cate magnesia determinations in these samples by the proposed method and by the complexometric method. The standard deviation of the first method s_1 was compared with that of the other, s_2, in order to compare the precisions of the two procedures. The variance ratio F exceeded the tabulated values. Hence there is evidence of a real disparity between the two estimates and the precision of the proposed method is superior to that of the other (see also the coefficient of variation V_x). The evidence for a positive bias of the volumetric method may here be regarded as conclusive. The results of Table 2 also give a view of the total errors of both procedures.[19] They were calculated as the ratio of the sum of the absolute error and twice the standard deviation to the true value.

Summary—A simple and sensitive method for determining magnesium in silicates low in aluminium and iron (glass, clay, feldspars, *etc.*) is presented. The method is applicable in the classical procedure of silicate analysis and magnesia is determined with Eriochrome Cyanine R in an ammonium buffer solution at pH 11.5. There is no interference by elements likely to occur in such samples. The accuracy and the precision of the proposed method are superior to those of the complexometric method. The limit of detection is 0.007% MgO.

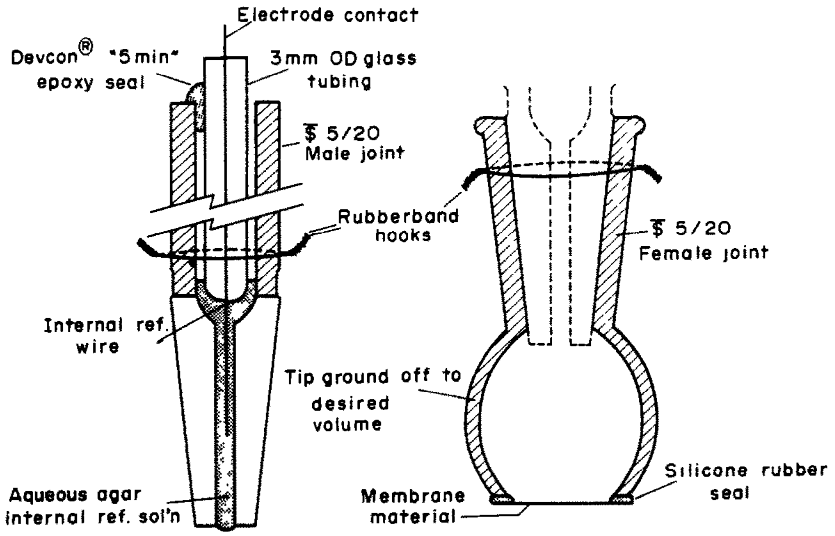

Fig. 1. Construction details of the versatile liquid ion-exchange electrode body.

sodium, a glass-membrane electrode made from LAS 15-25 glass.[1,2] This response should be of interest to researchers using liquid ion-exchange membrane electrodes with long-chain alcohols as the ion-exchanger solvent.

A good approximation to the EMF of an electrochemical cell containing an ion-selective electrode with a fixed internal electrode is given by an extended Nikolsky equation[3]

$$E_{\mathrm{cell}} = E' + \frac{RT}{z_i F} \ln \left[a_i + \sum_{j=1}^{N} K_{i,j}^{\mathrm{Pot}} a_j^{z_i/z_j} \right]$$

where E_{cell} is the measured potential of the cell containing the ion-selective electrode, E' is constant for a particular electrode–reference pair and includes contributions from the internal and external reference electrodes and junction potentials, R, T, F, and z_i have the usual meanings, a_i is the activity of the primary ion in the sample solution, $K_{i,j}^{\mathrm{Pot}}$ is the potentiometric selectivity coefficient and a_j is the activity of an interfering ion in the sample solution.

The electrode body developed during this study allows easy removal of the tip for exchanging membranes, rinsing and refilling of exchanger, and removing water or bubbles. The exchanger volume can be reduced by grinding down the tips, which is useful if the exchanger material is expensive or difficult to obtain. If stocks are kept of internal reference units and tips with several types of membranes, an electrode can be assembled and in use within 5 min. The electrodes cost <$5 each to make.

EXPERIMENTAL

Instrumentation

Cell potentials were measured with a Vibron Model 33B-2 Vibrating Capacitor Electrometer as a null detector and impedance matcher to a Rubicon Type B High Precision Potentiometer. Response times were monitored by connecting a Sargent SRL recorder to the output of the electrometer. The electrode and a saturated KCl reference electrode (Corning 476050) were immersed in the test solution in a 125-ml jacketed beaker maintained at 25° ± 0.02° by circulating water, and stirred by a magnetic stirrer, all placed inside a Faraday cage, except the water pump.

Reagents

Reagent-grade chemicals were used without further purification. All solutions were prepared in doubly distilled water and stored in polyethylene bottles. Halide solutions were standardized against silver nitrate. n-Decanol was distilled at 0.15 mmHg and 60–61°, the middle third being taken for use. The purity was checked by infrared spectroscopy, GLC, and refractive index. Phase-separating membranes for the liquid ion-exchanger electrodes were cut from "Millipore" HA 0.45 μm plain white cellulose acetate filters. Lithium chloride–4% agar internal filling solutions were prepared by adding 1 g of Difco "Bacto-Agar" to 25 ml of 0.1*M* lithium chloride, and heating, with stirring, in a container placed in boiling water, until all the agar had dissolved.

Electrode construction

The electrodes were made in two parts from ₮5/20 ground-glass joints (Fig. 1). A silver wire was sealed into a 3-mm o.d. glass tube, either with epoxy glue or by melting the glass tube directly around the wire. The exposed end of the silver wire was coated electrolytically with silver chloride to form the internal reference electrode, which was inserted into the male joint and attached at the side on top, leaving an air gap for filling the joint with the lithium chloride–agar solution. Devcon "5-Minute Epoxy" was used so that immersion in boiling water allowed easy disassembly. The tube was filled by dipping into hot agar solution. It was found that if a small amount of agar was allowed to solidify outside the tip, it was easier to assemble the complete electrode without trapping air-bubbles at the tip. Grinding a small flat on the ground-glass surface of the male joint resulted in a vented reservoir which minimized the hydrostatic pressure differences across the membrane and allowed easy replacement of the solvent-exchanger medium lost by dissolution in test solutions. The membrane tip was made by grinding down the ₮5/20 female joint until the desired exchanger volume was obtained. The membrane was attached with silicone rubber sealant, which provided a flexible and inert seal. The electrode was assembled by filling the tip with the ion-exchanger solution and slowly inserting the internal reference unit, taking care that no air-bubbles were trapped. The two pieces were then held together by two rubber bands.

Procedures

Repeated additions of standard stock solutions were made to a known volume of doubly distilled water until little significant change in cell potential was observed. When caesium hydroxide was used to raise the pH of test solutions to approximately 9.4 in some studies, the following procedure was used. A known volume of doubly distilled water was transferred to the beaker (thermostatically controlled) and allowed to come to thermal equilibrium. A small syringe needle connected to plastic tubing was used to bubble a stream of nitrogen through the solution for 40 min to remove acidic gases such as carbon dioxide. A known amount of standard caesium hydroxide solution was then added by micropipette to raise the pH to the desired value. The nitrogen flow was maintained over the top of the solution during the experiment to ensure that carbon dioxide would not be reabsorbed.

Single-ion activity coefficients were estimated from the Davies equation[4]

$$\log_{10}\gamma_i = -0.51\,z_i^2[I^{1/2}/(1 + I^{1/2}) - 0.3\,I]$$

where γ_i is the single-ion activity coefficient at 25° in water, I the ionic strength of the test solution, and z_i the charge on the ion.

RESULTS

New electrodes made with freshly distilled n-decanol exhibited either zero response or very slight response to anions, but after soaking in $0.1M$ lithium chloride for 18–24 hr gave increasingly cationic response until the Nernstian slope was reached. When the decanol in the electrode was replaced or small amounts were added to replace losses due to dissolution and leakage, the electrode again needed a presoaking period to establish full response.

Figure 2 shows the response of an electrode, already soaked in lithium chloride solution, to lithium, sodium, and potassium chloride solutions. Each curve is based on 35 data points. Caesium hydroxide was added to raise the pH of the test solutions to 9.4. The tailing of response at low activity for both lithium and sodium is due to the caesium ion interference, and starts where the ion concentrations are approximately equal to the $2 \times 10^{-5}M$ of the caesium. A 90% response was reached in ~15 sec and equilibrium potentials were usually obtained within 1 min, with a drift of less than 0.2 mV/hr. Potentials could be measured to within ±0.1 mV at higher concentrations and ±1.0 mV at concentrations of approximately $10^{-5}M$. The "noise" of the electrode potential was usually a function of the magnetic stirrer speed. The electrode resistance appeared to be about the same order of magnitude as that of the standard glass electrode.

$K^{\text{Pot}}_{\text{Li,Na}}$ was found to be 0.30 from the potentials measured in the different solutions. Since the sodium and potassium curves superimpose, $K^{\text{Pot}}_{\text{Li,K}}$ was also 0.30.

To verify that the electrode behaviour was not a function of the anion used, lithium nitrate, sulphate, and perchlorate were also studied. The chloride and nitrate curves superimposed exactly, but the sulphate curve had a slightly higher slope, 60.0 mV/decade as compared to the 57.5 mV/decade for the other two salts. This difference can probably be explained by the fact that the response varies gradually over a period of time in any case, and the experiments were not conducted with electrodes of the same age.

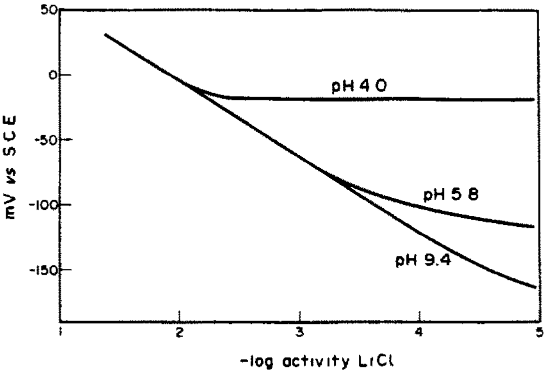

Fig. 3. Response of n-decanol electrode at 25°C to LiCl solutions at pH 4.0, 5.8, and 9.4.

As a further check on the effect of anions the other lithium halides were investigated. At concentrations $>10^{-2}M$, severe downward drifts in potential were observed on successive additions of the bromide or iodide. This drift is probably due to the transport of the halide ion through the low-dielectric membrane as an ion-pair with lithium, which occurs more readily at higher concentrations, causing mixed potentials at the internal Ag/AgCl reference electrode.

The limit of detection for this electrode is pH-dependent (Fig. 3). Solutions of pH < 4 gave very limited response to changes in lithium activity, but the electrode showed nearly linear EMF–log activity curves for hydrochloric acid solutions from 10^{-1} to $10^{-6}M$ with a 53.5 mV/decade slope. From these data and from Fig. 3, $K^{\text{Pot}}_{\text{Li,H}}$ was calculated to be ~50–100.

To study the behaviour of the electrode in strongly basic media, lithium and sodium hydroxide solutions were used. The results were almost quantitatively the same as those obtained with the chlorides (Fig. 2). Again the tailing that appeared was due to the interference from caesium hydroxide which was added to adjust the pH. From the difference in potential for $10^{-3}M$ solutions, $K^{\text{Pot}}_{\text{Li,Na}}$ was found to be 0.33, indicating that the electrode response and selectivity were affected little by strongly basic solutions.

To prove that the selectivity for lithium was not due to an ion-exchange mechanism on the "Millipore" cellulose acetate filter, a Lexan "Nucleopore" 0.4-μm filter, which should not possess ion-exchange properties, was substituted for the "Millipore". The results for pH 9.4 lithium and sodium chloride solutions are shown in Fig. 4. The

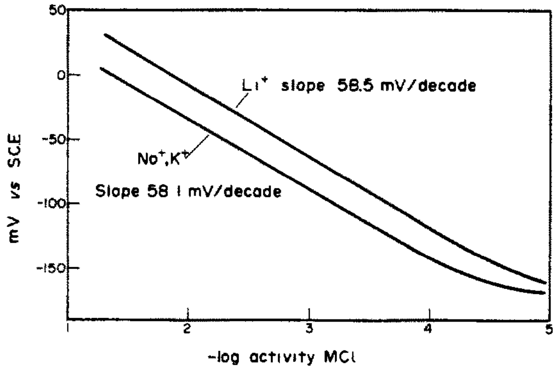

Fig. 2. Response of the n-decanol electrode to LiCl, NaCl, and KCl solutions at pH 9.4 and 25°C.

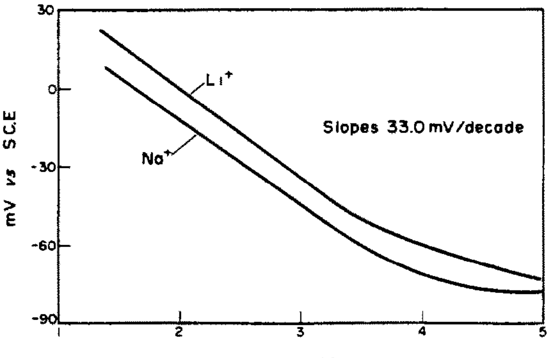

Fig. 4. Response of the n-decanol electrode to LiCl and NaCl solutions, with a "Nucleopore" filter membrane.

Table 1 Experimentally determined activities of "unknown" LiCl solutions

Actual activity of unknown solutions, *M*	Experimentally determined activity, *M*	Relative error %
1.47×10^{-2}	1.50×10^{-2}	+2.3
8.25×10^{-3}	8.21×10^{-3}	−0.5
5.23×10^{-3}	5.39×10^{-3}	+3.1
3.18×10^{-3}	3.07×10^{-3}	−3.6
2.81×10^{-3}	2.21×10^{-3}	−4.3
9.56×10^{-4}	9.29×10^{-4}	−2.8

curves were obtained after soaking the electrode for 24 hr in 0.1*M* lithium chloride (as for the "Millipore" electrodes). The response to both ions was linear over only a short range, and the slopes for both ions were 33 mV/decade. From this slope and the difference in potentials at a given activity, $K^{\mathrm{Pot}}_{\mathrm{Li,Na}}$ was calculated to be ~0.4, close to that obtained with the "Millipore" filter, indicating that the selectivity is due only to the n-decanol. The reduced slopes obtained with the "Nucleopore" membrane are probably attributable to insufficient pre-equilibration times.

A suitable pH buffer–ionic strength adjustment medium could not be found for use with the electrode. All those tried—various amine salts and organic bases—gave rise to such a potential that low activities could not be investigated, and the electrode showed little selectivity between univalent ions. Organic bases often inhibited or altered the electrode response by apparently dissolving in the n-decanol.

Table 1 shows the results of a number of typical lithium determinations on pure solutions. They suggest that in the 10^{-2}–$10^{-3}M$ region the errors are determined primarily by the reproducibility of the potential readings.

CONCLUSIONS

Lithium salts are known to be somewhat selectively extracted from aqueous solutions by higher alcohols. This phenomenon may be the origin of the selectivity for lithium relative to sodium observed for the n-decanol–water interface electrode.

Liquid–liquid membrane electrodes have been described before, *e.g.*, in the classic work of Haber and Klemensiewicz[5] and more recently by Liteanu and Mioscu[6] who showed that liquid–liquid interface potentials are functions of hydrogen-ion concentration in the aqueous phase.

The results of this study indicate that a long-chain alcohol such as n-decanol has the ability to complex and transport alkali metals through an organic membrane. The electrode exhibits linear near-Nernstian cationic response from 10^{-1} to approximately $5 \times 10^{-5}M$ for lithium ion, and the exhibited selectivity seems to be a property due to the solvent rather than the membrane. The response of the n-decanol system is relatively unaffected by the anions used in the test solutions. The slope of the electrode response varies slightly with the age of the electrode, but is usually within 56–58 mV/decade as long as the n-decanol is replaced at fairly frequent intervals. With suitable calibration, the electrode could be used to determine the activities of unknown lithium solutions with errors of less than 5%. The selectivity coefficients for lithium relative to sodium or potassium are ~0.30–0.33. $K^{\mathrm{Pot}}_{\mathrm{Li,Na}}$ is nearly the same as that of the LAS 15–25 glass electrode for lithium ion. $K^{\mathrm{Pot}}_{\mathrm{Li,H}}$ was found to be ~50–100. However, because of the overall lack of selectivity towards other univalent ions and the stringent pH-control needed to detect low activities, the electrode would be rather limited for practical lithium determinations in other than pure solutions of lithium salts. However it should be noted that long-chain alcohols such as n-decanol have often been used as solvents in liquid-membrane ion-exchanger electrodes[7,8] and the response of this system to alkali metal ions should be taken into consideration in ISE research where true responses of experimental systems might be altered by this effect.

Summary—An electrode selective for lithium relative to other alkali metal ions is described. The sensor is based on n-decanol as both the liquid membrane and exchanger. The electrode exhibits more than 3 decades of linear near-Nernstian response and has selectivity comparable to the LAS 15–25 glass univalent-cation electrode.

DETERMINATION OF LEAD IN PROPELLANT SAMPLES BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

EDGARDO J. WOOD, ROBERTO GONZALEZ, JUAN A. BLANCO
and ALBERTO O. RUCCI

Laboratorio de Quimica Analitica, CITEFA, V. Martelli, Pcia. Bs. As., Argentina

(*Received 2 September* 1975. *Accepted 5 November* 1975)

Lead salts such as the resorcylate, salicylate, stearate and 2-ethylhexoate and the red oxide (minium) are employed as modifiers of propellants. Classical techniques[1,2] for the determination of lead in powder formulations involve wet oxidation of the sample with nitric and sulphuric acids followed by determination of lead in the residue, either as the sulphate or the chromate. These are lengthy procedures and the determination as molybdate[3] is also time-consuming. Macorkindale and Lamond[4] reported the use of perchloric acid, achieving complete oxidation of the propellant sample in approximately 1 hr. The lead in the resulting solution was determined by polarography or by complexometric titration with EDTA. The U.S. MIL-STD-286B[5,6] specifies the determination of lead in propellants by an atomic-absorption technique. This method (T 311.5)[5] achieves complete oxidation of the specimen with nitric and perchloric acids, but is hazardous and requires the use of a good fume-cupboard made from non-organic materials. A second method (T 316.1)[6] specified in the American Standard, recommends incomplete digestion in nitric acid and the residual organic matter can clog the capillary inlet of the atomic-absorption spectrophotometer. This technique also suffers from matrix effects.

The present work was undertaken to improve the lead extraction procedure in the analysis of powders and 10% acetic acid was used to extract the lead from different types of propellants. The present paper compares the results so obtained with those of the gravimetric chromate method.

EXPERIMENTAL

Apparatus

Lead extractions were performed in 300-ml Erlenmeyer flasks fitted with reflux condensers (ground-glass joints).

All results were obtained with a Carl Zeiss PMQII Spectrophotometer with the FA2 flame attachment. A Servogor pen-recorder was used in conjunction with a Zeiss TE-converter. The lead resonance line at 283.3 nm was used.[7] An oxidizing non-luminous air–acetylene flame was used.

Reagents

All solutions were prepared with glass-distilled water and all chemicals used were of analytical-reagent grade. A stock solution of lead was prepared from lead nitrate and contained 5% v/v nitric acid. Stock and calibration solutions were made up to volume with 10% v/v acetic acid.

Sample preparation

Samples used in this study included cast and extruded double-base propellants and double- and single-base casting powders. Propellant samples were prepared by grinding to approximately 20-mesh in a Wiley mill,[8,9] but casting powder granules were not ground.

Procedure

The following extraction procedure is applicable to all the powder formulations mentioned. For extruded double-base propellants there is an alternative technique for lead extraction, which does not require complete dissolution of the sample. In all cases the sample should not be larger than 2.0 g.

Place an accurately weighed amount of sample containing 0.0075–0.015 g of lead in an Erlenmeyer flask containing 10 ml of 10% v/v acetic acid. Add 50 ml of acetone and reflux until dissolution is complete. (The acetone can be omitted, if desired, but 20 ml of glacial acetic acid must be used and the dissolution takes longer, 40–60 min.) While the solution is still hot add 100 ml of 10% v/v acetic acid (180 ml of distilled water if glacial acetic acid was used as solvent) with stirring, in order to obtain a fine-grained or fibrous precipitate (avoid the formation of a thick gummy precipitate). Boil gently for 5 min under reflux, then filter hot into a 500-ml volumetric flask containing 10 ml of glacial acetic acid. Add 100 ml of 10% v/v acetic acid to the residue, reflux for 5 min, into the volumetric flask then filter and repeat this step twice more, once with 100 ml of 10% v/v acetic acid and finally with 40 ml of distilled water. (If acetone was used as the solvent, use 50 ml of 10% v/v acetic acid and 90 ml of water for the last two extractions.) Make up to the mark with 10% v/v acetic acid, mix, and measure the lead by atomic-absorption spectrophotometry, adding acetone to the standards in order to obtain the same concentration as in the sample solution. The standards should contain 15–30 ppm of lead.

An alternative method applicable only to extruded double-base propellants is as follows. Transfer an accurately weighed amount of the specimen containing 0.0075–0.015 g of lead to an Erlenmeyer flask. Add 100 ml of 10% v/v acetic acid and reflux for 30 min. Transfer the hot supernatant liquid into a 500-ml volumetric flask containing 10 ml of glacial acetic acid. Add 100 ml of 10% v/v acetic acid to the residue and reflux for 15 min. Transfer to the volumetric flask and repeat the extraction one with 100 ml of 10% v/v acetic acid and finally with 90 ml of distilled water, using extraction times of 10 min. Make up to the mark with 10% v/v acetic acid. Determine the lead content by atomic-absorption spectrophotometry.

RESULTS

To establish the validity of the technique, the lead content of several samples was determined by the procedure described and also by the chromate method.[2] The results are given in Table 1. It can be seen that, in all cases, good agreement was obtained.

A study of the precision showed the relative standard deviation to be 3.1% (ten replicates), which is satisfactory.

Table 1. Comparison of propellant lead content determined by the gravimetric chromate method and the proposed procedure

Sample	Chromate method Pb, %	Acetone–10% acetic acid extraction/AAS Pb, %	10% acetic acid extraction/AAS Pb, %
Cast propellant A	1.75	1.73	
Cast propellant B	1.59	1.60	
Casting powder C	1.72	1.75	
Casting powder D	2.30	2.29	
Casting powder E	1.85	1.79	
Extruded double-base propellant F	0.97		1.00
Extruded double-base propellant G	1.15		1.13
Extruded double-base propellant H	1.39		1.41

DISCUSSION

The proposed procedure was used satisfactorily for a number of solvent-free and cast double-base propellants and double- and single-base casting powders containing lead salicylate, lead 2-ethylhexoate, lead stearate and lead resorcylate. Some variation will be needed for powder formulations containing red lead oxide (minium), such as dissolution in 20 ml· of glacial acetic acid. However, it has been established that the present extraction procedures are satisfactory for the samples studied.

It appears likely that the extraction of lead from the sample with 10% acetic acid is controlled by the complexing action of the nitrocellulose. The ability of the polymer to form a stable complex with the metal ion has a decisive effect on the extraction efficiency. Cast formulations are not completely extracted with 10% acetic acid even if finely ground material (80-mesh or finer) is used. Porous samples of casting powders obtained by prior extraction with methylene chloride did not give complete extraction of lead, even though the amount extracted was larger than that from non-porous samples. Only when the sample was completely dissolved in acetone or glacial acetic acid was total lead extraction achieved. On the other hand, with highly plasticized extruded propellants, complete extraction was achieved with 10% acetic acid from milled samples (20-mesh), without treatment with acetone or glacial acetic acid.

Important advantages of the proposed method are its safety and simplicity. It avoids sample digestion with strong acids and the use of a dilute acetic acid solution (to remove matrix materials) avoids matrix interferences (*e.g.*, effects of the nitrocellulose polymers) on the properties affecting nebulization rate. The extracted material never constituted more than 0.1% of the final solution even when acetone or glacial acetic acid was used. It is unnecessary to use the method of standard additions or to match standard and sample solutions (except for acetone content).

We have found that the proposed technique is also suitable for copper extraction, allowing simultaneous determination of lead and copper in propellants.

Summary—A procedure is described for the determination of lead in different types of propellant samples by atomic-absorption spectrophotometry. The method is simple, rapid and avoids the use of strong acids and prior sample digestion. Complete lead extraction is achieved with 10% acetic acid. The results obtained by the proposed method are compared with those obtained by the gravimetric chromate method. The variation of the efficiency of lead extraction with sample type is discussed.

SOLVENT EXTRACTION OF COPPER(II) WITH CHLORENDIC ACID

SELMAN A. BERGER
Department of Sciences, John Jay College of Criminal Justice, City University of New York,
445 West 59 St, New York, New York 10019, U.S.A.

(*Received* 21 *August* 1975. *Accepted* 12 *November* 1975)

Long-chain monocarboxylic acids, including versatic, naphthenic, and capric acids have been used as extractants for such metal ions as Fe(III),[1,2] Cu(II),[3–6] Ni(II),[7,8] and Co(II).[2,6,9] In many cases, these metal species have been found to be extracted as polymers into benzene as solvent. Cu(II) has been particularly noted as being capable of forming dimeric complexes with acetic acid,[10] as well as with the other monocarboxylic acids listed above. Recently, chlorendic acid, a hexachloro-substituted norbornyl 1,2-dicarboxylic acid, has been studied as an agent for extracting Fe(III) into both MIBK and benzene. In both cases only monomeric species are extracted.[11] In this work, the equilibrium between Cu(II) and chlorendic acid will be studied to compare the parameters with those for the monocarboxylates.

EXPERIMENTAL

Reagents

Copper(II) solutions were prepared from reagent grade $Cu(ClO_4)_2.6H_2O$. Chlorendic acid was obtained from Hooker Chemical Co. (Niagara Falls, N.Y.). Benzene and methyl isobutyl ketone (MIBK) were of reagent grade and used without further purification.

Apparatus

Solutions were shaken automatically. The pH was measured with a Fischer Accumet model 520 pH-meter equipped with a combination glass and calomel electrode. Absorption spectra were recorded with a Beckman DB-G spectrophotometer, and atomic-absorption measurements were made with the Jarrell-Ash model 810 atomic-absorption spectrometer.

Equilibration and analysis

Ten-ml aliquots of Cu(II) solution were shaken with equal volumes of chlorendic acid dissolved in either MIBK or benzene. The pH was adjusted by dropwise addition of either concentrated perchloric acid or 10% sodium hydroxide solution. After equilibration for designated time periods, the phases were allowed to settle, and the aqueous phase was separated, and filtered to remove any suspended drops of the organic phase. The pH of the aqueous phase was measured and then the phase was analysed by atomic-absorption spectroscopy.

RESULTS AND DISCUSSION

Equilibrium considerations

The generalized equilibrium expressions for the solvent extraction of metal ions with dibasic acids has been derived previously,[12] and given as follows,

$$\log D = \log K_{ex} + \frac{1}{x}\log x + (p + q + r)\log\overline{[H_2L]} + (2p + q)\,pH + \frac{(x - 1)}{x}\log\overline{[Cu(II)]} \quad (1)$$

The equation may be rewritten as,

$$\frac{1}{x}\log\overline{[Cu(II)]} - \log[Cu(II)] = \log K_{ex} + \frac{1}{x}\log x + (p + r + q)\log\overline{[H_2L]} + (2p + q)pH \quad (2)$$

The species in the organic phase are designated by the horizontal bar, while other parameters are defined as follows:

D = distribution coefficient
K_{ex} = overall equilibrium constant
p = number of L^{2-} species
q = number of HL^- species
r = number of H_2L species
x = degree of polymerization

The equation may be used to determine the various extraction parameters empirically, by use of a graphical slope technique.

Extractions as a function of metal concentration

Figure 1 illustrates the plot of log D *vs.* $\log\overline{[Cu(II)]}$ at different equilibrium pH ranges. Since K_{ex}, $\overline{[H_2L]}$, pH, and x remain reasonably constant in the ranges studied, the slope of the plot, $(x - 1)/x$, may be used to calculate x, the degree of polymerization, from equation (1). Curves

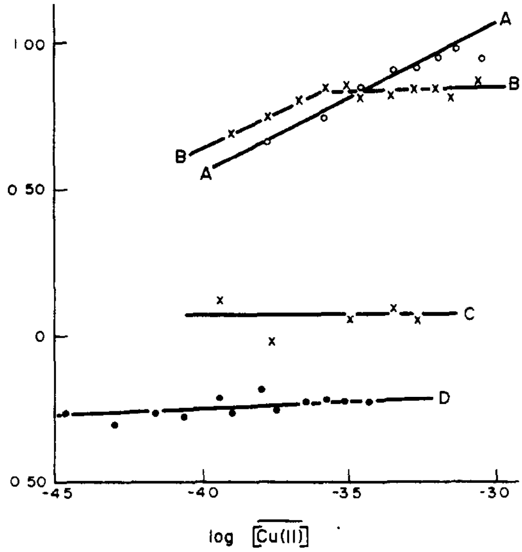

Fig. 1. A plot of log D *vs.* $\log\overline{[Cu(II)]}$. A: $[Cu(II)]_{in}$ = 0.2×10^{-3}–$1.0 \times 10^{-3}M$, $\overline{[H_2L]}_{in}$ = 0.10M, pH_{eq} = 4.7–5.0. B: $[Cu(II)]_{in}$ = 0.1×10^{-3}–$1.0 \times 10^{-3}M$, $\overline{[H_2L]}_{in}$ = 0.10M, pH_{eq} = 4.6–4.9; C: $[Cu(II)]_{in}$ = 0.2×10^{-3}–$1.0 \times 10^{-3}M$, $\overline{[H_2L]}_{in}$ = 0.10M, pH_{eq} = 3.5–3.7; D: $[Cu(II)]_{in}$ = 0.1×10^{-3}–$1.0 \times 10^{-3}M$, $\overline{[H_2L]}_{in}$ = 0.10M, pH_{eq} = 3.2–3.5

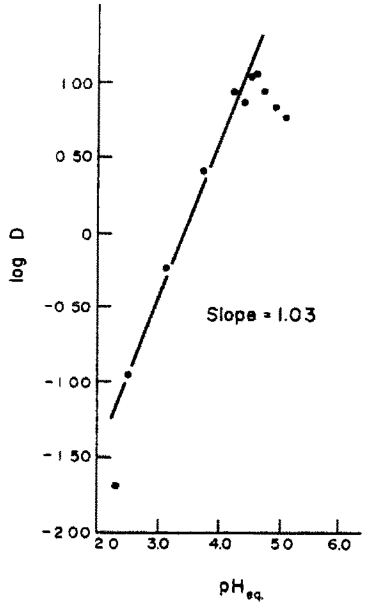

Fig. 2. A plot of log D *vs.* equilibrium pH. $[Cu(II)]_{in}$ = $1 \times 10^{-3}M$, $[\overline{H_2L}]_{in} = 1.0 \times 10^{-1}M$.

A and B, in the equilibrium pH ranges 4.7–5.0 and 4.6–4.9 respectively, show slopes equal to 0.5, which corresponds to values of $x = 2$, indicative of the extraction of dimeric species. While curve B flattens out at higher metal concentrations, it would be anomalous to infer that a monomer is being extracted, since existence of the polymer would be favoured at higher concentrations.[13] In the lower pH ranges, 3.2–3.5 and 3.5–3.7 for curves C and D, slopes equal to zero are obtained, implying that monomeric complexes are favoured.

Extraction as a function of equilibrium pH

In Fig. 2 the plot of log D *vs.* equilibrium pH is shown. Experimentally, the pH was changed by dropwise additions of either perchloric acid or sodium hydroxide solution. The slope of the line in the pH range 2.5–4.5 is equal to 1.03, which corresponds to the extraction of a metal ion with a charge of +1 from the aqueous phase. At first, one would think that the partially hydrolysed $Cu(OH)^+$ is extracted; however, equilibrium calculations for this pH range indicate that the concentration of $Cu(OH)^+$ is miniscule compared to the concentration of Cu^{2+}.[14] However, the extraction of $CuHL^+$ as the main aqueous species would explain the slope of +1.

To test this hypothesis for the extraction of a dimerized species, equation (2) would have to be used since in the case of polymerization there is a dependence of the extraction on the metal ion concentration. However, plotting (log $[\overline{Cu(II)}])/x$ − log [Cu(II)] *vs.* pH for $x = 2$, still gives a slope equal to unity, implying the extraction of $CuHL^+$ for the dimer as well as for the monomer.

At pH values greater than 4.5, the distribution coefficients begin to decrease, probably due to the formation of anionic Cu^{2+}-chlorendic acid complexes which are back-extracted into the aqueous phase. In this pH range, 4–5, chlorendic acid exists as H_2L only to the extent of 0.01–3.3% ($pK_{a1} = 2.60$, $pK_{a2} = 4.76$). At higher pH ranges, the proportion of $L^{2-}:HL^-$ increases, indicating that more highly dissociated ligands are present in the aqueous phase, increasing the likelihood of the formation of hydrophilic anionic Cu^{2+}-chlorendates. Similar phenomena were observed by Dyrssen in the extraction of metal–β-diketonates.[15]

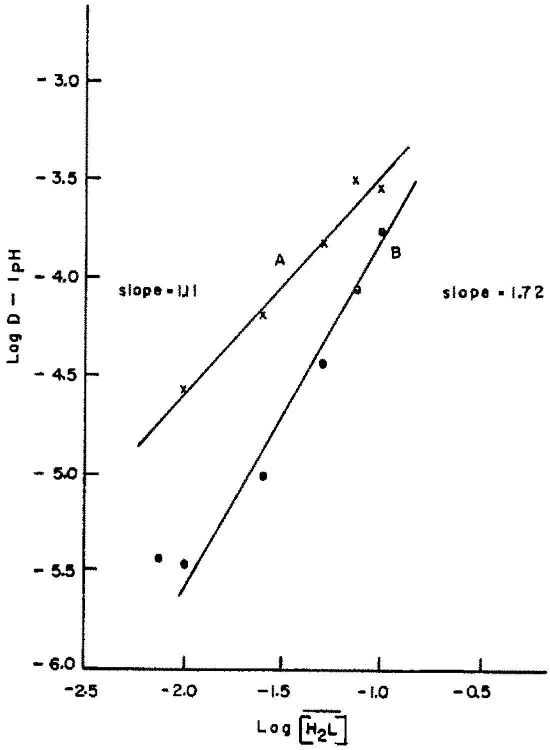

Fig. 3. Plot of log D − 1 pH *vs.* log $[\overline{H_2L}]$. Curve A: $[Cu(II)]_{in.} = 1 \times 10^{-3}M$, $[\overline{H_2L}]_{in.} = 0.1 \times 10^{-1} - 1.0 \times 10^{-1}M$, $pH_{eq.} = 3.6$–4.5. Curve B: $[Cu(II)]_{in.} = 1 \times 10^{-3}M$, $[\overline{H_2L}]_{in.} = 0.075 \times 10^{-1} - 1.0 \times 10^{-1}M$, $pH_{eq} = 4.7$–5.8.

Extraction as a function of ligand concentration

In the pH range 3.6–4.5, which was found to yield monomeric species, the slope of the plot of log $D - (2p + q)$pH *vs.* log$[\overline{H_2L}]$, for $2p + q = 1$, gives a slope equal to 1.11 for line A, Fig. 3. This is indicative of the extraction of a 1:1 chlorendic acid–Cu(II) complex, most probably $[Cu(II)(L^{2-})]$.

However, in the higher pH range 4.7–5.8, curve B, the slope of the plot of log D − pH *vs.* log $[\overline{H_2L}]$ is equal to 1.72, indicating a 2:1 complex. This would imply the extraction of $[Cu(II)(HL^-)_2]_2$ and/or $[Cu(II)(L^{2-})\cdot H_2L]_2$. Again, since a dimer is expected to be extracted in this range, the plot of (log$[\overline{Cu(II)}])/x$ − log[Cu(II)] − pH *vs.* log$[\overline{H_2L}]$ still generates a slope equal to two.

Effect of extracting solvent

In the equilibrium pH range 2.0–6.0, Cu(II) is not extracted into benzene. This is very unusual since other monocarboxylate–Cu(II) complexes are very readily extracted.[3–6] Apparently, whatever complex forms in the aqueous phase is much too polar to be extracted into the non-polar benzene. However, MIBK, being a polar solvent, would be much more likely to extract a highly polar complex. In addition, the presence of the carbonyl oxygen atom, a co-ordinating donor, would probably cause some interaction between the complex and the solvent, thus enhancing the extraction efficiency.

With MIBK, the extractions proceed quite rapidly, achieving equilibrium within 15 min.

Summary—The solvent extraction of Cu(II) with chlorendic acid has been studied. The composition of the extracted species appears to be a function of pH. In the pH range 3.2–4.6, a monomeric species exists $[\mathrm{Cu(II)}(L^{2-})]$, while at pH values greater than 4.5, a dimer in the form of $[\mathrm{Cu(II)}(L^{2-})\cdot H_2L]_2$ and/or $[\mathrm{Cu(II)}(HL^-)_2]_2$ is extracted.

ANALYTICAL DATA

FORMATION CONSTANTS FOR THE COBALT(II) CHLORIDE–1-NITROSO-2-NAPHTHOL SYSTEM IN ETHANOL–BENZENE MIXTURES*

Vincenzo Caruncio, Roberto Bedetti and Mauro Tomassetti
Istituto di Chimica Analitica dell'Università di Roma, 00185 Rome, Italy

(*Received* 25 *July* 1975. *Accepted* 14 *October* 1975)

The earlier investigations on the complex species obtained from cobalt(II) chloride and 2-nitroso-1-naphthol in ethanol–benzene solvent mixtures[1,2] have been repeated for the isomeric ligand 1-nitroso-2-naphthol.

EXPERIMENTAL

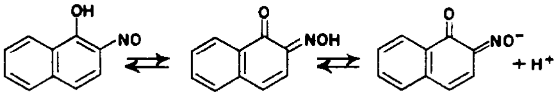
Materials, apparatus and operative conditions were the same as previously described.[1,2]

RESULTS AND DISCUSSION

The absorbance of the reaction mixtures ($C_L/C_M = 10$) increases slowly, becoming constant in about 1 hr. The spectrophotometric results at 500, 525 and 550 nm were processed by the mole-ratio[3] and Asmus (modified by Klausen and Langmhyr)[4] methods to determine the complexation ratios of the species and the conditional formation constants (Table 1). The absorption spectrum does not alter meaningfully with changing solvent medium; this is confirmed in the literature.[5]

The β' values obtained from the data for the different wavelengths were in good agreement. Increasing the ethanol content in the mixture raises the L/M complexation ratio to 4:1. The presence of such a species with a unidentate ligand is confirmed in other solvents.[6].

The same interpretations as before[1,2] can be applied to these results; 1-nitroso-2-naphthol should be present mainly in the quinonoid form (**IIa, IIb**) in all the four solvent mixtures investigated:



(I) (IIa) (IIb)

The tautomeric equilibrium for this ligand is reported to be shifted to the right (forms **IIa, IIb**) quantitatively (visible, ultraviolet, and NMR spectra),[7,8] while for the isomer 2-nitroso-1-naphthol the equilibrium seems to be strongly dependent on the solvent.[8,9] When the ethanol content is high, the donicity of the solvent mixture is relevant; the naphthol can hardly co-ordinate the cobalt by its quinonoid oxygen, the electrons of which are strongly bound in the benzene ring resonance, particularly because of the competitive action exerted by the solvent. At lower ethanol percentages, the donicity of the solvent diminishes, so the naphthol can act as a bidentate ligand. Uni- and bidentate complexation by the nitrosonaphthols is in agreement with the structural conclusions presented by Sathe and Shetty[10] about the species formed by the ligand in its quinonoid form with copper(II).

The formation constants of the cobalt(II) complexes with the two isomers are very similar (they differ by only one order of magnitude at most). This is in accordance, at least

Table 2. Absorptivities (10^3 l. mole^{-1}.cm^{-1}) for cobalt(II) chloride–1-nitroso-2-naphthol (ϵ_1) and cobalt(II) chloride–2-nitroso-1-naphthol (ϵ_2) systems calculated graphically at 525 nm, for ligand excess ($C_L/C_M = 10$)

Ethanol concn., % *v/v*	ϵ_1	ϵ_2*

in principle, with the acidity constants of the two ligands, which were found polarographically to be different by one logarithmic unit (in aqueous solution).[11] The most striking difference is presence of the ML_2 species in the 2-nitroso-1-naphthol system in 50% ethanol medium, but not with the isomer investigated here; this is to be interpreted only through the differences in the tautomeric equilibria and the effect of the solvent. Increasing the benzene concentration shifts the equilibrium to the left for the 2-nitroso-1-naphthol isomer, favouring bidentate ligand action and an ML_2 species.

The molar absorptivities of the complexes formed with the two isomers are similar (Table 2) and not appreciably influenced by changing the medium.

Summary—The values of conditional formation constants for the cobalt(II) chloride–1-nitroso-2-naphthol system were determined at 25° in ethanol–benzene mixtures of different compositions by spectrophotometry in the visible region. Comparisons were made with the results previously obtained with the isomeric ligand 2-nitroso-1-naphthol. In both cases the L/M complexation ratio of the species found increases with increasing ethanol content of the medium.

GAS–LIQUID CHROMATOGRAPHIC STUDY OF MONOSUBSTITUTED BENZALDEHYDE ISOMERS

Albertine E. Habboush and Ismail K. Al-Hitti
College of Science, University of Baghdad, Iraq

(*Received* 4 *June* 1974. *Revised* 8 *January* 1975. *Accepted* 30 *October* 1975)

Gas–liquid chromatography has been used for the identification and separation of aromatic compounds, including aldehydes.[1,2] Procedures have been given for the detection of benzaldehyde and some of its derivatives.[3,4] Prabucki and Lenz[5] reported the separation of aromatic aldehydes on a mixture of polyethylene glycol isophthalate and polyethylene glycol 400. The selectivity of stationary liquid phases was studied by several workers[6–11] but only a few investigators have used aldehydes as test compounds.[12,13]

In the present work, general quantitative separation of monosubstituted benzaldehydes on liquid phases of various physical and chemical characteristics has been achieved and the selectivity of these liquid phases for benzaldehyde isomers investigated.

Table 1. Packing specification of the columns

Stationary phase	Density, g/cm	Loading, % w/w	Weight of liquid phase, g	Maximum operating temp. °C	Solid support	Mesh size

Summary—The values of conditional formation constants for the cobalt(II) chloride–1-nitroso-2-naphthol system were determined at 25° in ethanol–benzene mixtures of different compositions by spectrophotometry in the visible region. Comparisons were made with the results previously obtained with the isomeric ligand 2-nitroso-1-naphthol. In both cases the L/M complexation ratio of the species found increases with increasing ethanol content of the medium.

GAS–LIQUID CHROMATOGRAPHIC STUDY OF MONOSUBSTITUTED BENZALDEHYDE ISOMERS

ALBERTINE E. HABBOUSH and ISMAIL K. AL-HITTI
College of Science, University of Baghdad, Iraq

(*Received* 4 *June* 1974. *Revised* 8 *January* 1975. *Accepted* 30 *October* 1975)

Gas–liquid chromatography has been used for the identification and separation of aromatic compounds, including aldehydes.[1,2] Procedures have been given for the detection of benzaldehyde and some of its derivatives.[3,4] Prabucki and Lenz[5] reported the separation of aromatic aldehydes on a mixture of polyethylene glycol isophthalate and polyethylene glycol 400. The selectivity of stationary liquid phases was studied by several workers[6–11] but only a few investigators have used aldehydes as test compounds.[12,13]

In the present work, general quantitative separation of monosubstituted benzaldehydes on liquid phases of various physical and chemical characteristics has been achieved and the selectivity of these liquid phases for benzaldehyde isomers investigated.

Table 1. Packing specification of the columns

Stationary phase	Density, g/cm^3	Loading, % w/w	Weight of liquid phase, g	Maximum operating temp. °C	Solid support	Mesh size
Silicone oil MS200/50 (SO)	0.971	20	3.40	225	Chromosorb P	60 – 80
Silicone gum rubber (SGR) (Se – 301)	–	2.5	0.527	250	Chromosorb G AW – DMCS	80 – 100
Apiezon L (APL)	–	20	3.40	325	Chromosorb P	80 – 100
Di(2-ethylhexyl) sebacate (DEHS)	0.912^{25}	20	3.40	175	Chromosorb P	60 – 80
Dinonyl phthalate (DNP)	–	10	1.031	150	Chromosorb W	80 – 100
2,4,7-Trinitrofluorenone (TNF)	–	10	0.995	200	Chromosorb W	80 – 100
Versamide 930 (VS)	–	2	0.191	250	Chromosorb W AW – DMCS	80 – 100
Polypropylene glycol (PPG) (L.B.– 550 – X)	0.984	15	1.73	150	Chromosorb W	80 – 100
Apiezon L + Bentone 34 (APL + 34)	–	10 + 10	1.814	250	Chromosorb W	80 – 100

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 451 fractometer equipped with a thermistor-type thermal-conductivity detector was used. The recorder was a 2.5-mV Honeywell Electronic unit. Nitrogen was used as the carrier gas. The average column temperature was controlled to within 0.2°. The columns (2 in. long and $\frac{1}{4}$-in. o.d.) were specially made to specification by Perkin-Elmer, U.K. They were U-shaped, made from stainless steel, and covered with asbestos sleeves to ensure uniform heating. The composition of the liquid phases and the packing specifications of the columns are shown in Table 1.

Samples

Equal weights of the isomers (Fluka, purest available) were blended in 3-ml cylindrical Pyrex cells. Sample sizes ranged from 0.1 to 4 μl for liquid isomers and from 0.2 to 8 μl of 10% w/w solution in acetone for solid isomers. Samples were injected with a 10-μl Hamilton syringe with a 1-in. fixed needle.

RESULTS AND DISCUSSION

Flow-rates were found to be optimum at 25 ml/min at NTP and this value was used throughout. Each injection for an individual isomer or mixture of isomers was repeated at least twice and the results were found to be reproducible.

The specific retention volumes, V_g^0, were calculated according to Littlewood *et al.*[14] The retention volume for the air-peak was taken as zero. Specific retention volumes for monosubstituted benzaldehydes at different column temperatures on the liquid phases examined are listed in Table 2.

The general elution order of the benzaldehyde isomers was mainly *o*-, *m*- and *p*. The *o*-isomers were resolved from *m*- and *p*-isomers and had the shortest retention volumes with the exception of *o*-methoxybenzaldehyde. This is mainly atttributed to the "*ortho*" effect, the intramolecular hydrogen-bonding that occurs between the formyl group and *o*-substituents, which minimizes the interaction of the *o*-isomers with the liquid phases. However, the fluoro, chloro and nitro groups, which possess higher inductive effects in the *o*-position, will decrease the basicity of the carbonyl groups and reduce their association with the liquid phases.

The elution order of *m*- and *p*-benzaldehydes followed the order of their dipole moments, with the exception of *m*- and *p*-nitrobenzaldehydes on APL + 34, and *m*- and *p*-fluorobenzaldehydes on DNP, DEHS, PPG and APL + 34. The reversed elution order in the first case may be attributed to the two partial negative charges on the nitro groups in the *p*-position, which may be attracted by the large positive charges on APL + 34, while the boiling point and dispersion forces have a greater influence on the elution order in the second case.

The most selective liquid phase for the separation and quantitative determination in this investigation is APL + 34, followed by DNP and DEHS, which is probably due to its special activity toward aromatic isomers. DNP and DEHS selectively resolved fluorobenzaldehydes, but only partial resolution of these isomers was obtained on PPG.

Acknowledgements—The authors are grateful to Dr. Sabri M. Farroha for his interest and helpful suggestions, and are indebted to the Head of the Chemistry Department, College of Science, and to the University of Baghdad for providing necessary requirements during the course of the work.

Summary—Monosubstituted benzaldehyde isomers have been studied quantitatively on nine stationary liquid phases of various physical and chemical characteristics and at different operating temperatures. Apiezon 1 + Bentone 34, dinonyl phthalate and di(2-ethylhexyl)sebacate are found to be selective for quantitative separation of the isomers studied.

ANNOTATION

THERMODYNAMIC EXAMINATION OF pH MEASUREMENTS

BJØRN BERGTHORSSON
Chemistry Department B, The Technical University of Denmark,
DTH 301 DK-2800 Lyngby, Denmark

(*Received* 20 *October* 1975. *Accepted* 25 *November* 1975)

Consider the acid–base reaction

$$A_1 + B_2 \rightarrow A_2 + B_1 \qquad (a)$$

where A_1,B_1 and A_2,B_2 are two conjugate acid–base pairs in the Brønsted–Lowry sense. If the extent of the reaction is denoted by ξ the affinity for the reaction can be expressed by

$$-\left(\frac{\delta G}{\delta \xi}\right)_{T,P} = -\Delta\mu^\circ + RT\ln\frac{a_{A_1}}{a_{B_1}} - RT\ln\frac{a_{A_2}}{a_{B_2}} \qquad (b)$$

μ being the chemical potential and a the activity of a component at temperature T. If now both acid–base pairs refer to the same aqueous solution, the affinity is zero; if, further, A_2,B_2 represents the pair H_3O^+, H_2O, equation (*b*) can be rearranged to

$$p = \log\frac{a_{H_2O}}{a_{H_3O^+}} = \frac{\Delta\mu^0}{RT\ln 10} + \log\frac{a_B}{a_A} = -\log K + \log\frac{a_B}{a_A} \qquad (c)$$

which gives the thermodynamic definition of p, its relation to pH, and its relation to the well-known Henderson–Hasselbach equation, K being the equilibrium constant.

Electromotive force, p, *and pH*

Consider now the electrochemical reaction

$$A + e^- \rightarrow B + \tfrac{1}{2}H_2 \qquad (d)$$

where A,B is an acid–base pair. The electromotive force, E, of this half-reaction is given by

$$E = E^0 - \frac{RT}{F}\ln\frac{a_B}{a_A} - \frac{RT}{F}\ln a_{H_2}^{\frac{1}{2}} \qquad (e)$$

If the acid–base pair is H_3O^+, H_2O then, as known, the value zero is given to E^0. When E refers to this acid–base pair it will be denoted by E_w in what follows; further, it is assumed that the activity of hydrogen is always the same for any two expressions which give a difference ΔE. When this is the case the difference

$$E_1 - E_2 = E_1^0 - \frac{RT}{F}\ln\frac{a_{B_1}}{a_{A_1}} - \left(E_2^0 - \frac{RT}{F}\ln\frac{a_{B_2}}{a_{A_2}}\right) \qquad (f)$$

expresses the thermodynamic affinity of reaction (*a*). If the pair A_2,B_2 represents H_3O^+, H_2O, then

$$E - E_w = E^0 - \frac{RT}{F}\ln\frac{a_B}{a_A} + \frac{RT}{F}\ln\frac{a_{H_2O}}{a_{H_3O^+}} \qquad (g)$$

All half-reactions (*d*), referring to the same solution, have the same electromotive force. Therefore, if E and E_w refer to the same solution, (*g*) may be rearranged to

$$p = \log\frac{a_{H_2O}}{a_{H_3O^+}} = \frac{-E^0 F}{RT\ln 10} + \log\frac{a_B}{a_A} = -\log K + \log\frac{a_B}{a_A} \qquad (h)$$

However, if two acid–base pairs, A_1,B_1 and A_2,B_2, do not refer to the same solution but to the solutions X and S, respectively, then equation (*h*) is valid for each solution and

$$p_X - p_S = \log\left(\frac{a_{H_2O}}{a_{H_3O^+}}\right)_X - \log\left(\frac{a_{H_2O}}{a_{H_3O^+}}\right)_S = \frac{-(E_1 - E_2)F}{RT\ln 10} = \frac{-(E_X - E_S)F}{RT\ln 10} \qquad (i)$$

which shows that an electrometric determination of p_X in comparison with p_S—if p_S is selected as a standard—results in a pH determination if, and only if, the activity of water is the same in both solutions. A consistent electrometric determination of pH involves this extra restriction which is not necessary when p is measured.

The present operational definition of pH should, strictly speaking, be modified by adding this restriction.[1] However, this will hardly be generally accepted, and this problem can probably be solved most easily by accepting the present definition as prescribing the measurement of the quantity p. When desired, the activity of water may be kept constant, whereby Δp will give ΔpH.

By assigning a value to one of the solutions, *viz.* solution S, a value can be found for the other. For this purpose it is more meaningful and useful to assign p values instead of pH values to solutions prepared from buffer substances, *e.g.*, as prescribed by the National Bureau of Standards.[2] It is often pointed out that a pH scale—*e.g.*, the NBS scale—only has significance for dilute solutions where the activity of the water is practically the same as for pure water.[3,4] One notices that the results of these considerations are not conditioned by such an assumption about the composition of the systems involved.

The thermodynamic basis of the operational definition may be elucidated further by means of the following expression derived from (*b*) and (*h*).

$$p_X - p_S = \log\frac{Q_{1,2}}{K_{1,2}} = \left(\frac{\delta G}{\delta \xi}\right)/RT\ln 10$$

where $Q_{1,2}$ is a mass-action expression of the same form as the equilibrium constant $K_{1,2}$; both are associated with reaction (*a*). Thus the present operational definition can be said to prescribe an evaluation of the instantaneous rate of change of G (at constant T and P) with respect to the extent of the Brønsted–Lowry acid–base reaction (*a*) in which any two acid–base pairs may participate as long as the one pair belongs to solution X and the other to solution S.

Summary—The electrometric determination of pH is essentially an evaluation of the thermodynamic quantity $-\log a_{H_3O^+}$ from a measurement of an electrical potential difference between two electrodes. It is accordingly necessary to examine the electrometric method in light of thermodynamic concepts in order to disclose the meaning of experimental pH values and their limitations. In this paper it is shown by thermodynamic considerations that the evaluation of $-\log a_{H_3O^+}$ is actually a special case of the evaluation of the thermodynamic quantity

$$\log \frac{a_{H_2O}}{a_{H_3O^+}}$$

The operational definition of pH prescribes a general method to evaluate this quantity, but not $-\log a_{H_3O^+}$ as commonly believed.

PRELIMINARY COMMUNICATIONS

MANGANESE(IV) AS AN OXIDIMETRIC REAGENT IN SULPHURIC ACID SOLUTIONS

S.K. Mandal and B.R. Sant

Regional Research Laboratory, Bhubaneswar 751004, India

(*Received* 11 *March* 1976. *Accepted* 30 *March* 1976)

During studies on the behaviour of oxidizing agents on a tetrachlorohydroquinone (TCHQ) column,[1] we observed difficulty in reducing potassium permanganate in acidic medium. Preliminary experiments showed that permanganate solution prepared in sulphuric acid of high concentration (*ca.* 9*M*) changes its colour from pink to yellow in about 24 hr. This reaction is initially very vigorous and takes place with evolution of oxygen. The solution, when passed through a TCHQ column, is reduced quantitatively to manganese(II). Addition of a measured and excessive amount of iron(II) and back-titration with a standard dichromate solution shows that a 2-electron reaction occurs. We therefore suggest that manganese(IV) is formed from permanganate at high sulphuric acid concentration.

Manganese(IV) salts are strong oxidizing agents. The standard potential[2] of the redox system $Mn^{4+} + 2\underline{e} \rightarrow Mn^{2+}$ is 1.577 V (*cf.* $Mn^{4+} + \underline{e} \rightarrow Mn^{3+}$, 1.62 V; $Mn^{3+} + \underline{e} \rightarrow Mn^{2+}$, 1.511 V; $MnO_4^- + 8H^+ + 5\underline{e} \rightarrow Mn^{2+}$, 1.52 V). The older literature cited by Mellor[3] reported the reduction of permanganate in concentrated sulphuric acid, but there was little evidence for formation of manganese(IV).[4-6] Some authors[7-10] have reported the formation of manganese(IV) by reduction of permanganate with alkaline tellurite or by oxidation of manganese(II) with alkaline hydrogen peroxide in the presence of excess of tellurate, which stabilizes the manganese(IV). Desideri[11] studied the mechanism of permanganate reduction at a platinum electrode and presented evidence for the existence of manganese(III) and MnO^{2+} as intermediates in presence of manganese(II) and sulphuric acid. Kharabadze[12] reported the production of sulphates of manganese(III) and (IV) by the anodic dissolution of manganese metal in concentrated sulphuric acid.

This preliminary investigation reports the conditions under which manganese(IV) can be obtained in sulphuric acid solution and its use as an oxidimetric reagent. Potassium permanganate solutions in 9*M* sulphuric acid were found to be reduced within 12 hr. The choice of sulphuric acid concentration was somewhat arbitrary. At lower acidities conversion of permanganate into manganese(IV) was slow, but for purposes of titrimetry it is not desirable to go above this acidity. The solution is yellow in dilute and dark-brown in concentrated solutions.

Spectrophotometric studies

The absorption spectrum of a dilute solution of potassium permanganate (8×10^{-5}*M*) in sulphuric acid was scanned from 200 to 600 nm at various time intervals. There is a gradual decrease in the permanganate concentration and after about 7 - 8 hr there is no permanganate left. The absorption spectrum of a 12-hr old 2×10^{-4}*M* manganese(IV) solution in 9*M* sulphuric acid is shown in Fig. 1. There is a shoulder at 265 - 285 nm, but no maximum was observed for manganese(IV) in the visible region although permanganate and manganese(III) show maxima at 546 and 500 nm respectively. Manganese(III), which is stable in pyrophosphate medium, does not absorb in the ultraviolet region.[13]

Preparation of standard manganese(IV) solution

To prepare a 0.05M solution, dissolve about 7.9 g of potassium permanganate in 9M sulphuric acid with vigorous stirring, preferably by magnetic stirrer, over a period of 6 - 8 hr. Leave the solution overnight, then make it up to 1 litre with 9M sulphuric acid and then standardize it as follows:

(i) With iron(II) sulphate solution. Make 25 ml of iron(II) solution (previously standardized with permanganate or dichromate) 1 - 5M in sulphuric acid, and titrate it with the manganese(IV) solution in the presence of a drop of ferroin indicator.

(ii) With sodium oxalate solution. Heat 25 ml of sodium oxalate solution (in 1 - 5M sulphuric acid) to 70°, and titrate it with the manganese(IV) solution. The end-point is indicated by a light pink colour, presumably due to manganese(III).

The titre deteriorates by 0.1 - 0.2% per day and solutions need to be standardized daily.

Manganese(IV) as an oxidimetric reagent

Our initial studies have shown that manganese(IV) can act as an oxidizing agent for almost all the conventional reductants, e.g., Fe^{2+}, VO^{2+}, As^{3+}, $C_2O_4^{2-}$, I^- etc. It is also observed that it oxidizes cerium(III) to cerium(IV). Potentiometric titrations of manganese(IV) (platinum electrode) with Fe^{2+}, VO^{2+}, and Ce^{3+} all give two potential breaks, presumably due to the reduction of manganese(IV) first to manganese(III) and then to manganese(II). However, the first break is very small (slope 2.5 mV/0.05 ml) and only the second is useful (slope about 270 mV/0.05 ml). Equilibration of the electrode potentials takes about 3 min in the end-point region). The reverse titrations are also possible but show only the change from manganese(IV) to manganese(II) (slope about 270 mV/0.05 ml at the end-point for iron, less for the others). Manganese(IV) can be used as an oxidimetric reagent for the quantitative estimation of a variety of reductants. Detailed analytical studies and kinetics of the reduction of permanganate to manganese(IV) are now in progress and will be published later.

A NEW CHELATE-FORMING RESIN WITH DITHIZONE FUNCTIONAL GROUP PREPARED BY THE CONVERSION OF AN ANION-EXCHANGE RESIN

H. Tanaka, M. Chikuma*, A. Harada, T. Ueda and S. Yube

Faculty of Pharmaceutical Sciences, Kyoto University,
Sakyo-ku, Kyoto 606, Japan

(Received 6 April 1976. Accepted 8 April 1976)

For the concentration and collection of heavy metal ions by a chelating resin, the presence of the thiol group as the chelating group on the resin is desirable because of its selectivity and ability to form stable chelates. Some effective thiol-containing chelating resins for the adsorption of heavy metal ions have been synthesized.[1–4] However, the introduction of the thiol group into the resin matrix is not easy. Further, the resin is not easily recoverable after adsorption of metal ions. Some chelate-forming granules have been introduced for the same purpose.[5–7] They are easily prepared, but their exchange capacity is not as high as that of the chelating resin.

We have prepared a chelate-forming resin of a new type, by the simple procedure described below, namely by the treatment of common strongly basic anion-exchange resin with a sulphur-containing chelating agent which involves the functional group for the anion-exchange together with the chelating group. We selected a sulphonic acid derivative of dithizone  (**I**), as chelating agent. **I** was synthesized from p-hydrazinobenzenesulphonic acid and carbon disulphide as follows. Carbon disulphide (1.5 ml) and ethanol (60 ml) were added to about 40 ml of an aqueous solution of p-hydrazinebenzenesulphonic acid (6 g) and sodium hydroxide (1.3 g) and the solution was refluxed for several hours. After the solution was cooled, addition of 200 ml of ethanol gave a white precipitate. The precipitate (1 g), dissolved in a small amount of water, was added to 25 ml of ethanol containing 0.2 g of sodium hydroxide. The solution immediately turned red. The red precipitate deposited by the addition of acetone (200 ml) was collected by filtration. Thin-layer chromatography of the product (solvent; methanol) gave one spot. **I** is stable as its sodium salt both in aqueous solution and the dry state, but is very unstable as the free acid. The spectral properties of **I** (Fig. 1) are similar to those of dithizone.

The chelate-forming resin was obtained when 1 g of the anion-exchange resin (Amberlite IRA 400 in the chloride form, 100 – 200 mesh) was stirred with 50 ml of aqueous solution of various amounts of **I**.

The exchange capacity for **I**, examined by the batchwise method, was 1.9 mmole per g of dry resin. The time required for the saturation of the resin with **I** was 2 – 3 hr, and only 20 min was needed for the adsorption of about a third of this amount, and this is enough for practical use of the resin. The resin thus prepared, if stored in a refrigerator, is stable for at least three weeks.

---

*To whom requests for reprints should be addressed.

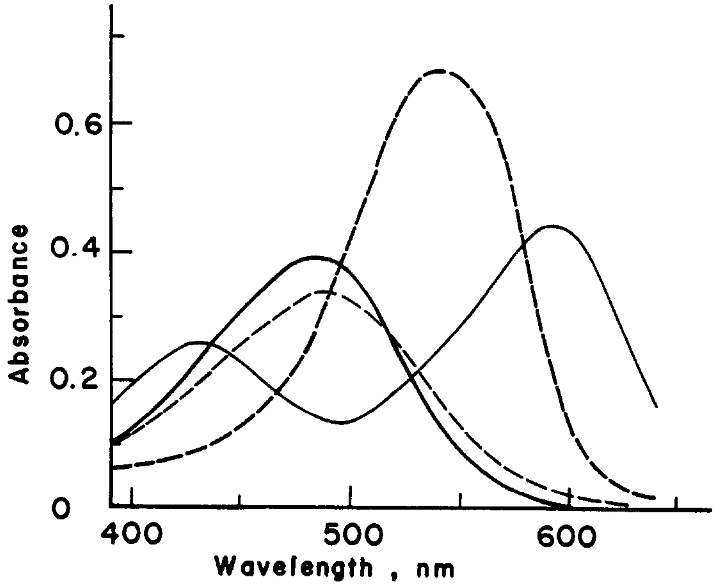

Fig. 1. Absorption spectra of 2.5 x 10^{-5}M sulphonic acid derivative of dithizone, I. (——)pH 1.2, (- -) pH 12.0, (——) pH 1.2 with 1.25 x 10^{-5}M Hg^{2+}, (- -) pH 12.0 with 2.5 x 10^{-5}M Hg^{2+}.

The occurrence of ion-exchange between the resin and I was confirmed by the release of an equal number of moles of chloride ion (determined by Mohr's method). I is, however, not eluted from the resin even with 2M sodium hydroxide. The strong adsorption of I on the resin matrix may be explained in terms of both ion-exchange and some physical adsorption. In fact, dithizone is considerably adsorbed on the resin matrix, but without release of chloride.

The behaviour of the resin towards mercury(II) is shown in Fig. 2. The binding ratio of Hg(II) to I on the resin was found to be about 1:2 from Fig. 2, and the composition of the mercury(II) chelate with I in the pH range 1.0 - 5.4 was also 1:2 (mole-ratio method). This means that the I on the resin was utilized completely for the effective adsorption of mercury(II).

The mercury(II) adsorbed could not be released by 20% mineral acid solution, but it was released almost completely by concentrated hydrochloric acid, as shown in Table 1, and the original resin was recovered. The eluate was violet after the treatment with concentrated hydrochloric acid and the absorption spectrum of the eluate was found to be similar to that of isomerized dehydrodithizone.[8] The resin recovered could be used repeatedly for the adsorption of mercury(II) by the same procedure.

