectrometric procedures because of their homogeneity. Nevertheless very little material is consumed for a single exposure and the influence of possible inhomogeneities on our results cannot be excluded. The standards exhibit widely different errors in their certified concentrations. For example, NBS-661 is specified to within 0·5% relative for Ni and 45% relative for Sn. Table 8 summarizes these data for the different reference materials.

One of the major problems in spark-source mass-spectrometry is spectral interference. A number of interferences were identified and the corresponding isotopes were omitted. The agreement between the results obtained by mass spectrometry and neutron activation for the iron sample is an indication that interferences are virtually absent from the data in Tables 2 and 3. Special attention was given to the occurrence of unusual isotopic ratios and to widely scattered S_R values as indicators for possible spectral interferences.

Influence of instrumental parameters

A number of instrumental conditions which might have an effect on the analysis have been studied, with NBS-SRM 661 steel standard as sample.

Duty cycle. The effect of changes in pulse length was investigated by taking 3 identical exposures and varying the pulse length (20, 40 and 80 μsec). In order to cover the concentration range from ppm to matrix, this was done for 5 different exposures. All these mass spectra were recorded on the same photoplate. The intensities of the mass-lines were measured and the reproducibility was calculated (Table 7, column 4). Comparison with the standard deviation at fixed pulse length (Table 7, column 3) by using the statistical F-test shows that there is no significant contribution from the changes in pulse length to the precision. The effect of changes in pulse repetition frequency (30, 100, 300, 1000, 3000 and 10,000/sec), was studied in the same way. Again, no systematic trends could be observed and the precision decreased by an insignificant amount. The experiments above indicate that changes in duty cycle do not cause considerable changes in the analytical results, supporting the findings of Short and Keene[13] and Owens and Giardino.[18]

Radiofrequency spark voltage. The effect of changes in the radiofrequency spark voltage was determined in a similar way. Some of the results are plotted in Fig. 3. It was found that changes in radiofrequency voltage did not degrade the precision. This is consistent with the results found by Wong,[19] who indicated that "analytical results are not significantly affected by changes in applied r.f. voltage".

Accelerating voltage. The influence of changing the accelerating voltage seems to be more important (about 10% r.s.d.). This effect however could not be studied with sufficient accuracy; indeed, variation of the accelerating voltage changes the ion-energy and hence necessitates adjustments in the applied electrostatic field. In addition, the trajectory of a given kind

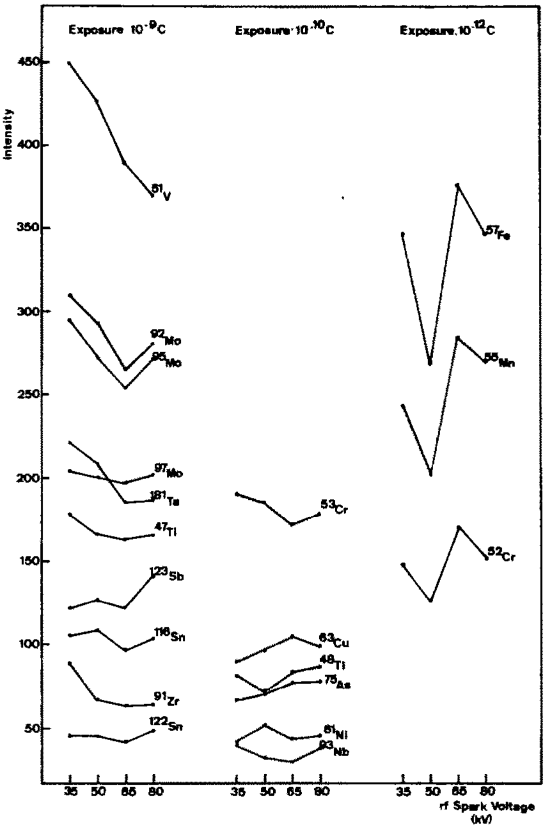

Fig. 3. Variation of photographically measured intensities with the radiofrequency spark voltage.

of ion through the magnetic field changes and so affects the transmission. Further study is needed to elucidate the relative contribution of these effects to the recorded line intensity.

CONCLUSIONS

Significant differences were found to exist between relative sensitivity coefficients for different elements in the same standard, but relative sensitivity coefficients of an individual element did not change significantly from standard to standard in spite of the widely differing concentration levels. A precision of about 15% was obtained. Comparison with neutron-activation analysis showed that the accuracy of spark-source analyses of steel and iron samples, using the experimentally determined sensitivity coefficients, was of the same order. The random variation of the spark plasma, the densitometer error and the heterogeneous distribution of the trace elements may be regarded as the prime precision-limiting factors in the overall analytical error. Better precision may be obtained when the internal standard (isotope) has about the same concentration as the impurities so that long exposures are used and the influence of monitor measurement errors is decreased. For the precise determination of relative sensitivity coefficients, it is imperative to use reliable, well-characterized standards; unfortunately, the NBS steel standards used in this work have an average uncertainty of about 7% for the elements determined here. Relative sensitivity coefficients cannot be determined if spectral interferences occur. Variations in pulse length, pulse repetition frequency and spark voltage do not have a large influence on the precision.

A RAPID FIRE-ASSAY/ATOMIC-ABSORPTION METHOD FOR THE DETERMINATION OF PLATINUM, PALLADIUM AND GOLD IN ORES AND CONCENTRATES: A MODIFICATION OF THE TIN-COLLECTION SCHEME*

P. E. MOLOUGHNEY and G. H. FAYE
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 21 *July* 1975. *Accepted* 9 *October* 1975)

Summary—The tin-collection scheme of fire-assaying has been simplified to permit the rapid and accurate determination of platinum, palladium and gold in ores and related materials. The presence of tellurium in the charge ensures that the precious metals remain insoluble during the parting of the tin button with hydrochloric acid. The residue is easily collected and dissolved and the resultant solution analysed for the precious metals by AAS. The accuracy of the method has been established by application to five diverse certified reference materials.

The tin-collection scheme[1–4] for the determination of the precious metals in ores and concentrates has been used in our laboratories for approximately 10 years. Its accuracy, reliability and versatility have been well proved in interlaboratory studies.[5–7]

When this scheme is applied to the determination of gold, silver, and the platinum-group metals, solutions derived from tin assay buttons are treated by rather tedious ion-exchange and extraction processes and the analysis is finished either spectrophotometrically or by atomic-absorption spectrophotometry (AAS).[3] However, it is often necessary to determine only platinum, palladium and possibly gold, and a simplified procedure would be desirable.

The basis for such a method was recognized several years ago when it was established that the intermetallic compounds formed by platinum, palladium, and gold with tin are essentially insoluble in the hydrochloric acid used to part the tin-assay button.[1–2] However, it was also observed that copper and nickel tend to increase the solubility of the precious metals during the parting operation.

Tellurium has been used to precipitate platinum, palladium, rhodium and iridium by reduction[8] and it is known to form intermetallic compounds such as $PtTe_2$, $PdTe_2$.[9] Tellurium was therefore added to the fire-assay charge to assess it as a "carrier" or "fixing agent" for platinum, palladium and gold. The results showed that an easily collected insoluble residue containing the three precious metals is formed quantitatively during the decomposition of the tin-assay button in hydrochloric acid. This forms the basis of the proposed method, which is rapid, accurate, and widely applicable.

EXPERIMENTAL

Apparatus

Furnaces. A 15-kW Globar type with suitable thermocouple and temperature controller, capable of accommodating 6 40-g assay crucibles and maintaining their temperature at 1250°. A Jelrus "Handy-Melt" portable electric furnace. (Jelrus Technical Products Corp. New Hyde Park, N.Y.) or similar. The Jelrus is a small vertical furnace equipped with removable graphite crucibles, used in this work for melting tin-base assay buttons before their granulation in water. It is recommended that after 4–6 months of relatively constant use the bottom of the crucibles be examined for small holes.

Reagents

Tin (IV) oxide. B.D.H. reagent-grade is preferred because it has consistently given a gold blank value of 150–200 ng/g.

Tellurium powder. Reagent grade.

Standard solutions of platinum, palladium and gold. Prepared by dissolving accurately weighed quantities of Johnson Matthey "Specpure" sponge in *aqua regia*. Each solution is evaporated to dryness, then the residues are dissolved in concentrated hydrochloric acid and the solution evaporated to dryness again, this being repeated several times. Finally, the salts are dissolved in, and diluted to volume with, $1M$ hydrochloric acid. The gold solution is standardized gravimetrically by the classical fire-assay procedure with lead, and the platinum and palladium solutions are standardized spectrophotometrically.

Mixed cadmium–copper sulphate solution.[10] Prepared by dissolving 98 g of $CuSO_4.5H_2O$ and 57 g of $3CdSO_4.8H_2O$ in 500 ml of $12M$ hydrochloric acid and 300 ml of water, followed by dilution to 1 litre with water

Flux for fire-assay. SnO_2 40 g, Na_2CO_3 50 g, $Na_2B_4O_7$ 10 g, flour 35 g, Te 25 mg, silica 10–20 g according to the amount of silica in the sample, make enough flux for a sample up to 1 assay-ton (29·17 g) in size.

Procedures

Although aspects of certain of the following procedures have been described previously,[3] they are repeated here for completeness and for the convenience of the reader.

Pretreatment of samples

Roasting. Before the crucible fusion procedure, all samples except those of copper-nickel matte are roasted at 750–800° for approximately 1 hr to decompose sulphides and volatilize arsenic and antimony. The sample is placed on a shallow fire-clay dish and stirred intermittently during the roasting process. In cases where only a few grams of material (particularly sulphides) are to be roasted, the sample is placed on a bed of silica to prevent possible loss of the resultant calcine to the surface of the dish (the silica is included as part of that required in the flux above).

Leaching of copper-nickel matte. Leaching is performed to remove the bulk of the copper and nickel from the residue of precious metals. The sample, weighing up to 2 assay-tons, is placed in a 1500-ml beaker and treated with 25 g of ammonium chloride and 100–200 ml of 12*M* hydrochloric acid. The sample is heated until the amount of insoluble matter appears not to exceed 2–3 g. With large samples, it may be necessary to treat the residue once or twice more with fresh acid after intervening filtrations. The combined sample solution (approximately 100 ml) is diluted with an equal volume of water and the solution containing most of the nickel and copper is filtered through a moderately fast paper. The solids are completely washed onto the paper with dilute (~5%) hydrochloric acid. The washed residue and paper are dried at ~110° for about 1 hr and then mixed with the recommended assay flux for fusion.

Chromite. Chromite is not completely decomposed during the fusion process, and samples containing an appreciable proportion of it must be subjected to a pretreatment that will decompose it. This can be done by sintering with sodium peroxide. The sample is mixed with 1·5 times its weight of sodium peroxide, then placed on a 10-g bed of silica in a roasting dish and roasted at 700° for about 1 hr. The sinter cake and underlying silica are ground together in a mortar and mixed with the flux for the crucible fusion process. The weights of sodium peroxide and silica are subtracted from the weights of sodium carbonate and silica, respectively, in the flux described above.

Procedure for preparation of buttons

Powdered samples. For powdered samples, the standard assay practice of blending the samples with the flux on glazed paper and transferring the charge to a "40-gram" crucible is followed.

Solutions (synthetic samples for method development). When solutions are to be mixed with the flux, approximately one-third of the flux is placed in the crucible and a 30-cm square of thin, commercial wrapping-film is pressed into the crucible to form an envelope, and then the remainder of the flux is transferred into this envelope. With a spatula, a cavity is formed in the bed of flux and the sample solution is transferred slowly into the depression so as to avoid wetting the film or crucible walls. The crucible is then heated in a drying oven at 110° for at least 2 hr. After drying, the material in the wrapping film is ground in a mortar, mixed well, and placed back in the film in the crucible. It is to be noted that, after drying, the salted portion of the charge is lumpy and difficult to pulverize and mix with the rest of the charge. This could lead to occasional spurious results (Table 2).

Fusion. The crucible is placed in the assay furnace at 1250° for about 90 min to fuse the charge. At the completion of the fusion period, the melt should not be viscous or lumpy nor should there be extensive crust formation at the top of the melt.

The melt is poured into a conical steel mould and, when it is cool, the tin button is separated from adhering slag by tapping with a small hammer.

Granulation of buttons. The button is placed in the crucible of the Jelrus furnace, from which air is purged by nitrogen delivered through a ceramic tube placed directly over the button. The temperature is increased until the button melts (600–1000° depending upon composition), then the melt is poured into a pail of water to granulate the alloy. Any large pieces are easily reduced in size with metal shears.

Analysis of granulated tin buttons. Each sample of granulated tin alloy is treated with 150 ml of 12*M* hydrochloric acid in a covered 600-ml beaker and heated until the excess of tin has dissolved and vigorous evolution of bubbles from the residue has ceased. A further 15–25-ml portion of acid is added and the sample is boiled for approximately 10 min. Water is added to give a volume of approximately 400 ml and the residue is allowed to settle The supernatant solution is decanted through a filter pad The residue in the beaker is washed several times, by decantation, with 15% v/v hydrochloric acid, the washings being passed through the filter pad.

The residue in the beaker is treated with a mixture of 15 ml of 12*M* hydrochloric acid and 5 ml of 30% hydrogen peroxide, and the beaker is heated gently for a few minutes to ensure complete dissolution of the residue. The residue on the filter pad is eluted with 20 ml of a 3:1 mixture of 8*M* hydrochloric acid and 30% hydrogen peroxide, and added to the beaker.

Approximately 50 mg of sodium chloride are added, and the sample solution is evaporated to dryness. When the evolution of fumes has nearly ceased, the beaker is removed from the evaporator and the sides are washed with ~10 ml of a 7:2 mixture of hydrochloric and hydrobromic acids. The sample is again evaporated to dryness to volatilize the remaining tin. The beaker is cooled, 10–15 ml of 12*M* hydrochloric acid are added and, while the beaker is being swirled, 30% hydrogen peroxide is cautiously added until it is evident that an excess is present. The beaker is heated for a few minutes, then, after cooling, the sides are washed with water. After filtration of the solution through a fast paper into a 400-ml beaker and washing of the paper several times with 15% hydrochloric acid, approximately 5 ml of *aqua regia* are added and the solution is evaporated to approximately 1 ml.

To the cooled sample solution, 5 ml of cadmium–copper sulphate solution is added and the mixture is transferred to a 25-ml volumetric flask and diluted to volume with water. The platinum, palladium and gold content of the sample is then determined by AAS. Any silver, rhodium, ruthenium or iridium remaining in the solution will not interfere.

NOTE. For milligram amounts of the precious metals, the solution obtained after the volatilization of tin is filtered into a 100–500-ml flask and diluted to volume with 15% hydrochloric acid to prevent hydrolysis. An aliquot is taken and treated by the procedure given above.

Calibration for AAS. Calibration curves for gold and palladium are linear in the ranges 0·2–3 ppm and 0·4–3 ppm respectively. However, for the determination of platinum it is necessary to use the interpolative method with standard solutions

Correction for gold in stannic oxide. Because all batches of stannic oxide tested in this laboratory were found to contain gold, it is deemed necessary to carry a blank through the analytical scheme.

RESULTS AND DISCUSSION

Effect of tellurium on precious metals during the determination by AAS

To determine the magnitude of possible interference by tellurium in the AAS determination of the three precious metals, synthetic solutions were prepared in which the Te:precious metal ratio was varied over an appreciable range. Each solution was evaporated

to approximately 1 ml and then conditioned for atomization by the procedures described above. The results, given in Table 1, show that tellurium has a moderate depressant effect on the determination of the precious metals when the Te:precious metal ratio is approximately 1000:1. However, in subsequent tests (Table 2) it was established that the amount of tellurium required (*i.e.*, ~ 15 mg) to act as an effective carrier during the fusion of the charge would ultimately result in a lower ratio in the final solution for atomization and, consequently, not interfere. The results in Table 1 also confirm that cadmium–copper sulphate buffer solution prevents interelement interference among the three precious metals,[10] at least in the ranges investigated.

Efficiency of tellurium as carrier during fusion and parting of tin button

To establish the efficiency of tellurium as a "carrier" during fusion and button-parting steps, a number of fire-assay charges were salted with tellurium, platinum, palladium and gold, and 0·5 g each of copper and nickel oxides to simulate ore samples. These samples were fused to produce tin buttons which were each analysed for the precious metals according to the procedures given above. The results of these tests, given in Table 2, show that when tellurium is not present, the recovery of the precious metals from the tin button is incomplete in most cases. Because it is known that collection of the precious metals by tin is quantitative, the losses no doubt occurred during the parting operation.

In earlier work, the hydrochloric acid–stannous chloride solution obtained on dissolution of the tin button was not boiled with additional fresh acid to reduce the amount of undissolved copper. Under those conditions, quantitative recoveries of platinum, palladium and gold were often achieved. In the present method, the parting step is protracted to ensure that there is less than approximately 0·1 g of copper in the residue. This amount, when diluted to 25 ml will not interfere subsequently in the AAS determination of the precious metals. (For example, by the procedure given above, less than 0·05 g of copper remained in the residue obtained on the parting of a granulated tin button that originally contained 0·75 g of copper.)

The results in Table 2 indicate that when 15–20 mg of tellurium are added to the charge, sufficient tellurium enters the button to act as a carrier for at least 7 mg of combined platinum, palladium and gold during the hydrochloric acid parting step. Of course, in practice, most samples would contain substantially less than milligram amounts of the precious metals (*e.g.*, Table 3).

In certain experiments with blank charges containing 50–200 mg of tellurium, it was found that a significant proportion of finely divided tellurium remained at the surface of the melt during fusion and subsequently stained the crucible wall at the top of the

melt. In these tests the solubility of tellurium in tin may have been exceeded. In any case, using the recommended quantity of 25 mg ensures that sufficient tellurium ultimately appears in the button to act as an effective carrier for the precious metals.

The finely divided, amorphous, tellurium–precious metals residues from several synthetic samples were examined by microscopical methods and analysed by electron-microprobe techniques, and no discrete tellurium compounds could be identified.

A substantial fraction of the silver and rhodium that may be in the tin button will dissolve during parting, even when tellurium is present. Results from previous work,[11, 12] suggest that the same would be true for iridium and ruthenium. In any case, none of these metals, in the concentrations expected in the parting residue, will interfere ultimately with the AAS determination of platinum, palladium or gold.[3, 10]

Application to certified reference materials

The proposed method was applied to four certified reference materials prepared by the Canadian Certified Reference Materials Project, and also to a certified ore recently prepared by the National Institute for Metallurgy of South Africa. The analyses were performed in quintuplicate by the appropriate procedures described above, and the results are given in Table 3.

With the possible exception of the gold value for matte sample PTM-1, all results are in excellent agreement with the certified or recommended values for the five reference materials. Moreover, except for gold in MA-1, the coefficient of variation of the results by the proposed method is lower than the average of the coefficients of variation for the laboratories which participated in the certification of the reference materials.

CONCLUSION

The proposed modification of the tin-collection method, in which tellurium acts to prevent dissolution of platinum, palladium and gold during parting of the button in hydrochloric acid, offers several advantages over alternative fire-assay methods. It is simple and rapid; a set of samples can easily be carried from the fusion step through to completion within a working day. It is widely applicable and uses a flux of essentially fixed composition for all type of sample. No major separation steps are required to isolate and separate the precious metals after the fusion, *e.g.*, scorifications, ion-exchange or solvent extraction procedures, therefore potential losses are minimized. Its accuracy has been well established by analysis of a number of diverse certified reference materials.

Acknowledgement—The authors are grateful to J.H.G. Laflamme of CANMET for the electron-microprobe analyses performed in connection with the development of the method.

SPECTROFLUOROMETRIC DETERMINATION OF THIOPURINES—I
6-THIOGUANINE

A. D. Thomas
Department of Chemistry, University of Aberdeen, Old Aberdeen, Scotland

(*Received* 25 *August* 1975. *Accepted* 2 *November* 1975)

Summary—6-Thioguanine is oxidized to the corresponding *S*-oxide by reaction with hydrogen peroxide in 50% acetic acid at 50° for 5 min. The *S*-oxide is highly fluorescent and a rapid and sensitive fluorometric method of determination of thioguanine at the ng/ml level in water and μg/ml level in blood serum and urine has been developed on the basis of this reaction. The method has been used for the determination of thioguanine in blood and urine samples.

6-Thioguanine (2-amino-1,6-dihydro-6-thiopurine, I Fig. 1) is a chemotherapeutic drug used as an immunosuppressive agent and for treatment in the advanced stages of leukemia.[1,2] Very few methods have been reported for its determination although a spectrophotometric procedure has been used.[3] Spectrofluorometric methods of analysis generally have lower limits of detection than spectrophotometric methods. Although thioguanine is only weakly fluorescent it is often possible to modify non-fluorescent compounds chemically and so produce a fluorescent product (fluorophors).[4a,5] This can sometimes be done by oxidation.[6] Oxidation of thioguanine with 30% hydrogen peroxide in 50% acetic acid has been found to give a fluorescent product and a rapid and sensitive spectrofluorometric method of analysis for thioguanine has been developed which utilizes this reaction. The product of the oxidation appears to be the *S*-oxide of thioguanine (II in Fig. 1).

EXPERIMENTAL

Reagents

Thioguanine. The Koch-Light product was recrystallized before use.

Hydrogen peroxide. 30% (100-volume).

Acetic acid 50%. Analytical reagent grade glacial acetic acid diluted 1:1 (v/v) with distilled water.

Serum. Whole human blood (40–50 ml) was collected, allowed to coagulate in test-tubes and then centrifuged for 25 min. The serum collected (20–30 ml) was kept refrigerated (5°) until needed. No deterioration was observed after storage for 3 weeks.

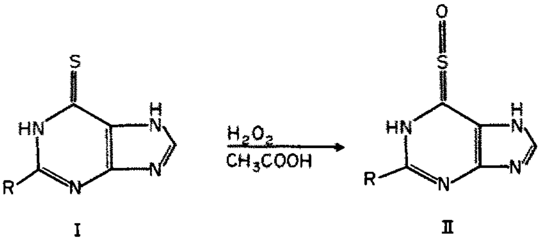

Fig. 1. Oxidation of 6-thioguanine (I, R = NH_2) to the *S*-oxide (II, R = NH_2) or of 6-mercaptopurine (I, R = H) to the *S*-oxide (II, R = H).

Sodium tungstate dihydrate solution, 10% *w/v.* $Na_2WO_4 \cdot 2H_2O$ (10 g) was dissolved in distilled water and the solution diluted to 100 ml.

Fluorescent reference standard. An approximately $10^{-5}M$ solution of ovalene in a solid polymer, manufactured by Perkin-Elmer, was used (excitation/emission wavelengths 340/480 nm).

Procedure

A stock solution of thioguanine in 50% acetic acid (300–400 μg/ml) is prepared by dissolving the thiopurine, with heating, in the acid. This solution is stable for at least 1 month at room temperature. A suitable aliquot of the stock solution is then oxidized by reaction with hydrogen peroxide at 50° for 5 min. The ratio of thioguanine solution to hydrogen peroxide is normally 10:1, *e.g.*, 1 ml of thioguanine solution to 0.1 ml of hydrogen peroxide.[6]

Calibration curve. After oxidation the solution is made up to standard volume (25 or 50 ml) with distilled water. This solution serves as a dilute oxidized stock solution of thioguanine (hereafter called the oxidized stock solution) and is stable for at least 24 hr. A calibration curve can then be constructed by taking appropriate aliquots of the oxidized stock solution, adjusting the pH to 6–7 with dilute sodium hydroxide solution (disodium hydrogen phosphate/potassium dihydrogen phosphate buffer, pH 6.9, can be added if desired), diluting to standard volume and measuring the fluorescence at 330/415 nm (excitation/emission).

Analysis of blood and urine samples. Blood serum (0.5 ml) is diluted with distilled water (2.0 ml) and 0.6*N* sulphuric acid (0.25 ml), mixed, and the protein precipitated by addition of sodium tungstate solution (0.25 ml).[4b] After centrifuging, 1.0 ml of the clear, protein-free serum is transferred into a standard flask, 3.0 ml of acetic acid (50%) are added, followed by 0.3 ml of hydrogen peroxide and the solution is oxidized by heating at 50° for 5 min. The solution is then diluted to volume (25 ml) with distilled water, a 1-ml aliquot is transferred into a 10-ml standard flask, the pH is adjusted to 6–7 and finally the solution is made up to volume and analysed. Care should be taken when transferring the deproteinated serum that no precipitated protein is carried over, otherwise high and variable blanks will result. A calibration curve is prepared by adding various volumes of standard aqueous thioguanine solution to 0.5-ml portions of serum, diluting with exactly enough water to give a volume of 2.0 ml, then deproteinating with sulphuric acid and sodium tungstate, and analysing as for serum samples.

For analysis of urine samples, 3 ml of acetic acid and 0.3 ml of hydrogen peroxide are added to 1 ml of urine in a 10-ml standard flask, then the mixture is heated at 50° for 5 min, and diluted as for the blood-serum samples. A calibration curve is prepared by adding various amounts of a thioguanine solution in 50% v/v acetic acid to the urine contained in the standard flask (25 ml), before the oxidation.

Apparatus

Fluorescence measurements were made with a Farrand spectrofluorimeter with 10-nm band-pass, fitted with a 150-W xenon arc lamp, RCA IP 28 photomultiplier, Honeywell Electronic 15 chart-recorder, and 10 × 10 × 45 mm quartz cells. All fluorescence spectra were uncorrected for instrumental artefacts.

Absorption spectra were obtained with a Unicam SP 800B recording ultraviolet spectrophotometer.

All glassware was cleaned by soaking overnight in dilute nitric acid, rinsing thoroughly with distilled water and then acetone, and allowing to dry.

RESULTS AND DISCUSSION

Acetic acid (50%) is a useful solvent for oxidations with hydrogen peroxide and has been recommended for the oxidation of phenothiazines.[6] Under these conditions, namely a 10:1 ratio of thioguanine solution in 50% acetic acid (*ca.* 350 μg/ml) to hydrogen peroxide, oxidation of thioguanine is complete after 20 min at room temperature (*ca.* 18°). It is, however, more convenient to carry out the reaction at 50°, oxidation then being complete after 5 min, and these reaction conditions were used throughout this study. A dilute solution of oxidized thioguanine (0.6 μg/ml) was stable for at least 24 hr.

Figure 2 shows the effect of pH on the fluorescence intensity of the oxidized thioguanine. On completion of oxidation the acetic acid is neutralized with sodium hydroxide to pH 6–7. A phosphate buffer can also be added, although experience has shown it is not essential, because of the wide pH-range for optimum fluorescence intensity.

Fluorescence characteristics

The absorption and fluorescence spectra of the oxidized product are shown in Figs. 3 and 4. The absorption spectrum of the unoxidized thioguanine in dilute acetic acid is also shown in Fig. 3. The excitation/emission wavelengths used for fluorescence analysis were 330 and 415 nm respectively, and the limits of detection and determination were 2 and 4 ng/ml respectively. The limit of detection is defined as that concentration of solution which gives a net signal equal to 4 times the standard deviation of the blank signal, and the limit of determination as the lowest concentration on the linear portion of the calibration curve (4–400 ng/ml). The standard deviation was 2 ng/ml for a thioguanine level of 110 ng/ml (15 replicates).

Analysis of blood and urine samples

A blood sample was collected from a patient undergoing thioguanine chemotherapy, but it was not possible to detect the presence of the drug in the sample. This may be due to a number of factors. Moore and Le Page[3] found that thioguanine was absorbed very rapidly from the blood stream of mice, and converted into either thiouric acid or various nucleotides. It was also rapidly eliminated in the urine. Further, the amount of thioguanine in the blood at any one time did not exceed 3% of the dose given. The blood used for analysis here was taken approximately 3 hr after the patient had received a 40-mg dose of thioguanine. It is possible therefore, that the concentration of thio-

* Of sample.

† Concentration of the solution (µg/ml) analysed to determine the standard deviation; 15 solutions were analysed for the urine samples and 6 for the blood samples.

guanine in the blood stream would already have been below the detection limit at the time of sampling.

When different amounts of thioguanine were added to the control blood serum, before deproteination, and the sample was analysed as outlined above, an excellent linear calibration curve was obtained. Comparison of this curve with one obtained by adding thioguanine to the serum after deproteination, but before oxidation, showed that a large (but reproducible) amount of thioguanine (45%) is lost with the precipitated protein. This loss was confirmed by adding 10.35 µg of thioguanine to each of six samples of serum before the deproteination, and an equivalent amount (3.45 µg) to six samples of deproteinated serum, these being the amounts needed to give a final concentration of 0.35 µg/ml. Oxidation and analysis were then carried out and the fluorescence intensities for the two sets of solutions compared. They were 0.97 for the serum and 1.57 for the deproteinated serum (standard deviation 0.01 for both), indicating 45% loss during the deproteination.

The limit of detection for thioguanine in blood serum (Table 1) was obtained by addition of thioguanine to the serum before deproteination and subsequent oxidation. The loss of thioguanine from the serum during deproteination is compensated by a 95% enhancement of the fluorescence signal caused by the presence of the tungstate ion. The limiting detectable concentration of thioguanine in blood serum, allowing for deproteination, oxidation and dilution, is 2 µg/ml.

No urine samples were collected from the patient, so specimens from a healthy person were collected and various amounts of thioguanine were added. The limit of detection in urine samples is shown in Table 1, and is the same as for blood serum, despite the absence of any deproteination procedure, because of the high blank values obtained with urine. The conditions used for oxidation of thioguanine in blood and urine samples were chosen because they were found to give the highest signal-to-blank ratio and hence the lowest limit of detection. The limit of detection will probably vary from sample to sample because of differences in blank values and fluorescence backgrounds.

Comparison with other methods

Thioguanine has been determined by biological assay,[7] radio-tracer[8] and spectrophotometric[3] methods. In each case the limit of detection for the particular method has not been quoted, although the spectrophotometric method appears to be capable of determining blood levels of thioguanine in the 2–5 µg/ml range. It is not clear whether this value is the lower limit of detection for the method or has been obtained by extrapolation from more concentrated solutions. Although the limit of detection for thioguanine blood levels by the spectrofluorometric method is also 2 µg/ml, the analytical procedure would appear to be more rapid than any of the three methods mentioned above. Finkel,[9] in an independent study, has also reported a fluorometric method of determination of thioguanine, based on the fluorescence of the sulphonic acid of thioguanine, formed by oxidation with alkaline permanganate; the method has a comparable limit of detection for thioguanine (3 µg/ml). The analytical procedure however, requires more operations than the present method. The application of Finkel's method to the analysis of biological samples has not as yet been reported.

Oxidation product

Oxidation of thiopurines to the disulphide, or the sulphinic or sulphonic acid is well documented.[10,11] Oxidation to a thiopurine-*S*-oxide is rather less common and only one *S*-oxide, that of theophylline, has been isolated.[11,12] Other *S*-oxides have been prepared and their presence in solution has been demonstrated by a blue colour obtained when a ferric chloride solution is added to the suspected *S*-oxide. Oxidation to the *S*-oxide has generally been achieved with 30% hydrogen peroxide in either dimethylformamide (DMF) or dimethylsulphoxide (DMSO).[11,12] Oxidation of thioethers to the *S*-oxide by 30% hydrogen peroxide in acetic acid in the presence of traces of sulphuric acid has also been reported.[13] Walter *et al.*[12] have oxidized 6-mercaptopurine (**I**, Fig. 1) to the *S*-oxide with hydrogen peroxide in DMSO. This was repeated and the presence of the *S*-oxide indicated by addition of ferric chloride solution. Oxidation of thioguanine under the same conditions gave a similar result with the ferric chloride solution. The absorption spectrum

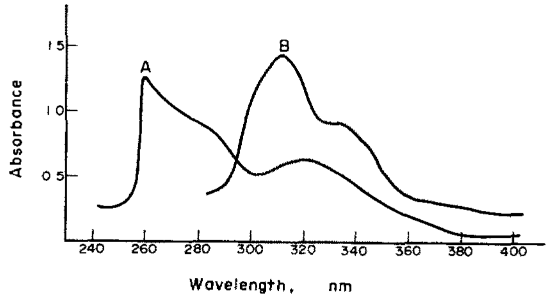

Fig. 5. Absorption spectra. **A**, Thioguanine oxidized with H_2O_2/DMSO. **B**, 6-mercaptopurine oxidized with H_2O_2/DMSO.

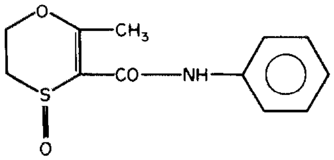

Fig. 6. "Vitavax" (5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide) *S*-oxide.

of the *S*-oxide of thioguanine in DMSO was similar to that of the oxidation product of thioguanine in acetic acid (Figs. 3 and 5). The *S*-oxide of thioguanine in DMSO was also fluorescent with excitation/emission wavelengths at 330/395 nm. Oxidation of thioguanine with alkaline permanganate, which is known to form the sulphonic acid of thioguanine, resulted in a different absorption spectrum from that of the product of hydrogen peroxide oxidation (Fig. 3). It would appear then, that the product of oxidation of thioguanine by hydrogen peroxide is the *S*-oxide of thioguanine (**II**, Fig. 1). The *S*-oxide of mercaptopurine mentioned above fluoresced in DMSO solvent at 360/420 nm; its absorption spectrum had the same general shape as that of the oxidation product of thioguanine [Figs. 3 and 5].

CONCLUSION

Besides the *S*-oxides of thioguanine and 6-mercaptopurine the *S*-oxide of vitavax [5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide, Fig. 6] formed by oxidation with Ce(IV) is reported to be fluorescent.[14] The procedure outlined here may, therefore, have some potential as a method for spectrofluorimetric determination of thiopurines and sulphur-containing compounds such as thiouracil and 2,4-dithiouracil.

Currently, the Orion Model 92–81 perchlorate-selective electrode, as characterized by Rechnitz,[1] has a broad spectrum of uses such as the determination of solubilities of perchlorate salts,[1] the determination of vicinal glycols[2] and the determination of perchlorate levels in solution. However, it is possible that problems have arisen owing to its poor selectivity with respect to hydroxide ion. For this reason the preparation and preliminary investigation of a better perchlorate-selective electrode was initiated. The electrode, a liquid-membrane type, is based on the perchlorate salt of tetrakistriphenylphosphinesilver(I). The range and selectivity of the electrode have been studied and the results indicate an improvement over the Orion model, most markedly in the selectivity with respect to hydroxide.

EXPERIMENTAL

Reagents

The salt was prepared as described by Cotton and Goodgame:[3] 1·55 g of silver perchlorate were dissolved in 4 ml of hot abslute ethanol and added to a solution of 7·87 g of triphenylphosphine in 30 ml of hot ethanol. The solid which precipitated immediately was filtered off, and recrystallized from acetonitrile (3 g in 125 ml), and the crystals were washed with methanol and dried *in vacuo*. The triphenylphosphine was obtained from the J. T. Baker Chemical Co. and the silver perchlorate from the G. F. Smith Chemical Co. All other chemicals used were reagent grade. Elemental analysis gave the following results: C, 69·1%; 4·9%; calculated for $C_{72}H_{60}AgClO_4P_4$, C, 68·82%; H, 4·82%. An approximately 2 mM solution of the salt in nitrobenzene was used as the exchanger.

Apparatus

The electrode was assembled in the versatile liquid-membrane body developed by Hildebrandt.[4] The porous membrane was a 0·45-μm "Millipore" filter. For most experiments, the internal reference electrode was an aqueous agar gel 2M in sodium chloride and 1M in sodium perchlorate, in contact with a Ag/AgCl element. The external reference electrode was a Corning 4·0M sodium chloride–calomel reference electrode. The electrodes were placed in a jacketed cell, kept at a constant temperature of 25·0°, containing about 50 ml of sample solution which was stirred continuously. Potentials were measured with the apparatus described in reference 5 and the pH was measured with a Beckman Research pH-meter.

RESULTS AND DISCUSSION

Electrode response

The potential measured as a function of perchlorate-ion activity and concentration is shown in Fig. 1. At $>10^{-5}M$, the response is $-58{\cdot}65 \pm 0{\cdot}20$ (95% confidence limit) mV per decade of activity. From 10^{-5} to $10^{-6}M$, the response is smaller, yet still shows enough change in potential from that of the base electrolyte for semiquantitative determinations to be made in this region. Single-ion activities were estimated from the extended Debye–Hückel equation:

$$-\log f_i = \frac{0{\cdot}5 Z_i^2 \sqrt{\mu}}{1 + \sqrt{\mu}}$$

The range was measured in the presence of 0·002M acetate buffer ($\mu = 0{\cdot}002$, pH = 5·07). It was found that when no background electrolyte was used, the slope was non-Nernstian. Acetate was employed because of its favourable selectivity constant. In 10^{-3}–10^{-1} M solutions of perchlorate, stable readings (drift < 0·05 mV/min) were obtained within 1 min. With more dilute solutions, up to 5 min were necessary. At concentrations of $<10^{-6}M$, as long as 15–20 min were needed to obtain a stable reading. Stability of readings was not a function of speed of stirring.

Effect of other anions

Selectivity coefficients ($K_{ClO_4^-/X}$) were determined by the separate-solution method and checked with the more accurate mixed-solution method. In the separate-solution method, the potentials of the electrode were measured first in 0·0091M sodium perchlorate and then in 0·0091M solutions of the sodium salts of various potentially interfering anions. (For bivalent anions, 0·0027M solutions of the disodium salts were used to keep the ionic strengths nearly equal). The selectivity coefficients were then calculated from the equation:[6]

$$\log_{10} K_{ClO_4^-/X} = \frac{E_{ClO_4^-} - E_X}{59{\cdot}1} + \log_{10} a_{ClO_4^-} - \frac{1}{z_X}\log_{10} a_X$$

The mixed-solution method was employed for Cl^-, OH^-,

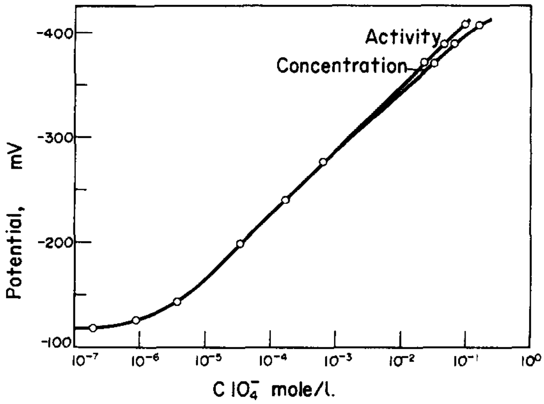

Fig. 1. Response of perchlorate-selective electrode in acetate buffer ($\mu = 0{\cdot}002$, pH = 5·07) as a function of activity and of concentration.

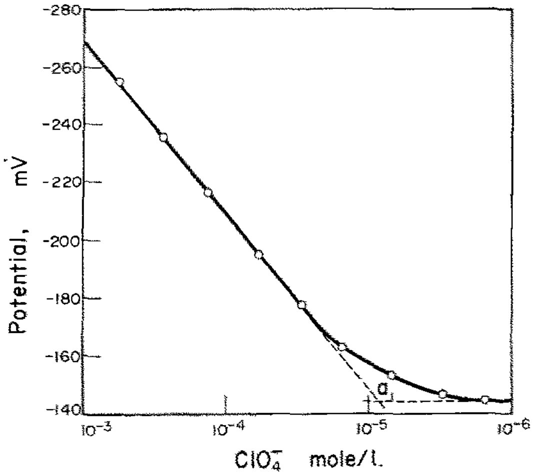

Fig. 2. Typical curve obtained by mixed-solution method for the perchlorate-selective electrode. Interfering electrolyte is $10^{-1}M$ sodium hydroxide.

NO_3^-, acetate and SO_4^{2-}. The interfering anions were used at a nearly constant concentration of 0·0091*M* (0·0027*M* for SO_4^{2-}). Known volumes of perchlorate were then added to this solution of interfering anion and the potential was recorded after each addition. A plot such as that in Fig. 2 was obtained. The selectivity coefficients were calculated from the equation:[6]

$$K_{ClO_4^-/X} = \frac{a_{ClO_4^-}}{a_X^{1/z_X}}$$

where z_X is the charge on the interfering anion, a_X the single-ion activity and $a_{ClO_4^-}$ is the activity of perchlorate at which the first observable potential change is noticed. This activity is obtained from the graph in Fig. 2. The selectivity coefficients obtained this way agreed acceptably with those from the separate-solution method.

Fluctuations of less than 0·5 mV were observed for the stable readings in the separate-solution method, with little or no drift. Response time in the mixed-solution method was similar to that mentioned previously.