Recently the preparation and properties of a similar type of resin, loaded with 8-quinolinol-5-sulphonic acid, which is useful for the collection of various kinds of metal ions, were reported briefly.[9] Resins with a sulphur-donor group may be significant for the selective collection of heavy metal ions. This new type of resin may be particularly useful because it is very easily prepared and the original resin can be recovered.

Acknowledgement - The authors are indebted to Dr. Yoshimasa Tanaka of Okayama University for his helpful advice on the preparation of I. The authors wish to thank the Ministry of Education, Japan, for a Grant-in-Aid (No. 011013).

THE INFLUENCE OF HALIDES ON AMPEROMETRIC COMPLEX-FORMATION TITRATIONS WITH THE ROTATING MERCURY ELECTRODE

G. DEN BOEF and F. FREESE
Laboratory for Analytical Chemistry, University of Amsterdam, Nieuwe Achtergracht 166,
Amsterdam 1004, The Netherlands

(*Received* 5 *December* 1975. *Accepted* 17 *December* 1975)

Summary—The interference of halides with complexometric titrations, indicated by means of the anodic wave of the ligand at a rotating mercury electrode, has been studied theoretically. The effect of halides strongly depends on the pH of the solution. In alkaline solutions there appears to be no interference by chloride at all. A critical value for the halide concentration can easily be found for any medium. The theoretical predictions have been verified experimentally.

Amperometric complex-formation titrations using a rotating mercury electrode as indicator electrode have been described.[1,2,3] The method enables micromolar concentrations of metal ions to be determined. In order to maintain constant values of the conditional stability constants of the metal complexes formed, the titration solution has to be buffered. Proper choice of the pH can improve the selectivity of the titrations. Low pH values further the selectivity for the determination of metal ions forming very stable complexes with the titrant,[1,3] whereas high pH values are favourable for the selective titrations of metal ions that complex only negligibly with hydroxyl ions and ions of the alkaline buffer systems.[2] The first group contains such metal ions as copper(II), thorium(IV) and gallium(III), whereas the alkaline earths ions belong to the latter group.

As the concentration of the ligand during the titration is monitored by means of the anodic dissolution of the electrode, the possible interference of halide ions has to be considered. The half-wave potential of the anodic ligand wave becomes more negative with increasing pH. Hence the interference by halides will be less serious in alkaline solutions.

In a previous paper[1] a few scattered results were given for the influence of chloride and bromide on the titration of copper(II) with TRIEN. In the present communication the problem will be treated more systematically.

THEORETICAL

The theoretical treatment will be given for the influence of halides on determinations at a dropping mercury electrode. The electrode reactions are supposed to be reversible, which is correct for d.c. polarography.[4,5]

The current–voltage curve for the anodic dissolution of mercury in a medium containing a ligand L that forms 1:1 complexes with mercury(II), is given[1] by (25°, SCE)

$$E = 0.608 + 0.0295 \log \alpha_{\mathrm{L(H)}} - 0.0295 \log K_{\mathrm{HgL}} + 0.0295 \log (i/i_{\mathrm{d}} - i) \quad (1)$$

It has been assumed that the species involved in the electrode reaction have the same diffusion constant and that the only side-reaction is that of L with protons.

Taking the value of K_{HgL} as 10^{22} and tabulated values of $\alpha_{\mathrm{L(H)}}$, the half-wave potential $E_{\frac{1}{2}(\mathrm{L})}$ can be given as a function of pH. For the anodic dissolution of mercury in a medium containing halides two possibilities arise, *i.e.*, the formation of the insoluble mercury(I) halide or the formation of a mixture of mercury(II) halide complexes. The two cases will be treated separately. When an insoluble mercury(I) halide is formed the current–voltage curve is given by

$$E = 0.543 + 0.0295 \log S_{\mathrm{Hg_2X_2}} - 0.059 \log \frac{i_{\mathrm{d}} - i}{k_{\mathrm{X}}} \quad (2)$$

as derived by Kolthoff and Miller.[6] Assuming a limiting current of 10 μA for a $10^{-3}M$ halide solution, k_{X} will have a value of 10^4 μA. 1. mole^{-1}.

For the current–voltage curve in the case of complex-formation of mercury(II) with halides, we also start with the Nernst equation,

$$E = 0.608 + 0.0295 \log [\mathrm{Hg}^{2+}]_{\mathrm{s}} \quad (3)$$

in which $[\mathrm{Hg}^{2+}]_{\mathrm{s}}$ is the concentration of mercury(II) at the electrode surface. The reaction at the electrode surface is

$$\mathrm{Hg} + \bar{n}_{\mathrm{s}}\mathrm{X}^- \rightleftharpoons \mathrm{HgX}_{\bar{n}_{\mathrm{s}}}^{2-\bar{n}_{\mathrm{s}}} + 2\mathrm{e}$$

Charges for X and the complexes will be omitted in the rest of the paper; $\bar{n}_{\mathrm{s}}$ represents the average ligand number at the surface of the electrode. The average ligand number $\bar{n}$ is defined by Bjerrum as

$$\bar{n} = \frac{\sum_{1}^{n} n\beta_n[\mathrm{X}]^n}{\sum_{0}^{n} \beta_n[\mathrm{X}]^n} \qquad (4)$$

Thus $\mathrm{HgX}_{\bar{n}_s}$ stands for a mixture of complexes of Hg(II) with X, the composition of which is fixed by $[\mathrm{X}]_s$, the concentration of the free halide at the electrode surface.

For the problem under study, simplifications can be made, leading to an explicit relationship between potential and current, but this is not so in general. As the general case may be of interest for other applications as well, it seems useful to give the full derivation here.

In equation (3) $[\mathrm{Hg}^{2+}]_s$ has to be replaced by an expression taking into account the reaction between Hg(II) and X at the electrode surface. The extent to which Hg(II) reacts with X can adequately be described by means of the side-reaction coefficient $\alpha_{\mathrm{Hg(X)}}$.

$$\alpha_{\mathrm{Hg(X)}} = \frac{\sum_{0}^{n} [\mathrm{HgX}_n]}{[\mathrm{Hg}^{2+}]}$$

Hence

$$E = 0.608 + 0.0295 \log \frac{\sum_{0}^{n} [\mathrm{HgX}_n]_s}{\alpha_{\mathrm{Hg(X)}_s}}$$

or

$$E = 0.608 - 0.0295 \log \alpha_{\mathrm{Hg(X)}_s} + 0.0295 \log \sum_{0}^{n} [\mathrm{HgX}_n]_s \qquad (5)$$

The current–potential relation can be derived by assuming a steady state at the electrode surface.[7] This means for the halide ion X that the supply of X to the electrode surface by diffusion, which is proportional to $\{[\mathrm{X}]_{\mathrm{bulk}} - [\mathrm{X}]_s\}$, is just compensated by the amount of X consumed per unit of time by Hg(II) produced at the electrode surface, which is $\bar{n}_s i/2F$.

Hence

$$i = i_a + i_c = \frac{k_\mathrm{X}}{\bar{n}_s} \{[\mathrm{X}]_{\mathrm{bulk}} - [\mathrm{X}]_s\} \qquad (6)$$

where i_a and i_c represent the anodic and the cathodic current respectively.

The supply of Hg(II) in any form per unit of time is $i/2F$, which in the steady state is compensated by the diffusion of mercury(II) and its halide complexes into the bulk of the solution, which is proportional to

$$\sum_{0}^{n} [\mathrm{HgX}_n]_s$$

if Hg(II) and its halide complexes have the same diffusion coefficient.

Hence

$$i = i_a + i_c = k_{\mathrm{Hg(II)}} \sum_{0}^{n} [\mathrm{HgX}_n]_s \qquad (7)$$

Substitution of (7) into (5) leads to

$$E = 0.608 - 0.0295 \log \alpha_{\mathrm{Hg(X)}_s} + 0.0295 \log \frac{i}{k_{\mathrm{Hg(II)}}} \qquad (8)$$

The current–potential curve can now be drawn by means of equations (6) and (8) starting with $[\mathrm{X}]_s$ as a parameter. For every value of $[\mathrm{X}]_s$ a value for $\alpha_{\mathrm{Hg(X)}_s}$ and for $\bar{n}_s$ can be calculated. Then the corresponding values of E and i can be obtained. The equations (6) and (8) reflect the continuous change in the average ligand number of the mercury(II) halide complexes formed at the electrode surface, down to $\bar{n}_s = 0$ at the final rise of the current–voltage curve. It can also be seen from equation (6) that a limiting current

$$i_d = \frac{1}{\bar{n}_s} k_\mathrm{X} \{[\mathrm{X}]_{\mathrm{bulk}} - [\mathrm{X}]_s\}$$

may occur when two conditions are fulfilled: (*a*) $[\mathrm{X}]_s$ must be negligible with respect to $[\mathrm{X}]_{\mathrm{bulk}}$, (*b*) $\bar{n}_s$ must remain constant over a certain concentration range $\Delta\log[\mathrm{X}]$ of the halide.

From equations (6) and (8) it can be seen that this limiting current will develop over a potential range

$$\Delta E = 0.0295\, \bar{n}_s \Delta\log[\mathrm{X}]$$

In practice, halides will not interfere when present in concentrations of the same order of magnitude as the compounds involved in the titration reaction, as under these circumstances the anodic ligand wave can always be seen in the polarogram even when the anodic halide wave occurs at the same potential. Therefore the interference of halides only has to be considered for concentrations large with respect to the concentration of the species to be determined. Whether the interference will be serious or not, will—from a polarographic point of view—depend on the potential at the point of intersection of the halide wave and the ligand wave, relative to the half-wave potential of the ligand wave. The current value at the point of intersection will always be low in comparison with the limiting current of the halide wave. We may assume that at these relatively low currents the halide concentration at the electrode surface will not differ much from that in the bulk of the solution. This means that for our present purpose $\alpha_{\mathrm{Hg(X)}_s}$ in equation (8) may be replaced by the constant value $\alpha_{\mathrm{Hg(X)}_{\mathrm{bulk}}}$, which results in

$$E = 0.608 - 0.0295 \log \alpha_{\mathrm{Hg(X)}_{\mathrm{bulk}}} + 0.0295 \log \frac{i}{k_{\mathrm{Hg(II)}}} \qquad (8a)$$

from which the initial rise of the current–potential curve can be drawn directly.

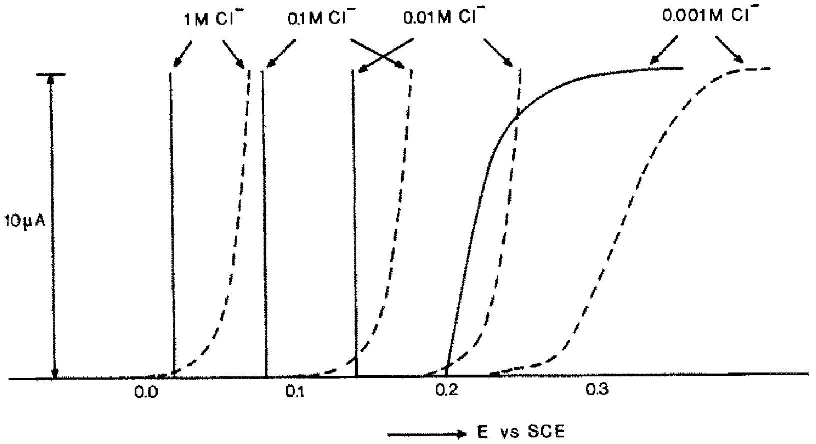

Fig. 1. Current–voltage curves, calculated for the anodic oxidation of mercury at a DME in solutions of different concentrations of chloride. Solid lines: $2Hg + 2Cl^- \rightarrow Hg_2Cl_2 + 2e$; Dotted lines: $Hg + nCl^- \rightarrow HgCl_n^{(2-n)+} + 2e$.

Figure 1 presents some polarograms according to equations (2), (6), (8) and (8a) for chloride concentrations 1, 10^{-1}, 10^{-2} and $10^{-3}M$. Both k_X and $k_{Hg(II)}$ have been taken as 10^4 μA. 1. mole^{-1}. Values for log $\alpha_{Hg(Cl)}$ and $\bar{n}$, given in Table 1, have been calculated with log $\beta_1 = 6.7$; log $\beta_2 = 13.2$; log $\beta_3 = 14.1$ and log $\beta_4 = 15.1$. $S_{Hg_2Cl_2}$ has been taken as $10^{-17.7}$. It can be seen from Fig. 1 that under all circumstances there is interference due to the formation of Hg_2Cl_2. The same holds for bromide. For iodide however, complex formation begins to predominate in about $5 \times 10^{-2}M$ solutions, but this is of no practical significance, as iodide interferes already in lower concentrations. So in the following only the interference by the formation of Hg_2X_2 will be considered. Furthermore the discussion will be restricted to complexometric titrations with EDTA as the ligand.

Table 1. Values of $\alpha_{Hg(Cl)}$ and $\bar{n}$ for various values of [Cl⁻]

[Cl⁻], *M*	log $\alpha_{Hg(Cl)}$	$\bar{n}$
1	15.15	3.89
10^{-1}	11.61	2.92
10^{-2}	9.24	2.09
10^{-3}	7.20	2.01

Figure 2 presents polarograms at different pH values according to equation (1) for a concentration of EDTA of about $10^{-3}M$ ($i_d = 10$ μA and log $K_{HgL} = 22$) and polarograms according to equation (2) for different concentrations of chloride. Serious interference is assumed to start when the concentration of chloride reaches a critical value at which the interfering current–voltage curve and the current–voltage curve of the ligand intersect at the half-wave potential of the ligand wave. The values of the interfering concentrations of chloride calculated in this way have been compared with experimentally obtained values.

EXPERIMENTAL

Polarograms with the dropping mercury electrode were taken with a Metrohm E polarograph. The buffers[3] and titration equipment[1-3] were the same as used before. Half-wave potentials of the ligand wave were determined by

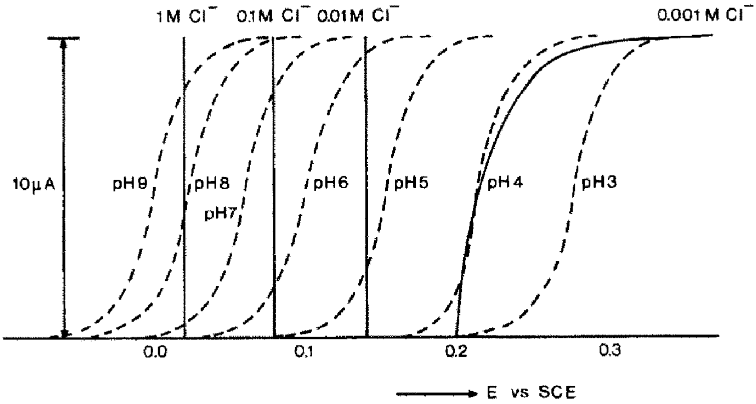

Fig. 2. Current–voltage curves, calculated according to equation (1) ($i_d = 10$ μA, dotted lines) for different pH values, and according to equation (2) (solid lines) for different concentrations of chloride.

Table 2. Critical values for [Cl$^-$] in the case of $10^{-3}M$ EDTA at a DME

pH	Buffer	[Cl$^-$], M
3.50	phthalate	0.001
4.55	phthalate	0.005
4.50	acetate	0.005
5.00	acetate	0.01

derivative polarography. Interference was assumed to occur when the peak at the half-wave potential vanished owing to the presence of the halide.

Table 2 gives the values of the chloride concentration at which the half-wave peak disappears for different pH values in the case of an EDTA concentration of $10^{-3}M$. There is good agreement between the results in Table 1 and the theoretical conclusions from Fig. 2. Table 3 gives similar results for $10^{-4}M$ EDTA. Table 4 gives some results for measurements of half-wave potentials of $10^{-4}M$ EDTA in the presence of bromide. The agreement between the experimental results and the theoretical predictions, which are not given for bromide here, is also very good.

So far, theoretical considerations and experimental results have been compared for the anodic wave at the dropping mercury electrode. It can be expected that the situation will not alter much when a rotating mercury electrode is used, indicating lower concentrations of the ligand at higher sensitivity in the presence of the same concentrations of halide.

In equation (1) the values of i and i_d will not alter much, as the possible increase of the current due to the fact that a rotating electrode is used is nearly compensated by the decrease of the current due to the smaller concentrations of the compounds involved in the titration reaction. Moreover the half-wave potential will remain the same. Hence the overall change in the wave will be small.

The curve of equation (2) will remain the same at the initial rise of the current–potential curve, where $i \ll i_d$, because the last term in equation (2) originates from $0.059 \log[X]_s$, which for $i \ll i_d$ may be written as $0.059 \log[X]_{bulk}$. Hence the lower part of the curve of equation (2) at a certain value of $[X]_{bulk}$ will be the same for the rotating and the dropping electrode.

As the halide wave [from equation (2)] and ligand wave [from equation (1)] remain nearly unaltered, the conclusions obtained from Tables 2–4 for the interference of halides with the ligand wave for concentrations of the ligand of 10^{-4} or $10^{-3}M$ at the dropping electrode will remain the same for the interference of halides with titrations involving ligand concentrations of $10^{-5}M$ at the rotating electrode.

Table 3. Critical values for [Cl$^-$] in the case of $10^{-4}M$ EDTA at a DME

pH	Buffer	[Cl$^-$], M
5.05	acetate	0.001

7.0	maleate	$[Cl^-] = 10^{-2}$
7.0	maleate	$[Br^-] = 10^{-4}$
9.0	tris	$[Cl^-] = 10^{-1}$
9.0	tris	$[Br^-] = 10^{-2}$

Table 6. Critical values for [Cl$^-$] in the titration of $10^{-5}M$ copper(II) with TRIEN and DTPA at a rotating mercury electrode

pH	Buffer ($10^{-2}M$)	Titrant	[Cl$^-$], M
5.0	acetate	TRIEN	0.001
5.0	acetate	DTPA	0.005
7.0	maleate	TRIEN	0.01
9.0	tris	TRIEN	0.1
9.0	tris	DTPA	0.5

If, however, the interfering process would be the formation of mercury(II) halide complexes the electrode would take a more negative potential and the interference would become more serious. As we have already seen, mercury(II) halide formation will in general not be the interfering process.

All these considerations neglect the differences between current–voltage curves obtained with a dropping and a rotating electrode. Nevertheless, the experimental results, obtained for titrations at a rotating electrode in the presence of chloride and bromide, appear to be in agreement with the theoretical considerations given for the dropping electrode.

Table 5 gives the values of the chloride and bromide concentrations which do not interfere with the determination of $10^{-5}M$ copper(II) with EDTA at different pH values. As DTPA and TRIEN have slight advantages over EDTA as a titrant for copper(II) a number of determinations with these ligands have been carried out in the presence of chloride. Some typical results are given in Table 6. When DTPA is used as the titrant, slightly larger amounts of halides can be tolerated. When TRIEN is used, the titration curves show sharper end-points.

L'ESTIMATION DE L'ERREUR, INTRODUITE DANS LE DOSAGE DES ELEMENTS A L'ETAT DE TRACES DANS LES ROCHES, LIEE AUX CARACTERISTIQUES STATISTIQUES DE LEUR REPARTITION

H. JAFFREZIC*

Groupe des Sciences de la Terre du Laboratoire "Pierre-Sue", C.E.N./Saclay, Boite Postale No. 2,
91190 Gif sur Yvette, France

(*Reçu le* 16 *octobre* 1975. *Accepté le* 9 *novembre* 1975)

Résumé—L'analyse des éléments à l'état de traces dans les roches peut être soumise à de nombreuses causes d'erreur. On peut en distinguer deux grandes catégories: les erreurs liées à l'échantillon analysé, c'est-à-dire à la méthode d'échantillonnage, à la préparation de l'échantillon (broyage et homogénéisation), à la répartition des éléments dans cet échantillon, et, les erreurs dues à la technique d'analyse utilisée. Dans cet article, nous nous intéressons plus particulièrement à l'erreur due à la répartition des éléments dans la poudre de roche à analyser. Une méthode expérimentale relativement rapide et simple est utilisée pour évaluer l'importance de ce genre d'erreur dans quelques échantillons types. Cette méthode est fondée sur l'analyse par activation neutronique. La variance d'échantillonnage a été aussi déterminée en fonction de la masse de la prise d'essai. Les résultats montrent que des analyses faites sur des prélèvements de petite quantité de poudre peuvent entraîner des erreurs importantes sur le résultat final (erreur d'un facteur deux ou plus dans la détermination du hafnium dans un granite au niveau d'une prise d'essai de 10 mg). Un modèle théorique simplifié nous permet d'expliquer les résultats expérimentaux tout au moins qualitativement.

Le développement relativement récent de la géochimie est une conséquence directe des progrès réalisés en chimie analytique. En particulier, les méthodes physiques ou instrumentales rapides, fondées sur la comparaison d'un signal émis par un étalon et l'échantillon à analyser, soumis à une excitation (action sur le cortège électronique ou sur le noyau des atomes) sont maintenant communément utilisées pour le dosage des éléments majeurs et des éléments à l'état de traces dans les roches et les minéraux.

La quantité et la qualité des résultats disponibles s'en trouvent considérablement accrues.

Les problèmes analytiques ne sont pas tous pour autant résolus. Il suffit pour s'en convaincre, de se référer aux nombreuses compilations publiées dans la littérature, concernant les étalons de roches aussi bien américains que français. En voici quelques exemples.

Pour les éléments majeurs:

Roche	Elément	Coefficient de variation, %	Référence
G_2	Al_2O_3	3	1
G_2	SiO_2	1,5	1
DRN	Al_2O_3	3,7	2
DRN	SiO_2	1,6	2

Pour les éléments à l'état de traces:

Roche	Elément	Etendue (range) *ppm*	Référence
G_2	Zr	250–400	1
G_2	Rb	108–503	1
DRN	Co	20–70	2
DRN	Rb	52–82	2

Nous avons pris ces exemples au hasard à titre indicatif. Mais, ceux-ci montrent bien que, si pour les éléments majeurs la concordance est bonne entre différentes méthodes et différents laboratoires, la situation est assez inquiétante en ce qui concerne les éléments à l'état de traces.

Il s'agit là d'une constatation d'ordre général. L'examen critique des principales causes d'erreurs qui peuvent affecter les données géochimiques est d'une importance primordiale, puisque la vérification des théories géochimiques en dépend.

Parmi les causes possibles, Shaw[3] en distingue trois principales:

—une hétérogénéité possible au niveau de l'ensemble géologique étudié

—une erreur due à l'échantillonnage sur le terrain (celle-ci découlant de la première)

—une erreur due à l'analyse chimique.

---

*Détaché du Centre de Recherches Pétrographiques et Géochimiques de Nancy.

On peut en ajouter une, due au prélèvement d'une partie de l'échantillon en vue de l'analyse (cette erreur étant également liée à l'hétérogénéité éventuelle de l'échantillon).

Les troisième et quatrième points concernent directement l'analyste. Nous nous proposons dans ce qui suit d'étudier l'incidence de la taille des prélèvements sur le dosage des éléments à l'état de traces.

MODELES D'ECHANTILLONS

L'échantillon de roche qui parvient au laboratoire d'analyse, se présente sous la forme d'une poudre dont la taille moyenne des grains est d'environ 80 μm. Au niveau du grain cette poudre est hétérogène, et cela d'autant plus que la roche d'origine est composée de plusieurs espèces minérales. Le soin apporté à la préparation de l'échantillon broyé peut également jouer un rôle important.

Wilson[4] dans une étude théorique partant de l'hypothèse d'une distribution binomiale des grains montre que l'erreur relative introduite de ce fait dans le dosage d'un élément est inversement proportionnelle à la racine carrée du nombre de grains n contenu dans l'échantillon analysé. Soit:

$$S_R = \sqrt{\frac{K'}{n}} \quad \text{ou} \quad S_R = \sqrt{\frac{K}{m}}$$

où m est la masse de la prise d'essai, K et K' sont des constantes qui dépendent des proportions relatives des différentes espèces minérales et de leur densité. Ingamells *et al.*[5,6] dans une série d'articles consacrés au même problème proposent d'utiliser la constante K comme "constante d'échantillonnage". K a en effet la dimension d'une masse. C'est la masse de la prise d'essai telle que "le coefficient de variation dû à l'échantillonnage", soit de 1%. Cette constante est alors caractéristique d'un élément dans une poudre de roche déterminée. Une telle donnée serait précieuse pour l'utilisation des étalons de roche. Elle permet de choisir la taille du prélèvement convenable pour l'analyse.

Malheureusement, ce modèle qui a pour origine la distribution binomiale n'a pas un caractère général. Un effet de ségrégation éventuel n'apparaît pas.

Une "théorie générale de l'échantillonnage" développée de manière semi empirique par Visman[7,8] en s'appuyant sur des "modèles *à priori*" de population conduit à donner à la fonction $S_R = f(m)$ la forme:

$$S_R = \sqrt{\frac{A}{m}} + B$$

où A et B sont des constantes. A s'identifie à la constante K précédemment définie, B est la composante de la variance due à un effet de ségrégation. Duncan[9] dans une critique de la théorie de Visman donne des justifications théoriques à cette formulation et met en garde contre le fait qu'il s'agit là aussi d'une approximation. En particulier B ne peut évidemment pas être un terme constant lorsque la taille du prélèvement augmente. C'est un terme approximativement constant dans un certain domaine de taille d'échantillon.

Ces quelques rappels faits, nous nous proposons d'étudier le comportement des éléments en traces dans cette optique, c'est-à-dire de déterminer expérimentalement la fonction $S_R = f(m)$ dans des cas concrets (S_R sera exprimé en % de la teneur de l'élément).

PRINCIPE DE LA METHODE

Nous avons utilisé l'activation neutronique comme technique analytique. Il n'est pas nécessaire pour résoudre notre problème de déterminer les teneurs des éléments. Nous utilisons simplement le fait que la radioactivité mesurée pour un élément donné est proportionnelle à la masse de cet élément, ou, en ramenant à l'unité de masse de l'échantillon, à la teneur en cet élément.

Soit:

$$t_i = k_i A_i$$

ou t_i est la teneur en un élément i, A_i le résultat de la mesure de radioactivité en nombre de désintégrations par unité de temps, et k_i une constante qui dépend des caractéristiques nucléaires de l'élément et de l'intensité du flux de neutrons utilisé.

Si on irradie simultanément n échantillons, k_i est identique pour tous. Dans ces conditions, nous pouvons écrire:

$$\sigma(\log t_i) = \sigma(\log A_i) \qquad (1)$$

$\sigma(\log k_i)$ étant nul puisque k_i est une constante (le flux de neutrons étant constant comme nous l'indiquons plus loin). Si les erreurs sont faibles, elles sont assimilables à des différentielles. L'expression:

$$\frac{\sigma(t_i)}{\bar{t}_i} = \frac{\sigma(A_i)}{\bar{A}_i} = 10^{-2} S_{R_i}$$

est équivalente à (1) ($\bar{t}_i$ est la teneur moyenne dans les n échantillons; $\bar{A}_i$ est la moyenne des mesures de radioactivité pour les n échantillons irradiés simultanément).

Dans la pratique nous avons travaillé sur les séries de prélèvements de 150, 100, 50 et 10 mg. Chaque série comportait $n = 12$ à 25 prélèvements. La technique d'irradiation a été décrite par ailleurs.[10] Les mesures de radioactivité ont été faites au moyen d'un détecteur solide (germanium dopé au lithium) et nous avons estimé la variance pour chaque série j et chaque élément i par:

$$S_i^2 = \frac{\sum_{j=1}^{n} (A_{ij} - \bar{A}_i)^2}{n-1}$$

d'où

$$S_{R_i} = \frac{100 S_i}{\bar{A}_i}$$

A ce stade se pose le problème de savoir si S^2 est bien une estimation de la "variance d'échantillonnage". En effet des contributions importantes pourraient intervenir à divers niveaux:

—erreur due à des variations du flux de neutrons,

—erreur due à la pesée de l'échantillon,

—erreur due à la variation de géométrie des échantillons par rapport au détecteur,

—erreur due à la mesure de la radioactivité.

En ce qui concerne les trois premiers points, nous avons constaté que les erreurs sont négligeables par rapport à la quatrième. Cette dernière cause est prédominante et peut seule entrer en considération.

Il est possible de l'estimer. En effet: les phénomènes de désintégration sont décrits par la loi de Poisson[11] pour laquelle la moyenne est égale à la variance. Le nombre de désintégrations N mesuré étant très élevé, on admet que ce nombre appartient à une distribution de Gauss de moyenne N et d'écart type $\sqrt{N}$.

D'où

$$S_d = \frac{100\sqrt{N_i + B_i}}{A_i}\% \text{ (avec } N_i - B_i = A_i)$$

où S_d est l'écart type sur la mesure de radioactivité, N_i le nombre de désintégrations mesuré dans la zone d'énergie qui concerne l'élément i, et B_i le bruit de fond dans cette zone.

Dans bien des cas, un test de comparaison entre S_R et S_d n'est pas nécessaire.

Voici quelques valeurs caractéristiques:

Elément	S_R, %	S_d %
Th	5	0,2
Co	2,3	0,4
Ta	2,3	0,7
Rb	1,5	1,2
Ni	3,7	3,7

Nous avons éliminé les cas litigieux, c'est à dire ceux pour lesquels le test de comparaison $S_R^2 = S_d^2$ contre $S_R^2 > S_d^2$ (test de χ^2) n'était pas significatif ou tout juste significatif, soit en pratique $S_R > 2S_d$ (exemple de Rb dans le tableau précédent).

RESULTATS

Les résultats obtenus pour deux étalons du C.R.P.G. (Nancy, France) GA et GSN, qui sont des granites et pour une obsidienne (verre naturel) sont reportés en coordonnées log–log sur les figures. La masse du prélèvement est portée en abscisse et en ordonnée, les valeurs de S_R en pour cent.

Cette représentation est commode en particulier dans le cas où la fonction $S_R = f(m)$ est de la forme $S_R = \sqrt{K/m}$. La courbe représentative est alors une droite de pente $(-\frac{1}{2})$ et le point d'intersection de cette droite avec la droite $S_R = 1$ donne la valeur de K.

Cas de GSN (*Fig.* 1)

Il apparaît que le modèle le plus simple est compatible avec nos résultats pour tous les éléments étudiés dans GSN. Dans le tableau suivant, nous donnons quelques valeurs de K pour différents éléments dans cet étalon.

Elément	*K, mg*
Cs	60
Co	100
Sc	40
Ta	60
Th	400
Hf	1000

Ce résultat montre que si on veut doser le hafnium dans le granite GSN en utilisant des prises d'essai de 10 mg, il faudra faire 100 dosages pour espérer avoir une précision de 1% sur la teneur en hafnium.

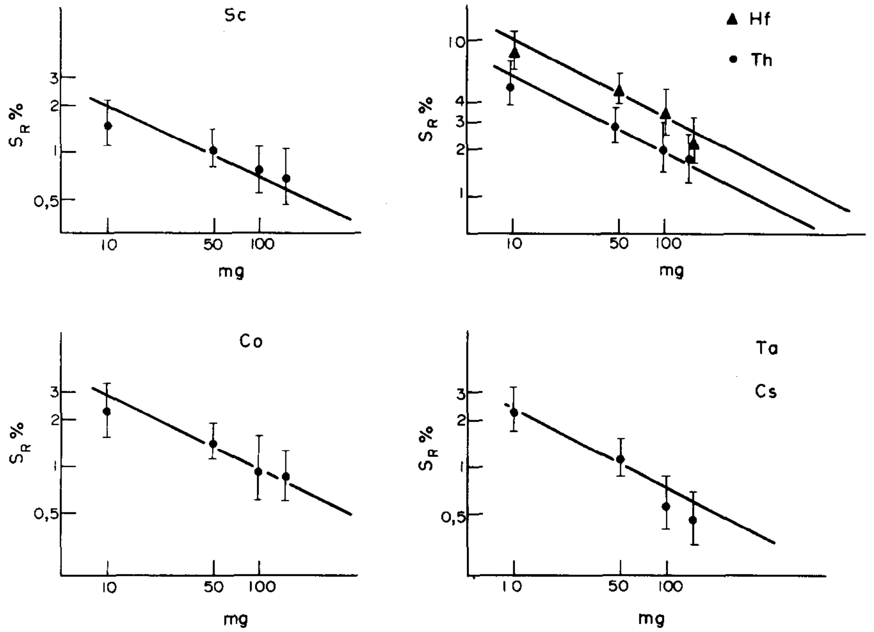

Fig. 1. Granite GSN. Evolution du coefficient de variation en fonction de la masse des prélèvements.

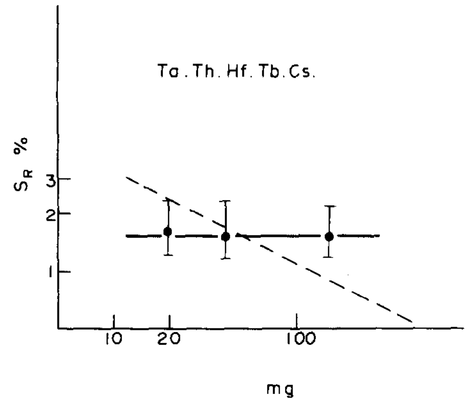

Fig. 2. Obsidienne. Evolution du coefficient de variation en fonction de la masse des prélèvements. La droite de pente $(-\frac{1}{2})$ en pointillés représente l'homogénéisation parfaite.

On ne peut évidemment pas extrapoler ces droites jusqu'à des masses voisines de 1 mg ou inférieures, mais il est à craindre qu'un dosage n'ait plus de sens à ce niveau.

Il faut remarquer aussi que pour des éléments tels que Cs, Co, Sc qui sont normalement associés à des éléments majeurs, les valeurs de K sont loin d'être faibles.

Cas de l'obsidienne (*Fig.* 2)

L'obsidienne est un verre. Tous les éléments doivent y être particulièrement bien répartis de manière uniforme. Nous constatons que tous les éléments se comportent de la même manière et que dans la gamme de 10 à 150 mg "le coefficient de variation dû à l'échantillonnage" est faible 1,5% mais constant. Cela ne peut s'expliquer que par la présence d'une phase qui n'est pas de l'obsidienne (ce qui est exact, l'obsidienne représente 95% environ de l'ensemble) et surtout que la poudre n'a pas été correctement homogénéisée après le broyage. Seule la composante de ségrégation intervient.

Le modèle

$$S_R = \sqrt{\frac{A}{m} + B}$$

convient dans ce domaine de 10 à 150 mg avec $A/m \ll B$.

Cas du granite GA (*Fig.* 3)

La situation est beaucoup plus complexe pour GA. Le hafnium et le zirconium se trouvent sous forme de zircons ($SiZrO_4$) qui sont des grains bien individualisés et répartis régulièrement dans la poudre de roche. Le modèle simple $S_R = \sqrt{K/m}$ s'applique parfaitement à ces deux éléments. Constatons seulement que la valeur de K pour le hafnium est particulièrement élevée ($K = 5000$ mg) cinq fois plus forte que celle annoncée pour GSN.

Pour des éléments tels que Th, Ta, Ce, Tb (lanthanides d'une manière générale), qui ne sont pas associés à des éléments majeurs, on observe des courbes comportant un plateau (ou tout au moins une variation très faible de S_R). Si m augmente, S_R tend vers 0. Pour les masses inférieures à 10 mg on doit s'attendre à une augmentation de la valeur de S_R.

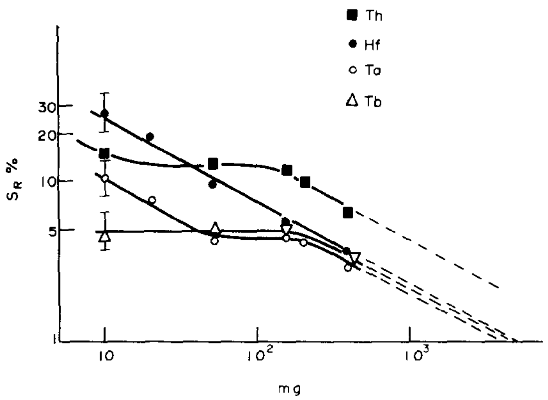

Fig. 3. Granite GA. Evolution du coefficient de variation en fonction de la masse des prélèvements.

Ce type de variation a d'ailleurs été décrit par Duncan[9] comme une "possibilité".

Ces formes de courbes traduisent un défaut d'homogénéisation. Aucun des deux modèles proposés ne permet de les décrire totalement. Nous avons déjà dit plus haut que le terme B de la formule $S_R = \sqrt{(A/m) + B}$ n'était qu'approximativement constant et ceci dans un domaine limité.

MODELE PROPOSE

Supposons que la poudre soit décomposée en n zones fictives, la proportion de zone i étant f_i ($i = 1,2\ldots$ et $\Sigma f_i = 1$).

Pour établir l'expression de la variance, nous admettons les hypothèses suivantes:

—la taille des prélèvements est petite devant la taille de chaque zone; dans ce cas, le nombre de prélèvements qui pourrait se faire sur une "frontière" entre deux zones est négligeable;

—un grain de poudre peut contenir ou ne pas contenir l'élément à doser et dans les grains qui contiennent cet élément, sa concentration y est constante;

—tous les grains ont la même dimension et dans une zone donnée, ils sont répartis uniformément.

Dans une zone i, la probabilité de rencontrer un grain contenant l'élément à doser est f_i. Pour un prélèvement de taille n grains, l'espérance du nombre de grains X_i contenant l'élément est $EX_i = np_i$.

La variance de X_i est $\sigma^2(X_i) = EX_i^2 - (EX_i)^2$ avec $\sigma^2(X_i) = np_i(1 - p_i)$.

Pour l'ensemble des zones, c'est à dire pour la totalité de la poudre, la variance est:

$$\sigma^2 = EX^2 - (EX)^2$$

avec $EX = \Sigma_i f_i EX_i$ et $EX^2 = \Sigma_i f_i EX_i^2$. Soit en exprimant EX_i et EX_i^2 en fonction de n, p_i et f_i:

$$\sigma^2 = \Sigma f_i np_i(1 - p_i) + \Sigma f_i(np_i)^2 - (\Sigma f_i np_i)^2$$

ou une valeur relative:

$$\sigma_R^2 = \frac{\Sigma f_i p_i(1 - p_i)}{n(\Sigma f_i p_i)^2} + \frac{\Sigma f_i p_i^2 - (\Sigma f_i p_i)^2}{(\Sigma f_i p_i)^2} \qquad (2)$$

Remarques

1. Dans cette expression, si $f_i = 1$ (ce qui entraîne $f_2 = f_3 \ldots f_i \ldots = 0$) le second terme est nul et

$$\sigma_R^2 = \frac{(1 - p)}{np} \qquad (3)$$

où p est une constante caractéristique de la poudre et n est proportionnel à la masse m du prélèvement. La formule (3) s'écrit: $\sigma_R^2 = A/m$ (A = constante).

2. Tant que la taille des prélèvements reste très inférieure à la taille des zones, le second terme de l'expression (2) est constant et σ_R est de la forme:

$$\sigma_R^2 = \frac{A}{m} + B$$

Ces deux formules sont celles proposées au paragraphe "modèles d'échantillons".

Il est évident que si la taille des prélèvements croît, le nombre de zones distinctes diminue. L'écart entre les f_i diminue également et σ_R^2 tend vers zéro.

EXEMPLE NUMERIQUE

Supposons que i puisse prendre deux valeurs $i = 1$ et $i = 2$. Si nous nous plaçons dans une partie de la courbe $S_R = f(m)$ où S_R est constant, le premier terme de l'expression (1) est nul et σ_R s'écrit:

$$\sigma_R^2 = \frac{(k^2 - 1)f_1 + 1}{[(k - 1)f_1 + 1]^2} - 1$$

avec $k = P_1/P_2$; f_1 peut être défini comme le degré d'homogénéisation de la poudre. Il est possible d'estimer f_1 connaissant σ_R^2 (estimé expérimentalement pour S_R^2) et k (estimé par le rapport des deux valeurs extrêmes de la série de mesures).

Pour l'obsidienne nous trouvons $f_1 = 0{,}95$ (avec $k = 1{,}07$ et $S = 0{,}015$). Pour le granite GA (élément = terbium), nous trouvons $f_1 = 0{,}80$ (avec $k = 1{,}19$ et $S = 0{,}05$).

Le modèle que nous venons de décrire distingue bien les deux composantes de la variance et surtout met en évidence ce qui les caractérise: une dépendance directe vis à vis de la taille du prélèvement pour la première composante et pour la seconde, sous certaines conditions, une indépendance (en première approximation).

Nous avons là une description de l'allure des courbes expérimentales et une possibilité de déterminer certains paramètres de la poudre de roche, en particulier le degré d'homogénéisation.

CONCLUSION

Il nous paraît essentiel que pour les étalons de roche internationaux, une description la plus complète possible de leurs caractéristiques statistiques soit donnée.

Ces renseignements sur l'homogénéité des poudres sont importants pour l'utilisateur (et pour le fabricant); ils permettent de choisir la masse de prise d'essai compatible avec une certaine précision et aussi de tester efficacement une procédure analytique.

Nous avons constaté que le seul paramètre proposé par Ingamells (A = constante d'échantillonnage) est insuffisant dans bien des cas.

Nous pensons que la donnée complète de la fonction $\sigma_R = f(m)$ soit sous forme graphique, soit sous forme d'une description statistique, est indispensable pour l'utilisation correcte des étalons de roche. Cela est surtout vrai pour le dosage des éléments à l'état de traces, mais aussi pour les éléments majeurs si les prélèvements sont petits (quelques milligrammes par exemple).

METAL OXIDE ELECTRODES AS SENSORS IN COMPLEXOMETRIC TITRATIONS

ADAM HULANICKI and MAREK TROJANOWICZ
Institute of Fundamental Problems in Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 3 *September* 1975. *Accepted* 12 *January* 1976)

Summary—EDTA titrations of lead and manganese, and of some other ions by using these as indicator ions, have been followed potentiometrically with PbO_2 and MnO_2 electrodes. Explanations are put forward for the anomalies observed in the titration curves. With the MnO_2 electrode, formation of an Mn(III)–EDTA complex is responsible for the diminished potential breaks. With the PbO_2 electrode the decrease in the potential break and the distortion of the curves in acid solution may be due to reaction between electrode coating and titrant. The MnO_2 electrode has been used for titrations of Ba^{2+}, Ca^{2+}, Cd^{2+} and Cu^{2+} with errors < 1%.

Ion-selective membrane electrodes have tended to replace metal and amalgam electrodes for end-point indication in potentiometric titrations. However, it seems that for several ions metal oxide electrodes may be useful either in direct potentiometry or as end-point sensors in titrations.

Oxide electrodes were originally used for the measurement of pH.[1] The potential of an electrode consisting of a metal Me and its oxide $MeO_{n/2}$ may be expressed by

$$E = E^0_{Me^{n+}/Me} + \frac{RT}{nF}\ln K_{s0} - \frac{RT}{F}\ln a_{OH^-} \qquad (1)$$

where K_{s0} represents the solubility product of the oxide. This equation can be transformed into

$$E = E^0_{MeO_{n/2}/Me} + \frac{RT}{nF}\ln a_{H^+} \qquad (2)$$

When the metal oxide electrode is in contact with a solution of the metal ions in a different oxidation state from that in the oxide, then the potential-determining reaction may be described by

$$MeO_{n/2} + nH^+ + (n-m)e \rightleftharpoons Me^{m+} + nH_2O$$

and the potential given by

$$E = E^0_{MeO_{n/2}/Me^{m+}} - \frac{RT}{(n-m)F}\ln a_{Me^{m+}} + \frac{n}{(n-m)}\cdot\frac{RT}{F}\ln a_{H^+} \qquad (3)$$

or, when the pH and the ionic strength are constant,

$$E = E^0_{pH=const.} - \frac{RT}{(n-m)F}\ln a_{Me^{m+}} \qquad (4)$$

According to this equation the oxide electrode could, in principle, be used for a direct measurement of Me^{m+}, or in a potentiometric titration of this ion, or of other ions by using the technique of an indicator ion.[2]

Polarized platinum electrodes coated with oxides of Mn(IV), Pb(IV) or Bi were used by Kraft[3] in potentiometric titrations. Nomura and Nakagawa[4] used a Pt/MnO_2 electrode as indicator for the complexometric titration of various ions. Vandael[5] used a platinum helix coated with lead or bismuth oxide for the same purpose. Wang and co-workers[6] detected titration end-points with an electrode consisting of PbO_2 in paraffin. The shapes of the titration curves were often unexplained.

In this study the application of platinum electrodes, coated electrolytically with MnO_2 or PbO_2, as indicator electrodes in chelatometric titrations has been investigated. A mechanism is put forward as an explanation of the observed irregularities in their behaviour.

EXPERIMENTAL

Potentials were measured with Radiometer pHM 26 and Wroclaw N-512 ELPO pH-meters. Radiometer K 401 calomel and G 222 B glass electrodes were used, and indicator electrodes were prepared by anodic deposition of oxides on a 0.7-cm^2 platinum foil under conditions used in electrogravimetry.[7]

All reagents were of analytical grade. Doubly distilled water was used for the preparation of solutions. The concentrations of standard solutions were established by the usual methods.

DISCUSSION AND RESULTS

Direct chelatometric titrations

The variation of the electrode potentials as a function of pH was studied for $10^{-3}M$ solutions of manganese(II) and lead(II) with and without an excess of EDTA (Fig. 1). The curve 1 for Mn^{2+} is linear up to pH 9 with slope of 120 mV/pH, in good agreement with the 118 mV/pH predicted by equation (3). The curvature at high pH is due to the formation of hydroxo-complexes. Titrations should be possible above pH 8, but it was found that stable potentials are reached only very slowly, which make the titrations rather impractical.

The potentials of the PbO_2 electrode were much less reproducible than those of the MnO_2 electrode

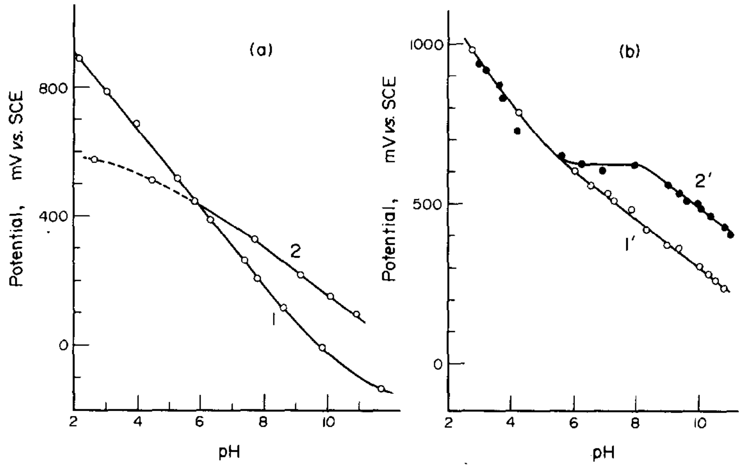

Fig. 1. Potential–pH relationship for MnO_2 (*a*) and PbO_2 (*b*) electrodes in solutions containing Mn^{2+} and Pb^{2+} ions, respectively: 1,1′—10^{-3} *M* Me^{2+}; 2,2′—10^{-3} *M* MeEDTA + 10^{-3} *M* EDTA.

and the agreement between the calculated and experimental values for a titration was poor (Fig. 2). The rate of titration significantly influences the results, which usually have a positive error (2–10% for titrations in acetate and ammonia buffers). In the first part of the titrations the potential of the PbO_2 electrode is adequately described by the equation:

$$E = E^0_{PbO_2/Pb^{2+}} - \frac{RT}{2F}\ln\frac{[Pb^{2+}]}{\alpha_{Pb}} + \frac{2RT}{F}\ln[H^+] \quad (5)$$

where α_{Pb} is the side-reaction coefficient for Pb^{2+} taking into account the presence of hydroxide and buffer. However, at pH < 6.5 for a lead concentration of about $10^{-6}M$ the system PbO_2, Pb^{2+} is thermodynamically unstable in aqueous solution. When the titrant is added in excess, the potential after the end-point should be given by the equation:

$$E = E^0_{PbO_2/Pb^{2+}} + \frac{RT}{2F}\ln\frac{[Y']K'_{PbY}}{[PbY']} + \frac{2RT}{F}\ln[H^+] \quad (6)$$

where Y represents the EDTA ligand, and K'_{PbY} the conditional stability constant of the complex. However the potential of the system PbO_2, PbY is much more positive and the reaction

$$2PbO_2 + 2H_2Y^{2-} \rightleftharpoons 2Pb(II)Y^{2-} + O_2 + 2H_2O \quad (7)$$

tends to proceed to the right. As a result of this the ratio [Y′]/[PbY′] decreases and the potential slowly decreases after the end-point. Wang found[6] that the maximum sometimes observed for this titration curve does not correspond exactly with the end-point. Reaction (7) is a source of positive error even when the titration curve has a conventional S-shape. Because of these errors, the titration does not seem likely to have any useful applications.

Chelatometric titrations with indicator ion

In this type of titration the potential of the indicator electrode[2] should be given by the equation:

$$E = E^0_{MeO_2/Me^{2+}} - \frac{RT}{2F}\ln\frac{C^0_{Me}K'_{NY}}{\alpha_{Me}\left(K'_{MeY}\dfrac{[NY']}{[N']} + K'_{NY}\right)} + \frac{RT}{F}\ln[H^+] \quad (8)$$

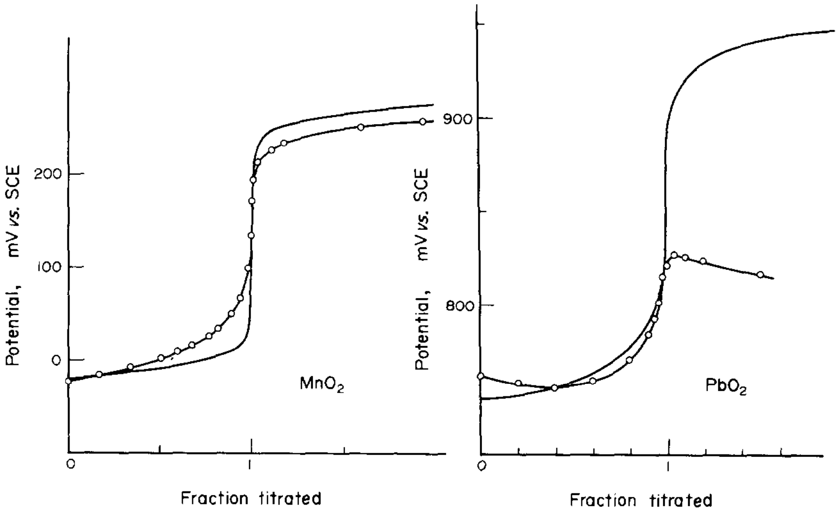

Fig. 2. Complexometric titration of 10^{-3} *M* solutions of Mn^{2+} and Pb^{2+} with MnO_2 (pH 9.3) and PbO_2 (pH 4.6) indicator electrodes: solid lines—theoretical curves; points—experimental data.

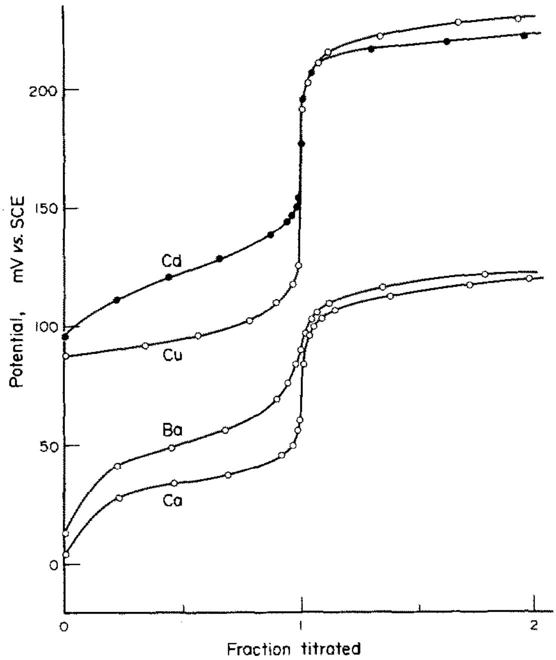

Fig. 3. Titration of $10^{-3}M$ solutions of various metal ions with MnO_2 indicator electrode in 1*M* ammonia buffer at pH 9 (Cd^{2+}, Cu^{2+}) and at pH 10 (Ba^{2+}, Ca^{2+}), $C^{\circ}_{Mn} = 10^{-5}M$.

where N represents the ion titrated, C°_{Me} the total concentration of the indicator ion and K' the conditional stability constant of the complex indicated by subscript.

In the case of the MnO_2 electrode, titrations of $Ba^{2+}, Ca^{2+}, Cd^{2+}$ and Cu^{2+} with EDTA were investigated in various buffers, in the presence and absence of dissolved oxygen (Fig. 3). The potential breaks observed are adequate for a determination of the end-point when concentrations of 10^{-3}–$10^{-4}M$ are used. As expected, the concentration of the indicator ion ($10^{-5}M$) does not affect the change in potential. The potentials observed at the beginning of the titrations ($f = 0$) are close to those predicted theoretically (Figs. 4,5) but those observed after the end-point ($f = 2$) are not, the difference being 150 or 190 mV in the presence or absence of oxygen, respectively, independent of pH and the cation being titrated. Similar discrepancies have been observed by Nomura and Nakagawa.[4]

To explain this behaviour we have considered the following reaction:

$$MnO_2 + Mn(II)Y^{2-} + H_2Y^{2-} + 2H^+ \rightarrow 2Mn(III)Y^- + 2H_2O \quad (9)$$

studied previously by Yoshino *et al.*[8] Because of formation of $Mn(III)Y^-$ the titrated solutions become yellowish after the end-point and the disproportionation of $Mn(III)Y^-$ gives a dark precipitate of MnO_2. In calculating the electrode potential the following equilibria should be considered:

$$MnO_2 + 4H^+ + 2e \rightleftharpoons Mn^{2+} + 2H_2O \quad (10)$$

$$Mn^{3+} + e \rightleftharpoons Mn^{2+} \quad (11)$$

$$Mn^{3+} + Y^{4-} \rightleftharpoons Mn(III)Y^- \quad (12)$$

Using the standard potentials, the following equation for the electrode potential can be arrived at:

$$E = 2E^0_{MnO_2/Mn^{2+}} - E^0_{Mn^{3+}/Mn^{2+}} + \frac{RT}{F}\ln\frac{[Y^{4-}]^2 K_{Mn(III)Y}[H^+]^4}{[Mn(III)Y^-]} \quad (13)$$

To compare this expression with experimental data the concentration of $Mn(III)Y^-$ should be eliminated, as it cannot be estimated directly.

From the stability constant of the complex

$$K_{Mn(III)Y} = \frac{[Mn(III)Y^-]}{[Mn^{3+}][Y^{4-}]} \quad (14)$$

and the equilibrium constant

$$K = \frac{[Mn^{3+}]^2}{[Mn^{2+}][H^+]^4} \quad (15)$$

of the redox reaction

$$MnO_2 + Mn^{2+} + 4H^+ \rightleftharpoons 2Mn^{3+} + 2H_2O \quad (16)$$

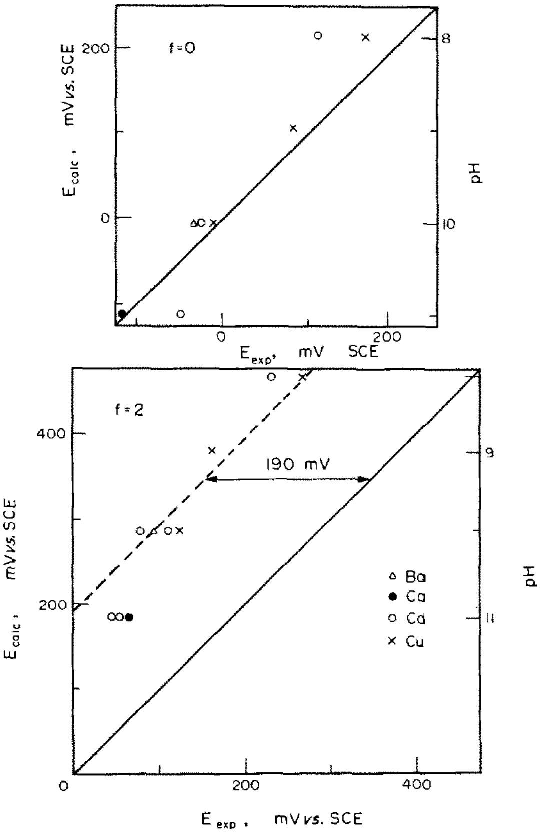

Fig. 4. Comparison of theoretical and experimental potentials of MnO_2 indicator electrodes in titrations of various metal ions in 1*M* ammonia buffer in the absence of oxygen for $C^{\circ}_{Mn} = 10^{-5}M$ at $f = 0$ and $f = 2$.

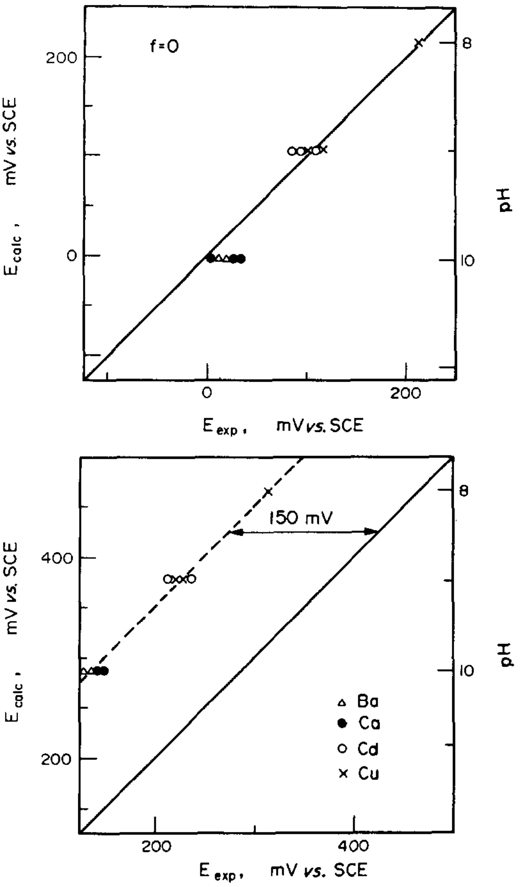

Fig. 5. Comparison of theoretical and experimental potentials of MnO_2 indicator electrodes in titrations of various metal ions in $1M$ ammonia buffer in the presence of oxygen for $C^{\circ}_{Mn} = 10^{-5}M$ at $f = 0$ and $f = 2$.

calculated from the redox potentials as equal to $10^{-8.45}$, one can obtain the following expression for the concentration of $Mn(III)Y^-$:

$$[Mn(III)Y^-] = K_{Mn(III)Y}K^{1/2}[Mn^{2+}]^{1/2}[Y^{4-}][H^+]^2 \tag{17}$$

which may be substituted in (13) to give the potential as:

$$E = 2E^0_{MnO_2/Mn^{2+}} - E^0_{Mn^{3+}/Mn^{2+}} + \frac{RT}{F}\ln\frac{[Y^{4-}][H^+]^2}{K^{1/2}[Mn^{2+}]^{1/2}} \tag{18}$$

When no $Mn(III)Y^-$ is formed, which is assumed to be the case, the potential of the electrode should be described by the equation:

$$E = E^0_{MnO_2/Mn^{2+}} - \frac{RT}{F}\ln\frac{[H^+]^2}{[Mn^{2+}]^{1/2}} \tag{19}$$

The difference between (19) and (18) is independent of both the cation titrated and the pH of the solution, and is given by

$$\Delta E = E^0_{MnO_2/Mn^{2+}} - E^0_{Mn^{3+}/Mn^{2+}} + \frac{RT}{F}\ln\frac{[Y^{4-}]}{K^{1/2}} \tag{20}$$

Table 1. Determination of various metal ions with MnO_2 indicator electrode

Metal ion	pH	Amount, *μmole* Taken	Found	Error, %
Ba^{2+}	10·0	97·1	97·4	+0·3
			96·8	−0·3
			97·5	+0·4
Ca^{2+}	10·0	95·3	95·7	+0·2
			95·5	—
			95·3	−0·2
			95·4	−0·1
			95·4	−0·1
Cd^{2+}	9·0	96·8	97·3	+0·5
			97·2	+0·4
			97·2	+0·4
			97·5	+0·7
Cu^{2+}	9·0	100·1	101·0	+0·9
			100·6	+0·5
			101·2	+1·1
			100·3	+0·2

When calculated for $C_Y = 10^{-3}M$, and using the standard potentials,[9] the value of ΔE is 177 mV, in very good agreement with the experimental values, thus lending support for the proposed reactions scheme.

Though the formation of $Mn(III)Y^-$ is not a disadvantage in a practical titration, the slowness of the electrode to give stable potentials is. However, with a 3-min wait after addition of titrant, reasonable results were obtained (Table 1).

With the PbO_2 electrode the curve of potential *vs.* pPb does not depend on the presence of other cations if no Pb^{2+} is added. From the potential *vs.*

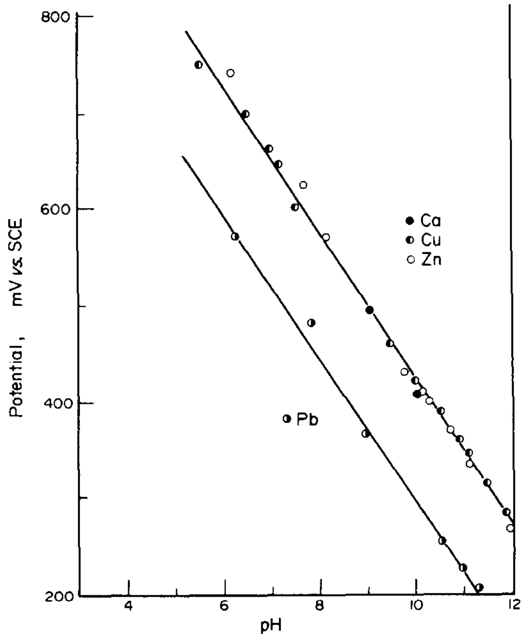

Fig. 6. Potential–pH relationship for PbO_2 electrode in 10^{-3} M solutions containing Pb^{2+}, Ca^{2+}, Cu^{2+} or Zn^{2+}.

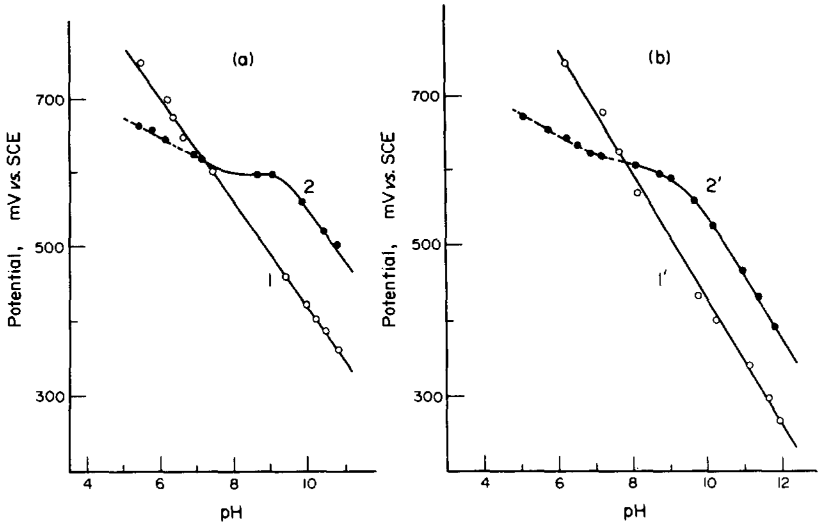

Fig. 7. Potential–pH relationship for complexometric titration of Cu^{2+} (*a*) and Zn^{2+} (*b*) with PbO_2 indicator electrode: 1,1'—10^{-3} *M* Me^{2+}; 2,2'—10^{-3} *M* MeEDTA + 10^{-3} *M* EDTA.

pH relationship (Fig. 6) it follows that in all instances the position of the equilibrium of the reaction

$$PbO_2 + 2H^+ \rightleftharpoons Pb^{2+} + 1/2\,O_2 + H_2O \quad (21)$$

depends on the lead-ion concentration, and is shifted to the right to such an extent, that in titrations of other cations it is not necessary to add Pb^{2+} as indicator ion.

As the potential–pH diagrams in the presence of Cu–EDTA and Zn–EDTA (Fig. 7) indicate that below pH 8, PbO_2 should dissolve from the electrode, titrations should only be possible at pH higher than this, which was confirmed by experimental titration curves (Fig. 8). It was found, contrary to what was stated by Wang,[6] that titrations in acetate medium were of no practical utility since the electrode reacts with the solution. Further, titrations in alkaline media are not recommended because of the large positive errors (Table 2).

Table 2. Determination of various metal ions with PbO_2 indicator electrode

Metal ion	pH	Amount, *mmole* Taken	Found	Error, %
Ca^{2+}	9·0	0·0973	0·1047	+7·6
			0·1040	+6·9
	10·1		0·1050	+7·9
Cu^{2+}	9·0	0·1050	0·1065	+1·4
			0·1090	+3·8
Zn^{2+}	8·0	0·0999	0·1035	+3·6
	9·1		0·1042	+4·3
			0·1025	+2·6
	9·4		0·1070	+7·1
	9·8		0·1040	+4·1

Both the experiments and the calculations clearly indicate that the MnO_2 and PbO_2 electrodes cannot perform reliably as sensors in titrations, because they

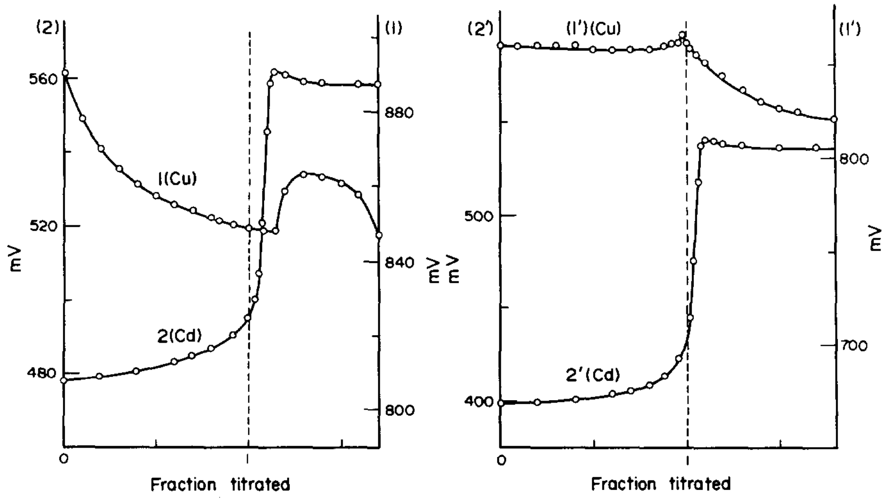

Fig. 8. Complexometric titration with PbO_2 indicator electrode in 0.1 *M* acetate buffer (1,1') and 0.1 *M* ammonia buffer (2,2'): 1,2—10^{-3} *M* Cu^{2+}; 1',2'—10^{-3} *M* Cd^{2+}.

are thermodynamically unstable under the titration conditions, although the MnO_2 electrode can be used under certain circumstances. The application of PbO_2 electrodes reported by other workers must be based only on the relative slowness of the reactions under some conditions, but stable and reproducible potentials should not be expected.

ADDITIONAL RESULTS ON THE VALUE OF THE FARADAY

WILLIAM F. KOCH and HARVEY DIEHL
Department of Chemistry, Iowa State University, Ames, IA 50011, U.S.A.

(*Received* 4 *August* 1975, *Accepted* 11 *January* 1976)

Summary—Repetition of the authors' earlier high-precision coulometric titrations of 4-aminopyridine by the hydrazine–platinum anode and back-titration methods, at the National Bureau of Standards, has yielded a new value for the Faraday, almost identical with the earlier value but with lower uncertainty. The earlier value has been recalculated, using a new value for the density of 4-aminopyridine. The weighted average of the new and old values is 96486.57 1972 NBS coulombs per equivalent, the standard deviation of the mean being 0.48 coulombs per equivalent (4.9 ppm).

During 1975, Koch, Hoyle and Diehl[1] reported a high-precision coulometric titration of 4-aminopyridine carried out at Iowa State University (ISU) by two methods and calculated a value for the Faraday. We have now repeated both titrations at the National Bureau of Standards (NBS), where one of us (W.F.K.) was a guest worker during the spring of 1975, taking advantage of the better electrical circuitry and the national standards of electricity, time and mass there.

EXPERIMENTAL WORK

Electrical circuitry and standards

A block diagram of the basic circuitry used in the work at NBS is shown in Fig. 1. A 100-mA constant-current source, designed and built by Mr. Bruce F. Field of NBS, was used during the major portion of each titration. The current from this source was adjusted so that the potential drop across a standard resistor was exactly that of a Weston unsaturated cell. The cell and the potential drop over the resistor were arranged in opposition and the difference in potential was measured with a Leeds & Northrup Digital Linear Amplifier, Model 9829-D, capable of detecting 0.1 μV. Periodic adjustments were necessary to maintain the balance at zero, but deviations never exceeded 1 ppm/hr.

The standard resistor, nominally 10 ohms, manufactured by the Leeds & Northrup Company, was a wire-wound spool resistor without a protective canister, and was specifically adapted for coulometric work by Dr. Vincent E. Bower of NBS. The resistor was immersed in a well-stirred oil-bath kept at 26.5°. The resistance under these conditions was 9.999757 ohms (standard deviation 2×10^{-7} ohm) as calibrated against the national working standard of resistance one week before the work reported in this paper.

The Weston unsaturated cell was placed within an enclosure, the temperature of which was controlled to ±0.01°. The potential of this cell was compared, before each titration, with a set of four saturated Weston cells (Guildline Instruments, Standard Cell Enclosure Model 9152T4, Number 2300) which in turn was calibrated weekly against the national working standard. The value of the cell changed from 1.0190386 to 1.0190380 V during the three weeks of the work; the standard deviation of the mean was 2×10^{-7} V. The value obtained on the day of each titration was used in the calculations.

For the region of the equivalence-point of each titration, a constant-current source designed and built by Dr. Richard S. Davis, of NBS, was used. The output was approximately 3.35 mA, the exact value being obtained during each titration by measuring the potential drop across a standard resistor, with a well-calibrated voltmeter, Data Precision Digital Multimeter 2540A1.

Both current sources were allowed to warm up through a dummy load having a resistance comparable to that of the titration cell, about 150 ohms. A switching system of mercury-wetted relays, built by Dr. Richard S. Davis, was used to switch from the dummy load to the titration cell, simultaneously triggering the timer. No significant switching transients were observed.

Weighing

The weight-burette was weighed on a Mettler single-pan semimicro balance, Type B6. The internal weights of this balance were calibrated with a set of Ainsworth Class M stainless-steel weights, NBS Calibration Test Number 232.09/307, 15 September 1971, which had been repeatedly checked at NBS since 1971. 4-Aminopyridine was weighed on a Mettler single-pan microbalance, Type M5/SA, by the double substitution method, only the 2-g and the 5-mg weights of the Class M set being used.

All weighings were corrected to true mass, using 1.2682 g/ml for the density of 4-aminopyridine (pycnometer

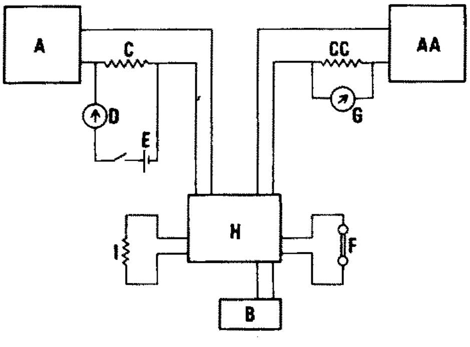

Fig. 1. Circuitry of the coulometric titration apparatus at the National Bureau of Standards. A, Constant-current source (100 mA); AA, constant-current source (3.35 mA); B, electronic timer; C, standard resistor (10 ohm); CC, standard resistor (200 ohm); D, null-point detector; E, unsaturated Weston cell; F, titration cell; G, voltmeter; H, relays and switches; I, dummy load.

method, using xylene previously saturated with 4-aminopyridine as the transfer medium and subjecting the xylene-4-aminopyridine mixture to vacuum before final filling), 1.0504 g/ml for the density of the perchloric acid (direct pycnometric measurement), 7.89 g/ml for the density of the Class M weights, 7.77 g/ml for the density of the internal weights of the semimicro balance, and for the density of air, a value obtained by weighing a Baxter's globe (the one used earlier at ISU, a recalibration at NBS agreeing with the value used earlier within 1 part per thousand). The correction to true mass was calculated by using the equation

$$\text{Weight}_{\text{vacuum}} = \frac{\text{Weight}_{\text{air}}[1 - (d_{\text{air}}/d_{\text{weights}})]}{[1 - (d_{\text{air}}/d_{\text{sample}})]}$$

rather than the usual approximation form.[2] An error of 1 part per thousand in the density of 4-aminopyridine causes an error of 0.7 ppm in the correction factor.

Timing

A General Radio Counter, Model 1192-B was tied directly to the 10-kHz NBS standard time signal and was accurate to better than 1 msec.

Titrations

These were identical to those previously described,[1] except that approximately 1 g of 4-aminopyridine was dissolved in the electrolyte before the pre-electrolysis and pretitration in all the titrations, including the standardizations of perchloric acid. This was done (1) to make the inflection-points of the pretitration and the final titration more nearly identical, and (2) to make the computer method of locating the inflection-point applicable to all titrations.

RESULTS

Data and results of the titrations are given in Tables 1 and 2. Estimated values for the systematic errors are given in Table 3. These were combined and the combined value combined with the random error as outlined in earlier papers.[1,3] The values for the Faraday thus obtained were:

By the hydrazine–platinum anode method

$F = 96486.58$ 1972 NBS coulombs per gram-equivalent weight

$\sigma_i = 0.56$ 1972 NBS coulombs per gram-equivalent weight

$\sigma_{\bar{x}} = 0.23$ 1972 NBS coulombs per gram-equivalent

By the back-titration method (platinum cathode)

$F = 96486.53$ 1972 NBS coulombs per gram-equivalent weight

$\sigma_i = 0.67$ 1972 NBS coulombs per gram-equivalent weight

$\sigma_{\bar{x}} = 0.27$ 1972 NBS coulombs per gram-equivalent weight

These values were averaged by the weighting method used in the earlier paper;[1] the weighted average is

$F = 96486.55$ 1972 NBS coulombs per gram-equivalent weight and the standard deviation of the mean is 0.57 coulombs per gram-equivalent weight or 5.9 ppm (combined random and systematic errors).

Most of the systematic errors in the work at NBS were markedly lower than those in the work at ISU;[1] see Table 3. The uncertainty in the e.m.f. of the unsaturated Weston cell used at NBS was more than one order of magnitude smaller than that of the cell used at ISU, which was estimated by Mr. Wayne A. Rhinehart to be 4 ppm. The uncertainties arising from the resistance standard, timing and null-point detection were negligible in comparison with the major errors. The timing device used at NBS was tied directly to the national standard time signals, giving an improvement of more than an order of magnitude over the timing device used at ISU. Improvement in the measurements of mass resulted largely from the use of a more sensitive balance in the weighing of the weight-burette in the back-titration method.

Because the 4-aminopyridine titrated in the work at NBS was prepared in identical fashion to that titrated at ISU, the purity was treated as before. The end-point in each titration at NBS was located by computer treatment of the data exactly as had been done at ISU;[4] hence the uncertainties remain the same. The uncertainty in the molecular weight is believed by E. Cohen and B. N. Taylor (private com-

munication) to be 3 ppm calculated by $\sigma^2_{\text{m.w.}} = (5\sigma_c)^2 + (6\sigma_H)^2 + (2\sigma_N)^2$; this is a more formally correct method than the weighted average method used in the earlier paper. This uncertainty reflects the maximum range of variation in all measurements reported on the isotopes of carbon and hydrogen and is not an error in the normal sense; to the extent that it can be so considered, it is used here, subject to revision after a determination of the isotope ratios in the 4-aminopyridine has been made.

The random error in the standardization of the perchloric acid was essentially the same in the work at both institutions, the same being true for the random error in the back-titrations. The reduction in the random error in the anodic titrations by a factor of three was particularly satisfying in that it added support to the validity of the hydrazine–platinum anode method[5] for titrating weak bases. It had been noticed that the current source in the 'Coulometric Analyzer" used at ISU was beginning to deteriorate

Table 3. Summary of systematic errors (ppm) affecting the titrations of 4-aminopyridine made at Iowa State University and at the National Bureau of Standards

during the later stages of the work and finally, after the titrations were completed, did require replacement of a capacitor; this could explain the larger scatter in the titrations done by the hydrazine–platinum anode method at ISU.

Combination of present and earlier values for the Faraday

The value for the Faraday reported in our earlier work, 96486.69 (8.4 ppm) 1972 NBS coulombs per gram-equivalent weight, was based on the value 1.2695 g/ml for the density of 4-aminopyridine. Recalculation with the new value for the density (obtained by vacuum treatment) and the larger value for the uncertainty in the molecular weight yields 96486.62 (8.9 ppm). The value for the Faraday obtained by averaging this value with the new value yields

$F = 96486.57$ 1972 NBS coulombs per gram-equivalent weight

$\sigma_{\bar{x}} = 0.48$ 1972 NBS coulombs per gram-equivalent weight = 4.9 ppm

Values for the Faraday obtained since 1959 are listed in Table 4. The agreement of the value reported in the present paper with that of Craig *et al.* (as recalculated) is strikingly good, the difference being only 1.5 ppm. A weighted average of the results of Craig *et al.*, Marinenko and J. Taylor (the average of their values being used), and the present work has been calculated, Table 4. The range from the low value of the present work to the high value of the Marinenko and Taylor work is 3.8 ppm, just about equal to one standard deviation of the mean (combined random and systematic errors).

Table 4. Summary of recent values for the Faraday

Author, location, year, method	Value of the Faraday (uncertainty, *ppm*) A_{BI69}, *sec. mole*$^{-1}$
1. Craig, Hoffman, Law and Hamer, NBS, 1960. Dissolution of silver. Recalculated*	96486.72 (6.8)
2. Marinenko and Taylor, NBS, 1968. Reduction of benzoic acid†. Recalculated*	96487.30 (12)

4. Weighted average* of 2 and 3	96486.95 (9.6)
5. This work (weighted average of titrations at ISU and NBS)	96486.57 (4.9)
6. Weighted average of 1, 4, 5	96486.67 (3.7)
7. Cohen and Taylor‡, NBS, 1973. Indirect, calculated	96484.56 (2.8)

* As recalculated by Cohen and Taylor in 1973, ref. 6, pp. 679, 704.

† Uncertainty includes random and systematic errors and is in terms of the standard deviation of the mean, expressed in parts per million.

‡ Ref. 6, pages 704, 717.

The conclusion must be drawn that the work leading to the lower value for the Faraday as calculated by Cohen and B. N. Taylor[6] (see also ref. 1, page 727, col. 1) from other physical measurements should be re-examined. Alternatively, if the electrochemical value is incorrect, the electrode process in water must be more closely examined for some basic flaw common to such different processes as the anodic dissolution of metallic silver, the anodic generation of hydrogen ions, and the cathodic generation of hydroxyl ions. Establishing a value for the Faraday by electrochemistry in a non-aqueous solvent might contribute to the solution of this problem.

Acknowledgements—One of us (W. F. Koch) wishes to thank the Science and Humanities Research Institute of Iowa State University for a research appointment during the Spring and Summer of 1975 which made it possible to work at the National Bureau of Standards. We both wish to thank Drs. B. N. Taylor, V. E. Bower and R. S. Davis of the Electricity Division of the Institute for Basic Standards of the National Bureau of Standards for making the facilities of the laboratory available and for assisting in very material ways in the work.

NEW IODOMETRIC METHODS FOR THE MICRODETERMINATION OF ARSENIC IN ORGANIC COMPOUNDS

Y. A. Gawargious, L. S. Boulos and B. N. Faltaoos
National Research Centre, Dokki, Cairo, Egypt

(*Received* 30 *July* 1975. *Revised* 18 *January* 1976. *Accepted* 25 *January* 1976)

Summary—New methods are described for the iodometric microdetermination of arsenic in organic compounds after wet digestion or oxygen flask combustion. After evaporation of the arsenic solution to dryness and dissolution of the residue in water, acetone is added and the solution is treated with iodide–iodate and the iodine liberated (by the interfering acids and the first dissociation step of arsenic acid) is reduced with thiosulphate. The KH_2AsO_4 left is then reacted with zinc sulphate in presence of excess of KI and KIO_3. Acetone is added and the liberated iodine is titrated with thiosulphate. This titration corresponds to the second and third dissociation steps of arsenic acid and is used to calculate the arsenic content of the compound. When arsenicals not containing sulphur are decomposed by the oxygen flask method, the arsenic acid solution obtained is reacted directly with zinc sulphate in presence of KI and KIO_3 and the iodine released is titrated with thiosulphate. In this case, the titration corresponds to all three dissociation steps of arsenic acid. The average recoveries obtained by the two methods are 99.5 and 99.9%, respectively.

Several methods are available for the determination of arsenic in organic compounds after wet digestion[1] or oxygen flask combustion.[2,3] Most are based on production of arsenate which is then determined gravimetrically,[1,4] potentiometrically,[5] colorimetrically,[2,3] or by atomic-absorption spectrophotometry.[6] Iodo- and iodimetric methods are familiar[1] for arsenic though both suffer from drawbacks. The reaction of arsenic acid with iodide in acidic medium has been reported[1] to be very sensitive to pH. The titration with iodine yields better results, but involves a rather lengthy and involved procedure.

In the present work, new iodometric methods are described for the microdetermination of arsenic in organic compounds, similar in principle to the methods proposed for phosphorus,[7,8] exploiting the hydrogen ions of arsenic acid. Thus, the arsenic acid, obtained after sample decomposition, is allowed to react with zinc sulphate and on addition of potassium iodide and iodate, iodine is liberated, which is titrated with standard thiosulphate.

EXPERIMENTAL

Apparatus

A 500-ml oxygen flask, the stopper of which is provided with a silica spiral (5 or 6 turns) made from a 7–8 cm length of 2-mm diameter tubing. The spiral is sealed at one end to a rod protruding from the stopper, and tapered upwards at the lower end. The tapering end of the spiral, which replaces the conventional platinum holder, is situated in the centre of the conical flask. The spiral is a slightly modified version of that advocated by Belcher *et al.*[3] for submicro work.

Reagents

All reagents were of AR or MAR grade except where otherwise mentioned, and doubly distilled water was always used.

Sodium thiosulphate solution, 0.05 and 0.01*M*, standardized against potassium iodate solutions of suitable concentrations.

Potassium iodide solution (0.1*M*), potassium iodate solution (0.02*M*), zinc sulphate solution (~0.1*M*).

Procedures

Wet digestion method. Transfer 6–8 mg of sample carefully into the bottom of a 25-ml Kjeldahl flask, add 1 ml each of concentrated sulphuric and nitric acids, and heat cautiously till the appearance of SO_3 fumes. Add a further 0.5 ml of concentrated nitric acid, heat to fuming and repeat the same step after addition of 0.5 ml of 30% hydrogen peroxide, continuing repetition until the digest becomes colourless. Continue heating till practically all the sulphuric acid has been removed. Cool and transfer the contents of the flask quantitatively into a 25-ml glass dish, with small portions of water, and evaporate to dryness on a boiling water-bath.

Dissolve the residue in *ca.* 5–7 ml of hot water and transfer the solution into a 100-ml conical flask. Add 10 ml of acetone and 2 ml each of 0.1*M* KI and 0.02*M* KIO_3 solutions. Stopper the flask and after 5 min titrate the liberated iodine, first with 0.05*M* sodium thiosulphate to a pale yellow and then with 0.01*M* thiosulphate solution till colourless. Then add 1 ml of ~0.1*M* zinc sulphate, ~100 mg of solid KI and ~50 mg of KIO_3. Stopper the flask and after 5 min again add 10 ml of acetone. Titrate the liberated iodine with 0.01*M* sodium thiosulphate till colourless. Run a blank experiment with benzoic acid as sample. Since the reaction sequence corresponds to $H_2AsO_4^- \equiv I_2 \equiv 2S_2O_3^{2-}$, then 1 ml of 0.01*M* $Na_2S_2O_3 \equiv$ 0.3746 mg of As, and the percentage of arsenic in the organic compound is

$$As = \frac{37.46\,(Y - X)M}{W} \times 100\%$$

where Y and X are the titration volumes (ml) for the sample and the blank respectively, M is the molarity of the thiosulphate solution, and W is the weight (mg) of the sample.

Oxygen flask method. For arsenicals containing no sulphur weigh enough sample to give at least 0.7 mg of arsenic. Transfer it onto a piece of ashless filter paper, and (if necessary) add 5 mg of potassium nitrate as an aid to combustion. Fold the paper twice at right angles and roll it up to fit into the quartz spiral. Burn the sample as usual in a 500-ml oxygen-filled flask containing 3 ml of conc. nitric acid. Shake the flask occasionally during the next 10 min, then rinse the stopper and walls of the flask with ~2 ml of conc. nitric acid. Place the flask on a steam-bath and evaporate the solution to dryness; repeat the evaporation step twice, adding 3 ml of water each time. Dissolve the residue in 5 ml of water and add 1 ml of 0.1M zinc sulphate solution, followed by solid KI (~100 mg) and KIO_3 (~50 mg). Stopper the flask and leave it aside for 5 min. Titrate the iodine with 0.01M sodium thiosulphate solution, using starch as indicator. Run a blank experiment with benzoic acid as sample.

Since the reaction corresponds to $2H_3AsO_4 \equiv 3I_2 \equiv 6S_2O_3^{2-}$, 1 ml of 0.01$M$ $Na_2S_2O_3 \equiv 0.2497$ mg of As, and the arsenic content of the sample is

$$\frac{24.97\,(Y-X)M}{W} \times 100$$

where Y, X, M and W have the same meanings as before.

For compounds containing sulphur as well as arsenic, proceed similarly up to the end of the evaporation steps. Then dissolve the residue in 5 ml of hot water and apply the double titration procedure described for the wet digestion method, starting with the first addition of acetone, and using the same method of calculation.

RESULTS AND DISCUSSION

The two methods are based on complete conversion of the arsenic into arsenic acid, the protons of which are used to produce an equivalent amount of iodine in the iodide–iodate reaction.

The wet digestion method

It would be desirable not to have to use an acidic digestion medium, but none was known that would decompose all the compounds tested. With the mineralization method used, the problem is to get rid of the excess of acid. This should be possible by repeated evaporations since arsenic acid dehydrates at 180–200° to As_2O_5 without loss of arsenic and As_2O_5 is stable up to 380°.[9] Only above this temperature does decomposition to As_4O_6 occur ($2As_2O_5 = As_4O_6 + 2O_2$). However, it was found that a variable amount of sulphuric acid was always left, causing high or low apparent recoveries of arsenic, depending on the relative amounts of acid left in the sample and blank solutions.

In contrast to sulphuric acid, other acids (*e.g.*, halogen acids and/or nitric acid) expected to arise from digestion of samples containing acidic elements other than arsenic, do not interfere since these are completely eliminated in the repeated evaporation steps.

However, to make the procedure generally applicable to any arsenic-containing compound, the problem of interferences was overcome completely by incorporating the two-step titration method advocated previously[7] for the analogous determination of phosphorus.

In the first step, the arsenic acid and any other acid remaining are allowed to react in aqueous acetone medium with KI and KIO_3:

$$6H_3AsO_4 + IO_3^- + 5I^- \rightarrow 6H_2AsO_4^- + 3H_2O + 3I_2$$

$$6HX + IO_3^- + 5I^- \rightarrow 6X^- + 3H_2O + 3I_2.$$

The total iodine liberated, due to arsenic(V) and any other acidity, is removed by titration, first with 0.05M thiosulphate, to avoid excessive dilution, till pale yellow, and then with 0.01M thiosulphate till colourless. This titration value is not needed, of course, in the calculation. In the second step, the dihydrogen arsenate is allowed to react with zinc sulphate whereby zinc arsenate is formed along with liberation of an equivalent amount of protons, which then react with KI and KIO_3, both added this time in solid form to avoid dilution, with quantitative liberation of iodine, which is directly titrated with 0.01M thiosulphate, to a colourless end-point. The titration value obtained in this second step is used to calculate the arsenic content of the organic sample.

$$2H_2AsO_4^- + 3Zn^{2+} \rightarrow Zn_3(AsO_4)_2 + 4H^+$$

$$6H^+ + 5I^- + IO_3^- \rightarrow 3H_2O + 3I_2$$

As in the case of phosphorus determination,[7] the acetone in the medium allows complete reaction, in the first step, of the traces of interfering acids, while making the arsenic acid function only as a monobasic acid. The presence of acetone also renders the iodine colour very bright yellow, so the iodine also acts as the indicator. To improve the end-point detection the acetone is added in two portions, one along with the iodide–iodate mixture for the first reaction, followed by titration after a 5-min waiting period, and the second only just before the second titration so that the reaction with zinc sulphate has enough time to proceed rapidly and completely.

Satisfactory results (Table 1) were obtained, showing an average absolute error of ±0.3% and an average recovery of 99.5%. Arsenazo [3-(2-arsonophenylazo)-4,5-dihydroxy-2,7-naphthalene disulphonic acid] gave *ca.* 3.5% low arsenic recovery probably because of impurity and/or incomplete decomposition. The blank values did not exceed 0.06 ml of 0.01M thiosulphate solution which is considered reasonable for such a rather lengthy digestion procedure (up to 6 hr). It was the slowness of the decomposition that led to development of the oxygen flask method.

The oxygen flask method

Preliminary tests with the ordinary platinum sample holder and saturated bromine-water or hydro-

Table 1. Iodometric microdetermination of arsenic in organic compounds by the wet digestion method

Compound	Weight, *mg*	As, % Calc.	As, % Found	Recovery, %
Triphenylarsine	4.936	24.46	24.2	98.9
	5.805		24.2	99.0
	7.871		24.8	101.4
n-Butylarsonic acid	4.956	41.15	41.6	101.0
	6.100		40.8	99.2
Phenylarsonic acid	4.344	37.09	37.4	100.9
	7.006		36.8	99.2
Benzylarsonic acid	4.106	35.67	35.4	99.2
	5.520		36.0	100.9

Arsenazo	6.010	13.13	12.7	96.6
	8.416		12.7	96.7

gen peroxide as absorption medium gave very low arsenic results. This was not unexpected, because arsenic has been reported[10] to alloy with platinum. Thus, a modified version of the quartz spiral stopper, introduced previously,[2,3] was used, but the arsenic values found were still low, indicating incomplete decomposition and/or incomplete oxidation of As(III) to As(V). Although it is customary to use alkaline hypobromite[3] or alkaline hydrogen peroxide[4] as absorption medium to obtain arsenic(V),[3] the use of alkaline medium was ruled out because the present method is based on the acidity of the arsenic acid.

Trials were then made with concentrated nitric acid as absorbent. In addition to oxidizing As(III) to As(V), the excess of nitric acid was easily and smoothly removed by heating on a boiling water-bath, leaving a white residue of arsenic acid which dissolved easily in hot water. Addition of zinc sulphate to this solution gave a precipitate of zinc arsenate and an equivalent amount of protons, the arsenic acid acting as a tribasic acid:

$$2H_3AsO_4 + 3Zn^{2+} \rightarrow 2Zn_3(AsO_4)_2 + 6H^+$$

The protons liberated can be determined by the iodide–iodate reaction. The volume should not exceed 6–7 ml for the precipitation reaction to proceed quantitatively within 5 min, and an equal period should be allowed for complete iodometric reaction.

The use of concentrated nitric acid as the absorbent succeeded for all the samples analysed except thorin and 4-dimethylaminoazobenzene-4′-arsonic acid, which gave results 6–9% low. About 5 mg of potassium nitrate, mixed with the sample before wrapping in the ashless filter paper flag, proved highly efficient

Table 2. Iodometric microdetermination of arsenic in organic compounds by the oxygen-flask method

* Calculated on the basis of 3-fold amplification.

† Calculated on the basis of 2-fold amplification.

as an auxiliary oxidant during combustion. In addition to raising the arsenic recoveries to an average of *ca.* 98 and 99% for these two compounds, respectively, the potassium nitrate caused no interference, and may conveniently be added to any arsenical sample.

Satisfactory results (Table 2) were obtained. As expected, nitrogen and halogens did not interfere, because their products are readily expelled in the evaporation steps. The effect of halogens was tested by addition of micro-amounts of hydrochloric acid, bromine-water, and iodine either to the absorbed combustion products of triphenylarsine or in blank experiments.

On the other hand, sulphur-containing arsenicals could not be successfully analysed by the simple oxygen flask procedure, owing to the incomplete removal of sulphuric acid in the evaporation step, but this problem was readily solved by applying the two-step procedure developed for the wet digestion method. Arsenazo yielded better arsenic recoveries by the oxygen flask method than by wet digestion. Thorin, however, gave 2% low recovery, possibly ascribable to impurity. The results in Table 2 show an average absolute error of ±0.3% and overall average recovery of 99.9%. The blank values (0.04 ml of 0.01M thiosulphate) were smaller than those for wet digestion.

Conclusions

The oxygen flask method is superior in the following respects: (*i*) it is simpler and less tedious than the wet digestion method; it offers a 3-fold amplification (except for the sulphur arsenicals) compared with the 2-fold amplification for the wet-digestion method; (*ii*) in general it gives the better results.

Phosphorus, of course, interferes quantitatively, as expected from the previous work[7,8] but compounds containing both arsenic and phosphorus are not very common.

NON-DESTRUCTIVE MULTI-ELEMENT PHOTON-ACTIVATION ANALYSIS OF ENVIRONMENTAL MATERIALS

TOYOAKI KATO, NOBUYOSHI SATO* and NOBUO SUZUKI
Department of Chemistry, Faculty of Science, Tohoku University, Sendai, Japan

(*Received* 18 *July* 1975. *Revised* 8 *December* 1975. *Accepted* 14 *January* 1976)

Summary—A non-destructive method of photon-activation analysis with 30-MeV bremsstrahlung followed by high-resolution gamma-spectrometry has been developed for multi-element determination in ambient air and in air-pollution emissions. The sample materials were the NBS standard reference material, Fly Ash, and atmospheric particulates collected on a Millipore filter. Simultaneous irradiation of the sample with synthetic multi-element standards containing 33 elements has shown that the technique can determine up to 21 elements in a single sample. The method is simple and gives reproducible results.

Because of increasing concern with environmental pollution problems, attempts have been made to develop methods for the elemental analysis of water, air and soil. The most immediate problem is the analysis of air-pollution samples and many laboratories are devoted to this task.[1] Any method employed must be sensitive, accurate, versatile, and if possible, capable of the simultaneous determination of many elements. Because air-pollution samples have complex, ill-defined matrices, wet methods may introduce errors by loss or contamination of trace species. Many of these difficulties are avoided by activation analysis, without chemical treatment, before irradiation. Neutron-activation analysis has been applied to the measurement of many elements in atmospheric particulate materials,[2–9] but this method is not capable of analysing for all elements of environmental significance. Lead, which has unsuitable nuclear properties, is determined by atomic-absorption spectrophotometry or X-ray fluorescence, although pulse methods[10,11] to detect the 0.8-sec ^{207m}Pb, or fast neutron,[12] photon-[13–16] and charged-particle[17–19] activation may be used. The advantage of multi-element determination is shared by activation analysis and photon- and particle-excited X-ray fluorescence,[20–23] but severe matrix effects are encountered with the last technique.

Photon activation shares with thermal neutron activation the advantages of homogeneous activation, but produces an entirely different range of nuclides by (γ,n), (γ,p) and other photonuclear processes. A number of reviews on the principles and general features of photon-activation analysis,[24–27] useful compilations or listings of the nuclear characteristics of the products,[28–31] and gamma-ray spectrum catalogues[32–34] are now available. Aras *et al.*[35] have demonstrated the multi-element capability of photon-activation analysis in air-pollution studies by presenting abundance data for 14 elements in atmospheric particulate materials. Chattopadhyay and Jervis[16] also reported an instrumental method for the simultaneous determination of 30 elements in market-garden soils, using a 45-MeV linear accelerator.

The present paper describes the multi-element analysis of the NBS standard reference material, SRM-1633 Fly Ash, and of atmospheric particulates collected on Millipore filters from the urban atmosphere.

EXPERIMENTAL

Samples and comparison standards

The NBS standard reference material 1633 Fly Ash is provided in finely powdered form. It is prepared by the U.S. National Bureau of Standards for intercomparison purposes.[36] It was used as 1-g samples packed in aluminium foil and pressed into a disc 13 mm in diameter and 5 mm thick.

A Millipore AA membrane filter (0.8 μm pore diameter) was used for atmospheric particulate collection. A piece 20 × 25 cm was cut from the original sheet and particulates were collected by pumping 1000 m^3 of air through this filter at 0.62 m^3/min. Collections were carried out on the roof of the four-storey Miyagi Prefectural Office Building in Sendai, Japan. The filter sample was cut in two and each half was placed in the cavity of a stainless-steel hydraulic press and compacted into a cylindrical pellet 13 mm in diameter and 5 mm thick. A similar piece of unused filter was treated in the same way to provide a blank.

Comparison standards used in this work were synthetic multi-element pellets containing the elements of interest distributed evenly in a matrix of boric acid. These standards were prepared by mixing 33 elements, in the form of their oxides, at appropriate concentration levels with boric acid. In preparing these standards, reagents with a chemical purity of 99.99% or better were used. A 1-g

Table 1. Concentrations of elements in the synthetic multi-element standard

Concentration level, *ppm*	Element
10,000	Ca, Cl, Na, K
5000	Mg
200	Br, Cr, Cu, Fe, Mn, Ni, Pb, Ti, Zn
50	Ag, As, Ba, Cd, Ce, Co, Cs, I, In, Mo, Nb, Rb, Se, Sr, Sb, Te, Tl, Y, Zr

sample of this mixture was pelleted for irradiation. Table 1 gives the concentration levels of the elements in these pellets.

Irradiation

A linear electron accelerator of Tohoku University was the bremsstrahlung source. The sample and the comparison standard pellets were stacked in a silica tube so that the standards were placed at the front and back of the sample for simultaneous irradiation. The tube was placed in a water-cooled sample holder and was aligned along the beam axis with the front face of the tube 10–15 cm from the photon-producing converter (2-mm thick Pt foil). A typical irradiation was performed with a 70-μA beam of 30-MeV electrons. The precise experimental details have already been reported.[37] The irradiation time was 2 hr for Fly Ash and 6 hr for atmospheric particulates and filter blanks. No significant chemical decomposition of the organic filter material was observed.

Counting and evaluation

Gamma-rays were observed with a lithium-drifted germanium detector with a sensitive volume of 33 cm^3, ORTEC Model 8101–0525, and its output was coupled to a 4096-channel pulse-height analyser (Toshiba Electric Co. Ltd., Japan). The counting system had a resolution of 2.4 keV for the 1332-keV gamma-line of ^{60}Co. Counting was repeated for increasing intervals over a period of one month or longer. For short-lived nuclides, ^{38}K and ^{34m}Cl, the counting time was progressively increased from 4 to 16 min. During this interval, a 50-mm thick Lucite plate was placed between the sample and the detector to absorb positrons from a number of positron-emitting nuclides. For nuclides with intermediate half-lives, counting times of 30–60 min, and for long-lived nuclides, counting times of 5-20 hr, were used. After measurement of the short-lived nuclides, the aluminium wrapper for Fly Ash was rejected and the contents were again wrapped in fresh aluminium foil for further counting. The gamma-rays were characterized by comparison with the gamma-spectra obtained by irradiating the pure elements, and listed with nuclear data.[38] In obtaining full-energy peak areas, total peak counts were computed and background contributions were subtracted, assuming linear variation of background over the peak of interest. Decay curve analyses were used to check for interferences. A mean specific activity for any specified gamma-ray in terms of the peak areas from the standards on both sides was used for calculating the abundance of the element in question in a sample.

RESULTS AND DISCUSSION

Gamma-rays observed

Typical gamma-ray spectra measured at several different decay times after irradiation of the atmospheric particulate sample are shown in Figs. 1–3, together with those of the multi-element standard measured at comparable decay times. As observed in the multi-element analysis of biological materials,[39] determination of the elements giving rise to short-lived nuclides could only be achieved for those which emitted gamma-rays with high energies, because of the swamping 511-keV annihilation radiations from positron-emitters. In the case of atmospheric particulate samples, such high activity was mainly due to 20-min ^{11}C from the organic filter material. The only products used for measurement at earlier decay times were 7.71-min ^{38}K and 32-min ^{34m}Cl. After a decay time of 1 day, however, almost all products of interest could be observed in gamma-ray spectra. For quantitative measurements, consecutive counting has been required, over periods up to 10 days, to check for spectral interferences. At this stage, all of the elements in the comparison standard, except Ag, Ba and Te, could be measured. The elements identifiable in both the sample and standard have been determined quantitatively. In selecting the peaks used for quantitative measurement, the intensities, spectral interferences and peak-to-background ratios were taken into account. Table 2 gives the elements determined and the peaks selected, together with time intervals for measurements after irradiation, practical limits of detection and major competing nuclear reactions. The spectral interferences caused by overlapping gamma-rays have been studied with the aid of a list of prominent gamma-rays emitted by various products from irradiation of each pure element with 30-MeV bremsstrahlung.[30] Most of these problems could be solved by decay analyses of the counting data, when the gamma-ray peaks given in Table 2 were selected. To rule out the 808-keV peak of ^{47}Ca, measurements of cobalt by the 811-keV peak were made 30–40 days after irradiation. Similarly, long decay periods were used for cerium to eliminate the contribution by the 160-keV peak of ^{47}Sc. Zinc was measured by using the 185-keV peak of ^{67}Cu rather than the 1115-keV peak of ^{65}Zn, because of the interference by the 1121-keV peak of ^{46}Sc.

The practical detection limits were estimated from the spectral data of the atmospheric particulate (Sample 1 in Table 4). These are the amounts of the elements giving a full-energy peak area corresponding to three times the standard deviation of the area under the peak of interest, from a particulate sample collected from 500 m^3 of urban air, with 6-hr irradiation time with a 70-μA beam of 30-MeV electrons, counted with a 33-cm^3 Ge(Li) detector for periods as stated. It is difficult to define the detection limits since they depend on the experimental conditions and the nature of the matrix.

Fly ash

Lehmden *et al.*[40] mentioned that fly ash from a coal-fired heat-generation source is important for two reasons. It has a matrix similar to that of emissions

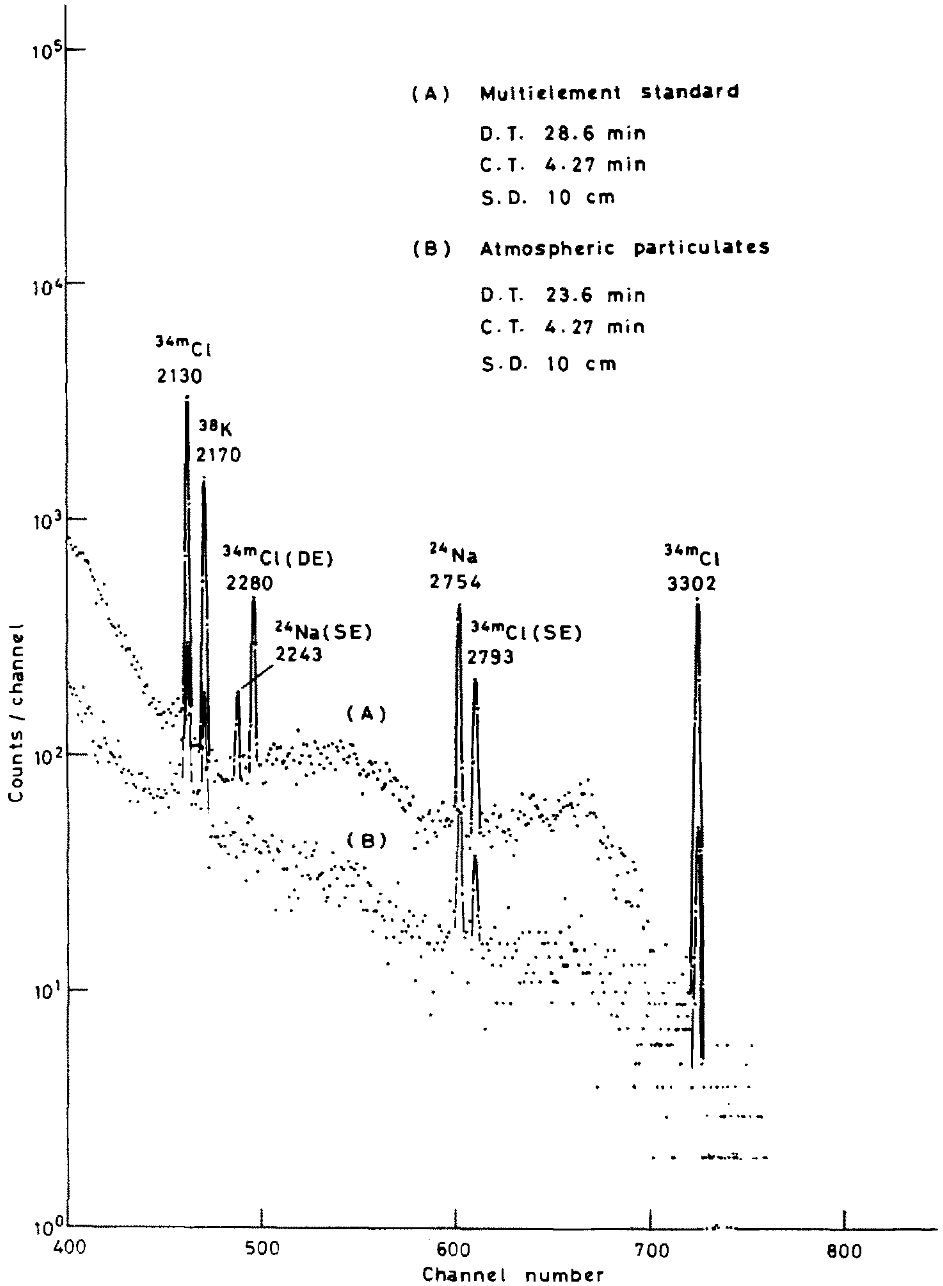

Fig. 1. Gamma-ray spectra for short-lived nuclides taken with a 33-cm^3 Ge(Li) detector after a 6-hr irradiation of an air-filter sample and a multi-element standard with 30-MeV bremsstrahlung. D.T. and C.T. designate the time interval between irradiation and counting, and the counting period, respectively; S.D. indicates source-to-detector distance; SE and DE designate single and double annihilation photon escape peaks, respectively; values on each peak are energies in keV.

to the atmosphere, but with a larger particle size, and there is interest in the removal of trace elements in coal-fired processes. Elemental abundances in Fly Ash for 17 elements have been obtained (in duplicate) and results are given in Table 3, together with literature values where available.[16,36] Error limits are based on counting statistics of sample and standards. They are the overall statistical errors associated with subtraction of the background under the full-energy peak of interest so as to obtain the net counting rates for the sample and the standards and comparison of the sample with a mean specific activity from standards on both sides of the sample. There are possibilities of contributions to the (γ,n) or (γ,p) reactions used for abundance determination from (γ,pn), (γ,α) and (γ,αn) reactions with elements adjacent in the Periodic Table (Table 2). Detailed nuclear considerations based on the experimental yields of the photo-nuclear

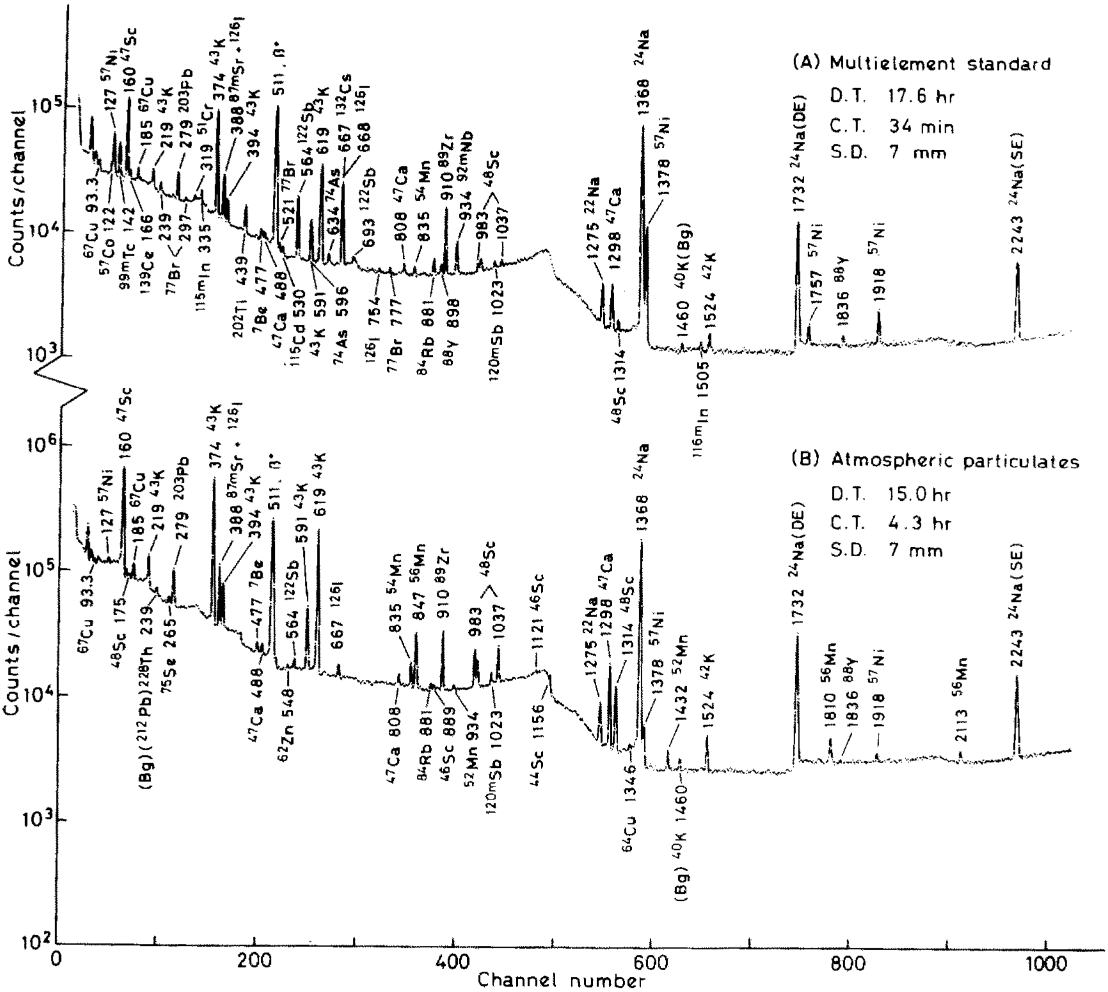

Fig. 2. Gamma-ray spectra taken at an intermediate decay time with a 33-cm^3 Ge(Li) detector after a 6-hr irradiation of an air-filter sample and a multi-element standard with 30-MeV bremsstrahlung. Bg indicates peaks occurring in natural background; see also caption for Fig. 1.

reactions of various types[28] showed that in most instances these secondary contributions did not produce serious interference problems.

Calcium was determined either by the ^{44}Ca(γ,p)^{43}K or by the ^{48}Ca(γ,n)^{47}Ca reaction. Of the peaks of ^{43}K and ^{47}Ca, the 374- and 619-keV peaks of ^{43}K and the 1298-keV peak of ^{47}Ca were found to produce precise values of calcium concentration. The values obtained from these three different peaks fell within the range $\pm 2\%$ for all samples. The calcium results given were the average of the values from these peaks (Tables 3–5).

For titanium, of the peaks of the three isotopes, ^{47}Sc, ^{48}Sc and ^{46}Sc, the 160-keV peak of ^{47}Sc gave the highest full-energy peak. Although ^{47}Sc could also be produced by the β^--decay of ^{47}Ca, interferences from its decay were not significant at earlier decay times for this material. The 1314-keV peak of ^{48}Sc was also used for determinations and the average values from these two peaks are listed (Tables 3–5).

In the determination of manganese by using the ^{55}Mn(γ,n)^{54}Mn reaction, the major source of interference is from iron by the ^{56}Fe(γ,pn)^{54}Mn reaction. When an amount of pure iron was irradiated with 30-MeV bremsstrahlung, an activity ratio of 1.03×10^{-3} was obtained as the ratio of the 835-keV full-energy peak of ^{54}Mn to the 847-keV full-energy peak of ^{56}Mn. The ^{54}Mn activity due to the ^{55}Mn(γ,n)^{54}Mn reaction for a given sample was, therefore, calculated by multiplying the count rate under the 847-keV peak by 1.03×10^{-3} and then subtracting this value from the count rate under the 835-keV peak corrected for decay to the end of irradiation. A correction of 56% was required for Fly Ash.

In the magnesium determination utilizing the ^{25}Mg(γ,p)^{24}Na reaction, aluminium interferes through the reaction ^{27}Al(n,α)^{24}Na. A separate irradiation of equal quantities of magnesium and aluminium under identical conditions resulted in a ^{24}Na production

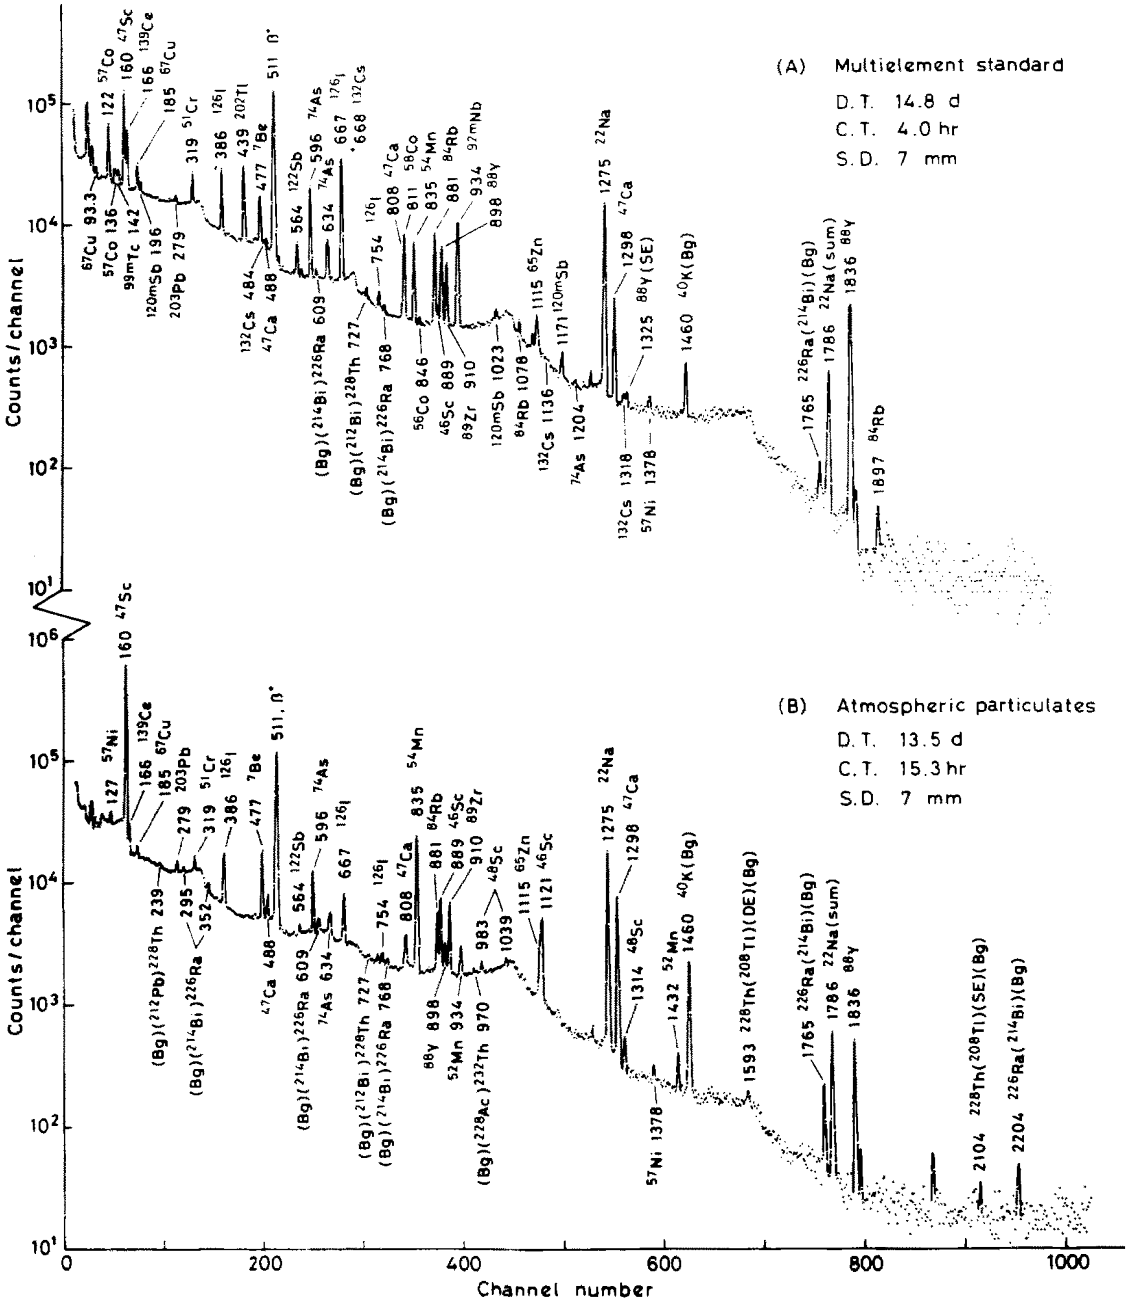

Fig. 3. Gamma-ray spectra for long-lived nuclides taken with a 33-cm^3 Ge(Li) detector after a 6-hr irradiation of an air-filter sample and a multi-element standard with 30-MeV bremsstrahlung. Bg indicates peaks occurring in natural background; see also caption for Fig. 1.

rate from aluminium which was only 0.5% of that from magnesium. By means of spectrophotometric measurement followed by solvent extraction with 8-hydroxyquinoline,[41] we obtained a value of 11.9% for aluminium in Fly Ash. From this value, the $^{27}Al(n,\alpha)^{24}Na$ contribution to the total ^{24}Na activity could be estimated to be 3.7%.

The peaks of ^{203}Pb (279 keV), ^{115}Cd (530 keV), ^{126}I (667 keV) and ^{67}Cu from zinc (185 keV) were also observed, but not used for abundance determinations for this material because of the low peak-to-background ratios. Chlorine could not be determined because of its low abundance.

As seen in Table 3, the reproducibility of the method is satisfactory. The average relative deviations for all the elements determined here, based on the duplicate samples, were within ±5%. The precision observed in our results is high because of the specific sample–multi-element standards configuration used, which would minimize the errors due to photon-flux

inhomogeneities. Although the data from NBS are not complete, the agreement, where comparable, is excellent. In comparing our results with those of Chattopadhyay and Jervis,[16] the agreement is more satisfactory for trace elements than for major elements. There is a wide range in the reported concentrations of many elements in several samples having similar matrices (prepared by the U.S. Environmental Protection Agency for intercomparison purposes,) and Lehmden *et al.*[41] have stressed the heterogeneous

nature of samples of this sort. As an example, the presence of the large iron-containing particles in Fly Ash would be a contributory source of the wide variation in reported iron concentrations (5.3–25%).

Atmospheric particulates

Apart from the 17 elements determined in Fly Ash, chlorine, iodine, lead and zinc were also determined. The results obtained are shown in Table 4. The observed concentrations appear to be in the range found for other urban areas in Japan,[8,9] although the number of determinations is too limited for real comparison.

The $^{56}\mathrm{Fe}(\gamma,\mathrm{pn})^{54}\mathrm{Mn}$ contribution to the total $^{54}\mathrm{Mn}$ activity was estimated as described above, and it was found that the corrections required for the air-filter samples ranged from 11 to 14%. To check for interference from aluminium in the magnesium determination, aluminium concentrations were measured spectrophotometrically. A relatively high value of 15.5 $\mu g/m^3$ was observed for sample 1 in Table 4 and a correction of 2.6% was required in this case. When considering the Al:Mg ratios (2, or 3 at most), routinely observed in air-filter samples from industrial and urban areas,[3,6] this source of interference may not pose serious problems.

Filter blank

A critical requirement for the method is that the filter material used should have very small blanks for the elements to be determined. Table 5 gives the concentrations of the elements, determined by photon activation analysis, in the Millipore filters used, together with the literature data,[42–44] where available. Considerable variations can occur from one batch of filter material to another and also over the area of a single

sheet. The blank values for all elements except chlorine were sufficiently small to require only minor blank corrections. The chlorine blanks in our filters were large, about 63% of the total amount of chlorine observed in an air sample. Large chlorine blanks have also been reported for polystyrene membrane filters.[35,42] Millipore filters are considered to be disadvantageous in neutron-activation analysis, for they tend to disintegrate during irradiation, but this filter can be used in photon-activation analysis and is easy to use, has a low blank, and a high particle retentivity.

CONCLUSION

The present method is promising for the study of air pollution and can be applied to a wide range of environmental materials as a useful complement to other analytical methods. In addition to the elements determined in atmospheric particulates by Aras *et al.*,[35] other elements such as Co, Fe, K, Mg, Mn, Rb, Sr and Y have been determined in this work. Manganese can be determined if careful correction is made for the iron contribution. Both Rb and Sr in atmospheric particulate materials can be determined much more easily than by instrumental neutron-activation analysis. For Y, as well as Pb and Zr, non-destructive analysis by thermal neutron activation is not generally attainable, because of their adverse nuclear properties. Such difficulties are not inherent in photon activation analysis. The concentrations of 20 or more elements in the same sample can be measured with reasonable sensitivity and reliability.

Acknowledgements—The authors express their appreciation to members of the LINAC machine and radioisotope groups at the Institute of Nuclear Science, Tohoku University, for their co-operation with the irradiations. They are also grateful to members of the Environmental Pollution Research Centre of Miyagi Prefecture for their kind assistance in sample collections.

USE OF ZEO-KARB 226 AND DOWEX A-1 IN THE ANALYSIS OF HIGH-PURITY ZINC AND ZINC-BASE ALLOYS FOR Tl AND In

S. GANAPATHY IYER, P. K. PADMANABHAN, L. D. NAIR and CH. VENKATESWARLU
Analytical Chemistry Division, Bhabha Atomic Research Centre, Bombay-400 085, India

(*Received* 26 *November* 1975. *Accepted* 17 *January* 1976)

Summary—Utility of Zeo-Karb 226 and Dowex A-1 for the separation of Tl and In at 5-ppm level from high-purity zinc and zinc-base alloys has been investigated. With Zeo-Karb 226 (NH_4^+), Tl^+ is conveniently separated from these materials and also from many other cations, with 1.0*M* ammonium nitrate as the eluent. It is subsequently determined with Rhodamine B. This separation principle is also applied to the analysis of Pb–Tl alloys. Both Tl and In (along with Fe) are preconcentrated on Zeo-Karb 226(H^+) from a solution of the sample at pH 3.0. Suitable methods of subsequent determination of Tl and In are described. In the case of Dowex A-1(H^+), Tl^{3+}, In^{3+}, Fe^{3+} and Cu^{2+} are retained from a solution of the sample at pH 2.0. An *o*-phenanthroline solution at pH 2.0 elutes all but traces of Cu^{2+}. In^{3+} along with Fe^{3+} is eluted with 1.0*M* hydrochloric acid. Finally, Tl is eluted with 2.0*M* hydrochloric acid containing sulphurous acid.

It is necessary to control the thallium and indium contents at less than 10 and 5 ppm respectively in high-purity zinc and zinc-base alloys used in the die-casting industry.[1] Before their photometric determination, they are separated from associated elements by solvent extraction.[2,3] Use of cation- and anion-exchangers is reported for the separation of Tl and In from other cations, but not from these materials.

The ease with which Zn^{2+} forms complexes with EDTA[4] and other complexing agents[5,6] (citrate, tartrate, oxalate and pyrophosphate), unlike Tl^+, forms the basis of cation-exchange separation of thallium in zinc dusts, electrolytes *etc*. Separation of thallium from antimony in presence of zinc on a cation-exchanger by using 20% sodium hydroxide solution as the eluent is also reported.[7] Sulphuric acid (1*M*) is also used to separate thallium from zinc and other elements.[8] Thallium is separated from zinc on an anion-exchanger, on the basis of formation of the anionic chloro-complex by Zn^{2+} and not by Tl^+ in hydrochloric acid medium.[9] On an anion-exchanger in carbonate form zinc and many other cations are retained while Tl^+ passes through.[10]

Indium is separated from zinc and other elements on strong acid cation-exchangers with sulphosalicylic acid,[5,11] ethylenediammonium dihydrochloride,[12] lithium chloride,[13] ammonium sulphate or sulphuric acid[14] and hydrochloric acid.[15] Similar separations on anion-exchangers in hydrochloric acid,[16] EDTA,[17] ammonium carbonate[18,19] and ammonium sulphate[14] media are also reported.

This paper describes the use of Zeo-Karb 226 in H^+ and NH_4^+ forms and Dowex A-1 (H^+) for the separation of trace amounts of thallium and indium from high-purity zinc and zinc-base alloys and their determination at 5-ppm level.

EXPERIMENTAL

Reagents

Thallium solution. Thallous nitrate (1.30 g) was dissolved in a litre of acidified water and standardized gravimetrically by the chromate method.[20] This solution was diluted (as and when required) to give a working thallium solution of 10 μg/ml concentration.

Indium solution. The zone-refined metal (0.960 g) was dissolved in hydrochloric acid, made up to 1000 ml, and standardized by EDTA titration.[21] This solution was diluted (as and when required) to give a working solution of 10 μg/ml.

^{204}Tl and ^{114m}In were supplied by the Isotope Division of our Research Centre. All other reagents were of analytical grade.

Ion-exchangers

The preparation of Zeo-Karb 226 in the ammonium[22] and hydrogen ion[23] forms and Dowex A-1 (H^+)[24] was described earlier.

Instruments

Absorbance measurements were made with a matched pair of "Corex" cells (10-mm path-length) on a Beckman Model DU spectrophotometer. The β- and γ-counters were fabricated by the Electronics Division of this Research Centre.

Zeo-Karb 226 (NH_4^+)

Univalent alkali metal ions are separated from multivalent cations by selectively eluting with 0.1*M* ammonium solution from Zeo-Karb 226 (NH_4^+).[22] Since the exchanger has much greater affinity for Tl^+ than alkali metals ions owing to its high polarizability, K_d values of Tl^+ and some typical multivalent cations were determined as a function of ammonium nitrate concentration in the solution phase, by equilibrating 25 ml of the aqueous phase at pH 3–5 (avoiding precipitation) with 0.25 g of the exchanger for 4 hr. The results are given in Table 1. The K_d-value of Tl^+ decreases to less than 10 in presence of 1.0*M* ammonium nitrate, while those of the other ions are considerably higher.

Separation of thallium from other ions. The conditions of elution of Tl^+ were studied with 2.0 g of ion-exchanger.

Table 1. K_d values of metal ions at different concentrations of NH_4^+ on Zeo-Karb 226 (NH_4^+) (0.25 g)

Metal ion	K_d				
	—	0.5*M* NH_4^+	1.0*M* NH_4^+	1.5*M* NH_4^+	2.0*M* NH_4^+

Table 2. Separation of Tl from multivalent cations (Tl taken = 1.00 mg)

Metal ion	Taken, *mg*	Found, *mg*	Tl found, *mg*
Mg^{2+}	11.3	11.3	0.99
Ni^{2+}	11.7	11.7	1.03
Zn^{2+}	11.4	11.5	1.01
Pb^{2+}	10.4	10.4	1.03
UO_2^{2+}	10.0	10.0	1.00
In^{3+}	11.6	11.5	1.01
Th^{4+}	11.0	10.9	1.00

Based on this, the following procedure was developed to separate 1.0 mg of thallium from about 10 mg each of the multivalent ions Mg^{2+}, Ni^{2+}, Zn^{2+}, UO_2^{2+}, Pb^{2+}, In^{3+} and Th^{4+}. The results, in Table 2, show quantitative separation of thallium.

Procedure. Binary mixtures of thallium(I) and a multivalent cation were prepared in 1.0*M* ammonium nitrate at a pH of 3–5 and passed through a column of Zeo-Karb 226 (1.0 × 10.0 cm) (NH_4^+ form) at a flow-rate of 1 ml/min, followed by 100 ml of 1.0*M* ammonium nitrate. Thallium in the effluent was determined by the Rhodamine B method[25] with 50 ml of aqueous phase and 10 ml of benzene phase. The other cation was then eluted with 100 ml of 2.0*M* nitric acid and determined by a suitable method.