Table 1. Selectivity coefficients for the perchlorate-selective electrode

		$K_{ClO_4^-/X}$	
Anion (X)	*E, mV**	Separate solution	Mixed solution
ClO_4^-	−168·9	—	–
NO_3^-	−13·8	$2{\cdot}4 \times 10^{-3}$	$2{\cdot}8 \times 10^{-3}$
OAc^-	+27·7	$4{\cdot}7 \times 10^{-4}$	$1{\cdot}6 \times 10^{-4}$
OH^-	+25·0	$4{\cdot}3 \times 10^{-4}$	$8{\cdot}3 \times 10^{-5}$
Cl^-	−16·0	$2{\cdot}6 \times 10^{-3}$	$2{\cdot}4 \times 10^{-4}$
HCO_3^-	+35·8	$3{\cdot}4 \times 10^{-4}$	–
$H_2PO_4^-$	+39·6	$2{\cdot}9 \times 10^{-4}$	–
SO_4^{-2}	+35·0	$2{\cdot}2 \times 10^{-5}$	$3{\cdot}4 \times 10^{-5}$
HPO_4^{-2}	+22·0	$3{\cdot}9 \times 10^{-5}$	–

* These potential values refer to pure solutions of sodium salts of the anions listed and were used to calculate the separate-solution selectivity constants given in column 3.

For these tests the phosphate concentration was $2{\cdot}7 \times 10^{-3}M$ ($\mu = 0{\cdot}0082$) and all other anion concentrations were $9{\cdot}1 \times 10^{-3}M$ ($\mu = 0{\cdot}0091$).

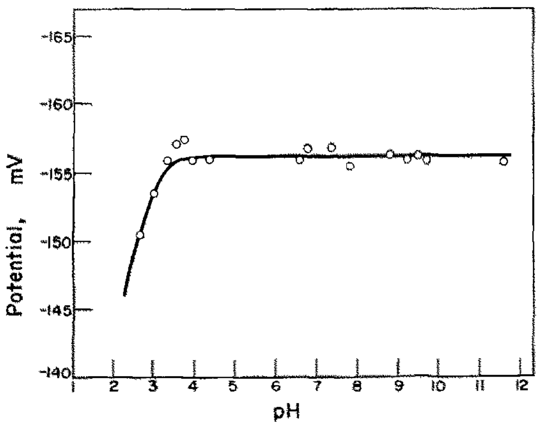

Fig. 3. Effect of pH on the response of the perchlorate-selective electrode. Perchlorate concentration was 0·002*M*.

Selectivity coefficients are given in Table 1. All interferences measured are well within acceptable ranges and are comparable to those given by Orion[7] and those reported by Rechnitz,[1] with the exception of that of hydroxide. At least a 10^4-fold improvement in selectivity is found here.

The effect of pH on the electrode response was determined by the addition of 0·1*M* perchlorate or sodium hydroxide to adjust the pH of a solution of 0·002*M* perchlorate. In Fig. 3 the change in potential is given as a function of the measured pH. Potentials plotted in Fig. 3 have been corrected for dilution in the case of sodium hydroxide additions and for the added perchlorate in the case of perchloric acid additions. Note that the potential scale of Fig. 3 is offset by approximately 120 mV from that of Figs. 1 and 2. This is due to the fact that a different external reference electrode was used for this experiment and the aqueous agar internal reference gel contained a higher concentration of sodium chloride than was used in the other experiments. The useful pH range for the electrode is from 3 to 12. Over this range the potential varies less than 5 mV

Conclusion

The new perchlorate-selective electrode described in this paper has been shown to be superior to the Orion electrode as regards its selectivity with respect to hydroxide ion. Other common anions show very similar selectivities to those reported for the Orion product. Low perchlorate concentrations in basic solutions can now be estimated without the difficult corrections based on the large selectivity coefficient ($K_{ClO_4^-/OH^-}$) characteristic of the Orion model 92–81 electrode

Summary—A new liquid-membrane ion-selective electrode for perchlorate ion based on tetrakistriphenylphosphine silver(I) perchlorate in nitrobenzene is described. Its dynamic range and selectivities relative to most common anions are comparable to those of the Orion model 92–81 perchlorate sensor However, it suffers much less hydroxide-ion interference than the Orion product.

DETERMINATION OF TRACE AMOUNTS OF BARIUM IN SILICATE ROCKS AND MINERALS BY ION-EXCHANGE CHROMATOGRAPHY AND ATOMIC-ABSORPTION SPECTROPHOTOMETRY*

ROBERTO FRACHE

(*Received* 20 *May* 1975. *Accepted* 28 *July* 1975)

In geochemical analyses it is often necessary to determine alkali and alkaline earth metals. Most of these determinations are easily carried out by conventional analytical techniques such as atomic-absorption spectrophotometry (for Ca, Li, Mg and Sr) and flame emission photometry (for Na, K and Rb).[1]

To complete the range of determinations we have tried to determine trace amounts of barium in rocks and minerals by atomic-absorption spectrophotometry (AAS) because of the absence of data obtained with this technique for standard silicate rocks. The physical methods employed in barium determination are direct reading spectrography, optical spectrography, X-ray fluorescence spectrometry and neutron-activation analysis,[2,3,4] but these are expensive and not readily available. The difficulty with determining trace amounts of barium by AAS is the existence of strong matrix effects.[5,6] The present work overcomes this difficulty by a prior ion-exchange separation.

EXPERIMENTAL

Interferences

The determination of barium by AAS suffers from two kinds of interference from the very high calcium concentration found in most rock and mineral samples. The CaOH formed in the flame has an emission band with a maximum at 554 nm, overlapping the analytical line (553·4 nm) for barium. Source modulation improves the situation but when the calcium concentration is very high the emission saturates the detector, giving a background too high to permit reliable analysis. Further the radiation at 553·5 nm may be absorbed by the CaOH molecules.[7,8] These interferences have been shown to be due to the presence of alkaline earths.[9,10] In addition, lanthanum also interferes in the determination of barium[8] owing to the presence of LaO which has an absorption band with a maximum at 553·6 nm.[11]

Aluminium has also been shown to interfere in the determination[12] of alkaline earth metals and this effect is removed by the addition of a lanthanum solution[13] when strontium is determined. Koirtyohann and Pickett[14] reported a study of the interference of aluminium in the determination of barium and showed that this was less than 1% for an Al:Ba ratio of 1000:1. These authors eliminate the aluminium interference by adding lanthanum solution (for Ca and Sr determination) and take account of the interference caused by the LaO band. Maruta *et al.*[15] observed that aluminium forms refractory compounds which are not easily dissociated and may be responsible for the depressant effect of aluminium on the barium absorption. They suggested suppressing aluminium interferences by the addition of oxine and ammonium chloride. Magnesium oxide also gives an interfering band at a wavelength of 553·5 nm.[14] Silicon interferes when in the form of sodium silicate but this interference is due to sodium. Alkali metals reduce the ionization of barium atoms, with consequent enhancement of the atomic absorption.[14] All these interferences give rise to poor reproducibility in the atomic-absorption and flame emission determination of barium when performed directly on the original sample.

Further, the interference is sufficiently strong to invalidate results obtained by the method of standard additions. Therefore we have recognized the necessity of separating barium from other elements in the matrix. The separation of barium is carried out by ion-exchange chromatography. This technique gives quantitative separations of a large number of ions[16,17] and it may be applied to rock analysis.[18–23] Ba^{2+} may be separated from other cations on ion-exchange resins, employing aqueous alcoholic solution of hydrochloric acid as eluents. Strelow[24] and other workers[25] have shown that ethanol is the most satisfactory alcohol for this purpose. A synthetic sample, containing major and some trace elements, was prepared in order to test the separation. Weighed amounts of pure salts of the most important interfering elements were mixed in the ratio appropriate to common rock samples. Silica is absent from this mixture because in the pretreatment of a rock sample with a hydrofluoric–perchloric acid mixture, silica is removed by volatilization of the fluoride. In any case, after passage through a cation-exchange resin, silicate anions are separated from the other ions. Table 1 shows the composition of the synthetic sample and that of the basalt BR (C.R.P.G.–A.N.R.T.). Major elements are expressed as oxides—trace elements are expressed as metals.

The separation is carried out on the strong acid sulphonated resin. Dowex 50 × 8, 200–400 mesh, H^+-form. The resin column is 18 cm long and 2·2 cm in diameter. All elements (except Ba) are eluted with 3*M* hydrochloric acid in 20% aqueous ethanol. Barium is eluted with 3*M* hydrochloric acid; the elution curve is plotted from results on 10-ml aliquots of eluate, in Fig. 1. The elements are determined in each fraction by AAS (Al, Fe, Mg, Ca, Ba and Sr) and flame emission photometry (Na, K).

In this separation heavy rare earth elements are eluted together with strontium, and light rare earth elements are retained (and successively eluted) with barium.[23,24] Nevertheless we did not think it necessary to separate light rare earth elements (lanthanum in particular) because of the

Table 1. Matrix element/barium ratios of synthetic sample and basalt BR

Ratio	Synthetic sample	Basalt BR
Al_2O_3/Ba	103	97
Fe_2O_3/Ba	110	123
MgO/Ba	139	127
CaO/Ba	141	131
Na_2/OBa	34	29
K_2/OBa	13	13
Sr/Ba	1·3	1·3

very small amounts of these elements present in common rock and mineral samples.

To confirm the reproducibility of the method, the separation was performed on aliquots of the synthetic solution. In six aliquots, each containing 12·0 mg of barium, 11·7, 11·7, 11·4, 11·5, 11·5 and 11·8 mg were found. The quantitative determination of the separated barium is carried out by AAS, employing a nitrous oxide–acetylene flame, with potassium as ionization suppressor.[5,14] The sensitivity of the method (1% absorption) is about 0·2 ppm barium.

Reagents

Hydrochloric acid (*3M*) *in 20% ethanol.*

Potassium solution, 10^5 *ppm* (19% solution of potassium chloride).

Standard solution of barium, 100 *ppm.*

Apparatus

A Metrohm Multi-dosimat E-415 automatic sampler–microburette and an atomic-absorption spectrophotometer Jarrell-Ash "Atomsorb" Model 82·271 equipped with a B-5 Kipp and Zonen recorder were used; the source was a Westinghouse hollow-cathode lamp.

Column packing and calibration

Fill a borosilicate glass tube with dry Dowex 50 × 8 resin (200–400 mesh) to give a column height of 18 cm and wash it with 300 ml of 3*M* hydrochloric acid. Wash with water until free from any acid reaction.

Weigh 1·4369 g of barium carbonate into a large beaker. Add 10 ml of 1:1 v/v hydrochloric acid and 100 ml of water. Pour into a 1 litre graduated flask and make up to the mark with water. Dilute this solution 1:10 with water to provide a 100-ppm barium solution and store in polythene bottles. Pipette 1, 3, 5, 7 and 11 ml portions of this solution into separate 100-ml graduated flasks. Add 10 ml of 10^5-ppm potassium solution to each flask and dilute to 100 ml. Pour 10 ml of the 10^5-ppm potassium solution into a further 100 ml flask and dilute to 100 ml to provide the calibration curve blank. Aspirate the solution into a 5-cm laminar-flow burner employing a nitrous oxide–acetylene flame, setting the monochromator to a wavelength of 553·5 nm. Measure the recorded signals, subtracting the blank. Plot the curve of measured absorbance against concentration.[26]

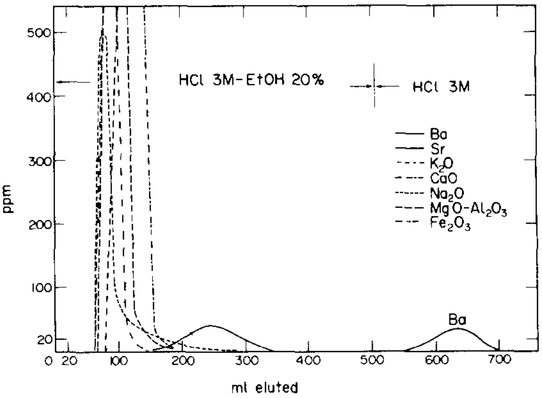

Fig. 1 Synthetic sample elution curve.

Analytical procedure

Weigh out 1 ± 0·0001 g of finely powdered (120-mesh) sample, in a PTFE dish. Moisten the powder with water to avoid spattering. Add 10 ml of 40% hydrofluoric acid and 10 ml of 70% perchloric acid, mixing with a platinum or PTFE rod. Allow to stand overnight in the fume-cupboard and then heat to dryness. Add 10 ml of hydrofluoric acid and 10 ml of perchloric acid and heat to dryness. Add 5 ml of perchloric acid and heat to dryness. Add 20 ml of water and 5 ml of hydrochloric acid. Repeat this procedure but without a sample, to obtain a blank solution.

Transfer the solution to a 100-ml graduated flask and dilute to 100 ml. Pass the sample solution through the ion-exchange column at a flow-rate of 2·5 ± 0·3 ml/min. Elute with 500 ml of 3*M* hydrochloric acid in 20% ethanol (all major elements which can be determined with the commonly used methods are present in this portion). Elute with a further 500 ml of 3*M* hydrochloric acid and evaporate the barium solution to about 50 ml. Transfer to a 100-ml graduated flask with rinsing, add 10 ml of 10^5-ppm potassium solution and dilute to 100 ml with water. This treatment is also performed on the blank solution. Aspirate

the sample and blank solutions into the burner as described previously. Correct the sample absorption by subtracting the blank. Calculate the barium concentration by reference to the calibration curve.

BX-N (bauxite) and DT-N (disthene) samples are not easily solubilized by the acid attack and a fusion procedure is adopted for these samples, as follows.

Weigh out 1 ± 0·0001 g of finely powdered sample, in a platinum crucible. Add 2·5 of 5:1 sodium carbonate–boric oxide mixture and mix. Heat on a bunsen burner to expel carbon dioxide and transfer to a muffle at 1000° for about 20 min. Cool and dissolve the melt in 5 ml of hydrochloric acid and 200 ml of water. Evaporate the solution to about 70 ml, transfer to a 100-ml graduated flask and dilute to volume. This procedure requires a blank from 2·5 g of fusion mixture and 5% hydrochloric acid. The solutions are passed through ion-exchange columns and analysed as described above.

RESULTS AND CONCLUSION

Barium contents of the standards are shown in Table 2. Recommended or median values are those indicated by Flanagan[27] for U.S.G.S. samples (W-1, AGV-1, BCR-1, DTS-1, PCC-1, GSP-1, G-2), and for C.R.P.G.-A.N.R.T. samples (BR, GA, GH, GR). Range values are indicated by Flanagan[2] for the samples cited and by De la Roche and Govindaraju[3,4] for the other samples. These authors report one value only for the BX-N and DT-N samples. Feldspar FK-N and granite GS-N are new C.R.P.G.-A.N.R.T. standards. All values found are in good agreement with the recommended or median values and the ranges reported.

MICRO AND SUBMICRO IODOMETRIC DETERMINATION OF ARSENITE AND SULPHITE IONS BY AMPLIFICATION REACTIONS

AMIR BESADA, Y. A. GAWARGIOUS and S. Y. KAREEM

Microanalytical Research Laboratory, National Research Centre,
Dokki, Cairo, Egypt

(*Received* 27 *March* 1975. *Revised* 12 *July* 1975. *Accepted* 18 *August* 1975)

Both chemical and physicochemical methods are available for the determination of arsenite and sulphite. Arsenite, after treatment with various oxidants, can be determined gravimetrically as magnesium ammonium arsenite[1] or as quinoline molybdoarsenate.[2] Cyanotungstates or molybdates,[3] ceric sulphate,[4] *N*-bromosuccinimide,[5] sodium peroxymolybdate[6] or potassium permanganate[7,8] have been utilized as redox reagents for the volumetric determination of arsenite. Potentiometric,[9] biamperometric,[10] and spectrophotometric[11] methods have also been described.

Methods for sulphite include oxidation by iodine[12,13] or by permanganate and iodine monochloride,[14] complexometry,[15] spectrophotometry,[16] potentiometry,[17] and polarography [18]

Because amplification reactions increase the sensitivity of determination of some ions,[19,20] the present work was aimed at extending their use to determination of arsenite and sulphite.

The arsenite method is based upon oxidation with periodate, masking of the excess with molybdate, and subsequent iodometric titration of the liberated iodate. The method for sulphite depends upon oxidation with iodine in a bicarbonate medium, extraction of the excess with chloroform, oxidation of the resulting iodide with bromine-water, and finally iodometric titration of the iodate produced. In this way, the degree of amplification involved in the two iodometric methods is 3- and 6-fold, respectively.

EXPERIMENTAL

Reagents

The reagents used were of analytical grade and doubly distilled boiled-out water was always used.

Ammonium molybdate tetrahydrate, 10% *aqueous solution.*

Arsenite ($NaAsO_2$) *solutions*, 0·05 *and* 0·5 *g/l.*

Buffer solution, *pH* 2·5–3. Prepared by adding *ca.* 110 ml of glacial acetic acid to 40 ml of 0·2*M* sodium acetate.

Potassium iodide. Aqueous solutions, 1 and 10%, prepared daily.

Potassium periodate solutions. Prepared fresh by dissolving (*A*) 1 g or (*B*) 2 g of the recrystallized salt in 600 ml of water, and kept in amber bottles.

Sodium thiosulphate, 0·002 *and* 0·01*M solutions.* Standardized against potassium iodate solutions.

Iodine solution, 0·13%, *in chloroform.*

Sodium sulphite solution The anhydrous salt (0·2 g) dissolved in water (1 litre).

Arsenite procedure

Introduce a portion (1–4 ml) of the sodium arsenite solution containing 0·05–0·20 mg into a 100-ml conical flask, add 5 ml of periodate solution *A* followed by 5 ml of the buffer solution, and immerse the flask in a water-bath at *ca.* 70° for 6 min. Cool, add 5 ml of each of the molybdate and the 1% potassium iodide solutions, stopper the flask, and leave aside for 2 min in a dark place. Then, titrate the liberated iodine with 0·002*M* thiosulphate, using starch as indicator as usual. Carry out a blank experiment and calculate the arsenite content.

1 ml of 0·002*M* thiosulphate = 0·0433 mg of $NaAsO_2$

For amounts of sodium arsenite between 0·20 and 2·0 mg, use 10 ml of periodate solution *B* and heat in the water-bath for 25 min at 60–70°. After cooling, add 10 ml of the molybdate solution and 5 ml of the 10% iodide solution and complete the determination as before, including a blank, using 0·01*M* thiosulphate solution for the titration.

1 ml of 0·01*M* thiosulphate ≡ 0·2165 mg of $NaAsO_2$

Sulphite procedure

Transfer a 1–10 ml portion of the test solution containing 0·2–2·0 mg of sodium sulphite into a 100-ml separating funnel, add 20 ml of 5% potassium bicarbonate solution followed by 5 ml of iodine solution and shake for 5 min. Add 10 ml of water, mix thoroughly and then leave till the layers have completely separated. Discard the chloroform layer and remove traces of iodine from the aqueous layer by extraction with three 10-ml portions of chloroform. Transfer the aqueous layer quantitatively into a 250-ml conical flask, add 3 ml of 2*M* sodium acetate solution and 5 ml of saturated bromine-water and stir the solution for 15 min on a magnetic stirrer. Destroy the excess of bromide by dropwise addition of formic acid (*ca.* 0·4 ml), add 20 ml of the acetate–acetic acid buffer, 2 ml of 10% potassium iodide solution, and titrate the liberated iodine with 0·01*M* sodium thiosulphate, adding starch as indicator just before the end-point. Run a blank and calculate the amount of sodium sulphite.

1 ml of 0·01*M* thiosulphate ≡ 0·1050 mg of Na_2SO_3

RESULTS AND DISCUSSION

The arsenite method

Potassium periodate in slightly acidic medium has been reported[21] to be a suitable reagent for the direct oxidimetric titration of arsenic(III), with diphenylamine as indicator. The reaction, which is catalysed by iron(II), proceeds according to the equation.

$$As^{3+} + IO_4^- + 2H^+ \rightarrow As^{5+} + IO_3^- + H_2O \qquad (i)$$

This reaction formed the basis of the amplification method developed in the present work:

$$AsO_2^- + IO_4^- \rightarrow AsO_3^- + IO_3^- \qquad (ii)$$

$$IO_3^- + 5I^- + 6H^+ \rightarrow 3I_2 + 3H_2O \qquad (iii)$$

During the development of the method from reaction (*ii*), the following factors were studied to optimize the conditions.

Reaction time and temperature. At room temperature the oxidation of microgram amounts (50–200 μg) of sodium arsenite was found to proceed slowly, so recovery was quantitative only after 35-min reaction time. Raising the reaction temperature to *ca.* 70° enabled complete oxidation to occur after 6 min. For larger amounts (0·5–2·0 mg), however, heating at 70° for 25 min was necessary.

Effect of pH. The optimum pH value for the periodate oxidation was found to be 3. Higher pH renders the reaction rather sluggish, as might be expected from equation (*i*). On the other hand, pH values lower than 3 gave rise to inconsistently high (*ca.* 3–5%) recoveries of arsenite. This may be ascribed to partial oxidation of the iodide added, by the arsenate ion produced, and to incomplete masking[22] of the unreacted periodate with molybdate.

The function of the molybdate. As in previous work,[22] complete masking of the unreacted periodate was achieved by addition of a large excess of ammonium molybdate (5 ml of a 10% solution) at pH 3, which is stated to be the optimum value for masking. The excess of molybdate also proved to play another role, namely preventing oxidation of added iodide by the arsenate ion resulting from the reaction, probably by formation of arsenomolybdate complexes.

The procedure finally developed was applied to determination of amounts of sodium arsenite ranging between 50 μg and 2·0 mg. Highly satisfactory results (Table 1) were obtained. The maximum and minimum recoveries are 101·2 and 99·0% and the average recovery is 99·9%. All the values in Table 1 were calculated on the basis of a 3-fold amplification, which proves that the molybdate-catalysed 4-fold amplification reaction,[19] involving the additional reaction

$$AsO_3^- + 2I + 2H^+ \rightarrow AsO_2^- + I_2 + H_2O \qquad (iv)$$

does not take place.

The blank values found were reasonable; periodate solution *A* gave a negligible value, solution *B* gave a maximum value of 0·24 ml of 0·01*M* thiosulphate. The latter blank value is probably due to the 25-min heating period as compared with the 6-min period employed in case of solution *A*.

The sulphite method

The usual iodimetric determination[12,23] of sulphite is based on the reaction:

$$SO_3^{2-} + I_2 + H_2O \rightarrow SO_4^{2-} + 2HI \qquad (v)$$

Much controversy exists in the literature[12,23] regarding the iodimetric titration of sulphite. The main errors are loss of SO_2 by volatilization, air-oxidation of sulphite and the precipitation of sulphur as represented in the following equations:

$$H_2SO_3 + 4HI \rightarrow 2I_2 + S + 3H_2O \qquad (vi)$$

$$3H_2SO_3 \rightarrow 2H_2SO_4 + S + H_2O \qquad (vii)$$

Table 1. Micro and submicro determination of sodium arsenite by oxidation with periodate

Sodium arsenite, *mg*		
Taken	Found	Recovery*,%
2·000	1·980	99·0
	1·996	99·8
1·500	1·498	99·9
	1·492	99·5
0·500	0·499	99·8
	0·498	99·6
0·200	0·1990	99·5
	0·1999	100·0
0·150	0·1500	100·0
	0·1497	99·8
0·100	0·1004	100·4
	0·0995	99·5
0·050	0·0503	100·6
	0·0506	101·2

* The average recovery is 99·9%.

The latter reaction (*vii*) is said to be catalysed[23] by hydriodic acid. Certainly, on subjection of the method to a drastic check, persistently low (3–4%) sulphite recoveries were obtained. Despite the sources of inaccuracy inherent in this method, it is still the one in use for the assay of sulphite, probably because of the popular iodimetric finish. The apparent inaccuracies motivated our search for an accurate method preferably retaining the simple and rapid iodometric finish.

The method developed is based on the reactions:

$$Na_2SO_3 + I_2 + 2HCO_3^- \rightarrow Na_2SO_4 + 2I^- + 2CO_2 + H_2O \qquad (viii)$$

$$2I^- + 6Br_2 + 6H_2O \rightarrow 2IO_3^- + 12HBr \qquad (xi)$$

$$2IO_3^- + 10I^- + 12H^+ \rightarrow 6I_2 + 6H_2O \qquad (x)$$

As clear from equations (*viii*)–(*x*), each mole of sulphite is ultimately equivalent to 12 iodine atoms. Thus, this method gives a 6-fold amplification as compared with the original direct iodimetric method shown in equation (*v*).

During the working out of the procedure, it was realized that the potassium bicarbonate plays a significant role, not only shifting the reaction towards complete oxidation of sulphite, but also eliminating reactions (*vi*) and (*vii*). A further advantage is that no volatilization of SO_2 occurs, in contrast to the direct iodimetric method[23] in acidic medium.

However, experiments with increasing amounts of sulphite (0·2–2·0 mg) revealed that the concentration of bicarbonate should be increased proportionally (2·0–20·0 ml of 5% solution) indicating that its role is definitely not simply an effect of pH, which remains almost constant at *ca.* 8·3 throughout the whole range of bicarbonate added. If the weight ratio of potassium bicarbonate to sodium sulphite was lower than 500, the sulphite recoveries were always low. Fortunately, however, although a deficiency of bicarbonate must be avoided, a larger excess does not affect the accuracy. A representative series of results, showing the effect of bicarbonate concentration on the sulphite recovery, is given in Table 2.

It was interesting to test whether the reaction would also proceed quantitatively at a higher pH value. For this purpose, 5% potassium carbonate solution (pH 10·5) was used. Very high and inconsistent values were obtained, amounting to about double the expected sulphite recoveries. This may be due to formation of hypoiodite in such an alkaline medium. Hypoiodite can easily oxidize the iodide added for the iodate titration, giving rise to an additional amount of iodine and erroneously high recoveries.

Regarding the use of iodine as oxidant for the sulphite, an aqueous solution is not suitable in the present work owing to the necessity of dissolving the iodine in potassium iodide which interferes seriously throughout the procedure

Table 2. Effect of concentration of bicarbonate and iodine on the oxidation of sodium sulphite

* The average recovery is 99·3%.

except in the last step of the iodate–iodide reaction. A chloroform solution of iodine, however, proved not only suitable for quantitative oxidation but also made the susceptibility of sulphite to air-oxidation negligible This may be due to chloroform vapour over the organic–aqueous suspension almost preventing access of air to the solution during the oxidation step.

The amount of iodine required for oxidation depends, of course, on the sulphite concentration under test, and 0·5 ml of the iodine solution (about 50% excess) was found sufficient for complete oxidation of 0·2 mg of sodium sulphite (*cf*. Table 2). For larger amounts of sulphite more iodine is required, and the 5·0 ml required for oxidation of the largest amount of sulphite to be determined (2·0 mg) was found not to affect the results for the smallest (0·2 mg) and was therefore chosen for the general procedure

The procedure gave satisfactory results (Table 3). The minimum and maximum recoveries are 98·5 and 101·0% and the average recovery is 99·3%. The blank value found for the sulphite method did not exceed 0·22 ml of 0·01*M* thiosulphate

Summary—Two methods are described for the micro and submicro iodometric determination of arsenite and sulphite ions involving 3- and 6-fold amplification reactions, respectively. The arsenite method is based on oxidation with an excess of periodate, masking of the unreacted periodate with molybdate, and final iodometric titration of the iodate released. The sulphite method depends upon oxidation with iodine and removal of its excess by extraction with chloroform, and oxidation of the iodide formed to iodate, which is determined iodometrically as usual. The two methods are simple, rapid, and accurate. The average recoveries obtained are 99·9 and 99·3% for arsenite and sulphite, respectively.

DETERMINATION OF THE ELEMENTAL SULPHUR CONTENT OF MINERALS AND ORES

H. F. STEGER
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology,
Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 4 *June* 1975. *Accepted* 13 *June* 1975)

Elemental sulphur can be formed at the surfaces either during the comminution or flotation of a sulphide mineral or ore.[1–3] Indeed, it has been suggested tentatively[4] that it is elemental sulphur which renders sulphide-mineral surfaces hydrophobic during flotation. A method to determine accurately the elemental sulphur content of minerals or ores would, therefore, be useful in a study of both the effect of comminution on sulphide minerals and the mechanism of flotation.

In all existing methods, the elemental sulphur is extracted from the mineral or ore with acetone,[5] benzene,[6] carbon disulphide[6,7] or chloroform.[8] A direct ultraviolet spectrophotometric determination of sulphur is often possible[6,8] but the presence of other sulphur compounds such as sulphates, thiosulphates and xanthates or of extraneous organic matter which also absorb in the ultraviolet will interfere.[9] (The presence of S^{2-}, SO_3^{2-}, SO_4^{2-} and $S_2O_3^{2-}$ was shown not to interfere, however, if monohydric alcohols were used as solvent.[10]) Moreover, traces of oxidizing impurities in the solvent could lead to high results for materials having a very low elemental sulphur content. The preparation of high-purity solvents can be laborious.

This paper describes a method in which elemental sulphur is separated from the sample by vaporization in a closed tube. The sulphur then undergoes continuous sublimation in a section of tube heated by a furnace, with movement, in a flow of nitrogen, towards a cold-finger condenser. The sulphur is ultimately determined by spectrophotometry in ethanol.

EXPERIMENTAL

Materials

Sublimed sulphur (Fisher Scientific Co.) was washed with hot distilled water until free from acid and any iodine-consuming substances, twice recrystallized from pyridine–ethanol,[9] heated at 110° for 2 hr to convert any amorphous sulphur into the rhombic form[11] and then crushed to pass a 100-mesh sieve.

A sulphur–sodium chloride mixture was prepared as test material to evaluate the variables that affect the efficiency of the apparatus (described below) for the determination of elemental sulphur by sublimation. The sodium chloride served only to facilitate the weighing of small amounts of sulphur. Approximately 250 mg of sulphur and 6 g of sodium chloride were ground together in an automated mortar grinder for 1 hr to achieve thorough mixing. The sulphur content was found by ethanol extraction to be 4·89 ± 0·07% (6 determinations)

The procedure developed was applied to two certified reference ores, MP-1[12] and KC-1,[13] and galena. A massive sample of galena was crushed, and the 65–100 mesh fraction was collected and purified from siliceous matter by heavy-liquid separation. A small portion of this prepared galena was then ground to finer than 400-mesh. A sample of KC-1, hereafter denoted by KC-1 (T), which had been kept at 67° and 62% relative humidity for 7 weeks was also analysed for elemental sulphur. The KC-1 gained 2·57% in weight because of oxidation.

Apparatus

The easily constructed apparatus (Fig. 1) consisted of a 20-cm and a 35-cm section of Pyrex tube (22 mm outside diameter) connected with a ₮ 19/38 glass joint, the female joint being attached to the 20-cm tube, hereafter called the "collector tube". The open end of the 35-cm tube, the "reactor tube", contained a removable plug with a gas-dispersion tube to pass nitrogen through the system. The open end of the collector tube was also equipped with a female ₮ 19/38 joint to accommodate a cold-finger condenser. A small outlet tube near this latter joint allowed the nitrogen to escape. The Pyrex tubes were inserted into the ports of a 23-cm horizontal-tube furnace (30 mm inside diameter) so that the tip of the condenser was at the port of the furnace. The connected tubes were not in contact with the furnace tube. The temperature was controlled with a variable transformer and monitored with a Pt, Rh/Pt thermocouple.

Procedure

The absorption spectrum of sulphur in ethanol was essentially the same as that found by Heatley and Page.[9] Beer's law was obeyed at 274 nm for sulphur concentrations from 0 to 49 μg/ml. A second calibration curve for 0–8 μg/ml, applicable to samples of very low sulphur content, was prepared by scale expansion of the range 0–0·2 absorbance units. The temperature of all solutions used in the preparation of the calibration curves was kept at 20·0 ± 0·1°. A Unicam SP 1800 Spectrophotometer and AR 25 Linear Recorder were employed for all measurements.

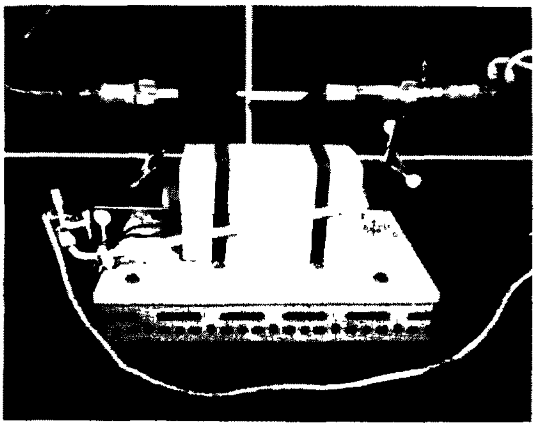

Fig. 1. Apparatus for the determination of the elemental sulphur content in minerals and ores by sublimation.

Sublimation method. The sample was weighed into a glazed porcelain boat (60 × 10 × 8 mm, Coors) and inserted into the reactor tube to rest approximately in the centre of the furnace. The plug with gas inlet tube was repositioned and the sulphur allowed to vaporize under the selected temperature and time conditions. The nitrogen flow-rate was 30 ml/min. At the conclusion of the reaction period, the collector tube was removed from the furnace and connected to either a 50- or 100-ml round-bottom flask (Ŧ 24/40) containing 12 or 25 ml of 95% ethanol, respectively, by means of a short connector constructed from Ŧ 24/40 and Ŧ 19/38 male joints. (Teflon sleeves were used with all Ŧ connections.) The ethanol was heated under reflux for 15 min to dissolve the sulphur that had sublimed onto the cold-finger condenser and wall of the collector tube. After cooling, the ethanolic sulphur solution was transferred to a 25- or 50-ml volumetric flask, brought to 20° in a thermostat and diluted to the mark. The absorbance at 274 nm was measured and the sulphur concentration determined from the calibration curve. For the evaluation of the variables affecting the determination of elemental sulphur, 20·1 ± 0·1 mg samples of sulphur–sodium chloride mixture were used. For the determination of elemental sulphur in MP-1, KC-1 or galena, 0·5-g samples were used.

Extraction method. The elemental sulphur in MP-1, KC-1 and galena was also determined by extraction into ethanol. About 0·5 g of sample and 25·00 ml of ethanol were heated under reflux for 4 hr, allowed to cool and centrifuged at 1800 rpm for 30 min to ensure complete separation of solid matter. The absorbance at 274 nm was measured and the spectrum in the range 250–350 nm was recorded for comparison with that of elemental sulphur.

RESULTS AND DISCUSSION

The effect of the temperature of the furnace on the fraction of sulphur recovered is illustrated in Fig. 2. The heating period was 3 hr and a sample weight of ~ 20 mg of sulphur–sodium chloride mixture was chosen to yield ~ 1 mg sulphur. It was decided semi-arbitrarily that all further developmental work on this method would be performed at 123° It was considered that the rate of recovery was acceptable and that significant decomposition of the mineral or ore sample would probably not occur at this temperature. It should be pointed out that there is, of course, no reason why any other furnace temperature in the 115–140° range (with an appropriate heating period) should not be equally successful.

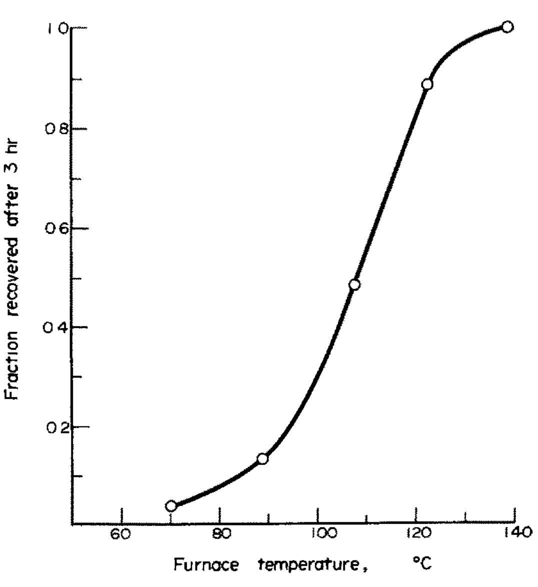

Fig. 2. Fraction of elemental sulphur recovered during a 3-hr heating period, as a function of the furnace temperature.

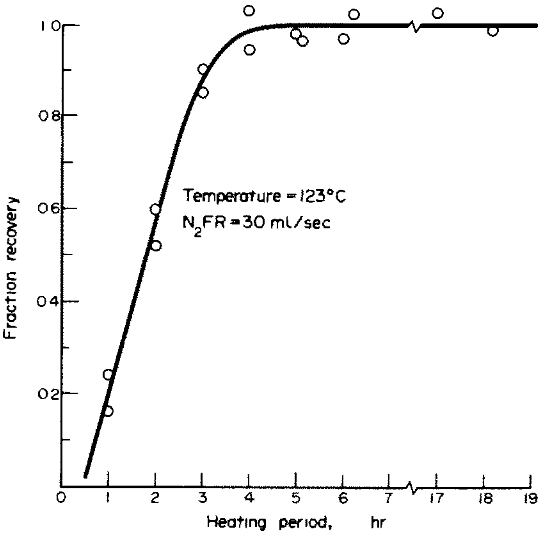

Fig. 3. Fraction of elemental sulphur recovered as a function of the heating period.

The effect of the duration of heating on the fraction of sulphur recovered at a furnace temperature of 123° is shown in Fig. 3. With short heating times, the fraction of sulphur recovered showed a slight dependence on the way the sample was packed in the boat. This is, of course, because the sulphur volatilizes more readily if the sample is more loosely packed. The packing, however, is immaterial if the heating period is long enough for complete sulphur recovery. With heating times of 4 hr or longer, 1 mg sulphur can be recovered (and subsequently determined) by the sublimation technique with a precision of ~ 3%. The same precision was also obtained for the recovery of 0·5 and 0·25 mg of sulphur (4 trials each; results not shown) with heating for 6 hr.

Because the samples for the determination of elemental sulphur in minerals or ore will be appreciably larger than those of the sulphur–sodium chloride mixture, heating time of 6 hr was chosen for subsequent work, to ensure sufficient margin for the complete recovery of sulphur. Subsequent tests indicated that the recovery of sulphur was complete in a 6-hr heating period at nitrogen flow-rates of 5–85 ml/min.

In order to test possible interferences in this sublimation method, trial runs with samples of ~ 10 mg of sodium sulphate, sulphite and thiosulphate (all analytical grade); potassium ethyl xanthate (Eastman Kodak twice recrystallized from ethanol–petroleum ether) and ethyl dixanthogen[14] were performed. In all cases, no elemental sulphur was detected. Ethyl dixanthogen distilled, but without apparent decomposition; this is discussed further below.

The results for the determination of elemental sulphur in MP-1, KC-1 and galena are summarized in Table 1. One very long heating period was used in one run for each of MP-1 and KC-1 to illustrate that 6 hr was indeed sufficient for complete sulphur recovery. The results by ethanol extraction and by sublimation are in good agreement with the exception of those for KC-1 (T) and the 400-mesh galena. The spectrum (in the region 250–330 nm) of the ethanol extract of KC-1 (T) is depicted in Fig. 4. Also shown is the theoretical elemental sulphur spectrum having the same absorbance at 274 nm; this spectrum was calculated from predetermined values of the molar absorptivity of elemental sulphur in ethanol. It is apparent that in the region 250–265 nm the determination of elemental sulphur

Table 1. Elemental sulphur in minerals or ores

* Non-typical sulphur spectrum.

in KC-1 (T) by ethanol extraction is subject to interference. If it is assumed that the sublimation technique gives an accurate determination of elemental sulphur in KC-1 (T), the theoretical contribution of sulphur to the spectrum of the ethanol extract can be calculated. The contribution due to non-elemental sulphur components can, therefore, be calculated and is illustrated in Fig. 4. Similarly, the ethanol extract of 400-mesh galena did not give a typical elemental sulphur spectrum. The superiority of the sublimation technique, at least for these two examples, is clearly apparent.

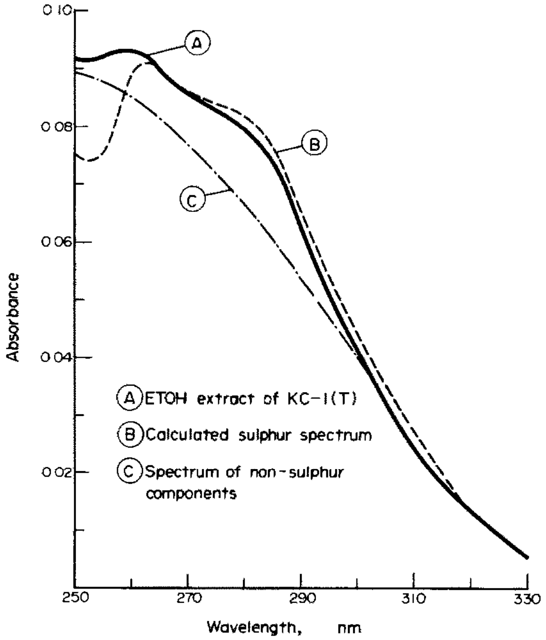

Fig. 4. Spectra pertaining to the ethanol extract of KC-1 (T).