Separation of Tl in zinc-base and Pb–Tl alloys. When 1.0 g of zinc was taken in 30 ml of 1.0*M* ammonium nitrate and passed through 12 g of exchanger (column 2.0 × 16.5 cm), followed by ammonium nitrate, zinc was found in the first 100 ml of effluent. An examination of the column revealed considerable channelling, due to the shrinkage of the exchanger on changing from the NH_4^+ to the Zn^{2+} form. This was obviated by equilibrating the zinc solution with 6.0 g of the exchanger in a beaker and then transferring this onto a column of another 6.0 g of exchanger. Under these conditions, all the Tl^+ was found in the first 200 ml of effluent, with no zinc appearing in the first 400 ml. In fact, the zinc band on the exchanger moved very little. Then synthetic samples of zinc-base alloys and high-purity zinc (zone-refined, from Chemistry Division of our Research Centre) were prepared and analysed following the procedure given below. The results are given in Table 3.

This principle is also successfully applied for the analysis of Pb–Tl alloys and the results are included in Table 3.

Procedure for zinc and zinc-base alloys. A 1.000-g sample is dissolved in 25 ml of 6*M* hydrochloric acid in a beaker. The solution is evaporated to dryness. The residue is dissolved in about 30 ml of 1.0*M* ammonium nitrate and the pH adjusted to 3.0. Then 6.0 g of the exchanger are added and stirred well. Meanwhile, a column of another 6.0 g of the exchanger (2.0 × 8 cm) is prepared. The contents of the beaker are transferred to the column, and the

* Composition as given in Table 3.

effluent is collected. The column is washed with 250 ml of 1.0*M* ammonium nitrate. The volume of the combined effluent is reduced to 100 ml by boiling and 20 ml of concentrated hydrochloric acid are added. Tl is oxidized with 5 ml of bromine water. Excess of bromine is boiled off. After cooling, the pH is adjusted to 3.0 and the solution passed through a column of 1.0 g of Zeo-Karb 226 (NH_4^+), followed by 10–20 ml of water. The effluent is rejected. Tl^{3+} is eluted with 50 ml of 2.0*M* hydrochloric acid and determined by the Rhodamine B method (described earlier).

Procedure for Pb–Tl alloys. About 0.5 g of sample is accurately weighed and dissolved in dilute nitric acid in a beaker. The solution is evaporated to near dryness. Then 4.0 g of ammonium nitrate are added and dissolved in 50 ml of water. The pH is adjusted to 3.0. To this 2.0 g of Zeo-Karb 226 (NH_4^+) are added and stirred. Meanwhile 2.0 g of fresh exchanger are made into a column (1.5 × 6 cm). The contents of the beaker are transferred to the column quantitatively, followed by washing with 200 ml of 1.0*M* ammonium nitrate. Thallium present in the 250 ml of effluent is determined by the iodide method.[26] Lead is eluted from the column with 100 ml of 1.0*M* nitric acid and determined complexometrically with EDTA.[27]

Zeo-Karb 226 (H$^+$)

From the variation of K_d values of several cations on Zeo-Karb 226 (H$^+$) as a function of pH,[23] separation of In and Tl from high-purity zinc and zinc-base alloys appears feasible. Hence, the elution behaviour of In, Fe(III), Tl(III), Al, Sn(IV), Zn, Cu(II), Mg, Pb and Cd at pH 3.0 on a column (1.0 × 8.0 cm) of exchanger was studied, at a flow-rate of 1 ml/min. In, Tl and Fe were sorbed quantitatively, while the rest passed out readily when eluted with 200 ml of water at pH 3.0. This gives an easy method of preconcentration of Tl and In. Since the accompanying iron can be taken care of in the determination of Tl and In, the procedure given below was developed for the separation of Tl and In together from Zn and other associated elements. The two were subsequently determined in different aliquots. The results obtained are given in Table 4.

Procedure. About 5 g of zinc or alloy sample are accurately weighed into a beaker, dissolved in 50 ml of hydrochloric acid (1:1), and the solution is evaporated to dryness. The salts are dissolved in 50 ml of 2.0*M* hydrochloric acid and 5 ml of bromine water are added to oxidize Tl^+ to Tl^{3+}. Excess of bromine is boiled off. The solution is diluted to 100 ml and the pH adjusted to 3.0. This solution is passed through a preconditioned column containing 2 g of Zeo-Karb 226 (H$^+$) at a flow-rate of 1 ml/min. The column is washed with 200 ml of water at pH 3.0. The effluent is rejected. Then 50 ml of 2.0*M* hydrochloric acid are passed through the column at the same flow-rate. The effluent is collected in a 50-ml flask (up to the mark).

A 10-ml aliquot is taken in a separating funnel, 1 ml of phosphoric acid [to complex Fe(III)] is added, and the Tl content determined by the Rhodamine B method described earlier.

A 30-ml portion of the 50 ml is evaporated in a beaker. The residue is dissolved in 5 ml of 6*N* sulphuric acid, and transferred to a separating funnel with 5 ml of water. Then 10 ml of 3*M* potassium iodide are added and equilibrated with 6 ml of butyl acetate. The aqueous layer is rejected. Then 2 ml of 2% oxine solution in butyl acetate are added to the organic phase and mixed. This solution is scrubbed with 5 ml of potassium cyanide solution (10% KCN + 1*M* NH_3 in 2:3 ratio). The aqueous phase is discarded. The water droplets from the stem of the separating funnel are removed with a filter paper. The organic phase is transferred to a 10-ml volumetric flask and made up to volume with butyl acetate. The absorbance is measured at 400 nm against a corresponding reagent blank. The indium content is computed from a calibration curve.

Dowex A-1 (H$^+$)

Among the ions derived from the metals present in zinc-base alloys, Tl^{3+}, In^{3+} and Cu^{2+} exhibit high K_d values on this exchanger at pH 1.0 and 2.0.[28] Hence, their behaviour on a column (1.0 × 4.0 cm) was studied, by taking the solutions at these pH values and washing with water at the same pH. Tl^{3+} is strongly retained on the exchanger at both pH values, without elution on washing with 100 ml of acidified water. In the case of In^{3+} and Cu^{2+}, elution starts in the first 25 ml of washing at pH 1.0, but not at pH 2.0, even in 50 ml. A 0.01*M* *o*-phenanthroline solution at pH 2.0 elutes Cu^{2+} but not In^{3+} and Tl^{3+}. Experiments were then carried out on the elution of Tl and In with hydrochloric acid of different concentrations in presence and absence of sulphurous acid. Tl^{3+} is retained at any acidity between 0.4 and 2.0*N* while indium is eluted quantitatively with 50 ml of 1.0*N* acid and more than 50 ml of 0.4*N* acid. Hence, 1.0*N* acid is preferred to elute In^{3+} selectively. In presence of sulphurous acid Tl^{3+} is eluted with 2.0*N* acid. Since this acidity is convenient for its subsequent determination with Rhodamine B, other acid concentrations have not been tried.

Based on the information above, the procedure given below was found to be quite satisfactory for a sequential separation of Tl and In in zinc-base alloys and their determination at 5-ppm level.

Procedure. A 5.0-g sample is dissolved and Tl^+ oxidized to Tl^{3+} as described under *Zeo-Karb 226 (H$^+$)*. The pH of the solution is adjusted to 2.0. This solution is passed through a column (1.0 × 4.0 cm) of Dowex A-1 (H$^+$) (100–200 mesh) at a flow-rate of 1 ml/min. The column is washed with 100 ml of water at pH 2.0 to remove practically all the zinc and aluminium. Then it is washed with 100 ml of $0.01M$ *o*-phenanthroline at pH 2.0 to remove copper. Iron and indium are then eluted with 50 ml of $1.0M$ hydrochloric acid. In^{3+} is determined by the oxine method described earlier. Tl is then eluted with 50 ml of $2.0N$ hydrochloric acid containing sulphurous acid (1.2%). This solution is boiled to remove sulphur dioxide, cooled, oxidized and then analysed by the Rhodamine B method, described earlier.

DISCUSSION

The K_d value of Tl^+ on Zeo-Karb 226 (NH_4^+) is quite high (6.56×10^3). As such it is difficult to separate it from multivalent cations, which are primarily sorbed. However, in presence of $1.0M$ ammonium nitrate, the K_d value of Tl^+ decreases to a negligible value (<10), while those of multivalent ions are still considerably higher. Hence $1.0M$ ammonium nitrate is able to elute Tl^+ selectively, leaving many multivalent cations on the exchanger.

This principle is successfully applied to analyse high-purity zinc and zinc-base alloys for traces of Tl and also for the analysis of Pb–Tl alloys. When higher amounts of material are taken for analysis, the exchanger shrinks on sorption of the sample and channelling occurs. This was obviated by sorbing the sample by mixing it with the exchanger in a beaker and then transferring it to a column of the exchanger.

In the determination of Tl by the Rhodamine B method, a large excess of ammonium nitrate caused positive interference. This excess of ammonium salt is reduced by employing the same exchanger (smaller quantity) but oxidizing Tl to the tervalent state for its sorption and then eluting with acid.

Indium cannot be separated by employing the salt form of Zeo-Karb 226. However, this exchanger in H^+ form was shown to be useful to separate Tl and In together from zinc and some other associated ions, thus allowing the determination of both the elements, different aliquots being used.

The property of Dowex A-1 of functioning as a chelating as well as an anion-exchanger under suitable conditions is utilized to achieve a sequential separation of Tl and In from zinc-base alloys. At pH 2.0, ions such as Fe^{3+}, In^{3+}, Tl^{3+} and Cu^{2+} are sorbed through chelation, while Tl^{3+} in hydrochloric acid is held as an anionic chloro-complex.

It should be mentioned that elution of Cu^{2+} with 100 ml of $0.01M$ phenanthroline is not quantitative. Out of 5000 μg of Cu taken, about 150 μg remain on the column. Elution is not continued further for two reasons. The small amount of Cu coming out with indium does not interfere in the determination of the indium. Secondly, eluting the last traces of Cu may require an unduly large volume of phenanthroline solution.

Lead has a K_d value of 390 at pH 2.0. Hence it may be retained on the exchanger at the beginning, but since its K_d falls to 140 in presence of phenanthroline, it is likely to be eluted along with the copper. In view of this, its behaviour was not studied in detail. However, it was taken in the synthetic samples to ascertain whether it interferes in the present analysis.

X-RAY PHOTOELECTRON SPECTROMETRIC AND X-RAY FLUOROMETRIC STUDIES OF SULPHUR COMPOUNDS ON THE SURFACE OF COPPER PLATES EXPOSED TO THE ATMOSPHERE

KATSUO MURATA® and SHIGERO IKEDA
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka, Japan

(*Received* 20 *October* 1975. *Accepted* 27 *November* 1975)

Summary—X-Ray photoelectron spectroscopy (XPS) and XRF as techniques for monitoring air pollution are compared. Sulphide and oxides of sulphur (SO_2, SO_3 and SO_4^{2-}) have been determined on copper plates exposed for different lengths of time to an atmosphere containing hydrogen sulphide. The total amount of sulphur increases with the time of exposure but the sulphide reaches a constant value after 59 days. An interpretation of the mechanism of oxidation of hydrogen sulphide is offered.

Many studies on air pollution have been performed by using atomic absorption,[1] atomic fluorescence,[2] the ring-oven technique,[3] and X-ray fluorescence.[4] These methods are suitable for qualitative identification and quantitative determination of elements, but not for identifying their chemical form or species. Speciation, *i.e.* the determination of species, is desirable in order to understand the chemical processes in the environment and to follow the corrosion processes going on in an atmosphere containing corrosive gases. X-Ray photoelectron spectroscopy (XPS) differentiates between chemical species of an element and is a potentially useful tool for environmental studies.[5] The present investigation was undertaken to analyse the surface of a metal plate exposed for varying periods to the atmosphere. Sulphur compounds and a copper plate were selected for the study, first because the oxidation states of sulphur and copper may be correlated with XPS chemical shifts and secondly because a copper plate is easily corroded.[6–8]

EXPERIMENTAL

Commercial copper plates (JIS tough-pitch 35 × 35 × 0.35 mm) were stored in a vacuum desiccator after treatment by the following processes: soak in warm ethanol for 1 hr then wash successively with water, 1*M* hydrochloric acid and ethanol, and then dry in an air blast. The copper plates were placed under a screen (situated in various meteorological sampling stations) to avoid rainwater. Standard sulphur solutions for X-ray fluorometric determination were prepared by the procedure of Pope *et al.*[9] X-Ray fluorometric measurement was performed by using a Rigaku Gigerflex, type SXA 3, with a germanium analysing crystal and chromium target X-ray tube.

X-Ray photoelectron spectra were obtained on an AEI-ES 200 electron spectrometer, using Al $K_{\alpha 1,2}$ X-ray radiation. The photo-emission chamber was maintained at 10^{-7} mmHg. The binding energies of the photoelectrons were determined, assuming the energy of carbon 1*s* electrons to be constant at 285 eV.

RESULTS AND DISCUSSION

X-Ray fluorescence studies

Figure 1 shows a typical X-ray fluorescence spectrum of sulphur on the surface of copper. A sharp sulphur K_α line is observed at 110.7° (2θ) without any interference from other elements. A calibration curve based on this line is linear up to a concentration of 100 μg/cm² [log S (μg/cm²) = 1.090 log *C* (count/10 sec) − 4.160]. In order to test the validity of the calibration curve, known amounts of sulphur were added to the sample. A recovery of approximately 100% was obtained when the added sulphur was below

No. 3	A	59	15	10.5
No. 4	A	206	49	12.3
No. 5	B	12	7.7	4.4
No. 6	C	28	0.82	

* Stations A and B are in an area polluted with H_2S, A being 1.5 km from the pollution source, and B 0.3 km. Station C is in an unpolluted area.

50 μg/cm^2 though the recovery varied somewhat at the sulphur level of 100 μg/cm^2. X-Ray fluorometric (XRF) determinations of sulphur for six samples are given in Table 1. All samples produce black compounds on the surface of copper plate, indicating the formation of copper sulphides or copper (II) oxide.

At station A the total sulphur increases steadily with the number of days of exposure to the atmosphere up to 59 days when a constant value is obtained. At station B the rate of adsorption of sulphur is greater, whilst at station C it is lower. These results correspond with the position of each station.

X-Ray photoelectron spectroscopic studies

Figure 2 shows a typical photoelectron spectrum of a copper plate exposed to the atmosphere. Elements such as carbon, oxygen, sulphur, and copper are readily detectable on the surface of the plate.

Sulphur 2p *photoelectron spectra*

There is a correlation between binding energy and oxidation number in inorganic sulphur compounds,[7,10,11] sulphide [S(−II)] has the lowest binding energy (160.8 eV) and sulphate [S(VI)] the highest. Sulphite [S(IV)] and sulphur [S(0)] are also distinguishable, having binding energies of 165.8 and 164.5 eV, respectively.

Figure 3 shows typical sulphur and copper 2*p* photoelectron spectra for samples 1, 2, 4 and 6. Only the peak at 161.7 eV, corresponding to S^{2-} species, is observed on the surface of the copper plate exposed to H_2S gas in the desiccator. Since no satellite Cu 2*p* peaks, which are characteristic of Cu(II) compounds, are observed, the black compound produced on the surface is probably Cu_2S. Sulphur 2*p* peaks for samples 2 and 4 are roughly divisible into two groups having lower and higher binding energies, indicating sulphide (S^{2-}) species and sulphur oxide (SO_2, SO_4^{2-}, SO_3) species, respectively. Species such as SO_3^{2-} and S^0 are unlikely. The peak at higher binding energy is so broad that it contains components of other species. Craig *et al.*[12] reported that the peak in the vicinity of 170 eV binding energy consists of three components, SO_3, SO_4^{2-}, and SO_2, as shown in Fig. 4. The resolution of our spectrometer is not good enough to distinguish these species so we shall class SO_3, SO_4^{2-}, and SO_2 together as *sulphur oxides.* At station A the ratio of sulphur oxides to sulphide changes with the length of exposure. If no oxidation of sulphide occurred on the copper plate, the ratio would be almost constant in the course of time. Actually oxidation reactions of sulphide must proceed since the ratio changes with the exposure time. The unexpected higher ratio of sulphur oxides to sulphide as shown in Fig. 3*b* may be attributed to the prompt production of sulphur oxides from hydrogen sulphide early in the exposure. Kishi *et al.*[13] have recently investigated the mechanism of

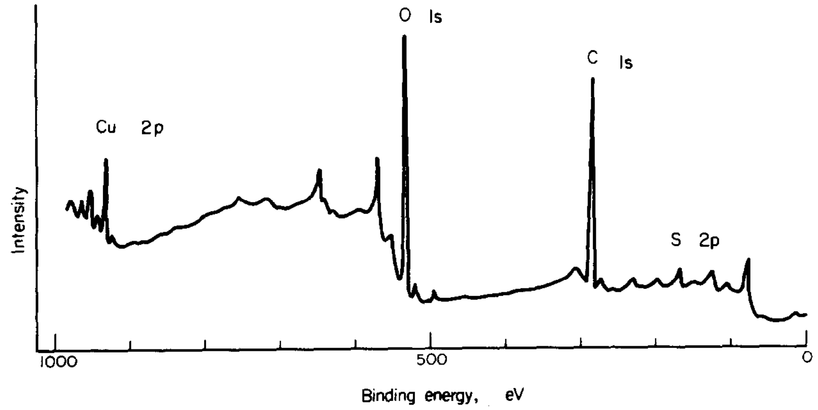

Fig. 2. X-Ray photoelectron full spectrum of a copper plate exposed to the atmosphere.

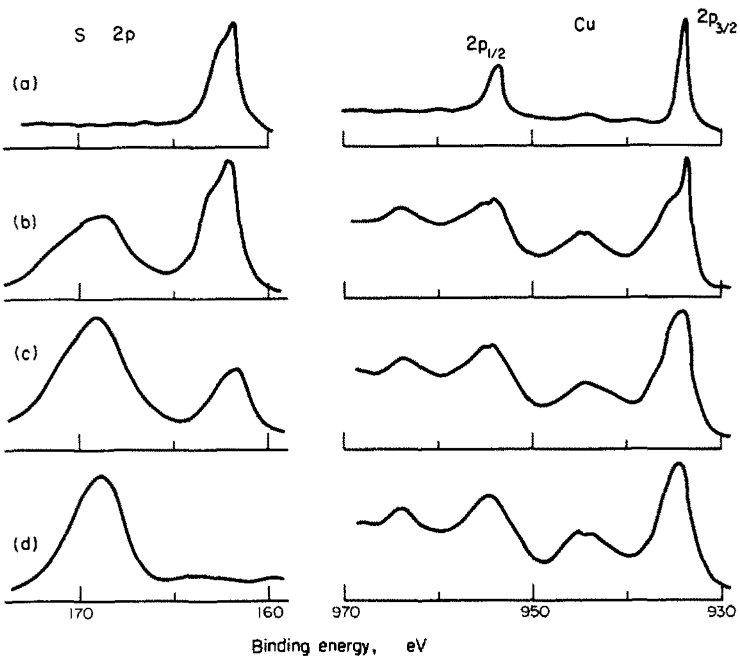

Fig. 3. Photoelectron spectra of S 2*p* and Cu 2*p*: (*a*) sample 1; (*b*) sample 2, (*c*) sample 4, (*d*) sample 6.

the interaction of hydrogen sulphide with adsorbed oxygen on lead, by XPS. According to their results, the oxygen 1*s* peak height decreased on exposure of the "oxidized" surface, which had been exposed to oxygen at 2×10^{-5} mmHg for 100 sec, to hydrogen sulphide. Accompanying the decrease in the oxygen 1*s* intensity was the emergence of the sulphur 2*p* peak: initially the sulphur 2*p* binding energy is about 163.5 eV, but later it is 160.6 eV. It would be expected from these experimental results that atmospheric hydrogen sulphide would react with the oxygen previously chemisorbed on the copper surface and with the metallic copper at the same time. Therefore nearly equivalent amounts of sulphur oxides and sulphide are produced in the early stages. In time, the oxidation of sulphur compounds takes place on the copper plate, as shown by the increase in the peak due to sulphur oxides (Fig. 3*c*). The concentrations of sulphide for samples 2–5 are given in the last column of Table 1. They were estimated from the ratio of sulphide to sulphur oxides, obtained from the sulphur 2*p* photoelectron spectra, assuming that the XPS cross-section of sulphur 2*p* and the escape depth of sulphide and sulphur oxides are approximately the same. As evident from Table 1, the sulphide concentration increases in the early stages, but during the 59–206 day period the concentration of sulphide increases only slightly, while the concentration of sulphur oxides increases considerably. The following interpretation is given for these results. The dilute hydrogen sulphide liberated in the atmosphere is adsorbed on the surface of the copper plate. The adsorbed gas immediately reacts with the previously chemisorbed oxygen and the metallic copper in the presence of oxygen and moisture, resulting[14] in the production of sulphur oxides and Cu_2S as follows:

$$2H_2S + 3O_2 \rightarrow 2SO_2 + 2H_2O$$

$$2Cu + S^{2-} + H_2O + \tfrac{1}{2}O_2 \rightarrow Cu_2S + 2OH^-$$

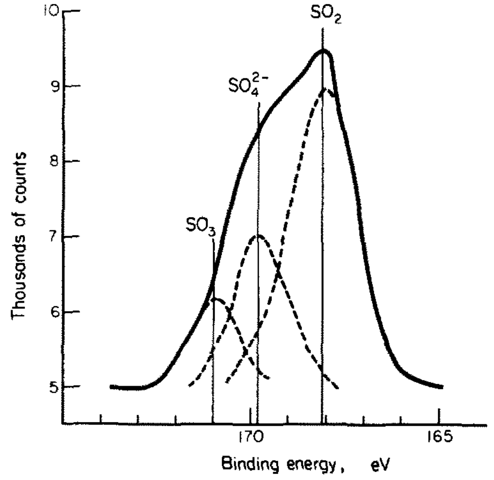

Fig. 4. Sulphur 2*p* spectrum of MgO exposed to SO_2. [Redrawn from reference 12].

Available sites on the copper surface are gradually occupied and used up by H_2S gas in the course of time. A steady state is reached with respect to sulphide in the atmospheric environment. Then the rate of copper(I) sulphide formation decreases, since the hydrogen sulphide can react with the metallic copper only after permeating the surface layers of sulphide and sulphur oxides. However, the amount of sulphur

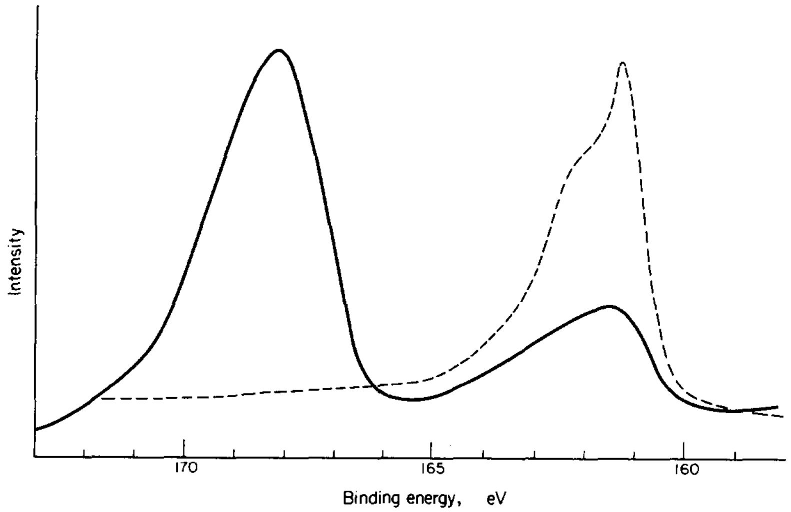

Fig. 5. S 2*p* photoelectron spectrum of a copper plate, previously treated with H_2S, then exposed to ozone. ---- Cu + H_2S; —— (Cu + H_2S) + O_3 (Intensities of the two spectra are not on the same scale).

oxides increases, by the oxidation of the surface sulphide layers, the catalytic oxidation of hydrogen sulphide on the copper plate, and the adsorption of sulphur oxides from the atmosphere.

In the laboratory experiment, hydrogen sulphide reacts immediately with the copper plate to produce black copper sulphides. At this point, sulphide species are the only sulphur compounds on the surface of the plate. When the plate is exposed to ozone ($\sim$ 1000 ppm) in the desiccator, the sulphide peak intensity decreases considerably and the intense peak of sulphur oxides appears as shown in Fig. 5. This implies that the oxidation of sulphide on the surface of the copper plate is possible during the long exposure to the atmosphere. This oxidation would start on the surface layers of sulphide. Blyholder *et al.*,[15] who studied infrared spectra of H_2S adsorbed on Fe and Ni, showed that H_2S in the atmosphere could interact dissociatively with both metallic and oxide surfaces of particles in the atmosphere. The ease with which H_2S interacts with the different kinds of surface suggests that heterogeneous reactions play a major role in the oxidation of H_2S in the atmosphere.[15] There are instances when sulphide acts as a catalyst.[16–18] Therefore the contribution from the catalytic oxidation of hydrogen sulphide on the sample plate must also be considered. It is, of course, expected that small amounts of atmospheric SO_2 and sulphuric acid mist are also adsorbed on the surface of the copper plate, as is found for sample No. 6 (Fig 3*d*).

Two reaction pathways are to be considered for the oxidation of hydrogen sulphide. One is heterogeneous oxidation of hydrogen sulphide on the surface of the copper plate as mentioned above. The other is homogeneous photo-oxidation in the atmosphere, followed by adsorption of the sulphur oxides on the copper plate. The oxidation following direct photolysis of H_2S is unlikely to occur in the atmosphere since this gas does not absorb ultraviolet radiation of wavelength longer than 260 nm.[19] It results from reaction of atoms or radicals produced by the photolysis of other species such as NO_2 and H_2O_2 in the following way:

$$NO_2 \xrightarrow{h\nu} NO\cdot + O\cdot$$

$$H_2O_2 \xrightarrow{h\nu} 2OH\cdot$$

The oxidation of hydrogen sulphide then proceeds in two steps:[20]

$$H_2S \xrightarrow{1} SO_2 \xrightarrow{2} SO_3.$$

The first step hardly occurs in the absence of the absorbing species mentioned above. However the second proceeds since SO_2 has absorption bands at 294 and 384 nm. Therefore if there are sufficiently high concentrations of oxidants such as NO_2 and O_3 in the area polluted with H_2S gas, both hydrogen sulphide and sulphur oxides produced by photo-oxidation are adsorbed on the copper plate. Photo-oxidation is most likely to occur in urban districts where the concentration of oxidants such as NO_2 is high.

Copper 2p *photoelectron spectra*

It is well known that the existence of copper 2*p* satellites is an easy guide for the determination of oxidation states of copper.[8,14] The existence of satellites is associated with paramagnetic species. Cu(II) has a paramagnetic $3d^9$ structure while Cu(I) has a filled 3*d* subshell. The copper 2*p* spectrum readily identifies Cu(II) species, but fails to destinguish between Cu(0) and Cu(I).

The surface of sample 1 shows the production of black sulphide. Since no satellites are observed in the copper 2*p* spectrum as shown in Fig. 3*a*, the reaction product should be not CuS but Cu_2S.

Samples 2–6 have satellites in the copper $2p$ spectrum, indicating the existence of Cu(II). Moreover the peaks of Cu $2p_{1/2}$ (*ca.* 954 eV) and Cu $2p_{3/2}$ (*ca.* 934 eV) are broader than those of Cu(0). This is due to the appearance of new peaks having slightly higher binding energy. The peak height of the new peaks increases with the exposure times. Therefore these new peaks would indicate the formation of Cu(I) and Cu(II), because similar peaks are observed for a sample of copper exposed for a few days to air saturated with water vapour.[21] Broadening of peaks would be due to the superimposition of the peaks of Cu(0), Cu(I), and Cu(II) with slightly different binding energy. Since CuS and Cu_2SO_4 are unstable and change into $CuSO_4$ in moist air, Cu_2S and $CuSO_4$ are expected to be the predominant copper compounds containing sulphur.

CONCLUSION

In the areas polluted with hydrogen sulphide, hydrogen sulphide liberated from the source diffuses into the atmosphere. In urban areas part of the gas is photo-oxidized in the presence of oxidants such as NO_2. However the photo-oxidation would be unlikely to occur in rural surroundings, where the concentration of oxidants is low. There most of the gas falls on the surface of the earth. Thus hydrogen sulphide is adsorbed on the copper plate. The adsorbed gas immediately reacts with metallic copper and the chemisorbed oxygen in the presence of the atmospheric moisture and oxygen, with the formation of Cu_2S species and sulphur oxides on the surface of the copper. The Cu_2S gradually changes into $CuSO_4$ as the end compound during long exposure. Additional H_2S is adsorbed on the Cu_2S layers, and a part of it permeates to react with metallic copper. This adsorbed gas is oxidized catalytically on the surface of Cu_2S to produce SO_2 and SO_3. Thus the increment of sulphide is small, while the increment of sulphur oxides is great because of additive contributions from the oxidation of Cu_2S, the catalytic oxidation of H_2S, and the atmospheric SO_2 and sulphuric acid mist.

Thus XRF and XPS are valuable techniques for monitoring air pollution and understanding of the process of corrosion of copper.

SOLVENT EXTRACTION OF GOLD

N. R. Das and S. N. Bhattacharyya
Nuclear Chemistry Division, Saha Institute of Nuclear Physics, 92, Acharya Prafulla Chandra Road, Calcutta-700009, India

(*Received* 15 *May* 1975. *Accepted* 26 *January* 1976)

Summary—The separation of gold by solvent extraction is reviewed.

Liquid–liquid extraction, in favourable circumstances, combines a high degree of selectivity with the ability to concentrate minute amounts of material and to segregate the minor from the major constituents of complex mixtures. It is sometimes possible to find conditions such that a particular constituent of a mixture is removed exclusively and essentially quantitatively in a single extraction. Also it is easier than precipitation for handling large samples.

The extracted metal ion is usually incorporated in a neutral chelate molecule or an ion-association complex. Ion-association systems may be of different types, but that in which the solvent plays a specific role is particularly important. The metal ion forms an anionic complex with anions such as chloride or nitrate, which then "associates" with a protonated oxygen-containing organic solvent such as an ether. The classic example of such a system is the extraction of iron from 6*M* hydrochloric acid with ether, where the complex $HFeCl_4(C_2H_5)_2O$ is formed.[1] A similar type of behaviour is also observed for gold.[2,3] The formation of an extractable species by a suitable solvent would therefore depend on the efficiency of formation of such ion-association systems. The strength of the solute–solvent interaction will determine the extraction efficiency of the solvent used, or rather the distribution coefficient of the solute. It would be of great value to an analytical chemist to know beforehand the order of distribution coefficients of different solutes in various solvents. Some generalizations have been made by Morrison and Freiser.[4] In a homologous series, the lower members are more efficient solvents than the higher ones.[5,6] A knowledge of the dissociation constant of the solvent complex in the organic phase is important since this may also affect the distribution coefficient.[6–21] Further, the two phases must separate quickly and efficiently, and this is dependent on several factors. Thus quick separation of phases is ensured by a larger interfacial tension[22] between them, low viscosity of the organic phase, high density difference between the two solvents, and low solubility of the organic solvent in the aqueous phase.

Radiochemical, colorimetric and various spectrometric methods (such as atomic absorption and flame emission) complement solvent extraction since the organic phase may be analysed directly. Solvent extraction is particularly well suited for the purification of radioisotopes.

This review will be confined to the liquid–liquid extraction of gold, of which no comprehensive recent survey is available, though Beamish *et al.* earlier made a general review of the methods of separation and colorimetric determination of gold.[23]

Studies on the solvent extraction of gold as its chloride complex were first reported by Lenher and Kao[5] in 1926. They examined the extraction of gold into various esters, especially ethyl acetate. By this method gold can easily be separated from other elements, *e.g.*, Na, K, Mg, Ba, Fe, Al, Sr, Ca, Cr, Mn, Co, Ni, Zn, Hg, Cu, Cd, Pd, Bi, Sb, As, and Sn. Use of ethyl acetate as an extractant for gold from hydrochloric acid medium was studied by several other workers, who separated it from irradiated copper,[24] platinum,[25] refined silver,[26] fission products,[27] irradiated biological materials,[28] rocks, minerals,[29,30] sulphide ores, meteorites,[31] petrochemicals[32] and sea-water.[33] Ethyl acetate is, however, seldom used nowadays, because of its solubility in water.

Ether also finds application as a good extractant for gold.[34,35] It is particularly useful in extracting gold from nitric acid solution; the distribution coefficient is dependent on the acid concentration. The effects of temperature and salting-out agents have been studied and the complex $HAu(NO_3)_4$ has been postulated.[36,37]

Methyl isobutyl ketone (MIBK) has been found to be very useful in extracting gold from waste cyanide solution.[38] Here Au(I) is initially oxidized to Au(III) by permanganate in hydrochloric acid medium. The method is, however, not free from interferences. Along with gold, Cr(VI), Mo(VI), Ga(III), As(V), Sb(V), Sn(IV), Se(IV), Te(IV) and Ge(IV) are also partially extracted. The extraction of Au(III) by MIBK at different hydrochloric acid concentrations has been studied.[39–43] The distribution of the gold depends on the concentrations of both the gold and the hydrochloric acid, without a definite dependence on either alone. If an excess of hydrobromic acid is present, MIBK is very efficient.[44] Maeck *et al.*[45] examined the extraction of Au(III) as a quaternary ammonium salt (tetrapropylammonium) from *aqua regia* medium into MIBK. A coloured complex is formed and is the basis of a spectrophotometric determination. A complete recovery of Au(III) directly from *aqua regia* (diluted) medium with MIBK was reported[46] recently, the only interferences being due to the partial extraction of Ag, As and Sb.

Tributyl phosphate (TBP) in xylene, chloroform or iso-octane, and trioctylphosphine oxide (TOPO) in chloroform also find wide application[47] in the extraction of gold. The species that is extracted is supposed to be of the form $[H_3O^+ \cdot 3R_3PO \cdot yH_2O][AuX_4^-]$, where R is the butoxy or octyl group and X is chlorine or bromine. A solution of 50% TBP in toluene was found[48] to extract gold quantitatively from $3M$ hydrochloric acid containing lithium chloride as salting-out agent. The great potentiality of alkylphosphine oxides as analytical extractants has been utilized[49] in extracting Au(I) with tri-n-octylphosphine oxide or 2-ethyl-n-hexylphosphine oxide in cyclohexane, at different hydrochloric acid concentrations.

The extraction of gold(I) cyanide into organic solvents[50] containing tertiary amines has been studied. Au(I) is reported[51,52] to occur in the organic phase as $HAu(CN)_2$, which is solvated with one molecule of tertiary amine. The extraction is dependent on the pH of the aqueous phase. The extraction of Au(I) cyanide by a series of quaternary ammonium salts has also been examined[53,54] and a trioctylmethyl ammonium salt was observed to be the most effective extractant. Groenewald[55] described a very sensitive method for extraction of gold from its cyanide solution into a di-isobutyl ketone solution of trioctylamine (TOA) or trioctylmethylammonium chloride (TOMA). Ca and Mg ($2 \times 10^{-3}M$) and Cu, Fe, Zn and Mn (2×10^{-3}–$5 \times 10^{-5}M$) do not interfere. The solvent n-butyl acetate containing trioctylamine has also been found[56] suitable for the extraction of Au(I) cyanide directly. The aqueous phase has to be adjusted to pH 4 to ensure quantitative extraction. A highly selective method for the extraction of Au(III) from sulphuric acid into a chloroform solution of trioctylamine (TOA) has been described by Adam and Přibil.[57]

Murphy and Affsprung[58] observed that a gold chloride complex forms a precipitate with tetraphenylarsonium chloride, which can be extracted with chloroform. The extracted species is supposed to be the ion-pair $[(C_6H_5)_4As^+][AuCl_4^-]$. Interference due to iron is suppressed by means of fluoride and none of the platinum metals interferes when present in concentration one tenth that of the gold. The same reagent has been recommended [59] for the substoichiometric determination of gold after neutron activation. The presence of Sb, Te and nitrate, however, hindered the extraction. By using tetraphenylarsonium chloride Alimarin and Perezhogin[60] determined traces of gold in Pb, Bi, Cu and Zn. No interference was observed even when the primary base metals or osmium were present to the extent of ~ 1 g. The authors were able to determine 5×10^{-11} g of gold with an error of about ±5% by using the substoichiometric principle in neutron-activation analysis.

In a study by Rakovskii *et al.*[61,62] the large organic tetraphenylguadinium cation (TPG) was used for substoichiometric extraction of gold as $[Au(SCN)_4^-][TPG^+]$ into chloroform, but it was observed that the presence of Pd hindered the separation of the phases. No such problem occurred in the substoichiometric extraction of $AuCl_4^-$ with TPG in 1,2-dichloroethane.

A solution of tetrabutylammonium perchlorate in chloroform can be used as an ion-association extractant for tetrachloroaurate(III). Bravo and Iwamoto[63] showed that the distribution coefficient can be increased to 3×10^3 by variation of the $([Bu_4N^+][ClO_4^-])_{org}/[ClO_4^-]_{aq}$ ratio.

The reagent *p*-dimethylaminobenzylidenerhodanine in isoamyl acetate was found to be a selective extractant for gold from hydrochloric acid medium by Cotton and Woolf.[64] Poluektov,[65] however, preferred to use the reagent in benzene–chloroform medium for separation of gold in presence of a few drops of $1M$ nitric acid.

A method of determination of gold with Cu, Zn or Hg–diethyldithiocarbamate (DDC) in acid medium by means of radiometric titration, using tetrachloromethane as the solvent has been described.[66,67] End-points corresponding to molar Au:DDC ratios of 1:1 and 1:2 were observed on the titration curve of gold(III) when DDC was used as the titrant. The compounds formed successively are $[Cl_2Au(DDC)]$ and $[Au(DDC)_2]^+Cl^-$. The first compound is completely extracted into trichloromethane or benzene and the extractibility of the second compound increases with increasing solvent polarity. Gold(I) forms only one compound with DDC, AuDDC. For determination of gold present as impurity in beryllium metal, Negina and Zamyatnina[68] used the reagent in chloroform. Eugene[69] also used Cu–DDC solution for substoichiometric separation of gold isotopes from irradiated meteorites.

Selective extraction of gold with a solution of 0.01–$1M$ dibutyl sulphide from hydrochloric acid medium has also been reported.[70,71] Either chloroform or benzene may be used as the diluent.

Block *et al.*[72] also studied the distribution of many metal bromides, including that of gold, at various hydrobromic acid concentrations. The percentage of gold extracted into the organic solvent varies from 99.5% to 99.9% in the hydrobromic acid concentration range 1–$3M$.

The extraction properties of a number of elements with dibutyl phosphorothioic acid was studied by Handley.[73,74] The relative order of extraction was found to be Pd(II) > Au(III) > Cu(I) > Hg(II) > Ag(I) > Cu(II) > Bi(III) > Pb(II) > Cd(II) > Ni(II) > Zn(II).

The various systems referred to above are summarized in Table 1.

Table 1. Extraction systems

Aqueous phase	Organic phase	Sample studied	References
2–7*M* HCl	Diethyl ether	Rocks, meteorites	127–131
2*M* HCl	Diethyl ether	Quartz	34
8*M* HCl	Diethyl ether	Impurities	81
HCl	Diethyl ether	Platinum metals, mercury	3, 7, 8, 82
HBr	Diethyl ether	Aluminium	35
HI	Diethyl ether		88
8*M* HNO_3	Diethyl ether		36, 37
Aqua regia	Diethyl ether	Platinum	25

SHORT COMMUNICATIONS

TITRIMETRIC DETERMINATION OF THIOCYANATE AND THIOSULPHATE IONS BY OXIDATION WITH IODINE IN ALKALINE SOLUTION

R. BELCHER, SARAH SAU-TUNG LIAO and ALAN TOWNSHEND
Chemistry Department, Birmingham University, P.O. Box 363, Birmingham, B15 2TT, U.K.

(*Received* 13 *November* 1975. *Accepted* 6 *December* 1975)

As shown in a review,[1] one of the most well-known and useful amplification methods is the reaction in which iodide ions are oxidized to iodate ions by chlorine or bromine. After removal of excess of the oxidant, the iodate ions formed are reduced by addition of more iodide ions, in acid medium, to give three molecules of iodine for each original iodide ion. This method has often been applied indirectly to other ions which show a quantitative relationship with iodide. For example, Gawargious[2] recently applied an indirect amplification for determination of arsenic by oxidizing arsenite ions to arsenate ions with iodine. After extraction of the excess of iodine, the iodide amplification reaction was applied.

In the present work, thiocyanate and thiosulphate ions are oxidized by iodine in alkaline solution to sulphate ions. In both procedures, the excess of iodine is extracted with chloroform; the iodide ions resulting from the redox reaction are retained in the aqueous phase and then the amplification reaction is applied.

Thiocyanate

In a hydrogen carbonate medium (pH 8.2), thiocyanate ions are oxidized by an excess of iodine to sulphate ions:[3]

$$SCN^- + 4I_2 + 4H_2O \rightarrow SO_4^{2-} + ICN + 7I^- + 8H^+$$

On acidification with sulphuric acid to pH 2.5, which is necessary for the subsequent amplification reactions, the iodine cyanide reacts with iodide ions to give iodine and hydrocyanic acid:

$$ICN + I^- + H^+ \rightarrow I_2 + HCN$$

This molecule of iodine together with the excess of iodine is extracted into chloroform. Hence the overall reaction can be considered to be

$$SCN^- + 3I_2 + 4H_2O \rightarrow SO_4^{2-} + 6I^- + 7H^+ + HCN$$

Bromine water is added to this aqueous solution to oxidize iodide ions to iodate ions:

$$3Br_2 + I^- + 3H_2O \rightarrow IO_3^- + 6H^+ + 6Br^-$$

and to convert hydrocyanic acid into bromine cyanide:

$$Br_2 + HCN \rightarrow BrCN + H^+ + Br^-$$

Finally, after the destruction of the excess of bromine with formic acid, potassium iodide is added and the following reactions take place:

$$IO_3^- + 5I^- + 6H^+ \rightarrow 3I_2 + 3H_2O$$
$$BrCN + 2I^- + H^+ \rightarrow I_2 + HCN + Br$$

Thus from each original thiocyanate ion, 19 molecules of iodine are obtained.

Thiosulphate

In sodium hydroxide solution (pH 12), iodine forms hypoiodite ions, which oxidize thiosulphate ions to sulphate ions:[4]

$$I_2 + 2OH^- \rightarrow OI^- + I^- + H_2O$$
$$S_2O_3^{2-} + 4OI^- + 2OH^- \rightarrow 2SO_4^{2-} + 4I^- + H_2O \quad (1)$$

On acidification, the excess of hypoiodite is converted into iodine, which is then extracted into chloroform. The amplification reaction is then applied to the iodide left in the aqueous solutions. Hence each original thiosulphate ion gives rise to 24 molecules of iodine.

Investigation of reaction conditions

Effect of pH. The oxidation reactions described are carried out in alkaline medium, and because iodine oxyanions are involved the oxidation potentials will be independent of the pH, and the reactions possible will be different from those in acidic solutions. In alkaline solutions, iodine is capable of oxidizing thiocyanate and thiosulphate ions to sulphate ions. However, the pH values required are different. For thiocyanate, a hydrogen carbonate medium (pH 8.2) is sufficiently alkaline for the oxidation. At higher pH values, for example, in sodium hydroxide solution (pH 12), inconsistent results are obtained after different reaction times, as shown in Table 1, and in acidic medium (pH 5 acetate buffer) the results are low (Table 1) because sulphate is not the end-product and a smaller consumption of iodine is to be expected.

Table 1. Effect of pH on oxidation of thiocyanate and thiosulphate ions by iodine

Solution added (10 ml)	pH	Titration volume, *ml*, for	
		SCN^-*	$S_2O_3^{2-}$†§
NaOH (1*M*)	12	6.7–9.5†	9.65
$NaHCO_3$(10% v/v)	8.2	7.40	4.00
Acetate buffer	5.0	4.5	
H_2SO_4(0.1*N*)	1		2.40

* Expected value for 22.5 μg of SCN^- is 7.39 ml of $2 \times 10^{-3}M$ $Na_2S_2O_3$.

† Oxidation period varied from 30 min to 9 hr.

§ Expected value for 44.8 μg of $S_2O_3^{2-}$ is 9.60 ml of $2 \times 10^{-3}M$ $Na_2S_2O_3$ for oxidation to SO_4^{2-} and 2.40 ml for oxidation to $S_4O_6^{2-}$.

Table 2. Range of applicability of the thiocyanate determinations

Thiocyanate taken, *μg*	2.7	4.5	9.0	22.5	45.0	90.0
No. of determinations	3	3	3	11	3	2
Mean recovery, % (titration)	103.2	100.6	99.8	99.7	99.2	98.8
Mean recovery, % (spectrophotometry)	98.8	100.1	97.4	99.9	100.1	100.4
Final volume for spectrophotometry, *ml*	50	100	100	250	500	1000

For thiosulphate oxidation, a sodium hydroxide solution (pH 12) is necessary; hydroxide ions participate in the redox reaction [reaction (1)]. Low results are obtained in a hydrogen carbonate medium, as shown in Table 1. In acidic medium (pH 1), two thiosulphate ions are oxidized by one molecule of iodine, to the tetrathionate ion (Table 1).

After complete oxidation of either anion by iodine, acidification to ≤pH 2.5 is necessary. The excess of hypoiodite is converted into iodine, which is then extracted by chloroform. The remaining aqueous solution is suitable for the amplification reaction as described above, and the iodine formed is titrated with standard thiosulphate solution or measured spectrophotometrically.[5]

The extraction of iodine was originally done by using four 10-ml aliquots of chloroform and shaking momentarily until the aqueous and organic phases were thoroughly mixed. The blank titration obtained by this procedure was 1.5–2.0 ml of $2 \times 10^{-3}M$ sodium thiosulphate. Increasing the number of extractions and the volume of chloroform gave no improvement. However, with a 1-min shaking at each extraction, four 10-ml aliquots of chloroform gave a blank of 0.5–0.6 ml of $2 \times 10^{-3}M$ thiosulphate. The use of different mineral acids for acidification, such as sulphuric or perchloric acid, led to no significant difference in the blank.

Precision and range of applicability

The coefficients of variation were calculated for eleven measurements of both ions. For 22.5 μg of thiocyanate, the coefficient of variation obtained by the titrimetric method was 0.6%, and that by spectrophotometry was 0.8%. For 44.8 μg of thiosulphate, the coefficient of variation for the titrimetric finish was 0.7%; for 33.6 μg and the spectrophotometric finish, it was 0.9%.

The determination of both anions was essentially at the trace level. The results were quantitative (>98.5% recovery) in the ranges 2.7–90 μg (>98.5% recovery) for thiocyanate and 4.5–90 μg for thiosulphate (Tables 2 and 3).

Interferences

The following cations and anions in 100-fold weight ratio to the ion being determined did not interfere in the determination of 23 μg of thiocyanate: Cd^{2+}, Pb^{2+}, Zn^{2+}, Ca^{2+}, Cr^{3+}, Co^{2+}, Na^{+}, K^{+}, Cl^{-}, Br^{-}, NO_3^{-}, SO_4^{2-}, CO_3^{2-}, ClO_4^{-}. Fe^{3+}, Cu^{2+} and Hg_2^{2+} interfered, as did anions which participated in redox reactions with iodine, such as $S_2O_3^{2-}$, SO_3^{2-}, S^{2-} and AsO_3^{3-}. These anions (and thiocyanate, but, of course, not thiosulphate) also interfered in the determination of 45 μg of thiosulphate, but of the cations tested, only Fe^{3+} and Hg_2^{2+} interfered.

EXPERIMENTAL

Reagents

Potassium thiocyanate. The analytical-reagent grade material, dried under vacuum at 80° for 24 hr, was weighed out (7.557 mg) by microbalance and dissolved in 1000 ml of distilled water. This stock solution was stable over a long period.

Sodium thiosulphate. A 0.1*M* solution prepared from standard ampoules (and stabilized with sodium carbonate), was diluted to $2 \times 10^{-3}M$. This solution is stable for two weeks when kept in the dark. A $2 \times 10^{-4}M$ solution must be prepared daily and was used as the stock solution for investigation of the determination of thiosulphate. All solutions were standardized against the potassium iodate solution.

Potassium iodate. The analytical-reagent grade material, dried at 180° was weighed out (0.2354 g) and dissolved in 1000 ml of distilled water. This stock solution is used for standardizing the thiosulphate solution and for the spectrophotometric calibration curve.

Amplification procedures

Thiocyanate (2.7–90 μg). In a 250-ml separating funnel, mix 10 ml of 10% sodium hydrogen carbonate solution and thiocyanate solution containing not more than 90 μg of thiocyanate. Add 3 drops (0.5 ml) of saturated iodine solution in chloroform and mix well by shaking. After 5 min, add 4 ml of 4*N* sulphuric acid; extract the iodine released, with four 10-ml portions of chloroform, shaking consistently for 1 min at each extraction. Completely transfer the aqueous layer to a 100-ml stoppered-flask; add 1 ml of saturated bromine water and swirl periodically during the next 5 min. Add 3 ml of 90% formic acid to destroy the excess of bromine, and add 1.5 g of potassium iodide (analytical-reagent grade). Titrate the solution with $2 \times 10^{-3}M$ thiosulphate after 5 min (1 ml of $2 \times 10^{-3}M$ $Na_2S_2O_3$ solution ≡ 3.04 μg of SCN^{-}). Alternatively, dilute to a standard volume equivalent to a thiocyanate concentration of 0.1 ppm and measure the absorbance of the solution at 350 nm in a 10-mm glass cell with distilled water in the reference cell;[5] obtain the iodine concentration (and hence

Summary—Thiocyanate (2.7–90 μg) and thiosulphate (4.5–90 μg) ions are oxidized by iodine in alkaline media to sulphate ions. After acidification, the excess of iodine is extracted into chloroform, and the iodide ions formed in the redox reaction subjected to an amplification reaction. Either a titrimetric or a spectrophotometric finish may be used. Each thiocyanate and thiosulphate ion results in the ultimate production of 19 and 24 iodine molecules, respectively.

yl-4-phenyl-6-(2-pyridyl)pyrimidine (**I**) and 2-methyl-4,6-bis(2-pyridyl)pyrimidine (**II**) with pyridalacetylpyridine.[2] From benzamidine hydrochloride and benzalacetylpyridine[2] or pyridalacetophenone, 2,4-diphenyl-6-(2-pyridyl)-pyrimidine (**III**) resulted. From benzamidine and pyridalacetylpyridine, 2-phenyl-4,6-bis(2-pyridyl)pyrimidine (**IV**) was the result. Picolinamidine hydrochloride and benzalacetophenone yielded 2-(2-pyridyl)-4,6-diphenylpyrimidine (**V**).

Attempts to use 3-pentene-2-one, benzalacetone, or crotonophenone in the same general procedure as above to prepare other compounds desired were unsuccessful. Pyridalacetone[3] was unavailable. Further attempts to condense the amidines previously mentioned with various diketones by the method of Pinner[4] or of Haley and Maitland[5] were also unavailing.

The chromogenic reactions of the successfully synthesized compounds have been evaluated with various metal ions, and the results are reported here.

EXPERIMENTAL

Preparation of trisubstituted pyrimidines

A mixture of 0.005 mole of amidine hydrochloride, 0.1 mole of unsaturated ketone, 0.01 mole of potassium hydroxide, and 25 ml of ethanol was heated for 3 hr on a steam-bath. After evaporation of half the alcohol, an equal volume of water was added. The resulting precipitate was filtered off, dried and crystallized from the solvent indicated in Table 1. **I** and **V** gave oils, which were extracted with ether; the ether was then evaporated and the residue crystallized from the solvent indicated. In the preparation of **II**, sodium ethoxide was substituted for potassium hydroxide. Elemental analyses, yields, and melting points are listed in Table 1.

Chelation studies

The procedures, reagents, and standard solutions have been described before.[6] Spectra were recorded with a Cary Model 14 spectrophotometer.

RESULTS AND DISCUSSION

All five of the new compounds yielded coloured complexes with copper(I) but not with any other ion in tests with dilute metal ion solutions. Thus the expectation that these would prove to be specific chromogens for copper(I) proved valid. Such specificity undoubtedly arises because the bulky methyl or phenyl substituents adjacent to the co-ordinating nitrogen atoms in the ligands sterically hinder complete attainment of octahedral (but not of tetrahedral) co-ordination of bidentate ligands. Copper(I) readily accommodates to tetrahedral co-ordination and is the only metal ion to be both fully complexed and to give an intense colour. This type of specificity has been observed previously for numerous examples of similarly substituted ferroin-type compounds.[7]

Compound **III** lacks sufficient solubility in aqueous media to be used as a practical colorimetric reagent. Reliable spectral data could not be obtained for its brown copper(I) chelate, because it proved insoluble in all solvents tested.

The results of studies to determine optimum formation conditions and spectral characteristics of the copper(I) chelates are summarized in Table 2. Two of the compounds, **I** and **II**, exhibit properties attractive for analytical application as copper reagents. Absorbances of their copper(I)-chelate solutions follow Beer's law and are sufficiently high to allow detection of $1.1 \times 10^{-6}M$ copper(I), with a path-length of 1 cm and an absorbance of 0.010. They compare favourably in sensitivity with previously reported copper-specific chromogens.[7,8]

The results are also of interest in providing further guidelines for synthesis of new and perhaps superior reagents. For example, the results for **III**, **IV** and **V** clearly indicate that a phenyl group *ortho* to a ferroin group will exert an adverse influence on the absorptivity of the copper(I) chelate, and reduce the solubility and stability. In the case of **IV** it is observed that its copper(I) chelate dissociates appreciably on moderate dilution with ethanol, an indication of its low stability. For the spectral study of this chelate, the alcohol content of the solutions was kept to a minimum to reduce fading but still provide sufficient solubility for the complex. Under these conditions it was necessary to filter off the excess of **IV**, which precipitated, before spectral measurement of its chelate.

Another interesting feature is that, unlike most copper(I) chelates with ferroin-type ligands, the chelates of **II** and **IV** are only partially extractable into isoamyl alcohol. Furthermore the extracts differed in colour from the aqueous phase. The low extractability and solvent-dependent spectral characteristics of these two copper(I) chelates are believed to be associated with either the unco-ordinated pyridyl or the non-utilized second ferroin group that each of their ligands possesses.

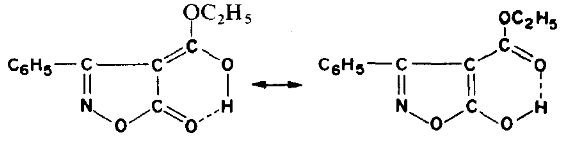
3-PHENYL-5-ISOXAZOLON-4-CARBOXYLIC ACID ETHYL ESTER AS A SELECTIVE REAGENT FOR THE SPECTROPHOTOMETRIC DETERMINATION OF IRON(III)

F. Corigliano and S. Di Pasquale

Istituto de Chimica Analitica, Università di Messina, Italy

(*Received* 20 *October* 1975. *Accepted* 30 *October* 1975)

Earlier studies have shown that 3-phenyl-5-isoxazolon-4-carboxylic acid ethyl ester (HIs) (I) is a monoprotic medium strong acid which reacts as a ligand with iron(III), giving three successive complexes.[1] The uncharged species is extractable into methyl isobutyl carbinol (hexol) as a red chelate. The reaction is selective and sensitive. Under suitable conditions, the reagent can be used for the spectrophotometric determination of iron(III).



(I)

EXPERIMENTAL

Reagents

Standard iron(III) solutions. Precipitated iron(III) hydroxide was dissolved in hydrochloric or perchloric acid. The solutions obtained were then standardized gravimetrically.

3-Phenyl-5-isoxazolon-4-carboxylic acid ethyl ester. The reagent was synthesized by the method of Stagno d'Alcontres *et al.*[2] and recrystallized from diethyl ether. A stock solution (0.01*M*) was prepared by dissolving the appropriate amount of the reagent in methyl isobutyl carbinol (hexol).

Buffer solutions. Potassium hydrogen phthalate (0.1*M*) and hydrochloric acid or sodium hydroxide solutions were used to prepare buffer solutions of pH 2.2–5.0.

All other chemicals used were analytical-reagent grade.

Procedure

To a suitable aliquot containing 13.5–135.0 μg of iron, add 10.0 ml of 0.01*M* solution of HIs in hexol, keeping the pH at 2.2–5.0 with a buffer solution. Make the volumes of both phases 10 ml and shake for 5 min. Separate the organic layer and measure its absorbance at 490 nm against a hexol blank. Calculate the iron concentration from a previously prepared calibration curve.

RESULTS AND DISCUSSION

Absorption spectra and reaction conditions

The complex exhibits maximum absorbance at 490 nm where the reagent does not absorb. The colour of the complex in the organic phase is stable.

The absorbance at 490 nm is constant over the pH range 2.2–5.0 for $10^{-2}M$ HIs concentration. For general purposes, full colour development requires a total reagent concentration $\geqslant 1.4[H^+] + 0.003 + 3[Fe(III)]$, as revealed by equilibrium studies.[1] A further excess does not interfere.

The system adheres to Beer's law up to 15.0 ppm of iron. The optimum range for accurate determination, as evaluated from a Ringbom plot, is 1.35–13.5 ppm. The sensitivity of the colour reaction is 0.013 $\mu g/cm^2$ (at 490 nm), with molar absorptivity 4.2×10^3 $l.mole^{-1}.cm^{-1}$.

The precision of the method has been checked by measuring the absorbance of 10 samples, each containing a final concentration of 6.7 ppm of iron. The mean absorbance was 0.500 with standard deviation 0.007.

Composition and instability constants

The values of the partition coefficient (5.5) and dissociation constant (1.4×10^{-2}) of HIs, the formula of the extracted complex, ($FeIs_3$), its partition coefficient (10.5) and formation constant (5.6×10^9) have been obtained by partition methods.[1,3] The formation of higher complexes than the neutral species can be ignored owing to the maintenance of unvarying metal distribution at higher ligand concentration and pH.[3] This is consistent with the chelating properties of the ligand.

Effect of other ions

The effect of various ions was studied at pH 2.5. The general procedure was followed, except that the solutions of foreign ions were added before the reagent solution. The method is selective.

With 6.0 ppm of iron(III), the following ions present in the amounts (in ppm) shown in parentheses did not cause a deviation of more than ±2% in absorbance from that expected: borate (250), nitrate (3000), nitrite (2000), phosphate (1000), arsenate (4000), sulphate (5000), chloride (3000), bromide (2000), thiocyanate (2000), acetate (4000), tartrate (5000), citrate (4000), cyanide (300), fluoride (100), oxalate (200), Ag (500), Tl(I) (3000), Mg (1000), Ca (2000), Sr (4000), Pb (1500), Mn(II) (2500), Fe(II) (2500), Cd (5000),

The complex exhibits maximum absorbance at 490 nm where the reagent does not absorb. The colour of the complex in the organic phase is stable.

The absorbance at 490 nm is constant over the pH range 2.2–5.0 for $10^{-2}M$ HIs concentration. For general purposes, full colour development requires a total reagent concentration $\geqslant 1.4[H^+] + 0.003 + 3[Fe(III)]$, as revealed by equilibrium studies.[1] A further excess does not interfere.

The system adheres to Beer's law up to 15.0 ppm of iron. The optimum range for accurate determination, as evaluated from a Ringbom plot, is 1.35–13.5 ppm. The sensitivity of the colour reaction is 0.013 μg/cm^2 (at 490 nm), with molar absorptivity 4.2×10^3 l.mole^{-1}.cm^{-1}.

The precision of the method has been checked by measuring the absorbance of 10 samples, each containing a final concentration of 6.7 ppm of iron. The mean absorbance was 0.500 with standard deviation 0.007.

Composition and instability constants

The values of the partition coefficient (5.5) and dissociation constant (1.4×10^{-2}) of HIs, the formula of the extracted complex, ($FeIs_3$), its partition coefficient (10.5) and formation constant (5.6×10^9) have been obtained by partition methods.[1,3] The formation of higher complexes than the neutral species can be ignored owing to the maintenance of unvarying metal distribution at higher ligand concentration and pH.[3] This is consistent with the chelating properties of the ligand.

Effect of other ions

The effect of various ions was studied at pH 2.5. The general procedure was followed, except that the solutions of foreign ions were added before the reagent solution. The method is selective.

With 6.0 ppm of iron(III), the following ions present in the amounts (in ppm) shown in parentheses did not cause a deviation of more than ±2% in absorbance from that expected: borate (250), nitrate (3000), nitrite (2000), phosphate (1000), arsenate (4000), sulphate (5000), chloride (3000), bromide (2000), thiocyanate (2000), acetate (4000), tartrate (5000), citrate (4000), cyanide (300), fluoride (100), oxalate (200), Ag (500), Tl(I) (3000), Mg (1000), Ca (2000), Sr (4000), Pb (1500), Mn(II) (2500), Fe(II) (2500), Cd (5000), Hg(II) (4000), Al (2000), As(III) (2000), Bi (200), Cr(III) (2000), La (400), Ti(IV) (50), Th (2000), V(V) (1000), Mo(VI) (200), W(VI) (300). Barium (5000), cobalt(II) (800), nickel (300), copper(II) (60) and zinc(II) (900) react with HIs, giving slightly soluble complexes, which do not give rise to any appreciable colour in the hexol phase. Palladium(II) (100) and uranium(VI) (500) give extractable yellow complexes with negligible absorption at 490 nm. Reducing agents for Fe(III) should be absent.

When required, a better selectivity can often be achieved at lower pH (1.5) and/or higher reagent concentration ($4 \times 10^{-2}M$).

NEW SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF PHENOLIC HORMONES

SAAD S. M. HASSAN* and M. T. M. ZAKI
Research Microanalytical Laboratory, Department of Chemistry, Faculty of Science,
Ain Shams University, Cairo, Egypt

(*Received 3 October* 1975. *Accepted 8 December* 1975)

Few methods are available for spectrophotometric determination of phenolic hormones (oestrogens and catecholamines); most of them are neither selective nor specific. Reactions with concentrated sulphuric acid alone[1] and in combination with phenolic compounds (the Kober reaction)[2] have been reported for the determination of oestrogens and many other steroid hormones having either an —OH or a $>C{=}O$ group or both. The Kober reaction, combined with the Ittrich extraction of the fluorescent colour complex, with an organic solvent containing a solution mediator, has been widely used for both spectrophotometric[3] and fluorimetric[4] estimation of oestrogens. However, the colour and fluorescence developed by these reactions depend on the acid concentration, heating time, presence of oxidant, type of solvent and excitation wavelength.

Steroids containing the $—CH_2CO—$ group are determined by reaction with *m*-dinitrobenzene (the Zimmermann reaction).[5] This reaction was satisfactorily applied to the determination of oestrone.[6] Antimony trichloride[7] and hydrazine[8] have been also used for the determination of some oestrogenic hormones containing the carbonyl function (*e.g.*, oestrone and equilenine) but progestanes and androgens react similarly. Reactions with heteropoly acids[9,10] and iodic acid[11] have been utilized for the determination of oestrogens[9] and catecholamines,[10,11] but none of these reactions is free from interferences by other non-phenolic hormones.

However, selective reactions for the determination of oestrogens and catecholamines, by virtue of their phenolic character, have been advocated. These are based on coupling reactions of oestrogens[12] and catecholamines[13] with diazotized amines or condensation of oestrogens with phthalic anhydride[14] under suitable reaction conditions. Reaction with ferric chloride in presence of air has been reported as fairly specific for adrenaline,[15] and the reaction with iodine[16] allows the estimation of noradrenaline in presence of adrenaline. The accuracy of these methods depends on critical adjustment of the experimental conditions.

The present paper reports a new simple method for the spectrophotometric determination of oestrogens and catecholamines by reaction with nitric acid followed by treatment with alkali. The effect of reaction temperature, time, solvent, and alkali concentration have been investigated and the optimum experimental conditions for successful application of this reaction to the determination of oestrone, oestradiol, ethinyloestradiol, adrenaline and noradrenaline are described. The reaction is specific and selective for phenolic oestrogens with regard to other steroid hormones of the progestane and androgen classes.

EXPERIMENTAL

Reagents

All the reagents used were of analytical-reagent grade unless otherwise specified. Stock solutions of oestrone, oestradiol, ethinyloestradiol (Nutritional Biochemical Corporation, U.S.A.), adrenaline and noradrenaline (B.D.H.) were prepared by dissolving 3 mg of each in 10 ml of ethyl alcohol. The purity of the hormone samples was not less than 99%.