Possible interference due to ethyl dixanthogen adsorbed by minerals or ores was tested as follows. A sample of KC-1 was equilibrated with an ethanolic solution of ethyl dixanthogen. Although ethyl dixanthogen was indeed adsorbed by KC-1, it could not be detected by either the ethanol extraction or sublimation determination of elemental sulphur. These two methods, however, gave widely different results for elemental sulphur, neither of which agreed with that of untreated KC-1. The same observation but to a lesser extent was noted for KC-1 equilibrated with potassium ethyl xanthate in ethanol. It is thought that this observation may give some insight into the interaction between xanthate or dixanthogen and the mineral or ore, and a study is now under way to elucidate the mechanism of this interaction.

Sensitivity

Because of instrument noise in the expanded scale, the limit of instrument response to sulphur in ethanol was 0·16 μg/ml when 1-cm cells were used. The sensitivity can, therefore, be calculated to be 0·2 μg/ml.[15] For analytical purposes, however, it is doubtful whether results for sulphur less than 0·5 μg/ml are truly significant.[10]

The sensitivity can be improved as follows. First, the sample size may be increased. Here, however, a prolongation in heating period may become necessary. Second, the sulphur may be dissolved in less than 25 ml of ethanol or longer path-lengths can be used, or both. Another possibility might be to extract a large sample (*e.g.*, 50 g) with ethanol, concentrate the extract by evaporation *e.g.*, on NaCl, then sublime.

Summary—A new technique has been developed to determine trace quantities of elemental sulphur in minerals and ores. After separation from the sample by sublimation, the sulphur is determined spectrophotometrically in ethanol. Sulphide, sulphite, sulphate and thiosulphate do not interfere. The effect of the presence of xanthate or dixanthogen is discussed briefly.

RAMAN SPECTRA OF PHENOTHIAZINE AND SOME PHARMACEUTICAL DERIVATIVES

BARBARA KURE* and MICHAEL D. MORRIS
Department of Chemistry, University of Michigan, Ann Arbor, MI 48104, U.S.A.

(*Received* 22 *August* 1975. *Accepted* 25 *September* 1975)

Phenothiazines are widely used as antipsychotic drugs and for this reason there has been much effort devoted to the spectroscopic characterization of these compounds. Although the infrared spectra of phenothiazines have been well characterized,[1] there have been no reports of the Raman spectra. Raman spectrometry appears useful in the identification of phenothiazines because of the presence of carbon–sulphur bonds and because the technique is well suited to the examination of solids, the physical form of most pharmaceutical preparations. In the present communication we report the spectra of several solid phenothiazines in the 600–1600-cm^{-1} region and present preliminary assignments of the major bands.

EXPERIMENTAL

The formulae of the substituted phenothiazines studied are presented in Table 1. Compounds **I** (trifluoropromazine hydrochloride) and **II** were obtained from the Squibb Institute. Compounds **III** and **IV** were obtained from Searle Laboratories. These compounds were used without further purification. Unsubstituted phenothiazine (Aldrich Chemical Co.) was recrystallized from benzene.

Raman spectra were recorded on a Spex 1401 double monochromator equipped with a cooled RCA C31034 photomultiplier and both photon-counting and d.c. detection systems. He–Ne 632·8-nm excitation (25–35 mW at the sample) was employed. Samples were irradiated for about 30 min in the laser beam to remove residual fluorescence. Samples were introduced into the laser beam as powders contained in standard glass melting-point capillaries. All spectra were recorded with 10 cm^{-1} resolution.

RESULTS AND DISCUSSION

The Raman spectra of the phenothiazines examined are presented in Table 2. Because the samples were examined as polycrystalline solids, depolarization ratios were not taken.

The phenothiazine spectra can be interpreted as derived from the spectra of diphenylamine, diphenyl sulphide and the various saturated compounds which make up the side-chains. Such an approach is valid, since the phenothiazine is known to be folded about the S–N axis, with a dihedral angle between the phenylene rings of about 140–154°, depending on the substitution pattern.[2,3] Thus, the two phenylene rings are more or less independent and the spectra will be closely related to those of simpler substituted benzenes. The ring mode dominated by symmetric phenylene–sulphur stretching appears at 670–680 cm^{-1} for the phenothiazines investigated. In diphenyl sulphide (liquid) this vibration occurs at 668 cm^{-1}.[4] The differences may be attributed to both the difference in the phase and to the presence of an *ortho*-substituent in phenothiazine and possibly to the difference in the C–S–C bond angle. This band is in the same region as the C–C out-of-plane deformation, which is responsible for the infrared absorption

in the 690-cm^{-1} region.[4,5] Overlap with this mode, which is active in *ortho*-disubstituted benzenes,[6] cannot be ruled out.

The asymmetric phenylene-sulphur stretches occur in the 1070-1090-cm^{-1} region. In diphenyl sulphide this band occurs at around 1080 cm^{-1}.[4,5]

The medium intensity symmetric phenylene-nitrogen stretch is found at 1240-1250 cm^{-1}. In solid diphenylamine, this vibration is observed in the infrared at 1250 cm^{-1}.

The intense 1040-cm^{-1} band we assign to a C-H ring deformation. This is a strong band at 1040 cm^{-1} for diphenylamine and at 1026 cm^{-1} for diphenyl sulphide.[4] A weaker C-H deformation occurs at 1165-1175 cm^{-1} and is observed at 1153 cm^{-1} for diphenyl sulphide.[4]

In the spectrum of unsubstituted phenothiazine a pair of ring modes occurs at 1570 and 1605 cm^{-1}. These are the two components of a ring-stretching mode (l and k in Whiffen's notation). In the spectra of the ring-substituted phenothiazines, three bands occur in this region, owing to the non-equivalence of the two phenylene rings. We have not attempted detailed assignments of the bands due to vibrations of the alkyl side chains. We present only a few general assignments, but do not attribute bands to individual amines or alkyl groups.

The pharmaceutical derivatives have a group of bands between 800 and 900 cm^{-1}, due to symmetric C-N-C stretches of the tertiary amino groups.[8] The asymmetric C-N-C stretches appear as strong bands at 1100-1110 cm^{-1}. Similarly, the band at 1310-1325 cm^{-1} is assignable to a methylene twisting mode of the alkyl chains common to all of the substituted phenothiazines.[9]

Further refinement of these spectra and their extensions to higher and lower frequencies are in progress and will be reported at a later date.

THE DETERMINATION OF METALLIC IRON IN THE PRESENCE OF FAYALITE

I. J. Bear and P. R. Strode®

CSIRO Division of Mineral Chemistry, P.O. Box 124, Port Melbourne, Victoria 3207, Australia

(*Received* 20 *August* 1975. *Accepted* 7 *October* 1975)

A current investigation in these laboratories, into the treatment of low-grade tin ores, involved the reduction of tin calcines under various conditions. During the analysis of these reduced calcines difficulty was encountered in determining metallic iron. The reduced samples contained metallic iron, tin and tin-iron alloys, tin and iron oxides, aluminium-iron oxides (hercynite), and iron silicate (fayalite, $2FeO.SiO_2$).

It was confirmed that metallic iron can be determined satisfactorily in the presence of iron oxides (both ferrous, ferric and complex oxides such as hercynite) by methods such as those of Kraft and Fischer[1] or Blum and Searl[2] whereby the sample is treated with bromine in methanol under reflux conditions. The oxide residue is subsequently filtered off, washed with methanol, and, following the evaporation of alcohol from the filtrate, the iron equivalent to the metallic iron content is determined in dilute hydrochloric acid solution.

The method above, however, does not give accurate results for metallic iron when iron silicates such as fayalite are present in the sample to be analysed. The errors arise because fayalite is attacked by hydrogen bromide which apparently forms in the alcoholic solution of bromine even when moisture is rigorously excluded.[3] In Fig. 1, (*a*) and (*b*), are shown portions of the X-ray diffraction patterns of a synthetic sample containing iron (II) oxide, silica, and approximately 6% fayalite before and after treatment with bromine in methanol. It is clear that most of the fayalite has been dissolved during this treatment.

Several variations of the method of Kraft and Fischer[1] were studied in order to overcome this problem. It was found that whereas iodine in methanol did not attack the fayalite, the metallics—tin, iron, and iron-tin alloys—were halogenated only slowly. A more satisfactory variation was to treat the sample with bromine alone under reflux, then evaporate all excess of bromine before extracting the iron in the 690-cm^{-1} region.[4,5] Overlap with this mode, which is active in *ortho*-disubstituted benzenes,[6] cannot be ruled out.

The asymmetric phenylene–sulphur stretches occur in the 1070–1090-cm^{-1} region. In diphenyl sulphide this band occurs at around 1080 cm^{-1}.[4,5]

The medium intensity symmetric phenylene–nitrogen stretch is found at 1240–1250 cm^{-1}. In solid diphenylamine, this vibration is observed in the infrared at 1250 cm^{-1}.

The intense 1040-cm^{-1} band we assign to a C–H ring deformation. This is a strong band at 1040 cm^{-1} for diphenylamine and at 1026 cm^{-1} for diphenyl sulphide.[4] A weaker C–H deformation occurs at 1165–1175 cm^{-1} and is observed at 1153 cm^{-1} for diphenyl sulphide.[4]

In the spectrum of unsubstituted phenothiazine a pair of ring modes occurs at 1570 and 1605 cm^{-1}. These are the two components of a ring-stretching mode (1 and k in Whiffen's notation). In the spectra of the ring-substituted phenothiazines, three bands occur in this region, owing to the non-equivalence of the two phenylene rings. THE DETERMINATION OF METALLIC IRON IN THE PRESENCE OF FAYALITE

I. J. Bear and P. R. Strode®

CSIRO Division of Mineral Chemistry, P.O. Box 124, Port Melbourne, Victoria 3207, Australia

(*Received* 20 *August* 1975. *Accepted* 7 *October* 1975)

A current investigation in these laboratories, into the treatment of low-grade tin ores, involved the reduction of tin calcines under various conditions. During the analysis of these reduced calcines difficulty was encountered in determining metallic iron. The reduced samples contained metallic iron, tin and tin–iron alloys, tin and iron oxides, aluminium–iron oxides (hercynite), and iron silicate (fayalite, $2FeO.SiO_2$).

It was confirmed that metallic iron can be determined satisfactorily in the presence of iron oxides (both ferrous, ferric and complex oxides such as hercynite) by methods such as those of Kraft and Fischer[1] or Blum and Searl[2] whereby the sample is treated with bromine in methanol under reflux conditions. The oxide residue is subsequently filtered off, washed with methanol, and, following the evaporation of alcohol from the filtrate, the iron equivalent to the metallic iron content is determined in dilute hydrochloric acid solution.

The method above, however, does not give accurate results for metallic iron when iron silicates such as fayalite are present in the sample to be analysed. The errors arise because fayalite is attacked by hydrogen bromide which apparently forms in the alcoholic solution of bromine even when moisture is rigorously excluded.[3] In Fig. 1, (*a*) and (*b*), are shown portions of the X-ray diffraction patterns of a synthetic sample containing iron (II) oxide, silica, and approximately 6% fayalite before and after treatment with bromine in methanol. It is clear that most of the fayalite has been dissolved during this treatment.

Several variations of the method of Kraft and Fischer[1] were studied in order to overcome this problem. It was found that whereas iodine in methanol did not attack the fayalite, the metallics—tin, iron, and iron–tin alloys—were halogenated only slowly. A more satisfactory variation was to treat the sample with bromine alone under reflux, then evaporate all excess of bromine before extracting the iron

Asterisks = fayalite peaks.

bromide with methanol (Fig. 1). This has been developed, and constitutes the proposed method described here.

EXPERIMENTAL

Sample materials

In order to test the accuracy of the proposed method a synthetic fayalite free from metallic iron was required. Fayalite is difficult to prepare, however, in pure form. When it is made by reducing mixtures of iron oxides and silica the reaction is incomplete at low temperatures (below 1000°),[4] although it is known that fayalite will form more readily at such temperatures when aluminium is present.[5] A synthetic fayalite was therefore prepared by reducing a mixture of analytical grade iron(III) oxide (Merck) and kaolin (Suprex clay) with 10% carbon (Colcarb Grade I, activated carbon) at 870° for 60 min in an enclosed vibrated silica reactor. The initial mixture contained a small excess of iron(III) oxide (about 6%) over the stoichiometric requirement to form fayalite from the silica in the kaolin. X-Ray diffraction revealed no free silica or metallic iron in the product, and apart from a trace of magnetite, iron was present either as iron(II) oxide or orthosilicate. No crystalline aluminium phase other than hercynite could be detected. The total iron content of the sample was determined by chemical analysis to be 41·0%. From the X-ray diffraction pattern and chemical analysis a fayalite content of 60–70% was indicated.

An iron–tin alloy was used as a source of metallic iron, since the metallic iron was in this form in the reduced tin calcines for which the method was developed. This alloy was prepared by melting iron and tin metal in an alumina crucible in an induction furnace. The iron content was found to be 74·6% and the tin content 25·4%.

Reagents

All chemicals should be of analytical reagent quality. The methanol used should contain no more than 0·1% water.

Procedure

Transfer an accurately weighed sample, containing up to 100 mg of metallic iron, into a 100-ml conical flask (ground-glass joint). Add 10 ml of bromine (cooled to 5°), fit a reflux condenser, and reflux at 58° for 1 hr to ensure complete dissolution of the metallic iron and tin. After cooling, remove the condenser, and pass dry air through the flask to remove excess of bromine. Do not heat the sample too strongly (above 60°), or loss of iron bromide may result Trap the excess of bromine (if necessary) by bubbling the effluent gases through 5*M* sodium hydroxide. To prevent formation of hydrogen bromide, which will react with the fayalite, exclude water from the reagents and glassware during the bromination process and during and immediately after removal of excess of bromine. Store the samples, if required, in a desiccator over phosphorus pentoxide.

When the bromine has been completely removed, add 70 ml of methanol to the flask and stir magnetically at 60° for 30 min to dissolve the iron bromides. After cooling, filter this solution through a filter of pore-size < 0·5 μm (Millipore BDWP or equivalent) and wash the residue well with methanol.

Transfer the filtrate to a 300–400 ml beaker and evaporate it to 20 ml. Add 50 ml of hydrochloric acid and again evaporate to 20 ml to remove the methanol. Transfer this solution into a 100-ml volumetric flask and make up to volume with distilled water—solution A.

Carefully transfer the filter pad containing the residue to a zirconium or nickel crucible and ignite at about 600° to remove organic matter. When cool, add to the residue 4 g of sodium peroxide, mix, and fuse at about 600° until a homogeneous liquid flux is obtained. Cool, then add distilled water (about 20–30 ml) slowly to the fusion mixture, with a watch-glass covering as much as possible of the crucible. When the reaction has ceased, transfer the reaction mixture into a 150-ml beaker and wash the crucible with 20 ml of concentrated hydrochloric acid, followed by distilled water, transferring these washings to the beaker Heat to boiling to dissolve the solids and remove any dissolved hydrogen peroxide. Cool, transfer the solution into a 100-ml volumetric flask, and make up to volume with distilled water—solution B.

Take suitable aliquots of solutions A and B, make them 4*N* in hydrochloric acid, heat, reduce the iron to iron(II) with 10% stannous chloride solution, adding 2 or 3 drops in excess, cool, add 10 ml of 4·5% mercuric chloride solution, 90 ml of 0·5*N* sulphuric acid and 10 ml of orthophosphoric acid (1 + 1) and let stand for 5–10 min. Titrate with 0·01*N* potassium dichromate, using barium diphenylaminesulphonate as indicator.

The titration of solution A gives the amount of metallic iron and that of solution B the iron present as oxide or fayalite.

If a titration volume greater than 5 ml cannot be obtained it is preferable to determine the iron by atomic-absorption spectrometry, using iron standards containing the same matrix as the samples.

RESULTS AND DISCUSSION

To test the effectiveness of the separation technique a series of synthetic fayalite and metallic iron mixtures was prepared from the metallic tin–iron alloy and synthetic fayalite mentioned earlier. The mixtures prepared, and the results of their analysis by the proposed method, are listed in Table 1.

The method has been successfully applied to the analysis of reduced tin calcines containing a wide concentration range of metallic iron. Four reduced tin calcine samples were prepared under different conditions to give:

(A) high metallic iron (as iron–tin alloy) and negligible fayalite content; (B) moderate metallic iron and high faya-

† Including fayalite.
§ Negligible fayalite content.

lite content; (C) low metallic iron and high fayalite content; (D) very low metallic iron and high fayalite content.

The nature of these samples was confirmed by X-ray diffraction. Table 2 compares the results obtained by using the proposed method (bromine alone) for all four samples and the bromine–methanol method of Kraft and Fischer for samples A, C and D and that of Blum and Searl for sample B. The bromine-in-methanol results for metallic iron in samples B, C, and D (high fayalite content) were much too high to correlate with the X-ray diffraction data. X-Ray data for the residues from these samples after treatment with bromine in methanol showed also that for samples B, C, and D some fayalite was dissolving with the metallic iron. In sample A (negligible fayalite) the two methods gave the same result.

The use of bromine in methanol to separate metallic tin from tin(IV) oxide (cassiterite) has been demonstrated by Tsukahara, Yamamato and Tonomura.[6] The present authors' proposed method (bromine alone) has resulted in metallic tin being separated from tin(IV) oxide simultaneously with the separation of metallic iron from fayalite. However, as in the bromine-in-methanol method, complete recovery of the tin in the filtrate was not achieved, because of the loss of tin(IV) bromide as the methanol evaporated. Addition of sulphuric acid did not reduce the loss of tin(IV) bromide, as it does for tin(IV) chloride,[7] and so far the concentration of metallic tin in the samples has been determined by difference.

Summary—In a proposed new procedure the sample is treated with bromine, the excess of bromine removed, and the residue extracted with methanol. After filtration the filtrate is evaporated to remove methanol and the bromides are dissolved in hydrochloric acid for determination of metallic iron. The oxide residue from the filtration is fused in sodium peroxide and then dissolved in hydrochloric acid for the determination of iron present either as oxide or silicate. Iron in the hydrochloric acid solutions from the residue and filtrate is determined either by titration with standard potassium dichromate solution or by atomic-absorption spectrometry.

EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF COPPER(II) WITH 1,1,1-TRIFLUORO-3-(2-THENOYL)ACETONE

Hideo Akaiwa, Hiroshi Kawamoto and Fujio Izumi*
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376, Japan

(*Received* 18 *September* 1975. *Accepted* 1 *November* 1975)

The spectrophotometric determination of copper(II) with 1,1,1-trifluoro-3-(2-thenoyl)acetone (HTTA) has been reported[1,2] to have the drawback that the maximum absorption of the extracted species, $Cu(TTA)_2$, at around 340 nm cannot be used because of the interference caused by the residual HTTA which shows a strong absorption band near 340 nm. Similar interference occurs in the method using 1,1,1-trifluoro-3-(2-thiothenoyl)acetone.[3] An improved method uses adduct formation of $Cu(TTA)_2$ with pyridine.[4] It is now shown that the excess of HTTA can be removed by scrubbing with sodium hydroxide solution without any decomposition of $Cu(TTA)_2$ if chloroform is used as a diluent, and a highly sensitive method results.

EXPERIMENTAL

Reagents

A standard solution of copper(II) (100 μg/ml) was prepared by dissolving copper(II) sulphate pentahydrate in distilled water. Acetate buffer, pH *ca* 5.4, prepared by mixing 0.2*M* sodium acetate and 0.2*M* acetic acid was purified by shaking with 0.001*M* HTTA in chloroform; the aqueous phase was washed with chloroform three times and filtered.

General procedure

Transfer the sample solution containing not more than 10 μg of copper(II) to a separatory-funnel. Add, if necessary, 5 ml of 4% potassium fluoride solution for masking. Adjust the pH to *ca*. 5.4 by addition of acetate buffer, then shake the aqueous phase vigorously for 3 min with 10 ml of 0.001*M* HTTA in chloroform. Allow the phases to separate and draw off the extract into another separatory-funnel. Add 10 ml of 0.005*M* sodium hydroxide and shake the mixture for 4 min. Measure the absorbance of the organic phase at 344 nm against a reagent blank.

RESULTS AND DISCUSSION

Effect of organic solvent

Table 1 lists the absorbances obtained with use of different organic solvents. Values of the partition coefficients of $Cu(TTA)_2$, P_{MA}, calculated from the literature data,[5–7] are also shown. The resistance of the extracted $Cu(TTA)_2$ to attack by hydroxide is explained in terms of the differences in P_{MA} for the five solvents. Since the decomposition of $Cu(TTA)_2$ is considered to occur in the aqueous phase, a high P_{MA} value will lead to increased resistance to the alkali treatment. In particularly, the hydrogen-bonding of chloroform to copper(II) β-diketonates[8] may result in a higher value of P_{MA} than with the other solvents.

Table 1. Effect of organic solvent on the absorbance

Solvent	Absorbance	log P_{MA}
Cyclohexane	0.123	-2.52
Xylene	0.496	—
Benzene	0.541	1.12
Carbon tetrachloride	0.549	0.72
Chloroform	0.621	1.41

Absorption spectra

Figure 1 shows the absorption spectra of the $Cu(TTA)_2$ complex in chloroform and of the reagent blank, obtained by the procedure described, showing almost complete removal of the residual HTTA in the organic phase. The complex has maximum absorbance at 344 nm, molar absorptivity 4.9 × 10^4 l. $mole^{-1}.cm^{-1}$ in good agreement with that measured for a chloroform solution of crystalline $Cu(TTA)_2$. Therefore, the decomposition of $Cu(TTA)_2$ during the alkali treatment was confirmed to be negligible.

Effect of pH

Copper(II) is efficiently extracted over the pH range 5–6.2, but extraction is incomplete outside this pH range, hence a pH of 5.4 was adopted.

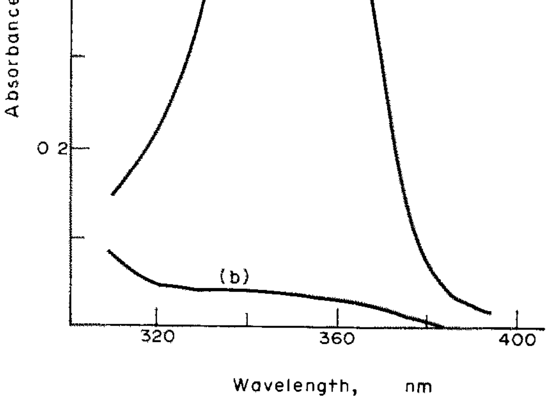

Fig 1. Absorption spectra of (a) $Cu(TTA)_2$ chelate and (b) reagent blank in chloroform. Cu(II): 8 μg.

Calibration curve

The calibration curve obtained at pH 5.4 is linear over the range 0–10 μg of copper(II). In 9 determinations of 5 μg of copper(II), the absorbance was 0.399 ± 0.003, the relative standard deviation being 1.0%. The Sandell sensitivity

---

*Present address, National Institute for Researches in Inorganic Materials, Sakura, Niihari, Ibaraki 300-31 is 0.0013 μg/cm^2, is considerably higher than that for the dithizone method (0.0022 μg/cm^2) or the HTTA–pyridine method (0.0023 μg/cm^2).

Interferences

No interference in determination of 5 μg of copper(II) was observed for 1 mg of Mg, Ca, Sr, 100 μg of Mn(II), Zn, Ag(I), Cd, Hg(II), Pb, and 20 μg of Co(II), Ni. Forty times as much as Al, Fe(III), and Cr(III) as copper(II) taken will interfere seriously because of formation of hydrolysis products, but these metals can be masked by adding 5 ml of 4% potassium fluoride solution before adjusting the pH.

Determination of copper(II) in natural water

The present method was applied to the determination of copper(II) in a natural water sample taken from the Watarase river. The analytical value (five determinations) was 0.060 ± 0.001 μg/ml. The average recovery, tested by doing four determinations with 5 μg of copper(II) added to the sample solutions, was 101%

ANALYTICAL DATA

A POTENTIOMETRIC STUDY OF THE COMPLEXES FORMED BETWEEN Ni(II) AND Zn(II) AND 3-MERCAPTOPROPIONIC ACID

H. F. DE BRABANDER*, H. S. CREYF, A. M. GOEMINNE and L. C. VAN POUCKE†

Department of General and Inorganic Chemistry, University of Ghent, Ghent, Belgium

(*Received* 11 *March* 1975. *Revised* 28 *August* 1975. *Accepted* 3 *September* 1975)

In earlier investigations[1–4] the complexation of the metal ions Ni^{2+} and Zn^{2+} with the following thiols as ligands was studied: 2-mercaptoethanol (MEL), 3-mercapto-1,2-propanediol (MPD), thioglycollic acid (TGA) and thiolactic acid (TLA).

Not much work has been done on the complexation of 3-mercaptopropionic acid (3-MPA). Saxena and Gupta[5,6] studied the Ni^{2+} and Cd^{2+} complexes of this ligand and found only mononuclear complexes. This is not surprising, taking into account that the range of total metal ion concentration used was rather restricted. In the present work the complexation of Ni^{2+} and Zn^{2+} with 3-mercaptopropionic acid is studied over a large concentration range. This ligand is interesting for comparison of the results with those obtained for TGA and TLA, since the carboxyl group is substituted in the β-position relative to the $-SH$ group.

EXPERIMENTAL

Apparatus

A digital pH-meter "Radiometer pHM52" was used, equipped with a G 202 C glass electrode and a saturated calomel electrode as reference. The glass electrode was standardized with an NBS standard 0·01*M* borax buffer, pH 9·18 at 25°.[7] All solutions were kept at 25°.

Reagents

Stock solutions (0·2*M*) of nickel and zinc nitrate were prepared and standardized as before.[1,2] 3-Mercaptopropionic acid (3-MPA) was obtained from Fluka and redistilled just before use. Aqueous solutions of 3-MPA are stable for a long period if they are prepared with oxygen-free water and regularly flushed with pure nitrogen.[9] All solutions were made up to an ionic strength of 0·5 with potassium nitrate (Merck *p.a.*) to keep the activity coefficients as constant as possible.

Procedure

The titration procedure for zinc was as described before.[1] The total metal ion concentration was varied from 0·001 to 0·016*M*. The initial ligand concentration was five times the total metal ion concentration. The reaction of nickel(II) with 3-MPA was too slow for direct titration. Therefore a series of 50-ml volumetric flasks was prepared, containing solutions with constant total metal ion and ligand concentrations but increasing amounts of base. A 25-ml aliquot of each solution was diluted to 50-ml with 0·5*M* potassium nitrate, giving a second series with half the original total metal ion concentration. A constant pH-value was obtained after 1 hour.

Calculations

The calculations were performed with a number of computer programs written in FORTRAN IV. All programs were executed on a Siemens 4004/150 computer.

RESULTS AND MATHEMATICAL TREATMENT

The symbols used are those listed earlier,[3] except that B represents Ni^{2+} or Zn^{2+} (and B the total metal ion concentration), A represents 3-MPA (and A the total ligand concentration).

The protonation constants $\log K_{H_i}$ of the carboxylate and mercapto group of 3-mercaptopropionic acid (3-MPA) were calculated by a method described by Thiers, Van Poucke and Herman[9] and found to be 4·16 and 10·10 respectively.

With a general computer program ZPAF the formation functions $Z(pa)_B$ were calculated as before.[3] A proportionality factor described before[10] was used to calculate $[H^+]$ from the activity of the hydrogen ion.

The formation curves for the Zn^{2+}/3-MPA complex all crossed at a value $Z = \pm 1{\cdot}45$, forming a real or pseudo cross-over point. From graphical analysis of the formation curves[11,12] it appeared that a mixture of mononuclear complexes BA, BA_2 and a "core + links" series $B(A_6B)_n$ with $n_{max} = 3$ was very probable. To find out which complexes were really present the computer program PNUC was used.[4]

This program is based on minimization of the function U related to the difference between calculated and experimental Z-values:

$$U = \Sigma(Z_{cal} - Z_{exp})^2 \tag{1}$$

The standard deviation of Z is given by

$$\sigma^2(Z) = U_{min}/(n_{exp} - n_{par}) \tag{2}$$

where n_{exp} is the number of experimental points and n_{par} is the number of complexes. This calculation is repeated for different complex compositions, and the set of complexes that is really present will give the lowest values of U_{min} and $\sigma(Z)$.

The calculation is started with guessed stability constants. Bad guesses can ruin the calculation. If the guess for a certain stability constant is too low, its contribution to U is negligible and the constant remains unchanged during the calculation. The best guesses are 3–5 log β units higher than the finally obtained results.

† Present address: Department of Chemistry, Limburgs Universitair Centrum, B-3610 Diepenbeek, Belgium.

Input values for a complex B_QA_P can be calculated[13] from

$$\log \beta_{Q,P}(\text{guessed}) = 2{\cdot}1\,(Q-1) + P.pa \qquad (3)$$

where pa is the value of $-\log a$ for $B = 0{\cdot}016$ and $Z = 0{\cdot}5$.

The distribution of complexes ($\alpha_{q,p}$) was calculated from

$$\alpha_{q,p} = \frac{100\,q\beta_{q,p}b^q a^p}{B} \qquad (4)$$

The results for the zinc system are given in Table 1. The possible complexes are BA, BA_2, B_2A_2, B_3A_4 and B_4A_6. The complexes BA and B_2A_2 are rejected and the system Zn^{2+}/3-MPA can be represented by the formation of the complexes BA_2, B_3A_4 and B_4A_6.

The formation curves for the Ni/3-MPA system are shown in Fig. 1. The "core + links" theory could not be applied. As there is no "cross-over" point a mixture of poly- and mononuclear complexes is not very probable. Below $Z = 0{\cdot}7$ the spacing of the curves points to a "core + links" series $(A_2B)_n$, also found for other Ni^{2+} thiol complexes.[2-4] For $Z > 0{\cdot}7$ the spacing changes and all formation curves tend to a value of $Z_{max} = 2$, so complexes with a ligand/metal ratio of 2 are very probable. This system was also treated with the program PNUC, starting with two complexes B_3A_4 and B_3A_6, and adding sequentially all complexes with less than seven metal ions and a ligand/metal ratio < 2. The mononuclear complexes BA, BA_2, BA_3 and the polymeric complexes $(BA_2)_n$ with $n = 1$–9 were also tested The complexes were accepted or rejected as described elsewhere.[4] The lowest value for U_{min} and $\sigma^2(Z)$ was found for a mixture of complexes B_5A_{10}, B_6A_{12}, B_6A_9 and B_6A_{11}. As can be seen from Table 2 the predominant species are B_6A_{12} and B_6A_9

DISCUSSION

The complexes formed between Ni^{2+} and 3-MPA are totally different from the Zn^{2+} complexes of 3-MPA, which are analogous with those formed with TLA and TGA.

This different behaviour is not yet understood. From earlier measurements it was found that ligands such as MEL and MPD, containing the –SH group as the only complexing group, form polymeric complexes $B(A_2B)_n$ with high values of n. The implant of a second complexing group on the molecule can block the growth of the polymeric chain. The second group competes with the –SH and after formation of some links it can be energetically favourable to fill up the empty co-ordination places around Ni^{2+} with the second group instead of the –SH group. This may be the reason why complexes higher than B_3A_4 are lacking in the system Ni^{2+}/cysteamine.[1] By analogy with polymer chemistry we could call this a termination reaction, or the second group a "stop" group.

The second group can also confer an extra charge on the complex This is the case for TGA, TLA and 3-MPA. While the complexes of MEL, MPD and 2-MEA have two positive charges, the complexes of Ni^{2+} with TGA, TLA and 3-MPA receive two negative charges per BA_2 link. High charge on a complex will not be favourable for the stability of that complex.

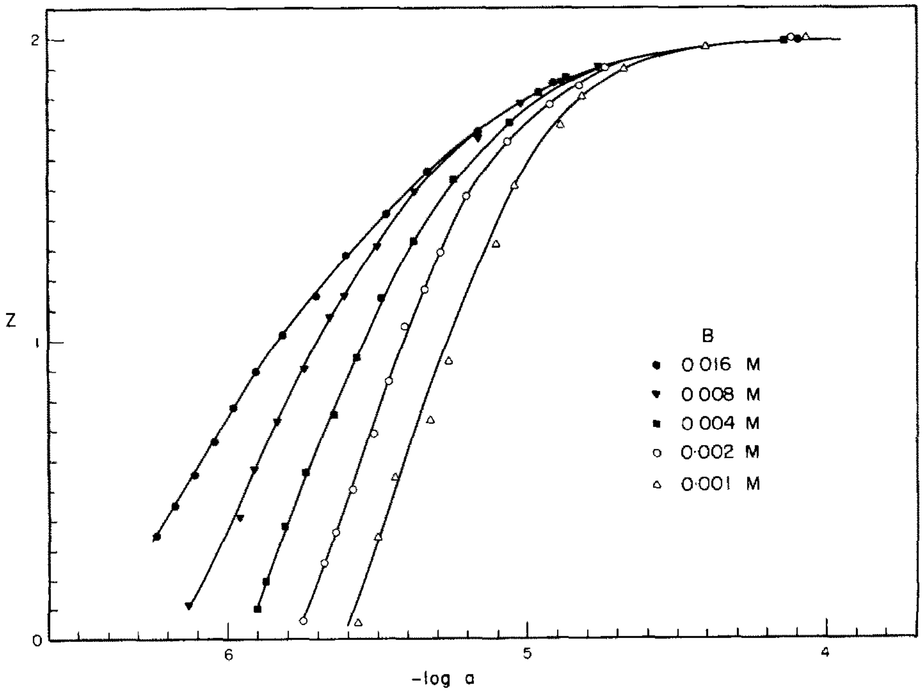

Fig. 1. The formation curves of the system nickel(II)-3MPA.

Table 2. Stability constants for Ni^{2+}/3-MPA complexes from treatment with PNUC

System	$\log \beta_{q,p}$	$x_{q,p_{max}}$	present	U_{min}	$\sigma^2(z)$
B_5A_{10}	64·54	16	+	0·2166	$0·31 \times 10^{-2}$
B_6A_{12}	78·94	86	+		
B_6A_9	63·58	68	+		
B_6A_{10}	67·80	<4	(±)−		
B_6A_{11}	73·31	12	+		
B_5A_{10}	64·49	16	+	0·2122	$0·30 \times 10^{-2}$
B_6A_{12}	78·89	83	+		
B_6A_9	63·58	69	+		
B_6A_{11}	73·60	23	+		
B_6A_{12}	79·03	83	+	0·2135	$0·29 \times 10^{-2}$
B_6A_9	63·61	73	+		
B_6A_{11}	73·36	13	+		
B_6A_{12}	79·10	99	+	0·2284	$0·31 \times 10^{-2}$
B_6A_9	63·63	82	+		

This could explain the complex formation between Ni^{2+} and 3-MPA. If, in the case of Ni^{2+}, a six-membered chelate, less stable than a five-membered chelate, is not able to stop the growing of the polymeric chain, the formation of higher complexes will be inhibited by the higher charge on the complexes.

Summary—The composition and stability constants of the complexes formed between Ni^{2+} and Zn^{2+} and 3-mercaptopropionic acid (3-MPA) were studied by a potentiometric method at 25° and in 0·5*M* KNO_3. For the system Zn^{2+}/3-MPA a mixture of the mononuclear complex BA_2 and the polynuclear complexes B_3A_4 and B_4A_6 was found (B means the metal ion and A the ligand). The system Ni^{2+}/3-MPA can be represented by the complexes B_5A_{10}, B_6A_{11}, B_6A_9 and B_6A_{12}. In this series the last two complexes are predominant.

PRELIMINARY COMMUNICATION

THE DETERMINATION OF GLYCEROL IN WATER BY FLOW-INJECTION ANALYSIS - A NOVEL WAY OF MEASURING VISCOSITY

D. Betteridge
Chemistry Department, University College of Swansea,
Swansea SH2 8PP, U.K.

J. Růžička
Chemistry Department A, Technical University of Denmark,
2800 Lyngby, Denmark

(Received 12 March 1976. Accepted 15 March 1976)

In a typical determination by flow-injection analysis a measured amount of sample is injected into a flowing stream of colour-forming reagent and the absorbance of the solution is continuously recorded at some suitable distance down-line.[1-4] The reaction between reagent and sample gives rise to a peak in absorbance, having a height proportional to the amount of sample injected.

The parameters such as flow-rate, sample size and length of tubing between the sample-injection point and the detector, are selected so that a linear relationship exists between peak height and concentration of sample. However there is necessarily some mixing of sample plug and the flowing stream of reagent. The extent of mixing will be reflected in the shape of the observed peak, and most obviously in the peak height. The degree of mixing will be a function of the viscosity of the sample solution. We have tested this hypothesis by injecting solutions of glycerol in water, which are widely used as standards for viscometry, into a flowing stream of water. The flowing stream had some colouring matter added so that the sample plug was identified by a reduction in absorbance.

EXPERIMENTAL

Apparatus

The flow-injection analyser has been described elsewhere.[1-4] Samples of 100 µl or greater were introduced by hypodermic syringe into a sample-injection block, whilst those of 50 µl were admitted through a newly designed sample inlet. A flow-rate of 4 ml/min was maintained. The absorbance was measured at 620 nm in a flow-cell with optical path of 10 mm. Occasionally there was some sample contamination from the previous sample, if it contained a high proportion of glycerol. It was rapidly washed away by water or the next sample. Substitution of Teflon or polyethylene tubing made no difference. The length of the tube was 1.4 m, bore 1.0 mm, for the set of experiments shown in Fig. 1.

Solutions

Mixtures of glycerol and water were made up by weighing each component. The flow-solution was 0.001% Bromothymol Blue in water, buffered at pH 9.2 with a borate buffer.

RESULTS

The results shown in Table 1 and Fig. 1 show that with pure glycerol there is virtually no dye in the sample plug, but the dye occurs increasingly as the concentration of glycerol is lowered. The method can be used to determine extremely rapidly the composition of a wide range of glycerol-water mixtures. The results obtained during trial runs in which tube lengths, flow-rates and sample size were varied suggest that it would be easy to obtain

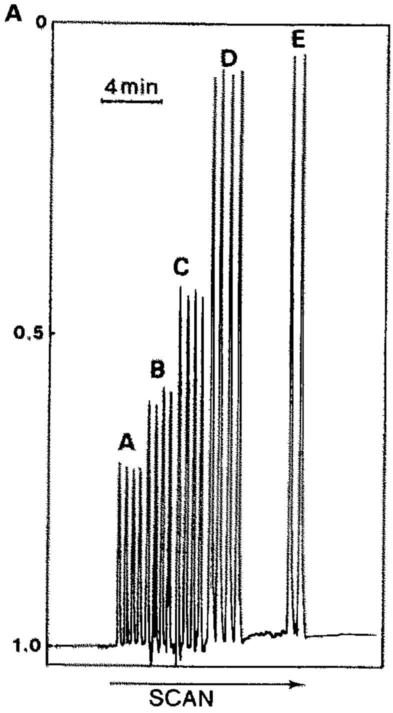

Fig. 1. Chart response from flow-injection of 100-µl samples of glycerol-water mixtures into a flowing stream of water (for details see Table 1)

Table 1. Chart response for flow-injection of 100-µl samples of glycerol-water mixtures of different viscosity

† Interpolated for 21.8° from values (cP) in ref. 5

precise results for the composition over a narrow range. The method should be generally applicable to the determination of the composition of mixtures of miscible liquids.

The viscosity of the sample is an important factor in the extent of mixing and these results suggest that there is the possibility of measuring viscosity simply and rapidly by injection-flow analysis.

Many more experiments will be required to assess the validity of this hypothesis, but the present results have far-reaching implications for the scope of flow-injection analysis and could not have been obtained with "Auto-Analyzers" which depend on air-bubbles to separate samples. They also point to the need to ensure that the viscosities of sample and standard solutions are equal, or at least maintained constant throughout a run on the flow-injection analyser. This may present a special problem in clinical analysis, where serum samples have considerably higher viscosity than aqueous standards.

CHLOROFORM EXTRACTION OF METAL ETHYL XANTHATES FROM HYDROCHLORIC ACID MEDIA

ELSIE M. DONALDSON
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 14 *October* 1975. *Accepted* 10 *November* 1975)

Summary—The chloroform extraction of 32 elements (Fe, Co, Ni, Zn, Cd, Ge, Sn, Pb, V, As, Sb, Bi, Cu, Ag, Au, Mn, Re, Ga, In, Tl, Ce, Se, Te, Cr, Mo, U, Pt, Pd, Rh, Ir, Ru and Os) from 0.1–10*M* hydrochloric acid media in the presence of potassium ethyl xanthate has been studied. The oxidation states in which some elements react, and potential analytical separations, are discussed. Pd(II), As(III) and Se(IV) are completely extracted as ethyl xanthate complexes, Te(IV) is almost completely extracted, and Au(III) is largely extracted over the range of acid concentration investigated. Mn(II), Zn, Rh(III), Ir(IV), Ru(III), Os(IV), Cr(III), Cr(VI), Ce(III) and Ce(IV) are not extracted. Ge is partly extracted from 6–10*M* media as the chloro-complex. Depending on the acid concentration, the remaining elements are all partially extracted as xanthate complexes.