Procedure

Construct a standard calibration curve for each hormone by transferring 0.20, 0.40, 0.50, 0.70, 0.90, 1.00 and 1.20 ml portions of the stock solutions to 20-ml graduated tubes. Evaporate to complete dryness on a boiling water-bath. Cool, add 1.0 ml of 16*M* nitric acid and place the tubes for 10 min in a water-bath controlled at 50 ± 5° for oestrogens (oestrone, oestradiol, ethinyloestradiol) or

Cool, add 1.0 ml of 16*M* nitric acid and place the tubes for 10 min in a water-bath controlled at 50 ± 5° for oestrogens (oestrone, oestradiol, ethinyloestradiol) or

---

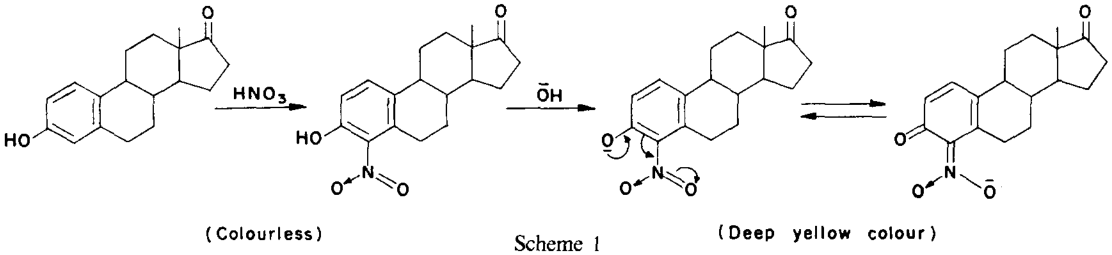
* To whom inquiries and requests for reprints should be addressed.

100° for catecholamines (adrenaline, noradrenaline). The heating time should be strictly adhered to. Cool, add 4 ml of 5*M* sodium hydroxide portionwise and make up to 10.0 ml with ethyl alcohol. Mix and allow to stand for 5 min at room temperature. Measure the absorbance, in 10.0-mm cuvettes, at 430, 385, 430, 380, 380 nm for oestrone, oestradiol, ethinyloestradiol, adrenaline, noradrenaline respectively, against a blank prepared under identical conditions. Draw a graph of the absorbance against hormone concentration. Follow the same procedure with samples of unknown concentrations.

RESULTS AND DISCUSSION

Nature of the reaction

To investigate the nature of the reaction, oestrone was nitrated at 50° and the reaction product was isolated, recrystallized from methanol and identified. The infrared spectrum of the product showed strong absorption peaks at 1350 and 1540 cm^{-1} due to the symmetrical and asymmetrical $—NO_2$ stretch. The absorption band observed at 810 cm^{-1} is probably due to out-of-plane deformations of two adjacent hydrogen atoms on an aromatic ring, whereas



Scheme 1

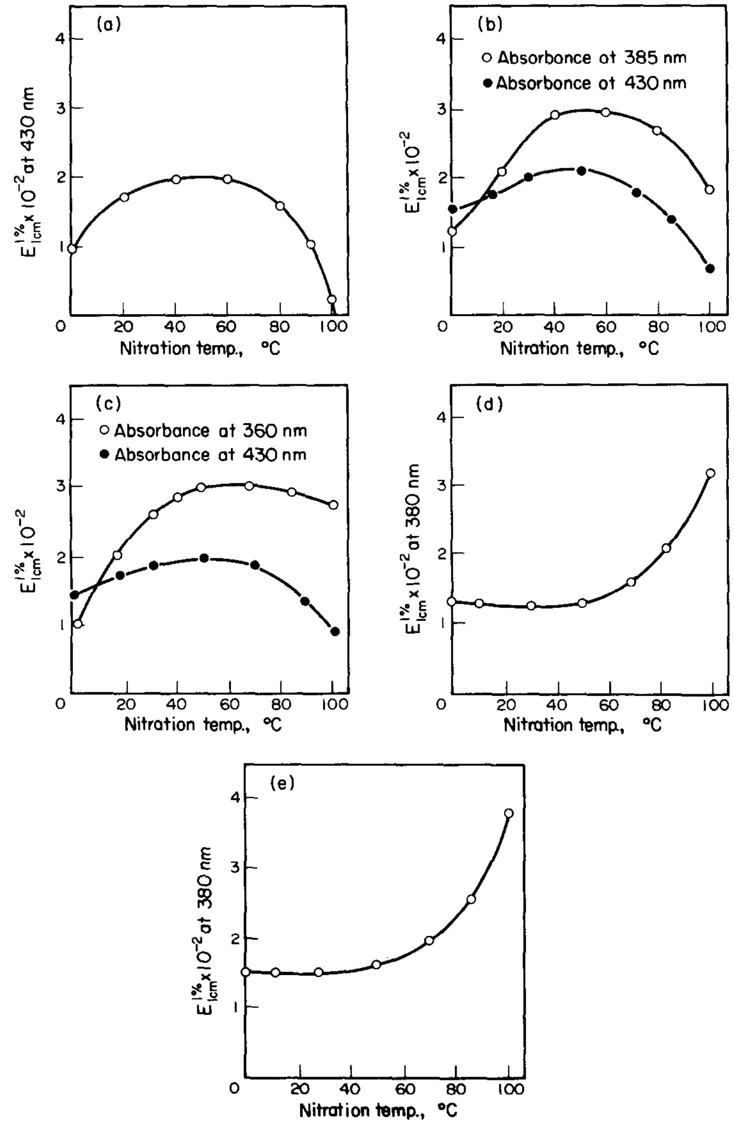


Fig. 1. Effect of nitration temperature on the absorbance of the nitration products of: (a) oestrone, (b) oestradiol, (c) ethinyloestradiol, (d) adrenaline and (e) noradrenaline, in sodium hydroxide solution.

the broad absorption band at 3100–3700 cm^{-1} belongs to the bonded —OH group.[17] Hence oestrone undergoes an electrophilic substitution reaction in position 4 under the present reaction conditions. The phenolic group, by virtue of its $+M$ effect, and the —CH_2— group, by its $+I$ effect, activate the 4-position of the aromatic nucleus. β-Naphthol is known to undergo electrophilic substitution in the α-position, which is reactive as is position 4 in oestrogens.[18] In addition, the absorption spectrum of the nitration product of oestrone, in sodium hydroxide medium, was compared with the spectra of *o*-, *m*-, and *p*-nitrophenols. *o*-Nitrophenol displays the same spectrum. Most probably, all other phenolic hormones undergo reactions of similar nature.

The formation of coloured species from the nitration products of oestrone in alkaline media is ascribed to the ability of the *o*-nitrophenate ion to tautomerize to yield the quinonoidal nitronic acid salt.[19] The formation of the aci-form is accompanied by an increase and extension of the conjugated system. Consequently, the reaction of oestrone may be represented by Scheme 1.

It is well known that the reaction of nitrophenols with alkalis is usually used for their quantitative determination.[20]

Effect of nitration temperature and time

Reaction of phenolic hormones with 16*M* nitric acid for 10 min was investigated at temperatures ranging from 0 to 100°. Oestrone, oestradiol and ethinyloestradiol show maximum and constant absorption at 430, 385 and 430 nm, respectively, on nitration at 40–60°C. With nitration at above 70°, a gradual decrease of the absorbance values is observed, which is probably due to oxidative side-reactions. However, nitration at 100° is recommended for adrenaline and noradrenaline (Fig. 1).

The effect of nitration time on the absorbance of the products was also investigated by carrying out the nitration reaction for 5, 10, 15, 20 and 30 min at 50° for oestrogens and at 100° with catecholamines. A heating time of 10 min is considered optimal for all the hormones under investigation (Fig. 2), but must be strictly adhered to.

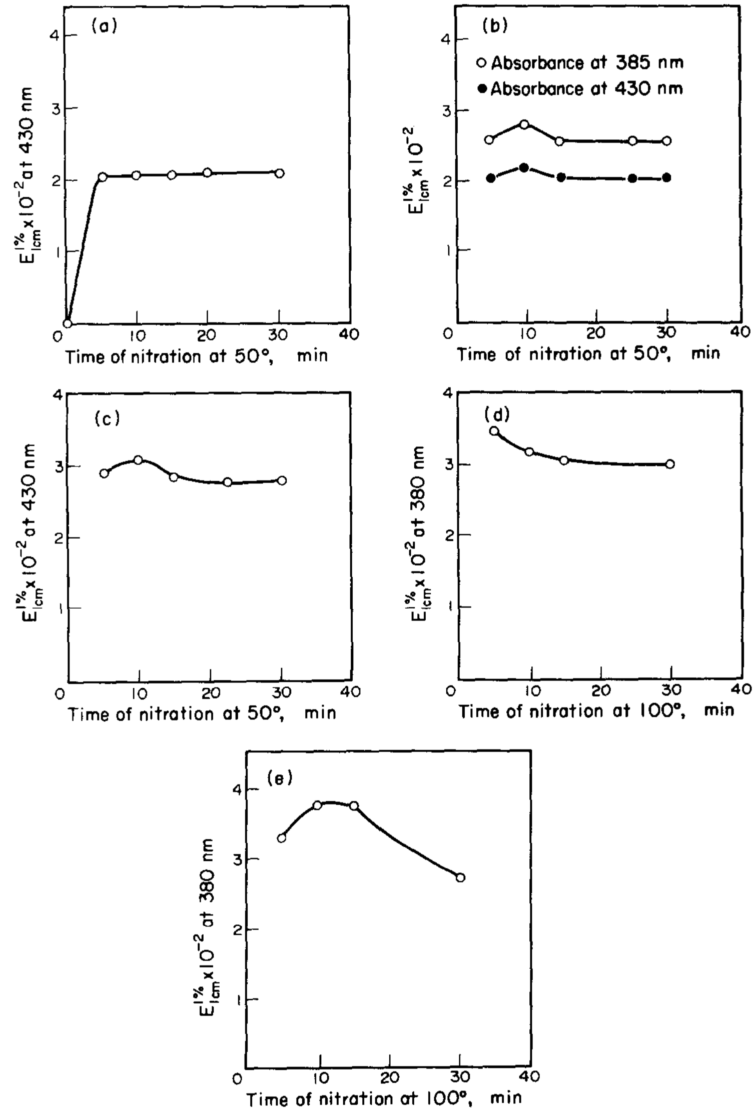

Fig. 2. Effect of nitration time on the absorbance of the nitration products of: (a) oestrone, (b) oestradiol, (c) ethinyloestradiol, (d) adrenaline and (e) noradrenaline, in sodium hydroxide solution.

Effect of solvent and alkali concentration

Since 1 ml of 16*M* nitric acid is used in the nitration reaction, 0.7 g of sodium hydroxide is needed to render the solution alkaline. Higher amounts of alkali (up to 1.2 g) do not affect the absorbance values. The intensity of the coloured nitration products after addition of sodium hydroxide was tested in various water-miscible organic solvents (*e.g.*, ethyl alcohol, acetone, dimethylformamide and dioxan). A 50% v/v concentration of ethyl alcohol proved to be the best, since there was no precipitation but maximum absorbance.

Determination of phenolic hormones

Nitration of oestrone, oestradiol, ethinyloestradiol, adrenaline and noradrenaline under the present conditions, followed by treatment with alkali gives products which display absorption maxima at 430 nm ($E^{1\%}_{1\,\mathrm{cm}}$ 187), 385 nm ($E^{1\%}_{1\,\mathrm{cm}}$ 263), 430 nm ($E^{1\%}_{1\,\mathrm{cm}}$ 183), 380 nm ($E^{1\%}_{1\,\mathrm{cm}}$ 284) and 380 nm ($E^{1\%}_{1\,\mathrm{cm}}$ 353), respectively. Beer's law is obeyed at these maxima over the range 0–500 μg of hormone in the 10-ml volume of the final solution. In a series of analyses with hormone concentrations of 10–50 μg/ml, the results obtained showed an average recovery of 98.9% and a relative standard deviation of ±0.5%.

Advantages and limitations

The present method offers two main advantages over the Kober–Ittrich reaction,[2–4] which is widely used for the analysis of oestrogens, namely simplicity and selectivity. The selectivity towards other non-phenolic steroid hormones (*e.g.*, testosterone, progesterone and androstanalone) was tested. The accuracy of the results is not affected by the presence of these steroids in up to 1000-fold molar ratio to the oestrogenic hormones, since they do not respond to the nitration reaction. On the other hand, these steroids develop intense colours in concentrated sulphuric acid solution[1] and consequently they interfere when the Kober–Ittrich reagent (hydroquinone in concentrated sulphuric acid) is used.

The present method gives results at least as accurate as those obtained by the Kober–Ittrich procedure, probably because the latter reaction is susceptible to the effect of sunlight, solvent contamination, and concentration of sulphuric acid.[2–4] These experimental variables require careful adjustment and precautions.

On the other hand, the method is less sensitive than the Kober–Ittrich reaction.[21] The least amount that can be determined by the nitration reaction with acceptable accuracy is 10 μg/ml in the final solution (*i.e.*, 100 μg of the hormone). Although a lower concentration (2 μg/ml) can be satisfactorily determined by using a 5-cm cell, the sensitivity is still below that of the Kober–Ittrich reaction.

Comparison with the methods based on the red colour developed on oxidation of catecholamines[22] shows that the present method compares favourably with many of them in both sensitivity and selectivity and is simpler than most.

Summary—A new simple, selective and accurate spectrophotometric method is described for the determination of mono- and dihydric phenolic hormones (oestrogens and catecholamines) by nitration at 50° and 100°, respectively, for 10 min, followed by treatment with alkali. Coloured products with absorption maxima at 430, 385, 430, 380 and 380 nm, linearly proportional to the concentration of oestrone, oestradiol, ethinyloestradiol, adrenaline and noradrenaline, respectively, are obtained. Information is presented on the effect of nitration time, temperature, solvents, and alkali concentration. The method is satisfactorily applied to the determination of these hormones in the range 10–50 μg/ml in the final solution, of volume 10 ml. The relative standard deviation is ± 0.5% and no interferences are caused by non-phenolic hormones.

EXTRACTION AND DIRECT SPECTROPHOTOMETRIC DETERMINATION OF RUTHENIUM WITH ETHYL-α-ISONITROSOACETOACETATE

M. R. Patil and B. C. Haldar
Inorganic and Nuclear Chemistry Laboratory, Institute of Science, Bombay-400032, India

(*Received* 24 *September* 1975. *Accepted* 23 *November* 1975)

Beamish[1] has reviewed the reagents used up to 1965 for the spectrophotometric determination of ruthenium. Of these, thiourea,[2] dithio-oxamide,[3] *p*-nitrosodimethylaniline[4] and 1,10-phenanthroline[5] are the best. However, in the thiourea method Fe(III), Co(II), Cr(III), Os(IV), Ni(II), Cu(II) and Pd(II) interfere and the sensitivity is low. Dithio-oxamide is more sensitive than thiourea, but other platinum metals interfere. In the *p*-nitrosodimethylaniline method, exact adjustment of pH is required, the absorbance due to the reagent is appreciable, and the colour development is not complete even after heating for 50 min. Further, the tolerance limit for other platinum metals has not been studied. With 1,10-phenanthroline, the development of colour is not complete even after 2 hr and the precision is low. The last two methods also require distillation of ruthenium tetroxide. The present paper describes determination of ruthenium with ethyl-α-isonitrosoacetoacetate (HEINA), which has already been used for Pd(II).[6]

EXPERIMENTAL

Reagents

Ethyl-α- isonitrosoacetoacetate was prepared as reported earlier.[6] Analytical-grade chemicals and reagents were used. Stock ruthenium solution was prepared by dissolving 1 g of pure ruthenium(III) chloride in 20 ml of 10*M* hydrochloric acid by heating on a water-bath and diluting to 100 ml with water. Ruthenium in the stock solution was estimated as ruthenium metal.[1] The solution was further diluted as required. Radioisotopes were obtained from the Isotope Division, Bhabha Atomic Research Centre, Bombay, India.

Procedures

Extraction. To an aliquot of ruthenium chloride solution (containing 1 mg of ruthenium), 2.0 ml of 5% solution of HEINA in water were added and the pH was adjusted to the desired value with hydrochloric acid or sodium hydroxide solution. The mixture was heated on a boiling water-bath for 15 min, cooled and treated with 5 ml of 10*M* lithium chloride, then equilibrated for 2 min with 10 ml of benzyl alcohol. The phases were separated and ruthenium estimated in each by the rubeanic acid method.[7] The pH of the equilibrated aqueous phase was measured. The extraction coefficient was calculated. In the study of the extraction in the presence of other ions, the ion of interest was added before the reagent. Radioactive tracers, if available, were used to follow the extraction of other ions. The value for the separation factor, *S*, defined as

$$S = \frac{\text{Extraction coefficient of ruthenium}}{\text{Extraction coefficient of the element of interest}},$$

was calculated.

Spectrophotometric determination. To a solution containing 1–180 μg of ruthenium, 2 ml of 5% solution of HEINA in water were added and the pH was adjusted to 5 with sodium acetate–acetic acid buffer (total volume 5 ml). The solution was heated for 15 min, cooled, treated with 5 ml of 10*M* lithium chloride and equilibrated (2 min each time) with two 5-ml portions of benzyl alcohol. The organic extracts were collected in a 10-ml measuring flask and made up to the mark with benzyl alcohol, if necessary. The absorbance of the solution was measured at 470 nm, against benzyl alcohol. The amount of ruthenium was determined from a calibration curve prepared by the same procedure. The calibration plot was linear over the range 1–180 μg of ruthenium per 10 ml of extract.

RESULTS AND DISCUSSION

Extraction

The extraction was studied over wide range of experimental conditions. The extraction coefficient (Table 1) for ruthenium varies with the pH of the solution being maximal over the pH range 4–6. The extraction is improved considerably if the aqueous solution is heated to boiling for at least 15 min before the equilibration with benzyl alcohol (Fig. 1), and is quantitative at pH 5 from 5*M* lithium chloride (heated for 15 min). Benzyl alcohol is the most satisfactory solvent (Table 1). The extraction is not significantly affected by phosphate, pyrophosphate, chloride, bromide, iodide, chlorate, nitrate, sulphate, persulphate, sulphite, oxalate, tartrate, citrate, thiosulphate, thiocyanate and EDTA. Only cyanide, iodate and bromate suppress the extraction. The interference by iodate and bromate can be removed by adding iodide and heating on a water-bath for 15 min.

The separation factors given in Table 2 indicate that ruthenium can be efficiently separated from a number of elements, but Pd(II), Rh(III) and Pt(IV) are extracted along with the ruthenium into benzyl alcohol under the conditions used. However, ruthenium can be

Table 2. Separation factors for different ions in the extraction of Ru–HEINA complex into benzyl alcohol from 5*M* LiCl solution at pH 5.0 Ruthenium taken, 1.0 mg; 10 ml of each phase

Separation factor	Ions
$>10^6$	Fe(III),* Sn(II),† Ni, Sb(III)†
$>10^5$	Sc, Ca, Mn(II), PO_4^{3-}, Na, Cu(II),* La,* Re(VII), Cr(III),* W(VI), Ce(III), Zn, Zr, Cs, Cd, Mo(VI), K, Pt(IV),§
$>10^4$	Tl(I), Pt(IV),‡
$>10^3$	Co(II), Ag, Ir(IV).
$>10^2$	Pt(VI).
>1	Rh(III), Pd(II).

* In the presence of citrate.
† In the presence of tartrate.
§ Solvent used CCl_4.
‡ Solvent used $CHCl_3$.

separated from rhodium and platinum by extraction into carbon tetrachloride. The recovery of ruthenium is more than 99% if the aqueous phase at pH 5 is equilibrated thrice with equal volumes of carbon tetrachloride. Separation from palladium can be achieved by extracting palladium into chloroform containing 1% HEINA, from 1*M* acetic acid medium; the loss of ruthenium from the aqueous phase is negligible.

Spectrophotometric determination

The absorption spectrum of ruthenium–HEINA in benzyl alcohol shows an intense peak at 470 nm. The absorbance due to the reagent is negligible at this wavelength (Fig. 2). Beer's law is obeyed over the range 0.1–18 µg of ruthenium per ml. The molar absorptivity is 1.05×10^4 $l.mole^{-1}.cm^{-1}$. The absorbance shows no significant change in 5 days.

An HEINA concentration corresponding to HEINA: Ru = 40 is sufficient for the extraction and colour development of 100 µg of ruthenium. However, in the presence of 10 mg of other ions which interact with HEINA, it is necessary to use 100 mg of HEINA for the extraction of 100 µg of ruthenium.

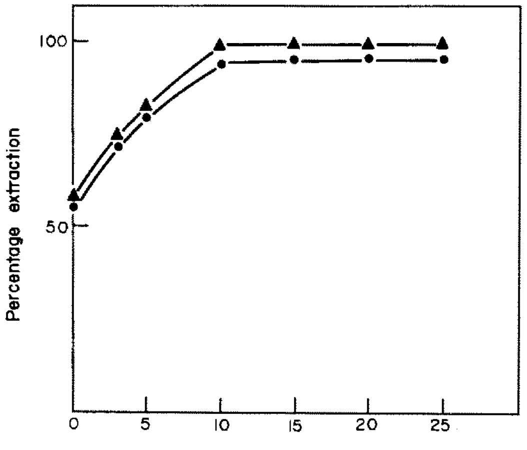

Fig. 1. Extraction of ruthenium as a function of heating time. In the absence of LiCl (●) and in the presence of 5*M* LiCl (▲).

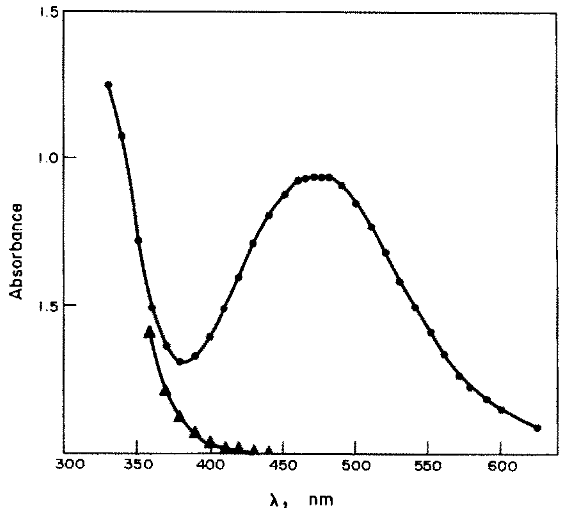

Fig. 2. Absorption spectra of Ru–HEINA complex (●) and HEINA (▲) in benzyl alcohol. Ru = $0.84 \times 10^{-4}M$, HEINA = $620 \times 10^{-4}M$.

Up to 10 mg of the following ions will not interfere in the spectrophotometric determination of ruthenium: Mn(II), Cu(II), Zn, Cd, U(VI), Mg, Ca, Ba, V(IV), Pb, Mo(VI), W(VI), Th, Be, Hg(II), Ag, Te(VI), and the anions mentioned earlier. Up to 5 mg of Os(IV), or 1 mg of each of Au(III), Se(IV) and Se(VI) will have no significant effect on the colour in the benzyl alcohol extract. The interference by the iodate and bromate can be removed as already described. Fe(II), Fe(III) and Cr(III) do not interfere in the presence of tartrate. Up to 100 µg of Pd(II), Pt(IV), Rh(III), Ir(IV) and 500 µg of Co(II) can be tolerated if the absorbance is measured at 540 nm. At this wavelength 2 µg of ruthenium in 10 ml of benzyl alcohol gives an absorbance of 0.014.

The precision and accuracy of the proposed method were tested by analysing solutions containing known amounts of ruthenium. The average of 10 determinations of 5.0 µg in 10 ml of solution is 5.0 µg and the standard deviation is 0.1 µg.

Summary—Ruthenium is extracted by benzyl alcohol from 5*M* LiCl containing ethyl-α-isonitrosoacetoacetate at pH 4–6. The extraction is quantitative if the solution is heated to boiling for 15 min. The benzyl alcohol extract shows maximum absorbance at 470 nm and at this wavelength Beer's law is obeyed over the ruthenium concentration range 0.1–1.8 µg/ml. The error is 4% for 0.5 µg/ml.

RAPID SPECTROPHOTOMETRIC DETERMINATION OF RUTHENIUM WITH DIETHAZINE HYDROCHLORIDE

H. SANKE GOWDA and P. G. RAMAPPA
Postgraduate Department of Chemistry, University of Mysore, Manasa Gangotri, Mysore 570 006, India

(*Received* 3 *September* 1975. *Accepted* 20 *November* 1975)

There are few satisfactory methods for spectrophotometric determination of ruthenium.[1] Most use an almost neutral reaction medium and require either heating or a long time for the colour development. During investigation[2] of its reaction with palladium(II), diethazine hydrochloride (DH) was found to give a red colour with ruthenium(III) instantaneously in the presence of sulphuric or hydrochloric acid. This reaction is now utilized for rapid spectrophotometric determination of ruthenium(III).

EXPERIMENTAL

Reagents

DH solution. Prepared in doubly distilled water, stored in an amber-coloured bottle in a refrigerator, and standardized.[3]

Ruthenium solution. Ruthenium(III) chloride (~1 g) dissolved in 500 ml of doubly distilled water containing sufficient hydrochloric acid to give a concentration of 1*M*. Standardized gravimetrically[4] by precipitating the hydrous oxide, igniting in air, reducing in hydrogen, and cooling in an atmosphere of carbon dioxide. More dilute solutions were prepared as needed.

All other reagents were analytical grade and were used without further purification.

Procedure

Transfer an aliquot of sample solution, containing 25–260 μg of ruthenium, to a 25-ml volumetric flask. Add sufficient sulphuric acid for its final concentration to be 1.5*M*. Add 5 ml of 0.2% DH solution. Dilute to volume with doubly distilled water. Measure the absorbance at 515 nm *vs.* a reagent blank. Prepare a calibration curve in the same way.

RESULTS AND DISCUSSION

The complex gives maximum absorption at 515 nm, where neither the reagent nor ruthenium(III) has significant absorption. A Job plot and the molar-ratio method both indicate a 1:1 complex. Ion-exchange studies show the complex is cationic. When formed in hydrochloric acid the complex shows higher sensitivity but lower stability with time and a narrower Beer's law range than when prepared in sulphuric acid medium. Buffering does not further stabilize the complex. The absorbance is unchanged when the sulphuric acid concentration is varied between 0.1 and 2.2*M*. At least a tenfold excess of reagent is needed for completeness of reaction, so 5 ml of 0.2% solution is adequate for the range covered. The colour is stable for about 40 min in sulphuric acid medium but only 10 min in hydrochloric acid. The absorbance is not affected by temperature in the range 5–70°. The order of addition of reagents is not critical.

The complex obeys Beer's law over the range 1.0–10.4 ppm of ruthenium. The optimum range (Ringbom plot[5,6]) is 2–9 ppm. The molar absorptivity is 5.35×10^3 $\text{l.mole}^{-1}.\text{cm}^{-1}$ and the sensitivity is 0.019 $\mu g/cm^2$ for an absorbance of 0.001. The absorbance of six solutions containing 4 ppm ruthenium had a maximum relative deviation of 1.5% and an average relative deviation of 0.45%.

The following amounts (μg/ml) of foreign ions were found to give less than 2% error in the determination of 4 ppm of ruthenium: UO_2(II) 1200; Ni(II) 1000; Cu(II) 200; Co(II) 25; Ir(III) 8; Pt(IV) 6; Rh(III) 6; phosphate 2600; sulphate 2500; fluoride 2500; acetate 2400; chloride 2200; oxalate 1800; nitrate 1200; EDTA 1000; bromide 700; iodide 10. Thiosulphate, Os(VIII), Pd(II), Au(III), Ag(I), Ce(IV), Fe(III) and V(V) interfere seriously.

The sensitivity is higher than that with thiourea.[4] *p*-Nitrosodimethylaniline[7] is more sensitive than the new reagent but the permissible acidity range is narrow and heating is required. The major advantage of DH is the rapidity of the reaction at room temperature. Uranium, which is frequently associated with ruthenium, is tolerated up to 1200 ppm, which is another major advantage.

The fuel for the initial core loading of the Experimental Breeder Reactor II is an alloy of 95% uranium, 2.5% molybdenum, 2% ruthenium and smaller amounts of zirconium, palladium and rhodium. Synthetic mixtures containing the metals corresponding to this alloy were prepared and the ruthenium content was determined. The results are given in Table 1.

Table 1. Determination of ruthenium in synthetic mixtures

HYDROGEN PEROXIDE DETERMINATION WITH LUMINOL AND A NEW CATALYST

VĚNCESLAV PATROVSKÝ
Research Building Institute, Prague 10, Czechoslovakia

(*Received* 2 *September* 1975. *Accepted* 23 *November* 1975)

Luminol is 3-aminophthalic acid hydrazide or 5-amino-2,3-dihydro-1,4-phthalazinedione. This compound has been known for a long time.[1] and recommended for detection of blood and hydrogen peroxide.[2–5] In alkaline solution at about pH 12.5 it exhibits an intense blue luminescence with hydrogen peroxide, but only in the presence of a suitable catalyst. Haemoglobin and related substances, like haemin or blood, have been used, and various metal ions[6] or metal complexes.[7] Potassium ferricyanide causes strong luminescence even in the absence of peroxide. Some other compounds (hypochlorite, ozone, sulphite, chlorine, carbon dioxide) produce weak or short-lasting luminescence which must be taken into account if less than 0.0005% H_2O_2 is to be determined. Some other compounds destroy this luminescence in an unknown manner, but in water analysis only hypochlorite need be removed (by about 0.1 g of urea or ammonium chloride). Luminescence due to hypochlorite or ozone appears even in the absence of the catalyst and vanishes during one minute. Calcium and magnesium in concentration higher than 100 mg of the oxide per litre may be masked by a stoichiometric amount of EDTA (in large excess EDTA diminishes the luminescence intensity).

Hydrogen peroxide is formed from dissolved oxygen in water by various forms of radiation, *e.g.*, sound, radioactivity, ultraviolet and solar rays and by static or magnetic and bioelectric agents,[7–9] so a method for its determination in minute amounts is needed. Although haemoglobin as catalyst has been improved by mixing it with Cu-triethanolamine complex, [5,10] its use is inconvenient. It is now found that the cobalt(III)-triethanolamine complex reacts in the same way and gives the same intensity as haemoglobin.

EXPERIMENTAL

Reagents

Luminol solution, 0.05% in 5% sodium hydroxide solution. Stock 0.3% and 0.03% hydrogen peroxide solutions were prepared from 30% peroxide and standardized by permanganate titration.

A solution of the catalyst was prepared by dissolving 0.5 g of cobaltous nitrate and 2.5 ml of triethanolamine in about 50 ml of water, leaving the solution open to the air and occasionally stirring it. After 3–4 hr this solution was heated to about 80° (to destroy some traces of hydrogen peroxide formed by auto-oxidation), cooled and diluted with water to 100 ml.

Apparatus

Luminescence intensity was evaluated with a transistorized amplifier (silicon transistors) and a CdS photoresistor, according to the scheme in Fig. 1. An ammeter with two sensitivity ranges was used. Cells of 100 or 150 ml capacity can be used. Before measurement the zero is set with resistor R_1.

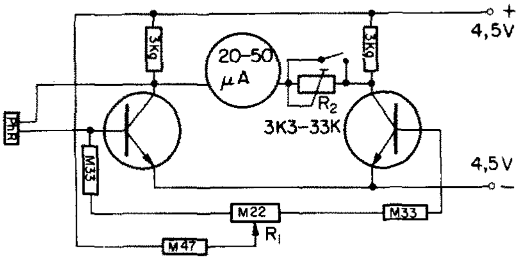

Fig. 1. Transistorized amplifier for luminosity measurement. PhR photoresistor; R_1 zero setting; R_2 sensitivity range.

Procedure

To 100–140 ml of water add 5 ml of 0.05% luminol solution and enough standard peroxide solution to give a final concentration of 0.0002–0.005% H_2O_2 and dilute accurately with water to 150 ml. Then add 5–8 drops (or 0.3 ml) of Co–TEA solution, mix well, place the cuvette in the dark chamber and measure the luminescence intensity at exactly the same time after mixing for all samples (10 or 15 sec).

The procedure for samples is the same, but with 140 ml of test water and no peroxide. A blank solution measurement is necessary. A calibration curve is shown in Fig. 2. Because the luminescence intensity decreases rapidly (by 20–30% in 30 sec), the measurement must be done at a fixed time after the solution is mixed and this time should be as short as possible. Alternatively the decay curve may be scanned (Fig. 3). For hydrogen peroxide levels below 0.0001% a photomultiplier with suitable measurement devices must be used. Freshly prepared luminol solution is not suitable, because the enol–keto equilibrium must be reached, which occurs after about 48 hr.

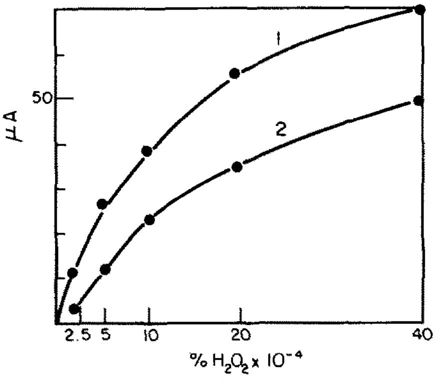

Fig. 2. Calibration curve for 0.0002–0.004% H_2O_2 in 150 ml final volume. Curve 1, luminosity after 5 secs. curve 2, luminosity after 60 sec. when catalyst has been added and mixed.

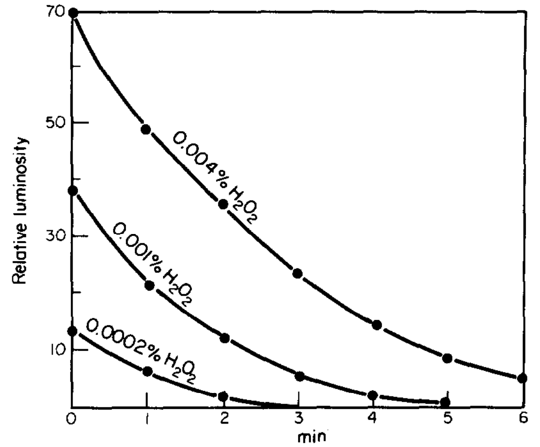

Fig. 3. Luminosity decay 10 sec after reagent mixing for three H_2O_2 concentrations, pH 12.5, temperature 18°.

RESULTS AND DISCUSSION

It was found that varying the pH between 11 and 13, the amount of luminol solution between 3 and 10 ml and of the catalyst solution between 4 and 10 drops (0.2–0.5 ml) has little or no effect on the luminescence intensity. Above pH 13 and below pH 10 the intensity decreases rapidly. The luminescence is approximately of the same intensity and duration as obtained by using haemoglobin.

Interferences and practical use

There are many positive and negative influences on luminol luminescence and further investigation is necessary. In most cases hydrogen peroxide may be detected or determined with good reproducibility, because its solution in water does not contain interfering compounds. Irradiated or activated water may also contain radicals such as $\cdot HO_2$, which can react with luminol, but our knowledge of such radicals is still poor. By use of the luminol reaction hydrogen peroxide may also easily be detected in diethyl ether.

SPECTROPHOTOMETRIC DETERMINATION OF VANADIUM(V) AND ITS APPLICATION TO VANADIUM STEELS CONTAINING CHROMIUM, MOLYBDENUM, TUNGSTEN AND MANGANESE

Bijoli Kanti Pal, Birendra Kumar Mitra and Syamal Chattopadhyay*
Department of Chemistry, Jadavpur University, Calcutta-700032, India

(*Received* 20 *August* 1975. *Accepted* 17 *December* 1975)

N-Substituted hydroxylamines have long been regarded as group reagents for vanadium(V), forming coloured chelates with it. Because of their greater aromaticity, diaryl hydroxylamines, in general, produce greater intensity of colour. The nature and position of the substituents can also improve the selectivity.

Ever since the introduction of BPHA (*N*-benzoylphenylhydroxylamine) by Shome[1] as a reagent for vanadium, several of its analogues have been similarly used but none is entirely free from interference, expecially from the elements used to make alloy steels.

We have been unable to obtain satisfactory results with the *N*-benzoyl-*o*-tolylhydroxylamine method[2,3] or with the *N*-*p*-methoxybenzoyl-*m*-tolylhydroxylamine method[4] when analysing alloy steels containing chromium, molybdenum, tungsten, cobalt and vanadium. We therefore sought a new reagent of the hydroxylamine type, and have found one in the reagent described in this paper.

The colour is stable for several days. The stability of the vanadium chelate may be attributed to the increased basicity of the donor atom. The selectivity of the method may be attributed to steric hindrance due to the presence of one methyl group in the *ortho* position of each of the phenyl rings.

EXPERIMENTAL

Reagents

The reagent *N*-*o*-toluoyl-*o*-tolylhydroxylamine was prepared according to the method described earlier,[5] and used as a 0.4% solution in chloroform. All chloroform used was freed from alcohol and other impurities beforehand by washing first with a few drops of sulphuric acid and then successively with dilute ammonia and water, then distilled and dried over anhydrous sodium sulphate.

All reagents were of analytical-reagent grade. Solutions of niobium and tantalum were prepared by pyrosulphate fusion of the oxides and dissolution of the cooled melt in oxalate–tartrate solution.

A standard solution of vanadium(V) was prepared from ammonium metavanadate dissolved in dilute ammonia and then diluted to a known volume with doubly distilled water; it was standardized by iron(II) titration.[6] Other standard solutions were prepared from it by appropriate dilution.

General procedure

An aliquot of vanadium(V) solution was mixed in a separating funnel with an equal volume of 8*M* hydrochloric acid, 5 ml of 0.4% reagent solution and 5 ml of chloroform. The mixture was shaken thoroughly for a few minutes and the reddish-violet chloroform layer was separated, dried over anhydrous sodium sulphate and quantitatively transferred to a 25-ml volumetric flask. The aqueous layer was similarly extracted with two further 5-ml portions of chloroform, separated, dried and transferred to the same 25-ml flask. The combined extracts were then diluted to 25 ml with chloroform. The absorbance was measured at the absorption maximum, 510 nm.

RESULTS AND DISCUSSION

Characteristics of the complex

The complex has maximum colour intensity in 2–6*M* hydrochloric acid medium. Maximum intensity is reached instantaneously at room temperature and is constant for about 4 days. A volume of 5 ml of reagent solution was found more than sufficient for complete development of the colour with 10 μg/ml of vanadium. Excess of reagent has no adverse effect.

The system obeys Beer's law over the vanadium concentration range 0.5–10 μg/ml. The optimum concentration range[7] is 2–8 μg/ml. The relative error per 1% absolute photometric error[8] is 2–7%. The Sandell sensitivity[9] calculated for an absorbance of 0.001 is 0.011 μg/cm^2. The molar absorptivity is 4.75×10^3 l. mole^{-1}.cm^{-1}.

Job's method,[10] the molar-ratio method,[11] and the slope-ratio method[12] all showed a 1:2 metal:ligand complex to be formed.

Effect of diverse ions

In determination of 4 μg of V(V) per ml, there was no interference from 20 mg (this is not the tolerance limit) each of Fe(III), Co(II), Ni, Cu(II), Cd, Hg(II), Ca, Mg, Be, Mn(II), Al, Cr(III), Cr(VI), $S_2O_8^{2-}$, Mn(VII), Mo(VI), W(VI), U(VI), Sn(IV), Zr, Hf, Ti(IV) (masked with fluoride), Nb, Ta, oxalate, citrate, tartrate, EDTA (disodium salt), fluoride, sulphate, nitrate and perchlorate. For Pd(II), the tolerance limit was found to be 5 mg. Both SCN^- and H_2O_2 cause negative errors.

Steel analyses

BCS Nos. 220 HS and 64b HS were analysed for vanadium by the method described below, the results being 1.31 and 1.37% for 220HS (certified value 1.35%) and 1.95, 1.97 and 2.00% for 64b HS (certified value 1.99%).

Procedure. About 0.6 g of the steel, in a covered 250-ml beaker, was treated with 10–15 ml of *aqua regia* and left aside for 10–15 min. When the initial brisk reaction had subsided, the solution was evaporated, on the hot-plate, to ~5 ml. Then 5 ml of concentrated hydrochloric acid were added and after heating for a few minutes the solution was cooled to room temperature, diluted with 10–15 ml of doubly distilled water and filtered. The precipitated tungstic acid was washed with hot 1*M* hydrochloric acid until free from iron (tested with thiocyanate). The combined washings and filtrate were transferred into a 100-ml volumetric flask and diluted to the mark with water. A 1-ml aliquot of this solution was pipetted into a separating funnel and treated with 2–3 ml of freshly prepared 4% potassium persulphate solution (or dilute permanganate solution until the solution appeared faintly pink) and an equal volume of 8*M* hydrochloric acid was added to make the acidity nearly 4*M*. The vanadium was then extracted and measured as in the general procedure.

Acknowledgements—It is a pleasure for one of us (S.C.) to thank C.S.I.R. (India) for awarding him a scholarship, and also Jadavpur University for providing him with all the laboratory facilities during the execution of his research project. The authors are thankful to Professor Emeritus A. K. Majumdar of this University for his keen interest in the problem and his encouragement.

Summary—A newly synthesized reagent, *N*-*o*-toluoyl-*N*-*o*-tolylhydroxylamine is used in a sensitive and selective spectrophotometric method for determination of vanadium(V). The method has been successfully applied to vanadium determination in Mn–Mo–Cr–V steels. The system in 2–6*M* hydrochloric acid medium obeys Beer's law at 510 nm in the range of vanadium concentration from 0.5 to 10.0 μg/ml.

AN AUTOMATIC ELECTROMETER RANGING CIRCUIT FOR A SPARK-SOURCE MASS-SPECTROMETER*

R. J. CONZEMIUS and G. A. SLEEGE†

Ames Laboratory–ERDA and Department of Chemistry, Iowa State University, Ames, Iowa 50010, U.S.A.

(*Received* 13 *August* 1975. *Accepted* 30 *November* 1975)

Electrical measurements of ion-current signals from spark-source mass-spectrometers present unique experimental difficulties.[1] One of these is the automatic ranging of a sensitive electrometer amplifier during the sequential measurement of different ion-signals by peak-switching technique. These ion-signals, which commonly fluctuate between zero and high current,[2] are too erratic for commercial auto-rangers. This paper describes briefly an electronic circuit which satisfactorily performs automatic attenuation on a Cary 401 MR electrometer used for measuring spark-source mass-spectrometer ion-signals. The general electrical detection system has already been described.[3,4,5]

A block diagram of the circuit is given in Fig. 1. Electrical inputs required for the circuit are at the left of the figure. Electrical outputs are at the top, and operator switch controls are at the bottom of the figure. The purpose of the circuit is to find the proper range in which the average value of the electrometer signal for a specific spectral ion-beam (NUCLIDIC ION in Fig. 1) is closest to 25% of full scale. A variable time period (INTEGRATE TIME switch) determines the sampling time in which the ranging is performed. The instantaneous level of the TOTAL ION BEAM in the spectrometer, monitored by a separate amplifier, is also input to the circuit. If this total ion-current falls below a preset level during the ranging period, then the auto-ranger restarts the range-finding procedure. This is done because experience has shown that certain ion-signals are extraordinarily high (or low) just before failure of the ion-source to provide a spark-breakdown.

The auto-ranger determines the electrometer gain-setting in two steps, called COARSE RANGE and FINE RANGE, with a MASTER COARSE/FINE CONTROL. During coarse ranging the output of the electrometer is sampled to determine if it is between 10 and 95% of full scale. If the output is outside this range, the coarse range is appropriately changed and the output is again sampled. The fine range is determined by integrating the electrometer output for a preset time. The integrated value determines one of five ranges to be set for the measurement. Ranging will not go below a preset LOWEST RANGE. Both coarse and fine ranging are accomplished in the same manner. When ranging, two shift registers (SHIFT REGISTER logic) are used: one for up-ranging and the other for down-ranging. The outputs of the shift registers are applied to an up/down decade counter in RANGE CONTROL, which contains the range. Zero corresponds to the most sensitive range and 9 corresponds to the least sensitive range.

The auto-ranger can be operated in two modes, manual or auto, as selected by the operator. In the manual mode the decade counter is forced to the setting of the MANUAL RANGE switch and in the auto mode the decade counter is influenced by up or down clock inputs controlled by the SHIFT REGISTER logic. Activation of the auto-ranger for this mode is recognized by a signal on ACTIVATE AUTO-RANGE. Completion of auto-ranging is externally recognized by a high signal on AUTO-RANGE COMPLETE. RANGE DISPLAY is a seven-segment LED digit. The BCD to DECIMAL DECODER activates the appropriate RELAY DRIVERS and the RANGE RECORDING interface.

The timing sequence for the auto-ranger is given in Fig. 2. Three sequences are of interest: FINE CONTROL, COARSE CONTROL, and MASTER COARSE/FINE CONTROL, as shown in the figure. General control is maintained by MASTER COARSE/FINE and the sequence starts with START COARSE. After 1 msec

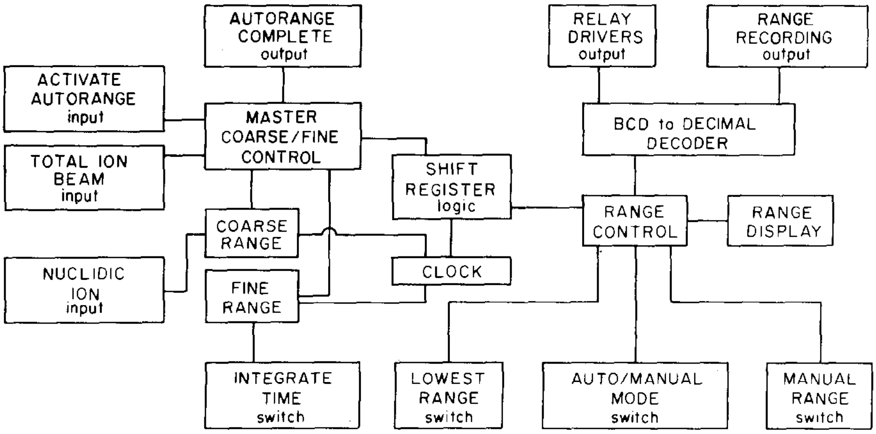

Fig. 1. Block diagram for auto-range circuit.

† Current address: Fisher Controls, Marshalltown, Iowa 50158.

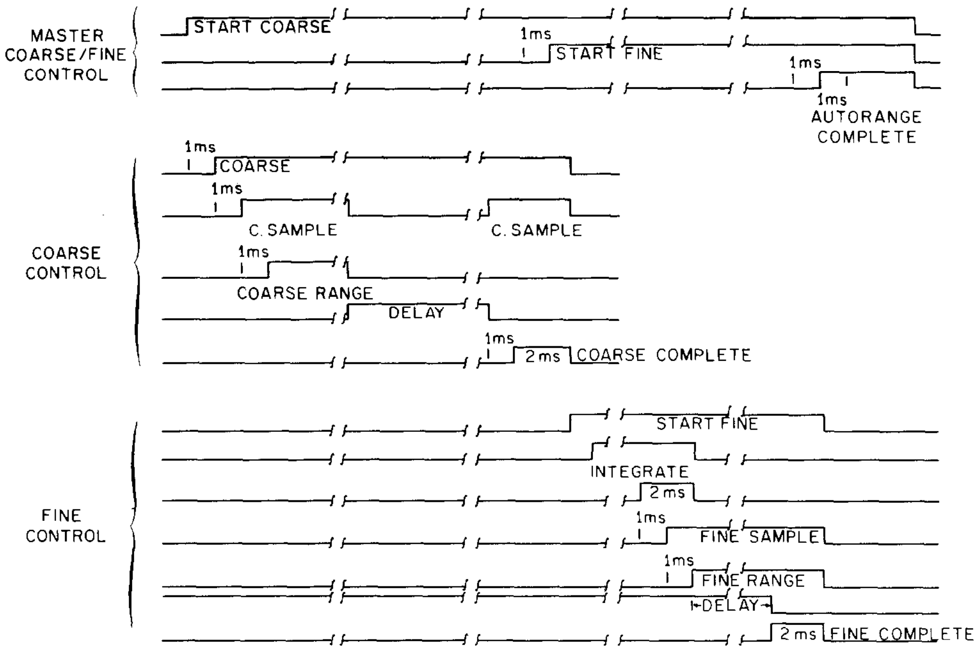

Fig. 2. Timing diagram.

COARSE CONTROL is initiated when signal COARSE goes high as indicated. The NUCLIDIC ION input is sampled at signal C SAMPLE. If the input is less than 10 or greater than 95% of full scale then a COARSE RANGE change occurs. When the coarse-range change is completed there is a DELAY before the input is again sampled. If the input is between the 10 and 95% levels the COARSE COMPLETE signal goes high, thus ending coarse ranging.

Fine ranging starts when START FINE is high. The fine-range sequence consists of a period of integration of the NUCLIDIC ION input, a sampling of an INTEGRATE output, a FINE RANGE change if necessary, and a DELAY for the electrometer to settle. The integration period is determined by an RC network which is controlled by the INTEGRATE TIME switch-setting. The most satisfactory integration period has been found to be approximately 3 sec. As a result of the integration sampling, the range is changed up or down by the number of clock pulses at the CLOCK input of an up-shift register or a down-shift register in the SHIFT REGISTER logic. After a delay, signal AUTO-RANGE COMPLETE ends the auto-ranging sequence. The circuit has performed satisfactorily for the past two years. A complete circuit diagram with pertinent annotation can be obtained upon request. Please address inquiries to Robert J. Conzemius, Ames Laboratory, Iowa State University, Ames, Iowa 50010. The authors wish to thank Harry J. Svec and Willard L. Talbert for their advice and support, and David F. Anderson who constructed the circuit.

DETERMINATION OF 8-HYDROXYQUINOLINE WITH *N*,2,6-TRICHLORO-*p*-BENZOQUINONEIMINE

J. A. JOSEPH and L. SZEKERES
Chromalloy Pharmaceuticals Inc., Los Angeles, California 90066, U.S.A.

(*Received* 25 *June* 1975. *Accepted* 4 *September* 1975)

8-Hydroxyquinoline (oxine) is used as an antiseptic, antiperspirant, and deodorant and is also widely used as an analytical reagent; for these and other reasons there are several methods for the determination of this compound. For determination of microamounts of oxine, spectrophotometric methods[1,2] are the most suitable. Microdetermination of oxine also provides indirect microdetermination of several cations.

It is well known that *N*,2,6-trichloro-*p*-benzoquinoneimine (chlorimide) forms blue indophenol derivatives with phenols which have an unsubstituted *para*-position,[3] and it has been used for determination of pyridoxine,[4–7] potassium guiacol sulphonate,[8] salicylamide,[9] and phenylephrine.[10]

In this paper we describe a new and convenient spectrophotometric method for the determination of 8-hydroxyquinoline in complex mixtures. This procedure is based on our observation that an isopropyl alcohol–water solution of 8-hydroxyquinoline forms at pH 8 a stable blue indophenol derivative with *N*,2,6-trichloro-*p*-benzoquinoneimine.

EXPERIMENTAL

Reagents

All chemicals and reagents used in this work were either USP or NF grade. *N*,2,6-Trichloro-*p*-benzoquinoneimine (Eastman Kodak) was used without further purification; a solution of 12 mg in 100 ml of isopropyl alcohol was prepared. This solution must be prepared fresh before use.

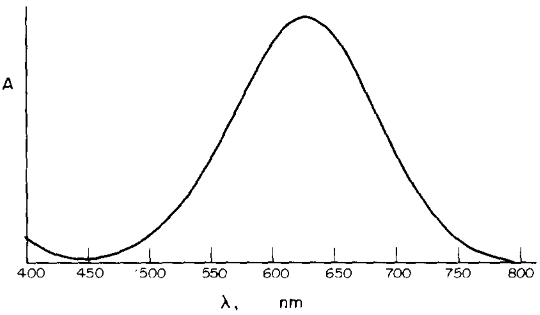

Fig. 1. Absorption spectrum for 8-hydroxyquinoline indophenol derivative.

The buffer solutions used were (*a*) 16 g of ammonium chloride and 16 ml of ammonia solution (sp.gr. 0.910) per 100 ml of solution, (*b*) 20% w/v sodium acetate solution.

A stock solution containing 35–60 mg of 8-hydroxyquinoline (accurately weighed) was prepared in 80 ml of ethyl alcohol and when dissolution was complete, the solution was diluted to 100 ml with ethyl alcohol; 10 ml of this solution were diluted to 100 ml with isopropyl alcohol, and 10 ml of this stock solution were diluted to 100 ml with isopropyl alcohol to provide the working standard solution.

Test solution

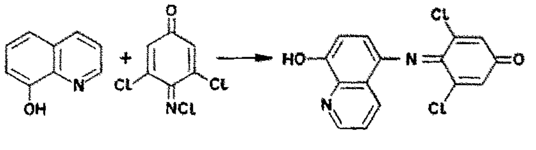
A weighed sample, equivalent to 35–60 mg of 8-hydroxyquinoline, was dissolved in about 80 ml of ethyl alcohol and diluted to 100 ml with the same solvent, then 10 ml of this solution were diluted to 100 ml with isopropyl alcohol. This solution was filtered through a dry Whatman No. 41 filter paper, and the first 30 ml of filtrate were discarded. Then 10 ml of the clear filtrate were diluted to 100 ml with isopropyl alcohol.

Procedure

Five ml of the test solution or the working standard are placed in a dry flask fitted with a ground-glass stopper. To this solution are added 2 ml of isopropyl alcohol, 1 ml of ammonia buffer, 1 ml of sodium acetate solution and 1 ml of *N*,2,6-trichloro-*p*-benzoquinoneimine reagent. The mixture is shaken for a few sec. After a few min the solution becomes blue. After 5–6 min the absorbance at 625 nm (Fig. 1) is measured against isopropyl alcohol in 1-cm cells. The oxine content is calculated by simple proportion from the data for the standard.

DISCUSSION

The reaction is



producing an acid–base indicator which is red at pH < 6.2 and blue at pH > 8.2. The colour intensity is therefore dependent on the pH, but the solutions are buffered at pH 9.2–9.4, so the pH is without effect. The normal colour of the isopropyl alcohol solution of the reagent is pale yellow, but it slowly turns pink on storage. The pink solution gives a green product with oxine and should not be used. The colour reaches maximum intensity within 5–6 min and remains stable for several hours.

An advantage of this method is that it is usable in the presence of salicylic acid, which interferes in the determination of 8-hydroxyquinoline with ferric ions as reagent. Generally phenol derivatives which have an unsubstituted *para*-position interfere with the determination. The double dilution and filtration are used to eliminate insoluble filler materials *etc*. from pharmaceutical and other preparations.

The error for 0.2–0.7 mg of oxine in the final 100 ml of solution is ±3% (Table 1) the relative standard deviation being 1.3%.

SOME OBSERVATIONS ON THE INTERFERENCES IN FLAMELESS ATOMIC-ABSORPTION SPECTROMETRY OF MAGNESIUM

KIYOHISA OHTA and MASAMI SUZUKI®

Department of Chemistry, Faculty of Engineering, Mie University, Kamihama-cho, Tsu-shi, Mie-ken 514, Japan

(*Received* 23 *September* 1975; *Accepted* 8 *December* 1975)

Little has been said about the interference mechanism in flameless atomic-absorption spectrometry. Aggett and West[1] suggested that interferences in carbon-filament atomization occur in the vapour phase rather than as a result of a reaction on the filament itself and this idea is supported by the results of experiments with a double-filament arrangement. Aggett and Sprott established that the interferences may originate both on the surface of the graphite rod and in the vapour phase immediately above the rod.[2]

The present communication describes a detailed examination of interference effects, made on the magnesium system with a metal micro-tube atomizer[3] in an attempt to obtain understanding of the phenomenon.

EXPERIMENTAL

Apparatus

Atomic-absorption measurements were made with a Nippon Jarrell-Ash 0.5-m Ebert-type monochromator coupled to an R 106 photomultiplier tube (Hamamatsu TV Co.) and JEOL AA-HMA signal-control unit as a signal-amplifier. The output signal from the signal-control unit was displayed on an Iwatsu DS 5016 dual-beam "synchroscope" with a time constant of 1 μsec.

A molybdenum micro-tube (25 mm long and 1.5 mm i.d.)[3] was used as atomizer. Two small indentations (1 mm in depth and 1 mm in diameter) were made 3 mm apart in the central part of the interior of the micro-tube to accommodate the sample. The micro-tube assembly was mounted in the absorption chamber (300 ml volume) which was purged with argon at a flow-rate of 460 ml/min and hydrogen at a flow-rate of 20 ml/min. The micro-tube was fabricated and mounted on two supports so that there was no localized variation in tube temperature.

A magnesium hollow-cathode lamp (Hamamatsu TV Co.) was used as source. The radiation from it was unmodulated, for fast tracing of the output from the photomultiplier. The spectral line used was 285.2 nm. In order to limit radiation from the micro-tube reaching the photomultiplier, a slit was placed in front of the micro-tube. The voltage signal from the atomizer and the absorption signal were recorded simultaneously by using the two beams of the synchroscope, and the temperature was determined from the voltage signal, which was previously related to the temperature measured by optical pyrometer. A deuterium lamp was used for checking whether interferents absorbed radiation.

Reagents

Chloride solutions were used for all elements tested. Solutions were transferred to the indentation in the micro-tube with a home-made glass micropipette.

Measurement technique

Atomization from separate sample indentations. A magnesium solution was placed in one indentation in the micro-tube and the interfering ion (in 1000-fold amount) in the other, and the samples were dehydrated slowly by operating the tube at low power for about 30 sec. After cooling of the tube, high power was applied for atomization of magnesium and interferent. The diffusional mixing of the two atom-clouds in the micro-tube was assumed to be sufficient, on the basis of observations of the escape-times of the atom-clouds from both ends of the tube, and of the absorption profiles.

Mixture-atomization. A mixture of magnesium and interfering ion was placed in one of the indentations, and the tube was heated as above.

RESULTS AND DISCUSSION

Interference studies were carried out on 4 pg of magnesium and 1000-fold amounts of potentially interfering ions. Interfering ions studied include Na, Al, Ca, Cr(III), Mn(II), Fe(III), Co(II), Ni, Cu(II), Zn, Se, Sr, Sn, Pd, Te and Pb. Atomization was performed at 1600°, which was optimum for magnesium. Simultaneous synchroscope traces or temperature and absorption profiles showed that only 0.1 sec was needed to raise the tube temperature from 600 to 2000°, and the magnesium absorption was started after attainment of the selected temperature. The absorption profiles of magnesium in the presence of most potential interferents were similar to that of magnesium alone in both atomization processes, though the absorption of magnesium was somewhat reduced in the mixture-atomization process. A deuterium lamp was used to check for non-atomic absorption by the foreign ions. Exceptions were Zn, Pb, Mn and Cr. Zinc and lead caused broadened absorption profiles for magnesium, with a long tail when the mixture-atomization process was used, as shown in Fig. 1. These profile shapes may result from delayed atomization of magnesium, probably because of compound formation in the indentation. Chromium gave interfering effects (broadened absorption profiles) with magnesium in both atomization processes. Observation of the absorption profile for atomization from separate indentations would suggest that the interaction was partially occurring in the vapour phase. It is known that chromium(III) chloride reacts with hydrogen at 400° to form chromium(II) chlor-

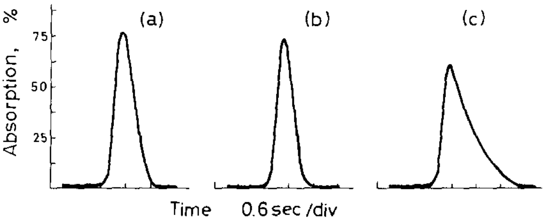

Fig. 1. Synchroscope traces of atomization of magnesium: *a*, pure magnesium; *b*, magnesium in one indentation and zinc in the other; *c*, mixture of magnesium and zinc in one indentation. Atomization temperature, 1600°.

ide, which is present as the dimer (Cr_2Cl_4) in the vapour phase at 1500°. The probable mechanism of chromium interference in atomization from separate sample indentations is delayed atomization of magnesium due to partial interaction with chromium chloride in the vapour phase. The absence of interference from other elements tested in atomization from separate indentations may be due to their chlorides being sufficiently dissociated at 1600° Aggett *et al.*[1,2] proposed an interference mechanism involving vapour-phase condensation or co-precipitation of analyte atoms in an atmosphere saturated with a large excess of gaseous foreign metal atoms or molecules, in carbon-filament atomization. McIntyre *et al.*[4] described the severe interference by chromium when copper and nickel were atomized with a molybdenum filament, and use of a purge-gas mixture of 5% hydrogen in argon, and suggested that the interelemental interference occurs at least partially in the vapour phase.

The use of hydrogen in the absorption chamber was necessary to protect the molybdenum tube from oxidation. Otherwise, atomization with a molybdenum tube was not possible. The metal micro-tube atomizer provides an environment with uniform temperature throughout it, and the effective lifetime of the free atoms may be considerably longer than when a filament system is used. Therefore, the dissociation may be more effective in the micro-tube than with the filament.

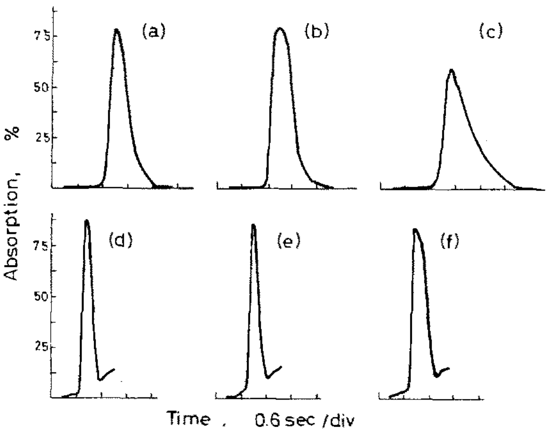

Fig. 2. Synchroscope traces of atomization of magnesium: *a* and *d*, pure magnesium; *b* and *e*, magnesium in one indentation and lead in the other; *c* and *f*, mixture of magnesium and lead in one indentation. Atomization temperature, 1600° for *a*, *b* and *c*; 2200° for *d*, *e*, and *f*.

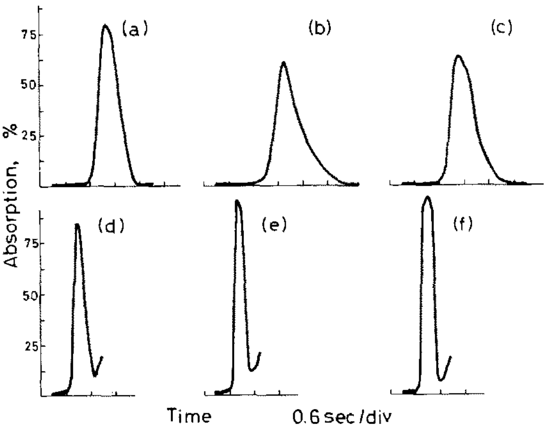

Fig. 3. Synchroscope traces of atomization of magnesium: *a* and *d*, pure magnesium; *b* and *e*, magnesium in one indentation and chromium in the other; *c* and *f*, mixture of magnesium and chromium in one indentation. Atomization temperature, 1600° for *a*, *b* and *c*; 2200° for *d*, *e* and *f*.

The interferences in mixture-atomization appear to be complex. No correlation could be found between interference effects and any physical properties, such as boiling points, melting points and vapour pressures of the magnesium salts or the interfering salts.

Elevated temperature (2200°) helped to reduce interferences as shown in Figs. 2 and 3. This may be due to effective atomization in the micro-tube atomizer. Atomization at higher temperature is recommended for minimizing interferences provided a fast-response detection system is applied.

Summary—Interferences in flameless atomic-absorption spectrometry of magnesium were investigated by the use of a molybdenum micro-tube atomizer with a double indentation. Two atomization processes were compared in order to understand the interference mechanism: atomization from separate indentations, and mixture-atomization. Most elements tested gave no interference in atomization from separate indentations, whereas magnesium absorption was somewhat reduced in mixture-atomization. However, zinc and lead caused broadened absorption profiles in mixture-atomization. Chromium interfered in both atomization processes. The origin of these interferences is discussed.