In a recent review[1] on the solvent extraction of metal xanthates, particularly those formed by ethyl xanthate, the characteristics and analytical uses of these complexes were described. Much of the information in this and previous reviews[2–5] appears in obscure Soviet journals and other papers not readily accessible to Western readers, or for which English translations are not available. In many cases, the abstracts of these papers do not provide information on the optimum range of pH or acid concentration required for the extraction of the elements under consideration, or the extent to which some are extracted from relatively strongly acidic media.

Published data,[6] and information obtained by the author in previous work, involving the separation of molybdenum from tungsten[7] and bismuth from lead[8] by chloroform extraction of their ethyl xanthate complexes, suggested the possibility of the simultaneous group extraction of xanthates of elements such as arsenic, antimony, bismuth, selenium and tellurium from hydrochloric acid media. For this reason, it was considered worthwhile to investigate the extraction of the ethyl xanthate complexes of these and other elements into chloroform from 0.1–10*M* hydrochloric acid media. It is expected that such separations will be useful in the atomic-absorption analysis of metalliferous materials for many of these elements at levels ranging from minor to trace.

EXPERIMENTAL

Reagents

Solutions of selenium(IV), cobalt(II), chromium(III) and (VI), rhenium(VII), cerium(III) and (IV), uranium(VI) and thallium(I) were prepared from analytical-reagent grade salts by dissolving them in water.

Solutions of rhodium(III), ruthenium(III), iridium(IV), osmium(IV) and iron(II) were prepared by dissolving appropriate salts in water plus sufficient 10*M* hydrochloric acid for the final hydrochloric acid concentration to be 1*M*. Solutions of molybdenum(VI), arsenic(III), vanadium(V) and germanium were prepared by dissolving the oxides in dilute sodium hydroxide solution and adjusting the pH of the solutions to ~7 with dilute hydrochloric acid.

Nickel, zinc and manganese(II) solutions were prepared by dissolving the metals in hydrochloric acid. An iron(III) solution was prepared by dissolving the metal in hydrochloric acid and oxidizing with hydrogen peroxide. Solutions of bismuth, lead, indium(III) and copper(II) were prepared by dissolving the metals in nitric acid. A cadmium solution was prepared by dissolving cadmium carbonate in hydrochloric acid. Silver and gallium solutions were prepared by dissolving silver sulphate and gallium oxide in nitric acid. Aliquots of these solutions were evaporated to dryness to remove the acids before extraction.

Gold(III), platinum(IV) and palladium(II) solutions were prepared by dissolving the metals in *aqua regia*. Aliquots of the gold and platinum solutions were evaporated to dryness on a hot water-bath, 10 drops of *aqua regia* were added and the solutions were evaporated to dryness in a stream of air before extraction, to prevent thermal decomposition of the salts. Aliquots of the palladium solution were evaporated to dryness on a hot water-bath before extraction.

A stock solution of tin(IV) was prepared by dissolving the metal in 10*M* hydrochloric acid and diluting to volume with the same acid solution. A working solution, 1*M* in hydrochloric acid, was prepared by 10-fold dilution of this solution.

A solution of antimony(III) was prepared by dissolving antimony potassium tartrate in water containing sufficient tartaric acid for its final concentration to be 1%, and adjusting the pH of the solution to ~7 with dilute ammonia solution.

A solution of tellurium(IV) was prepared by dissolving tellurium dioxide in sufficient 10*M* hydrochloric acid for the final solution to be 0.5*M* in hydrochloric acid.

All these working solutions were prepared so as to have a 100 μg/ml concentration of the element concerned, and weighings based on formula weights were taken as correct. Analytical-reagent grade chloroform was used without further purification.

General procedure for extraction

Sufficient 10*M* or concentrated hydrochloric acid to provide the range 0.1–10*M* was added to 150-ml beakers, each

Au	Atomic-absorption spectrophotometry	(242.8 nm)
Mn	Spectrophotometry as permanganate	(546 nm)
Re	Spectrophotometry as thiocyanate	(425 nm)
Ga	Atomic-absorption spectrophotometry	(294.36–294 42 nm doublet)
In	Polarography	
Tl	Polarography	
Ce	Spectrophotometry after oxidation to cerium(IV)	(350 nm)
Se	Spectrophotometry with 3,3'-diaminobenzidine hydrochloride	(420 nm)
Te	Spectrophotometry with thiourea	(330 nm)
Cr	Spectrophotometry as chromate	(366 nm)
Mo	Spectrophotometry as thiocyanate	(460 nm)
U	Spectrophotometry with sodium azide	(360 nm)
Pt	Spectrophotometry with stannous chloride	(405 nm)
Pd	Spectrophotometry as iodide	(408 nm)
Rh	Spectrophotometry with stannous chloride	(475 nm)
Ir	Spectrophotometry with *o*-dianisidine	(530 nm)
Ru	Spectrophotometry with thiourea	(620 nm)
Os	Spectrophotometry with thiourea	(480 nm)

containing 5-ml aliquots of a solution of the appropriate metal (i.e., 500 μg of the metal), or the residue obtained after evaporation of an aliquot to dryness (Note 1). Each solution was transferred to a 125-ml separatory funnel and diluted to 50 ml with water. Ten ml of chloroform were added, followed by 1 ml of freshly prepared 20% potassium ethyl xanthate solution, and the solution was extracted immediately (Note 2) by shaking for 1 min. The chloroform phase was drained into a 150-ml beaker. The aqueous phase was extracted twice more, in a similar manner, with 5-ml portions of chloroform and 1 and 0.5 ml of xanthate solution, then the aqueous phase was washed by shaking it for ~30 sec with 5 ml of chloroform. The combined extracts were treated with 10 ml of 50% v/v nitric acid (Note 3) and chloroform was removed by evaporation on a hot water-bath. Depending on the volatility and other properties of the element investigated, and the method used for its determination, the resulting solution was subsequently either evaporated to dryness, or treated with suitable acids or *aqua regia*, and evaporated to fumes or to dryness.

The amount of the metal in the chloroform extract was determined by the methods listed in Table 1. The percentage of metal extracted was then calculated from the initial known total amount of metal and that found in the organic phase after a triple extraction.

Notes

1. Tests with selenium, tellurium, arsenic, antimony and thallium in their highest oxidation states were carried out after oxidation of these elements with 0.5% potassium permanganate solution, in dilute (0.5*M* or less) hydrochloric acid media before the adjustment of the acid concentration of the solution with 10*M* or concentrated hydrochloric acid and subsequent dilution to 50 ml with water. In tests with platinum and gold, 5-ml aliquots of the solutions in 0.5 and 1*M* hydrochloric acid media, respectively, were also treated with permanganate solution to ensure that these elements were in their highest oxidation states before extraction.
2. Because of the instability of many metal xanthate complexes, the extraction was performed immediately after the addition of chloroform and xanthate solution.
3. Extracts obtained during tests with ruthenium(III) were evaporated to dryness with hydrochloric acid alone, to prevent loss of ruthenium as the volatile tetroxide.

RESULTS AND DISCUSSION

The degree of extraction of a number of elements into chloroform, as ethyl xanthate complexes, from 0.1–10*M* hydrochloric acid media is given in Table 2 and Figs. 1–4. The acid concentrations shown are the initial concentrations of the solutions before the addition, in three successive extraction stages, of a total volume of 2.5 ml of 20% potassium ethyl xanthate solution. The oxidation states of the elements shown are those in which they were initially added. Although arsenic, antimony, thallium and tellurium

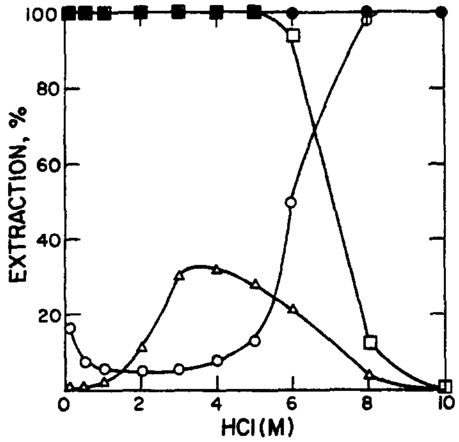

Fig. 1. Extraction of As(III) (●), As(V) (○), Sb(III) (□) and Sb(V) (△) as a function of HCl concentration.

are known to react with xanthate in their lower oxidation states, tests with these elements, and selenium, were also carried out in their highest oxidation states because of the known reducing action of xanthates.[1] Tests with other metal ions (not shown) showed that manganese(II), zinc, rhodium(III), iridium(IV), ruthenium(III), osmium(IV), chromium(III) and (VI) and cerium(III) and (IV) are not extracted from 0.1–10*M* hydrochloric acid. Germanium(IV) is partially extracted (~27–90%) from 6–10*M* media, not as a xanthate complex, but as the chloro-complex.

Iron, cobalt, nickel and cadmium

Table 2 shows that iron(III), cobalt(II) and nickel are partially extracted at low hydrochloric acid concentrations, particularly in the range 0.1–2*M*. The extraction of these ions is reasonably consistent with reported data.[1] The erratic results obtained for iron(III) can be attributed to its partial reduction by xanthate during or before the extraction.[9,10] The low extraction of iron(II) from 0.1–1*M* hydrochloric acid may be due to aerial oxidation before the extraction, because it has been reported that iron(II) does not react with xanthate.[9,10]

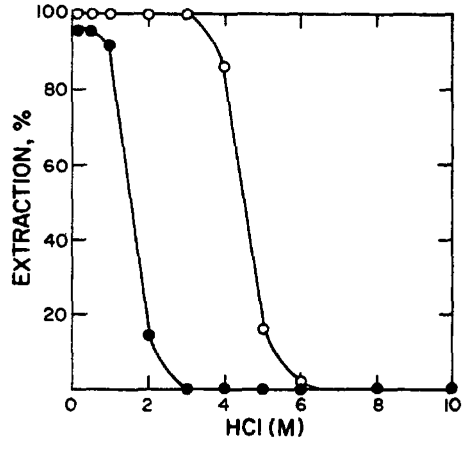

Fig. 2. Extraction of Pb(II) (●) and Bi(III) (○) as a function of HCl concentration.

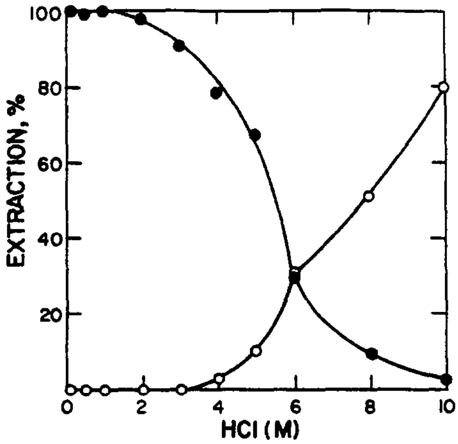

Fig. 3. Extraction of Mo(VI) (●) and Re(VII) (○) as a function of HCl concentration.

The high percentage of cadmium extracted from 0.1*M* hydrochloric acid is not consistent with earlier data, because cadmium ethyl xanthate has been reported as being insoluble in chloroform and other non-polar solvents (carbon tetrachloride, benzene, dichloroethane and petrol).[9]

Gallium, indium and thallium

Gallium(III) and indium(III) are partially and almost completely extracted, respectively, as colourless ethyl xanthate complexes from 0.1*M* hydrochloric acid. No references to the extraction of these complexes were found in the literature. However, solid complexes with the formulae $Ga(EX)_3$ and $In(EX)_3$, (EX = ethyl xanthate) have been reported.[11]

The low extraction of thallium(I) from 0.1*M* hydrochloric acid is consistent with earlier work[12,13] in which a number of colourless xanthate complexes of thallium(I) were found to be of limited solubility in non-polar solvents. A solid thallium(III) complex, $Tl(EX)_3$, has been prepared[11] but its solubility in organic solvents has not been reported. Table 2 shows that the thallium(III) complex (yellow) is moderately extracted into chloroform from 0.1*M* hydrochloric

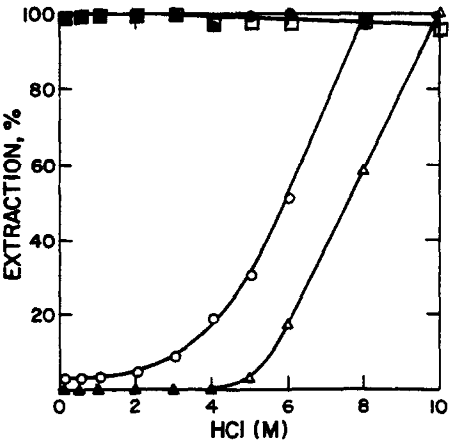

Fig. 4. Extraction of Se(IV) (●), Se(VI) (○), Te(IV) (□) and Te(VI) (△) as a function of HCl concentration

acid. The degree of extraction first decreases with increase in acid concentration, then increases somewhat over the range 4–6M acidity. The increase is probably due to the extraction of the thallium(III) chloro-complex. The ethyl xanthate complex is considerably more soluble in di-isopropyl ether than in chloroform.

Tin, copper and silver

Tin(IV) is partially extracted from 0.1–5M hydrochloric acid media. Previously, qualitative tests have shown that both tin(II) and (IV) can be extracted into carbon tetrachloride, chloroform and other non-polar solvents from weakly acidic media (pH ~4).[9] A solid tin(II) complex with the formula $Sn(EX)_2$ has been reported,[11] which suggests that tin(IV) is probably reduced during complex formation.

Table 2 shows that copper(II) is appreciably extracted over the whole range of acid concentration investigated. However, a yellow precipitate remained at the interface after the third extraction and the washing stage, and consequently erratic results were obtained in these tests. Presumably this was caused by the low solubility of copper(I) ethyl xanthate in chloroform. It has been reported that copper(II) is not directly reduced by xanthate ions but reacts to form copper(II) ethyl xanthate which rapidly decomposes to form copper(I) ethyl xanthate and dixanthogen. The copper(I) complex is reported to be insoluble in chloroform in the absence of pyridine.[14]

Silver(I) is only partially extracted as the ethyl xanthate complex from ~1M or less hydrochloric acid because of the partial formation of insoluble silver chloride. The degree of extraction at this or higher acidity (2–3M) is also influenced by the limited solubility of the yellow complex in chloroform. As with copper, some of the precipitate was not extracted and remained at the interface after the extraction and washing steps. Probably more complete extraction of up to ~500 μg of silver into chloroform from 2–3M hydrochloric acid can be obtained if larger volumes of solvent are used.

Gold, platinum and palladium

Table 2 shows that gold(III) is appreciably extracted over the whole range of acid concentration investigated. The extraction of a gold–ethyl xanthate complex has not been described previously, but the formation of a solid gold(I) complex has been reported.[11] In tests with gold(III), the extraction of the yellow complex appeared complete, and the dark yellow extract faded rapidly on standing, which suggests decomposition of the complex. It is considered that the reaction of gold(III) with ethyl xanthate is analogous to that of copper(II), *i.e.*, that gold reacts to form a gold(III) complex which rapidly decomposes to an insoluble gold(I) complex. A similar reaction has been observed for the gold(III) diethyldithiocarbamate complex.[11]

The extraction of platinum as a yellow ethyl xanthate complex has not been described previously, but Table 2 shows that it is partially extracted over the whole range of acid concentration investigated. A solid yellow compound with the formula $Pt(EX)_2$ has been reported,[15, 16] which indicates that xanthate reduces platinum(IV) to platinum(II) and that the latter reacts during complex formation.

Palladium(II) is completely extracted from 0.1–10M hydrochloric acid.

Vanadium and uranium

The extraction of both vanadium and uranium is consistent with reported data.[1] The orange–red uranium(VI) complex has been reported to be insoluble in chloroform and other non-polar solvents.[17] Presumably vanadium is reduced to vanadium(IV) by xanthate and reacts in the form of the VO^{2+} ion.[11]

Arsenic and antimony

Previous investigators[6] found that the optimum hydrochloric acid concentration for the quantitative extraction of arsenic(III) as the ethyl xanthate complex into carbon tetrachloride is 0.1–0.2M. Although Fig. 1 shows that it can be completely extracted into chloroform from 0.1–10M hydrochloric acid, tests showed that it is probably the chloro-complex that is extracted at high hydrochloric acid concentrations. In tests with arsenic(V), the increase in extraction from ~5–10M acid media is considered to be due to reduction of arsenic(V) by chloride[18] and subsequent extraction as either the arsenic(III) xanthate or chloro-complex. Arsenic(V) is not extracted as the chloro-complex from concentrated hydrochloric acid.[19] The degree of extraction from 0.1–4M acid media could be due to incomplete oxidation of arsenic (III) with potassium permanganate or partial reduction of arsenic(V) by xanthate before the extraction step.

The optimum hydrochloric acid concentration required for the quantitative extraction of antimony(III) as the ethyl xanthate complex into carbon tetrachloride has been reported as 1.8–2.5M.[6] Figure 1 shows that it can be completely extracted into chloroform from 0.1–5M hydrochloric acid. It is considered that antimony(V) probably extracts as the chloro-complex.[20]

Lead and bismuth

Previous investigators[6] found that the extraction of bismuth ethyl xanthate into carbon tetrachloride starts at pH 0.16 and becomes quantitative at pH 1–4. Figure 2 shows that bismuth is completely extracted into chloroform from 0.1–3M hydrochloric acid. The extraction of lead, also shown in Fig. 2, agrees reasonably well with earlier work.[1]

Molybdenum and rhenium

The acid conditions required for the extraction of molybdenum are shown in Fig. 3. Molybdenum(VI) is reduced by xanthate to molybdenum(V) and it is the latter that subsequently forms the xanthate complex.[21]

Although Fig. 3 shows that rhenium is partially extracted into chloroform from 4–10*M* hydrochloric acid, no references were found pertaining to the formation or extraction of a rhenium xanthate complex. Tests showed that rhenium, initially present in oxidation state (VII), is not extracted as a chloro-complex. It is known that rhenium(III) forms extractable complexes, with the general formula $ReCl_2(NR_2 \cdot CS_2)$, with dialkyldithiocarbamates,[22] which are analogous compounds to xanthates. Consequently, it may be possible that rhenium(VII) is reduced to rhenium(III) by xanthate and/or chloride ions in relatively concentrated hydrochloric acid media and that rhenium(III) subsequently reacts to form an analogous type of ethyl xanthate compound.

Selenium and tellurium

No previous study had been made of the conditions required for the extraction of selenium and tellurium as ethyl xanthate complexes, although it has been reported that these elements form extractable complexes in dilute acid media.[7,23,24] Figure 4 shows that selenium(IV) can be completely extracted into chloroform from 0.1–10*M* hydrochloric acid. It also shows that tellurium(IV) is completely, or almost completely, extracted (97–100%) under the same conditions. Tests showed that neither selenium(VI) nor tellurium(VI) is extracted as the chloro-complex into chloroform from concentrated hydrochloric acid media. It is considered that the extraction of these ions as xanthate complexes at high hydrochloric acid concentrations is due to their reduction by chloride ions,[25] xanthate ions, or both. Solid selenium and tellurium ethyl xanthate complexes, $Se(EX)_2$ and $Te(EX)_2$, in which the elements are present in the bivalent state, have been reported.[11] This indicates that selenium(IV) and tellurium(IV) are reduced by xanthate during complex formation.

ANALYTICAL APPLICATIONS

The results of the present work indicate that it is possible to separate arsenic, selenium, tellurium, palladium and possibly gold from all of the other elements investigated, except germanium, rhenium, platinum and copper, by chloroform extraction of their ethyl xanthate complexes from 10*M* or possibly concentrated hydrochloric acid. The group separation of arsenic, antimony, bismuth, selenium and tellurium from zinc, manganese, iron, copper and probably nickel and lead matrices should be possible by extracting from ~3*M* hydrochloric acid. Co-extraction of iron(III) can be avoided by reducing it to the bivalent state with ascorbic acid before extraction. Co-extraction of copper(II) can be eliminated by complexing it with thiourea. Complexation of other elements with tartrate and fluoride ions (*e.g.*, tungsten, titanium, niobium, tantalum and tin) is also possible.

Xanthate–chloroform extraction from acid media has been employed for the separation of molybdenum from rhenium[1] and of bismuth from lead.[8] Separation of rhenium from molybdenum may also be possible by extracting it from a concentrated hydrochloric acid medium. Separation of arsenic from antimony is possible by extracting it from 10*M* or concentrated hydrochloric acid. Depending on the hydrochloric acid concentration of the aqueous phase during extraction, group separations of numerous elements from elements such as aluminium, beryllium, manganese, zinc, chromium, calcium, magnesium, strontium, barium, rhenium and germanium can be accomplished by employing potassium ethyl xanthate in conjunction with cupferron[26] and/or ammonium pyrrolidinedithiocarbamate[27] as mixed chelating agents.

Care must be taken in applying the results shown in this paper to specific analytical problems because the extraction profiles of the elements, shown in Figs. 1–4 and Table 2, may change somewhat with factors such as the amount of the species to be extracted, the amount of matrix elements present, the presence of complexing agents (*e.g.*, tartrate or fluoride), and the amount of potassium ethyl xanthate and the volume of chloroform used for extraction.

SOLVENT EXTRACTION OF METAL XANTHATES

ELSIE M. DONALDSON
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology,
Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 14 *October* 1975. *Accepted* 1 *November* 1975)

Summary—The solvent extraction of metal xanthates is reviewed with emphasis on the characteristics and analytical uses of ethyl xanthate complexes. Elements reviewed include As, Sb, Bi, Cd, Co, Cu, Cr, Ga, Au, In, Fe, Pb, Mn, Hg, Mo, Ni, Pd, Pt, Re, Ag, Se, Te, Tc, Tl, Sn, U, V and Zn.

Although it has been known for a long time that alkyl xanthates react with metal ions to form extractable chelates of the type, $M(RCOS_2)_n$, few reviews have been published in English dealing with the analytical applications of xanthates and/or the solvent extraction of their metal complexes. Reviews on analytical reagents containing thiol and thione groups, including xanthates,[1] the analytical uses of metal xanthates,[2] and methods for the determination of xanthate by means of reactions with metal ions[3] have appeared in obscure Soviet and other journals, but unfortunately they are not available as English translations. Some relatively recent reviews[4–7] have appeared in English but the emphasis in these is on co-ordination chemistry rather than on analytical applications or solvent extraction.

Within the last 18 years, some information on the solvent extraction of metal xanthates has appeared in several books[8–10] dealing with the extraction of metal chelates; also a short review has been published in English.[11] However, in these sources combined, the extraction behaviour of only 16 elements was reviewed briefly, and the literature pertaining to other elements previously known to be extractable was not reviewed. Because of the increasing analytical use and potential importance of the solvent extraction of metal xanthates, and because recent work by the author[12] has shown that many more metal ions (*e.g.*, gallium, indium, gold, platinum and rhenium) can be extracted as xanthates than has been hitherto reported, it was considered that a comprehensive "up-to-date" review of the extraction and characteristics of metal xanthate complexes would be of interest to analytical chemists.

This review is concerned mainly with ethyl xanthate complexes because this reagent has been most widely used in analytical work. In cases where the original papers or English translations were not readily available, references have been made both to the papers and abstracts. The solvent extraction of 28 elements, arranged in roughly alphabetical order, is reviewed up to approximately mid-1975.

EXTRACTION AND CHARACTERISTICS OF METAL XANTHATES

Arsenic

Chakrabarty and De[13] studied the extraction of arsenic(III) ethyl xanthate into carbon tetrachloride from acid media and found that extraction occurs from hydrochloric acid that is $>0.01M$ and is quantitative from the $0.1M$ acid if a double extraction is used. The optimum acidity is 0.1–$0.2M$ hydrochloric acid. From $0.05M$ sulphuric acid a double extraction is also quantitative. After removal of the solvent by evaporation, arsenic is determined by a conventional iodometric method. Moderate amounts (up to ~ 80 mg) of fluoride, citrate, tartrate and EDTA do not interfere in the extraction. Lead, copper(II), cobalt(II), iron(III), antimony(III), bismuth, tin(IV) and vanadium(V) interfere.

Arsenic has been determined in foods by the molybdenum blue method, after its reduction to the tervalent state with potassium iodide, removal of liberated iodine with sodium thiosulphate, and isolation by xanthate–carbon tetrachloride extraction from a sulphuric acid medium.[14] Interference from antimony and tin is eliminated by washing the extract with concentrated hydrochloric acid containing stannous chloride. The solvent is removed by evaporation and arsenic(III) is oxidized with bromine before the spectrophotometric determination. Similar methods have been used for the isolation and subsequent determination of arsenic in zinc- and lead-base materials[15] and pyrite and pyrite ashes[16] after xanthate–carbon tetrachloride extraction from dilute and $\sim 2M$ sulphuric acid, respectively, followed by back-extraction (and oxidation) of the arsenic with bromine water. Antimony interferes in both methods.

Xanthate–carbon tetrachloride extraction of arsenic(III) has also been used for its isolation and subsequent determination in natural water, silicates and biological materials after its separation by co-precipitation with hydrous ferric oxide.[17] The colourless complex is partly extracted into carbon tetrachloride and other solvents (chloroform, dichloroethane, benzene and gasoline) at ~pH 4.[18]

Recent studies by the author have shown that arsenic(III) can be quantitatively extracted into chloroform from 0.1–10*M* hydrochloric acid.[12] Thermal studies have shown that it forms a 1:3 ethyl xanthate complex[19] with the formula $As(EX)_3$,[6] where EX is the ethyl xanthate ion ($C_2H_5OCS_2$).

Antimony

Chakrabarty and De[13] found that the colourless antimony(III) complex is extracted into carbon tetrachloride from >0.1*M* hydrochloric acid, a double extraction from the 1.8M acid being quantitative. The optimum acidity is 1.8–2.5*M*. From sulphuric acid media, the extraction starts at a concentration of 0.25*M* and is quantitative from the 0.75*M* acid (double extraction). After removal of the solvent by evaporation, antimony is determined by iodometric titration. Moderate amounts (up to ~25 mg) of lead, cobalt(II), iron(III), bismuth, tin(IV), fluoride, citrate, tartrate and EDTA do not interfere, but copper(II), arsenic(III) and vanadium(V) interfere seriously. In most of the above-mentioned methods for arsenic, antimony is co-extracted and interferes. Similarly to that of arsenic(III), the complex is partly extracted into carbon tetrachloride and other non-polar solvents at ~pH 4.[18]

Recent studies have shown that antimony(III) can be quantitatively extracted from 0.1–5*M* hydrochloric acid.[12] Thermal studies have shown that it forms a 1:3 complex[19] with the formula $Sb(EX)_3$.[6]

Bismuth

Chakrabarty and De[13] found that bismuth(III) ethyl xanthate is extracted into carbon tetrachloride at pH > 0.16, quantitatively at pH 1–4. The yellow extract can be employed for the spectrophotometric determination of mg-amounts of bismuth. Beer's law is obeyed, at 400 nm, over the concentration range 5–50 μg/ml. The complex is stable for 48 hr and its molar absorptivity is $287\,l \cdot mole^{-1} \cdot mm^{-1}$ at 400 nm. At pH 1.24, moderate amounts (up to ~25 mg) of cadmium, chromium(III), aluminium, fluoride, sulphate and EDTA do not interfere. Lead, copper(II), mercury(II), iron(III), arsenic(III), antimony(III), vanadium(V), citrate, phosphate and tartrate interfere seriously. These investigators claim that bismuth can be separated from arsenic by selective extraction at pH 4.5; arsenic(III) can subsequently be extracted from the residual aqueous phase at pH 1.0. Bismuth can also be extracted, at ~pH 4, into chloroform, dichloroethane, benzene and gasoline.[18]

The complex has been extracted into a 1:4 mixture of pyridine and ethyl acetate from a sodium formate medium.[20] The extract can be used for the spectrophotometric determination of bismuth. Beer's law is followed, at 420 nm, over the concentration range 0.06–0.14 mg/ml. In the presence of 0.1% sodium cyanide and 0.1% EDTA, the method is reported to be selective for bismuth in the presence of copper, cobalt, nickel and various other ions, but thallium, high concentrations of ammonia, and citrate interfere. Extraction from the stated medium into pyridine–ethyl acetate has also been used for the column chromatographic separation of bismuth ethyl xanthate and mixtures of other metal xanthates (cobalt, nickel, copper, iron, cadmium and mercury).[21]

Xanthate–chloroform extraction has been employed by the author, in the determination of lead in ores by EDTA titration, for the separation of bismuth from lead in a 2*M* hydrochloric acid–tartaric acid medium.[22] Recently, the author has also shown that bismuth can be quantitatively extracted from 0.1–3*M* hydrochloric acid.[12] Analysis of the bismuth ethyl xanthate precipitate[13] and thermal studies[19] have shown that it is a 1:3 complex with the formula $Bi(EX)_3$.[6]

Cadmium

According to Pilipenko and Ulko,[18] cadmium forms a white ethyl xanthate complex, at ~pH 4–9, that is not extracted into carbon tetrachloride, chloroform or other non-polar solvents. However, recent studies on the extraction of metal ethyl xanthates into chloroform from hydrochloric acid media have shown that cadmium is appreciably extracted (~85% in a triple extraction) from 0.1*M* hydrochloric acid initially containing 500 μg.[12] Probably complete extraction into chloroform can be obtained at pH > 1.

Sheyanova *et al.*[23] found that the cadmium benzyl xanthate complex can be completely extracted into chloroform in the pH range 1.9–5.2 with a 3:1 volume ratio of aqueous to organic phase and a 100–500-fold excess of reagent. They found that cadmium can be separated from large amounts of zinc at pH > 10.

The ethyl xanthate complex can also be extracted into a 1:4 mixture of pyridine and ethyl acetate from a sodium formate medium.[21] Solubility studies have shown that cadmium forms a 1:2 complex[24] while spectrophotometric and kinetic studies by the same investigators[25,26] indicate a 1:1 complex. The formation of a 1:2 complex is more probable and is supported by the fact that a solid complex with the formula $Cd(EX)_2$ has been reported.[27]

Cobalt

Pilipenko and Ulko[18] found that the green cobalt complex can be extracted into carbon tetrachloride and other non-polar solvents from weakly acid media or at pH up to ~9. They state that only cobalt ethyl xanthate can be extracted from an alkaline medium (*cf.* cadmium, manganese and copper). They developed a spectrophotometric procedure for the determination of cobalt in nickel salts, nickel metal, iron–nickel ores and steels, based on extraction of the complex into carbon tetrachloride from dilute hydrochloric or sulphuric acid media. The absorbance of the extract is measured at 465 nm. Interference from co-extracted nickel alone is eliminated by shaking the extract with

50% v/v ammonia solution; that from iron(III) (and nickel) by shaking it with ammoniacal ammonium tartrate solution. The solution of cobalt ethyl xanthate in the organic solvent was found to be stable for 3 days if kept under water. Spectrophotometric studies showed that cobalt and ethyl xanthate react in 1:2 ratio. Beer's law is obeyed over the concentration range of ~5–50 μg/ml. Large amounts of copper, mercury and silver interfere. This procedure was later adapted to the determination of cobalt in manganese ores and manganese-containing slags.[28]

Extraction of cobalt ethyl xanthate into amyl acetate (or methyl isobutyl ketone) has been employed for the separation of cobalt from zinc solutions containing nickel.[29] After adjustment of the pH to 5.8, sufficient potassium ethyl xanthate is added to precipitate nickel (molar ratio xanthate:nickel = 6:1). After extraction of the nickel, fresh xanthate solution is added to precipitate the cobalt, then the solution is oxidized by air before the extraction and subsequent spectrophotometric determination of cobalt. Air-oxidation of cobalt is recommended because it was observed that cobalt(II) reacts considerably more slowly with xanthate ions than does cobalt(III). The complex formed under these conditions was found to be a 1:3 complex.

Hayashi *et al.*[30] studied the effects of pH, ionic strength and ethyl xanthate concentration on the extraction of cobalt(II) into carbon tetrachloride. They found that the optimum pH range for practically quantitative extraction is 6.5–9. Beer's law is obeyed, the complex formed is a 1:2 complex, and the molar absorptivity is 1.34×10^3 l·mole^{-1}·mm^{-1} at 356 nm, the wavelength of maximum absorption. No evidence was found for a complex containing cobalt and xanthate in a higher combining ratio.

Xanthate–ethyl acetate extraction has been used for the spectrophotometric determination of cobalt in ores and alloys.[31] Cobalt is extracted (almost completely), in two extractions, at pH 5–9 in the presence of potassium chloride or sodium formate as salting-out agents, followed by direct measurement of the absorbance of the extract at 420 nm. Interference from co-extracted nickel is eliminated by shaking the extract with 1 or 2 drops of concentrated perchloric acid. Beer's law is obeyed over the concentration range 12–40 μg/ml. Copper is also extracted but can be masked with thiourea. The same investigators used a mixture of pyridine and ethyl acetate (1:4) for the extraction and subsequent determination of cobalt under approximately the same conditions.[20] They found that the solution of the xanthate–pyridine adduct obeys Beer's law, at 420 nm, over the concentration range 10–55 μg/ml. Moderate amounts of nickel (up to 0.1 mg in 0.2 mg of cobalt) do not interfere, but thallium, high concentrations of ammonia, and citrate do interfere. The modified extraction procedure was also applied to the separation of cobalt ethyl xanthate and mixtures of other xanthates (see bismuth) by column chromatography.[21]

Cobalt benzyl xanthate can be completely extracted into chloroform, at pH 0.9–5.2, with a 3:1 volume ratio of aqueous to organic phase and a 100–500-fold excess of reagent.[23] Recent studies have shown that the ethyl xanthate complex can be almost completely extracted into chloroform from 0.1*M* hydrochloric acid.[12] It can also be extracted from ammoniacal media with ethers[32] and chlorinated and aromatic solvents, particularly dichloromethane and cyclohexanone.[33]

There are divergent views in the literature about the composition of the cobalt ethyl xanthate complex, *i.e.*, whether the complex contains cobalt in oxidation state (II)[18,34] or (III).[32,35] According to Allison,[36] cobalt reacts in alkaline or weakly acidic media (~pH 4–10) to form a 1:3 cobalt(III) complex, while in strong acid media a 1:2 cobalt(II) complex is formed. Similarly, Zagyanskii[37] found that cobalt(III) xanthate is precipitated at high pH values, while in sulphate solutions, at pH 2.5–3.5, cobalt is precipitated mainly in the cobalt(II) state. He explained the formation of cobalt(III) xanthate [$Co(EX)_3$] by the formation of dixanthogen, which facilitates the oxidation of cobalt(II) xanthate [$Co(EX)_2$] to the cobalt(III) compound; apparently dixanthogen cannot be formed at pH values less than ~4–5.

Copper

Pilipenko and Ulko[18] reported that the yellow copper ethyl xanthate complex is insoluble in carbon tetrachloride, chloroform and other non-polar solvents. However, copper has been found to be co-extracted to a certain extent into some of these solvents and to interfere in various methods based on extraction of metal xanthates (*e.g.*, see arsenic, antimony, lead and nickel). Recent studies have shown that it is appreciably extracted into chloroform (~70–80% in three extractions) from 0.1–5*M* hydrochloric acid initially containing 500 μg of the element.[12]

Extraction of the complex into pyridine–ethyl acetate (1:4) from a sodium formate medium has been used for the separation of copper and other metal xanthates by column chromatography.[21] The extract of the copper–pyridine adduct can be employed for the spectrophotometric determination of copper.[20] Beer's law is followed, at 420 nm, for copper up to 40 μg/ml. Interference from cobalt and nickel is avoided by extracting from a 0.1% EDTA medium. Thallium, high concentrations of ammonia, and citrate interfere. Extraction of the complex into diethyl ether from alkaline media (pH 7–8.5) has been used as a fractional flotation test for copper.[8,38]

Pohlandt *et al.*[39] developed a spectrophotometric method for the determination of xanthate, based on extraction of the copper(II) complex into chloroform from an alkaline cyanide medium. The absorbance of the extract is measured at 305 nm. Measurement must be made immediately after extraction because of the instability of the extracted complex. In these studies, and in later solubility[24] and spectrophotometric[40] studies, copper and ethyl xanthate were found to combine in a 1:2 ratio, indicating that it is copper(II) that reacts. In earlier work[41,42] it was assumed that copper(II) and xanthate ions react directly (by a reduction process) to form copper(I) xanthate and dixanthogen. According to Pohlandt *et al.*[39] they react in two stages, *i.e.*, the formation of copper(II) xanthate and the subsequent decomposition of this compound into copper(I) xanthate and dixanthogen. They reported that copper(I) xanthate is insoluble in chloroform in the absence of pyridine.

Chromium

The green chromium(VI) complex is partially extracted into carbon tetrachloride, chloroform and other non-polar solvents from weakly acidic media (pH ~ 4).[18] It is reported that the complex is intensely coloured but that its formation is slow and not quantitative. Xanthate is purported to react not only with chromium(VI) but also with chromium(II) and, on long standing, with chromium(III). The absorption spectra of the reaction products in carbon tetrachloride, in the presence of excess of xanthate, indicated that the end-product is the same in each case. The composition of the extracted compound was not established, but it has been reported subsequently[43] that chromium(III) forms a dark blue compound with the formula $Cr(EX)_3$.

Neither chromium(VI) nor chromium(III) is extracted into chloroform from ~0.1–10*M* hydrochloric acid.[12]

Gallium

References pertaining to the extraction of a gallium(III) ethyl xanthate complex have not been found in the literature, but a white complex with the formula $Ga(EX)_3$ has been reported.[6] Recent studies by the author have shown that a colourless gallium(III) complex is partially extracted into chloroform (~28% in three extractions) from 0.1*M* hydrochloric acid initially containing 500 μg of gallium.[12] Complete extraction can probably be obtained at pH values >1.

Gold

Although the extraction of gold as an ethyl xanthate complex has not been reported previously, the formation and stability of a gold(I) complex has been studied.[44,45] Recently, it was shown that a yellow complex is appreciably extracted into chloroform (~80–90% in three extractions) from 0.1–10*M* hydrochloric acid initially containing 500 μg of gold(III).[12] The dark yellow extract faded rapidly on standing, indicating the formation and extraction of an unstable complex. It is considered that gold reacts initially to form a gold(III) complex that rapidly decomposes to yield a gold(I) complex.

Indium

The extraction of indium has not been reported previously, but recent studies have shown that a colourless indium(III) ethyl xanthate complex can be quantitatively extracted into chloroform from 0.1*M* hydrochloric acid.[12] The formula of the complex is reported to be $In(EX)_3$.[6]

Iron

The extraction of a brown iron(III) complex into carbon tetrachloride, chloroform and other non-polar solvents from media of pH ~ 4–7 has been reported.[18] Iron(III) has also been extracted from a sodium formate medium into ethyl acetate or a mixture (4:1) of ethyl acetate and pyridine.[21] It is co-extracted and interferes in many methods based on extraction of metal xanthates from weakly acidic and alkaline media (*e.g.*, see arsenic, bismuth, molybdenum, lead, cobalt and nickel). It is partly extracted into chloroform from 0.1–5*M* hydrochloric acid.[12]

According to Pilipenko and Ulko,[18] iron(III) is partially reduced by xanthates to iron(II) (presumably in dilute acid media), which is reported not to react with xanthate.[40] However, Allison[36] found that a blood-red precipitate, presumed to be iron(II) ethyl xanthate, is formed in oxygen-free solutions. Studies of the iron(III) system have shown that a very stable 1:3 complex is formed in the pH range ~3.5–11 (optimum pH = 10).[11,46] Studies by Allison[36] of the decomposition of solutions of xanthates in the presence of iron(III) have confirmed this combining ratio. The formula of the complex is reported to be $Fe(EX)_3$.[6]

Lead

The partial extraction of a colourless or pale yellow lead(II) complex into carbon tetrachloride, chloroform and other non-polar solvents at pH ~ 4 has been reported.[18] Recently, xanthate–carbon tetrachloride extraction of the complex from media ranging from neutral to ~0.005*M* nitric or hydrochloric acid has been suggested for the separation of lead before its titrimetric determination with EDTA.[47] Copper(II), cobalt(II), iron(III), mercury(II), zinc, cadmium, vanadium(V), fluoride, sulphate and EDTA interfere with the extraction. Interference from arsenic (III) can be eliminated by preferential extraction of lead at pH 6; that from antimony(III) by its preferential extraction from a 2*M* acid medium. Xanthate–carbon tetrachloride extraction has also been used for the separation of lead from silver at pH ~ 5, before its subsequent titration with EDTA.[48] It is claimed that complete extraction of up to 6 mg of lead can be obtained, at pH 3.5–6.5, in a single extraction, in the presence of 20 mg of xanthate and at least 15 ml of carbon tetrachloride; above pH 7 the rate of extraction becomes slow and the separation of silver is difficult. Silver is completely retained as a precipitate in the aqueous phase in the pH range 2.0–6.5.