SELECTIVE STRIPPING VOLTAMMETRIC DETERMINATIONS EMPLOYING CELLS FOR ELECTROLYSIS WITH SIMULTANEOUS ION-EXCHANGE OR SOLVENT EXTRACTION

KAREL ŠTULÍK and PETR BEDROŠ
Department of Analytical Chemistry, Charles University, Albertov 2030, 128 40 Prague 2, Czechoslovakia

(*Received* 20 *October* 1975. *Accepted* 25 *January* 1976)

Summary—Cells have been designed for stripping-voltammetry analyses employing graphite working electrodes and mercury film electrodes on a graphite support, permitting ion-exchange or solvent extraction separation simultaneously with the pre-electrolysis. The ion-exchange separation was tested on the determination of mercury in the presence of excess of copper(II), lead and cadmium and on the determination of bismuth in the presence of excess of copper(II). The solvent extraction separation was tested on the determination of mercury(II) in the presence of copper(II), lead and cadmium and the determination of copper(II) in the presence of bismuth. Very good results were obtained by using ion-exchange, where the sensitivity and precision of the determination are comparable with those obtained in the determinations without separation, the separation efficiency being very high, limited virtually only by the capacity of the ion-exchanger used. The solvent extraction separations yielded poorer results: the sensitivity of the determination is decreased substantially, the separation efficiency is not very high and difficulties arise from the adsorption of the organic phase on the electrode surface

The main problem in the application of stripping voltammetric techniques is that of achieving adequate selectivity in determinations on more complicated materials, while preserving as high a sensitivity as possible. Some aspects of this complex problem have already been treated in our previous papers.[1–3] Some improvement in the selectivity over classical stripping determinations with a mercury drop electrode can be achieved by using mercury-film electrodes and by using other than d.c. measuring techniques, such as a.c. voltammetry, square-wave voltammetry or pulse and differential pulse voltammetry. However, a preliminary separation step is frequently necessary. Preliminary separations are usually tedious and often lead to dilution of the sample, introduction of impurities and loss of the substance to be determined through adsorption, coprecipitation, *etc.* With solvent-extraction separations, some of these problems can sometimes be alleviated by performing the stripping determination directly in the organic phase after extraction (see, *e.g.*, refs. 4 and 5); however, the sensitivity of the determination is not very high, the stripping peaks obtained are usually broad and non-symmetrical, and the electrode surface may be affected by the organic solvents. Stripping voltammetry has already been combined with ion-exchange by pumping portions of the eluate from a chromatographic column into the electrolysis cell and performing the stripping determination in each portion of the solution.[6]

The present paper describes a technique for simultaneous separation and pre-electrolysis, which in many cases removes these difficulties.

EXPERIMENTAL

Chemicals and apparatus

All chemicals employed were of *p.a.* purity, obtained from Lachema, Czechoslovakia. Stock solutions of metal salts were obtained by dissolving the solid substances in water, except for mercuric nitrate solution, which was prepared by dissolving metallic mercury in dilute nitric acid. The solutions were standardized by EDTA titrations and dilute solutions for experiments were prepared immediately before the measurement.

Strongly acidic cation-exchanger Dowex 50W-X8 (50–100 mesh) in the H^+-cycle was employed for ion-exchange separations. For solvent extractions, ethyl acetate and a 0.0013% solution of dithizone in carbon tetrachloride was employed.

The solutions were deaerated by passage of nitrogen, freed from traces of oxygen by bubbling through solutions of sodium anthraquinone-β-sulphonate and chromium(II) chloride, regenerated with amalgamated zinc.

The stripping-voltammetry measurements were carried out by using two- and three-electrode polarographs constructed in the laboratory from operational amplifier modules connected to an EZ-7 linear recorder (Laboratorní přístroje, Czechoslovakia). A stream of nitrogen was employed for stirring the solutions and its flow-rate was kept constant by using a liquid manostat. The measuring cells employed will be described below in the sections dealing with the particular separation techniques.

A stationary graphite disk was employed as the working electrode. Spectral graphite (Elektrokarbon, Czechoslovakia) was impregnated under reduced pressure (water-pump) with paraffin at 100° for 5 hr. The electrodes (2 mm in diameter) were cemented in glass tubes and polished with metallographic papers (SIA, Switzerland; 2/0, 4/0, 6/0) and with damp velvet. In some experiments, glassy carbon (Le Carbone Lorraine, France) electrodes of the same dimensions, polished in the same manner, were employed. Mercury contacts were used. Mercury films were deposited *in situ* on the polished graphite or glassy carbon support according to Florence.[7] Platinum wire auxiliary and satu-

rated calomel reference (K 401, Radiometer) electrodes were employed. All potentials are referred to the saturated calomel electrode at the experimental temperature, 20 ± 2°.

Procedure

Unless otherwise stated, the measuring procedure involved the following steps: 5-min deaeration by passage of nitrogen, followed by 5-min pre-electrolysis at −0.8 V in the solution stirred with nitrogen; then the stirring was stopped (nitrogen was passed over the solution) and after a 30-sec rest period the stripping voltammogram was recorded at a scan rate of 600 mV/min. The working electrode was repolished with damp velvet before each measurement.

RESULTS AND DISCUSSION

Stripping determinations with ion-exchange

The first cell employed is shown in Fig. 1. The left-hand compartment contains the test solution (5 ml), the right-hand one contains the pure base electrolyte (5 ml) and the electrode system. The two compartments are separated by an ion-exchange column and the solution is circulated by a simple peristaltic pump through the ion-exchanger from the sample compartment into the measuring compartment and back into the sample compartment at a rate of 0.5 ml/min. Simultaneously, pre-electrolysis at the required potential is carried out.

This principle was tested by using the separation of Hg^{2+} from Cd^{2+}, Pb^{2+} and Cu^{2+} in dilute hydrochloric acid.[8] Mercury is not removed by the ion-exchanger under these conditions, but passes through the column and can be determined, while the other ions are retained. An example of this determination is shown in Fig. 2, curve (*a*). Hydrochloric acid (0.2*M*) serves as both the ion-exchange medium and the base electrolyte. It is evident that perfect separation is achieved (the small lead peak is caused by the presence of Pb^{2+} in the acid originally present in the measuring compartment). The separation can be performed successfully with substantially higher excesses of the interfering elements and the upper limit is determined only by the capacity of the ion-exchange column. Therefore, this technique is especially advantageous for complicated systems and also for studying ion-exchange, as very small amounts of substances eluted from the ion-exchanger are immediately determined.

The main disadvantages of the cell for routine work are that washing of the apparatus between the measurements is rather tedious and that the detection limit is higher than in the determination without separation, because the sample is diluted by the base electrolyte present in the measuring compartment, and the efficiency of the pre-electrolysis is lower at the start, until the whole sample volume in the left-hand compartment has been pumped through the ion-exchanger into the electrode compartment. Therefore, longer pre-electrolysis times are required for low concentrations. On the other hand, the reproducibility of the measurements is good (the relative standard deviation generally amounts to a few per cent).

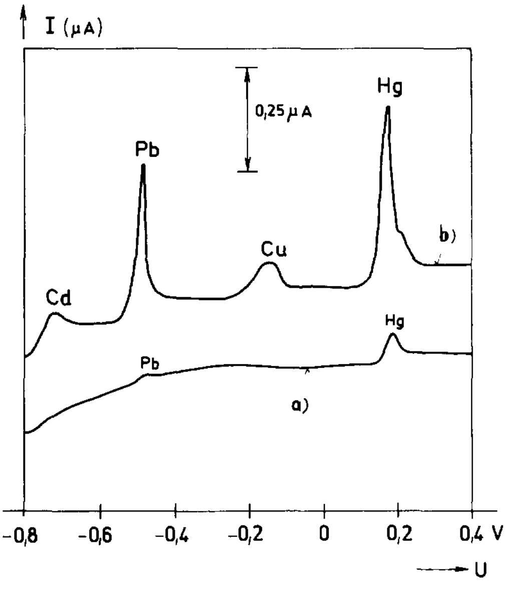

Fig. 2. Determination of $10^{-6}M$ Hg^{2+} in the presence of $10^{-4}M$ Cd^{2+}, Pb^{2+} and Cu^{2+}, employing simultaneous cation-exchange in 0.2*M* hydrochloric acid base electrolyte. Pre-electrolysis for 5 min at −0.8 V, volume of solution 5 ml. Scan rate 600 mV/min. (*a*) Determination in the cell depicted in Fig. 1, with circulating solution. (*b*) Determination in the cell depicted in Fig. 3, with cation-exchanger dispersed in the test solution.

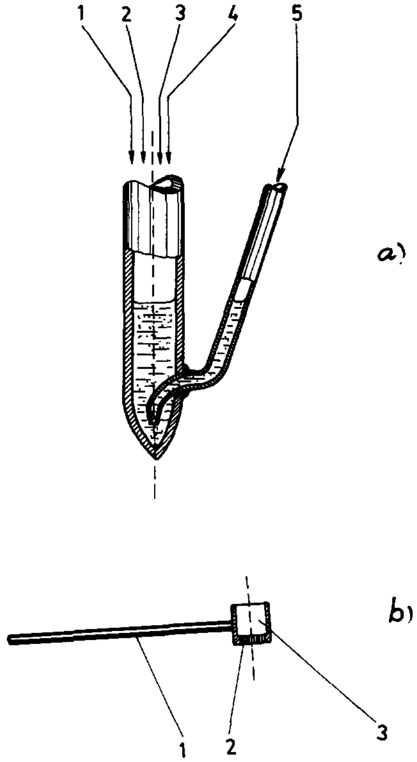

Fig. 3. (*a*) Cell for stripping determinations using ion-exchanger dispersed in the test solution. (1)—working graphite electrode, (2)—liquid bridge to SCE, (3)—auxiliary electrode, (4)—nitrogen inlet for passage above the solution, (5)—nitrogen inlet for solution deaeration and stirring. (*b*) Ion-exchanger measure. (1)—handle, (2)—frit, (3)—cylindrical glass vessel.

For routine determinations it is much more convenient to add ion-exchanger directly to the sample solution. The experimental technique is identical with that of common stripping-voltammetry determinations and the cell is very simple (see Fig. 3*a*). Constant amounts of pretreated ion-exchanger, stored in the base electrolyte, are added to the solution by using the measure depicted in Fig. 3*b*, after removal of the excess of solution from the resin by suction through the frit of the measure with a water pump (dry weight of resin added was 0.6 g). The solution is then deaerated for 5 min, electrolysed for 5 min, care being taken that the solution is sufficiently stirred with the stream of nitrogen, so that the cation-exchanger particles move through the bulk of the solution, and then the stripping voltammogram is recorded after settling of the exchanger.

The same determination was carried out as with the previous cell—see Fig. 2*b*. It can be seen that the separation is somewhat poorer than with the cell with solution circulation, owing to the smaller amount of ion-exchanger present, but the determination is substantially more sensitive, because the sample solution is not diluted and the pre-electrolysis efficiency is not decreased. Under the conditions used, the limit of detection was $2 \times 10^{-7}M$ Hg^{2+} (this value can be decreased substantially by using pre-electrolysis times longer than 5 min), the calibration curve was linear up to $5 \times 10^{-6}M$ Hg^{2+} and the maximum permissible concentration of interfering elements was $10^{-3}M$. Hence the separation efficiency was still very good. The standard deviation for relative determination of $10^{-6}M$ Hg^{2+} in the presence of $10^{-4}M$ concentrations of Cu^{2+}, Pb^{2+} and Cd^{2+}, calculated from 10 determinations, was 8.3% (for the determination of Hg^{2+} alone in the absence of the resin under these conditions, the limit of detection was $7 \times 10^{-8}M$ Hg^{2+} and the relative standard deviation for $10^{-6}M$ Hg^{2+} was 4.3%).

In order to test a determination employing the mercury-film electrode, bismuth was determined in the presence of copper. The test solution was $10^{-4}M$ in $Hg(NO_3)_2$ and the mercury film was deposited *in situ* during the 10-min pre-electrolysis at −0.8 V. The base electrolyte was 0.4*M* hydrochloric acid.[9] The determinations were carried out without and with 0.4 g (dry weight) of resin. Without ion-exchanger, Bi^{3+} down to $3 \times 10^{-9}M$ could be detected in the presence of up to 18 times as much Cu^{2+}. The relative standard deviation for the determination of $5 \times 10^{-8}M$ Bi^{3+} alone without the exchanger, calculated from 10 determinations, was 4.3%. In the presence of the exchanger, Bi^{3+} down to $10^{-8}M$ could be detected in the presence of up to $4 \times 10^{-5}M$ Cu^{2+} (4000-fold molar ratio). The calibration curve was linear for 10^{-8}–$10^{-7}M$ Bi^{3+} in the presence of $4 \times 10^{-5}M$ Cu^{2+}. The relative standard deviation calculated from 10 determinations

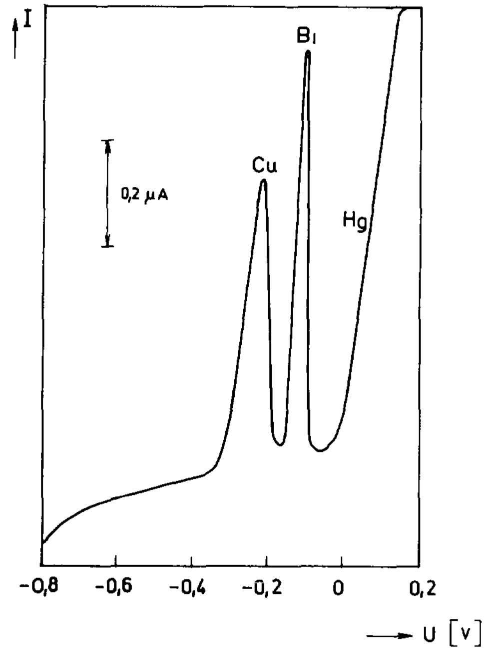

Fig. 4. Determination of $5 \times 10^{-8}M$ Bi^{3+} in the presence of $2 \times 10^{-7}M$ Cu^{2+} in the absence of the cation-exchanger. Pre-electrolysis 10 min at −0.8 V, base electrolyte 0.4*M* hydrochloric acid, $10^{-4}M$ Hg^{2+}, 2.5 ml sample volume, scan rate 800 mV/min.

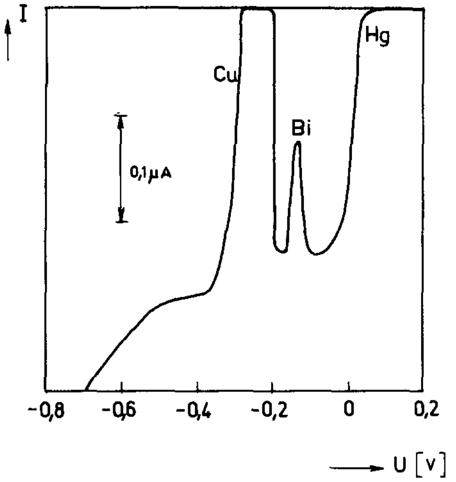

Fig. 5. Determination of $5 \times 10^{-8}M$ Bi^{3+} in the presence of $4 \times 10^{-5}M$ Cu^{2+}, with 0.4 g of the cation-exchanger dispersed in the solution. For experimental conditions see Fig. 4.

of $5 \times 10^{-8}M$ Bi^{3+} in the presence of $4 \times 10^{-5}M$ Cu^{2+} was 10.4%. Typical voltammograms are shown in Figs. 4 and 5.

It can be seen that the detection limit and reproducibility of the determination with the ion-exchanger present are not much poorer than in its absence and that good separations can be achieved. The procedure is very rapid and simple. No mechanical damage to the films deposited on the electrode, caused by the moving resin particles, was observed.

It can be generally concluded that simultaneous ion-exchange considerably improves the selectivity of stripping-voltammetric determinations, without adversely affecting the performance in any way. The ion-exchange equilibrium is established very rapidly under these conditions (in a much shorter time than the deaeration stage), so the separation efficiency depends only on the capacity of the ion-exchanger used. One limitation of these techniques lies in the necessity of using a base electrolyte which simultaneously satisfies the requirements of the separation and of the stripping determination. Only those systems can be analysed in which the species to be determined is not adsorbed on the resin but all the other species are: the capacity of the ion-exchanger must be large enough to remove all of the interfering species completely.

Stripping determinations with solvent extraction

The solvent extraction method is somewhat different from that involving the use of ion-exchangers. The sample solution and the base electrolyte are generally different and must be completely separated by a membrane containing the extraction system. The sample solution must have a composition that permits selective extraction of the determinand into the organic phase while the other components of the system remain unextracted, and the base electrolyte must ensure efficient back-extraction of the determinand into the aqueous phase. Moreover, the quickest possible passage of the substance through the organic layer must be ensured, to achieve sufficient sensitivity with reasonably short pre-electrolysis times. After several unsuccessful attempts, the cell depicted in Fig. 6 was finally constructed. The Teflon cell body contained two compartments separated by a layer of filter paper soaked with the appropriate organic phase. The compartments were placed at an angle to accommodate the electrodes and the nitrogen inlets as close to the membrane as possible in order to increase the sensitivity of the measurement.

The solutions (3 ml of each) were placed in the appropriate compartments and nitrogen was passed for 5 min. Then the pre-electrolysis was performed with the solutions stirred by the stream of nitrogen. The cell was tested for leakage by placing a solution of potassium permanganate in the left-hand compartment and water in the right-hand one. The compartments were separated by a layer of filter paper soaked in ethyl acetate. Traces of permanganate in the right-hand compartment were detected (spectrophotometrically) after 12 min.

The determination of $5 \times 10^{-6}M$ Hg^{2+} in the presence of 100 times as much Cd^{2+}, Pb^{2+} and Cu^{2+} was studied, using the extraction of mercuric ions into ethyl acetate from 0.125*M* hydrochloric acid and back-extraction into 0.1*M* nitric acid.[10] A typical stripping voltammogram is shown in Fig. 7. It can be seen that the separation is poorer than with ion-exchange and the sensitivity also considerably decreased ($5 \times 10^{-6}M$ Hg^{2+} yields a peak about 5 μA

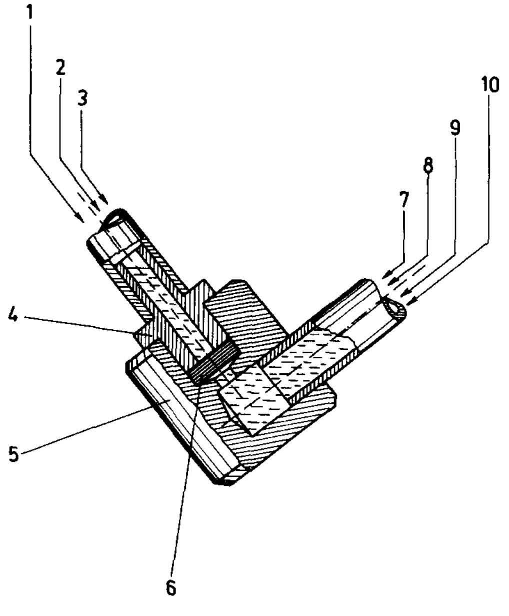

Fig. 6. Cell for stripping determinations with simultaneous solvent extraction. (1)—auxiliary electrode, (2,9)—nitrogen inlets for solution deaeration and stirring, (3,10)—nitrogen inlets for passage over the solution, (4,5)—Teflon body, (6)—layered filter paper soaked in the extractant, (7)—graphite working electrode, (8)—liquid bridge to SCE

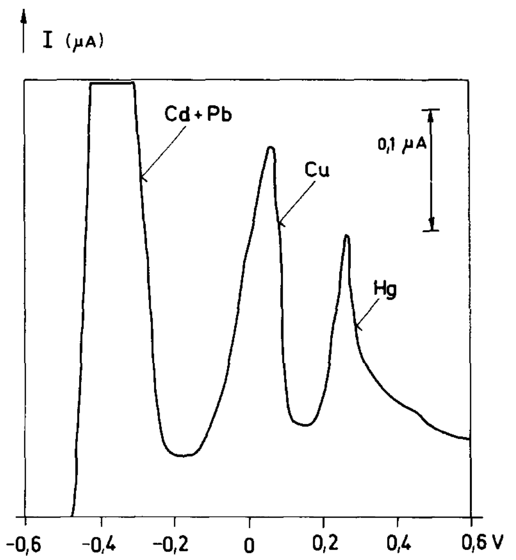

Fig. 7. Determination of $5 \times 10^{-6}M$ Hg^{2+} in the presence of $5 \times 10^{-4}M$ Cu^{2+}, Pb^{2+} and Cd^{2+} with simultaneous solvent extraction into ethyl acetate. Sample solution 3 ml, 0.125*M* in hydrochloric acid (left-hand compartment); 5 ml of 0.1*M* nitric acid (right-hand compartment); 5 min pre-electrolysis at −0.8 V, extraction layer 0.57 mm thick, scan rate 600 mV/min

Table 1. The effect of electrode passivation on the determination of mercury

0.42	+0.22
0.13	+0.15
0.04	+0.11
0.49*	+0.22

($5 \times 10^{-6}M$ Hg^{2+}, organic phase layer 1.35 mm thick, electric field applied across the membrane, other conditions identical with those described for Fig. 7).

* After a.c. prepolarization (±1.5 V, 50 Hz) for 3 min in the base electrolyte, followed by repolishing.

in height in the absence of the extractant, while in its presence the peak is only about 0.15 μA high). The reproducibility of this determination is also poorer than when using ion-exchange: the relative standard deviation, calculated from five experimental values, is 16%, compared with 4.4% in the absence of the extractant.

An attempt was made to improve the sensitivity and the efficiency by varying the membrane thickness and applying an electric field across the membrane (placing the auxiliary electrode in the sample compartment and carrying out electrolysis across the membrane). However, the use of thin membranes and of an electrical field leads to poor separation, while thick membranes render the measurement insensitive.

An additional difficulty lies in passivation of the electrode by the organic phase dissolved in the aqueous solution, occurring both with impregnated graphite electrodes and glassy carbon electrodes and manifested by a gradual decrease in the currents measured, and by a shift of the stripping peaks to more negative values. This phenomenon cannot be suppressed by simply polishing the electrode, and only prepolarization of the electrode in the base electrolyte for 3 min by applying 1.5 V a.c. (50 Hz) followed by polishing can restore the original state of the electrode surface (see Table 1). For this reason it is also impossible to carry out determinations in a two-phase system in the vessel, which otherwise would certainly be the simplest solution to the extraction–separation problem.

In order to test less polar organic systems which promise better separations, the determination of Cu^{2+} by using a mercury-film electrode was tested with separation from Bi^{3+} by extracting the copper from a solution of pH 1.5–2.0 (nitric acid) into a 0.0013% dithizone solution in carbon tetrachloride and back-extracting into 6*M* hydrochloric acid.[11] A typical stripping voltammogram is given in Fig. 8. The separation was very effective; copper ions passed through thick membranes, in the absence of an electric field across the membrane, and bismuth ions were not detected, but the passivation of the electrode, which could not be suppressed even by prepolarization, rendered the results irreproducible.

A certain advantage over the simple ion-exchanger method lies in the separation of the measuring space from the sample compartment, thus facilitating a much wider choice of media for the extraction and for the back-extraction with the electrochemical determination. Also the selection of organic extractants is very wide and applicable to a great variety of systems. However, it must be concluded that sol-

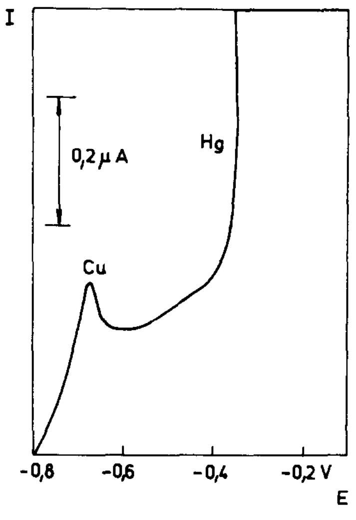

Fig. 8. Determination of $10^{-6}M$ Cu^{2+} in the presence of $10^{-5}M$ Bi^{3+} with simultaneous extraction into a dithizone solution in carbon tetrachloride. Sample solution 3 ml, pH 2 (left-hand compartment); 5 ml of $10^{-4}M$ Hg^{2+} in 6*M* hydrochloric acid (right-hand compartment); 5 min pre-electrolysis at −0.8 V, extraction layer 1.08 mm thick, scan rate 800 mV/min.

vent extraction is generally less suitable than ion-exchange if the technique described is to be useful in practice.

(*Reçu le* 12 *juin* 1975. *Accepté le* 9 *janvier* 1976)

Résumé—Un dosage précis de faibles masses d'uranium par coulométrie à potentiel contrôlé est proposé. Ce dosage permet d'obtenir des précisions de l'ordre de 0,1% pour des prises d'essai d'uranium de 0,1 à 1 mg et de 0,5% pour de très faibles masses (15 μg). Les améliorations, permettant ces résultats, qui ont été apportées à l'appareillage et en particulier aux composants de la cellule, sont exposées et discutées.

Depuis la sortie des nouveaux intégrateurs de grande qualité, la coulométrie a pris une importance nouvelle, et voit l'éventail de ses applications s'élargir du fait de la fidélité, de la précision et de la spécificité inhérentes à cette technique. En particulier, le dosage de l'uranium par coulométrie à potentiel contrôlé, étudié par Thomason,[1] Shults,[2] Kelley,[3] Goode,[4] Angeletti[5] et par Molina et Brigaudeau[6] permet des dosages à 0,1% de précision en utilisant des quantités d'uranium de l'ordre de 5 à 20 mg par titrage. Désirant préparer des solutions de références d'uranium isotopiquement purs ^{233}U, ^{235}U, ^{238}U, nous avons été amenés, vu le prix très élevé de ces isotopes, à étudier une méthode de dosage coulométrique de l'uranium sur de faibles prises d'essai (0,1 à 1 mg), tout en conservant une bonne précision. Cette méthode est classique quant à son principe: coulométrie à potentiel contrôlé en milieu H_2SO_4, utilisant la réaction électrochimique:

$$UO_2^{2+} + 2e^- + 4H^+ \rightleftharpoons U^{4+} + 2H_2O$$

Souhaitant obtenir un dosage sensible et précis tout en gardant un temps d'électrolyse assez court, nous nous sommes attachés:

(*a*) à obtenir un coefficient de cellule le plus grand possible (étude de la géométrie de la cellule et du régime d'agitation);

(*b*) à abaisser le courant résiduel faradaïque (utilisation de réactifs ultra-purs, soins apportés au dégazage);

(*c*) à évaluer avec précision le courant résiduel capacitif (utilisation d'un ensemble d'intégration permettant de mesurer avec précision de très petites quantités d'électricité);

(*d*) à éliminer les parasites électriques.

PARTIE EXPERIMENTALE

Appareillage

Cellule. En coulométrie à potentiel contrôlé, on mesure la quantité d'électricité correspondant à l'intégration du courant d'électrolyse:

$$Q = \int_0^t i_0 10^{-At}\,dt = \frac{20}{2.303A}(1 - 10^{-At}) \qquad (1)$$

avec A = coefficient de cellule.

D'après Ravenel et Soret,[7] nous voyons que lors d'un dosage coulométrique direct la mesure peut être arrêtée lorsque le rapport concentration finale sur concentration initiale est inférieur à l'erreur relative admise (0,1% dans notre cas):

$$\frac{C_t}{C_0} = \frac{i_t}{i_0} = 10^{-At} < 10^{-3}$$

d'où

$$t > 3/A$$

Pour obtenir un temps d'électrolyse court, il faut donc avoir un coefficient de cellule (A) élevé. Ce coefficient de cellule dépend de la géométrie de la cellule et des conditions d'agitation; il est proportionnel à S/V, S désignant la surface de l'électrode et V le volume de solution d'électrolyte. Dans le cas d'une électrode de mercure, dans une cellule cylindrique: $S/V = 1/h$ (h = hauteur de la solution). Il faut donc obtenir h le plus petit possible. Nous utilisons des cellules en "Plexiglas" poli, usinées avec précision (figure 1). Le diamètre intérieur de ces cellules est de 33,5 mm. La hauteur minimum de solution à introduire est h = 4 mm, soit un volume minimum de 2,5 ml.

Des comparaisons expérimentales nous ont amenés à concevoir l'agitateur (figure 1) de diamètre = 16 mm. La surface de cet agitateur est polie. En rotation, il ne provoque pas de projections de solution sur les parois de la cellule. Il porte une pointe centrale qui évite d'emprisonner une bulle gazeuse au moment du contact avec la solution, augmente la surface portante sur le mercure et stabilise celui-ci dans son mouvement de rotation.

Les coefficients de cellules obtenus dans ces conditions sont de l'ordre de $A = 0{,}012/S$. Pour un dosage à 0,1% près, il nous faut donc un temps d'électrolyse supérieur à 4 min.

Le support de cellules employé, est celui mis au point par la Section de Chimie Analytique du Plutonium et d'Electroanalyse (C.E.A.-C.E.N./Fontenay-aux-Roses).[8–10] Il est équipé d'un moteur SF MI dont la vitesse constante de rotation est de l'ordre de 3000/min. Nous lui avons apporté quelques modifications, afin de l'utiliser dans des conditions optimales. Un niveau à bulle, des pieds antivibratoires, un réglet pour repérer la position de l'agitateur, un manomètre de contrôle de la pression d'argon ont été ajoutés. Un berceau en acier inoxydable, qui reçoit la cellule, permet la translation verticale ainsi que le verrouillage

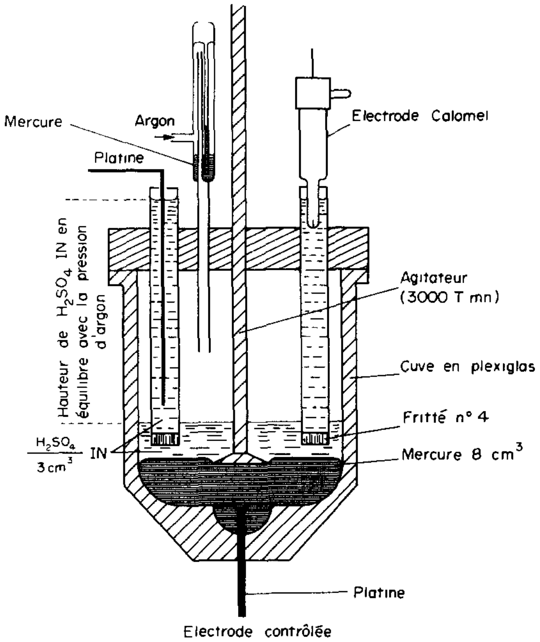

Fig. 1. Cellule de coulométrie.

de celle-ci sur le support, et assure la liaison électrique entre la masse et le fil de platine plongeant dans l'électrode de mercure. Cet appareil est placé dans une boîte à gants sous atmosphère d'argon.

Les caractéristiques de cet ensemble, l'utilisation de produits "ultra-purs", le soin apporté au dégazage, ont permis de réduire la valeur des courants résiduels de 10^{-5} à 10^{-6} A. D'autres améliorations portant sur l'ensemble d'intégration nous ont permis de réduire les courants parasites et de mesurer avec précision la quantité d'électricité non utilisée pour la réduction électrochimique des ions uranium.

Ensemble d'intégration. L'ensemble d'intégration se compose:

(*a*) d'un convertisseur tension-fréquence Hewlett-Packard type 2212 A, (taux de conversion: 10^5 impulsions par seconde pour 1 V; linéarité de 0,01% en pleine gamme; stabilité de ± 0,02% pour 8 hr) placé dans une cage de Faraday en cuivre;

(*b*) de résistances étalons AOIP type RE et REH (précision d'étalonnage de ± 0,02%);

(*c*) d'une échelle de comptage (compteur HVL type M 43 ou compteur ORTEC, modèle 715).

Nous vérifions périodiquement la linéarité de réponse de nos convertisseurs au moyen d'un générateur de tension continue Hewlett-Packard, modèle 740 B. Nous avons constaté que les convertisseurs sont d'une plus grande fiabilité dans la plage des tensions allant de 10^{-4} à 1 V.

Montage électrique (figure 2). Le montage électrique se compose:

(*a*) d'un potentiostat Tacussel, type PRT 20-2 X à réponse rapide;

(*b*) d'un enregistreur Tacussel, type EPL2 B fonctionnant en régime potentiométrique grâce à un tiroir type TV 11 GD [cet enregistreur placé aux bornes d'une résistance AOIP de 10 Ω trace la courbe $i = F(t)$ et permet de s'assurer du bon déroulement de la coulométrie (absence de parasites en particulier)];

(*c*) d'un voltmètre numérique Schneider, type Vn 954 qui contrôle le potentiel imposé à l'électrode de travail.

Ces appareils sont groupés dans une baie mobile alimentée en courant régulé à ± 1%. Un certain nombre de précautions ont été prises, afin de minimiser les perturbations d'origine électrique (liaisons par câbles coaxiaux, contacts en or, soudures à l'argent. Une diode placée dans le circuit supprime certains parasites réinjectés vers le potentiostat). Un commutateur de changement de gamme permet de choisir la résistance d'intégration en fonction de la quantité de l'élément à doser. Un interrupteur (*Z*) permet le contrôle de la dérive de la base zéro du convertisseur avant et après la coulométrie en court-circuitant la résistance de mesure. Une résistance de 500 Ω limite le courant dans le circuit, quand la mesure se fait sur la résistance étalon de 10 Ω.

Methode

Préparation de solutions d'uranium étalonnées. La préparation des solutions se fait à partir d'uranium métal électrolytique de très haute pureté. Un échantillon est décapé, puis séché sous courant d'azote et pesé dans une fiole conique préalablement tarée, dans laquelle se feront la dissolution et la mise en acidité convenable. Le métal est dissout dans l'acide perchlorique 11,5*M* à 60°, puis l'acide perchlorique est chassé par ébullition modérée en présence de l'acide sulfurique. Après refroidissement, on ajuste l'acidité à ≃ 1*N* avec de l'eau bidistillée (on opère de même avec l'oxyde d'uranium qui est préalablement porté à 900° dans un creuset en quartz, puis dissout en milieu acide nitrique 14*M*).

Préparation de la coulométrie On introduit dans la cellule environ 8 ml de mercure, puis 3 ml de l'acide sulfurique 1*N*. Le compartiment de l'électrode de référence et le compartiment de l'électrode anodique sont remplis de l'acide sulfurique 1*N* jusqu'à équilibre de la pression interne de l'argon. L'argon préalablement humidifié par barbotage dans une solution sulfurique 1*N*, est introduit dans la cellule au-dessus de la surface du liquide. Après un court dégazage, la solution subit une préréduction à −0,385 V/ECS jusqu'à l'obtention d'un courant résiduel constant (inférieur à 10^{-6} A). On procède alors à la mesure du "blanc" en prélevant dans la cellule 1 ml de solution préréduite que l'on remplace par 1 ml de solution acide ayant subi le même traitement que la solution d'uranium. On verrouille la cellule pour procéder à un dégazage de 5 min. La base zéro et le taux de conversion du convertisseur sont réglés, puis le potentiel 0,385 V/ECS est imposé et la mesure du blanc a lieu jusqu'à obtention du courant

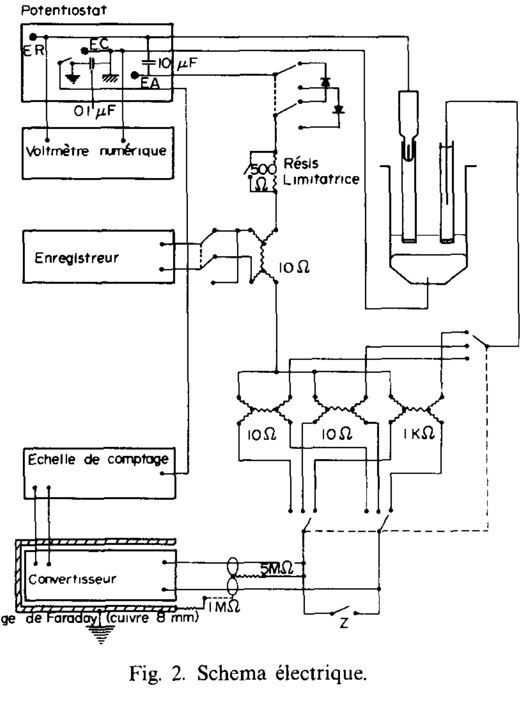

Fig. 2. Schema électrique.

résiduel (environ 10 min). On note le nombre d'impulsions sur l'échelle de comptage. Après la mesure, la dérive de zéro du convertisseur et la valeur du courant résiduel sont mesurées avec précision en plaçant le commutateur de changement de gamme sur 1000 Ω.

Pour la coulométrie de la solution d'uranium, 1 ml de solution d'électrolyte support est prélevé et remplacé par environ 1 ml de solution à doser. Le poids exact de cette aliquote est déterminé par différence de poids sur une balance Sartorius au 10 μg.

La suite des opérations se fait dans des conditions identiques à celles du blanc. La manipulation complète dure environ 1 hr.

Expression des résultats. La concentration cherchée est exprimée par la formule:

$$C = \frac{MN_u}{nFPKR} \tag{2}$$

ou M = masse atomique de l'élément; n le nombre d'électrons échangés; F = 96.487 C; K = le taux de conversion du convertisseur; R = la résistance de mesure; P = poids de la prise d'essai, $N_u = N_M - (N_R + N_Z + N_B)$; N_M = nombre d'impulsions lu sur le compteur; N_R = nombre d'impulsions ($N_R t$) correspondant à l'intégration du courant résiduel (I_R) pendant le temps de mesure (t); N_Z = nombre d'impulsions correspondant à la dérive éventuelle de la base zéro (Z_u) du convertisseur; N_B = nombre d'impulsions correspondant au blanc (ce nombre est à corriger du courant résiduel et de la dérive de la base zéro du convertisseur lors de la mesure de ce blanc). On a $N_Z = Z_u t$; en pratique $N_Z \leqslant N_u/5000$.

Les premiers résultats obtenus sur plusieurs solutions d'uranium sont consignés dans le tableau 1. Ils sont donnés dans l'ordre chronologique.

APPLICATIONS

Nous avons étudié la possibilité d'appliquer la méthode de dosage coulométrique à l'étalonnage d'une solution d'uranium 233 (teneur isotopique: 99,553%). Deux solutions étalonnées d'uranium naturel métal électrolytique et deux solutions étalonnées d'oxyde d'uranium naturel étalon ont été préparées et diluées à des aliquotes de la solution U3-2 dosée par coulométrie. Ces mélanges isotopiques ont été dosés en spectrométrie de masse, ce qui nous a permis de comparer les concentrations évaluées par chaque méthode. Les résultats sont donnés dans le tableau 2.

DISCUSSION ET CONCLUSION

Une étude statistique[11] montre qu'il n'y a pas de dérive détectable de l'appareillage et que notre méthode est reproductible. Nous avons obtenu un intervalle de confiance autour de la moyenne de +0,068%. La correction de bruit de fond ne dépasse pas 0,2% pour les quantités de l'ordre de 0,5 mg U. Enfin, nous avons constaté que les mesures sont justes dans le domaine considéré (0,5 à 8 mg d'uranium dosé).

Sur des quantités de 0,1 à 0,2 mg, les résultats sont encourageants. Bien que l'influence des corrections devienne plus importante, les résultats sont à peine différents de plus de 0,1% de la valeur théorique, ce qui est conforme à nos exigences de précision.

Ces résultats ont pu être acquis grâce à:

—des améliorations importantes sur les composants de la cellule et de son support, qui se sont traduites par un gain d'un facteur deux sur les coefficients de cellule précédemment publiés,

—l'élimination très poussée des parasites électrostatiques et hertziens, des surtensions à la fermeture du circuit,

—l'amélioration des contacts,

—l'emploi de réactifs ultra-purs.

Tableau 2

Coulométrie				Spectrométrie de masse		
Nombre de mesures	Concentration U total, *mg/g*	Concentration en ^{233}U pur. *mg/g*	S, %	Concentration en ^{233}U, *mg/g*	Nombre d'essais	S, %
12	$X = 0{,}6486$	$X_1 = 0{,}6457$	0,12	$X_b = 0{,}6461$	4	0,2

Nous avons réalisé des dosages sur des quantités de 15 à 30 μg. Les valeurs trouvées s'écartent de près de 0,5% de la valeur théorique; nous pensons cependant pouvoir améliorer ces mesures sur des faibles quantités (10 μg à 0,1% près), grâce à la conception d'une microcellule.

USE OF LONG CHAIN ALKYLAMINES FOR PRECONCENTRATION AND DETERMINATION OF TRACES OF MOLYBDENUM, TUNGSTEN AND RHENIUM BY ATOMIC-ABSORPTION SPECTROSCOPY—III

TUNGSTEN IN GEOLOGICAL SAMPLES

C. H. KIM, P. W. ALEXANDER and L. E. SMYTHE

(*Received* 15 *December* 1975. *Accepted* 4 *February* 1976)

Summary—Tungsten is determined by atomic-absorption spectroscopy after its reduction to the W(V)–thiocyanate complex with tin metal and extraction with Alamine 336 into chloroform. Atomic absorbance is measured on a final MIBK solution after evaporation of the chloroform and redissolution of the residue in MIBK. Interference effects are shown to be negligible for diverse cations and anions, including Fe, Cu, Cr, Co, Mo, Al and Bi. Analysis of geological samples with an exceptionally wide range of W content from 2.8 ppm to 10% is achieved with relative standard deviations better than 5%.

A rapid and reliable method for the determination of traces of tungsten in geological samples is not at present available. Existing gravimetric and spectrophotometric methods[1–3] are generally insensitive and suffer from interference problems. Atomic-absorption methods for tungsten in geological samples have been reported[4–7] but are not applicable to trace determinations. Thomas *et al.*[4] improved the sensitivity by addition of potassium as ionization suppressor and phosphate as releasing agent. Keller and Parsons,[5] and Quin and Brooks,[6] determined tungsten in ores after dissolving digested ore residues in alkali. Rao[7] developed a method for solvent extraction of tungsten into 3% Aliquat 336 in di-isobutyl ketone, followed by direct aspiration of the extract into a nitrous oxide–acetylene flame. All of these methods are suitable only for per cent level quantities of tungsten in ore samples because of the poor sensitivity of tungsten determination by AAS.

Recent methods include determination by flame emission with vidicon tube detection,[8] proton-activation analysis[9] and visible spectrophotometry by complexing with hydroquinone,[10] but these have not been applied to analysis of geological samples. Microgram quantities of tungsten in natural waters have been determined by Korrey and Goulden[11] by extraction with benzoin *anti*-oxime. They found interference from Fe(III), V(V) and Mo(VI), making the method unsuitable for geological samples. A rapid spectrometric method for tungsten in steels and wolframite[12] is based on extraction of the yellow W(V)–thiocyanate complex with 2% tribenzylamine in chloroform and measurement at 410 nm. The method has few interferences and a sensitivity of 0.013 μg/ml. Beer's law is obeyed up to 24 μg/ml. However, the proving trials of the method related only to relatively high concentrations of tungsten in special steels and there were no details of applicability to trace amounts of tungsten in most geological materials. The same authors considered extraction of the tungsten(V)–thiocyanate complex with other amines.

We recently reported a general method[13] for extraction and preconcentration of molybdenum, tungsten and rhenium with long-chain alkylamines, before atomic-absorption analysis. In this paper, we describe a detailed application of this method to the determination of tungsten at ppm levels in geological samples.

EXPERIMENTAL

Reagents and apparatus

All reagents have been described previously.[13] The atomic-absorption spectrophotometer used was a Varian Techtron AA5 and instrumental settings have also been reported.[13]

Procedure

The general procedure described previously[13] for determination of tungsten was its extraction from 50 ml of 3*M* hydrochloric acid containing 2 ml of 20% stannous chloride solution and 2 ml of 20% potassium thiocyanate solution into a solution of a long-chain alkylamine in chloroform, followed by evaporation of the chloroform from the separated organic phase and dissolution of the residue in methyl isobutyl ketone (MIBK). Tungsten in the final MIBK solution was then determined by atomic-absorption spectrometry.

This general procedure was modified for determination of tungsten in soils and geological samples in order to eliminate interference problems, as follows. Samples (0.100–1.000 g, 150 mesh) containing less than 600 μg of tungsten were dissolved by the method of Kim *et al.*,[14] giving a final solution of approximately 20 ml in 10*M* hydrochloric acid in a 50-ml beaker. A granular piece of tin

Table 1. The concentration of Alamine 336–$CHCl_3$ for extraction and the final volume of MIBK

Approximate content of W, *μg*	Colour of W–SCN in aqueous phase	Concentration of Alamine 336–$CHCl_3$, %	MIBK, *ml*
20	Very weak yellow	0.5	1.0
10–40	Weak yellow	0.5	2 0
25–100	Yellow	1.0	5 0
50–200	Strong yellow	1.0	10.0
100–600	Very strong yellow	1.0	25.0

metal (0.5–1.0 g) was added, followed by 1 ml of 20% stannous chloride solution and the solution was boiled for 20 min (some tin metal should remain). The solution was then cooled rapidly in ice-water and 2 ml of 50% sodium thiocyanate solution were added. As a source of thiocyanate ion, sodium thiocyanate was preferred because potassium would be precipitated by the perchlorate remaining in solution after the dissolution procedure for the geological samples. After 20 min reaction time, the solution was transferred to a 100-ml separating funnel, the beaker and tin metal being rinsed with cold water and further water added to a final volume of about 50 ml.

The tungsten was extracted with 10 ml of 0.5–1.0% Alamine 336 in chloroform by vigorous shaking for 2 min. The organic phase was drained into a 25-ml beaker or a 25-ml weighing bottle, depending on the final volume of MIBK required and the aqueous phase was washed with a second 10-ml portion of Alamine 336 in chloroform. The combined extracts were heated on a steam-bath to evaporate the chloroform and a few ml of MIBK were added to dissolve the residue. On cooling, the solution was transferred to a 25-ml volumetric flask and made up to volume with MIBK washings from the beaker. For low tungsten concentrations, 1–5 ml of MIBK were added directly to the 25-ml weighing bottle instead of the 25-ml beaker and the residue was dissolved in the MIBK by gentle warming after the stopper had been placed on the bottle. The absorbance of this final MIBK solution was then measured relative to pure MIBK as a blank, with the instrumental parameters previously specified.[13] A range of concentrations of Alamine 336 in chloroform and also of the final MIBK volume was required, depending on the tungsten content of the sample, as shown in Table 1.

RESULTS AND DISCUSSION

The general method for extraction of the thiocyanate complex of tungsten into chloroform solutions of long-chain aliphatic amines has been described previously.[13] From this work, Alamine 336 was chosen as the most suitable extracting agent and the following results give a more detailed account of the use of this method of analysis for tungsten in geological samples. In particular, when the previous method was applied to analysis of ores, some modifications were found to be necessary because of interference effects reported earlier[13] and methods are given below to overcome these problems. It is shown that less than 10 ppm of tungsten can be determined by this technique.

Effect of acid and other reagents

The effect of hydrochloric acid concentration on the extraction of the W(V)–thiocyanate complex into Alamine 336 in chloroform was investigated as shown in Table 2. A single extraction with 10 ml of 1% Alamine 336 in chloroform was carried out, over a range of hydrochloric concentrations from 3*M* to 10*M* in the aqueous phase. After evaporation of the extract, the residue was redissolved in MIBK and made up to 10 ml. The extractability was constant up to 7*M*, but decreased markedly at higher concentrations. Extraction from less than 3*M* hydrochloric acid was not tested, because of difficulties in control of acidity after the initial reduction in 15 ml of 10*M* hydrochloric acid. The final concentration of hydrochloric acid was chosen to be between 4 and 6*M*. Table 2 also shows the measured absorbance as a function of volume of 20% stannous chloride solution used for reduction of 0.200 mg of tungsten in 20 ml of 10*M* hydrochloric acid. A single extraction was carried out with 10 ml of 1% Alamine 336 in chloroform after complexing with 2 ml of 20% potassium thiocyanate solution. In addition, Table 2 shows the effect of varying the volume of potassium thiocyanate solution with the volume of 20% stannous chloride solution

kept constant at 2 ml. Little effect on absorbance was observed with either reagent, as shown previously[13] with Amberlite LA-1 as the extractant. For the purpose of applying this procedure to the determination of tungsten in geological samples, some modification to the reduction system was required, however.

Effect of Alamine 336 on absorbance of tungsten in MIBK

Table 3 shows the effect of varying concentrations of Alamine 336 in MIBK on the tungsten absorbance after the evaporation of the chloroform and dissolution of the residue in 10 ml of MIBK. Low absorbance values were obtained at amine concentrations less than 0.5%, owing to incomplete extraction.

The results also show that Alamine 336 can be used over a much wider concentration range than Amberlite LA-1[13] without effect on absorbance. This was attributed to the lower viscosity of Alamine 336 in comparison to Amberlite LA-1. Furthermore, there was no background absorbance by the MIBK solution up to a 10% content of Alamine 336. Therefore, pure MIBK can be used as a blank solution for the adjustment of zero absorbance.

Recovery of tungsten

Quantitative recovery of 0.200 mg of tungsten was obtained by extraction with solutions of Alamine 336 in chloroform in the concentration range 0.4–2.0%, as shown in Table 3. The degree of extraction achieved was an approximately 25% improvement over the extraction previously reported.[13] In general, double extractions with Alamine 336 concentrations greater than 0.4% in chloroform were used, depending on the quantity of tungsten in the sample solution, in preference to a single extraction, for quantitative recovery.

Interference effects

A wide range of cations and anions likely to be present in geological samples was tested for interference in the extraction of tungsten (0.200 mg), as shown in Tables 4 and 5. Each ion was added to 0.200 mg of tungsten in 20 ml of hydrochloric acid, in 100-fold to 1000-fold w/w ratio to tungsten. The tungsten was then extracted from the aqueous solution containing 2 ml of 20% stannous chloride solution and 2 ml of 20% potassium thiocyanate solution, into two 10-ml portions of 1% Alamine 336–chloroform. Serious interference was observed in the presence of large excesses of copper, iron and molybdenum. Copper caused difficulties in extraction by formation of a white precipitate of CuSCN. It was found that iron(III) in large excess (200 mg) was incompletely reduced by 2 ml of 20% stannous chloride solution. Molybdenum caused complications because of co-extraction into Alamine 336-chloroform as the thiocyanate complex. All these interferences caused a negative error in the tungsten absorbance.

Several anions were also tested for interference as shown in Table 5. When added in large excess in quantities ranging from 1 to 10 mmole, only nitrate interfered severely with the extraction owing to its strong oxidizing effect in concentrated hydrochloric acid. Most interferences, however, were satisfactorily eliminated by the use of tin metal as a reductant.

Reduction with tin metal

Interferences from Fe(III), Cu(II) and Mo(V) were eliminated by exploiting differences between the reduction potentials of tungsten and of these cations. For the quantitative extraction of tungsten or molybdenum as the thiocyanate complex, their oxidation state must be +V. If Mo(VI) can be reduced to Mo(III), the extraction of molybdenum can be prevented because Mo(III) is only weakly complexed by thiocyanate.[15,16] We found that when Sn(II) or Ti(III) was used at hydrochloric acid concentrations greater than 8*M* for the reduction of tungsten in the presence of molybdenum, W(VI) was quantitatively reduced to W(V) while Mo(VI) was reduced to Mo(III). Under these conditions the reduction of molybdenum was incomplete and Mo(III) was readily re-oxidized on standing in air. This instability caused difficulties in the clean extraction of the tungsten thiocyanate complex.

It was finally shown that tin metal alone or with Sn(II) was superior to other reducing agents for the reduction of tungsten in the presence of Mo(VI), Fe(III) and Cu(II). It was necessary to heat the 10*M*

hydrochloric acid solution containing tin metal to ensure complete reduction to Mo(III) and the solution was then cooled in ice-water to prevent re-oxidation. Sn(II) was added along with the tin metal to increase the rate of reaction, and the rate of consumption of tin metal was further increased by the presence of other oxidizing elements such as Fe(III), Cu(II), Cr(VI) and nitrate.

Table 6 gives results for the determination of tungsten in the presence of molybdenum and iron after reduction with the Sn/Sn(II) system. At least 90% recovery was obtained in the presence of 1000-fold ratio of molybdenum to tungsten. In addition, large amounts of Cu(II) were spontaneously reduced to copper metal by tin metal with the solution at room temperature. Greater than 90% recovery of tungsten was obtained from a mixture of 0.200 mg of tungsten and 200 mg of Cu(II). Nitrate interference

Drill core	5	8.0, 8.0, 7.5	3	7.83	0.5	3.77
171390 (1 g)	10	13.0, 12.0, 12.5	3	12.50	1.0	4.73

was also satisfactorily eliminated by reduction with Sn/Sn(II).

Calibration curve

The absorbance was a linear function of tungsten concentration in the range 5–25 ppm tungsten when × 10 scale expansion was used. The calibration allows the determination of tungsten in the range from 1.0 to 600 ppm in a sample by use of a range of final MIBK volumes from 1 to 25 ml. An absorbance reading of 0.05 was found to correspond to approximately 1.5 ppm of tungsten, *i.e.*, 1.5 μg of tungsten in 1 g of sample. This low content can therefore be determined satisfactorily by the present procedure with 1 ml of MIBK as the final solvent volume. The standard solutions were prepared by dilution of a stock solution of 100 ppm tungsten in the form of a W–SCN–Alamine 336–MIBK stock solution. These solutions were stable for more than two months, but absorbance measurements of solutions of geological samples must be completed within one or two days after preparation because of the complex nature of such solutions.

Results of sample analysis

Table 7 shows the analytical results for four different kinds of sample. The analytical results for the scheelites were in good agreement with the gravimetric values determined by Warman Equipment Ltd., except for the values obtained by colorimetry (No. 33 and 34). We assume that the high colorimetric results are a consequence of interference from iron and molybdenum. The analytical data from C.R.A., Queensland, for the drill core samples were obtained by X-ray fluorescence spectrometry *without* matrix correction. Results were generally in good agreement with independent laboratory values.

Studies of standard additions of tungsten to two different samples were also made and results are given in Table 8. Quantities of 5 and 10 μg of tungsten were added to 1 g of each sample before the solvent extraction. Total tungsten recoveries were in good agreement with the original values shown in Table 7.

All the results shown in Tables 7 and 8 gave relative standard deviations not exceeding about 5% over a wide range of tungsten concentration from 2.8 ppm to 10%. The method is rapid and determinations can be carried out batchwise with up to 50 samples, in an average time of about 10 min for each determination after the dissolution of the solid sample.

CONCLUSIONS

It has been found that tungsten can be determined in geological samples over a wide concentration range by atomic absorption, without serious interference from excesses of many metals, particularly iron and molybdenum, which interfere in the colorimetric method[12] when present in large excess. High sensitivity has been achieved by the extraction–preconcentration procedure with Alamine 336. The method has been shown to provide a rapid, sensitive procedure and has been applied for the first time to analysis of samples containing tungsten concentrations as low as 2.8 ppm and ranging up to 10%, with standard deviations better than 5%.

THE DETERMINATION OF PLATINUM IN REFORMING AND EMISSION-CONTROL CATALYSTS BY DIFFERENTIAL SPECTROPHOTOMETRY

SILVE KALLMANN
Ledoux & Company, Teaneck, N.J. 07666, U.S.A.

(*Received* 5 *September* 1975. *Revised* 13 *February* 1976. *Accepted* 24 *February* 1976)

Summary—Differential spectrophotometry is used in conjunction with the stannous chloride method to determine platinum with <1% relative error in reforming and emission-control catalysts. Detailed instructions are given for decomposition of the samples.

Because platinum-bearing catalysts have the ability to reform or rearrange the molecular structure of hydrocarbons, "reforming catalysts" have become of great importance to the petroleum industry.

Further, the enactment of the Federal Clean Air Act requires the introduction of platinum- and platinum–palladium-bearing catalysts in the form of catalytic converters in automobiles from 1975 models onward, to achieve satisfactory control of exhaust emission.

Both the reforming catalysts (~0.3 or ~0.6 Pt) and the emission-control catalysts (0.035–0.11% Pt) contain the platinum as a deposit on a substrate consisting mainly of γ-alumina, or, in the case of "octafining" catalysts, of γ-alumina plus silica. Rhenium (~0.3% or ~0.6%) is frequently present in reforming catalysts, and palladium (0.015–0.04%) in emission-control catalysts. The amount of α-alumina is usually small in fresh reforming catalysts. Spent reforming catalysts which, because of their platinum content, are usually recycled, may be contaminated with a variety of metallic impurities and carbon. In addition, because of high-temperature applications of some of these catalysts, part of the acid-soluble γ-alumina may be converted into α-alumina, which is acid-insoluble. The platinum in spent emission-control catalysts is not at present recovered.

Since the use of platinum-bearing catalysts involves substantial investment of money, the accurate determination of platinum represents a *sine qua non* in all financial transactions. Agreements between producers and consumers of both types of catalyst therefore generally specify platinum results to agree within 1% relative. This requirement can be met more easily in the case of the reforming catalysts, which have the higher Pt content.

The literature on determining platinum in catalysts is not extensive. For reforming catalysts an X-ray fluorescence approach was described by Lincoln and Davis.[1] Distillation of the platinum as the chloride, followed by the spectrophotometric *p*-nitrosodimethylaniline procedure, was suggested by Conrad and Evans.[2] Dissolution of the catalyst in hydrochloric acid, followed by a spectrophotometric stannous chloride finish, was used by Maziekin *et al.*[3] A gravimetric method based on the precipitation of platinum with dimethylphenylbenzylammonium bromide was suggested by Kuebler[4] who also recommended a spectrophotometric diaminobenzoic acid procedure for the determination of small amounts of platinum. There is no literature yet on the determination of platinum in emission-control catalysts, although it is known that the producers of the catalysts, as well as the A.C. Spark Plug Division of General Motors, have been investigating extensively various approaches using X-ray fluorescence spectroscopy.[5] Because of the high and fluctuating background, due to the various forms in which the alumina may be present, and because of the lack of meaningful standard samples, this technique does not yet appear to be capable of meeting the requirements for precision and accuracy, but may serve as a tool in quality control. The determination of platinum (and palladium) in emission-control catalysts by atomic absorption after collection of the platinum and palladium with either tellurium[6] or sodium formate[7] as precipitant has recently been reported. This technique is at present capable of providing platinum results with a relative standard deviation of about 1.5%. This falls somewhat short of the desired accuracy (error less than 1%).

The spectrophotometric determination of platinum by the stannous chloride system appears to be the best suited approach for the determination of platinum in both types of catalyst. It has been thoroughly investigated.[3,8–12] Ayres and Meyers[9] showed that it can be used for differential spectrophotometric measurement of platinum. It is this particular feature which makes the method attractive for the precise determination of platinum in both types of catalyst.

EXPERIMENTAL

Apparatus

Spectrophotometer. Beckman DU equipped with matched 1-cm cells.

Vitreous graphite crucibles. Obtainable from Société Le Carbon Lorraine, Paris, and Boonton, N.J.

Normal laboratory equipment. Muffle furnace, stoves, steam-bath, H_2S cylinders, glassware, alumina crucibles, Rose crucibles.

Optional equipment. Fire-assay furnace, scorifiers, and cupels.

Reagents

Sodium dimethylglyoximate solution, 2%.

Stannous chloride solution, 30%. Dissolve 300 g of $SnCl_2 \cdot 2H_2O$ by warming with 500 ml of concentrated hydrochloric acid and dilute to 1 litre with water.

Sodium formate solution, 25%.

Saturated solution of bromine in water.

Collection of the platinum

Fresh reforming catalysts containing only platinum. Decompose four different sample weights ranging between 10 and 12 g (Pt ~0.3%) or 7 and 9 g (Pt ~0.6%) in 600-ml beakers by heating with 200 ml of 6*M* hydrochloric acid on a hot-plate with a surface temperature of about 100°. (For precautions to guard against the pick-up of moisture and for the determination of "total solids" see reference 3.) Add from time to time a few ml of 30% hydrogen peroxide to aid in the dissolution of the platinum. Maintain the volume with 6*M* hydrochloric acid until dissolution is complete and the solution clear, then transfer to 1000-ml volumetric flasks. Should, however, a haze persist after 12 hr of heating, filter, and wash with hydrochloric acid (1 + 99). Transfer the clear solutions to 1000-ml volumetric flasks.

Platinum–rhenium catalyst. Decompose four different sample weights (chosen as above) in 600-ml beakers, by heating gently and with intermittent stirring, in a mixture of 100 ml of water, 20 ml of 25% sodium formate solution and 150 ml of sulphuric acid (1 + 1). When decomposition is complete, dilute to 400 ml with hot water, and simmer until the platinum has coagulated. Allow to cool, filter off on a retentive paper, and wash the beaker twice and the paper thoroughly with sulphuric acid (1 + 99). Wipe the beaker with a piece of moistened filter paper and add this to the funnel. Wash beaker and paper finally once with warm water. Keep the precipitation beaker, and either discard the filtrate or use it for the determination of rhenium.

Char the filter paper in a small porcelain crucible, gradually increase the temperature, and finally heat at about 750° for 10–20 min. After cooling, transfer the residue with a small stream of hot water to the precipitation beaker. Clean the crucible with 10 ml of hot *aqua regia* and add the solution to the beaker. Add an additional 15 ml of *aqua regia* to the beaker, heat for 5 min on a steam-bath, dilute with 25 ml of water, filter through a small paper into a 150-ml beaker, and wash the paper thoroughly with nitric acid (1 + 9).

Evaporate the solution to dryness on a steam-bath and repeat the evaporation twice with addition of 3 ml of 3*M* hydrochloric acid between successive evaporations. Dissolve the salts in 20 ml of 6*M* hydrochloric acid. Transfer the solutions to 1000-ml volumetric flasks.

Spent reforming catalysts. Heat four different sample weights ranging between 8 and 12 g in porcelain dishes for about 5 hr at 550° to destroy carbonaceous matter. Depending on the solubility of the alumina, treat the residue remaining after the ignition step either with sulphuric acid (1 + 1) and sodium formate as for Pt-Re catalysts or with sulphuric and phosphoric acids as for emission-control catalysts. Transfer the final solutions of the platinum to 1000-ml volumetric flasks.

Emission-control catalysts. The preferred method involves fire assay for the recovery of platinum and palladium in the residue.

Transfer different sample weights ranging between 12 and 18 g to 600-ml beakers. Add 50 ml of phosphoric acid and stir thoroughly with a rod to break up any lumps. Add 25 ml of water and stir. Add 50 ml of sulphuric acid, stir and place on a hot-plate with a surface temperature not exceeding 200°. Stir the solution intermittently during the heating. After the water has been expelled (5–10 min), dissolution of the sample is usually complete in about 20 min. If decomposition appears incomplete, cool for a few minutes, add 25 ml of water, and reheat.

Allow to stand, cool for about 10 min, add 100 ml of water, 15 ml of hydrochloric acid, and an excess of bromine water to effect dissolution of the platinum and palladium. Dilute with hot water to 400 ml and boil for a few minutes to expel excess of bromine. Small amounts of residual bromine do not interfere.

Add to the solution 5 mg of copper as chloride or sulphate solution, dilute to 500 ml with hot water, and pass hydrogen sulphide into the hot solution for about 20 min at a rate of about 300 ml/min. Again heat the solution to near boiling and repeat the treatment with hydrogen sulphide.

Filter off the sulphides on a 12-cm retentive paper containing a little filter pulp. Wipe the beaker and H_2S-tube with moistened filter paper and add this to the sulphides on the paper. Wash the beaker twice with sulphuric acid (5 + 95) containing some hydrogen sulphide, then once with cold water, adding the washings to the funnel. Set the beaker aside for further cleaning (see next paragraph). Wash the paper at least 12 times with the sulphuric acid (5 + 95) containing hydrogen sulphide, to remove the aluminium salts and phosphoric acid. Discard the filtrate.

Char the paper in a small alumina crucible in a muffle furnace at a low temperature, then heat to about 700° for 10 min. To the cooled crucible add 5 ml of hydrochloric acid and 2 ml of nitric acid, cover, and warm to dissolve the platinum and palladium. Wash the solution into a 150-ml beaker. Treat the 600-ml precipitation beaker with a little hot *aqua regia* and wash this solution also into the 150-ml beaker. Boil the combined solution to dissolve the platinum and palladium completely. Filter the solution through a small filter paper, into a 250-ml beaker, and wash thoroughly with nitric acid (2 + 98).

The residue may require treatment as below, if there is more than a few mg and it is discoloured. Otherwise, discard it, evaporate the filtrate to dryness on a steam-bath, and continue with the separation of Pt and Pd, as described below.

For treatment of the residue, ignite the paper in a 2-in. scorifier. Add 50 g of test lead, 20 mg of silver, and cover with 3 g of borax. Scorify until a lead button weighing about 20–25 g is obtained (this requires about 25 min at 900° and is complete when the molten lead is reduced in size to approximately 1 cm diameter in the centre of the molten slag). Cupel the lead button at approximately 900–950°. The resulting silver bead contains the traces of platinum and/or palladium retained by the material insoluble in *aqua regia.* Dissolve the silver in a 150-ml beaker in 20 ml of hot nitric acid (1 + 4). Add 3 ml of hydrochloric acid to precipitate the silver and dissolve platinum and palladium. Boil for about 5 min, dilute with 100 ml of water, and warm until the silver chloride has settled. Cool, filter off, and wash twice with nitric acid (2 + 98). Discard the silver chloride. Combine the filtrate with the main platinum- and palladium-bearing solution and evaporate to dryness on a steam-bath.

To separate platinum and palladium, dissolve the salts by heating with 30 ml of a mixture of concentrated perchloric and hydrochloric acids and water (2:1:97 v/v), cool, transfer the solution to a 125-ml separatory funnel, add 5 ml of sodium dimethylglyoximate solution and mix. Palladium will precipitate. Extract the palladium by shaking for 30 sec with 15 ml of chloroform. Run the chloroform phase into a 150-ml beaker if a palladium determination is required, otherwise discard it. Repeat the chloroform extraction until the solution is clear, indicating quantitative removal of the palladium.

Transfer the aqueous phase back to the 150-ml beaker previously used and evaporate the solution to dryness on a steam-bath. Add to the residue 10 ml of nitric acid and 5 ml of perchloric acid and evaporate to dryness at a low temperature. Stir the residue with a glass rod to ensure that all free perchloric acid is expelled. However, do not bake the salts.

Dissolve the residue by heating with 40 ml of 6*M* hydrochloric acid on a steam-bath. If the platinum content of the sample is 0.035% or less, wash the solution into a 100-ml volumetric flask. For a platinum content between 0.035 and 0.07% wash the solution into a 200-ml volumetric flask. For platinum contents between 0.07 and 0.15% use a 500-ml flask. Continue with the determination as in the next section.

If no fire-assay facilities are available, proceed as follows. Decompose the sample as already described. Filter the cold solution through a 12-cm retentive paper containing a little filter pulp, preferably by suction. Wipe the beaker with a piece of moistened filter paper and add this to the funnel. Wash the beaker twice and the paper ten times with dilute sulphuric acid (5 + 95). Reserve the filtrate. Ignite the paper in a vitreous graphite crucible at about 550°. Cool the crucible, wet the residue with a little water, add about 5 ml of hydrofluoric acid and 2 drops of sulphuric acid, and heat on a hot-plate until the silica and finally the acids have been expelled. Add 3–5 g of sodium bisulphate to the crucible, cover with a quartz or porcelain lid, and heat in a muffle furnace at 650° for about 20 min. Allow the crucible to cool, leach the melt in a 250-ml beaker with 50 ml of water and 5 ml of hydrochloric acid. Add a little bromine water to ensure complete dissolution of any platinum and/or palladium. Combine this solution with the filtrate reserved from initial dissolution. Precipitate the platinum and palladium with hydrogen sulphide as described above, omit the fire-assay treatment and continue with the separation of platinum and palladium.

Determination of platinum

Preparation of standards. The maximum concentration of platinum suitable for measurement is 65 μg/ml. The platinum for the standards must be weighed with an error of <0.1%. In view of the normal weighing error on microbalances, this means that a minimum of about 5 mg of platinum is needed. To make the standards, weigh on a microbalance such quantities of platinum that the platinum concentration in each sample will fall between that of two standards 5 μg/ml apart in concentration. The volumes of the standard solutions when ready for measurement (*i.e.*, after the reaction *etc.*) are best matched to those of the samples for which they are to be used. This means a maximum of 6.5 mg for a 100-ml flask, with 0.5-mg intervals between standards, 13 mg and 1-mg intervals for 200-ml flasks, 32.5 mg and 2.5-mg intervals for 500-ml flasks, 65 mg and 5-mg spacing for 1000-ml flasks. An alternative is to use appropriate portions of a platinum stock solution, always provided that the measurement error is <0.1% (weight fractions could be used, for example).

Transfer the standards to covered 50-ml beakers, and dissolve the platinum by warming with 5–15 ml of *aqua regia* (depending on the amount of platinum). After dissolution, wash off the cover-glass, evaporate the solution to dryness on a steam-bath, and repeat the evaporation twice, with addition of 1–2 ml of hydrochloric acid (1 + 3) in between. Dissolve the residue in 10 ml of hydrochloric acid (1 + 3), and transfer the solution to an appropriate volumetric flask.

Add to the volumetric flasks enough concentrated hydrochloric acid to make the final concentration 35% by volume. Add cold water until the flasks are three-quarters full and mix. Cool the solutions to 20 ± 2°. Add enough stannous chloride solution to make its final concentration 3% w/v. Dilute to volume and mix.

Allow the solutions to stand for 15 min to obtain maximum colour development, then measure the absorbance of standards and sample solutions as follows. Transfer sample solution and the two standards nearest to it in concentration to 1-cm cells. Using a wavelength of 403 nm, set the spectrophotometer zero with the lower standard in the light-beam. Then, measure the absorbance of the other standard and the sample relative to the lower standard. Repeat until the absorbance can be established within ±0.005 or better. Repeat for the other samples, using the appropriate pairs of standards.

Calculations. Calculate the amount of platinum in the sample as follows.

$$C_3 = \frac{(C_2 - C_1)A_2}{A_1} + C_1$$

where C_1 = mg of Pt in lower standard, C_2 = mg of Pt in higher standard, C_3 = mg of Pt in sample, A_1 = absorbance of higher standard, A_2 = absorbance of sample.

DISCUSSION

The decomposition steps described are applicable to any type of reforming and emission-control catalysts with the exception of those where, because of heat treatments, the catalyst has been largely converted into α-alumina. In the latter case, however, reasonably good recovery of platinum (about 99%) can be obtained as follows.

Mix the catalyst with a third of its weight of ammonium carbonate (to prevent the volatilization of any platinum halide) gradually heat to 1200°, cool, extract the platinum with *aqua regia*, and repeat the heating and extraction cycle on the insoluble residue. Alternatively, fuse the catalysts by fire-assay procedures with a flux consisting of litharge, borax, sodium carbonate and a reducing agent, such as starch, using silver and gold as collectors. Scorify the resulting lead button, if necessary, and cupel it to obtain a silver–gold bead containing the platinum. Dissolve the bead in dilute nitric acid, filter off the gold, and precipitate the silver as chloride. In the filtrate of the silver chloride determine the platinum as described in the main procedure. (For a discussion of various critical aspects of the fire-assay procedure and the treatment of the silver–gold bead see reference 14.)

Differential spectrophotometry

For a discussion of the optimum conditions for the colour development see reference 3. However, tests carried out in our laboratory indicate that it is not necessary to add aluminium chloride to the standards as required by reference 3. A 45-μg/ml platinum standard read against a 40-μg/ml standard gave identical absorbances of 0.213 ± 0.001 when read in the presence or absence of 45 mg of $AlCl_3 \cdot 6H_2O$ per ml.

The rationale for preferring differential measurement is as follows. A 20-μg/ml platinum solution will give an absorbance of about 0.8 in a 1-cm cell when

Table 1. Precision measurements

Amount of platinum used for zero adjustment setting, *mg*	Amount of platinum used to measure precision, *mg*	Volume, *ml*	Average absorbance reading	Precision of readings
0	0.50	100	0.203	±0.0025
5.00	5.51	100	0.204	0.0012
10.00	11.00	200	0.205	0.0014
25.03	27.52	500	0.204	0.0010
30.00	35.03	1000	0.203	0.0013
35.03	39.98	1000	0.203	0.0011
39.98	45.03	1000	0.204	0.0010
45.03	50.01	1000	0.204	0.0012
50.01	55.00	1000	0.203	0.0014
55.00	60.02	1000	0.203	0.0012
60.02	65.04	1000	0.202	0.0013
65.04	70.02	1000	0.198	0.0020

measured against water as reference. Suppose the measurement error is 1%. If an attempt is made to decrease the error by a factor of three by taking three times the concentration of platinum, the absorbance will be too high to be read even approximately. If, however, instead of water, standard platinum solutions are used for the zero-absorbance settings and the difference in platinum concentration of any pair of neighbouring standards is the same, then the difference in absorbance between neighbouring standards should also be the same (See Table 1), and correspond (if Beer's law is obeyed) to an absorbance of about 0.2 for a 5-μg/ml difference. Thus for a 54-μg/ml sample measured with the aid of 50 and 55 μg/ml standards (themselves prepared with <0.1% error) the overall error will be only about a tenth of the actual absorbance measurement error, so an absorbance error of 4% would still give an overall error of only about 0.4%.

In order to ensure that the measurements of the absorbances are matched by corresponding improvements in the platinum collection procedure, sample weights are intentionally chosen in the proposed methods so that they require the use of at least four different standards.

The maximum concentration of platinum which can be handled by the procedure is about 65 μg/ml in the solution measured. Above this, the slit-widths cannot be further adjusted and the colour system apparently departs from Beer's law. However, a small departure from Beer's law can be tolerated, if the platinum concentration does not exceed 70 μg/ml and not such a high degree of accuracy is required, since the measurement is still differential. Likewise, if the same concentration slightly exceeds that of the highest standard, meaningful results are obtained, as is illustrated by the following experimental results:

$$C_1 = 50.00\ \text{mg} \qquad C_1 = 55.05\ \text{mg}$$

$$C_2 = 55.05\ \text{mg} \qquad C_2 = 60.00\ \text{mg}$$

$$A_1 = 0.213 \qquad A_1 = 0.208$$

$$A_2 = 0.228 \qquad A_2 = 0.016$$

$$C_3 = \frac{(55.05 - 50.00)}{0.213} \times 0.228 + 50.00 = 55.41\ \text{mg} \qquad C_3 = \frac{(60.00 - 55.05)}{0.208} \times 0.016 + 55.05 = 55.42\ \text{mg}$$

Table 2

Type of catalyst	Pt reported, % Lab. A.	Lab. B	Umpire determination by proposed procedure, Pt, %	Relative standard deviation, %
Fresh catalyst (Pt only)	0.342	0.350	0.343	0.35
	0.330	0.340	0.333	0.40
	0.623	0.607	0.625	0.30
	0.644	0.632	0.640	0.28
Fresh catalyst (Pt–Re)	0.336	0.343	0.341	0.40
	0.328	0.320	0.321	0.43
Octafining catalyst	0.394	0.387	0.392	0.42
	0.399	0.409	0.403	0.57
Spent catalyst	0.297	0.313	0.301	0.35
	0.335	0.325	0.325	0.43
	0.343	0.352	0.344	0.42
	0.595	0.606	0.604	0.65
	0.613	0.627	0.614	0.70
	0.104	0.110	0.104	0.50

However, if an attempt is made to extend the measurements much beyond 0.25 absorbance units, because the system follows Beer's law, serious mistakes can be introduced as is demonstrated below.

Platinum concentration µg/ml	Absorbance measurement
25.06	0
30.06	0.197
35.06	0.387
40.06	0.559
45.00	0.694

The increase in the platinum colour follows Beer's law. The measuring device (photo tube), however, is unable to determine the linearity. Therefore the linearity cannot be proven by constructing a calibration curve, but only by the expedient of measuring differences in the absorbances in the range between 0 and 0.2.

Separation of platinum and palladium

For the determination of platinum in emission-control catalysts the platinum is separated by the dimethylglyoxime–chloroform extraction technique.[11,13] A re-examination of the optimum acid conditions led to the proposed perchloric acid–hydrochloric acid–water (2:1:97) medium. No palladium was found in the platinum fraction (detection limit 10 µg) and no palladium in the platinum fraction (detection limit 5 µg), when up to 10 mg of palladium was separated from up to 25 mg of platinum. Palladium can be determined in the chloroform extracts by evaporating off the chloroform layer, treating the residue with *aqua regia*, evaporating the solution to dryness, dissolving the salts in a measured volume of 2% potassium cyanide solution and determining the palladium by atomic-absorption spectroscopy, with palladium standards in cyanide medium.

Table 3. Effectiveness of the proposed procedure when applied to emission-control catalysts

Platinum added, *mg*	Palladium added, *mg*	Platinum found, *mg*	Error, %
5.035	2.0	5.04	+0.1

Verification of accuracy of procedures

No standard samples of either type of catalyst were available. However, in the case of fresh reforming catalysts, in the course of determining platinum by the proposed procedure on an umpire basis, comparative results became available which are reported in Table 2.

It should be emphasized that the proposed methods of separation are also applicable if ordinary spectrometry is employed and the consequent lower accuracy is acceptable.

Since neither standard samples nor reliable comparison samples of emission-control catalysts were available, the following tests were carried out to prove the effectiveness of the collection steps. To the filtrates from the hydrogen sulphide separation, obtained while analysing catalysts from three different producers, measured amounts of platinum and palladium were added in the form of solutions of the chlorides, the platinum metal being weighed individually on a microbalance. The solutions containing the platinum and palladium were then carried through all remaining steps of the procedure. The results are reported in Table 3.

ATOMIC-ABSORPTION SPECTROMETRY OF LASER-NEBULIZED SAMPLES

T. Kántor,* L. Pólos, P. Fodor and E. Pungor
Institute for General and Analytical Chemistry, Technical University, Budapest, Hungary

(*Received* 18 *November* 1975. *Accepted* 12 *February* 1976)

In flame-emission and atomic-absorption spectrometry, the solid sample introduction techniques applicable with simple table instruments have been the subject of several investigations. In recent developments some type of flameless atomization device such as a graphite tube furnace, a tantalum filament, an electric arc or a laser beam is used. The free atoms generated in this way can be detected directly. An alternative method involves the transport of the fine particles from the primary vaporization source into a secondary high-temperature zone where the aerosol particles are atomized and detected. The primary heating process can be considered as *thermal nebulization*. The following combinations of thermal nebulization and atomization–excitation sources are known: spark and flame,[1] d.c. arc and capillary arc,[2] d.c. arc and flame[3] and tantalum filament and inductively coupled radiofrequency plasma.[4] The arc and flame combination was developed in our laboratory for use with powdered samples.[5] Recently, a laser and flame combination has been introduced. Experiments with metals, solutions and non-metallic solid samples are described in this paper.

EXPERIMENTAL

In Fig. 1 an arrangement for a laser–flame combination is shown, which has a very simple transport system. A glass chamber is fixed by a rubber gasket around the mount of the objective lens. The chamber is open at the base to allow the exit of the laser beam and the entry of the sample vapours, and connected to the mixing chamber by the "ejector" which transports the sample by suction. A stoichiometric acetylene–air flame was used with an observation height of 10 mm. An air flow-rate of 11 l./min through the ejector nozzle produced a flow-rate of 3.2 l./min as carrier gas.

A Zeiss, Jena, Model LMA-1 laser microprobe apparatus was used, having a neodymium-doped glass laser rod, emitting at 1060 nm. The energy input and output are about 1000 and 1 J respectively at maximum. This apparatus operates without a Q-switch mode, and the pulse duration is 500 μs, comprising approximately 250 laser spikes. A Unicam Model SP 90A atomic-absorption spectrometer was used. Although the pulse duration of the laser beam was in the millisecond range, the duration of the half-peak absorption signal from the flame was about 1 sec, corresponding to the transit time of the aerosol through the transporting and mixing systems. No special demand on the response time of the detection unit is made and this is a critical point when direct laser atomization is used.[6,7] Statistical treatment of the peak signal and the integrated signal measurements has shown an equal precision, so that no integration is necessary with the laser–flame method.

The dimensions of the laser crater were studied for nickel-base alloys, as a function of the energy input and the focus. A distance of about 0.3 mm between the focus points of white light and of the infrared laser radiation was estimated. The best precision and absolute sensitivity were obtained with medium energy input and with focusing of the laser beam a distance of 0.3 mm above the sample surface (a displacement of 0.6 mm for the adjusting white light). Under these conditions a circular crater of 0.35 mm diameter was produced. No formation was detected of large droplets which might cause poor precision and low absolute sensitivity. Morton and co-workers[8] were able to produce deep conical craters without large droplet formation when perfect focusing and Q-switched laser beams were used.

In Fig. 2 an analytical curve for iron in nickel-base alloys is shown, each point representing an average of 5 measurements. The concentration range of iron is 8–92% and some alloys with high chromium and cobalt contents are also compared. The absorbance is proportional to iron concentration between 8 and 65% and variation of the major component has little effect. An average relative standard deviation of 7% was found.

In the application of the laser–flame method to solution analysis a photographic plate was used as the target. The photographic emulsion was developed after a strong exposure and showed high absorptivity for the laser light. A solution volume of 0.2 μl was applied to the emulsion surface and the residue was vaporized by a laser beam of medium energy. Analytical curves for sodium were linear up to 25 ng per 0.12 mm^2 whether plotted as peak absorbances without blank corrections or as integrated values from which the blank signal of the emulsion had been subtracted. Analytical curves having a similar character

were established for iron, cadmium, copper and zinc solutions.

Sodium in the 0.04–0.2% concentration range could be determined in the corundum plates used in the electronics industry. A series of these plates was analysed by other methods and were used as standards for the laser–flame method, the highest energy input being used.

RESULTS

In Table 1 the analytical performance for metals, solutions and solid (corundum) samples is summarized. In the first row data are given for those cases in which deep craters in alloys were produced. Some improvement in the relative detection limits appears, with a high loss in precision and absolute detection limit, but the average relative standard deviation is 10% and this is sufficient for many purposes. The absolute detection limits are in the ng range for the elements studied. Relative detection limits are calculated from the weight of gelatine (as organic matrix) removed by the laser beam.

CONCLUSIONS

These experimental results suggest that the formation of solid aerosols at elevated temperatures is governed by laws which allow us to use this process in quantitative analysis. The concentration of fine particles is proportional to the amount of the sample evaporated even under the conditions of non-stationary vaporization. The techniques are simple and make possible separate optimization of the nebulization and the atomization–excitation steps.

Summary—Thermal nebulization of nickel-base alloys, corundum plates and residues of solutions was performed with a laser beam. The solid aerosol was aspirated into an acetylene–air flame by an ejector. Linear analytical curves in wide concentration ranges were established and an average relative standard deviation of 10% was found. The detection limit is in the ng range for iron and copper, and lower for zinc, cadmium and sodium.

ACID-BASE EQUILIBRIA IN ETHYLENE GLYCOL—III
SELECTION OF TITRATION CONDITIONS IN ETHYLENE GLYCOL MEDIUM, PROTOLYSIS CONSTANTS OF ALKALOIDS IN ETHYLENE GLYCOL AND ITS MIXTURES

P. Zikolov, T. Zikolova and O. Budevsky
Faculty of Pharmacy, Academy of Medicine, Ekz. Josif No 15, Sofia, Bulgaria

(*Received* 27 *November* 1975. *Accepted* 16 *January* 1976)

The main purpose of this series of papers[1,2] is the development of a general approach for the selection of the most appropriate conditions for volumetric determination of acids and bases in ethylene glycol (EG). For many non-aqueous solvents this selection is usually made empirically, but in the present treatment a somewhat different approach is proposed. EG has properties very similar to water: amphiprotic behaviour, relatively high dielectric permeability, tendency to form hydrogen bonds *etc.*, which is why some methods used for the selection of suitable titration conditions in water could, in principle, be applied to EG. A number of methods based on examination of the titration curve are used for this purpose,[3–6] but the graphical method[5,6] is probably the easiest. For its application, the acid-base constants of all protolytes taking part in the titration equilibrium have to be known. That is why in the previous papers the autoprotolysis constants of EG and its mixtures[1] and the constants of some acid-base indicators[2] were determined.

The present paper describes the method for selection of the titration conditions. Since EG is most frequently used as a solvent medium for the titration of water-insoluble weak bases,[7] a number of alkaloids were studied in this investigation, and this necessitated determination of their protolysis constants in EG medium.

EXPERIMENTAL

Reagents

Ethylene glycol, its mixtures and the titrants were purified, prepared and standardized as described earlier.[1,2] Reagent-grade codeine and ephedrine were used after drying in a vacuum desiccator, without purification. Morphine, papaverine and quinine were prepared by making alkaline aqueous solutions of their hydrochloride and recrystallization from ethanol–ether mixture.

Apparatus and procedure

The protolysis constants were determined by potentiometric titration using a cell without liquid junction, equipped with a glass and a silver–silver chloride electrode:

$$\begin{array}{c} \text{glass} \\ \text{electrode} \end{array} \Big\| \, 0.1M(\mathrm{B + KCl + HCl}),\ \mathrm{SH} \,\Big|\, \mathrm{AgCl\text{-}Ag}$$

The experimental arrangement and the procedure was the same as before.[1] The temperature was kept at 25° ± 0.2°. Standardized 0.1*M* hydrochloric acid was used to titrate *ca.* 0.01*M* alkaloid solution in 0.1*M* potassium chloride. The titration was continued after the equivalence point so as to yield data which were used to calibrate the electrochemical cell for the particular experiment.

The e.m.f. of the cell (E) at 25° is given by the equation

$$E = E^{0'} - 0.05916 \log[\mathrm{SH_2^+}] \qquad (1)$$

The $E^{0'}$-value of the cell was calculated from the titration data after the equivalence point by means of equation (1). From this equation it follows that

$$\mathrm{p}c_{\mathrm{H}} = -\log[\mathrm{SH_2^+}] = \frac{E - E^{0'}}{0.05916} \qquad (2)$$

The protolysis of the conjugate acid ($\mathrm{BH^+}$) of the alkaloid (B) in EG or EG mixture (SH)* can be presented by the equation

$$\mathrm{BH^+ + SH = B + SH_2^+} \qquad (3)$$

The concentration ($K^c_{\mathrm{BH^+}}$) and the thermodynamic ($K_{\mathrm{BH^+}}$) protolysis constants are given by the equations:

$$K^c_{\mathrm{BH^+}} = [\mathrm{SH_2^+}]([\mathrm{B}]/[\mathrm{BH^+}]) \qquad (4)$$

$$K_{\mathrm{BH^+}} = \{\mathrm{SH_2^+}\}(\{\mathrm{B}\}/\{\mathrm{BH^+}\}) = K^c_{\mathrm{BH^+}} f_{\mathrm{SH_2^+}} (f_{\mathrm{B}}/f_{\mathrm{BH^+}}) \qquad (5)$$

Since $[\mathrm{BH^+}] = [\mathrm{HCl}] + [\mathrm{S^-}]$ and $[\mathrm{B}] = [\mathrm{B}]_{\mathrm{tot}} - [\mathrm{HCl}] - [\mathrm{S^-}]$, from (2) and (4) a relationship can be written, which is used in practice for calculation of the $\mathrm{p}K^c_{\mathrm{BH^+}}$-values:

$$\mathrm{p}K^c_{\mathrm{BH^+}} = \frac{E - E^{0'}}{0.05916} + \log \frac{[\mathrm{HCl}] + [\mathrm{S^-}]}{[\mathrm{B}]_{\mathrm{tot}} - [\mathrm{HCl}] - [\mathrm{S^-}]}$$

where [HCl] is the molar concentration of the added acid, $[\mathrm{B}]_{\mathrm{tot}}$ is the total concentration of the alkaloid base determined by a Gran plot,[8] and $[\mathrm{S^-}]$ is the molar concentration of the lyate ion of the solvent. The latter was calculated only for $\mathrm{p}c_{\mathrm{H}} > 10$, from the values of the concentration autoprotolysis constants.[1]

As an illustration of the method used for calculation of the protolysis constant, the experimental data from a potentiometric titration and their treatment for the determination of the $\mathrm{p}K^c_{\mathrm{BH^+}}$-value of codeine in EG are shown in Table 1.

---

* In this work as in the previous one,[1] the EG mixtures are treated as separate solvents with their own acid–base properties and dielectric constant.

3.200	−343.9	−482.8			
Mean $E^{0'}$ = −482.7 ± 0.2*					

Conditions: 20 ml of $1.08 \times 10^{-3}M$ codeine titrated with 0.1001 *M* hydrochloric acid in ethylene glycol 0.1*M* in potassium chloride. The base was neutralized with 2.160 ml of hydrochloric acid (this volume was determined by Gran plot).

* Confidence interval ($p = 0.95$)

If it is assumed that the activity coefficients in equation (5) are $f_{SH_2^+} = f_{BH^+}$ and $f_B = 1$, then the concentration constants determined in the described manner are equal to the thermodynamic ones. The identical values obtained for the constants by measurements at two different ionic strengths (0.1 and 0.05), confirm the validity of this assumption.

The protolysis constants of the conjugate acids of some alkaloids (pK_{BH^+}) determined in the present work in both EG and its mixtures are given in Table 2. In the same table the protolysis constants for the corresponding bases (pK_B) computed by the well-known relation $pK_B = pK_S - pK_{BH^+}$ are also given. The K_S values are the autoprotolysis constants of the solvent, determined in the previous work.[1]

OUTLINE OF THE METHOD

The theoretical titration curves of all the alkaloids were constructed. The curves were drawn by a graphical method,[6] based on the logarithmic concentration diagram, (lc-diagram). This type of diagram is widely used for the presentation of acid–base equilibria in aqueous media, but so far has not been applied to a non-aqueous medium. An essential difference when the lc-diagram is applied to a non-aqueous solvent is the length of the pH-scale, which, as well known, is defined by the autoprotolysis constant (pK_s) of the solvent. In Fig. 1 the construction of a titration curve for 0.01*M* codeine is shown. The left hand part represents an lc-diagram. Note that the length of the pH-scale, in accordance with the autoprotolysis constant of EG, is 15.7 units. The basic principles and construction details of the lc-diagram are discussed in full by Sillén[9] and other authors,[10,11] and therefore no details will be given here. It will only be mentioned briefly how titration curves are constructed by using an lc-diagram.

Point 1 in the lc-diagram (see Fig. 1) represents the initial pH-value of the EG solution 0.01*M* in alkaloid (B). This point is transferred to the right-hand part of the figure at position 1′ at $Y = 0\%$ added titrant. Point 2 represents the pH-value of a 0.001*M* solution of BH^+, hence 10% of the alkaloid **B** present has been converted into its conjugate acid BH^+. Therefore point 2 is transferred to 2′ at $Y = 10\%$. The crossing point 3 corresponds to the equality $[B] = [BH^+]$, hence this point is transferred to $Y = 50\%$ (3′). Point 4 corresponds to a pH-value of a solution which contains 10% of the initial concentration of the free base and point 4 is transferred to 4′ where $Y = 90\%$. Similar considerations transfer point 5 to 5′ at $Y = 99\%$, 6 to 6′ at $Y = 99.9\%$. Point 7 is the pH-value of a 0.01*M* solution of BH^+, hence 7 is transferred to 7′ at $Y = 100\%$. After this point the lyonium ions are in excess, consequently their concentration can be read from the SH_2^+-line. It is obvious then, that point 8 corresponds to a surplus of the acid, or $Y = 100.1\%$. Similarly, points 9, 10 and 11

† Symbols: EG—ethylene glycol, E—ethanol (10%), W—water (5%), EMK–Ch—ethyl methyl ketone–chloroform (5 + 5%).

are transferred to $Y = 101$, 110 and 200%. After the main points of the titration curve are known, it is an easy matter to draw the full line as shown in Fig. 1. The part of the titration curve which covers the pH-values corresponding to $Y = 99.9$–100.1% may be called the *equivalence region* of the titration curve. For end-points within this range of pH-values the error of the titration is less than or equal to $\pm 0.1\%$. It must be added that the equivalence region is easily found from the lc-diagram as shown by an arrow in Fig. 1.

After the theoretical curve is known, an appropriate acid–base indicator can be chosen for the detection of the end-point. Obviously the transition interval of the indicator must coincide with the equivalence region of the titration curve. As can be seen from Fig. 1, Bromophenol Blue (BPB) is a very suitable indicator for the accurate ($\pm 0.1\%$) determination of codeine in EG.

There is quite good agreement between the theoretical titration curve and the experimental data as shown in Fig. 1, where the open circles denote the experimentally measured pH-values. Also in accordance with theory, a very sharp colour change was observed with Bromophenol Blue as indicator.

Figure 2 shows the theoretical curves for $0.01M$ solutions of the alkaloids investigated, constructed similarly.

DISCUSSION

The results from this series of investigations show that acid–base equilibria in EG are simple and similar to those in water. This allows the application of methods commonly used in investigations of acid–base equilibria in water solutions. The utility of EG and its mixtures as a medium for the determination of water-insoluble weak bases has been proved by means of a detailed study.

From the theoretical curves (Fig. 2) it is shown that the visual titration error is $\pm 0.1\%$ for 0.01 or $0.1M$ solution of these alkaloids in EG and its mixtures, except for quinine and papaverine where the error may be up to $\pm 0.5\%$. The water content (5%) of EG, though it makes the titration conditions worse by shortening the equivalence region of the curve, does not affect the accuracy of the determination. It is found both theoretically and experimentally that the most suitable indicator for titration of the alkaloids investigated was Bromophenol Blue ($pK^c_{HI} = 6.49$), except for quinine, for which Bromocresol Green ($pK^c_{HI} = 7.38$) was best.

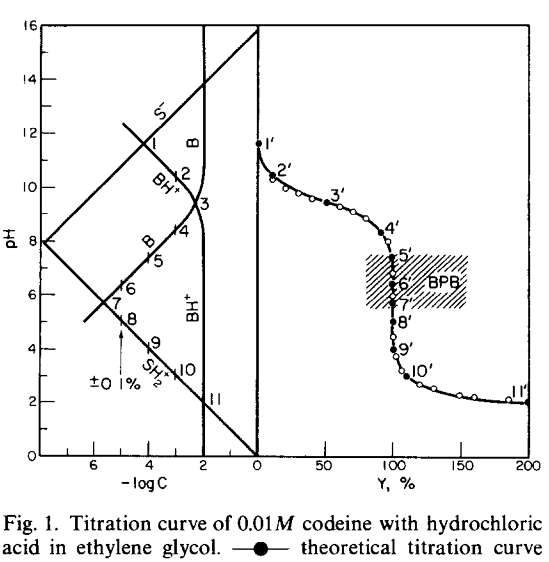

Fig. 1. Titration curve of $0.01M$ codeine with hydrochloric acid in ethylene glycol. —●— theoretical titration curve ○ experimental data

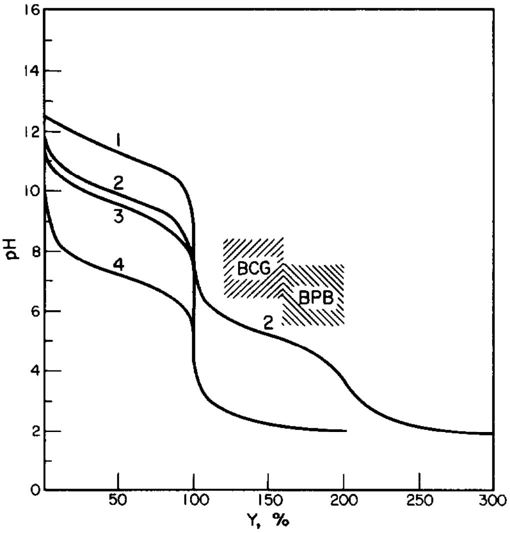

Fig. 2. Theoretical titration curves of $0.01M$ solutions of ephedrine (1), quinine (2), morphine (3) and papaverine (4) in ethylene glycol.

According to theoretical considerations,[12] the titration of bases is improved in solvents that decrease the K_S/K_B ratio, *i.e.*, increase the pK_{BH^+}-value. The pK_{BH^+}-values of the alkaloids in EG and EG mixtures, compared with the corresponding values in water, 10% acetone–water, methanol and formic acid[12] show that EG as medium provides better titration conditions.

The pK_{BH^+}-values in EG (Table 2) are on average 1.5 units higher than those in water. Since the protolysis of charged acids of the type BH^+ does not involve any charge separation [equation (3)], the decrease of the acid strength can be attributed to the lower basicity of EG.[13] Because EG is more acidic than water,[1,13] a greater basicity of the alkaloids should be expected. Nevertheless, Table 2 shows that the pK_B-values are on average 0.3 units higher in EG than in water. Since the protolysis of an uncharged base (B) is accompanied by charge separation, this difference can be explained by the influence of the lower dielectric permeability of EG. The addition of ethanol (10%) and ethyl methyl ketone–chloroform (5 + 5%) does not affect significantly the strengths of the bases and their conjugate acids. The addition of water, as expected, leads to an increase in the acid strength—the pK_{BH^+}-values are on an average 0.7 units lower in EG–water (5%) mixture than in pure EG.

The results obtained in this series of papers provide a means of avoiding the empirical approach for the selection of titration conditions for this non-aqueous solvent. The convenient potentiometric method permits an accurate determination of the constants needed for the construction of the theoretical titration curves. These curves constructed by the lc-diagram method allow a rapid and accurate enough prediction of the titration conditions, *viz.* evaluation of the titration error, choice of a proper indicator, appropriate concentration of the base to be titrated, *etc.* There is reason enough to expect that the same approch could be extended to other amphiprotic solvents possessing properties similar to those of EG.

Summary—Theoretical titration curves are used for the selection of appropriate conditions for the acid–base volumetric determination of weak bases in ethylene glycol medium. The theoretical curves for titration of some alkaloids are deduced graphically on the basis of the logarithmic concentration diagram. The acid–base constants used for the construction of the theoretical titration curves were determined by potentiometric titration in a cell without liquid junction, equipped with a glass and a silver–silver chloride electrode. It is shown that the alkaloids investigated can be determined accurately by visual or potentiometric titration. The same approach for the selection of titration conditions seems to be applicable to other non-aqueous amphiprotic solvents.

CONCENTRATION AND SEPARATION OF TRACE METALS WITH AN ARSONIC ACID RESIN*

James S. Fritz and Elizabeth M. Moyers
Ames Laboratory-ERDA and Department of Chemistry, Iowa State University,
Ames, Iowa 50010, U.S.A.

(*Received* 10 *November* 1975. *Accepted* 19 *January* 1975)

Because of their selectivity for heavy metals, chelating resins have been used for the concentration and separation of trace metals in food extracts,[1,2] oil-field brine,[3] industrial waste waters,[4] geological samples,[5] and sea-water.[6–8] Most of this work was performed on Dowex A-1 (Chelex 100), which has an iminodiacetic acid functional group. Dowex A-1 is a gel-type resin which undergoes pronounced swelling and shrinking. This resin has rather slow kinetics and a comparatively high affinity for calcium and magnesium.[6,9]

To meet the growing needs of ecological research in pollution control[10] and elsewhere, new chelating resins are continually being developed. Among those showing promise for trace metals are dithiocarbamate,[11,12] natural polymer,[13] 8-aminoquinoline,[14] polyamine–polyurea[15] and isothiouronium[5] exchangers. Hirsch *et al.*[16] started with a macroporous polystyrene–DVB resin and prepared a resin containing the iminodiacetic acid functional group and another containing an arsonic acid group. Macroporous resins are much less susceptible to swelling and shrinking and appear to have faster reaction kinetics than gel-type chelating resins.

A series of macroporous arsonic acid resins has now been prepared by a synthetic method similar to that used by Hirsch *et al.*[16] The effect of varying pore diameter and surface area on the properties of the final resins has been studied. These arsonic acid resins are now proposed for the concentration of trace metal ions from hard water and sea-water.

EXPERIMENTAL

Apparatus

A Milton Roy Pump No. 19-60029-003 or helium pressure was used to maintain a constant flow-rate through the resin column.

An RIDL AEC 320-3 single-channel analyser was used for counting the activity of the radiotracers, at a window setting of 1.3 MeV.

Plasma emission analyses were performed on the ICP-OES system built at Ames Laboratories.

Reagents

XAD-1, -2, and -4 macroporous resins were obtained from Rohm and Haas. The 150–200 mesh resin was prewashed with acetone and concentrated hydrochloric acid

For all trace analyses 0.5 g of resin IV was packed in a column measuring 2.8 × 0.6 cm.

^{54}Mn, ^{65}Zn, and ^{59}Fe gamma-emitters with 99% radiometric purity were obtained from New England Nuclear

Co. Synthetic sea-water was made according to Lyman and Fleming.[17]

All chemicals were of the highest available purity.

Synthesis

The synthesis used was adapted from methods used by Hirsch.[16] The resin was nitrated with a 60/40 v/v mixture of sulphuric and nitric acids at 65–70° after addition at 0°. It was reduced to the amine with mossy tin in conc. hydrochloric acid at 70–75°. The reduction product was slurried with 1*M* sodium hydroxide to remove tin salts, chilled to 0° in conc. hydrochloric acid, and diazotized by slow addition of 1*M* sodium nitrite. The resin was washed with sodium carbonate solution and coupled with sodium arsenite in aqueous soln at 70–75°. All reactions other than diazotization were allowed to proceed for half a day.

Infrared spectra of the phenylarsonic acid resins I, II and IV and the monomeric acid were taken on a Beckman IR7.

The 2.9 μm arsonic acid O–H stretch was visible for each of the three resins and matching bands in the region of 11.0–13.0 μm were found in the resins and the monomer that can be ascribed to the arsonic acid group.

Recovery

The recovery of trace metal ions was determined as a function of the effluent pH. One litre of distilled demineralized water containing 0.5 ppm of the metal ion was buffered to the appropriate pH and passed through the resin at a flow-rate of 7 ml/min. After collection and washing, the adsorbed metals were stripped from the column with 25 ml of 4.0*M* perchloric acid and determined by plasma emission, atomic absorption or colorimetrically with Arsenazo I.

Complexing agents

To 250 ml of distilled demineralized water containing 10 ppM (parts per milliard) of metal ion (including radiotracer) and 10 ppm of complexant, 5 or 6 drops of orthophosphoric acid were added. The phosphoric acid was added as a buffer and was necessary for 100% recovery of iron(III). The pH was adjusted to 5.0 and the solution was passed through the column at 7 ml/min. The metals were then stripped from the column with 25 ml of 4*M* perchloric and the activity of an aliquot of the effluent was measured.

Recovery of trace metals

One litre of distilled demineralized water, tap-water, or synthetic sea-water at pH 5 and containing 0.5 ppm of heavy metals was passed through the resin at 7 ml/min, followed by 100 ml of metal-free pH-5.0 solution, and the metals were eluted with 25 ml of 4*M* perchloric acid and determined by plasma emission or atomic absorption.

For trace metals at sub-ppM level, the procedure was similar, but with 5 ml of 2 μCi/ml tracer solution replacing the 0.5 ppm of heavy metals. Detection was by gamma emission.

In the analysis of the tap-water, no metal ions were added.

Separation of uranium(VI) from other heavy metals

A 1-litre sample containing 0.5 ppm of uranium(VI) and other heavy metals and 0.01*M* in EDTA was buffered to pH 5.0 with orthophosphoric acid and ammonia and passed through the resin column at 7 ml/min. The column was then washed with 100 ml of 0.01*M* EDTA at pH 5.0 and 100 ml of pH-5 wash-solution (both solutions buffered with phosphoric acid and ammonia). The column was then stripped with 25 ml of 4*M* perchloric acid. The uranium was determined colorimetrically and the other heavy metals were determined by plasma emission

Separation of thorium(IV) from other heavy metals

A litre sample containing 0.5 ppm of thorium(IV) and other heavy metals and 0.1*M* in perchloric acid was passed through the resin at 7 ml/min. The resin column was washed with 100 ml of 0.1*M* perchloric acid and the thorium was then stripped from the column with 25 ml of conc. perchloric acid and determined by plasma emission.

Batch abstraction of trace metals

Resin IV, 0.5 g, was added to 250 ml of pH-5.0 solution containing 2.0 ppm of the heavy metals. The solutions were stirred for 2, 6, or 24 hr before collection of the resin. The adsorbed metals were washed from the resin with 25 ml of 4*M* perchloric acid.

RESULTS AND DISCUSSION

Arsonic acid resins were prepared from XAD-1, -2, and -4, which are macroporous polystyrene–DVB resins of varying pore size and surface area. The arsonic acid resins are designated I, II and IV, corresponding to the numbers of the XAD-resin starting material. The physical properties of the three resins are summarized in Table 1. Each of the three resins contains a nitrogen-containing group as an impurity although less than reported by Hirsch.[16] The resin IV synthesis was repeated and the yield in each step was estimated by analysis for the appropriate functional group. Nitration gave approximately 1.2 nitro groups per benzene ring. Reduction to the amine gave approximately 0.8 amine group per benzene ring, 67% yield. Conversion into the arsonic acid then gave approximately 0.6 arsonic acid group per benzene ring for an overall yield of about 50%.

The ratios of arsonic acid group per benzene ring and acidic hydrogen atoms per benzene ring were calculated from the arsenic and hydrogen analyses, the average molecular weight per resin unit being based on the calculated arsonic acid content and the remainder assumed to be 50% styrene and 50% DVB. The acidic hydrogen content is more than the 2:1 ratio of H:As expected for an arsonic acid group and probably represents titratable protonated amine. Although the exact values may be somewhat in question the trend seems clear; conversion into the arsonic acid is highest in resin I and lowest in resin II The large pores in XAD-1 appear to lead to high reactivity In XAD-4 the very high surface area is able to compensate for the smaller pores and good conversion into the arsonic acid was obtained.

Table 1. Properties of the XAD-arsonic acid resins

	Surface area, m^2/g	Pore diam., Å	As/benzene ring	H/benzene ring	C, %	H, %	N, %	Kinetics
AsO_3H_2-XAD I	100	205	2.4	5.2	52.8	5.2_5	3.3	Slow
AsO_3H_2-XAD II	300	90	0.3	0.8	58.1	5.4	5.0	Rapid
AsO_3H_2-XAD IV	784	50	0.75	1.8	51.3	5.2	3.2	Rapid

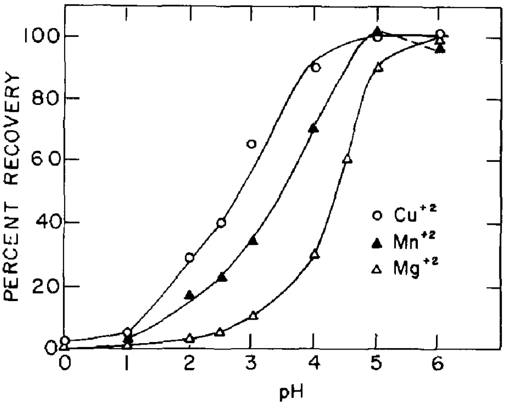

Fig 1. Effect of pH on recovery of Cu(II), Mn(II) and Mg(II).

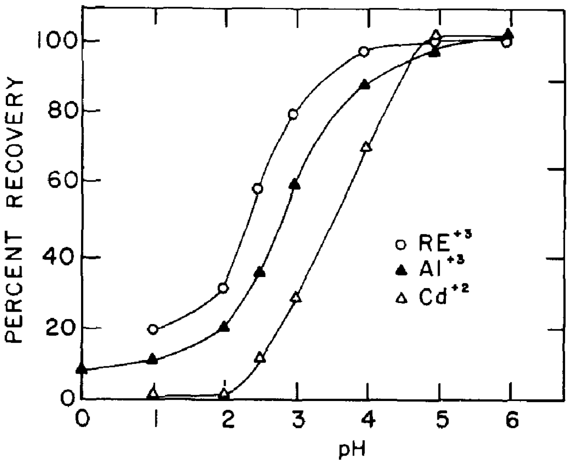

Fig. 3. Effect of pH on recovery of RE(III), Al(III) and Cd(II). (RE = rare earths).

Column experiments with various metal cations indicated that the kinetics of resins II and IV are excellent and those of resin I somewhat slow. Because of this and the higher capacity of resin IV (compared to resin II), resin IV was chosen for all subsequent experiments. This resin has little swelling tendency and is stable even in the concentrated acid and base solutions used to wash the resin and to strip some metal ions from the resin.

Small columns packed with resin IV were equilibrated with buffered aqueous solutions. Then solutions of various metal ions buffered to the same pH were passed through the column and the amount of metal ion retained by the column was determined. The degree of retention as a function of pH is plotted for various metal ions in Fig. 1–3. The selectivity order for metal ions, based on the assumption that the more stable complexes are retained at lower pH, is as follows: $Th^{4+} > UO_2^{2+} > RE^{3+} > Cu^{2+} > Pb^{2+} > Al^{3+}, Fe^{3+} > Zn^{2+} > Ni^{2+}, Co^{2+} > Cd^{2+}, Mn^{2+} > Mg^{2+}$ (RE = rare earths). This is in agreement with the order reported by Hirsch[16] of $Cu^{2+} > Zn^{2+} > Ni^{2+} > Co^{2+} > Mn^{2+} > Ca^{2+} > Mg^{2+}$.

Separation of thorium(IV) from all other metal ions studied was possible because of the affinity of resin IV for thorium at low pH values. Recovery of thorium at pH 1.0 was 102.5% (from spectrophotometric determination), with less than 1% of any of the other metal ions being retained. A successful separation of uranium(VI) from other metal ions was accomplished by adding EDTA to complex the foreign metal ions. Spectrophotometric analysis showed 98.3% recovery of uranium(VI) at pH 5.0 in 0.01*M* EDTA medium. Chromium(III) was the only interference (11% recovery).

Eight trace metals were added to demineralized water, tap-water and synthetic sea-water, the pH was adjusted to 5.0 and 1-litre samples were passed though a resin IV column. The sorbed metal ions were then eluted with 25 ml of 4*M* perchloric acid and the metal ions determined by plasma emission or atomic-absorption spectroscopy. The results, shown in Table 2, indicate excellent recovery except for chromium(III), which has a very slow reaction rate with ligands. With use of radiotracers, the experiment was repeated for three metal ions at the ppb (parts in 10^{12}) level. As shown in Table 3, the recovery is still quantitative within experimental error, even in the presence of a large

* Parts per milliard (10^9).

excess of sodium, magnesium and calcium salts. Triplicate analyses of tap-water were also carried out (Table 4).

The effect of complexing agents on the recovery of zinc(II), manganese(II) and iron(III) at 10 ppm concentrations was studied by adding a thousandfold w/w ratio of various complexing reagents. The added reagents included acetate, anthranilate, chloride, citrate, glycine, phosphate, salicylate, succinate, urea and EDTA. The recovery of manganese and zinc was unaffected by any of the complexants except EDTA. The recovery of iron was low in the presence of substances that form complexes having a stability constant greater than 10^8.

Comparative studies showed resin IV to be more effective for retention of trace metal ions when used in a column than for batch collection. For example, by the batch method recoveries were only about 90% for copper(II) and lead, 70% for iron(III), 40% for nickel, and 15% for cadmium.

Some calcium and magnesium is retained by the arsonic acid resin column at pH 5.0. If desired, about 95% of the calcium and magnesium retained by the column can be removed by elution with pH 4.0 buffer before the trace metal ions are stripped with 4–12*M* perchloric acid.

Acknowledgements—The authors wish to thank Walt Sutherland for the plasma-emission analyses and Gary Austin and John Richard for elemental analyses of the resins, and are grateful to the Rohm and Haas Co. for a gift of the XAD-1, -2, and -4 resins used in this work.

ORGANIC ACID SOLUTIONS IN THE CHROMATOGRAPHY OF INORGANIC IONS—IV

CATION-EXCHANGE OF Mn(II), Cd(II), Co(II), Ni(II), Cu(II), Al(III) AND Fe(III) IN TARTRATE MEDIA*

A. Dadone, F. Baffi and R. Frache
Instutute of General and Inorganic Chemistry of the University of Genoa, Genoa, Italy

(*Received* 7 *November* 1975. *Accepted* 5 *January* 1976)

The ion-exchange behaviour of inorganic ions in citric[1] and formic[2] acid media has been reported. Anion-exchange in tartaric acid media has been studied by Pitstick *et al.*[3] and Morie *et al.*[4,5] who describe the separation of some transition metals. Cation-exchange studies[6–9] have resulted in the resolution of a limited number of metal ions. Qureshi *et al.*[10] have separated Fe(III) and other metal ions in formic, oxalic, tartaric and citric acid media, but the only comprehensive investigation was made by Rouchaud *et al.*[11] They examined both cation- and anion-exchange and determined distribution coefficients for several ions in tartaric acid media containing nitric acid.

Summary—Macroporous arsonic acid resins with different pore sizes and surface areas were prepared and the properties compared. One of the resins was used for concentration of trace metal ions from dimineralized water, tap-water, and sea-water. The effect of pH and complexing agents on the recovery of metal ions was studied. A method for separation of uranium(VI) and thorium(IV) from each other and from other metal ions was developed.

ORGANIC ACID SOLUTIONS IN THE CHROMATOGRAPHY OF INORGANIC IONS—IV

CATION-EXCHANGE OF Mn(II), Cd(II), Co(II), Ni(II), Cu(II), Al(III) AND Fe(III) IN TARTRATE MEDIA*

A. Dadone, F. Baffi and R. Frache
Instutute of General and Inorganic Chemistry of the University of Genoa, Genoa, Italy

(*Received* 7 *November* 1975. *Accepted* 5 *January* 1976)

The ion-exchange behaviour of inorganic ions in citric[1] and formic[2] acid media has been reported. Anion-exchange in tartaric acid media has been studied by Pitstick *et al.*[3] and Morie *et al.*[4,5] who describe the separation of some transition metals. Cation-exchange studies[6–9] have resulted in the resolution of a limited number of metal ions. Qureshi *et al.*[10] have separated Fe(III) and other metal ions in formic, oxalic, tartaric and citric acid media, but the only comprehensive investigation was made by Rouchaud *et al.*[11] They examined both cation- and anion-exchange and determined distribution coefficients for several ions in tartaric acid media containing nitric acid.

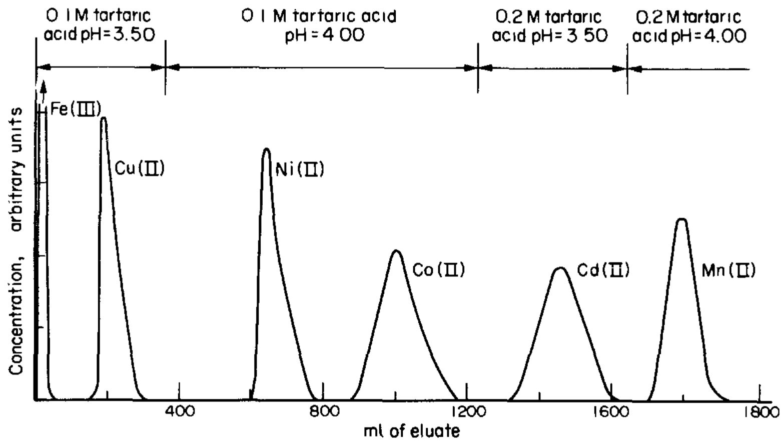

Fig. 1. Elution curves of Fe(III), Cu(II), Ni(II), Co(II), Cd(II) and Mn(II) in tartaric acid. Resin Dowex 50 W X8 (200–400 mesh), NH_4^+ form

In the present work we describe the cation-exchange of the ions Mn(II), Cd(II), Co(II), Ni(II), Cu(II), Al(III) and Fe(III), in tartaric acid solution at molarities between 0.1 and 1.0 and at pH values up to 10.

EXPERIMENTAL

The resin used was Dowex 50W X8, 200–400 mesh. It was converted into the NH_4^+-form with 3*M* ammonium chloride and washed with demineralized water. For the

n a. not adsorbed; s.a strongly adsorbed, ox. oxides.

batch experiments the resin was air-dried to constant weight at 70° and stored in a desiccator over silica gel.

The metal ions examined were used as 0.2*N* solutions of the chloride or nitrate salts, after standardization.

Eluents

The eluents were prepared from reagent grade chemicals. Tartaric acid was used at molarities of 0.1, 0.2, 0.3, 0.5 and 1.0. The pH was adjusted between 3.00 and 10.00 by the addition of ammonia or sodium hydroxide solution. Solid sodium hydroxide was used for the pH values 3.00, 3.25, 3.50 and 4.00 to avoid the precipitation of ammonium salts. For the pH values 8.00, 9.00 and 10.00, adjusted with conc. ammonia solution, increasing K_d values were obtained, while the uptake of the ions was zero from solutions adjusted with sodium hydroxide.

Determination of K_d values

The distribution coefficients (K_d) were determined by the batch equilibration method. Resin (0.5 g dry weight), 50 ml of the appropriate tartaric acid solution and 2 ml of the metal ion solution, were shaken for 15 hr at room temperature. After equilibration, the resin phase was separated by filtration and the ion concentration was determined on an aliquot of the filtrate, by atomic-absorption spectrophotometry, using the standard addition method.

Columns

For column experiments borosilicate glass tubes were used, 1.2 cm i.d., 28 cm long, fitted with sintered glass plates. The resin bed was 22 cm deep. Fractions (10 ml) were collected automatically and analysed by atomic-absorption spectrophotometry.

RESULTS AND DISCUSSION

Table 1 gives the distribution coefficients (K_d) obtained in the present work. In tartaric acid the K_d values decrease regularly with increase in the acid concentration. All the values are too high, however, to allow separations to be achieved in a short time with practical elution volumes. The K_d values decrease with increasing tartrate concentration at constant pH and with rising pH at constant tartrate concentration. The value for Fe(III) differs markedly from that reported by Qureshi.[10] The K_d values are in accord with the tendency of the ions to form tartrate complexes.[12] When amonia is used to adjust the pH, there is a regular decrease of K_d with increasing tartrate concentration at constant pH, and a regular increase of K_d at constant tartrate concentration with increasing pH, with the exception of Mn(II) which oxidizes, and Fe(III) and Al(III), which are not absorbed. The increase of K_d values can be ascribed to the formation of cationic ammine complexes.

From Table 1 we can predict the possibility of achieving several interesting separations.

Separation

Fe(III), Cu(II), Ni(II), Co(II), Cd(II) and Mn(II) were separated. The resin was preconditioned with five bed-volumes of the first eluent and samples were added in the same medium (0.1*M* tartaric acid at pH 3.5). The elutions were effected at an overpressure of 190 mmHg and the loading of the resin bed was 0.1 meq of each ion used. The flow-rate was 2.5 ml/min. Elution curves are shown in Fig. 1 and it can be seen that the peaks are sharp and well separated.

SPECTROPHOTOMETRIC DETERMINATION OF VANADIUM AS V(III) OXINATE

V. YATIRAJAM and S. P. ARYA
Department of Chemistry, Kurukshetra University, Kurukshetra 132119, Haryana, India

(*Received* 22 *October* 1975. *Accepted* 13 *January* 1976)

Almost all the numerous photometric methods for vanadium determination are based on vanadium(V) complexes. Only a few are based on vanadium(IV) complexes. There are even fewer methods[1–4] based on vanadium(III). Although some of them are highly sensitive, it would be advantageous to have methods with higher tolerance limits to analytically important elements to avoid preliminary separations. The limitation in using vanadium(III) appears to be its production and the stability of its complexes Electrolytic,[5] amalgam[6] or stannous chloride[4] reduction is frequently used for producing vanadium(III). A greater choice of reagents and conditions should be possible if introduction of metal ions can be avoided in the reduction.

Accordingly, we present below a method of producing vanadium(III) by sodium dithionite reduction and its extraction by oxine for its spectrophotometric determination.

EXPERIMENTAL

Reagents and solutions

Vanadium solution. A stock solution (10 mg of V/ml) was prepared from sodium metavanadate and standardized by the oxine method;[7] suitable dilution gave 100- and 10-μg/ml solutions.

8-Hydroxyquinoline. A 2% solution in carbon tetrachloride.

Sodium dithionite

Solutions of other elements. Prepared by dissolving suitable salts in water or dilute sulphuric acid to give 10 or 1 mg of element per ml.

Samples. Synthetic samples were prepared by mixing solutions of the ions to give the required compositions (see Table 4).

Rutile and ilmenite Finely powdered sample (1.0 g) was fused[8] with 5 g of fusion mixture in a platinum crucible for nearly 30 min. The melt was cooled and taken up in hot water. The insoluble residue was filtered off on Whatman No. 41 paper and washed 4 times with 5 ml of hot water each time. The filtrate was just acidified to litmus with dilute sulphuric acid and boiled to expel carbon dioxide. Any precipitate was filtered off, and washed twice with 5-ml portions of hot water. The filtrate and washings were cooled and made up to 5 ml. Aliquots of this solution were then used for the determination of vanadium by the procedure.

Determination procedure

To 20 ml of solution containing $\leq 175\ \mu$g of vanadium at pH 3–10, in a 150-ml separatory funnel, solid sodium dithionite (0.5–2.0 g) was added. After waiting for 2 min the funnel was stoppered and shaken gently for 2 min with 10 ml of the oxine solution in carbon tetrachloride, care being taken to release the pressure occasionally. After the layers had separated, the solvent phase was removed and passed through Whatman No. 41 paper (moistened with carbon tetrachloride) into a 25-ml volumetric flask. The extraction was repeated with another 10 ml of the oxine solution. Any complex sticking to the filter paper was washed into the flask, with oxine solution added dropwise. The solution was made up to the mark with carbon tetrachloride and mixed. The absorbance of the yellow complex was measured in 1-cm cells at 420 nm with a Beckman DU spectrophotometer, against a similarly treated reagent blank. The latter gave an absorbance of 0.006 against oxine in carbon tetrachloride.

Samples containing other elements. Masking agents were added after the reduction to vanadium(III), as shown in Table 3. In the case of tungsten, the tartrate was added to the solution at pH 8.5–10, before reduction.

RESULTS AND DISCUSSION

When sodium dithionite is added to mg amounts of vanadium(V) in slightly alkaline or acid solution, the pH decreases gradually, depending upon the amount of the reductant. The green solution obtained shows an absorption spectrum similar to the one obtained for vanadium(III) prepared by electrolytic reduction[2] or mercury reductor.[9]

When the solution is shaken with oxine in carbon tetrachloride a yellow complex is extracted quantitatively, showing an absorption peak at 420 nm. An initial pH of 3–10 before addition of dithionite gives a constant absorbance; the absorbance is lower if the initial pH is outside this range. Carbon tetrachloride is found to be the best solvent (Table 1), giving the highest absorbance. A single extraction with 10 ml of solvent was made from 20 ml of aqueous phase. The colour is not stable in other solvents except benzene, and in it has lower absorbance at the same λ_{max}.

The effect of various parameters on the V(III)-oxinate absorbance in carbon tetrachloride is shown in Table 2, the other conditions in each study being kept at the lower end of the optimum range. The optimum conditions for maximum absorbance are, initial pH of the aqueous phase 3–10, reduction with 0.5–2.0 g of sodium dithionite, 2 min waiting after mixing and 2–3 min equilibration with 2–4% oxine solution in carbon tetrachloride. A single extraction with oxine in carbon tetrachloride removes more than 99% of the vanadium but a second extraction with 10 ml of the solvent is recommended for 100% recovery

On the basis of Job's curves, the extracted species has a 3:1 ligand:metal composition.[10] The species has an

Table 1. Absorbance of vanadium(III)-oxinate complex in different solvents (V 5 μg/ml in the aqueous phase)

Solvent	Absorbance
Carbon tetrachloride	1.03
Benzene	0.995
Chloroform	0.858
Methyl isobutyl ketone	0.940
Amyl acetate	0.920
Amyl alcohol	0.662

Table 2. Dependence of the V(III)-oxinate extraction on different parameters (V 5 μg/ml in the aqueous phase)

Oxine/CCl_4, %	0.02	0.05	0.1	0.2	0.5	1.0	2.0–4.0

Sodium dithionite, *g*	0.1	0.2	0.5–2.0				
Absorbance	0.7	0.98	1.03				
Time of contact, *min*	0.25	0.5	1.0	2.0–3.0	5.0		
Absorbance	0.93	1.00	1.01	1.03	1.01		

absorption maximum at 420–425 nm, with sensitivity for vanadium of 0.004 μg/cm^2 (Fig. 1). At wavelengths shorter than 370 nm, the blank absorbs highly. There is no other peak at wavelengths up to 850 nm even at 0.8 mg/ml vanadium concentration. Beer's law is obeyed up 7 μg of V per ml of solvent phase. The absorbance remains constant for 45 min

Effect of diverse ions

Sodium chloride (5 g), sulphate (5 g), tartrate (2 g), acetate (3 g), thiourea (1 g) and ascorbic acid (1 g) have no effect on the extraction of vanadium. Only limited amounts of sulphosalicylic acid (0.4 g), thioglycollic acid (0.6 ml) and potassium cyanide (0.2 g) can be tolerated. Nitrate can be tolerated up to 5 mg/ml. Phosphate (2 g of the sodium salt) decreases the extraction. Fluoride and oxalate in ≥50 mg/ml and EDTA in ≥5 mg/ml concentrations mask the vanadium extraction completely.

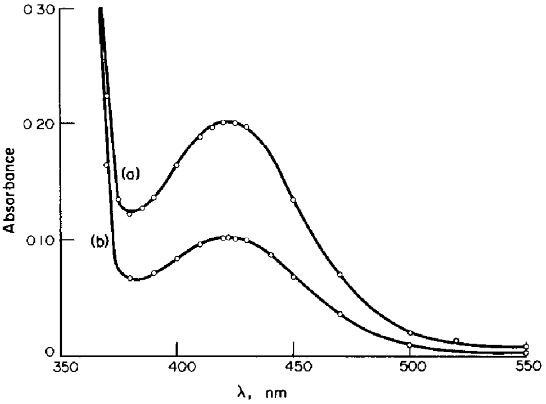

Fig. 1. Absorption spectrum of V(III)-oxinate; V—(a) 0.8, (b) 0.4 μg/ml of solvent phase.

* For an absorbance ≤ 0.002, in presence of masking agent, if any.

§ Added after reduction by sodium dithionite unless otherwise stated; cyanide and citrate were added as potassium salts and tartrate as the sodium salt.

† SSA = sulphosalicylic acid.

¶ TGA = thioglycollic acid added before reduction.

‡ Precipitates formed after dithionite reduction were filtered off before extraction.

On reduction with sodium dithionite at pH 3–7, mercury and lead give black, arsenic brown and cadmium yellow sulphide precipitates; strontium and barium give white precipitates of their sulphates. These precipitates need not be filtered off as they do not affect the extraction of vanadium. Any slight emulsion appearing at the interface is removed in the filtration of the organic phase. Bismuth and copper form black sulphide precipitates which should be filtered off before the extraction. Even then, some copper seems to be left, giving a yellow solution after extraction with oxine in carbon tetrachloride. This can be prevented by masking with sulphosalicylic acid after the reduction. Other elements, such as aluminium, zinc, uranium, iron, cobalt, nickel, titanium, antimony, tin and chromium give yellow or yellowish green solutions because of extraction of their oxinates. This can be prevented (up to the tolerance limit) by using the masking agents shown in Table 3. Addition of sulphosalicylic and thioglycollic acids lowers the pH but the same maximum extraction is obtained by increasing the time of equilibration to 4 min in the first extraction.

When the vanadium sample solution is brought to the desired pH, some of the hydrolysable ions precipitate. Dithionite is added without filtration of these precipitates as they do not interfere with the process of extraction. Only in the case of tin and antimony is thioglycollic acid to be added to the neutral solution before the reduction. Under these conditions, tin does not give any precipitate but antimony gives the orange-red sulphide which remains at the interface. If thioglycollic acid is not added, tin and antimony sulphides are precipitated and give an emulsion on shaking with the solvent. The thioglycollic acid also prevents the extraction of oxinates of these elements. In the case of titanium, the vanadium is adsorbed on the hydrolytic precipitate and hence the tolerance is very low. Molybdenum gives a brown precipitate on shaking with oxine in carbon tetrachloride, forming unbreakable emulsions and being partly extracted. Therefore, molybdenum must be separated. The tolerance limits cannot be raised because of the upper limits of masking agents for vanadium extraction.

Applications

The sensitivity of the method is double that obtained by using oxine or its derivatives with vanadium(V) and is rarely exceeded by other photometric methods for vanadium. With the masking agents suggested, the limits of tolerance of interfering elements are much higher than in the other methods. Only molybdenum interferes seriously. The reduction of V(V) to V(III) by dithionite is very convenient and rapid. The method uses ordinary reagents and takes 10 min or less in series. The use of a single heavier solvent is also an advantage.

Table 4. Analysis of samples by the proposed method

Summary—Vanadium(V) is rapidly reduced by dithionite to V(III) which is extracted as the oxinate into carbon tetrachloride. Vanadium is determined by measuring absorbance of the complex at λ_{max} = 420–425 nm with a sensitivity of 0.004 μg/cm^2 and Beer's law range of 0–7 μg/ml. Several mg of some important elements can be tolerated if they are masked. Molybdenum interferes seriously The method has been applied to synthetic samples, rutile and ilmenite with satisfactory results. Using ordinary reagents and taking 10 min or less in series for a determination, the method has a sensitivity rarely exceeded by others with a much higher tolerance for other elements.

GRAVIMETRIC DETERMINATION OF TUNGSTEN WITH TETRAPHENYLARSONIUM CHLORIDE AFTER ITS EXTRACTION AS THIOCYANATE

V. Yatirajam and Sudershan Dhamija
Department of Chemistry, Kurukshetra University, Kurukshetra 132119, Haryana, India

(*Received* 29 *September* 1975. *Accepted* 24 *December* 1975)

Analysis for low and high amounts of tungsten is required for natural and industrial samples containing some of the elements silicon, calcium, iron, manganese, cobalt, chromium, nickel, vanadium, molybdenum, copper, tin and bismuth. Except for the recent method of determination with iron(III) in thiocyanate medium,[1] the volumetric methods for tungsten are likely to give inconsistent and unreliable results.[2a] The gravimetric methods[2b,3a,4a] are based on precipitation as tungstic acid or as the tungstate of organic bases or easily volatilized cations. The process is hindered and the precipitates are contaminated by several elements of importance in tungsten materials, *e.g.*, phosphorus, silicon, iron, vanadium, chromium, arsenic, antimony and tin.[3b] The precipitates do not have definite composition and must be ignited to tungstic oxide. The barium and calcium tungstate methods are inconsistent and inaccurate[5] and the lead tungstate method requires preliminary precipitation of tungstic acid.[4b] All these methods are rather slow. The semimicro oxinate method is said to be unsuitable.[6]

Precipitation as tungstic acid in the presence of cinchonine is the most useful method for macro amounts, but is tedious, and contaminating elements have to be removed. The chromatographic,[3c] ion-exchange,[3c] precipitation,[3d] and solvent extraction[3e] methods handle only semimicro or micro amounts of tungsten and other elements in specific mixtures.