Micro-amounts of lead in human tissue have been determined by atomic-absorption spectrophotometry on the solvent phase after extraction of the ethyl xanthate complex into methyl isobutyl ketone at pH

3·5–9·5.[49] Copper(II) and phosphate interfere with the extraction, but copper can be masked with thiourea. It has been shown that lead is appreciably extracted into chloroform (~90–95% in three extractions) from ~0.1–1M hydrochloric acid initially containing 500 μg of lead.[12] Solubility[24] and spectrophotometric studies,[40] as well as studies of the decomposition of solutions of xanthates in the presence of lead,[36] show that lead and ethyl xanthate form a 1:2 complex with the formula $Pb(EX)_2$.[6]

Manganese

It has been reported that manganese does not react with xanthate.[18] However, a recent method for the determination of manganese in human tissue[50] is based on the extraction of manganese(II) ethyl xanthate into methyl isobutyl ketone, at pH 6.5–9.0, from a 10% ammonium acetate medium containing a large excess of xanthate (11%). Manganese is subsequently determined in the solvent phase by atomic-absorption spectrophotometry. Interference from nickel, copper(II), silver, cadmium, aluminium and zinc is eliminated by their preliminary extraction with 1% potassium ethyl xanthate solution and methyl isobutyl ketone. Manganese(II) is not extracted into chloroform in the presence of potassium ethyl xanthate from 0.1–10M hydrochloric acid.[12]

Mercury

A colourless or light yellow mercury(II) complex is reported to be partially extracted into carbon tetrachloride at ~pH 4.[18] Extraction of the complex into ethyl acetate or a mixture (4:1) of ethyl acetate and pyridine has been used for the separation of mercury xanthate from mixtures of other metal xanthates by column chromatography.[21] Studies of the decomposition of xanthate solutions in the presence of mercury show that the complex formed is a 1:2 complex.[36]

Molybdenum

Extraction of the red-violet molybdenum complex into a mixture (1:2) of petroleum ether and diethyl ether from a sulphuric acid medium, followed by spectrophotometric measurement of the absorbance of the extract, has been used for the determination of molybdenum in steel, iron,[51] tungstic acid and rhenium.[52] Extraction into chloroform from a 4% (or ~0.5M) hydrochloric acid medium has been used for the separation of molybdenum from rhenium in technical products before the spectrophotometric determination of rhenium.[53] Rhenium has also been determined spectrophotometrically in ores, minerals and industrial concentrates after separation of molybdenum by xanthate–chloroform extraction,[54] and in minerals (*e.g.*, molybdenite) after separation of molybdenum from a hydrochloric acid medium by successive extraction into a 1:1 mixture of carbon tetrachloride and benzene.[55]

Xanthate–chloroform extraction of the complex from a dilute sulphuric acid medium has been employed for the separation and gravimetric determination of molybdenum in tungsten.[56] Iron, nickel and vanadium are co-extracted and interfere in this method. Tungsten has been determined spectrophotometrically in steel by a thiocyanate method based on extraction of the tungsten thiocyanate complex into a mixture of isoamyl alcohol and chloroform.[57] The tungsten and co-extracted molybdenum thiocyanate complex are stripped from the extract with ammonia solution, followed by separation of the molybdenum by successive chloroform extraction of its xanthate complex from a weakly acidic medium. Recently, xanthate–chloroform extraction of molybdenum, from ~1.5M hydrochloric acid containing tartaric acid, has been employed for its separation from tungsten before the spectrophotometric determination of tungsten by chloroform extraction of its thiocyanate–diantipyrylmethane ion-association complex.[58] More recent work by the same author has shown that molybdenum can be completely extracted into chloroform, in three successive extractions, from 0.1–1.5M hydrochloric acid.[12]

Extraction of the molybdenum complex at pH 1.8–1.9 into chloroform, followed by spectrophotometric measurement of the absorbance of the extract, has been advocated for the microchemical determination of molybdenum (*i.e.*, 10 μg or less).[59] It is claimed that the chloroform solution of the complex is stable for a long time. Extraction into toluene at pH 1.11–1.56 (or from 0.02–0.08M acid) has also been advocated.[60] The stability of the complex after extraction into organic solvents is said to be highest in petroleum ether and toluene (3 days). It is stable for ~14, 10 and 6 min, respectively, in benzene, chloroform (*cf.* above) and carbon tetrachloride. It is unstable in diethyl ether, isoamyl alcohol, amyl acetate and methyl isobutyl ketone and the colour fades immediately. Chloroform extraction of the complex and direct spectrophotometric measurement of the extract, at 510 nm, has been used for the determination of molybdenum in steel after the removal of interfering elements (*e.g.*, iron and nickel) by electrolysis with a mercury cathode.[61]

Recently,[62] a method based on the separation of molybdenum by chloroform extraction of its ethyl xanthate complex from 1M hydrochloric acid, after reduction of molybdenum(VI) in 2M hydrochloric acid with hydrazine sulphate, has been proposed for the determination of molybdenum in ferromolybdenum and other complex materials. After decomposition of the complex with liquid bromine, molybdenum is stripped from the extract with a dilute alkaline hydrogen peroxide solution and subsequently determined by standard gravimetric, volumetric or spectrophotometric methods. Complete extraction of molybdenum is obtained from 0.2–1.5M hydrochloric acid. Tungsten(VI), iron(III), copper(II) and vanadium(V) are masked with tartaric acid, ascorbic acid, thiourea and potassium hydrogen fluoride, respectively, before extraction. Large amounts of copper, iron and vanadium then do not interfere. Antimony(III), bismuth (III), palladium(II) and tin(II) are completely, or almost completely, extracted under the proposed conditions. Nickel(II), lead(II) and cobalt(II) are partially extracted. Large amounts of EDTA, tartrate, oxalate, citrate, phosphate and fluoride suppress the extractions of molybdenum. More than 100 mg of molybdenum can be separated by extraction, depending on the concentration of xanthate and the volume of chloroform used. Chloroform, benzene, carbon tetrachloride and diethyl ether were found to be the best extractants.

A method based on extraction of a mixed molybdenum–ethyl xanthate–thiocyanate complex into acetophenone from 4–7*M* hydrochloric acid, followed by spectrophotometric measurement of the extract, at 380 or 470 nm, has been applied recently to the determination of molybdenum in steel.[63] The extract is stable for 48 hr. Iron is complexed with ascorbic acid, and chromium(VI) and vanadium(V) are reduced with ferrous ammonium sulphate before extraction. Beer's law is obeyed over the concentration range 1.2–13.8 ppm of molybdenum(VI). Tin(II), lead, arsenic(III), antimony(III), iron(II), oxalate, citrate, fluoride and phosphate, in 1000-fold amounts, and copper(II), cobalt(II) and nickel, in 15-fold amounts, do not interfere. Interference from rhenium is eliminated by prior separation of molybdenum by xanthate–acetophenone extraction from a hydrochloric acid medium.

Chloroform or carbon tetrachloride extraction of molybdenum isopropyl xanthate at pH ~ 5 has been employed recently for the direct spectrophotometric determination of molybdenum at 520 nm.[64]

Early investigators suggested various formulae, *i.e.*, $MoO_2(EX)_2$,[65] $Mo(EX)_2$[66] and $MoO(OH)_2(EX)_2$[59] for the molybdenum ethyl xanthate complex, in which molybdenum is presumed to be present as molybdenum(VI). Montequi and Gallego[67] first formulated these compounds as a binuclear 2:4 compound, $Mo_2O_3(EX)_4$, and established, by chemical means, that molybdenum is present in oxidation state(V). Later Malatesta[68] also established this stoichiometry but suggested that molybdenum is present in both oxidation states. According to spectrophotometric experiments by Pilipenko and Gridchina,[69] in which the complex was extracted into dichloroethane from a dilute acid medium, only molybdenum(V) takes part in the formation of the coloured complex because molybdenum(VI) is reduced to molybdenum(V) by the xanthate. The following equation illustrates this reaction:

$$2\,MoO_4^{2-} + 6\,C_2H_5OCS_2^- + 10H^+ \rightarrow [Mo_2O_3(C_2H_5OCS_2)_4] + (C_2H_5OCS_2)_2 + 5\,H_2O$$

Identical absorption spectra were obtained in tests with both molybdenum(V) and (VI). Molybdenum(III) and (IV) do not react with xanthate. The minimum acid concentration required for the reaction was found to be 0.03*M* and the complex remains stable at acid concentrations up to 4.8*M*. Further confirmation of the reducing character of xanthate ions during complex formation is evident from the fact that solid molybdenum(VI) xanthate complexes cannot be prepared.[70]

Nickel

The yellowish-brown nickel(II) ethyl xanthate complex can be extracted into carbon tetrachloride, chloroform and other non-polar solvents at ~ pH 4–7.[18] Nickel has been recovered from zinc solutions by extraction of the complex into amyl acetate or methyl isobutyl ketone at pH 5.8.[29] It has been determined in manganese ores and manganese-containing slags after xanthate–chloroform extraction of heavy metals, including nickel, from a hydrochloric acid medium.[28] Nickel as the ammine (and iron as the tartrate) is stripped from the extract with an ammoniacal tartrate solution and subsequently determined in the aqueous layer. Chloroform extraction of the xanthate complex has also been used for the determination of xanthate.[71] The xanthate in the extract is titrated with mercury(II) acetate solution in the presence of diphenylcarbazone as indicator.

Rao and Singh[72] found that nickel is almost completely extracted into ethyl acetate at pH 5–9 in the presence of potassium chloride or sodium formate as salting-out agents. The extract can be used for the spectrophotometric determination of 0.05–5 mg of nickel at 435–480 nm. Manganese, aluminium, zinc, cadmium, chromate, molybdate and tungstate do not interfere. Copper(II) can be masked with thiourea before extraction. Later Rao and Singh[31] used this procedure for the simultaneous extraction and spectrophotometric determination of nickel and cobalt in ores and alloys. A similar procedure[20] involving extraction of the nickel xanthate–pyridine adduct into a 4:1 mixture of ethyl acetate and pyridine was found to be less sensitive. This procedure was applied to the separation of nickel and mixtures of other xanthates by column chromatography.[21]

It has been shown that nickel ethyl xanthate is almost completely extracted into chloroform, in three extractions, from 0.1*M* hydrochloric acid initially containing 500 μg of nickel.[12] The complex is partially extracted from 0.5–6*M* hydrochloric acid. Solubility studies[24] and studies of the decomposition of xanthate solutions in the presence of nickel[36] show that it combines with ethyl xanthate in a 1:2 ratio. The formula of the complex is $Ni(EX)_2$.[6]

Palladium

Recently, a method for the extraction and spectrophotometric determination of mg-amounts of palladium with potassium benzyl xanthate has been reported.[73] The yellow palladium(II) complex is completely extracted into chloroform (in a single extraction) at pH 2, followed by spectrophotometric measurement of the absorbance of the extract at 460 nm. Extraction is complete in the pH range 1–7 and Beer's law is obeyed over the palladium(II) concentration range 0.95–4.73 mg/25 ml of chloroform. The chloroform solution of the complex is stable for several days. Interference from iron(III) and lead(II) can be eliminated by complexation with ammonium hydrogen fluoride and sodium acetate, respectively. Nickel, cobalt(II) and cerium(III) can be masked with EDTA. Mercury(II) and cadmium, in 25-fold amounts, interfere by forming insoluble white complexes which remain in the chloroform layer. Bismuth and copper(II) are co-extracted and interfere because of the yellow colour of their complexes. Rhodium(III), ruthenium(III) and platinum(IV), in 2-fold amounts, do not interfere. Interference from osmium(VIII) can be eliminated by its preliminary extraction into chloroform in the presence of hexamethylenetetramine and EDTA. Citrate, tartrate, fluoride, oxalate and EDTA, in 50-fold amounts, do not interfere. Vanadate and molybdate interfere by preventing formation of the palladium complex.

The same investigators also studied the chloroform extraction of palladium with potassium butyl xanthate.[74] Beer's law is obeyed, at 460 nm, over the palladium concentration range 8–50 mg/100 ml of chloroform. Extraction is quantitative over the same pH range but the optimum pH for rapid extraction is 2. All the interfering ions mentioned above also interfere in this method. Interference from iron(III), lead, cobalt(II), nickel, cerium(III) and osmium(VIII) can also be eliminated as described above.

In a recent method for molybdenum in ferromolybdenum and other complex materials,[62] based on its separation by xanthate–chloroform extraction, it was reported that palladium(II) is completely extracted as the ethyl xanthate complex under the conditions (1*M* hydrochloric acid) used for the extraction of molybdenum. More recent studies have shown that the yellow complex can be completely extracted into chloroform, in three extractions, from 0.1–10*M* hydrochloric acid.[12] The formula of the complex is reported to be $Pd(EX)_2$.[6]

Platinum

The extraction of platinum ethyl xanthate has not been reported previously. However, studies of the reaction of platinum with xanthate have shown that it forms a yellow compound with the formula $Pt(EX)_2$, in which platinum is present in the bivalent state.[75,76]

Recent studies by the author have shown that a yellow complex is partially extracted into chloroform from 0.1–10*M* hydrochloric acid containing 500 μg of platinum(IV).[12] The degree of extraction decreases with increasing acid concentration. Presumably platinum(IV) is reduced by xanthate and reacts in the bivalent state. The probability of platinum(IV) co-ordinating with four ethyl xanthate ions is remote.

Rhenium

References pertaining to the formation or extraction of a rhenium xanthate complex have not been found in the literature. Although solvent extraction of molybdenum xanthate from acid media has been employed for its separation from rhenium before the determination of either rhenium or molybdenum (see molybdenum), recent studies by the author have shown that rhenium is slightly extracted (5% in three extractions), presumably as a colourless ethyl xanthate complex, into chloroform from ~4*M* hydrochloric acid, and appreciably extracted (80%) from the 10*M* acid initially containing 500 μg of rhenium (VII).[12] Possibly complete extraction and separation from molybdenum can be obtained from concentrated hydrochloric acid. The oxidation state of rhenium in the complex is not known.

Selenium

The extraction of selenium has not been reported in earlier reviews of the solvent extraction of metal xanthates. However, it has been reported that selenium is co-extracted during the separation of molybdenum from rhenium by extraction of molybdenum ethyl xanthate into a mixture of carbon tetrachloride and benzene from a dilute hydrochloric acid medium.[55] Recent work by the author, involving the separation of molybdenum from tungsten, has also shown that selenium, initially present as selenium(IV), is completely co-extracted into chloroform from ~1.5*M* hydrochloric acid.[58] More recent studies have shown that a colourless complex is completely extracted into chloroform, in three extractions, from 0.1–10*M* hydrochloric acid containing 500 μg of selenium(IV).[12] The formula of the complex is reported to be $Se(EX)_2$, in which selenium is present in the bivalent state.[6] Presumably xanthate reduces selenium(IV) to selenium(II) and it is the latter that reacts during complex formation.

Silver

According to Pilipenko and Ulko[18] the yellow silver(I) ethyl xanthate complex is not extracted into carbon tetrachloride, chloroform or other non-polar solvents at pH ~ 4–9. However, it has been shown recently that silver is appreciably extracted into chloroform (90–92% in three extractions) from 2–3*M* hydrochloric acid initially containing 500 μg of the element.[12] The complex is not extracted at acid concentrations greater than 3*M*. At acid concentrations below 2*M*, the degree of extraction decreases because of the formation of insoluble silver chloride. Probably more complete extraction of the relatively insoluble complex can be obtained from 2–3*M* hydrochloric acid if larger volumes of chloroform are used. Also it would probably be preferable to extract from a sulphuric acid medium.

Tellurium

The extraction of a mahogany-red tellurium ethyl xanthate complex into diethyl ether in the presence of thiourea was reported almost 50 years ago.[77]

Recently, the author found that like selenium, tellurium(IV) is completely extracted into chloroform from ~ 1.5*M* hydrochloric acid.[58] More recent work has shown that it is completely, or almost completely, extracted into chloroform (97–100% in three extractions) from 0.1–10*M* hydrochloric acid containing 500 μg of tellurium(IV).[12] The formula of the complex is reported to be $Te(EX)_2$,[6] which suggests that tellurium(IV) is reduced to tellurium(II) by xanthate during complex formation, similarly to selenium.

Technetium

Jasim *et al.*[78] found that technetium(IV) or (VII) forms a purple-red ethyl xanthate complex that can be extracted into chloroform or carbon tetrachloride from ~ 1*M* hydrochloric or nitric acid. They used this extraction procedure for the separation of technetium from rhenium on the ultramicro scale.[79] Later, Kiba *et al.*[80] investigated the factors affecting the extraction and separation from rhenium more fully and found that, in the presence of an excess of xanthate, technetium(VII) can be completely, or almost completely (99%), extracted into carbon tetrachloride from solutions 0.1–2*M* in sulphuric, hydrochloric, perchloric or nitric acids, and at pH values up to ~ 2. They found that the best solvents are carbon tetrachloride, chloroform, 1,1,1-trichloroethane, xylene and di-isopropyl ether. Tetrachloroethylene, cyclohexane, amyl acetate, n-hexane, methyl isopropyl ketone and dichloromethane do not extract the complex. Vanadium(V), iron(III), cobalt(II), nickel, copper(II), molybdenum(VI) and uranium(VI) are partially co-extracted under the same conditions. Rhenium(VII) (25 mg) does not interfere with the extraction.

Thallium

The extraction of thallium(I) ethyl xanthate into chloroform from weakly acidic media has been investigated and the extracted species was found to be a 1:1 complex.[81] In later work,[82] a number of xanthates and a variety of solvents were examined. Polar solvents were found to be more efficient extractants than non-polar solvents. This was explained by assuming that the thallium(I) ion is co-ordinatively unsaturated, and that co-ordination sites open after chelation are occupied by water molecules. Because the relative ability of the solvent molecules to replace the water molecules will influence the degree of extraction, more polar solvents will co-ordinate more readily with the chelate and thus result in increased extraction.

Recent studies have shown that a colourless thallium(I) and a yellow thallium(III) ethyl xanthate complex can be partially extracted into chloroform (~ 8 and 50%, respectively, in three extractions) from 0.1*M* hydrochloric acid containing 500 μg of thallium(I) or (III).[12] The degree of extraction of thallium(I) decreases with increasing hydrochloric acid concentration, while that of thallium(III) first decreases, then increases, from ~ 4–6*M* hydrochloric acid, probably because of the extraction of its chloro-complex. The thallium(III) complex is more soluble in di-isopropyl ether than chloroform. The formulae of the complexes are reported to be TlEX and $Tl(EX)_3$.[6]

Tin

It has been reported that yellow tin(II) and tin(IV) ethyl xanthate complexes are extracted into carbon tetrachloride, chloroform and other non-polar solvents from a weakly acid medium (pH ~ 4).[18] Work by the author has shown that tin(IV) is partly extracted into chloroform (~ 75% in three extractions) from 0.1*M* hydrochloric acid containing 500 μg of tin, and that the degree of extraction decreases with increasing hydrochloric acid concentration.[12] Probably quantitative extraction can be obtained at pH values > 1.

Studies of the decomposition of ethyl xanthate solutions in the presence of tin have shown that the composition of the complex corresponds to the formula $Sn(EX)_2$,[36] which suggests that tin(IV) is reduced by xanthate during complex formation.

Uranium

In early work it was reported that the orange-red uranyl ethyl xanthate complex is both extractable[56] and non-extractable by chloroform and other non-polar solvents.[18] Zingaro[83] found that the complex formed in neutral or weakly acidic media is completely insoluble in chloroform and benzene but readily soluble in polar solvents such as alcohols, ethers and ketones. Spectrophotometric studies showed that it is a 1:2 complex.

Extraction of the ethyl xanthate complex into methyl isobutyl ketone at pH 3 has been used for the separation of uranium from thorium.[84] Tests with other alkyl xanthates showed that ethyl, isopropyl, n-hexyl and cyclohexyl xanthates give the best separation, and that dibutyl cellosolve and dibutyl carbitol are the best solvents. The complex has also been extracted into cyclohexanone from neutral solutions.[85] Only trace amounts of uranium(VI) are extracted into chloroform from 0.1–10*M* hydrochloric acid.[12]

Vanadium

The yellow vanadium ethyl xanthate complex can be extracted into chloroform,[56] carbon tetrachloride and other non-polar solvents from a weakly acidic medium.[18] Extraction of the complex has been used for the determination of vanadium in steel after the removal of iron and nickel by electrolysis with a mercury cathode.[61] Vanadium and molybdenum are simultaneously extracted into chloroform from a dilute acid medium and vanadium is subsequently determined by spectrophotometric measurement of the absorbance of the extract at 375 nm.

Recently, it has been shown that vanadium is partially extracted into chloroform (~ 64% in three extractions) from 0.1*M* hydrochloric acid containing

500 μg of vanadium(V).[12] The degree of extraction decreases with increasing acid concentration. Vanadium is not extracted from ~5–10*M* hydrochloric acid.

The formula of the ethyl xanthate complex has not been reported but an n-butyl xanthate compound with the formula $VO(nBuX)_2$ has been prepared and studied.[6] This suggests that vanadium(V) is reduced to vanadium(IV) by xanthate during complex formation.

Zinc

Pilipenko and Ulko[18] have reported that the colourless zinc ethyl xanthate complex can be extracted into carbon tetrachloride, chloroform and other nonpolar solvents from a weakly acid medium (pH ~ 4–7). Hayashi *et al.*[86] investigated the effects of pH, ionic strength and xanthate concentration on the extraction and found that, although it is not complete, optimum extraction occurs at pH 4.5–7.5. The complex is stable in chloroform, and the molar absorptivity is $2.03 \times 10^3\, l\cdot mole^{-1}\cdot mm^{-1}$ at 300 nm, the wavelength of maximum absorption. Zinc and ethyl xanthate were found to combine in a 1:2 ratio. The complex is not extracted into chloroform from 0.1–10*M* hydrochloric acid.[12]

Zinc benzyl xanthate can be completely extracted into chloroform, at pH 1.9–5.2, in the presence of a 100–500-fold excess of reagent.[23]

Although it has been claimed that zinc forms a 1:1 ethyl xanthate complex,[25,26,40] it is generally considered that a 1:2 complex with the formula $Zn(EX)_2$ is formed.[6,7]

AQUOMOLYBDENUM(III) CHLORIDE AS A REDUCING TITRANT

A POTENTIOMETRIC STUDY

S. R. SAGI and P. R. MOHAN RAO
Department of Chemistry, Andhra University, Waltair, India

(*Received* 31 *May* 1974. *Revised* 20 *August* 1975. *Accepted* 5 *November* 1975)

Summary—The use of aquomolybdenum(III) chloride as a reducing agent for the direct potentiometric titration of Ce(IV), Cr(VI), Fe(III), V(V), Mo(VI), U(VI) and H_2O_2 is described. The variation of the formal redox potentials of Mo(V)/Mo(IV) and Mo(IV)/Mo(III) in varying concentrations of hydrochloric, phosphoric and acetic acids is investigated. Aquomolybdenum(III) chloride is found to be a better reducing titrant than chloromolybdate(III) and gives better breaks in the titration curves. In the titration of molybdenum(VI) in 3*M* HCl the titration curve shows three jumps, corresponding to the reductions of Mo(VI) to Mo(V), and Mo(V) to Mo(IV) *via* an apparently intermediate oxidation state which presumably corresponds to a dimeric mixed-valence species. The aquomolybdenum(III) complex ion is a better reducing titrant than chloromolybdate(III) and has a wider applicability.

In an earlier communication[1] it was shown that green molybdenum(III) solutions contain cationic species and the orange-red solutions of molybdenum(III) contain anionic species.[2] A photometric study of the oxidation of these two species gave indications that the course of the reaction depends on the starting species of molybdenum(III), the nature of the oxidant, and the nature and concentration of the acid used. Of the two species, the cationic aquomolybdenum(III) chloride (green form) is more susceptible to aerial oxidation and more reactive.[3] Chloromolybdate(III) solution (obtained by reduction of molybdate in aqueous media of high hydrochloric acid concentration) has been reported to be a good reducing agent for titration of the common oxidizing agents.[4,5] The end-points of the titrations were determined potentiometrically. The susceptibility of these chloromolybdate(III) solutions to aerial oxidation varies with the concentration of the acid medium.

Except for a few observations[6] on the formal potentials of the Mo(V)/Mo(III) system a detailed study of the formal potentials of the Mo(IV)/Mo(III) system and Mo(V)/Mo(IV) system does not appear to have been made. The object of the present investigation is to determine the formal redox potentials of these systems and to investigate the utility of aquomolybdenum(III) chloride as a reducing titrant.

EXPERIMENTAL

Reagents

Molybdenum(III) chloride solutions (green form) can be obtained either by electrolytic reduction using platinum electrodes or by reduction with amalgamated zinc or aluminium. The electrolytic method is cumbersome and time-consuming. Moreover the molybdenum(III) chloride solutions obtained by electrolytic reduction are quickly converted into the orange-red form and are less green than the solutions obtained through reduction with amalgamated zinc or aluminium. This may be at least partly due to the slow conversion of the green form into the orange-red form. Also, according to Wardlaw *et al.*[7] both forms are oxidized by water when in contact with platinum. Hence the molybdenum(III) solutions used in this investigation were all prepared by reduction in a Jones reductor and standardized as already described.[1] In 1–2*M* hydrochloric acid the reagent shows no significant change in colour in 24 hr if kept under carbon dioxide, but after that period is transformed into the orange-red form.

Cerium(IV) sulphate solutions were prepared and standardized as described by Kolthoff and Belcher.[8] Uranium(VI) solutions were prepared from uranyl acetate. Vanadium(V) solutions were prepared from ammonium metavanadate after conversion into sodium vanadate in the usual manner. Other reagents were prepared by dissolving the analytical-reagent grade materials in the proper acid media, and standardized.

Molybdenum(IV) and molybdenum(V) solutions were prepared by appropriate oxidation of molybdenum(III) solutions with Ce(IV) sulphate.

Apparatus

The potential measurements were made with a platinum-wire indicating-electrode in the titration solution, a saturated calomel reference electrode and saturated potassium chloride bridge. All titrations were done with the solution under a carbon dioxide atmosphere.

RESULTS AND DISCUSSION

From the curves in Fig. 1, it is clear that (1) the formal potentials of Mo(IV)/Mo(III) and Mo(V)/Mo(IV) are influenced by the acid concentration, the values increasing with increasing acid concentration, (2) aquomolybdenum(III) chloride is a more powerful reducing agent than chloromolybdate(III) when oxidized to molybdenum(IV), (3) the molybdenum(IV) species obtained by the oxidation of chloromolybdate(III) is a more powerful reducing agent than that obtained by the oxidation of aquomolybdenum(III) chloride. We have also observed that in titrations with aquomolybdenum(III) chloride the potentials become stable faster than when chloromolybdate(III) is used, in the acid media studied.

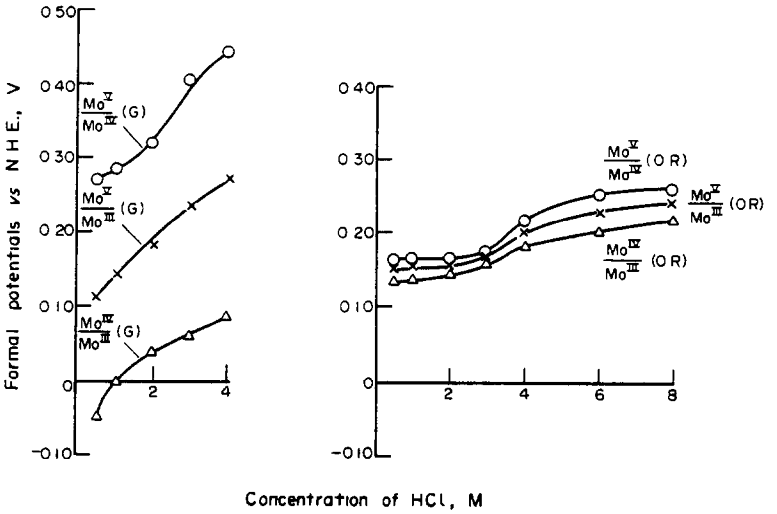

Fig. 1. Formal potentials of Mo(V)/Mo(III), Mo(V)/Mo(IV) and Mo(IV)/Mo(III) in media of varying concentrations of hydrochloric acid, using aquomolybdenum(III) and chloromolybdate(III) solutions as starting materials. A: green aquomolybdenum(III). B: Orange-red chloromolybdate(III).

The complicated nature of these species and their reactivities is also reflected in the results obtained in the photometric study of the oxidation of aquomolybdenum(III) chloride and chloromolybdate(III) by various oxidants.[1] In Fig. 1 the potentials computed[9] for the Mo(V)/Mo(III) system from the potentials of the Mo(IV)/Mo(III) and Mo(V)/Mo(IV) systems are also given. The values of the potentials reported[3,4] for the Mo(V)/Mo(III) system were 0.100 V and 0.300 V in 1.0*M* and 9.0*M* hydrochloric acid media respectively. The formal potentials of these systems in phosphoric and acetic acid media are given in Tables 1 and 2. The potential measurements were made on solutions containing the oxidized and reduced forms prepared in dilute hydrochloric acid medium and diluted with the appropriate acids of required concentration. Hence these solutions contain, in addition to the acids mentioned, hydrochloric

acid at a concentration of about $0.3M$. The general trend in the formal potentials of these systems with acid strength is similar to that for hydrochloric acid medium. The green solutions of molybdenum(III) obtained in sulphuric acid change rapidly to the orange-red form. Molybdenum(III) solutions are slowly oxidized in $>1.0M$ perchloric acid media.

These formal potentials are in agreement with the earlier observations[3] that molybdenum(III) chloride is a better reducing agent than chloromolybdate(III). Hence it was felt worthwhile to study this reagent as a reducing titrant. The results obtained in titration of common oxidizing agents used in volumetric analysis are summarized in Table 3. Some results for chloromolybdate(III) as reductant are given for comparison.

Titration of Ce(IV) in hydrochloric acid media more concentrated than $2M$ was not attempted owing to the possible oxidation of the medium by the oxidant.[10] In $>4M$ hydrochloric acid media, aquomolybdenum(III) chloride is converted into chloromolybdate(III) rather rapidly.

The results in Table 3 show the following.

(1) The potential break at the end-point is generally at least as steep with aquomolybdenum(III) chloride as with chloromolybdate(III).

(2) Uranium(VI) can be titrated with this new reductant. Uranium(VI) is reduced to uranium(IV) and molybdenum(III) is oxidized to molybdenum(V) in the process. Attempts to titrate uranium(VI) with chloromolybdate(III) failed to give stable potentials and a clear jump at the end-point.

(3) In the titration of molybdenum(VI) with aquomolybdenum(III) chloride in $2M$ hydrochloric acid medium only one clear jump [Mo(VI)–Mo(V)] is observed, while a titration in $3M$ hydrochloric acid medium gives three jumps, one for the reduction Mo(VI)–Mo(V) and two for the reduction Mo(V)–Mo(IV), one of these corresponding to an "intermediate" oxidation state, presumably involving a binuclear Mo(V)–Mo(IV) complex. For the same titration carried out with chloromolybdate(III) in $>4M$ hydrochloric acid medium only one jump, corresponding to Mo(VI)–Mo(V), is observed. At lower acidities no stable potentials are obtained. It may be noted in this connection that earlier workers concluded that this latter titration is possible only at very high acid concentration.[11]

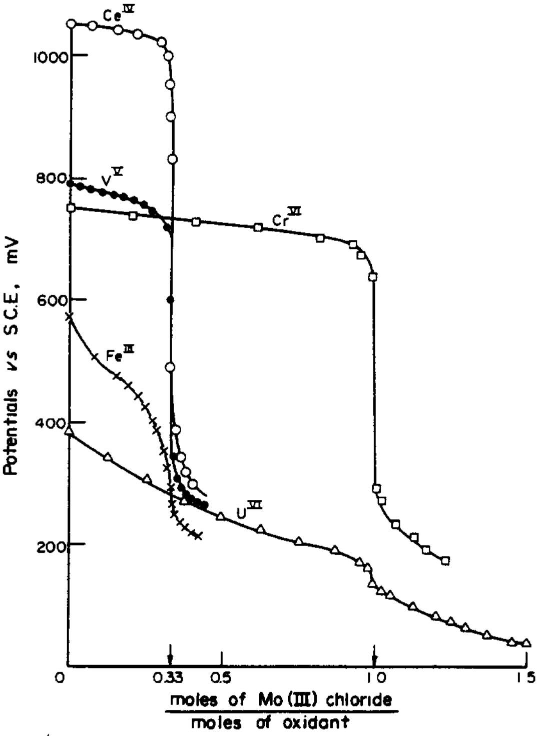

Fig. 2. Potentiometric titration curves. Reduction with aquomolybdenum(III) chloride: (*i*) Ce(IV)—Mo(III) in $1.0M$ hydrochloric acid medium; (*ii*) Cr(VI)—Mo(III) in $1.0M$ hydrochloric acid medium, (*iii*) Fe(III)—Mo(III) in $0.5M$ hydrochloric acid medium; (*iv*) V(V)—Mo(III) in $3.0M$ hydrochloric acid medium; (*v*) U(VI)—Mo(III) in $1.0M$ hydrochloric acid medium.

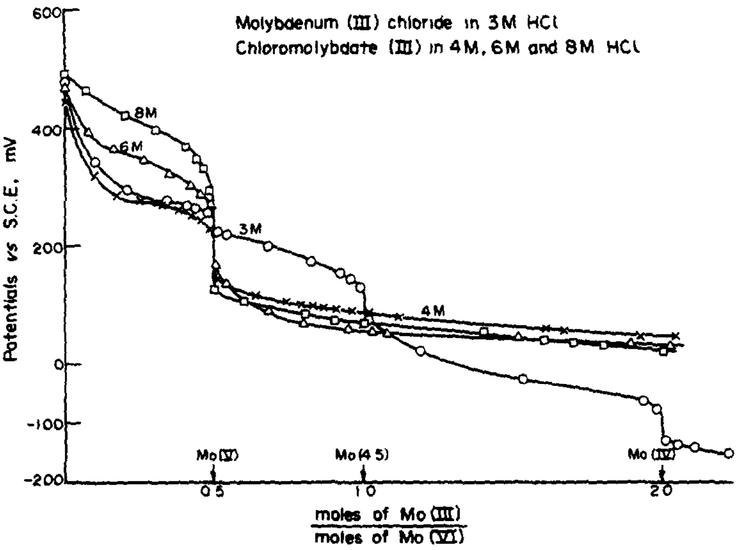

Fig. 3. Potentiometric titration curves for the reduction of molybdenum(VI) with molybdenum

(4) Aquomolybdenum(III) solutions can be used for the reductometric titration of hydrogen peroxide at low acidity.

The recommended concentrations of hydrochloric acid for quantitative titrations with the new reductants are 1.0*M* for Ce(IV), Cr(VI), U(VI) and H_2O_2, 3.0*M* for V(V) and Mo(VI) and 0.5*M* for Fe(III). The errors in these titrations are not more than 0.8%. Representative titration curves are given in Figs. 2–4.

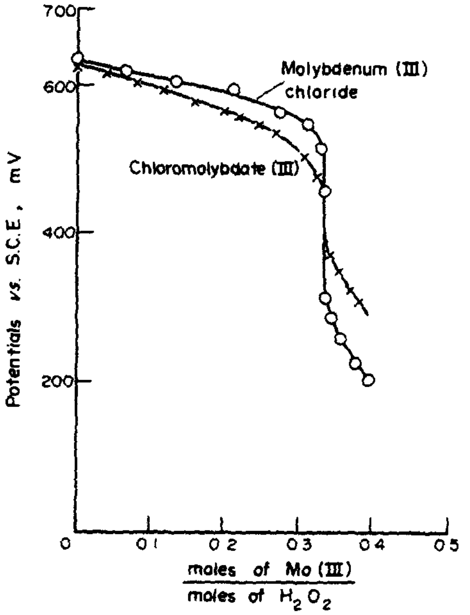

Fig. 4. Titrations of hydrogen peroxide with molybdenum(III).

(*Received* 6 *December* 1974. *Revised* 9 *July* 1975. *Accepted* 14 *August* 1975)

Summary—A simple titrimetric method for the determination of thiol and disulphide groups in biological samples with *p*-diethylaminophenylmercuric acetate as titrant, is suggested. Milligram amounts of cysteine (1–25 mg) are determined with a relative standard error not higher than 1%. The lowest determinable amount of cysteine is 0.1 mg (relative standard deviation 3%). The accuracy and the sensitivity are the same as in amperometric titration with mercuric chloride. The method has been successfully used for the determination of thiol groups in various biological samples.

In a number of studies in biochemistry, physiology, cytology and radiobiology, the thiol groups in proteins taking part in fundamental physiological processes[1–4] are to be determined. In the present paper, the commonest methods for determination of thiol groups are reviewed and the *p*-diethylaminophenylmercuric acetate method for the visual titration of SH-groups[5] is recommended.

For the determination of SH-groups amperometric titration with mercuric chloride is commonly used, with rotating platinum electrodes.[6,7] The main disadvantage is that mercuric chloride, like other inorganic compounds of mercury and silver, has a tendency to form a variety of mixed-ligand complexes containing a thiol group. Because of the technical difficulties mentioned above, a modification has been suggested[8–10] for tracing the effect of radioprotectors on the total concentration of SH-groups in the body tissues: the sample is homogenized in the presence of a substoichiometric amount of mercuric chloride solution and the reaction mixture is then titrated amperometrically with mercuric chloride.

This modification was used to solve a specific problem, that of finding the relative difference in the number of SH-groups in the tissues of an animal subjected to the influence of the protector and in those of a control animal, and was adequate for the purpose. The original method has been considerably simplified. According to our results, the relative standard deviation in analysis of a homogenized spleen by this modified method was 23% (the mean concentration of SH-groups being 1.2–1.5 μmole per 100 mg of tissue), compared with 10% by Kolthoff's method.[6,7]

The most common reagents for thiol groups are monofunctional organomercuric compounds, which react with different thiols strictly in 1:1 proportion.[11–13]

$$RHg^+ + R'S^- \rightarrow RHgSR'$$

The determination is usually carried out titrimetrically with indicators, and is the simplest, quickest and most convenient method.

A comparative study[14–16] of silver nitrate, mercuric nitrate and organomercuric compounds as titrants for thiol groups showed that polyfunctional organomercuric reagents are more selective with respect to SH-groups. An organomercuric cation (RHg^+) forms stepwise complexes with thiol groups to a far less extent than do Hg(II) and Ag(I), which accounts for the more accurate results. The visual titration with organomercuric reagents is as sensitive as the amperometric titration with mercuric compounds and is simple and reliable.[5]

Among organomercuric reagents, *p*-chloromercuribenzoic acid,[17–36] first suggested by Hellerman,[37–39] has become widely accepted; it can be obtained 99% pure. In one study[40] it was recrystallized three times, but in others, unfortunately, no attention was paid to the purity. Aqueous 0.005*M* solutions of *p*-chloromercuribenzoic acid in 0.01*M* sodium hydroxide are known to remain stable for less than a month, and regular standardization is necessary.

There are no reliable data on interferences. Judging by other organomercuric reagents,[5] chlorides in large quantities would be expected to interfere, so titration in physiological saline solution (0.9% NaCl) may yield erroneous results. The end-point is determined visually or spectrophotometrically. In the first case sodium nitroprusside is used as indicator for titrations done at pH 3.2–5.3, but it has low selectivity for thiol groups. Since the titration reaction is not instantaneous a back-titration with cysteine is used.[18,26,27,29]

A spectrophotometric method is based on the increase in absorption at 250–255 nm, when the thiol-compound reacts with *p*-chloromercuribenzoic acid.[41] The method is rather sensitive, and gives reliable results with $10^{-5}M$ concentration of thiol group. It can be used for photometric titration. The optimal pH range for photometric titration was not indicated. The increase in absorbance is measured at 250 nm (pH 7.0) or 255 nm (pH 4.6). The thiol groups of phosphorylase were also titrated photometrically in a more acidic medium at pH 2.3.[42]

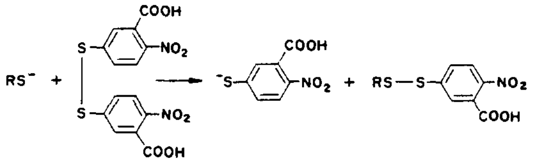
Various authors give different reaction times in their procedures. Since the rate of reaction of an organomercuric cation with different proteins varies, the time of colour development should be sufficient for constant absorbance to be reached.

The method used in the original study is somewhat unclear, and the authors of the papers that followed do not explain how the determination was carried out. Since the molar absorptivity for different mercaptides of *p*-chloromercuribenzoic acid varies, photometric titration is recommended.[4,43] The concentration of thiol groups has been found from a calibration curve[44] or from the molar absorptivity of the mercaptide,[45] but even under the most favourable conditions, the molar absorptivity varies and accurate determinations are difficult to obtain.

Because in photometric titration the same amount of *p*-chloromercuribenzoic acid is added to both the control solution and the active solution, it seems more reasonable to have a number of measuring flasks with equal amounts of protein to which increasing amounts of the organomercuric reagent are added. For each flask the absorbance is then measured, each time with respect to a similar solution containing an equivalent amount of water instead of protein. Titration can be carried out in a suitable vessel or in the cuvette of the spectrophotometer, and the dilution should be taken into consideration. Boyer seems to have used the first method, though he never stated it specifically. His report stating that one measurement of the absorbance is sufficient, once the excess of organomercuric reagent has been found, is open to criticism. In that case it would have been necessary to calculate the concentration of thiol from the molar absorptivity or to plot a calibration graph. Individual amino-acids would have been required and a calibration graph would have to be plotted for each one, since different mercaptides of *p*-chloromercuribenzoic acid have different absorption intensities. Another disadvantage of Boyer's method is that only pure solutions, free from the remnants of homogenized tissues, can be analysed. The different reaction rates of *p*-chloromercuribenzoic acid with thiols may yield low results in determination of the total number of thiol groups. Another point that gives rise to doubts is that for complete binding of thiol groups an excess of *p*-chloromercuribenzoic acid is required.[46] It is for this reason that back-titration of excess of organomercuric reagent is often used. Other organomercuric reagents have been suggested, but they have not found wide application.[47]

Because the titrimetric methods are not sensitive enough, photometric methods with organomercuric reagents have been explored,[47–56] but addition of a thiol only slightly affects the electronic structure of the reagent, and the spectra of the organomercuric reagents and the products are similar.[12,41]

For direct photometric determination of thiol groups 5,5′-dithio-bis(2-nitrobenzoic) acid is used (at pH 7.8–8.0).[57]; it forms a product absorbing in the neighbourhood of 412 nm.



Ellman's reagent is selective for a thiol group and the sensitivity of his method is the same as for photometric titration with *p*-chloromercuribenzoic acid. Ellman recommended measuring the absorbance 2 min after the beginning of the reaction, but in his later works[58,59] the time of measurement varies from 5 to 15 min. The method requires the removal of the remnants of the homogenized material from the solution before the analysis, and also that a correction be made for the absorbance of the excess of reagent.[58] The analysis of proteins which absorb in the region of 412 nm also proves rather difficult. The disadvantage of the method is the lower reactivity, compared to organomercuric reagents.[59]

A simple titrimetric method for thiols of different classes, using *p*-dimethyl- or *p*-diethylaminophenylmercuric acetate as titrant has been suggested.[5] The reagents are synthesized by simple mixing of solutions of mercuric acetate and the alkylaniline. Recrystallization from ethanol gives 100% pure substance. The reaction with thiols in an alkaline medium is almost instantaneous. Diphenylcarbazone is used as indicator (colour change pink → violet). In the determination of 1–50 mg amounts of thiols of different classes the relative standard deviation is 0.1–1.7% in slightly acidic, neutral and alkaline media. For titration of coloured thiols or samples containing sediments, an alkaline solvent, consisting of a saturated solution of sodium acetate in a mixture of benzene and ethanol (2:3) is added to improve end-point detection. The colour change is easily seen in the upper benzene layer.

EXPERIMENTAL

Reagents

p-Diethylaminophenylmercuric acetate was synthesized[60] and recrystallized from hot ethanol. Solutions were prepared by dissolving a precisely weighed amount in the minimal amount of warm ethanol, and then diluting with water. The titre stays constant for at least two months if the solution is kept in a dark bottle at room temperature. The solid remains stable for not less than two years, if stored in darkness and at room temperature.

A 0.2% solution of diphenylcarbazone in ethanol was used as indicator.

An 8*M* solution of urea was prepared in 1*M* ammonium acetate buffer medium at pH 8.5–10.0. In order to prevent the catalytic effect of metallic ions on oxidation of thiol groups, $10^{-6}M$ EDTA was added.

Test samples included cystine and cysteine hydrochloride monohydrate, lyophilized human serum albumin, with not less than 95% of albumin, lyophilized ox albumin, powdered egg albumin, crystallized pancreatic ribonuclease, crystalline trypsin, papain, a suspension of crystalline aldolase in 2.0*M* ammonium sulphate. Chromatographically pure reduced glutathione was used for preparing a standard solution.

Spleens from sacrificed mongrel white mice were quickly cut out and homogenized by hand in a glass homogenizer, in buffer solution for the determination of SH-groups and in 8*M* urea for the determination of disulphide bonds.

Solutions of cysteine (10^{-2}–$10^{-4}M$) in distilled water were prepared on the day of use. Weighed portions of cystine and proteins were dissolved in 8*M* urea at pH 8.5–10.0. A saturated solution of chemically pure sodium sulphite was prepared every 30 min. For the two-phase titrations, 10 g of sodium acetate trihydrate were dissolved in 400 ml of benzene and 600 ml of ethanol.

Gluten was obtained from first-grade flour by a standard method and frozen instantly. Later it was freeze-dried. The dry gluten was ground in a porcelain mortar into a fine powder containing 87% protein and 4% moisture. Gluten and egg protein were dispersed in 8*M* urea.

Ammonium acetate buffer solution was prepared from 1*M* acetic acid and ammonia solutions.

Procedures

Thiol-groups. Place 5–15 ml of a solution of 0.4–20 mg of substance in water or 8*M* urea in a 50-ml conical flask, add 0.5–1 ml of buffer solution, 5–15 ml of the benzene–ethanol solvent and 1–3 drops of indicator, and titrate with aqueous ethanolic solution of *p*-diethylaminophenylmercuric acetate until a permanent violet colour appears in the benzene layer.

Total number of thiol groups and disulphide bonds. Disperse an accurately weighed portion of raw egg protein or dry powdered gluten (lyophilized) in 8*M* urea at pH 9.0–10.0 on a water-bath at 35–40°C and add 0.2 ml of saturated sodium sulphite solution. After 2 min add 2–10 ml of benzene–alcohol solvent and titrate as above.

Thiol-groups in spleen. Add 2–10 ml of benzene–alcohol solvent and 1–3 drops of indicator to the homogenate, and titrate as above.

Amperometric determination of SH-groups. Place the sample solution, containing 0.08–15 mg of substance in water or in 8*M* urea, in a titration cell, add 15 ml of ammonium acetate buffer (pH 7.0–7.5) as background electrolyte, and titrate amperometrically with *p*-diethylaminophenylmercuric acetate solution 20–40 times as concentrated as the sample, at 0.7 V, using a wax-impregnated rotating graphite electrode and a saturated calomel reference electrode.

RESULTS AND DISCUSSION

The pH range for determining cysteine varies with the concentration of the titrant (Table 1). The optimal reagent concentration was found to be 5×10^{-3}–$2 \times 10^{-4}M$.

The lowest determinable amount of cysteine depends on the volume of $2 \times 10^{-3}M$ titrant that will give a definite change in the colour of 1–3 drops of the indicator.

The visual titration is as accurate and sensitive as the amperometric method.[61,62] Cysteine (1–25 mg) in the presence of cystine can be determined with a relative standard deviation of less than 1%. The lowest determinable amount is 0.1 mg (relative standard deviation 3%). Cystine (1–50 mg) was determined with a relative standard deviation of 0.1–3.5%. The results are presented in Table 2.

Table 1. The pH interval for cysteine titration by *p*-diethylaminophenylmercuric acetate, for different concentrations of the titrant

Titrant concentration, *M*	pH interval
1×10^{-2}	7.5–11.0
5×10^{-3}	8.0–11.0
1×10^{-3}	9.0–11.0
5×10^{-4}	9.5–11.0

The presence of disulphides, organic sulphides and sodium sulphite (0.5 ml of saturated solution) does not interfere. The effect of other foreign ions was studied earlier.[5] When cysteine hydrochloride was titrated, the indicator colour change at the equivalence point was more pronounced.

The methods used for determining disulphide bonds usually amount to determining the SH-groups after the disulphide bonds have been reduced.[15,63] The reduction of cystine by sodium sulphite, which is reversible to a certain extent, has been studied in great detail.[63] The excess required not only for reducing disulphide bonds but also for preventing thiol groups from oxidizing, was found.

The method proposed here can be used for determining cysteine in the presence of cystine as well as for determining their total amount after the cystine has been reduced.

Cysteine reacts rather slowly with aromatic mercury compounds, which makes it somewhat difficult to find the equivalence point. This fact is usually overlooked when thiol groups are directly titrated with *p*-chloromercuribenzoic acid or other organomercuric reagents. In the case of *p*-diethylaminophenylmercuric

† p-Chloromercuribenzoic acid.

acetate the reaction also slows down near the equivalence point, when the concentrations of the reacting substances decrease. Therefore, near the equivalence point the flask should be shaken briskly for some time between additions of titrant. Titration in the presence of the benzene–alcohol solvent overcomes this disadvantage. The amount of mixed solvent is sufficient to give a separate benzene layer when shaking is stopped. In determining cystine after its reduction, an excess of p-diethylaminophenylmercuric acetate should be added, and the surplus back-titrated with cysteine under the same conditions. The results from back-titration do not differ from those of direct titration.

We have used the proposed method for determining SH- and disulphide groups in certain amino-acids, proteins and in some biological samples. The results obtained were checked by the method of standard additions. Reduced glutathione was used as a standard solution. The number of thiol groups in glutathione was checked iodometrically.[64] The experimental results and those found in the literature are presented in Table 3.

The number of thiol groups in certain proteins was determined by amperometric titration with p-diethylaminophenylmercuric acetate. Conditions for the titration of thiols were found earlier.[5] In the present study, the optimal pH range for proteins was found to be 7.0–7.5 (ammonium acetate supporting electrolyte). Titration at pH values outside this range gives erroneous and irreproducible results. Results are given in Table 3. The amperometric method cannot be recommended in practice, since it has no advantages over the much simpler visual titration.

For determination of disulphide bonds in biological samples dispersion was effected by shaking with 8*M*

Table 4 Amount of SH-groups in the spleen of mongrel white mice according to results obtained by different methods of determination

	Visual titration with p-diethylaminophenylmercuric acetate	Amperometric titration by mercuric chloride	
		Kolthoff's method	Graevskii's modification
Mean SH content, μmole/100 mg of tissue	1.48	1.24	1.39
Number of determinations	112	111	15
Relative standard deviation, %	8.8	10.2	23.0

urea at pH 9.0–10.0 on an automatic mixer. Urea not only evenly disperses protein, but also encourages dissolution of S–S bonds.[73]

No free SH-groups were found in gluten protein. The content of disulphide sulphur was 0.56% of the total amount of protein. In raw egg protein the content of thiol sulphur was found to be 0.0149 ± 0.0006% and that of disulphide sulphur 0.0522 ± 0.0008%. In a comparative visual titration with *p*-diethylaminophenylmercuric acetate of SH-groups in 10 μmole of cysteine and an amperometric titration with mercuric chloride the relative standard deviations were 0–3.2% and 4.6–8.9% respectively.* Results for thiol groups in the spleens of mice, by both methods, are given in Table 4.

In 112 determinations, 1.48 μmole of SH-group were found, on average, per 100 mg of spleen, by visual titration with *p*-diethylaminophenylmercuric acetate, relative standard deviation 8.8%. In 15 amperometric titrations with mercuric chloride, the mean number of SH-groups per 100 mg of spleen was 1.24 μmole, relative standard deviation 10.2%. In the amperometric titration by the Graevskii modification,[8,9] the relative standard deviation was 23.0%.

The results prove that the visual titrimetric determination of SH-groups is somewhat more accurate than Kolthoff's amperometric titration with mercuric chloride, and greatly superior to the modification of this method.

It should be pointed out that not all organomercuric reagents react in a similar way with protein thiol groups. Thus, for example, the error of the titrimetric determination of cysteine with *p*-dimethylaminophenylmercuric acetate is higher than that with the *p*-diethyl analogue even though the reagents differ only in the substituent on the nitrogen atom.

Therefore, *p*-dimethylaminophenylmercuric acetate should not be used for determining cysteine though it is successfully used for determining thiols of other classes.

When the number of thiol groups is small, an indirect extractive photometric method seems to be the most effective for cysteine.[72] It is based on reacting a thiol with *p*-diethyl- or *p*-dimethylaminophenylmercuric acetate and subsequent extractive photometric determination of the excess of organomercuric reagent, by means of diphenylcarbazone in benzene. Amounts of 5–120 μg of cysteine ($6 \times 10^{-6}M$ and higher) are determinable with a relative standard deviation of 2–6%. This method is slightly more accurate that Ellman's photometric method using 5,5'-dithiobis(2-nitrobenzoic) acid.

Urea, sulphate, nitrate, phophate, 10-fold amounts of disulphide and 300-fold amounts of organic sulphides do not interfere. As in this case excess of the organomercuric reagent is added, all thiol groups have a chance of reacting. Much less time is required for the analysis than for Boyer's photometric titration. The extractive photometric method also makes it possible to do the determination with turbid homogenates and in the presence of coloured proteins, because the absorbance of the benzene extract is measured, which excludes substances insoluble in benzene. The extraction of other coloured substances into the benzene layer is of no consequence, since the absorbance is measured against a blank solution containing all the reactants except the organomercuric reagent.

ON THE COPPER(II)–EDTA–PAR SYSTEM FOR VISUAL AND PHOTOMETRIC END-POINT DETECTION IN IRON(III)–EDTA TITRATIONS

D. NONOVA and N. LIHAREVA
Department of Analytical Chemistry, University of Sofia, 1 Anton Ivanov Avenue, Sofia 26, Bulgaria

(*Received* 20 *August* 1975; *Accepted* 22 *October* 1975)

Summary—The copper(II)–EDTA–PAR system is proposed as indicator for direct EDTA titration of 0.2–20 mg of iron(III) in acetic acid medium. The precision and accuracy have been evaluated by spectrophotometric titration. Microtitrations determine down to 10 μg of iron. A logarithmic concentration diagram has been constructed to present the complex equilibria involved. In an interference study the masking agent ammonium fluoride was found to improve the end-point detection. The method has been applied successfully to practical standard samples and compares favourably with other EDTA titrations of iron.

The direct complexometric titration of iron(III) in routine analysis is a problem not yet satisfactorily resolved. The formation of the iron(III)–EDTA complex is slow at room temperature and heating is advisable, but not above 40–50° or hydrolysis may occur. Moreover, the end-point is not sharp when an indicator for iron(III) is used. Many procedures for the titration have been reported, some quite recently,[1–7] including an excellent review of the indicators available[6] in which 57 compounds were investigated. Undoubtedly, sulphosalicylic acid is among the most widely used,[6–12] but its colour transition depends greatly on the pH of the solution, and the colour disappears gradually and a little before the equivalence point. In addition, a large excess of the indicator is needed (this is generally the case for phenolic indicators in this titration). For these reasons, the problem seemed to us to be worth further investigation.

In our previous work[13] it was shown that the system Cu(II)–EDTA–PAR can be successfully used for direct EDTA titration of barium. The precision of the end-point prompted us to try the same reaction for titration of iron(III).

Iwamoto[8,14] used Cu(II)–EDTA–PAN and Cu(II)–EDTA–PAR system as indicators in his work on tartrate as an auxiliary complexing agent and buffer in the chelatometric determination of iron(III) and aluminium, but Momoki and Sekino[15] found the Cu(II)–EDTA–PAN end-point sluggish in EDTA titration of iron(III) in acetate buffer medium, because of hydrolysis. For the present study PAR was chosen because of its highly sensitive colour reaction with copper(II).

THEORY

The replacement equilibrium (omitting charges for simplicity) is

$$\mathrm{Fe} + \mathrm{CuY} + \mathrm{In} \rightleftharpoons \mathrm{FeY} + \mathrm{CuIn} \qquad (1)$$

It is possible to find the optimum conditions for this reaction provided the formation constants of the various species are available. Ringbom's data[16] for $K^{\mathrm{H}}_{\mathrm{MHL}}$ and K_{ML} for iron(III)–EDTA and copper(II)–EDTA were used; the conditional stability constant of copper(II)–PAR, $\log K'_{\mathrm{CuIn}} = 6.4$ at pH 3, was calculated from the data in our previous work.[17] These values were used to establish the following parameters.

(*a*) $\mathrm{pCu}_{\mathrm{trans}}$, needed to calculate $\Delta\mathrm{pFe}'$, which in turn is included in the equation for the titration error:[16,18]

$$\text{Relative error } \% = (10^{\Delta\mathrm{pM}'} - 10^{-\Delta\mathrm{pM}'})/(C_{\mathrm{M}}K'_{\mathrm{MY}})^{1/2} \qquad (2)$$

(*b*) The best Cu(II)–EDTA concentration according to the equation:[16,19]

$$\mathrm{pFe}' = \mathrm{pCu}_{\mathrm{trans}} + \log K'_{\mathrm{FeY}}/K'_{\mathrm{CuY}} + \log\,[\mathrm{CuY}]'/[\mathrm{FeY}]' \qquad (3)$$

where the side-reaction coefficient $\log \alpha_{\mathrm{Fe(Ac^-)}} = 0.8$ at pH 3 and $[\mathrm{Ac^-}] = 5 \times 10^{-2}M$, $\log \alpha_{\mathrm{Fe(OH)}} = 0.4$, $\log \alpha_{\mathrm{CuY(H)}} = 0.3$ and $\log \alpha_{\mathrm{Y(H)}} = 10.8$ were taken into account. Hence $\log K'_{\mathrm{FeY}} = 13.4$ and $\log K'_{\mathrm{CuY}} = 8.3$ were obtained and used in further calculations.

Accordingly, when 10^{-2} and $10^{-3}M$ iron(III) solutions are titrated, suitable values of $[\mathrm{CuY}]'$ are $10^{-5.8}$ and $10^{-6}M$ respectively. For practical application a concentration about ten times as great, *i.e.*, $10^{-5}M$ was always used. Thus, in titration of $0.01M$ iron(III) $\Delta\mathrm{pFe}'$ was 0.8 and the titration error only 0.001%, whereas for $10^{-3}M$ iron(III) $\Delta\mathrm{pFe}'$ was 1.3 and the error 0.01%.

To represent more clearly the rather complicated ionic equilibria in this study and offer an easy way of surveying the conditions of the complexometric titration in question, we constructed the logarithmic diagram shown in Fig. 1. Construction details will not be given, since they are described clearly elsewhere.[18,20–24]

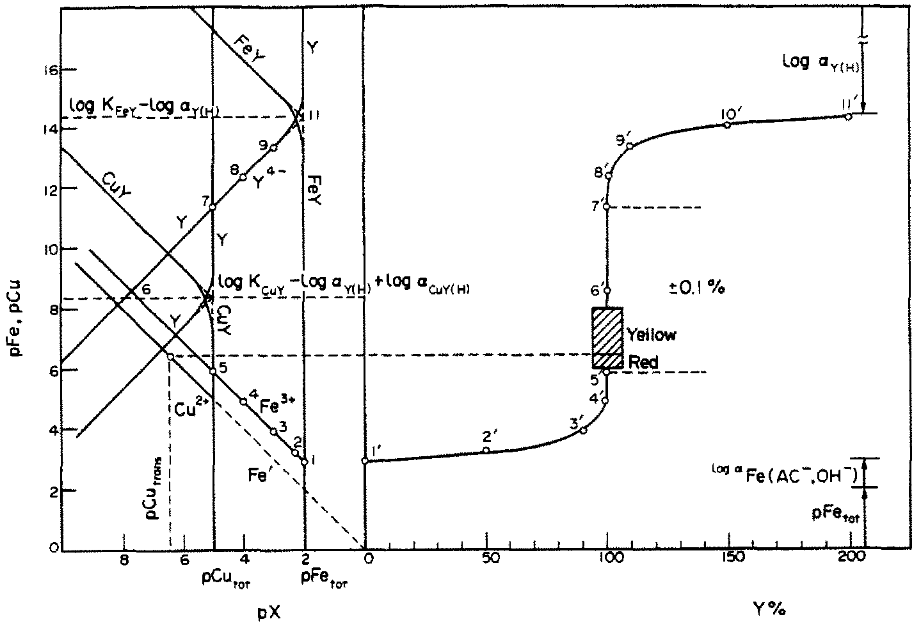

Fig. 1. Logarithmic-concentration diagram for the system Fe^{3+} + Cu^{2+} + EDTA and PAR as metallochromic indicator for Cu^{2+}. $C_{Fe} = 10^{-2}M$; $C_{CuY} = 10^{-5}M$; log $K_{FeY'} = 14.3$; log $K_{CuY'}$ + log $\alpha_{CuY(H)} = 8.3$; log $\alpha_{Fe(Ac^-, OH^-)} = 0.9$.

The diagram allows us to read the points needed to construct the titration curve and to evaluate directly the accuracy of the titration. The large break corresponding to ±0.1% error is obviously due to the high stability of the iron(III)–EDTA complex (log $K_{FeY} = 25.1$). Taking into account the sensitivity of the human eye, the indicator interval (shown only approximately) is asymmetric about $pCu_{trans} = 6.4$ in a direction favourable for titration. It is also evident that the transition interval of the indicator PAR coincides satisfactorily with the 0.1% error section of the titration curve, the equivalence point of the system Cu^{2+}–Y^{4-} being near the transition point of the colour change interval.

These considerations indicate convincingly that accurate results should be expected on a thermodynamic basis. However, in view of the tendency of iron(III) to form kinetically inert complexes, the reaction has been examined to prove experimentally the validity of these conclusions. Spectrophotometric titrations were performed to evaluate the precision of equivalence point detection[16,25] and the sensitivity and selectivity of the method.

EXPERIMENTAL

Reagents

Iron(III) chloride solution, 0.1*M*. Prepared from ferric chloride and standardized gravimetrically via ferric oxide. A 0.01*M* solution was prepared by dilution and checked potentiometrically with EDTA, a bright platinum indicator electrode being used.[8,10] Solutions of lower concentration were prepared by further dilution.

EDTA, 0.01 *and* 0.02*M solutions*. Prepared by dissolving the free acid.[8]

Copper(II)–EDTA solution, $10^{-3}M$. Prepared by dissolving the Koch-Light reagent and checked for free copper(II).

4-(2-Pyridylazo)resorcinol (*PAR*). A $1.00 \times 10^{-4}M$ aqueous solution was used for spectrophotometric titrations, and an aqueous 0.05% solution for visual titrations.

Acetic acid, 0.5*M and ammonia solution* were used for pH adjustment.

Ammonium fluoride, p.a. 0.1*M solution.*

Ammonium acetate, p.a., 10% *solution.*

All other inorganic chemicals used were of analytical-reagent grade.

Spectrophotometric titrations

Place the test solution in the titration cell, add 6 drops of copper(II)–EDTA solution, 2 ml of 0.5*M* acetic acid and 2 ml of $1.00 \times 10^{-4}M$ PAR*. A red-violet colour develops immediately. Dilute with distilled water to about 20 ml, stir (magnetic stirrer), and measure the absorbance at 520–530 nm after each addition of 0.002*M* EDTA, continuing the titration until the absorbance remains nearly constant during addition of 0.2–0.3 ml of titrant. Locate the end-point graphically.[26,27] The second intersection point corresponds to the amount of iron present. A typical titration curve is shown in Fig. 2 and results in Table 1.

Visual titration

Transfer a portion of test solution containing 0.25–5.5 mg of iron into a 100–150 ml beaker. Add 0.5 ml of copper(II)–EDTA solution, 2 ml of 0.5*M* acetic acid and if necessary adjust the pH to 2.7–2.9 with dilute acetic acid or ammonia solution, then dilute the solution to 50 ml with distilled water. Add indicator (2 or 3 drops of 0.05% solution) and titrate at room temperature with standard EDTA solution, with magnetic stirring. Near the end-point titrate slowly until the colour changes from red-violet to pure yellow (this takes 1 or 2 drops of titrant). The intense pink colour of the solution a little before the end-point gives useful warning. Typical results are given in Table 2.

---

* Preliminary tests might be performed to establish the best PAR concentration.

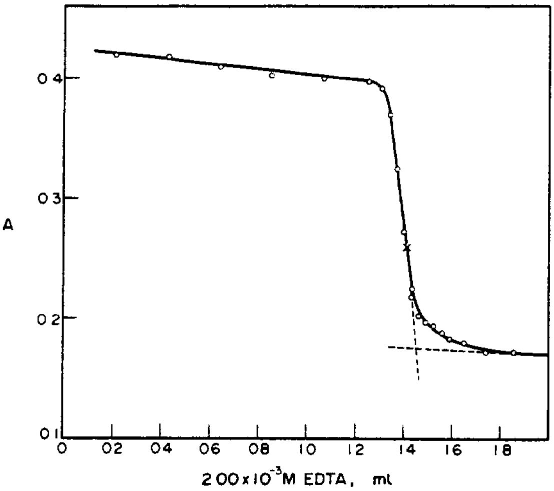

Fig. 2. Spectrophotometric titration of iron(III) with EDTA, using copper(II)–EDTA–PAR system as indicator. Fe 162 μg, $10^{-5}M$ CuY, 2 ml of 0.5M acetic acid and 2 ml of $10^{-4}M$ PAR are added. Total volume about 20 ml. Titrated with 0.002M EDTA at 530 nm.

RESULTS AND DISCUSSION

Spectrophotometric titration

The optimal difference in the absorptivities of the coloured species contributes to an abrupt change in absorbance after the end-point has been reached. Figure 2 shows the well-defined intersection and the absorbance jump of at least 0.2 units.

Ringbom's procedure applied to the spectrophotometric data gives the absorbance at the equivalence point by means of the equation:

$$A_{eq} = (A_{In}^{max} + A_{MIn}^{max}[M]'_{eq}K'_{MIn})/(1 + [M]'_{eq}K'_{MIn}) \qquad (4)$$

With $[Cu]'_{eq} = 10^{-6.65}$ and $[Cu]'_{eq} \cdot K'_{CuIn} = 0.56$, A_{eq} is found to be 0.261. By interpolation the equivalence point should occur at a consumption of 1.409 ml of titrant. The indicator correction is given by:

$$[MIn]_{eq} = C_{Ind}(A_{eq} - A_{In}^{max})/(A_{MIn}^{max} - A_{In}^{max}) \qquad (5)$$

where C_{Ind} is the total indicator concentration. The value $[MIn]_{eq} = 3.6 \times 10^{-6}M$ is obtained. The volume of 0.002M EDTA corresponding to this correction is 0.036 ml. Hence, the volume of EDTA reacted at the equivalence point is 1.445 ml, compared with the 1.448 ml required for the 162 μg of iron in the solution tested. The same quantity was obtained more easily by graphical extrapolation as can be seen from Fig. 2.

Table 1. Spectrophotometric titrations

Iron (III), μg	EDTA, M	n	EDTA consumed, *ml* Theoretical	Experimental ($\bar{x} \pm S$)
269	0.005	7	0.965	0.966 ± 0.004
162	0.005	3	0.579	0.579 ± 0.002
	0.002	7	1.448	1.452 ± 0.007
108	0.005	3	0.386	0.393 ± 0.007
	0.002	5	0.965	0.965 ± 0.004
54	0.002	5	0.483	0.494 ± 0.02
27	0.001	5	0.483	0.473 ± 0.01
11	0.001	5	0.193	0.206 ± 0.01

Table 2. Visual titration of iron(III)

Iron (III), *mg*	EDTA, M	No. of titns.	EDTA consumed, *ml* Theoretical	Experimental ($\bar{X} \pm S$)
5.39	0.01	5	9.65	9.68 ± 0.03
3.77	0.01	5	6.76	6.75 ± 0.02
2.69	0.01	10	4.825	4.837 ± 0.009
1.62	0.01	5	2.895	2.914 ± 0.007
1.08	0.01	7	1.930	1.937 ± 0.006
0.269	0.005	8	0.965	0.962 ± 0.015

The results in Table 1 show that good precision is attainable for 10–270 μg of iron.

Visual titration

The concentration range of iron(III) for visual titration was selected (Table 2) to ensure suitable volume of EDTA consumed, and to utilize the high sensitivity of the indicator reaction. The visual titration is less precise than the spectrophotometric titration of the same amount of iron. With the larger amounts of iron, the colour of the indicator complex is screened by the iron(III) species. Hence, the starting solution was yellowish and the pink colour appeared only when most of the iron(III) was complexed with EDTA. The addition of fluoride (see later) improves the colour characteristics of the solution.

Interferences

Synthetic mixtures were prepared with cations commonly found with iron. Most interferences are prevented by masking with ammonium fluoride and use of a relatively high acidity where few other metals form complexes with PAR and EDTA. The presence of fluoride improves the detection of the end-point. Results are shown in Table 3.

Of the cations studied which under these conditions could react with PAR, nickel, cobalt(II), zinc and cadmium interfere strongly, but as Table 3 shows, elements that generally appear in silicate materials do not.

Preliminary investigations have proved ammonium fluoride to be the best masking agent, the presence of which favours the titration by increasing the apparent intensity of the indicator-complex colour, first by formation of the colourless fluoride complexes of iron(III), and secondly perhaps by formation of a ternary copper(II)–PAR–fluoride complex, in which the unidentate halide ion occupies the fourth position in the inner co-ordination sphere of copper(II) (it was recently again proved[28] that PAR co-ordinates as a terdentate ligand). Fluoride is known to form ternary complexes with some metal–indicator complexes, giving an increase in absorption intensity and a small

bathochromic effect,[29] as observed here, this effect presumably being due to the strong electrophilic character of the fluoride influencing the π-electron system of the dye.[12]

Effect of acetate concentration

Because acetate forms rather stable complexes with iron(III), its effect was investigated and found to be dependent on both the acetate concentration and the pH. Acetate did not interfere provided the overall concentration was less than 0.1*M*, and the pH was not more than 2.9.

Determination of iron in standard samples

The usefulness of the procedure outlined above was tested by applying it to: (*a*) a Czechoslovak standard sample (1-01-002) with the following certified composition: Fe 69.16%, SiO_2 0.48% and Al_2O_3 0.55%, and (*b*) two standard talc samples (DDR) with the composition (*i*) moisture 0.1%, loss on ignition 25.0%, SiO_2 32.2%, TiO_2 1.5%, Fe_2O_3 6.52%, MgO 33.4%, CaO 1.1%, CO_2 23.2%; (*ii*) moisture 0.9%, loss on ignition 8.3%, SiO_2 48.1%, Al_2O_3 2.5%, Fe_2O_3 9.70%, MgO 30.5%, CaO 0.2%, K_2O 0.04%, Na_2O 0.03%, CO_2 0.2%.

The results are given in Table 4.

Procedure for Czech standard

Treat 0.2–0.4 g of the finely ground material in the usual way with concentrated hydrochloric acid and fusion of the residue with sodium carbonate in a platinum crucible.[18] Take special care not to use too great an excess of hydrochloric acid. Combine the solutions in a 250-ml volumetric flask and take a 10–20 ml fraction. Add 1 ml of copper(II)–EDTA solution, 3–5 drops of PAR, 1–2 ml of 0.1*M* ammonium fluoride and adjust the pH by first adding dilute ammonia (or sodium hydroxide solution) till the pH is about 2 and then ammonium acetate solution to pH 2.7–2.9. If necessary, use acetic acid to lower the pH. Titrate at room temperature, slowly near the end-point.

Procedure for talc

Weigh accurately about 0.5 g of the powdered air-dried sample and follow the procedure as described for analysis of a limestone.[30] Transfer the residue after ignition to a small porcelain dish and treat as usual. Filter off the silica, collect the filtrate and washings in a 100-ml volumetric flask, and titrate aliquots of appropriate volume in the same way as for the Czech Standard.

The results obtained for the standard samples indicate that the method has good accuracy and precision, sensitivity and selectivity, which allow a simple determination of iron in materials with similar composition.

Acknowledgement—The authors express their sincere thanks to Docent Dr. O. Budevsky from the Faculty of Pharmacy, Academy of Medicine for valuable discussions relating to the construction of the logarithmic diagram.

ELECTROCHEMICAL DETERMINATION OF HYDROGEN SULPHIDE IN AIR

JOHN M. SEDLAK® and KEITH F. BLURTON
Energetics Science, Inc., 85 Executive Boulevard, Elmsford, New York 10523, U.S.A.

(*Received* 6 *September* 1975, *Accepted* 21 *October* 1975)

Summary—A new method for the quantitative analysis of sub-ppm and high ppm levels of hydrogen sulphide is reported. The technique is based on the electrochemical oxidation of hydrogen sulphide at a potentiostatically-controlled, Teflon-bonded diffusion electrode. Two instruments (one portable and one a fixed-location instrument) were constructed and their operating characteristics evaluated. They were sensitive and selective, responded rapidly to the gas, and gave a linear relationship between steady-state signal and gas concentration. Excellent zero and signal stability indicate that the electrochemical sensor is not poisoned by the H_2S.

Hydrogen sulphide is a toxic, malodorous and corrosive gas which produces severe effects on the nervous system at low concentrations and causes fatalities at higher concentrations. It is produced by the anaerobic digestion of all types of excreta, in oil-fields and refineries, during the synthetic production of fibres, during heavy-water production, and during the Kraft pulping process. The concentrations met in practical situations, and hence the instrument range, will depend on the application. For example, the concentration in ambient air is 1–5 ppM,* v/v, the threshold limit for industrial exposure, set by the American Conference of Governmental Industrial Hygienists, is 10 ppm, and concentrations as high as 200 ppm over a short time are met on oil-drilling rigs. Clearly the analysis technique must not be paralysed by these high concentrations.

A large number of methods have been reported for the determination of hydrogen sulphide. The standard method for environmental samples involves collection by passage through a $Cd(OH)_2$ suspension followed by reaction with *p*-amino-*N*,*N*-dimethylaniline to form Methylene Blue.[1–3] The most widely used method involves collection by passing through a paper tape[4] impregnated with lead acetate,[5,6] mercuric chloride,[7] silver nitrate,[8] or potassium dicyanoargentate.[4] A more precise technique utilizes gas chromatography with a flame photometric detector,[9] but these instruments are limited by their inability to monitor continuously, by their complexity, and by the requirement of a.c. power and support gases.

Recently we described an electrochemical technique for the quantitative determination of carbon monoxide,[10–12] ethanol[13] and the oxides of nitrogen.[14] We now report the extension of this method to the measurement of hydrogen sulphide in the atmosphere. The method is based on the electrochemical oxidation of hydrogen sulphide at a Teflon-bonded diffusion electrode.[15] Two experimental monitoring systems were fabricated and tested to show the feasibility of this electrochemical technique for the measurement of hydrogen sulphide; one was a portable unit while the other was more suitable for continuous operation in corrosive and contaminated environments. We now report on the operating characteristics of these analysers.

EXPERIMENTAL

The smaller portable unit was 7 × 11 × 7 in., weighed 9 lb, and could be operated from a.c. mains or batteries. The larger, fixed-location instrument was 15 × 12 × 6 in., weighed 32 lb, and was mains-operated.

Each instrument comprised a pump, a flowmeter, an electrochemical sensor, and electronic circuitry. The fixed-location instrument also contained a water-bottle (250 ml). Test gases were passed over the surface of the water before entering the sensor, to adjust the water content of the sample gas approximately to the water vapour pressure of the 28% sulphuric acid electrolyte in the sensor. This permitted continuous operation with minimal change in the electrolyte concentration in the sensor.

The electronic circuitry (Fig. 1) consisted of a potentiostat to maintain the sensing electrode at 0·4 V *vs.* the reference electrode, impedance-matching circuitry for a low output-impedance (10 ohm), and provision for battery recharge. The low output-impedance rendered the system compatible with any commercial potentiometric recorder. The low power-requirements of the pump (0·3 W) and of the electronic components (0·25 W) enabled the portable instrument to be operated continuously on a "D" size nickel–cadmium battery for approximately 10 hr.

The same sensor was used in both instruments: it is similar to that previously described for the carbon monoxide analyser.[11,12] Sensing (W), counter (C) and reference (R) electrodes were Teflon–bonded diffusion electrodes.[15] The backs of these electrodes are open to the surrounding air,[11,12] and the electrochemical reaction occurs by gaseous diffusion to the electrocatalytic sites on the front (electrolyte) side of the electrode.[12] The reference electrode was catalysed with platinum, and although this is not a truly reversible electrode, its potential remained sufficiently constant during operation of the cell at 1·0 ± 0·03 V[12] Sensing and counter-electrodes contained a proprietary noble-metal catalyst material (Energetics Science, Inc.)

---

* ppM = parts per milliard, *i.e.* parts in 10^9.

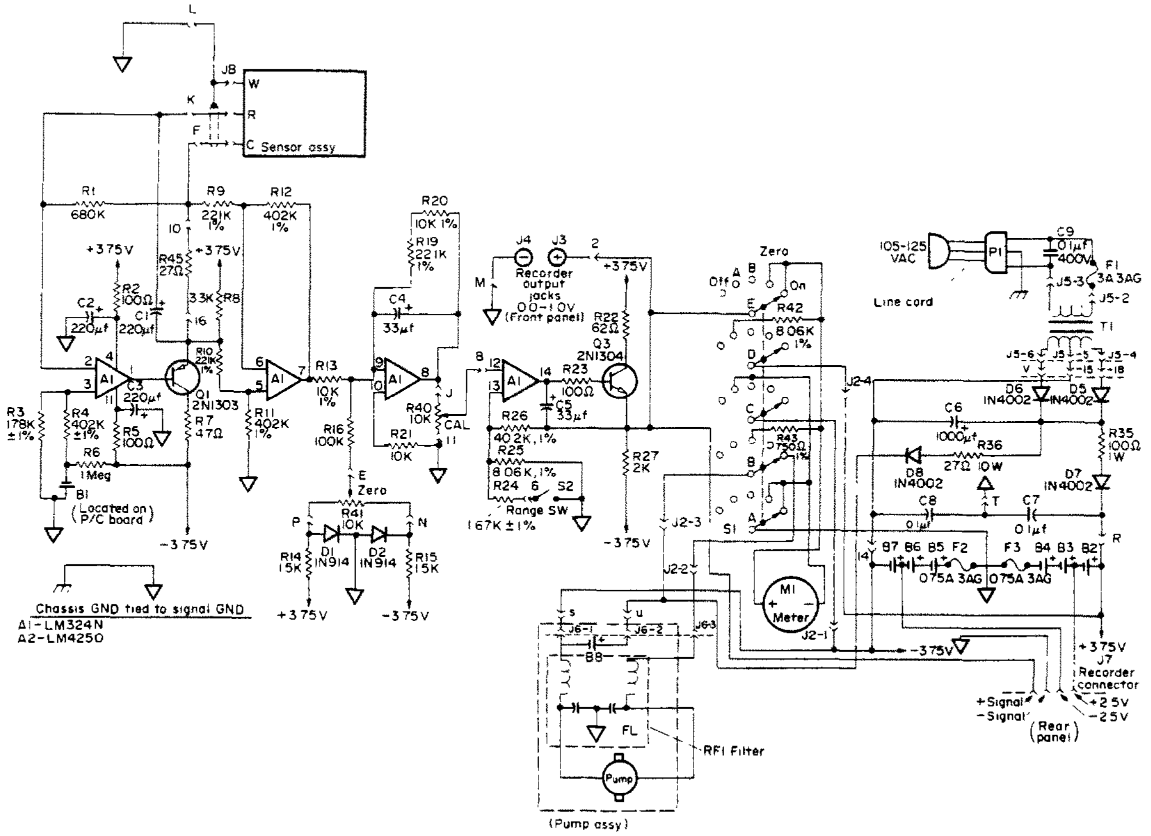

Fig. 1. Circuit diagram for portable hydrogen sulphide analyser. W—working electrode; C—counter-electrode; R—reference electrode.

The systems were set to zero either with pure air or by merely turning off the gas pump. The difference between these two methods was equivalent to less than 0·03 ppm H_2S, and therefore the use of purified air is only necessary when measuring low H_2S-levels. Response characteristics were determined by passing air with various hydrogen sulphide concentrations into the sensor at a fixed flow-rate of 0·7 l./min. The current generated by the electrochemical oxidation of the hydrogen sulphide was displayed on a panel voltmeter calibrated in ppm H_2S and recorded on a Hewlett-Packard Model 680 potentiometric recorder.

Standard gas concentrations were obtained either from cylinders or from permeation tubes. Cylinders of natural gas, CO, N_2O and COS diluted with air were obtained from Matheson Gas Products Co., H_2S and NO diluted with N_2, NO_2 and SO_2 diluted with air, and pure air ("zero air") were obtained from Airco Inc. Permeation tubes of H_2S, CH_3SH, C_2H_5SH and $(CH_3)_2S$ were obtained from Metronics Associates, Inc.

RESULTS AND DISCUSSION

The operating characteristics of both instruments and of the twenty electrochemical sensors used at one time or another in these instruments were similar. The data presented here are typical. Of necessity the larger instrument was always operated from a.c. while the smaller was operated from a.c. or d.c. No difference was observed between a.c. or d.c. operation as long as the batteries were maintained in a state of charge.

Instrument response time

Hydrogen sulphide is oxidized electrolytically in the instruments, and after introduction of a sample, the current generated rapidly reaches a steady-state value, i_l. Table 1 lists the elapsed times between admittance of the test gas and the attainment of 95% of i_1 (t_r), and between removal of the test gas and the decay of the steady-state signal to 5% of i_1 (t_d). The response was observed to quicken as the hydrogen sulphide concentration was increased.

The reaction of hydrogen sulphide at the catalytic surface comprises a series of discrete steps with several possible intermediates. Both SO_2 and SO_3^{2-} were readily electro-oxidized when introduced into the sensor, and therefore, it was concluded that the final reaction product of electro-oxidation of hydrogen sulphide was sulphuric acid, the reaction at the sensing electrode being

$$H_2S + 4H_2O \rightarrow H_2SO_4 + 8H^+ + 8e \qquad (1)$$

Table 1. Signal response and decay times

n_0, ppm H_2S	t_r, sec	t_d, sec	t_d/t_r
0·38	39	28	0·72
11	17	12	0·71
130	11	8	0·73

The reaction at the counter-electrode was

$$O_2 + 4H^+ + 4e \rightarrow 2H_2O \qquad (2)$$

thus giving an overall reaction of

$$H_2S + 2O_2 \rightarrow H_2SO_4 \qquad (3)$$

Previous work[12] showed that the response of the diffusion electrode to carbon monoxide followed a first-order law according to equations (4) and (5)

$$\text{signal rise: } i = i_1(1 - e^{-\lambda t}) \qquad (4)$$

$$\text{signal decay: } i = i_1 e^{-\lambda t} \qquad (5)$$

where i is the current (signal) at any time t, and λ is the sensor response-time constant. With carbon monoxide[11] λ was similar for signal rise and decay, and independent of the concentration.

In contrast, i–t results for 0·38, 11 and 130 ppm of hydrogen sulphide could not be fitted to either equation (4) or equation (5). The signal rise and decay for hydrogen sulphide were therefore described in terms of a second-order rate-law subject to boundary conditions) signal rise: $i = 0$ at $t = 0$ and $i = i_1$ as $t \rightarrow \infty$; signal decay: $i = i_1$ at $t = 0$ and $i = 0$ as $t \rightarrow \infty$. Then the sensor response characteristics are:

$$\text{signal rise: } di/dt = k_r(i_1 - i)^2 \qquad (6)$$

$$\text{signal decay: } di/dt = k_d i^2 \qquad (7)$$

As discussed below, i_1 was directly proportional to the hydrogen sulphide concentration, n_0. Thus, i_1 and n_0 can be substituted for one another without loss of generality except that the units of the rate constants k_r and k_d will change. Integration of equations (6) and (7) yields

$$\text{signal rise: } \frac{i_1}{i} = \frac{1}{n_0 k_r t} + 1 \qquad (8)$$

$$\text{signal decay: } \frac{i_1}{i} = n_0 k_d t + 1 \qquad (9)$$

Least-squares analyses of rise and decay data for a 0.38-ppm H_2S sample yielded equations (10) and (11)

$$\frac{i_1}{i} = 0.987 + 0.204/t; \qquad k_r = 1.29\,\text{sec}^{-1}.\text{ppm}^{-1} \qquad (10)$$

$$\frac{i_1}{i} = 0.982 + 0.744t; \qquad k_d = 1.96\,\text{sec}^{-1}.\text{ppm}^{-1} \qquad (11)$$

which are in good correspondence with theoretical equations (8) and (9). The instrument response to 11-ppm and 130-ppm H_2S samples was too fast for accurate abstraction of i–t data points from recorder traces. However, the variation of t_r and t_d with n_0 (Table 1) also suggests that k_r and k_d are dependent on n_0.

The linearity of the i_1/i *vs.* $1/t$ plots, and the observations that $t_d < t_r$ (Table 1) and that t_r and t_d decrease with increasing n_0 (Table 1) demonstrate that the overall electrochemical process is indeed a second-order reaction and that the rate can be represented by equations (6) and (7). This is in contrast to the first-order kinetics observed for electro-oxidation of carbon monoxide.

The rapid response of these instruments to hydrogen sulphide is important since high levels of this gas can be fatal in a short time (seconds). We have no explanation for the invariance of the t_d/t_r ratio with the concentration (Table 1). However, this does demonstrate the consistency of the data.

Relationship between signal and H_2S concentration

The relationship between signal and hydrogen sulphide concentration was studied in the concentration ranges 0–0·277 ppm and 0–153 ppm.

Seven concentrations in the range 0–0·277 ppm were prepared by using a permeation tube. The instrument was calibrated with the 0·277 ppm mixture, and readings were taken with the more dilute samples. Y (ppm H_2S found) was fitted to the following least-squares line as a function of X (ppm H_2S taken):

$$Y = 0{\cdot}0003 + 0{\cdot}9702\,X \qquad (11)$$

The standard deviation of the points from the line was only ±0·007 ppm H_2S.

A more elaborate set of measurements was taken over the 0–153 ppm range. Twenty-five (X, Y) data points obtained with four different sensors were fitted to the least-squares line

$$Y = 1{\cdot}02 + 0{\cdot}944\,X \qquad (12)$$

In this case the standard deviation was ±0·97 ppm H_2S. Both standard deviations include the uncertainties of sample preparation.

It is evident, therefore, that the signal is directly proportional to the H_2S concentration in the range tested.

Signal stability

Figure 2 shows the zero drift (expressed as ppm H_2S) of an instrument over 23 days. During this period the instrument was operated continuously on laboratory air and measurements were made only in the periods marked in the figure.

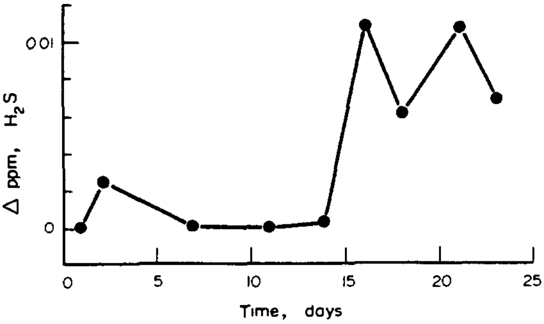

Fig 2. Cumulative zero drift on portable hydrogen sulphide analyser (no rezeroing of instrument during the 23-day period).

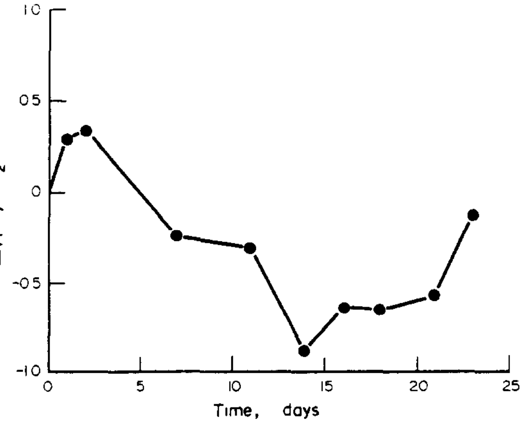

Fig. 3. Cumulative span drift on portable hydrogen sulphide analyser (no recalibration of instrument during the 23-day period). The same 30-ppm H_2S test gas was used for all measurements.

The results show that zero drift was insignificant over this period. In fact for a 0–1-ppm H_2S instrument the maximum zero drift was 0·5% of full scale per 24 hr (clearly the relative drift would be even lower for higher range instruments).

On the first day of these tests, the signal was also recorded for a mixture with 30 ppm hydrogen sulphide, and this measurement was repeated during the test period. The drift in the sensitivity is shown in Fig. 3. The weighted average signal, $\bar{n}_0$, was 29·7 ppm H_2S over the complete testing interval. The maximum change in sensitivity over a 24-hr period was always less than 1% of the signal.

In a series of short-term measurements, a 130-ppm hydrogen sulphide mixture was passed into the instrument for 20 min (maximum time possible with the Mylar sample bag used). The bag was then removed and within 3 sec a new one was connected. Forty-eight measurements were made on the recorder traces from a 90-min period to assess steady-state current-output fluctuations. The standard deviation of i_1 was ±0·54 ppm or ±0·42% relative.

These results show that the instrument does not need to be zeroed and calibrated frequently to ensure a satisfactory degree of accuracy.

Specificity of instrument response

The instrument is quite selective towards hydrogen sulphide, as shown by the results of interference studies shown in Table 2. These other gases are either common atmospheric pollutants or may be present at H_2S sources.

TABLE 2. RESPONSE TO SELECTED INTERFERENTS

Interference gas	Concentration tested, *ppm*	Concentration required to give signal equivalent to 1 ppm H_2S, *ppm*
CO_2	3000	No signal obtained
CH_4	95%	No signal obtained
C_2H_2	10	27
C_2H_4	15	No signal obtained
NO	41	7
NO_2	4	40
N_2O	100	No signal obtained
SO_2	11	8
CO	900	2000
CH_3SH	2	3
C_2H_5SH	1	3
$(CH_3)_2S$	1	No signal obtained
COS	22	No signal obtained

The potential interferent gas was introduced at a known concentration into the instrument under the same conditions used for the measurement of hydrogen sulphide. Further, a sample of natural gas was spiked with 0·5 ppm of hydrogen sulphide, and then was found to give the same signal as a 0·5-ppm mixture in air or nitrogen. None of the gases listed in Table 2 is as electrochemically active as hydrogen sulphide in the sensor and no gas filter was required to obtain this specificity.

ION-EXCHANGER COLORIMETRY—I

MICRO DETERMINATION OF CHROMIUM, IRON, COPPER AND COBALT IN WATER

KAZUHISA YOSHIMURA, HIROHIKO WAKI and SHIGERU OHASHI
Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka, Japan

(*Received* 8 *July* 1975. *Revised* 23 *September* 1975. *Accepted* 20 *November* 1975)

Summary—A new, sensitive, colorimetric method based on the direct measurement of light-absorption by an ion-exchange resin phase, which has sorbed the sample complex species, has been developed. Determinations of chromium(VI) with diphenylcarbazide, iron(II) with 1,10-phenanthroline, copper with Zincon and cobalt with thiocyanate have more than ten times the sensitivity obtainable with conventional solution colorimetry. The present method can be applied to natural water samples containing very low levels of these metals.

A spot-test with ion-exchange resin beads has been proposed by Fujimoto,[1] and by Kakihana and his co-workers.[2] This technique has various advantages for qualitative microanalysis. In this method, concentration and selective sorption of the chemical species to be identified may occur simultaneously. In some cases, the sample species are converted into complex anions of higher ligand number within an anion-exchange resin phase, leading to remarkable enhancement of the sensitivity.

In spite of a number of publications on the resin spot-test[3–8] and on the interpretation of resin-phase absorption spectra of the inorganic complexes,[9–13] no papers on the quantitative analytical application of these resin-phase spectra could be found. A new spectrophotometric microanalytical method, based on the direct measurement of the resin-phase absorbance after the sorption of sample species, has been developed for the determination of some transition metals.

In acid solution[14] diphenylcarbazide forms a soluble, red-violet cationic complex with sexivalent chromium, having a metal-ligand molar ratio of 3:2. This reaction has been utilized for the micro determination of chromium.[15] 1,10-Phenanthroline is known as a sensitive reagent for the colorimetric determination of iron. The very stable red complex cation $\mathrm{Fe(phen)_3^{2+}}$ is formed in weakly acidic, neutral and weakly alkaline media. A sensitive colorimetric method for copper with Zincon (2-hydroxy-5-sulphophenylazobenzylidenehydrazinobenzoic acid) was reported by Rush and Yoe.[16] They succeeded in determining zinc and copper in mixtures by appropriate adjustment of the pH. The spot-test for cobalt(II) with anion-exchange resin beads and ammonium thiocyanate was proposed by Fujimoto.[1] This test was very sensitive and specific.

The present paper describes the application of these colour reactions to quantitative studies on ion-exchange resins.

EXPERIMENTAL

Absorption measurements on the resin phase

The following ion-exchange resins were used, depending upon the mechanism of the colour development: Dowex 50 W-X2, $\mathrm{H^+}$-form (50–100 mesh and 100–200 mesh); Dowex 1-X2, $\mathrm{Cl^-}$-form (100–200 mesh). The mixture of resin, sample solution and reagent was shaken mechanically. The coloured resin beads were separated from the bulk solution and packed together with a small volume of the solution into a 1-mm quartz cell, by means of a pipette. The absorbance was measured with a Hitachi recording spectrophotometer, Model EPS-3T, a perforated metal plate being used as a neutral density filter (of absorbance 2.0) in the reference beam to balance the light intensities.

From the observed absorbance A at a given wavelength, the net absorbance A_{RC} of the complex species sorbed on the resin can be obtained from the equation

$$A_{\mathrm{RC}} = A - A_{\mathrm{soln}} - A_{\mathrm{R}} - A_{\mathrm{RL}} \qquad (1)$$

where A_{soln} represents the absorbance of the interstitial solution between the resin beads, A_{R} that of the resin background and A_{RL} that of the reagent in the cell. The absorbance due to the sample complex in the interstitial liquid may be neglected. The values of A_{RC}, A_{R} and A_{RL} are affected by the packing of the resin beads because of the change in path-length or scattering behaviour in the cell. The packing should therefore be reproducible. The following procedure was found to be adequate. The absorption spectrum of a resin layer containing no coloured species was measured against pure water. The absorbance at two different wavelengths, one corresponding to the absorption maximum of the coloured species and the other in a region where the resin alone absorbs (700–800 nm) was read from the chart. The absorbance difference may be assumed to be constant under the similar packing conditions. In practice, A_{R} at 700 or 800 nm was constant to within ±0.025. The value of A_{R} at the absorption maximum, in equation (1), was calculated from the absorbance difference and the measured value of A_{R} at 700 or 800 nm. Thus the net absorbance A_{RC} can be obtained by subtracting A_{R} from the overall absorbance. When A_{RL} cannot be neglected, $A_{\mathrm{RC}} + A_{\mathrm{RL}}$, instead of A_{RC}, is obtained by the same treatment.

Procedure for the determination of chromium(VI) with diphenylcarbazide

To a 200-ml water sample containing 0.01–0.3 μmole of chromium(VI), enough $5N$ sulphuric acid was added to make the concentration of this acid approximately $0.05N$. Then 5 ml of 0.25% acetone solution of diphenylcarbazide and 0.50 g of Dowex 50W-X2 (100–200 mesh) in the hydrogen form were added. The mixture was stirred for 15 min and the supernatant solution discarded, the residual resin slurry transferred to the cell and the absorbance measured at 550 nm.

Procedure for the determination of iron with 1,10-phenanthroline

To a 200-ml water sample containing 0.1–2 μmole of iron, 5 ml of $0.01M$ 1,10-phenanthroline, 5 ml of 10% hydroxylamine solution, 5 ml of $0.5M$ acetic acid–sodium acetate buffer (pH 5) and 0.50 g of Dowex 50W-X2 in the hydrogen form (100–200 mesh) were added and the mixture was stirred for 30 min. The coloured resin was collected and its absorbance measured at 514 nm.

Procedure for the determination of copper(II) with Zincon

To a 200-ml water sample containing 0.1–1 μmole of copper(II), 10 ml of $0.2M$ potassium hydrogen phthalate–sodium hydroxide buffer (pH 5.2) and 0.50 g of Zincon-treated resin were added and the mixture was stirred for 30 min. The resin was collected and its absorbance measured at 630 nm. The Zincon-treated resin was prepared by shaking 30 g of Dowex 1-X2 in the chloride form (100–200 mesh) with 50 ml of 0.1% Zincon–$0.02M$ sodium hydroxide solution for 1 hr.

Procedure for the determination of cobalt(II) with thiocyanate

To a 1000-ml water sample containing 2–20 μmole of cobalt(II), 20 ml of 50% ammonium thiocyanate solution and 0.50 g of Dowex 1-X2 in the chloride form (100–200 mesh) were added and the mixture was stirred for 30 min. The blue resin was collected and its absorbance measured at 630 nm.

All chemicals used were of analytical grade and all experiments were carried out at room temperature.

RESULTS AND DISCUSSION

Absorption spectra in resin and solution

The complex of chromium(VI) with diphenylcarbazide can be sorbed on cation-exchange resins and to some extent on anion-exchange resins by molecular interaction as well as by ion-exchange. The net absorbance curve of the sorbed complex was constructed from the difference between the resin phase curve and the resin background curve. The net resin-phase absorption spectrum of the complex is similar to that obtained in solution but the maximum is shifted to longer wavelengths (550 nm), as shown in Fig. 1. For quantitative studies the cation-exchange resin Dowex 50W-X2 (100–200 mesh) was used in $0.05N$ sulphuric acid medium.

Only cation-exchange resins sorb the iron(II)-1,10-phenanthroline complex and give the same absorption spectrum as that of an aqueous solution.

The Zincon complex of copper(II) has a molar ratio of 1:1 and has an absorption maximum at 600 nm in solution. The maximum for free Zincon is at 470 nm. When both species are sorbed on anion-exchange resins, the maxima shift to 630 and 570 nm respectively (Fig. 2). These maxima are so close that the combined spectrum usually exhibits only a shoulder at 630 nm. Consequently the absorbance at 630 nm may include a contribution from free Zincon. The copper–Zincon complex is not sorbed on anion-exchange resins from acidic solution, but the Zincon reagent is sorbed irreversibly from alkaline solution. The resin containing presorbed Zincon reagent was therefore added to acidic water samples. The excess

of uncomplexed Zincon was not desorbed during the equilibration.

Figure 3 shows the absorption spectrum of the cobalt(II)-thiocyanate complexes sorbed on the anion-exchange resin, together with spectra of the solutions for comparison. It may be seen that the resin spectrum is similar to that obtained with solutions in which the thiocyanate concentration is as high as $8M$ even when the thiocyanate concentration in the equilibrating solution is as low as $0.7M$. The tendency of the complex to change to one with higher ligand numbers in the anion-exchange resin phase may be exploited.

Time-dependence of colour development

Almost all of the chromium in 200 ml of sample solution is sorbed on the resin within 15 min equilibration (Fig. 4). The presence of other electrolytes, such as sodium chloride (at the concentration level found in sea-water) has no effect on the sorption rate of the complex. The chromium concentration can be determined with the aid of a calibration curve constructed by use of a fixed equilibration time, even though the sorption of chromium is not complete. Figure 4 also shows that the use of resin particles of larger size leads to a slower sorption rate. Equilibrium with Dowex 50W-X1 (50–100 mesh) and 200 ml of solution took more than 1 hr to reach.

The complete sorption of copper requires a long time, probably because of the slow rate of internal diffusion of the complex in the particles (Fig. 5). For rapid analysis it is convenient to equilibrate until just after the early sorption stage.

A study of the rate of development of the colour of the cobalt-thiocyanate complex indicates that with large sample volumes a longer equilibration time is required for quantitative sorption, but the sensitivity is increased (Fig. 6). There is no limitation upon the size of sample volume taken, but a large volume requires a longer equilibration time. The calibration curve should be prepared under the conditions used for the sample to be analysed.

Calibration

The calibration graph for chromium is reasonably linear in the concentration range 5×10^{-8}–$1.5 \times 10^{-6}M$, that for iron in the range

5×10^{-7}–$1 \times 10^{-5}M$, that for copper in the range 5×10^{-7}–$5 \times 10^{-6}M$ and that for cobalt in the range 2×10^{-6}–$2 \times 10^{-5}M$. Deviations are about ±5–10%.

Sensitivity

In Table 1 the sensitivity for each system is compared with that obtained with a conventional colorimetric method. The concentrations giving an absorbance of 0.50 are listed. In each case the sensitivity was about ten times that for conventional colorimetry.

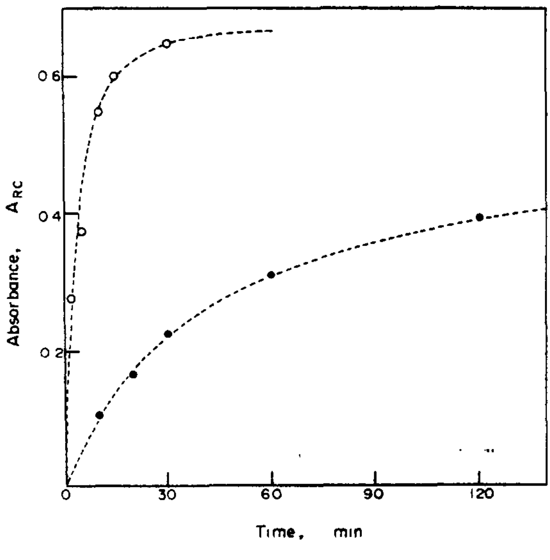

Fig. 6. Colour development of cobalt–thiocyanate complexes in the anion-exchange resin phase. Resin, Dowex 1-X2 (100–200 mesh, Cl^--form) 0.50 g. Solution, ● 6 μmole Co(II), 1000 ml + 50% NH_4SCN, 20 ml, ○ 6 μmole Co(II), 100 ml + 50% NH_4SCN, 10 ml.

Effects of foreign ions

Most metals which interfere in the colorimetric determination of chromium, such as vanadium(V), iron(III) and molybdenum(VI) did not interfere when present in up to one hundred times the concentration of chromium(VI). Table 2 shows that, with the exception of copper, errors in the range of 5–10% are obtained.

Iron(III), cobalt(II) and nickel(II) ions were found to interfere in the determination of copper when their concentrations exceeded ten times that of the copper (Table 3).

Table 4 shows the effects of several ions on the determination of cobalt(II). Iron(III) and high concentrations of alkali caused considerable interference.

Applications of ion-exchanger colorimetry

The present method may be applied to the analysis of natural water samples such as sea, river and lake water. The error of 5–10% is not excessive for the

COMPARISON OF FIGURES OF MERIT FOR FLUORIMETRIC ANALYSIS OF RHODAMINE COMPLEXES OF GALLIUM AND INDIUM BY EXCITATION WITH PULSED LASER AND BY XENON ARC SOURCES[*]

N. B. Zorov,[†] T. F. van Geel and J. D. Winefordner
Department of Chemistry, University of Florida, Gaineswille, Fl. 32611, U.S.A.

(*Received* 3 *April* 1975. *Accepted* 11 *September* 1975)

There are several reviews concerning the absorption and fluorescence spectrometric determination of gallium and indium by means of Rhodamine dyes.[1-3] The sensitivity of measurement of these complexes[4-6] and the optimum conditions for extraction and measurement of trace concentrations of indium *via* Rhodamine complexes[2, 7-9] have also been reported. Hitherto, there have been no reports on the optimization of experimental conditions in fluorimetry in order to obtain the best detection limits. In the present study, two different arrangements are used to determine analytical figures of merit for indium and gallium Rhodamine dye complexes: (*i*) a commercial spectrophotofluorimeter with a special high-intensity xenon source, and (*ii*) a fluorimetric system with a pulsed nitrogen laser as the excitation source (at 337·1 nm).

EXPERIMENTAL

Reagents

Rhodamine B and Rhodamine 6G were purified;[10] 1·5 × 10^{-5}*M* solutions of each dye in either water or 6*M* hydrochloric acid were prepared Hydrochloric (6*M*) and sulphuric acid (7·5*M*) solutions were prepared from the reagent grade concentrated acids; hydrobromic acid was redistilled and diluted with distilled water to prepare a 2*M* solution. Thiophene-free benzene was used for the extraction studies.

A standard gallium stock solution was prepared by dissolving 116·2 mg of gallium metal (99·999% pure) in 20 ml of 6*M* hydrochloric acid and diluting to 50·0 ml. A more dilute standard solution containing 0·02 ppm of gallium was prepared by dilution of the stock solution with 6*M* hydrochloric acid.

A standard indium stock solution was prepared by dissolving 388·5 mg of indium metal (99·999% pure) in 20 ml of hydrobomic acid with heating, and then diluting to 50·0 ml. A more dilute standard solution containing 0·02 ppm of indium was prepared by dilution of the stock solution with 2*M* hydrobromic acid.

Apparatus

Spectrofluorimeter. An Aminco–Bowman spectrophotofluorimeter with a 10-mm sample cell was used. An EIMAC (VIX-150-UV, Eimac Division, San Carlos, CA 94070) xenon arc lamp with integral reflector and powered by an EIMAC power supply replaced the conventional AMINCO source assembly. A potted Hamamatsu 1P21 multiplier phototube was powered by a separate high-voltage power supply. The photoanodic currents were measured with a low-noise nanoammeter.[11]

The pulsed nitrogen laser fluorescence system consisted of a 100-kW pulsed nitrogen laser (C950, AVCO Research Lab.) focussed onto the solution in a 10 × 10 mm quartz cuvette placed directly in front of a 250-mm focal length monochromator (EU-700, GCA/McPherson Instrument). An RCA 1P28 photomultiplier tube and boxcar integrator (Model 160, Princeton Applied Research Corp.) were used to process the pulsed signals, and a potentiometric recorder (Servoriter II, Texas Instrument), was used for the read-out. Flat, front-surface mirrors were used to obtain an additional pass of the laser pulse through the sample solution and to increase the fluorescence signal. In Fig. 1, a block diagram of the system is given.

Procedures

Determination of gallium. The analytical calibration curve is prepared by adding gallium (0·02, 0·04, 0·06, 0·08 μg) to 60-ml separating funnels, adding 0·5 ml of Rhodamine B (or Rhodamine 6G) solution in 6*M* hydrochloric

acid and then sufficient $6M$ hydrochloric acid to make the final volumes about 5 ml. The solutions are shaken to mix them thoroughly, then 5 ml of benzene are added, and the mixture is again thoroughly shaken for 1 min. After the organic solvent phase separates (about 10 min), the mixture is centrifuged at 3000 rpm for 4 min. The fluorescence signal of the benzene extract is measured (1 × 1 cm quartz cuvette).

Determination of indium. The analytical calibration curve is prepared by adding indium (0·1, 0·02, 0·03, 0·04 μg) to 60-ml separating funnels, followed by 0·5 ml of Rhodamine B (or Rhodamine 6G) solution in water, 5 ml of $7{\cdot}5M$ sulphuric acid and enough hydrobromic acid to make the final volume 7·5 ml. The solution is shaken to mix it thoroughly, 5 ml of benzene are added, and the mixture is thoroughly shaken for 1 min; the mixture is centrifuged as for gallium, and the fluorescence signal of the resulting benzene layer is measured.

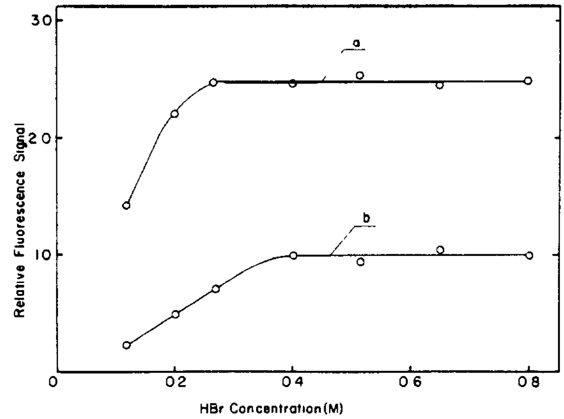

Fig. 2. Fluorescence signal of extracts of bromide complexes of indium with Rhodamine 6G (a) and Rhodamine B (b) as a function of hydrobromic acid concentration.

RESULTS AND DISCUSSION

Optimum conditions for extraction and measurement of gallium and indium

The extraction and measurement conditions for gallium were identical to those given previously,[12] but those for the indium complexes were examined in the present work.

Effect of acidity. The maximum fluorescence signal was obtained with Rhodamine B when the indium solution was made $5M$ in sulphuric acid before extraction; similar results were previously[13] obtained with Rhodamine 6G.

Effect of bromide concentration. The influence of hydrobromic acid concentration on the measured fluorescence signals of the indium-Rhodamine complexes is given in Fig. 2. For hydrobromic acid concentrations greater than about $0{\cdot}4M$, the fluorescence signals reached a plateau. For further comparative studies, a hydrobromic acid concentration of $0{\cdot}53M$ was chosen.

Fluorimetric limits of detection for gallium and indium

The limits of detection for gallium and indium Rhodamine B and Rhodamine 6G complexes obtained with the xenon arc source as well as with the pulsed nitrogen laser were determined and are listed in Table 1. For the continuum xenon source, the slope a and intercept b for the straight line analytical curves ($y = a + bx$) were determined as well as the standard deviation of the blanks (signal level), and these values are also listed in Table 1. The limits of detection for gallium and indium with Rhodamine 6G are lower by a factor of 5–8 than those of the best fluorimetric methods previously reported.[4,14] The two different excitation–detection methods that were used give comparable detection limits. However, the work of Smith *et al.*[15] and the present work with the simple nitrogen laser[16] system indicates the potential usefulness of laser excitation sources for fluorimetric measurements of molecules in the condensed phase.

ANALYTICAL APPLICATIONS OF ORGANIC REAGENTS IN HYDROPHOBIC GEL MEDIA—II

SELECTIVE PRECONCENTRATION OF MERCURY(II) WITH DITHIZONE OR THIOTHENOYLTRIFLUOROACETONE GEL[*]

(*Received* 3 *September* 1975. *Accepted* 9 *October* 1975)

In a previous paper,[1] we reported the potential use of dithizone gel beads for the selective trapping of mercuric ion from aqueous samples. Although dithizone is labile, its zinc chelate is very stable during prolonged storage on gel beads. In this easily prepared form it is a good extractant for mercuric ion. Other sulphur ligands, such as thiothenoyltrifluoroacetone (STTA)[2], are also effective for gel extraction of the same metal ion.

Mercury trapped on the gel-bead column can be back-extracted with a hydrogen halide solution, with a concentration factor of 100–200.

In this paper, we report a more detailed study on dithizone and STTA gel columns, and the back-extraction of mercury. Mercury in synthetic or natural sea-water at the ppm or ppM level, has been successfully preconcentrated by the proposed procedure.

EXPERIMENTAL

Reagents

Thiothenoyltrifluoroacetone [1,1,1-trifluoro-4-(2-thienyl)-4-mercaptobut-3-en-2-one] obtained commercially was used without further purification. Dithizone (analytical grade) and zinc dithizonate (laboratory preparation[3]) were recrystallized from chloroform. All other reagents were of analytical grade.

Procedures

Preparation of the gel beads and the column. Polystyrene beads (2% divinylbenzene)[§] were washed with acetone until the extract became colourless, dried at 110° for 24 hr and finally sieved to yield 80–100 mesh particles. The dry polymer beads (2 g) were soaked in 10 ml of a chlorobenzene solution containing 0·05–0·07% zinc dithizonate [$Zn(HDz)_2$] or 0·05% thiothenolytrifluoroacetone, for 24 hr at room temperature. The gel beads, after centrifugation, were suspended in water and packed into a glass tube (1·1 cm^2 × 25 cm) to give a column of 10 cm height. The interstitial volume of the column was 5·5–6 ml. Thus, the ratio of stationary to mobile phase is approximately 1, implying that the gel column extraction may be regarded as a multi-step extraction process between equal volumes of the two phases.

Column operation. All aqueous solutions to be passed through the column were presaturated with chlorobenzene.

The aqueous solution containing a known amount of metal ions was passed through the column at a given rate, and the effluent was collected in 10-ml fractions, which were analysed for metal ions (mercury with dithizone,[4] copper and zinc by atomic-absorption spectrophotometry at 324·7 and 213·9 nm respectively).

Mercury was back-extracted from the column with either 1*M* hydrobromic acid or 8*M* hydrochloric acid in the case of dithizone gel, and with sulphuric acid–potassium bromide solution (40 ml of 0·05*M* H_2SO_4 plus 10 ml of 10% KBr solution) in the case of STTA gel. The effluent was collected in 10-ml fractions, in which the mercury was determined with dithizone at pH 5–6.[4]

RESULTS AND DISCUSSION

The purpose of this investigation was to concentrate mercuric ion selectively from a very dilute aqueous solution onto the gel-bead column containing chelating agents of high selectivity for mercuric ion, and to recover it from the column by back-extraction into the aqueous phase for the final mercury determination.

Since our preliminary report on the use of the dithizone gel column,[1] we have used polystyrene gel beads rather than dibenzalsorbitol gel particles, because they result in more reproducible column performance.

Dithizone and thiothenolytrifluoroacetone[2] were chosen as the chelating agents because these were known to be highly selective for mercuric ion at low pH, and to have a high distribution ratio.

Dithizone gel

The poor durability of the free dithizone gel used earlier has been improved by using the zinc chelate.

At pH 1, the reactions proceed in two steps:

$$[Zn(HDz)_2]_g + 2[H^+]_w = [H_2Dz]_g + [Zn^{2+}]_w$$

$$[H_2Dz]_g + [Hg^{2+}]_w = [Hg(HDz)_2]_g + 2[H^+]_w$$

where H_2Dz represents dithizone, and suffixes g and w indicate the gel and aqueous phases, respectively. The colour change on the column and the analysis of the effluent support this reaction scheme.

The original pink colour of the zinc dithizonate gel turned to blue instantaneously as the acidic sample solution flowed through the column, then an orange zone of mercury dithizonate appeared gradually from the top of the column. Almost all the zinc on the column was eluted in the first few fractions of effluent, whereas the breakthrough of mercury was observed after conversion of the gel into the mercury complex form was complete, as shown in Fig. 1.

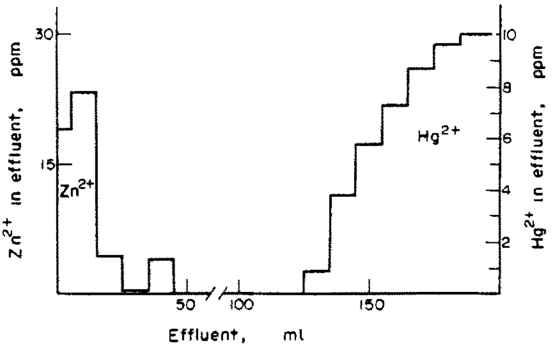

Fig. 1. Extraction of mercury(II) with zinc dithizonate gel column at pH 1.
Gel soaked with 0·068% $Zn(HDz)_2$ solution, flow-rate 1·5 ml/min.

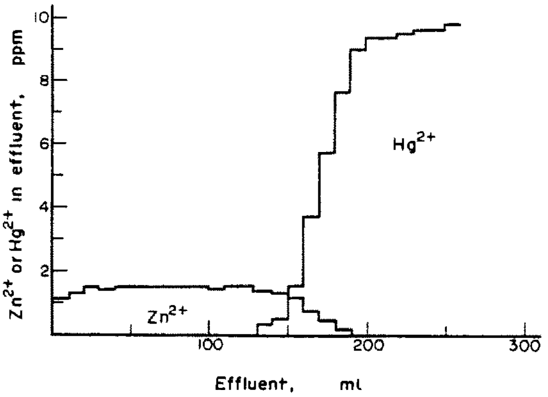

Fig. 2. Extraction of mercury(II) with zinc dithizonate gel column at pH 5·6.
Gel soaked with 0·046% $Zn(HDz)_2$ solution; flow-rate 1·5 ml/min.

At higher pH (5·6), however, the mercuric ion was extracted by direct exchange:

$$[Zn(HDz)_2]_g + 2[Hg^{2+}]_w = [Hg_2Dz_2]_g + [Zn^{2+}]_w + 2[H^+]_w$$

As the reaction proceeded, zinc ion was gradually released from the column whilst the mercuric ion was being extracted mainly as the secondary complex. Accordingly, the original pink colour of the column turned to orange-red from the top. This reaction scheme is also supported by the results shown in Fig. 2.

Mercuric ion extracted as the primary complex at low pH could be easily back-extracted by simply eluting with 1*M* hydrobromic acid or 8*M* hydrochloric acid, by analogy with the batch extraction process.[4] However, mercury extracted as the secondary complex, could not easily be back-extracted with these eluents.

Thus, extraction at low pH was preferable for preconcentration of traces of mercury, because of the higher selectivity as well as the quantitative recovery of mercury by the back-extraction, although the extraction capacity is only about half that at the higher pH.

The selectivity of dithizone for mercury becomes higher as the pH is decreased, and only metal ions such as palladium, silver, copper and mercury are complexed in a fairly acid (0·1–0·5*N*) solution.[4] On the other hand, the interference from halide ions becomes serious with decreasing pH. For example, the extraction of mercury from sea-water is quantitative at pH 2 but incomplete at pH 1.

Table 1 illustrates the preconcentration of mercury from synthetic and natural sea-waters spiked with a trace level of mercury. Sample solution, adjusted to pH 2 with sulphuric acid, was passed through the column, and after extraction, the column was treated either with 1*M* hydrobromic acid or 8*M* hydrochloric acid. As shown in the table, hydrobromic acid is more effective as a back-extractant than hydrochloric acid, because less is required for the quantitative recovery of mercury.

Under these conditions, copper may also be extracted by the gel. However, it remains on the column when mercury is back-extracted with 1*M* hydrobromic acid, because of the relatively low formation constant of tetrabromocopper(II) ($\beta_4 = 10^8$ for $CuBr_4^{2-}$ and $\beta_4 = 10^{21}$ for $HgBr_4^{2-}$).[5]

STTA gel

The extraction behaviour of mercuric ion with STTA has been investigated in some detail,[6,7] and the selectivity of STTA for heavy metal ions was found to be similar

to that of dithizone. Thus, mercuric ion can be selectively extracted with STTA from $\geq 1N$ sulphuric acid.

The capacity of the STTA gel column increased linearly with increasing concentration of STTA in the range 6–20 × $10^{-3}M$, indicating the formation of a 1:2 (metal: ligand) chelate. With $0{\cdot}02M$ STTA gel, an extraction capacity of 4·5 μeq/ml of gel bed was obtained. At a much higher STTA concentration, such as $0{\cdot}1M$, some STTA tends to leak into the aqueous phase during the column operation, although a higher extraction capacity such as 19 μeq/ml is attained, a value comparable with that obtained on the dithizone-impregnated polyurethane foam column.[8]

The stability constant of Hg–STTA seems to be slightly lower than that of mercury dithizonate, because mercury can be back-extracted from the STTA gel column with a mixture of 40 ml of $0{\cdot}05M$ sulphuric acid and 10 ml of 10% potassium bromide solution. This eluent will not back-extract mercury from the dithizone gel.

When up to 500 μg of mercury on the column is eluted with this mixture at a flow-rate of 1·5 ml/min, all the mercury is found in the first 50 ml of effluent.

The lower stability constant of the mercury STTA complex also means that the interference from halide ions is more serious. Thus, with the STTA gel quantitative extraction and recovery of mercury from sea-water required a pH $\geq$ 4.

Table 2 shows the result of the preconcentration of mercury from synthetic and natural sea-waters spiked with a low level of mercury. Samples were adjusted to pH 4 with sulphuric acid and passed through the column at a flow-rate of 1·5 ml/min. The rather poor recovery for 0·05 ppm Hg or less may be due to loss of mercury from the sample solution during storage, which is often experienced with very dilute mercury solutions.[9]

Summary—Mercury(II) at the sub-ppm level is selectively trapped on a column packed with cross-linked polystyrene gel beads soaked with zinc dithizonate or thiothenoyltrifluoroacetone. Mercury trapped on the beads can be back-extracted into the aqueous phase with a hydrogen halide solution. Mercury in sea water at ppm or ppM level has been successfully preconcentrated by this procedure.

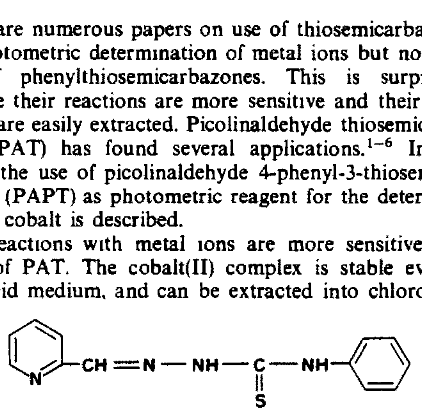
PICOLINALDEHYDE 4-PHENYL-3-THIOSEMICARBAZONE AS A SPECTROPHOTOMETRIC REAGENT FOR THE SELECTIVE DETERMINATION OF SMALL AMOUNTS OF COBALT IN THE PRESENCE OF IRON

J. L. Gomez Ariza, J. M. Cano Pavon and F. Pino
Department of Analytical Chemistry, Faculty of Sciences, University of Seville, Seville, Spain

(*Received* 4 *October* 1974. *Revised* 21 *July* 1975. *Accepted* 30 *November* 1975)

There are numerous papers on use of thiosemicarbazones for photometric determination of metal ions but none on use of phenylthiosemicarbazones. This is surprising, because their reactions are more sensitive and their complexes are easily extracted. Picolinaldehyde thiosemicarbazone (PAT) has found several applications.[1–6] In this paper, the use of picolinaldehyde 4-phenyl-3-thiosemicarbazone (PAPT) as photometric reagent for the determination of cobalt is described.

Its reactions with metal ions are more sensitive than those of PAT. The cobalt(II) complex is stable even in very acid medium, and can be extracted into chloroform.



PAPT

The classical reagents[9] for determining cobalt have various disadvantages. In recent years, numerous spectrophotometric determinations of cobalt have been proposed[10,11] but none has entirely solved the problem.

EXPERIMENTAL

Reagents

Picolinaldehyde 4-phenyl-3-thiosemicarbazone solutions. Make 0.1 and 0.05% w/v solutions in dimethylformamide, and 0.05% in chloroform.

Standardized cobalt solution.

Buffer solution, pH 4.7. Dissolve 56.0 g of sodium acetate and 25.0 ml of glacial acetic acid in water and dilute to a litre.

Dowex 50-X8 resin, sodium form.

All solvents and reagents were of analytical grade.

Synthesis of the reagent

4-Phenyl-3-thiosemicarbazide (4.6 g) was dissolved in 150 ml of hot ethanol and added to 3.0 g of picolinaldehyde in 35 ml of ethanol. The mixture was refluxed for 2 hr, and allowed to cool to room temperature. The yellow crystalline product was filtered off and recrystallized from ethanol. The yield was >80% (m.p. 204–205°: found C 60.8%, H 4.6%, N 21.8%, S 12.8%; calculated for $C_{13}H_{12}N_4S$; C 60.91%, H 4.71%, N 21.85%, S 12.50%).

Properties of the reagent

PAPT is sparingly soluble in water, moderately soluble in chloroform (4.01 g/l.), ethanol (2.91 g/l.), methanol (4.43 g/l.) and nitrobenzene (9.36 g/l.), and very soluble in dimethylformamide (168.20 g/l.) at room temperature.

Infrared spectra were obtained (KBr discs), and the bands assigned (cm^{-1}) to the stretching vibrations of —NH— (3300 s and 3110 m) >C=N (1595 s and 1540 s), and >C=S (1105, 1075, 1040 m and 835 w).

The ultraviolet spectrum of an aqueous solution of the reagent, in neutral medium, shows an absorbance maximum at 318 nm. This band undergoes a bathochromic shift to 356 nm in acidic medium, and in alkaline medium to 330 nm. Phillips and Merritt's method[12] was used for determination of the ionization constants, in 2% ethanol–water medium (1 ml of $2 \times 10^{-3}M$ PAPT solution in ethanol, diluted to 50 ml with distilled water). The values found were $pK_1 = 3.66$, $pK_2 = 10.47$.

Reactions with metal ions

The reactions of 36 ions with PAPT were tested at various pH values. The samples were prepared in 50-ml volumetric flasks, with 2 or 10 ppm of metal ion, 20 ml of 0.05% PAPT solution in dimethylformamide, 10 ml of buffer solution and dilution to 50 ml with distilled water; the spectrum from 350 to 700 nm was measured against a reagent blank. The most important results are summarized in Table 1.

Recommended procedures for the determination of cobalt(II)

In weakly acid medium. To a cobalt solution (10–100 μg of Co) in a 50-ml volumetric flask, add 20 ml of 0.05% PAPT solution in dimethylformamide, 10 ml of pH 4.7 acetate buffer, 10 ml of 0.5*M* potassium chloride and dilute to the mark with water. Measure the absorbance in 1-cm cells at 390 nm against a reagent blank.

In strongly acid medium. Place the cobalt solution (25–100 μg of Co in not more than 10 ml) in a 50-ml standard flask. Add 0.1 g of ascorbic acid, 10 ml of 0.1% PAPT solution in dimethylformamide, 10 ml of 2*M* hydrochloric acid and 10 ml of 0.5*M* potassium chloride and dilute to volume. Measure the absorbance, in 1-cm cells, at 430 nm against the reagent as blank.

By extraction of the complex. Place the sample solution, containing up to 20 μg of Co, in a separating funnel. Add 2 ml of pH 4.7 acetate buffer, 2 ml of 0.5*M* sodium perchlorate and dilute to 10 ml with water. Extract with 10 ml of 0.05% PAPT solution in chloroform, with vigorous shaking for 2 min; transfer the chloroform layer into a 25-ml calibrated flask, dilute to the mark with chloroform and dry with anhydrous sodium sulphate. Measure the absorbance at 400 nm against a blank obtained by extraction in the same way.

Determination of cobalt in steels. Dissolve 0.25 g of steel in 30 ml of *aqua regia* under reflux. Dilute the solution to 100 ml in a standard flask with distilled water. Analyse an aliquot of this solution by the "strongly acid medium" method. Any silica or tungstic acid precipitated should be filtered off.

RESULTS AND DISCUSSION

PAPT is amphoteric, with protonation of the ring nitrogen atom, and/or dissociation of a proton from the

thiol group. It is stable in dimethylformamide–water solution. Reducing agents do not affect it, but oxidizing agents, such as potassium persulphate and hydrogen peroxide, destroy it.

The benzene ring substituted on the thiosemicarbazone produces an auxochromic effect for the complexes formed, giving better sensitivity than other thiosemicarbazones.[2,13]

Reaction with cobalt

PAPT forms a yellow cobalt(II) chelate at pH 5 and 1, the wavelengths of maximum absorption being 390 and 420 nm, respectively (Fig. 1). The complex is formed rapidly and its absorbance remains stable for at least 24 hr. Reducing and oxidizing agents do not affect the cobalt-complex spectrum.

The complex is retained on a cationic ion-exchanger resin in weakly acidic but not in alkaline medium, probably[14] because of the equilibrium:

$$\mathrm{Co(HPAPT)_2^{2+} = Co(PAPT)_2 + 2H^+}$$

The absorbance–pH graph for the cobalt complex is shown in Fig. 2. The optimum pH range for complex formation is 4.4–6.9, so an acetate buffer is proposed.

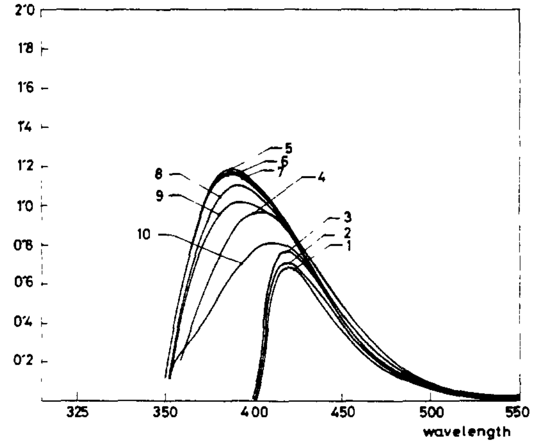

Fig. 1. Absorption spectra of solutions of the PAPT–cobalt complex (2 ppm) at the pH values indicated.

The stoichiometry of the complex is shown by the continuous variations method to be 1:2 metal:ligand at both pH 4.7 and 1.0. Therefore, two different species exist, each having the same cobalt:PAPT ratio. At low pH values the absorbance decreases because of the bathochromic shift of the reagent.

The optimum pH range for extraction of the complex into chloroform is 4–7 and sodium perchlorate is the best salting-out agent.

Analytical applications

In acetate buffer. Beer's law is obeyed at pH 4.7 for 0.2–2 ppm of cobalt and the molar absorptivity is 29.9×10^3 l·mole^{-1}·cm^{-1} (at 390 nm). The optimum concentration range, evaluated by Ringbom's method, is

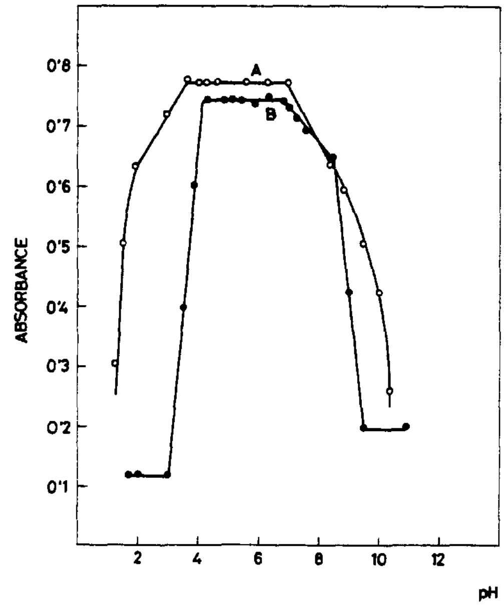

Fig. 2. Absorbance–pH graphs of the PAPT–cobalt complex: A, extracted into chloroform, 2 ppm cobalt (λ_{max} 400 nm); B, in homogeneous medium, 2 ppm of cobalt (λ_{max} 400 nm).

Table 2. Influence of foreign ions in cobalt determination at pH 1

Interference level, *ppm*				
1	2	5	25	50
Au(III)	Sn(II)	Hg(I)	Cr(III)	Pb
Cu(II)		Hg(II)	Ni	
V(V)				
Ag				
Pd(II)				
Pt(IV)				

Bi, W(VI), Ca, Fe(II), Mo(VI), Cd, Sr, Ce(III), Ba, Zn, Mn(II), Be, Al, Li, Rb do not interfere at the 100-ppm level.

Table 3. Determination of cobalt in steel

Steel type	Cobalt, %	
	Added	Found
Cr–Ni Steel I	1.95	1.86
Cr–Ni Steel I	0.97	0.90
Cr–Ni Steel I	0.46	0.43
Cr–Ni Steel I	0.23	0.22
AISI-316T	1.91	1.95
AISI-316T	0.95	0.98
AISI-316T	0.45	0.43
AISI-316T	0.24	0.25
AISI-316E	1.89	1.92
AISI-316E	0.96	0.89
AISI-316E	0.47	0.45
AISI-316E	0.23	0.21

0.2–2 ppm. The relative error (95% confidence limits) is ±0.2%.

The interferences for 1 ppm of cobalt were investigated: 100 ppm of W(VI), Mo(VI), As(III), Th, U(VI), Ca, Ba, Be, Sr, Mg, Rb, Li, PO_4^{3-}, SCN^-, citrate and tartrate, and 50 ppm of Mn(II) and Al ions did not interfere. Ag, Pb, Hg(I), Hg(II), Cd, Bi, Sn(II), Sn(IV), Au(III), Pd(II), Fe(II), Fe(III), Cu(II), Ni, Zn and V(V) ions interfere when they are present in concentrations below 1 or 2 ppm, and Cr in 10 ppm concentration.

In strongly acid medium. This is the most interesting procedure because it removes numerous interferences and, more importantly, the determination of cobalt in the presence of iron is made possible. Beer's law is obeyed between 0.2 and 2 ppm of cobalt. The molar absorptivity at 430 nm is 15.1×10^3 $l \cdot mole^{-1} \cdot cm^{-1}$. Ringbom's method shows that 0.8–1.5 ppm is the minimum-error range. The relative error (95% limits) is ±1.0%.

The interferences at the 1-ppm cobalt level have been investigated; the results are summarized in Table 2. The reaction is selective for cobalt(II) in the presence of up to 1000 ppm of iron.

By extraction. The optimum conditions have been indicated in the *Experimental* section. Beer's law is obeyed between 0.2 and 2 ppm of cobalt and the molar absorptivity at 400 nm is 29.5×10^3 $l \cdot mole^{-1} \cdot cm^{-1}$. A Ringbom graph shows that 0.8–2 ppm of cobalt(II) is the minimum-error range. The relative error (95% limits) is ±0.8%. The interferences are analogous to those observed in the acetate-buffer method.

Determination of cobalt in steels. The technique described above has been applied to the determination of cobalt in spiked samples of Hoepfner Gebr. Chromium Nickel Steel I, AISI 316-T Steel and AISI 316-E Steel*. The results are shown in Table 3 (average of 10 determinations).

---

*Chromium Nickel Steel I: Fe 68.15%, Ni 11.84%, Cr 17.77%, Mo 2.15% and C 0.09%. AISI 316-T Steel: Fe 65.1%, Cr 20.7%, Ni 11.4% and Mo 2.8%. AISI 316-E Steel: Fe 64.4%, Cr 19.8%, Ni 13.4% and Mo 2.4%.

Summary—The characteristics and analytical applications of picolinaldehyde 4-phenyl-3-thiosemicarbazone are described. This compound gives coloured reactions with cobalt(II), iron(II) and (III), nickel(II), copper(II), palladium(II) and other ions, that are much more sensitive than those with picolinaldehyde thiosemicarbazone. The 1:2 yellow cobalt(II) complex has been used for the spectrophotometric determination of cobalt in the presence of iron, and applied to steel analysis.

STUDY OF LIQUID–LIQUID EXTRACTION OF PERRHENATE WITH CYCLOHEXANONE IN DIFFERENT MEDIA

N. JORDANOV and M. PAVLOVA

Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sofia 13, Bulgaria

and

D. BOJKOVA

Higher Institute of Chemical Technology, Sofia 54, Bulgaria

(*Received* 14 *May* 1975. *Accepted* 19 *September* 1975)

The liquid–liquid extraction of ReO_4^- by means of different ketones has been the subject of a number of investigations.[1–15] The advantage of this extraction is that it can be carried out in acidic as well as in neutral or alkaline medium. Only a few investigations on the mechanism of this extraction are available[1,11,13] and it has not been completely elucidated. Cyclohexanone (Ch), which is one of the most useful ketones, has been used in this study. The purpose of the present work was to carry out a more detailed study of ReO_4^- extraction with cyclohexanone, elucidate some aspects of the extraction mechanism, and to show the possibility of separating molybdenum in determination of rhenium in molybdenum ores, concentrates and preparations.

EXPERIMENTAL

Reagents

Stock solutions of rhenium and molybdenum were prepared from $KReO_4$ and $(NH_4)_6Mo_{24}.4H_2O$. Cyclohexanone, b.p. fraction 155–156° was used. Its purity was checked by gas chromatography. All other reagents were of analytical grade.

Apparatus

Absorbance was measured with a CΦ-4 spectrophotometer. Radiometric measurements were carried out with Vakutronic V20 counting equipment. Atomic-absorption measurements were carried out with a Pye-Unicam SP 90B spectrophotometer.

Procedure

Distribution coefficients of rhenium were determined in two ways: radiometrically with ^{186}Re and photometrically by the thiocyanate method.[16] The concentration of rhenium in both phases was measured. Distribution coefficients of molybdenum were determined by means of atomic absorption. Equal volumes of the aqueous and organic phases (5 ml) were shaken in glass centrifuge tubes fitted with ground-glass stoppers. Equilibrium was attained after 5 min and the two phases were separated by centrifugation. The volume changes of the two phases for each point of the extraction curves have been taken into consideration when calculating the distribution coefficients.

RESULTS AND DISCUSSION

Extraction of ReO_4^- from different media

Curves for extraction of ReO_4^- with Ch from aqueous solutions of some mineral acids are shown in Fig. 1. Corresponding curves for aqueous solutions of the corresponding sodium salts and sodium hydroxide are shown in Fig. 2. No data for phosphate medium are presented, because of the low solubility of alkali metal phosphates.

The importance of the salting-out agent is evident. Ions interact with water in different ways depending on their electric charge and radius, affecting the structure of water and its activity[17] to different extents. The non-hydration of NO_3^- and Cl^- helps their own extraction, thus influencing unfavourably the ReO_4^- extraction. Probably, the decrease in extraction at higher acid concentrations is connected with the competitive extraction of the corresponding anions or condensation of perrhenate in the presence of the acids.[18,19]

There is no information about the extraction of ReO_4^- with Ch from solutions of phosphoric acid, hydrochloric acid, sodium carbonate and sodium hydroxide. Distribution coefficients for some other media (sodium sulphate, ammonium sulphate) determined by us differ from the reported values[1] by approximately one order of magnitude but we found their salting-out efficiencies to be in the same order as reported by Gerlit *et al.*,[1] except for the changed places of OH^- and Cl^-.

Choice of diluent

Some "inert" diluents were tested. The most suitable appeared to be benzene and chloroform. Rhenium was extracted with 50% solution of Ch in the latter diluents

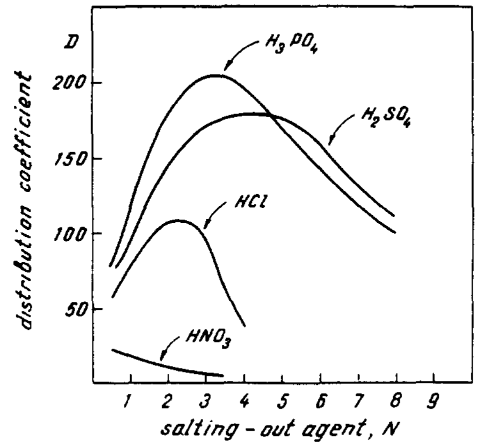

Fig. 1. Distribution of ReO_4^- by extraction with cyclohexanone from aqueous solutions of inorganic acids.

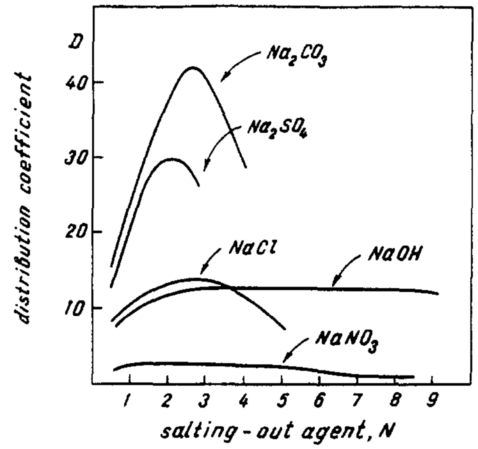

Fig. 2. Distribution of ReO_4^- by extraction with cyclohexanone from neutral and alkaline media.

from 2*N* sulphuric acid with $D = 0{\cdot}17$ and from 2*N* sodium hydroxide with $D = 0{\cdot}004$. The experimental data show that it is possible to carry out back-extraction of Re by adding diluent to the organic phase after the extraction.

Determination of solvation and hydration numbers

Solvation numbers were determined graphically from plots of log *D* *vs.* log [Ch] for different concentrations of the investigated media, using benzene and chloroform as diluents. The fact that irrespective of the nature of the diluent straight lines with equal slopes were obtained is regarded as evidence of the reliability of the result. The same value of the mean solvation number, namely $\bar{s} = 9{\cdot}6 \pm 0{\cdot}6$, with statistical certainty of 95%, was obtained when ReO_4^- was extracted with Ch from solutions of sulphuric acid, lithium sulphate, sodium sulphate and sodium hydroxide of different concentrations. When the extraction is performed from potassium sulphate medium $\bar{s} = 6{\cdot}0 \pm 0{\cdot}1$. Therefore when the cation and anion are both "positively" hydrated,[17] the extraction process proceeds by means of solvation with a greater number of Ch molecules than in the cases when the cation is "negatively" hydrated as in the case of the potassium ion.

Hydration numbers were determined by a modified Fischer method. Titrations were carried out in the presence of small concentrations of methanol and high concentration of pyridine.[20] Thus, the side-reaction between ketone and methanol, causing a liberation of an additional amount of water, was eliminated. The results show that in extraction of 0·02*M* solution of ReO_4^- in the presence of potassium sulphate, sodium sulphate and sodium hydroxide, the solvates which pass into the organic phase are not hydrated. The amount of water in the rhenium-containing extracts is equal to that found in blank tests. Thus, it may be deduced that cyclohexanone solvates the corresponding perrhenate directly without participation of water.

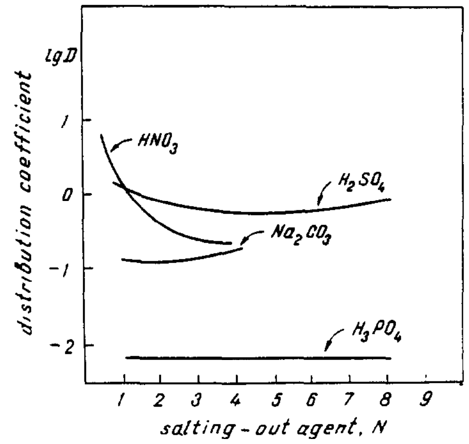

Fig. 3. Distribution of Mo(VI) by extraction with cyclohexanone from aqueous solutions of acids and sodium carbonate.

The extract obtained after extraction of ReO_4^- from sodium sulphate and sodium hydroxide medium was evaporated and the content of sodium and rhenium in the dry residue was determined. The two ions were present in amounts corresponding to their stoichiometric quantities in $NaReO_4$. Other evidence of the solvate mechanism of extraction of ReO_4^- from neutral and alkaline medium is the fact that anhydrous $NaReO_4$ is very soluble in cyclohexanone. The proposed solvate extraction mechanism does not agree with the suggestions of some other authors.[13]

When the extraction is carried out from 2*N* sulphuric acid, the differences in the water content of the blank test extracts and of those containing rhenium are statistically significant (according to Kaiser and Specker's criterion) and the hydration number found is 7. In this case, solvation of the protons takes place by means of bridge water molecules.

Extraction of Mo(VI) from different media

Similar investigations were carried out with Mo(VI) and nitric acid, sulphuric acid, phosphoric acid and sodium carbonate media. Extraction curves are shown in Fig. 3. It is seen that phosphoric acid solutions provide the best conditions for separation of rhenium from molybdenum. The separation coefficient in 3–4*N* phosphoric acid is $\beta = 3 \times 10^4$.

Rhenium is completely and selectively extracted from concentrates of high molybdenum content if extraction is carried out from sodium sulphate medium in the presence of the solid phase obtained after the decomposition of the sample with peroxide.

Determination of rhenium in molybdenum concentrates

A sample of molybdenum concentrate containing 5–10 μg of rhenium is mixed with 1 g of sodium peroxide in an iron or nickel crucible and the mixture is kept for 30 min in a molten state in a muffle furnace. When the melt is cool, 5 ml of water are added and the crucible is left for 30 min on a boiling water-bath. Then the contents of the crucible are transferred by means of 5 ml of 10% sodium sulphate solution into a centrifuge tube fitted with a ground-glass stopper. Extraction is carried out with 10 ml of Ch from sodium carbonate and sodium sulphate solution in the presence of the solid phase containing the major part of the molybdenum in the form of slightly soluble molybdates. The phases are separated by centrifugation. The organic phase is transferred into a separatory funnel, 10 ml of water are added and rhenium is back-extracted after addition of an equal volume of chloroform. Rhenium is determined in the aqueous phase by the thiocyanate method. The method has been applied to the determination of rhenium in non-standard molybdenum concentrates. A mean Re value of 92·8 μg/g was obtained with relative standard deviation 2·4% (9 replicates). The absence of a methodical error was checked by standard addition. The results for rhenium content are in very good agreement with the results obtained by other techniques for decomposition of the concentrate and extraction of rhenium.

Summary—A study has been made of the extraction of ReO_4^- from the following media: nitric, hydrochloric, sulphuric and phosphoric acids, and sodium nitrate, chloride, sulphate, carbonate and hydroxide solutions. The extraction curves were obtained and hydration and solvation numbers determined. It is concluded that in acidic medium the extraction follows a hydratosolvate mechanism; in neutral and alkaline medium only a solvate mechanism is observed. Similar investigations were carried out with molybdenum(VI). The separation of rhenium and molybdenum is discussed.

TITRATION OF METHYLENE BLUE WITH CHLOROMOLYBDATE(III)

S. R. Sagi and T. Bose Babu
Inorganic Chemistry Laboratories, Andhra University, Waltair, India

(*Received* 30 *July* 1975. *Accepted* 5 *November* 1975)

Knecht and Atack[1] titrated molybdenum(III) with a standard solution of Methylene Blue, the colour of the dye indicating the end-point. According to them the molybdenum(III) is oxidized to molybdenum(IV) and then to molybdenum(V). On the other hand Treadwell and Nieriker,[2] in their potentiometric titration of molybdenum(III) with Methylene Blue, observed only one break, corresponding to the oxidation of molybdenum(III) to molybdenum(V). The titration curve showed no indication of formation of molybdenum(IV) as an intermediate stage. Molybdenum(III) is known to exist in two forms (green and orange-red). According to Sagi and Rao[3,4] the green form is cationic aquomolybdenum(III) chloride and the orange-red form is anionic chloromolybdate(III). The type of molybdenum(III) obtained depends upon the method of preparation. Aquomolybdenum(III) chloride has a lower formal redox potential than chloromolybdate(III).[5,6] The two species behave differently with different oxidants.[3,7] The green form is stable only at hydrochloric acid concentrations $<4M$ whereas the orange-red form is stable in all concentrations of the acid.

The reaction of the two forms of molybdenum(III) with Methylene Blue has now been re-examined.

EXPERIMENTAL

Reagents

Methylene Blue solutions were standardized with a standard solution of titanium(III) chloride.[8,9]

Aquomolybdenum(III) chloride and chloromolybdate(III) solutions were prepared by reducing ammonium molybdate solution in $3M$ and $8M$ hydrochloric acid respectively, in a Jones reductor, and stored under carbon dioxide. They were standardized against standard cerium(IV) sulphate *via* oxidation with excess of ferric alum solution and titration of the iron(II) with ceric sulphate, with ferroin as indicator.[10]

Procedure

Known volumes of chloromolybdate(III) and aquomolybdenum(III) chloride were titrated with standard Methylene Blue solution in 1–$8M$ and 0.5–$4M$ hydrochloric acid media respectively, until the solution showed the colour of Methylene Blue. The orange-red form first became straw yellow, then pale green and finally blue; the green form first became reddish brown, then pale bluish green and finally blue. The end-points for the orange-red form were

TITRATION OF METHYLENE BLUE WITH CHLOROMOLYBDATE(III)

S. R. Sagi and T. Bose Babu
Inorganic Chemistry Laboratories, Andhra University, Waltair, India

(*Received* 30 *July* 1975. *Accepted* 5 *November* 1975)

Knecht and Atack[1] titrated molybdenum(III) with a standard solution of Methylene Blue, the colour of the dye indicating the end-point. According to them the molybdenum(III) is oxidized to molybdenum(IV) and then to molybdenum(V). On the other hand Treadwell and Nieriker,[2] in their potentiometric titration of molybdenum(III) with Methylene Blue, observed only one break, corresponding to the oxidation of molybdenum(III) to molybdenum(V). The titration curve showed no indication of formation of molybdenum(IV) as an intermediate stage. Molybdenum(III) is known to exist in two forms (green and orange-red). According to Sagi and Rao[3,4] the green form is cationic aquomolybdenum(III) chloride and the orange-red form is anionic chloromolybdate(III). The type of molybdenum(III) obtained depends upon the method of preparation. Aquomolybdenum(III) chloride has a lower formal redox potential than chloromolybdate(III).[5,6] The two species behave differently with different oxidants.[3,7] The green form is stable only at hydrochloric acid concentrations $<4M$ whereas the orange-red form is stable in all concentrations of the acid.

The reaction of the two forms of molybdenum(III) with Methylene Blue has now been re-examined.

EXPERIMENTAL

Reagents

Methylene Blue solutions were standardized with a standard solution of titanium(III) chloride.[8,9]

Aquomolybdenum(III) chloride and chloromolybdate(III) solutions were prepared by reducing ammonium molybdate solution in $3M$ and $8M$ hydrochloric acid respectively, in a Jones reductor, and stored under carbon dioxide. They were standardized against standard cerium(IV) sulphate *via* oxidation with excess of ferric alum solution and titration of the iron(II) with ceric sulphate, with ferroin as indicator.[10]

Procedure

Known volumes of chloromolybdate(III) and aquomolybdenum(III) chloride were titrated with standard Methylene Blue solution in 1–$8M$ and 0.5–$4M$ hydrochloric acid media respectively, until the solution showed the colour of Methylene Blue. The orange-red form first became straw yellow, then pale green and finally blue; the green form first became reddish brown, then pale bluish green and finally blue. The end-points for the orange-red form were sharp in 6–8*M* hydrochloric acid media but not at lower acid concentrations (because of slow reaction). For the green form, the end-points were not clear at any acid concentration, because the end-point reaction was slow.

The titrations were repeated potentiometrically. Titration of chloromolybdate(III) in 6–8*M* hydrochloric acid was best, because stable potentials were obtained in 2-3 min after each addition of titrant and a potential jump of 100 mV was obtained exactly at the visual end-point, whereas in 2–5*M* hydrochloric acid stable potentials were obtained only after waiting for 5–10 min after each addition of titrant and the potential jump was only 50–60 mV. With aquomolybdenum(III) chloride no potential jump was obtained until the solution had become blue, and 5–10 min were required for the potential to become stable after addition of the titrant, so satisfactory titrations could not be carried out.

Titrations of Methylene Blue with chloromolybdate(III) and aquomolybdenum(III) chloride in similar acid conditions by visual and potentiometric methods gave results similar to those for the titrations described above.

RESULTS AND DISCUSSION

The results obtained in the visual and potentiometric titrations of chloromolybdate(III) (*e.g.*, Fig. 1) showed that in 6–8*M* hydrochloric acid media the Methylene Blue is reduced to leuco-Methylene Blue and molybdenum(III) is oxidized to molybdenum(V) only. In less concentrated acid (2–5*M*) a fraction of the molybdenum(V) formed is oxidized to molybdenum(VI), the fraction increasing with decrease in acid concentration. This is expected from the variation of the formal redox potential of the Mo(VI)/Mo(V) couple in media of low hydrochloric acid concentration,[11] and confirms the results obtained by Sagi and Rao.[12] The results of the reverse titrations confirm these conclusions.

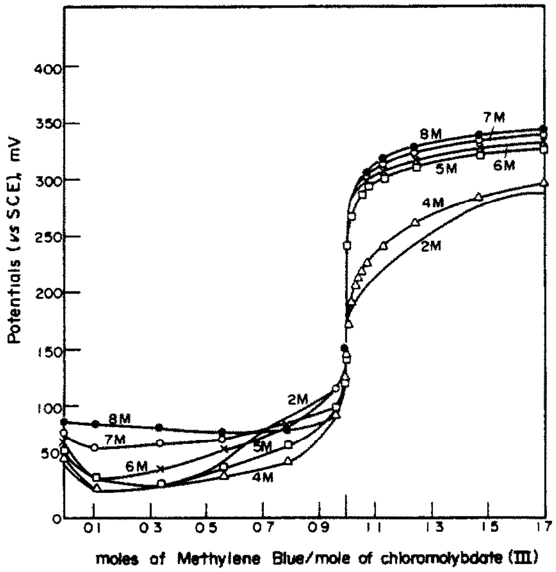

Fig. 1. Potentiometric titrations of chloromolybdate(III) with Methylene Blue in hydrochloric acid media.

The results obtained in the visual titration of aquomolybdenum(II) chloride with Methylene Blue show that oxidation to molybdenum(V) is incomplete even though aquomolybdenum(III) chloride is a more powerful reductant than chloromolybdate(III) (according to the formal redox potentials).

We consider that only 6–8*M* hydrochloric acid media are suitable for titration of Methylene Blue with molybdenum(III), which itself must be in the form of chloromolybdate(III).

Other reductometric reagents available for the direct titration of Methylene Blue are titanium(III) chloride,[8,9] chromium(II) sulphate,[13,14] iron(II) sulphate[15] and ascorbic acid.[16] Of these the titration with iron(II) is done slowly, with a 1-min wait after each addition of titrant. The titrations with ascorbic acid and titanium(III) require higher temperatures. Titanium(III) chloride and chromium(II) sulphate are highly susceptible to atmospheric oxidation whereas chloromolybdate(III) is less susceptible,[17] and the titrations with chloromolybdate(III) now proposed can be carried out at room temperature.

Summary—The reaction of Methylene Blue with aquomolybdenum(III) chloride and chloromolybdate(III) in hydrochloric acid media has been investigated. Chloromolybdate(III) can be satisfactorily used as a reductometric titrant for Methylene Blue in 6–8*M* hydrochloric acid medium. The end-point can be detected either potentiometrically or visually. Aquomolybdenum(III) chloride is not useful as a titrant for this estimation.

SPECTROPHOTOMETRIC DETERMINATION OF MAGNESIUM WITH ERIOCHROME CYANINE R IN ANALYSIS OF SILICATES

N. G. Elenkova and E. S. Popova
Higher Institute of Chemical Technology, Sofia 56, Bulgaria

(*Received* 22 *July* 1975. *Accepted* 22 *October*, 1975)

Samples containing large amounts of Ca and Mg are sometimes analysed by the classical technique, but this is prone to errors because of co-precipitation and solubility effects.[1] The alkaline earth metals are so easily co-precipitated with the ammonia group precipitate that reprecipitation and adequate washing of the precipitate is essential if high results for alumina and low results for Mg and Ca are to be avoided. Careful control of pH is also essential during the ammonia group precipitations to avoid alumina escaping precipitation and then being brought down in the oxalate or, more probably, the phosphate precipitations. For this reason the method is inconvenient in a routine laboratory.[2]

Most complexometric methods involve the determination of lime and of lime plus magnesia, the magnesia being obtained by difference, but difficulties arise in the lime determination and the complexometric determinations are not completely satisfactory either.[2–4]

The determination of small amounts of magnesium is often based on lake formation or indirect photometric determination.[3,4] Dyes used include Titan Yellow,[5–7] curcumin, 1,2,5,8-tetrahydroxyquinone, *etc.* It is very difficult to obtain accurate and reproducible results with lake-forming compounds because of variations in dyestuff samples, impurities in protective colloids, precipitation of the lake, rapid fading of the colour, and the uncertain effect of other metals.[3] The indirect photometric procedures are mostly based on the gravimetric methods, but so many manipulations are involved that there is a very great possibility of error.[3]

The development of the EDTA titration of magnesium with Eriochrome Black T as indicator suggested the use of this dye for a photometric procedure.[8] Interference by the alkaline earth metals is eliminated by precipitating them with sodium tungstate. Interference by Zn, Cu, Cd and Co is eliminated with potassium cyanide. Fluoride, phosphate, sulphate and oxalate should be absent.[3] Similar methods which utilize the formation of a coloured magnesium complex employ 2-[2-hydroxy-3-(2,4-xylylcarbamyl]-1-naphthylazophenol and its sulphonate as reagents.[9,10] Iron, copper and aluminium interfere by reacting with the reagent.

Magnesium can be determined in low concentration by spectrophotometric measurement of its 8-hydroxyquinoline complex. The magnesium must be almost completely isolated by extraction before its determination although the interference due to small amounts of Ni, Co, Cu, Ag, Au and Pt can be eliminated by masking with sodium cyanide.[3,11,12]

This paper describes an alternative method that is applicable to silicate materials that are low in iron and aluminium and is more sensitive and less subject to interference from common diverse ions. In a previous paper[13] we have shown that Mg and Eriochrome Cyanine R ERCR form a true solution of a well-defined coloured complex and that the reaction is complete in the pH range 11.0–11.5. The same reaction has now been used for direct magnesium determination in silicate analysis.

EXPERIMENTAL

Reagents

ERCR solution 0.01*M*. Dissolve 5.36 g of ERCR in 10 ml of nitric acid (1 + 1) and add 100 ml of water, 8 g of sodium chloride, 8 g of ammonium nitrate and dilute to 1 litre with water. This solution is stable for months.[14]

Standard magnesium solution, 0.001*M*. Dissolve 0.2033 g of $MgCl_2 \cdot 6H_2O$ in 1 litre of distilled water and standardize gravimetrically if necessary.[1]

Buffer solution. Mix 0.2*M* ammonia and 0.2*M* ammonium chloride in 32:1 ratio and add 25 ml of 25% ammonia solution (sp.gr. 0.91) per litre.

Spectral characteristics and optimum conditions

In Fig. 1 curves A and B show the absorption spectrum of ERCR in the presence and absence of magnesium at pH 11.5 in ammonium buffer solution. As shown earlier,[13] complex formation is complete in this medium and the absorbance is independent of pH in the range 11.0–11.5. The order of addition of reagents is immaterial. At pH 11.5 (chosen for the present work), a 1.5-fold molar excess of reagent is sufficient for complete complex formation, but it is better to use at least a 30-fold excess. The colour is essentially completely developed in 10 min and then remains unchanged for at least 1 hr.

Calibration curve and procedure

Weigh accurately a 0.5-g ground sample into a platinum dish. Decompose the sample and determine the silica.[1] After removal of the silica with hydrofluoric acid fuse the residue with 2 g of potassium pyrosulphate. Cool, add

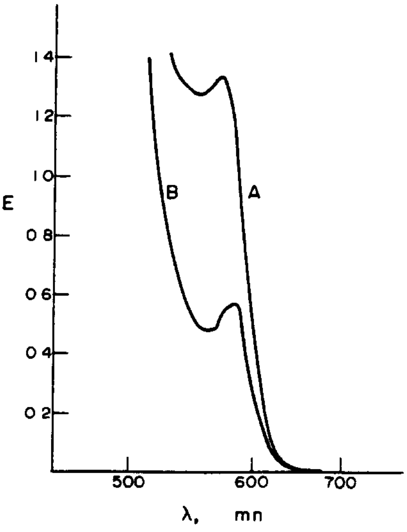

Fig. 1. Absorption spectra of (A) $1.5 \times 10^{-3}M$ ERCR/$1.5 \times 10^{-4}M$ Mg(II); (B) $1.5 \times 10^{-3}M$ ERCR.

water and 10 ml of 5% sulphuric acid to dissolve the fusion cake. Add the solution to the filtrate from the silica determination in a 500-ml volumetric flask. Dilute to the mark and pipette 100 ml into a 250-ml beaker. Add 1 or 2 drops of conc. nitric acid, boil for 1–2 min, add 1–2 g of ammonium chloride, precipitate R_2O_3 by adding ammonia solution (1 + 1) dropwise (pH ~ 8, universal indicator), keep warm for about 10 min and filter (coarse paper) collecting the filtrate in a 250-ml volumetric flask, cool and dilute to volume. Pipette an aliquot of 1 or 5 ml, depending on the magnesium content, into a 50-ml volumetric flask, add 7.5 of 0.01*M* ERCR, 25 ml of buffer solution and dilute to volume. Determine the absorbance of the solution at 570 nm against a blank as reference, using 30-mm cells.

To prepare the calibration curve transfer 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, 4.0 and 4.5 ml of the standard magnesium solution to 50-ml volumetric flasks, add to each flask 5 ml of the reagent blank, 7.5 ml of ERCR solution, 25.0 ml of buffer solution and dilute to volume with water. Determine the absorbance of each solution at 570 nm against a blank as reference, using 30-mm cells. Find the equation of the line $\Delta A = a + bC_{Mg}$ and test the constant a for equality to zero.[15,16]

The calibration curve should be linear over the range 2×10^{-5}–$10^{-4}M$ magnesium.

RESULTS AND DISCUSSION

Accuracy

The accuracy was tested in two principal ways: (*a*) by the absolute method in which a synthetic sample was employed, and (*b*) by the use of standard samples. Various amounts of magnesium were used because the determinate errors in the procedure may be a function of the amount present.[17,18] Many replicate analyses for Mg in synthetic samples, covering the range of concentration over which the method is applicable, when analysed by the method of least squares gave a linear relation between amount found and amount added, passing through the origin, with a slope equal to unity. Statistical analysis[15,16] showed the procedure to be free from both a constant bias and an error of relative type, *i.e.*, one that increases with the amount of Mg.

Determination of the accuracy of a method by use of pure solutions is only the first step in evaluation of the accuracy.[17] The effect of accompanying species in varying amounts must also be examined. Such a programme is so laborious that it is rarely, if ever, carried out to its full extent.[17] One way of reducing the labour is to consider the determination in a specified concentration range in a material of more or less fixed composition, both with respect to the elements which may be present and their relative amounts. By the use of suitable synthetic samples the effect of foreign elements on the Mg determination was thus systematically evaluated. We analysed four samples containing 12, 18, 24 and 48 μg of Mg, and various amounts of the elements to be studied for possible interference. The amounts of magnesium found from five separate determinations were compared by the *Student* criterion with the amount of magnesium taken. The investigation showed that the effect of the foreign substances is a function of their relative contents; there was no effect when the concentrations (in a notional "sample") were less than: CaO ~ 16%, MnO ~ 2%, ZnO ~ 2.0%, Al_2O_3 ~ 1%, Fe_2O_3 ~ 1.0% and TiO_2 ~ 1%. Thus we may conclude that our procedure is applicable to silicate glasses containing sodium, potassium, calcium and magnesium as major constituents as well as to feldspars, clays and others low in alumina and iron oxides.

The use of liquid synthetic samples does not always suffice, however.[17] We therefore also used standard samples of glass, clay, feldspars, china clay and sands. The results for glass are given in Table 1. The distribution was normal and a statistical analysis should be compatible with these data. We thought at first that the existence of a relative type of error in the data was related to the amounts taken for analysis. Therefore, to determine the adequacy of the sample size we tested statistically the significance of the differences between the mean values of different subsample volumes for each glass. For this purpose we compared the standard deviations of the subsamples by the Cochran criterion. The estimates were so close [see Table 2, data for the *G*-criterion—$G_{found} < G(95, k = 4, f = 4) = 0.68$] that the differences could have arisen by chance. Since our results were classified into more than two groups we also utilized analysis of variance.[16] The *F*-values showed (see Table 1) that there is no evidence for bias at the four levels of concentration [$F_{found} < F(95, f_1 = 3, f_2 = 16) = 3.24$]. Finally, the mean values for each subsample size were compared with the true composition by means of the *t*-criterion. The difference appears not to be greater than can be attributed to chance, since $t_{found} < t(95, f = 19) = 2.09$. As mentioned, since the different subsamples correspond to samples of different sizes, the results of Table 1 reveal that there were no determinate errors in the determination of MgO in glasses. These data were also used to test the accuracy of the method, expressed by the difference ΔX between the contents found and the true values μ (given in Table 1 as $\Delta X/\mu\%$). The precision of the procedure was measured by the coefficient of variation V_x, also given in the Table.

The proposed method was applied to the analysis of a series of samples. Table 2 shows the results of five repli-