In view of the industrial importance of tungsten, we present a method for its gravimetric determination as the tetraphenylarsonium salt, after its extractive separation as the thiocyanate from interfering elements.

EXPERIMENTAL

Reagents and solutions

Tungsten solution. Sodium tungstate solution was standardized volumetrically with iron(III).[1]

Tetraphenylarsonium chloride solution, 1%.

Potassium thiocyanate solution, 5*M*.

Tribenzylamine solution (*TBA*). A 2% w/v solution in distilled chloroform.

Mercury. Purified with nitric acid.[7]

Procedure

Determination as tetraphenylarsonium tungstate. To a slightly alkaline solution containing 5–60 mg of tungsten, add tetraphenylarsonium chloride solution in 50% excess or till precipitation is complete. Dilute to about 40 ml and adjust the pH to 2 (pH-meter) with hydrochloric acid (caution: tungstic acid starts to precipitate at pH < 1.5). Wash the electrodes with 1 ml of 0.01*M* hydrochloric acid and filter off on a sintered-glass crucible (porosity 4). Wash the precipitate successively with 4, 2, 2, 1, 1 and 1 ml of 0.01*M* hydrochloric acid. Dry for 45 min at 110–115°, cool it over fused calcium chloride in a desiccator and weigh it.

Extractive separation of tungsten as thiocyanate. Place the solution, containing not more than 50 mg of tungsten, in a 100-ml separating-funnel and adjust it to be 0.4*M* in potassium thiocyanate and 4*M* in hydrochloric acid in a final volume of 25 ml. Add 2 ml of mercury and shake the funnel vigorously for 1 min. Extract the tungsten thiocyanate complex with 25 ml of TBA/chloroform solution by shaking for 1 min. Separate the mercury and then transfer the solvent layer to another separating-funnel. Repeat the extraction with 5 ml of solvent. Strip the tungsten from the combined extracts with two 25-ml portions of water made just alkaline to litmus and containing 2 ml of 6% hydrogen peroxide, shaking for 1 min each time. Filter, then boil the combined back-extracts with enough hydrogen peroxide to oxidize tungsten and destroy the excess of thiocyanate. Acidify to pH $\nless 2$ and boil to destroy the hydrogen peroxide. Cool the solution and determine tungsten.

Modification for presence of vanadium and titanium. When vanadium and/or titanium are present, scrub the TBA extract with 20 ml of 7*M* hydrochloric acid for 1 min before stripping the tungsten.

Modification for presence of iron and silica. With up to 100 mg of iron and/or 50 mg of silica present, shake with mercury for 2-3 min, before extracting with TBA in chloroform.

Modification for presence of molybdenum. When molybdenum is present, adjust the sample solution to 2*M* in hydrochloric acid and to contain 3 g of tartaric acid for each 100 mg of tungsten, in a final volume of 10 ml. Then separate molybdenum by the xanthate method.[8] After separation of the last chloroform extract, adjust the aqueous phase to 4*M* in hydrochloric acid and 0.4*M* in potassium thiocyanate in a final volume of 35 ml, and then follow the general procedure.

RESULTS AND DISCUSSION

Determination as tetraphenylarsonium tungstate

Tungstate condenses to paratungstate (pH 3–4) and metatungstate (pH 1.5–3),[9] which are precipitated as tetraphenylarsonium salts. The precipitation starts at pH ~ 6 but the weight of the salt from a given amount of tungsten is quantitative and reproducible only for the pH range 1 5–4. The conversion factor tungsten/tetraphenylarsonium tungstate is 0.4468. A lapse of up to 1 hr between pH-adjustment and filtration, or a change of temperature from 25° to 40° has no effect. The filtrate and washings contain 1 μg of tungsten per ml; therefore the minimum possible volume should be used. The precipitate is highly soluble in hot water and acetone, and less so in alcohol, ether and chloroform. Tartaric, citric and oxalic acids prevent precipitation. In the presence of even traces of a large number of other elements,[10] heteropolytungstates are formed which are also precipitated by the tetraphenylarsonium ion. It is, therefore, possible to use this method only after prior separation of almost all other elements, as proposed in the procedure above.

Extractive separation of tungsten as thiocyanate

Generally, the methods already available suffer interference from iron, vanadium, chromium, cobalt, nickel, copper and especially molybdenum. The recent mercury–thio-

† The first six samples are analogous to stellite, tungsten steel, high-speed steel, K.S. magnet steel, Midvale HR and Spanish wolframite respectively.

cyanate–TBA method[11] for spectrophotometric determination of tungsten suffers interference only from molybdenum and niobium and is simple and rapid. It was therefore chosen for the extractive separation of tungsten.

Various parameters for extraction of 50 mg of tungsten were checked. The degree of extraction increases with acidity up to 4*M* hydrochloric acid and then decreases at higher acidity. It is maximal from 0.2 to 0.4*M* potassium thiocyanate, but the layers do not separate well at lower concentrations. A 2% solution of TBA in chloroform and 1 min reduction time gives maximum extraction but these levels are not critical. A single 1-min equilibration with an equal volume of just alkaline hydrogen peroxide solution strips the tungsten quantitatively, but repetition is recommended as a safety precaution. Smaller volumes of aqueous phase cause emulsions. The conditions selected give 99.7% extraction.

Alloying elements other than molybdenum (25% extracted) and niobium (10% extracted), titanium and vanadium accompany tungsten either not at all or only in traces. Titanium and vanadium can be almost completely removed by scrubbing with 7*M* hydrochloric acid before the stripping, without affecting tungsten. The traces of other elements are removed as the hydroxides by filtration of the alkaline peroxide solution. No tungsten is lost by adsorption on the small hydroxide precipitate. Thus tungsten can be separated practically quantitatively from iron, nickel, cobalt, chromium, vanadium, titanium, copper, bismuth, manganese, uranium, lead, zirconium, arsenic, antimony and silicon. Only molybdenum and niobium still accompany tungsten. Molybdenum can be conveniently removed quantitatively without loss of tungsten by xanthate extraction[8] from the initial sample solution in 2*M* hydrochloric acid containing tartaric acid. The aqueous phase is then adjusted to the optimum conditions for the mercury–thiocyanate–TBA extractive separation, in a total volume of 35 ml. Thus only niobium accompanies tungsten, and then only in part, but fortunately is rarely encountered in tungsten materials.

Chloride and acetate decrease the extraction of tungsten very slightly, sulphate, phosphate, citrate, tartrate, oxalate do so in that order (Table 1). Silicic acid does not cause any difficulty and therefore need not be removed for preparation of the tungsten sample solution.

Applications

The extractive separation method is generally applicable to all tungsten materials both natural and industrial. The separation and determination together take less than 2 hr for a single sample and much less in series. The method gives highly satisfactory results with a relative overall error of 0.1–0.2% over a range of 5–60 mg of tungsten (Table 2).

Summary—Small amounts of tungsten in natural and industrial samples can be freed from all important interfering elements by extraction of molybdenum by xanthate, reduction of tungsten by mercury and extraction of tungsten(V) thiocyanate into tribenzylamine, and finally back-extraction. The tungsten can be then determined as tetraphenylarsonium tungstate by precipitating it at pH 2–4, filtering it off and drying it at 110° for 45 min. An overall error of 0.1–0.2% is obtained for 5–60 mg of tungsten.

(*Received* 20 *August* 1975. *Accepted* 21 *November* 1975)

Cyanides have industrial applications such as extraction of noble metals, use as insecticides, in photography and the paper industry and in the preparation of various cyanogen derivatives. Reagents such as silver nitrate,[1] alkaline potassium permanganate[2] and iodine in alkaline medium[3] are used for the estimation of cyanide. We have now found chloramine-T (CAT) and dichloramine-T (DCT) give a two-electron oxidation of cyanide. Direct titration was found impracticable and a back-titration procedure was developed. The method can be extended to estimation of both cyanide and thiocyanate in a mixture.

EXPERIMENTAL

Reagents

CAT was purified by the method of Morris *et al.*[4] An approximately 0.1*N* solution was prepared and standardized by the iodometric method. DCT was prepared and purified by the method of Jacob and Nair.[5] An approximately 0.1*N* solution in glacial acetic acid (containing 10% acetic anhydride) was prepared and standardized by the iodometric method. Compounds of accepted grades of purity were used in preparing other solutions. Standard buffer systems were employed.[6]

Zinc cyanide was prepared by mixing zinc sulphate and potassium cyanide solutions in 1:2 molar ratio. The precipitate was washed with water and dried over anhydrous calcium chloride. Zn: theoretical 55.68%; found 55.8%.

Lead cyanide was prepared by mixing lead acetate and potassium cyanide solutions in 1:2 molar ratio. The precipitate was washed with ice-cold water and dried over anhydrous calcium chloride. Pb: theoretical 79.92%. Found 80.4%.

$K_2Zn(CN)_4$, $K_2Pd(CN)_4$, $K_2Hg(CN)_4$ and $KAg(CN)_2$ were prepared by standard methods[7] and their composition was checked.

Procedures

Soluble cyanides with CAT. Adjust the pH of the aqueous solution (containing 0.01–4.0 mmole of cyanide) to 4 with acetate buffer. Add it to a known volume (30–40% excess) of 0.1*N* CAT in an iodine flask and set aside for about 30 min, shaking occasionally. Rinse down with 20 ml of water, add 10 ml of 2*N* sulphuric acid and 10 ml of 20% potassium iodide solution and titrate with 0.1*N* sodium thiosulphate (V_1 ml). Run a blank with the same volume of CAT solution alone (V_2 ml of thiosulphate needed). The amount (x mg) of cyanide ion is given by $x = 13.00y(V_2 - V_1)$ where y is the normality of the thiosulphate.

Soluble cyanides with DCT. Add 0.01–4.0 mmole of cyanide dissolved in water or pH 4 buffer to a known volume (~70–80% excess) of 0.1*N* DCT containing about 30% of acetic anhydride. Complete the determination as with CAT.

Insoluble cyanides with CAT. For zinc cyanide dissolve the solid in dilute acetic acid, adjust the pH to 4, then treat as for soluble cyanide but with 1 hr standing time. For lead cyanide treat samples in pH-4 buffer as for soluble cyanides, but keep at about 70° for 30 min.

Insoluble cyanides with DCT. For zinc cyanide proceed as for soluble cyanides but allow 1 hr standing time. For lead cyanide add samples in pH-4 buffer to 70–80% excess of DCT, then enough acetic anhydride to react with all the water in the mixture, keep at about 40° for 30 min and complete as before.

Complex cyanides with CAT. Proceed as for soluble cyanides for potassium tetracyanozincate; for potassium tetracyanopalladate(II) do the same but boil for about 30 min before the back-titration; for potassium tetracyanomercurate keep at about 40° for 30 min; for potassium dicyanoargentate let stand at room temperature for 1 hr.

Complex cyanides with DCT. For the tetracyanozincate proceed as for soluble cyanides; for the other three compounds add the excess of DCT and enough acetic anhydride to remove the water, keep at room temperature for 30 min for the mercury complex, 60 min for the silver complex, and at 50° for 30 min for the palladium complex, and complete as before.

Blank titrations with CAT or DCT are carried out under the same conditions as for the determinations.

101.0	118.0	100.9	117.9	100.9	118.0

Soluble cyanide in presence of halide. Add excess of $\sim 0.5M$ zinc sulphate to precipitate zinc cyanide; filter it off, wash it with about 30 ml of ice-cold water till free from halide, dissolve it in dilute acetic acid and analyse as above.

Soluble cyanide and thiocyanate in a mixture. Determine the sum of cyanide and thiocyanate as for soluble cyanide, and then the cyanide (in another sample) by the procedure for cyanide in presence of halide (procedure I). Alternatively (procedure II) determine the thiocyanate in the filtrate as for soluble cyanide. If there is only enough for one sample, analyse the precipitate for cyanide and the filtrate for thiocyanate. The equivalent weight of thiocyanate is 7.25 g.

RESULTS AND DISCUSSION

The stoichiometry of oxidation of KCN by CAT (or DCT) can be represented by

$$\mathrm{KCN + RNClNa\,(or\ \tfrac{1}{2}RNCl_2) + H_2O \rightarrow KCNO + RNH_2\,(or\ \tfrac{1}{2}RNH_2) + NaCl\,(or\ HCl)}$$

where $R = p\text{-}CH_3C_6H_4SO_2$. The presence of KCNO in the reaction products was detected by spot-tests.[8,9] The sulphonamide was detected by paper chromatography. Benzyl alcohol saturated with water was used as the solvent, with 0.5% vanillin in 1% hydrochloric acid in ethanol as the spray reagent ($R_f = 0.91$)

In preliminary experiments it was found that the degree of oxidation of potassium cyanide in 30 min was maximal at pH 3–5, and quantitative with a 30–40% excess of CAT. With a 10–20% excess the reaction is complete only after 1 hr. In other media quantitative oxidation takes 2 hr with 30–40% excess of CAT. With DCT, oxidation was found to be quantitative if the titration medium contained 30% acetic anhydride.

Several methods[10–14] have been reported for the determination of cyanide and thiocyanate in a mixture. Rao and Murthy[15] have shown that CAT oxidizes thiocyanate in acid medium (pH 1–6) in about 30 min, with an eight-electron change per mole.

The maximum error in determination of 2–220 mg of various cyanides, simple and complex, ranged from 3% at the bottom of the sample weight range to just under 1% at the top. Results for mixtures are shown in Tables 1 and 2.

Summary—A simple and accurate method for the estimation of cyanide in salts and complexes is based on oxidation with chloramine-T (in pH 4 buffer) or dichloramine-T (in presence of acetic anhydride). The oxidation involves a two-electron change. Halides interfere with the estimation of KCN, but the interference can be eliminated by precipitating and determining zinc cyanide. A method for estimating KCN and KCNS in mixtures is also described.

EXTRACTION AND SPECTROPHOTOMETRIC DETERMINATION OF RUTHENIUM AND OSMIUM WITH THIOBENZHYDRAZIDE

S. C. SHOME, P. K. GANGOPADHYAY and S. GANGOPADHYAY
Department of Chemistry, Presidency College, Calcutta 700012, India

(*Received* 19 *March* 1975. *Revised* 16 *June* 1975. *Accepted* 21 *November* 1975)

Several organic reagents[1,2] containing the $-CS-\overset{|}{N}-N<$ group, *e.g.*, 1,4-diphenylthiosemicarbazide[3,4], 2,4-diphenylthiosemicarbazide,[4] *o*-hydroxythiobenzhydrazide,[5] have been proposed for the spectrophotometry of ruthenium and osmium. In the present communication thiobenzhydrazide is recommended as a suitable reagent for the extraction of ruthenium and osmium in chloroform and for the subsequent photometric determination of those metals in the presence of a moderately large excess of diverse ions commonly associated with them.

EXPERIMENTAL

Reagents

Ruthenium(III) chloride hydrate was dissolved in dilute hydrochloric acid and the solution standardized by the hydrolytic precipitation method.[6] Standard osmium solution[7] was made by dissolving a weighed amount of osmic acid in 0.1*M* caustic soda. Solutions for spectrophotometric measurements were prepared by appropriate dilution of the stock solution. Sodium acetate solution and dilute hydrochloric acid were used for the regulation of pH. All the reagents and chemicals used were of analytical-reagent grade.

Preparation and properties of thiobenzhydrazide. Thiobenzhydrazide was first prepared by Holmberg.[8] A slightly modified procedure was used, as follows. Dissolve 2.12 g of carboxymethyldithiobenzoate[9] in 15 ml of 1*M* sodium hydroxide and cool the solution in ice. Slowly add 1.0 ml of hydrazine hydrate (80%) dissolved in 10 ml of 1*M* sodium hydroxide. Allow the mixture to stand for 2 hr in an ice-bath. Neutralize with cold, dilute hydrochloric acid (the pH should remain between 5.5 and 6.5), leave in the ice-bath for 1 hr, filter, crystallize from tepid water and dry in vacuum. The pure compound melts at 71–72°.

Thiobenzhydrazide is appreciably soluble in water and highly soluble in most organic solvents. It is stable towards acids and very dilute alkalis, but is decomposed by concentrated nitric acid and strong oxidizing agents. The reagent should preferably be stored at below 15°.

An approximately 0.01*M* solution of thiobenzhydrazide solution was prepared in spectroscopic grade ethanol.

Spectrophotometric determination of ruthenium

Place a measured volume of ruthenium(III) chloride solution in a 100-ml separatory funnel, and dilute to 20 ml with hydrochloric acid and water so that the final hydrochloric acid concentration of the solution is 1–4*M*. Add 2–3 ml of 0.01*M* thiobenzhydrazide and heat on a boiling water-bath for 20–25 min. Cool and extract with four successive 5-ml portions of chloroform. Combine the extracts, dilute to 25 ml, dry with anhydrous sodium sulphate and measure the absorbance at 520 nm against chloroform.

Spectrophotometric determination of osmium

Place an aliquot of osmic acid solution in a 100-ml separatory funnel and dilute to 15 ml. Add 2 ml of 5% EDTA solution to mask the interfering ions, if any, and adjust the pH of the solution to 2.3–4.8. Add 2 ml of 0.01*M* thiobenzhydrazide (the final volume should be <20 ml) and allow to stand for 10 min. Extract with three successive 5-ml portions of chloroform, combine the extracts in a 25-ml volumetric flask and make the volume up to the mark. Dry the extract with anhydrous sodium sulphate and measure the absorbance at 385 nm or 480–490 nm against a reagent blank.

RESULTS

Characteristics of the complexes

The absorbance spectra of the thiobenzhydrazide complexes of ruthenium and osmium in chloroform are shown in Fig. 1. The absorbances remain constant for at least 24 hr. The concentration ranges for conformity to Beer's law are 0.73–7.33 μg/ml at 520 nm for ruthenium and 1.20–12.04 μg/ml at 385 nm and 1.20–18.06 μg/ml at 480–490 nm for osmium.

The optimal acidity for complete extraction of ruthenium is 1.0–4.5*M* hydrochloric acid and for osmium pH 2.30–4.80. The extraction coefficients and degrees of extraction of the ruthenium and osmium complexes into various solvents are shown in Table 1. From these data four successive extractions with 5-ml portions of chloroform should extract 99.9% of the ruthenium, and three such extractions should extract 99.8% of the osmium present.

The minimal reagent:metal ratios for complete colour development with ruthenium and osmium were 15:1 and 10:1 respectively. Molar-ratio studies[10] indicated that osmium (VI) forms a 1:2 metal: ligand complex. The composition of the ruthenium complex, however, could not be determined.

It may be pointed out that both ruthenium (VI) and ruthenium (III) give the same colour reaction with thiobenzhydrazide. Similarly osmium (VIII) and osmium (VI) produce the same colour with the reagent. It appears that ruthenium (VI) and osmium (VIII) are reduced to ruthenium-(III) and osmium (VI) respectively before complex formation.

The molar absorptivities, Sandell sensitivities[11] and optimal concentration ranges of the determination of ruthenium and osmium are given in Table 2.

Accuracy and precision

The relative mean errors were $<0.5\%$ and the relative standard deviations $<1\%$ for 2–4 mg of ruthenium, and 6–12 mg of osmium (10 replicates at each level).

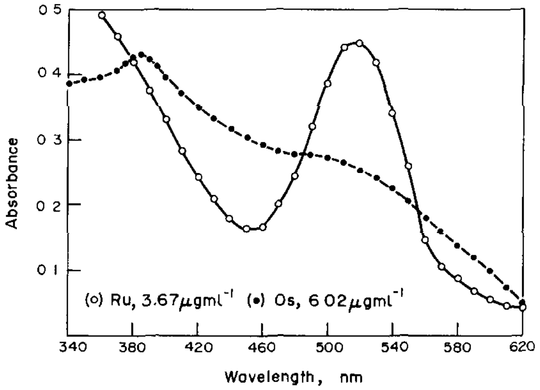

Fig. 1. Absorption spectra of thiobenzhydrazide complexes of rutheniun and osmium.

Interferences

The effect of a number of foreign ions was studied; the procedures involved appropriate acidity adjustment, use of EDTA as masking agent and sulphur dioxide as reducing agent. In some cases the extracts were centrifuged before the absorbance measurements. Osmium should be extracted as the thiobenzhydrazide complex before the determination of ruthenium. Table 3 shows the concentration of foreign ions that caused an error less than 2%.

Determination of ruthenium and osmium in a mixture

A mixture containing 91.7 μg of ruthenium and 150.5 μg of osmium was taken in a separatory funnel and 2 ml of 5% EDTA solution were added. The pH of the solution was adjusted to 4.5 and 2 ml of 0.01*M* thiobenzhydrazide were added The mixture was allowed to stand for 10 min, then was extracted with chloroform, and the osmium absorbance was measured at 480–490 nm. The acidity of the aqueous layer was then adjusted to be 3.0–4.0*M* in hydrochloric acid, 3 ml of 0.01*M* reagent solution were added and ruthenium was determined as described in the procedure. Errors in the determination of both metals were less than 2%.

DISCUSSION

Thiobenzhydrazide has been found to be a suitable reagent for the extraction and photometry of ruthenium and osmium. The method permits the determination of ruthenium selectively in the presence of diverse ions commonly

Table 2. Molar absorptivity, sensitivity and optimal concentration range for photometry of ruthenium and osmium

Wavelength *nm*	Molar absorptivity, *l. mole⁻¹. cm⁻¹*	Sensitivity, *μg/cm²*	Optimal concentration *μg/ml*

Benzene	0.17	14.6	9	90
Petroleum ether	—	—	1.24	55.6

associated with it, especially in the presence of other platinum metals. The sensitivity of the method for the determination of ruthenium is comparable to that of existing procedures for the metal. For osmium, the method is highly sensitive when the absorption measurements are made at 385 nm and rather less sensitive if the absorbances are measured at 480–490 nm. However, the longer wavelength is preferred because of the higher selectivity. Among other advantages of the reagent, ruthenium and osmium can be separated and subsequently determined spectrophotometrically.

Thiobenzhydrazide seems to be a potentially useful reagent for the determination of ruthenium and osmium in rocks and alloys. The metals may be brought into solution by $NaOH$–Na_2O_2 fusion[12] as ruthenium (VI) and osmium (VI) ions. The excess of peroxide should be destroyed before the metals are determined with thiobenzhydrazide as described above.

Summary—Ruthenium forms a pink complex with thiobenzhydrazide in hot 1.0–4.5*M* hydrochloric acid medium, which can be extracted with chloroform, and the extract shows maximal absorbance at 520 nm. The chloroform-extractable osmium–thiobenzhydrazide complex formed at pH 2.3–4.8 shows maximal absorption at 385 nm as well as at 480–490 nm. The colour of the extracts of both the complexes is stable for more than 24 hr and can be employed for the spectrophotometry of ruthenium and osmium in the presence of a considerable excess of diverse ions commonly associated with them. Ruthenium and osmium can be quantitatively separated from one another with thiobenzhydrazide.

SIMULTANEOUS TITRIMETRIC DETERMINATION OF POLYPHOSPHORIC AND SULPHURIC ACIDS IN A MIXTURE

REX W. SOUTER and RAFIK H. BISHARA
The Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, Indiana 46206, U.S.A.

(*Received* 21 *October* 1975. *Accepted* 11 *January* 1976)

Phosphoric acids with a high phosphorus pentoxide content are called "polyphosphoric acids."[1] Polyphosphoric and sulphuric acids both find use as dehydrating agents, especially in cyclodehydration—ring-closure reactions.[2–6] Analytical methods exist for analysis of concentrated phosphoric acids,[1] for titration of soluble phosphate compounds,[7] and for estimation of triphosphoric and pyrophosphoric acids in the presence of ortho- and metaphosphoric acids.[8] A complex procedure is available for titrimetric assay of nitric, phosphoric, sulphuric, and hydrochloric acids in the same sample.[9] Orthophosphoric acid may be titrated with sodium hydroxide but only two neutralization steps can be utilized.[10]

We report here an accurate, convenient method for assaying sulphuric–polyphosphoric acid mixtures used in the synthesis of 1,3,4-thiadiazoles.[11] Reaction yields are low if either concentrated sulphuric acid or polyphosphoric acid (PPA) alone is employed or they are mixed in other than a 1:3 (w/w) mixture. Calculation of percent by weight of each acid species is demonstrated.

EXPERIMENTAL

Titrations were done with a Brinkmann Metrohm E436 automatic titrator and a glass–calomel combination electrode. Standard 0.05*N* sodium hydroxide was used for all titrations

Before determining the percentages of sulphuric acid and PPA in the mixture, it is necessary to determine (*a*) the presence of hydrolysed PPA and (*b*) the experimental equivalent weights of PPA and sulphuric acid, using the same individual acids that were used to prepare the mixture.

Determination of hydrolysed PPA

Weigh 500 mg of the PPA into a 100-ml volumetric flask, dissolve it in water, dilute to volume, and mix. Pipette 5 ml into a suitable titration vessel, add 60 ml of water and titrate with 0.05*N* sodium hydroxide, with stirring to ensure only one sharp end-point.

Phosphoric acids with a high phosphorus pentoxide content are called "polyphosphoric acids."[1] Polyphosphoric and sulphuric acids both find use as dehydrating agents, especially in cyclodehydration—ring-closure reactions.[2–6] Analytical methods exist for analysis of concentrated phosphoric acids,[1] for titration of soluble phosphate compounds,[7] and for estimation of triphosphoric and pyrophosphoric acids in the presence of ortho- and metaphosphoric acids.[8] A complex procedure is available for titrimetric assay of nitric, phosphoric, sulphuric, and hydrochloric acids in the same sample.[9] Orthophosphoric acid may be titrated with sodium hydroxide but only two neutralization steps can be utilized.[10]

We report here an accurate, convenient method for assaying sulphuric–polyphosphoric acid mixtures used in the synthesis of 1,3,4-thiadiazoles.[11] Reaction yields are low if either concentrated sulphuric acid or polyphosphoric acid (PPA) alone is employed or they are mixed in other than a 1:3 (w/w) mixture. Calculation of percent by weight of each acid species is demonstrated.

EXPERIMENTAL

Titrations were done with a Brinkmann Metrohm E436 automatic titrator and a glass–calomel combination electrode. Standard 0.05*N* sodium hydroxide was used for all titrations

Before determining the percentages of sulphuric acid and PPA in the mixture, it is necessary to determine (*a*) the presence of hydrolysed PPA and (*b*) the experimental equivalent weights of PPA and sulphuric acid, using the same individual acids that were used to prepare the mixture.

Determination of hydrolysed PPA

Weigh 500 mg of the PPA into a 100-ml volumetric flask, dissolve it in water, dilute to volume, and mix. Pipette 5 ml into a suitable titration vessel, add 60 ml of water and titrate with 0.05*N* sodium hydroxide, with stirring to ensure only one sharp end-point.

Determination of experimental equivalent weight of sulphuric acid

Accurately weigh in triplicate 500 mg of the sulphuric acid into each of three 100-ml volumetric flasks. Dissolve in water, dilute to volume and mix well. From each solution, pipette 5.0 ml into small boiling flasks and dilute with 60 ml of water. Reflux the samples for 3 hr and then cool to room temperature. Quantitatively transfer each sample to a titration vessel and titrate, while stirring, with 0.05*N* NaOH through the single end-point.

The sulphuric acid is refluxed like the samples in order to treat any impurities in the same manner.

Determination of experimental equivalent weight of polyphosphoric acid

Accurately weigh in triplicate 500 mg of the PPA sample into 100-ml volumetric flasks. Continue as described for sulphuric acid; the hydrolysed samples will show two end-points in the titration.

Determination of percentages of sulphuric and polyphosphoric acids in the mixture sample

Accurately weigh in triplicate 500 mg of the mixed acid sample into 100-ml volumetric flasks. Continue as described in the previous section; two end-points will be obtained.

Calculations

The first step in the procedure, performed only on the stock PPA used to make the mixtures, ensures that each PPA sample will only have one end-point. The presence of more than one sharp end-point indicates partial hydrolysis, and the stock of that PPA should be discarded since part of its dehydrating strength is already lost.

The experimental equivalent weight of sulphuric acid is calculated as follows from the volume of sodium hydroxide required for titration:

$$\text{eq. wt. } H_2SO_4 = \frac{(\text{mg } H_2SO_4 \text{ in } 100\text{ ml}) \times (5.0\text{ ml})}{(100\text{ ml}) \times (\text{ml NaOH}) \times (\text{normality NaOH})}$$

Calculation of the experimental equivalent weight of PPA is done by using the volume of base necessary to reach the first end-point for each hydrolysed PPA sample:

$$\text{eq. wt. PPA} = \frac{(\text{mg PPA in } 100\text{ ml}) \times (5.0\text{ ml})}{(100\text{ ml}) \times (\text{ml NaOH}) \times (\text{normality NaOH})}$$

The volume of base required to reach the second end-point is also calculated. Theoretically, titration to the first end-point and from the first to the second end-point should consume the same volume. However, experimental work has shown the latter volume to be larger than the former, perhaps because of slight titration towards the third equivalence point of phosphoric acid.[10] Thus, the difference between the first and second end-points is divided by the volume for the first end-point, and this ratio is used later as a "volume correction factor" for the base consumed in titration of the acid mixtures.

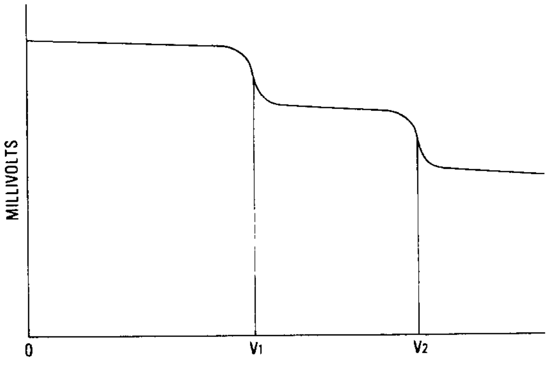

Fig. 1

For calculation of results of mixed-acid titrations refer to Figure 1.

For each such titration, the volume of base at each end-point V_1 and V_2 is calculated. V_1 is the volume of base required to titrate the sulphuric acid completely and the hydrolysed PPA to the first neutralization step. V_2 is V_1 plus the volume required to titrate to the second neutralization step of the hydrolysed PPA. The second neutralization step of hydrolysed PPA thus requires $V_2 - V_1 = V_3$. V_3 is divided by the volume correction factor calculated previously, to give the corrected volume of base necessary for titration of one equivalent of hydrolysed PPA, V_4. V_4 is subtracted from V_1 to give V_5, the volume of base equivalent to the sulphuric acid. The volumes V_4 and V_5 are used to calculate the amounts of PPA and sulphuric acid in the mixture:

$$\%\,\text{PPA} = \frac{(V_4, \text{ml}) \times (\text{normality NaOH}) \times (\text{eq. wt. PPA}) \times 10^4}{(\text{mg mixed acid}) \times 5}$$

$$\%\,H_2SO_4 = \frac{(V_5, \text{ml}) \times (\text{normality NaOH}) \times (\text{eq. wt. } H_2SO_4) \times 10^4}{(\text{mg mixed acid}) \times 5}$$

The orthophosphoric acid (H_3PO_4) equivalent to the stock PPA is calculated by using the volume of base needed to reach the first end-point for hydrolysed PPA:

$$\%\,H_3PO_4 = \frac{(\text{ml NaOH}) \times (\text{normality NaOH}) \times 98 \times 100 \times 100}{(\text{mg PPA}) \times 5}$$

The P_2O_5 equivalent to the PPA is then calculated from[10]

$$\%\,P_2O_5 = \%\,H_3PO_4 \times \frac{142}{196}$$

The amount of P_2O_5 in the mixed acid samples is calculated by.

$$\%\,P_2O_5 \text{ in mixture} = \frac{(\%\,P_2O_5 \text{ in PPA}) \times (\%\,\text{PPA in mixture})}{100}$$

RESULTS AND DISCUSSION

The equivalent weight of hydrolysed PPA must be experimentally determined for each lot used since the exact composition of PPA before and consequently after hydrolysis is unknown.[1] The equivalent weight of the sul-

Table 1. Assay results for synthetic acid mixtures

	Acid, %w/w taken	Acid, %w/w found	Relative error, %
PPA	77.3	78.3	+1.2
H_2SO_4	22 7	22.2	−2 2
PPA	57.5	57.6	+0.2
H_2SO_4	42.5	42.0	−1.2

Table 2. Typical assay results for PPA and H_2SO_4 in mixtures

Sample	H_2SO_4, %	Relative error	PPA, %	Relative error
1	24.2; 24.4	0.8	75.7; 76.1	0.5
2	25.0; 24.7	1.2	75.7; 75.6	0.1
3	24.2; 24.3	0.4	76.8; 77.1	0.4

phuric acid should also be experimentally determined in the manner used for sample assay. Typical equivalent weights found for hydrolysed PPA and sulphuric acid were 86.8 and 51.6, respectively. Typical values of the phosphorus pentoxide and orthophosphoric acid equivalents of the PPA were 83.4% (literature,[12] 83 0) and 115.3% (literature,[12] 115.0) respectively.

To test the accuracy of this method, synthetic mixtures were prepared and assayed. Results are presented in Table 1.

Precision of the determinations is good, as illustrated in Table 2 which presents duplicate assay results for both acids in several mixtures which were assayed.

A 3-hr reflux time was found adequate for complete hydrolysis of the PPA samples, although 8 hr has been used for ortho- and polyphosphate mixtures.[7] Some condensed phosphates have been shown to be completely hydrolysed in less than 4 hr.[13] In this work, 8 hr of reflux gave assay results essentially identical with those of 3 hr. Refluxing for 1.5 hr left the PPA incompletely hydrolysed.

This paper reports a convenient titrimetric method for determination of sulphuric and polyphosphoric acids in mixtures. Accuracy and precision are good and the method is useful to monitor the acid proportions, which are important to ensure correct dehydrating strength in chemical reactions.

Acknowledgements—The authors thank Mr. John D. Brunson for assistance in testing this method.

Summary—Polyphosphoric and sulphuric acids in a mixture may be determined simultaneously by titration. Experimental equivalent weights of the separate individual acids are first determined and these values are used to calculate weight percents for each acid in the mixture. Hydrolysis of the polyphosphoric acid (PPA) for three hours is necessary for quantitative conversion into orthophosphoric acid.

TOTAL SYSTEMATIC ERROR IN REDOX TITRATIONS WITH VISUAL INDICATORS—II EXPERIMENTAL VERIFICATION

Adam Hulanicki and Stanisław Głąb
Institute of Fundamental Problems in Chemistry, University, Warsaw, Poland

(*Received* 3 *September* 1975. *Accepted* 11 *January* 1976)

Equations were given in a previous paper,[1] describing the transition potential of an indicator (E), the end-point error (ΔV_T), the indicator consumption error (ΔV_I) and the total absolute titration error (ΔV). The transition potential depends on the formal redox potential of the indicator, its spectrophotometric characteristics and in most cases on the indicator concentration. The total systematic error is a function of the formal redox potentials of the titrant and titrand, and the transition potential of the indicator corresponding to the end-point potential of the titration.

In this study the calculated transition potentials and errors have been compared with the experimental values for some indicators. As model systems the following were chosen. Variamine Blue and 4-amino-4′-methyldiphenylamine as reversible one-colour indicators [titration of iron(II) with vanadium(V)]. Ferroin as a reversible two-colour indicator [titration of iron(II) with cerium(IV). Diphenylaminesulphonic acid as a pseudoreversible[2] one-colour indicator [titration of iron(II) with cerium(IV)].

EXPERIMENTAL

Evaluation of transition potential

The transition potentials were evaluated by the method proposed by Belcher *et al.*[3] with concentrations from 1×10^{-5} to $5 \times 10^{-4}M$, for the indicator in the titrated solution at the end-point.

All titrations were carried out in 200-ml beakers approximately 5 cm in diameter, with a magnetic stirrer, and a platinum–saturated calomel electrode pair for measurement of the potentials. The indicator was in most instances added as the $5 \times 10^{-3}M$ solution. The titrations were started with $0.1M$ titrant and the end-points were approached by adding a $0.01M$ solution for better evaluation of the colour-change and potential at the end-point.

In the case of Variamine Blue the colour changes from green to violet-red. The absorbance of solutions at the end-point was measured at $\lambda = 530$ nm where the oxidized form has an absorption maximum.[4] In several titrations the final absorbances were in the range 0.27–0.32.

For 4-amino-4′-methyldiphenylamine the colour change was similar, and the absorbances at 520 nm were in the range 0.26–0.33 at the end-point.

Ferroin changed from red to colourless at concentrations below $5 \times 10^{-5}M$, but above $1 \times 10^{-4}M$ a distinct two-colour change from red to blue-violet was observed. As the sensitivity of the eye to these two colours is different, the absorbance ratio at the end-point has been determined experimentally. Equal absorbances at 510 and 590 nm[5, 6] do not correspond to the point of visual colour change, but an absorbance ratio of 3:2, corresponding to a concentration ratio of 30:1, does. For this reason an M-value of 1.5 was used in the subsequent calculations.

Because diphenylaminesulphonic acid is a pseudoreversible indicator its apparent transition potential may change when some of the indicator has been destroyed by local excesses of the titrant. The amount lost depends on the rate of stirring and on the duration of the whole titration. Two sets of measurements were therefore made with this indicator—with total titration times 5 and 10 min. At the end-point the absorbance at 585 nm[7] was found to be in the range 0.3–0.7. At low concentrations of this indicator the solution changed from colourless to violet, but at higher concentrations, especially when the duration of the titration was longer, from green to violet. The experimental

Table 1. Conditions for titrations

Indicator	Titrand solution	E_x^0, V	Titrant	E_T^0, V

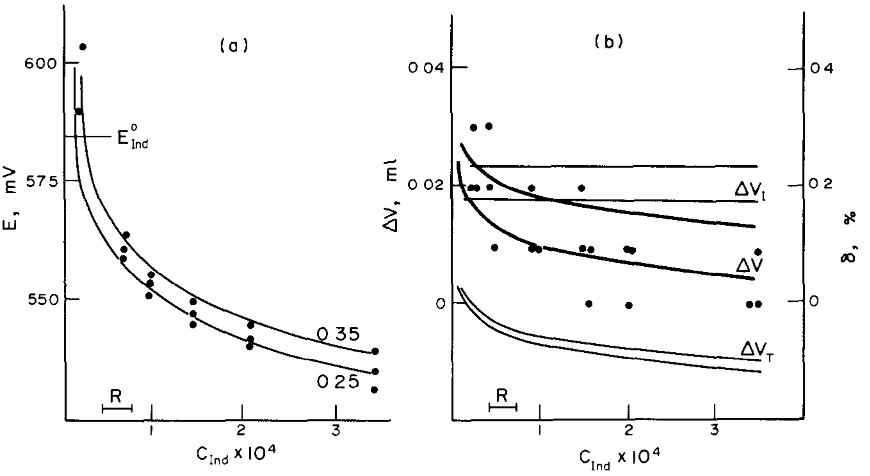

Fig 1 The change of transition potential (*a*) and titration error (*b*) as a function of indicator concentration for titration of iron (II) with vanadium (V), with Variamine Blue as indicator. Lines were calculated for $A = 0.25$ and 0.35. Points were obtained experimentally. ΔV_I—indicator consumption error, ΔV_T—end-point error, ΔV—total error R denotes usual concentration range of indicator.

transition potentials were not affected by the presence of phosphoric acid in the titrand solution.

Evaluation of total titration error

Titrations in the systems mentioned in Table 1 were carried out in parallel by using visual indicators and potentiometrically to the potential corresponding to the calculated equivalence point. The necessary formal potential values were estimated from the titration curves. The total experimental error was calculated as the difference between the results of the potentiometric and visual titrations, both performed under the same conditions and concentrations.

RESULTS AND DISCUSSION

Variamine Blue and 4-amino-4′-methyldiphenylamine are reversible one-colour indicators. However in titration of iron(II) with vanadium(V) the colour at the end-point changes from green to red-violet, because the vanadium(IV) is itself blue. This should not influence the validity of equations describing the transition potential and total error of titration. The formal redox potentials for these indicators are 0.585 V and 0.568 V respectively,[4, 7] under the titration conditions. The molar absorptivities of the oxidized forms are 7×10^3 and 6×10^3 $l.mole^{-1}.cm^{-1}$, respectively.[4, 7] The transition potential was calculated, assuming the absorbance at the end-point to be 0.25 or 0.35 (Figs. 1*a* and 2*a*). The agreement between calculated and experimental transition potentials for various indicator concentrations seems to support the assumptions.

The titration errors were also evaluated for the same experimental conditions (Figs. 1*b* and 2*b*). The precision of reading the volume of titrant (0.01 ml) results in some scatter in the experimental points around the calculated curve. The titration error was also calculated for the two values of absorbance at the end-point, *i.e.* 0.25 and 0.35, according to equation (13) and the appropriate equation in Table 3 in the previous paper.[1] Under the conditions of titration with the two indicators the following values of formal potentials were assumed: in titration with Variamine Blue: $E^0_x = 0.360$ V, $E^0_T = 0.865$ V; in titration with 4-amino-4′-methyldiphenylamine. $E^0_x = 0.317$ V, $E^0_T = 0.800$ V

With the reversible indicator ferroin, the situation is more complicated. At concentrations above $10^{-4}M$ it can

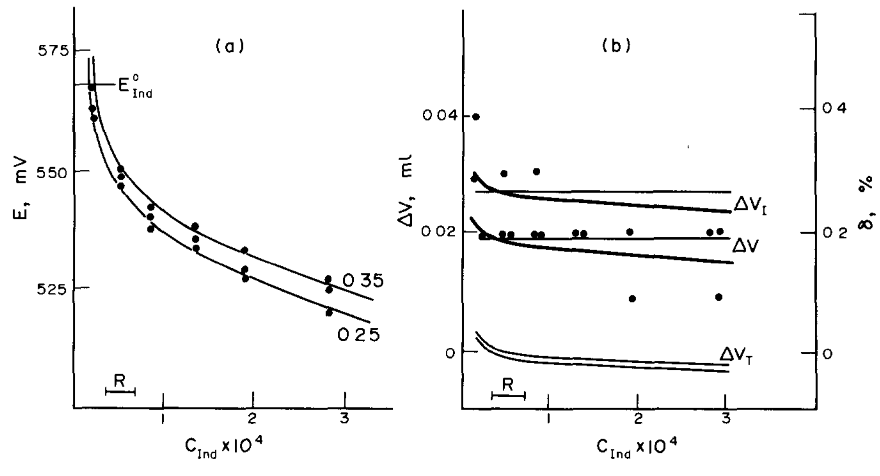

Fig. 2. The change of transition potential (*a*) and titration errors (*b*) as a function of indicator concentration for titration of iron (II) with vanadium (V), with 4-amino-4′-methyldiphenylamine as indicator. Symbols *etc.* as for Fig. 1.

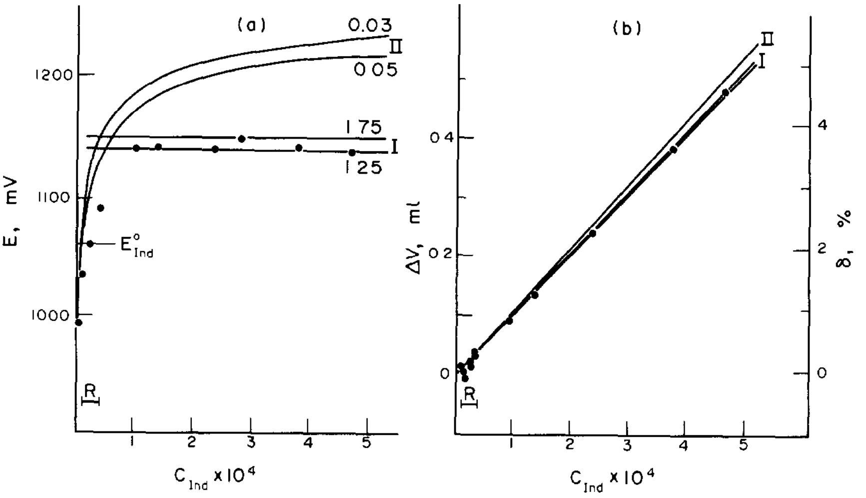

Fig. 3. The change of transition potential (*a*) and total titration errors (*b*) as a function of indicator concentration for titration of iron (II) with cerium (IV), with ferroin as indicator. Lines were calculated for a two-colour indicator (curves I) assuming $M = 1.25$ and 1.75, and a one-colour indicator (curves II) assuming $A' = 0.03$ and 0.05. Points were obtained experimentally. *R* denotes usual concentration range of indicator.

be considered as a two-colour indicator and its transition potential should therefore be independent of concentration (Fig 3*a* straight lines I). If ferroin is considered as a one-colour indicator then the transition potential would be expected to vary with concentration, as in the curves II, Fig. 3*a*. The measured potentials are in fact independent of concentration at higher indicator concentrations, whereas at lower concentrations they fit the predicted curve quite well. Because the indicator concentrations usually used in titrations do not exceed $5 \times 10^{-5}M$, ferroin should be treated in practice as a one-colour indicator. Two values of residual absorbance were used in the calculations for ferroin, namely 0.03 and 0.05, and for a two-colour indicator the ratio of absorbances at the end-point was accepted as $M = 1.25$ or 1.75. The value previously determined experimentally for this system is 1.5. The molar absorptivities for the reduced and oxidized forms of the indicator are 1.11×10^4 and 6×10^2 $\text{l mole}^{-1}.\text{cm}^{-1}$, and the formal redox potential is 1.06 V in 1*M* sulphuric acid.

The titration error in this system varies linearly with indicator concentration over a wide range, in spite of small differences in the slope depending on whether the system is considered as one- or two-colour (Fig. 3*b*) At higher indicator concentrations the two-colour relationship is in better agreement with the experimental data, and for the lowest concentrations either concept can be used. The linearity follows from the fact that the greater part of the error is due to titration of the indicator, since the large difference between the formal potentials of the titrand ($E^0_x = 0.683$ V) and the titrant ($E^0_T = 1.433$ V) leads one to expect that the end-point error would always be less than 0.01 ml.

In this example it is clear that the change from one- to two-colour indicator behaviour depends on the indicator concentration at which the observer can just perceive the colour of the oxidized form.

Diphenylaminesulphonic acid may be classified as a pseudoreversible indicator, because of the irreversibility of the chemical reaction, and also because of the instability of the oxidized form ($\tau_{1/2} = 13$ min in 1*M* sulphuric acid). The main assumption on which the equations for the transition potential and titration error are based is therefore not fulfilled, but it is interesting to see by how much the experimental values and those calculated for a reversible indicator differ.

The formal redox potential of the reaction

$$2\,\text{Ind}_{\text{red}} \rightarrow \text{Ind}_{\text{ox}} + 4e$$

may be determined from the half-oxidation potential ($E_{1/2} = 0.81$ V)[2] at a given concentration ($C_{\text{Ind}} = 8 \times 10^{-4}M$):

$$E^0_{\text{Ind}} = E_{1/2} + 0.059/4 \log C_{\text{Ind}} = 0.765 \text{ V}.$$

This value, and the molar absorptivity $\epsilon_{\text{ox}} = 1.4 \times 10^4$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ enable us to calculate the transition potentials for $A = 0.2$ and $A = 0.9$ (Fig. 4) and hence to compare the calculated total error with experimental data (Fig 5). The calculated error in the absence of phosphoric acid is negative because the difference between the formal potentials of the titrand and indicator is small ($\Delta E^0 = 0.082$ V) but in the presence of phosphoric acid the decrease in potential of the Fe(III)/Fe(II) system ($\Delta E^0 = 0.160$ V) brings the theoretical error to a small positive value, mainly due to consumption of titrant by the indicator.

The experimental errors are always more positive than the calculated ones. Up to $5 \times 10^{-5}M$ indicator concen-

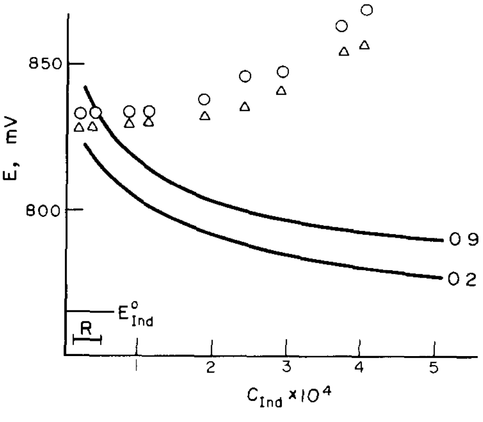

Fig. 4. The change of transition potential as a function of indicator concentration for titration of iron (II) with cerium (IV), with diphenylaminesulphonic acid as indicator. Lines were calculated for $A = 0.2$ and 0.9 Points were obtained experimentally for titration time 5 min (△) and 10 min (○).

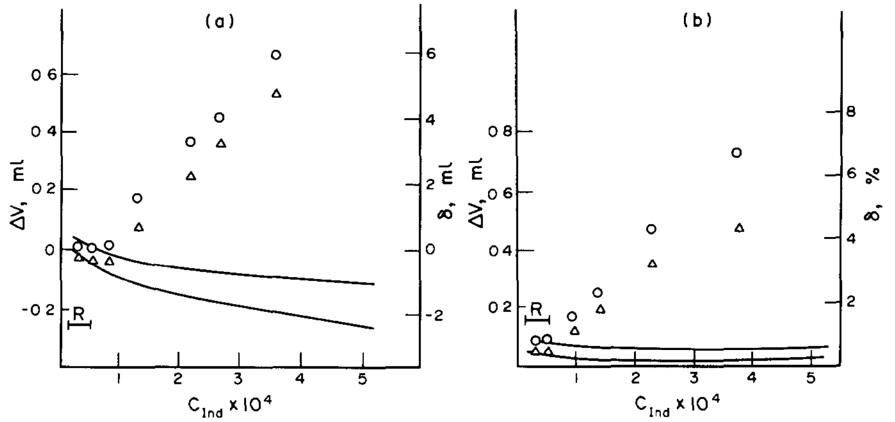

Fig. 5. The change of total titration errors as a function of indicator concentration for titration of iron (II) with cerium (IV), with diphenylamine sulphonic acid as indicator, in absence (*a*) and presence (*b*) of phosphoric acid. Symbols *etc.* as for Fig. 4.

tration the error is less than 0.05 ml (relative error 0.5%). For concentrations up to $1 \times 10^{-4}M$ in the absence of phosphoric acid the indicator consumption and end-point error compensate and the total error is still small. This is not the case when phosphoric acid is added, as is usually done in practice. At higher concentrations the error is always positive and too large to be acceptable in practice.

As decomposition of the indicator is time-dependent, the measurements were done for total titration times of 5 and 10 min. In the latter the error is significantly greater (more positive) indicating that the undesired process proceeds to a greater extent. Rapid titration is therefore advantageous, and the error can be further diminished by adding the indicator only shortly before the end-point. It must also be pointed out that effective stirring decreases local excesses of the titrant and therefore also decreases the total error.

This study clearly shows that for a reversible indicator the agreement between the calculated and experimental values of the titration error is quite good, and the equations presented may be used successfully for predicting the magnitude of the error. In the case of pseudoreversible indicators the equations give only the lowest possible value (in relative figures) of the error, whereas the real error is always more positive, and depends very much on the experimental conditions such as stirring, duration of titration etc.

Acknowledgement—The authors are greatly indebted to Professor R. Belcher, Chairman of the IUPAC Commission V-1, for stimulation of this study and his kind interest and discussion in the course of this work.

Summary—The equations for calculating the transition potential of a redox indicator and the total titration error have been verified experimentally. Good agreement has been obtained for reversible indicators such as Variamine Blue, 4-methyl-4′-aminodiphenylamine and ferroin. In the latter case it was shown that at the usual concentrations the indicator acts as a one-colour indicator, whereas for higher concentrations its behaviour is typical of a two-colour indicator. In the case of a pseudoreversible indicator—diphenylaminosulphonic acid—the calculated values give only the minimum error. In real conditions the error is always more positive.

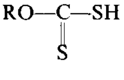
DETERMINATION OF ORGANOTRITHIOCARBONATES WITH IODINE AND IODINE HALIDES IN NON-AQUEOUS MEDIA

BALBIR CHAND VERMA and SWATANTAR KUMAR
Department of Chemistry, H.P. University, Simla 171001, India

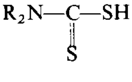
(*Received* 9 *December* 1975. *Accepted* 16 *January* 1976)

Xanthates, dithiocarbamates and organotrithiocarbonates are the salts of the corresponding xanthic (**I**), dithiocarbamic (**II**) and trithiocarbonic (**III**) acids respectively,



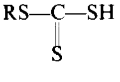
$\mathrm{RO{-}\underset{\Large S}{\overset{}{\underset{\|}{C}}}{-}SH}$

(**I**)



$\mathrm{R_2N{-}\underset{\Large S}{\underset{\|}{C}}{-}SH}$

(**II**)

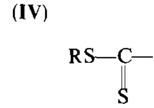


$\mathrm{RS{-}\underset{\Large S}{\underset{\|}{C}}{-}SH}$

(**III**)

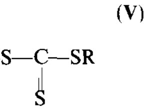
(R = alkyl or aryl groups)

and are characterized by the presence of the  $\mathrm{-C\langle^{S^-}_{S}}$ group. Because of their applications in analysis, industry, medicine and agriculture, their determination is of great interest and scope. Trithiocarbonates have found fewer applications than the other analogues. In spite of the tendency of these species to be easily oxidized to the corresponding dixanthogens (**IV**), thiuram disulphides (**V**) and bis[alkyl(aryl)mercapto thiocarbonyl] disulphides (**VI**) respectively, these compounds have not been widely studied by redox titrimetry. This is because of the tendency of these compounds to undergo decomposition with the acid media commonly used for redox titrations. Hence redox determination of these compounds in non-aqueous media is of value. Xanthates and dithiocarbamates have been determined in this way,[1–6] but the determination of trithiocarbonates by such methods does not appear to have attracted attention. This communication reports the use of iodine and iodine halides (monochloride, monobromide and trichloride) for the visual and potentiometric determination of trithiocarbonates in acetonitrile medium. The end-point in visual titrations is indicated by a sharp colour change from straw yellow to deep yellow (due to iodine) caused by the first drop of oxidant solution in excess. For potentiometric titration a platinum wire is used as an indicator electrode and an antimony or modified calomel electrode as reference



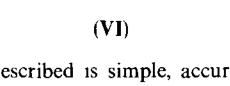
$\mathrm{RO{-}\underset{\Large S}{\underset{\|}{C}}{-}S{-}S{-}\underset{\Large S}{\underset{\|}{C}}{-}OR}$

(**IV**)



$\mathrm{R_2N{-}\underset{\Large S}{\underset{\|}{C}}{-}S{-}S{-}\underset{\Large S}{\underset{\|}{C}}{-}NR_2}$

(**V**)



$\mathrm{RS{-}\underset{\Large S}{\underset{\|}{C}}{-}S{-}S{-}\underset{\Large S}{\underset{\|}{C}}{-}SR}$

(**VI**)

The method described is simple, accurate, reliable and widely applicable.

EXPERIMENTAL

Apparatus

Potentiometric titrations were performed with an antimony or modified calomel (methanol saturated with potassium chloride was used instead of aqueous potassium chloride) reference electrode and a bright platinum wire indicator electrode.

Reagents

Acetonitrile. Distilled twice from phosphorus pentoxide.

Oxidants, 0.05N *in acetonitrile.* Iodine monobromide (solid) was prepared by the method of Popov and Skelly.[7] Commercially available iodine monochloride and trichloride were purified by reported methods.[8] Each oxidant solution was prepared by dissolving a little more than the calculated amount in the solvent. Iodine solution was standardized by titration against standard aqueous sodium thiosulphate. Iodine halides were standardized iodometrically in aqueous medium.

Trithiocarbonates. Prepared by shaking an equimolar mixture of the corresponding mercaptan, potassium hydroxide and carbon disulphide at a temperature below 10°. The compounds were recrystallized from suitable solvent mixtures and kept in a vacuum desiccator over phosphorus pentoxide.

Procedure

Aliquots of solutions of each compound in acetonitrile were taken in conical flasks (for visual titrations) or beakers (for potentiometric titrations) and diluted to 50–60 ml with the solvent. The solutions were cooled to room temperature and titrated visually or potentiometrically with standard (0.05*N*) iodine or iodine halide added from a microburette provided with a guard-tube for the protection from atmospheric moisture. In visual titrations, the end-point was marked by a sharp colour change from straw yellow to deep yellow.

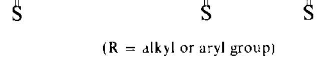
The solutions were magnetically stirred during potentiometric titrations. A sharp jump in potential was observed at the equivalence points. A series of potentiometric titrations was performed with different amounts of each compound and both electrode combinations.

The results of determinations with iodine monobromide (as a representative of these oxidants) are given in Table 1 Since the results obtained with both electrode assemblies agree closely, only one set (using platinum-modified calomel electrode assembly) is recorded in Table 1. The inflection points and potential jumps are also given.

RESULTS AND DISCUSSION

Johri and co-workers[9–11] have studied the oxidation of potassium trithiocarbonate, K_2CS_3, with various oxidants in acidic and alkaline media and have reported sulphate, carbon disulphide and/or elemental sulphur as the product(s) of oxidation, but no study seems to have been made of organic analogues.

The methods described here are based on oxidation with iodine in acetonitrile medium:



$$\mathrm{2RS{-}\underset{\Large S}{\underset{\|}{C}}{-}S^- + I_2 \rightarrow RS{-}\underset{\Large S}{\underset{\|}{C}}{-}S{-}S{-}\underset{\Large S}{\underset{\|}{C}}{-}SR + 2I^-}$$

(R = alkyl or aryl group)

§ Range of ten determinations.

In the titrations with iodine halides, iodine is formed as an intermediate which oxidizes the trithiocarbonates. The appearance and disappearance of the iodine colour (yellow) before the end-point can be readily seen. The end-point is indicated by the first permanent deep yellow colour.

Many trithiocarbonates (potassium salts of ethyl, n-propyl, isopropyl, n-butyl, isobutyl, n-amyl and benzyl trithiocarbonic acids) have been successfully titrated with iodine and iodine halides. The overall standard deviations calculated from the pooled data for all the visual and potentiometric titrations performed with 10 mg of each trithiocarbonate were 0.035 and 0.026 respectively. For 40 mg of each trithiocarbonate the values were 0.076 and 0.051 respectively.

The effects of some possibly interfering compounds was studied. No interferences were found from alkyl isothiocyanates, isocyanates, carbon disulphide and urea even when present in up to fivefold amounts relative to trithiocarbonates.

UNTERSUCHUNGEN ZUR BILDUNG VON *N*-NITROSO-NORNIKOTIN AUS NIKOTIN-*N*′-OXID

H.-J. KLIMISCH* und L. STADLER
Forschungsinstitut der Cigarettenindustrie e.V., Hamburg

(*Eingegangen am* 27. *Oktober* 1975. *Angenommen am* 12. *Januar* 1976)

Über das Vorkommen von *N*-Nitroso-Nornikotin (NNN) im Tabakrauch ist erstmals von Klus und Kuhn[1,2] und später von Hoffmann und Mitarbeitern[3] berichtet worden, wobei Werte bis zu 0,137 ppm im Tabakrauchkondensat gefunden wurden. Der Gehalt des Tabaks an NNN ist mit 0,3–90 ppm z.T. 10–100 mal höher als der des Kondensates.[3] Kürzlich wurde die biologische Aktivität des NNN als tumorerzeugende Substanz diskutiert.[4,5] Daher sind Untersuchungen zur Bildung des NNN von besonderem Interesse.

Für die Entstehung des NNN wurden bisher zwei Wege, nämlich die Bildung aus Nornikotin und aus Nikotin diskutiert,[1–3] wobei dem Nikotin aufgrund seiner höheren Konzentration größere Bedeutung zukommt. Eine Korrelation zwischen dem Nikotingehalt des Tabaks und dem NNN-Gehalt des Kondensates scheint gesichert zu sein;[2,3] ähnliches wird vom Nitratgehalt des Tabaks vermutet.[2] Dagegen lassen sich bisher keine eindeutigen Korrelationen des Alkaloid-, Nitrat- oder Nitritgehalts und des pH-Wertes im Tabak zum Gehalt an NNN im Tabak feststellen.[6] Bei *in vitro* Versuchen zur Bildung von NNN aus Nikotin und Nitrit lassen sich bei Raumtemperaturen nur geringe Mengen des Nitrosamins nachweisen. Bisher sind daher enzymatische oder bakteriologische Prozesse bei der Umwandlung von Nikotin zu NNN diskutiert worden

Von mehreren Autoren ist auf eine höhere Ausbeute an Nitrosaminen bei der Reaktion der tertiären Amine mit Nitrit, z.T unter dem Einfluß von Katalysatoren, hingewiesen worden.[7–9] In der vorliegenden Arbeit soll daher die *in vitro* Bildung von NNN aus Nitrit und Nikotin sowie Nikotin-*N*′-Oxid diskutiert werden.

MATERIAL UND METHODEN

Nikotin wurde unter Stickstoff im Vakuum über eine Vigreux Kolonne destilliert und wies nach dünnschichtchromatographischer Untersuchung keine nachweisbaren Verunreinigungen auf. Nikotin-*N*′-Oxid wurde nach einer Methode von Craig und Purushothaman[10] synthetisiert und als farblose Kristalle (Smp 151–153°) erhalten.

1. Umsetzung von Nikotin und Nitrit in wässriger Essigsaure

Ein g Nikotin wurde analog der Arbeitsvorschrift von Klus und Kuhn[2] unter Stickstoffbegasung in 25 ml 2,5*N* Essigsäure mit 1,725 g Natriumnitrit bei 20° bzw. 80° im thermostatisierten Wasserbad umgesetzt. Aliquote Proben wurden nach 15 Min, 60 Min und 240 Min entnommen, mit festem Na_2CO_3 alkalisiert, mit Benzol/Chloroform 8:2 ausgeschüttelt und auf 10 ml aufgefüllt. Die Komponenten wurden an einem dünnschichtchromatographischen System [DC-Fertigplatte Kieselgel 60 mit Fluoreszenzindikator F 254 (Merck AG); und Lösungsmittel Toluol:Isopropanol.10% wässriger Ammoniak (96:24:1)] getrennt und die Verbindungen mit Hilfe der König-Reaktion mit BrCN-Bedampfung sichtbar gemacht.

Halbquantitative Werte wurden über eine direkte Vermessung am Chromatogramm-Spektralphotometer (Zeiss AG) im Vergleich zu Eichkurven der jeweiligen Umsetzungsprodukte erhalten.

2. Umsetzung von Nikotin und Nitrit in Perchlorsäure

Wie vorher unter *1.* beschreiben wurde die Reaktion in 25 ml 10% wässriger Perchlorsäure [Methode von Lijinsky und Singer[9]] bei 20° bzw. 80° und 30 Min, 60 Min und 240 Min Einwirkungszeit durchgeführt und halbquantitative Werte des Unsetzungsproduktes NNN bestimmt.

3. Umsetzung von Nikotin-N′-Oxid und Nitrit in Perchlorsäure

Nikotin-*N*′-Oxid (0,2 g) wurde in einem 25 ml Kolben mit 5 ml 10% wässriger Perchlorsäure und 0,4 g Natriumnitrit bei 20° bzw. 80° umgesetzt. Aliquote Proben wurden nach 30 Min, 60 Min und 240 Min Umsetzungszeit entnommen, mit 2*N* Natriumhydroxid alkalisiert und mehrmals mit Methylenchlorid ausgeschüttelt. Aliquote Teile wurden an zwei dunnschichtchromatographischen Systemen getrennt:

(*a*) DC-Kieselgel 60/F 254 Platte (Merck AG); Fließmittel Chloroform:Methanol:Essigsäure (60:20:1)

(*b*) Fertigfolie Polyamid 11 (Macherey, Nagel & Co.), Fließmittel Benzol:Methanol.Dimethylformamid (93:5:2) Vom Umsetzungsprodukt NNN wurden halbquantitative Werte bestimmt

4. Umsetzung von Nikotin mit Nitrit in wässriger Perchlorsäure in Gegenwart von Formaldehyd

Reaktionen wie unter *2.* beschrieben, aber unter Zusatz von 1 ml 37% wässrige Formaldehydlösung.

5. Umsetzung von Nikotin-N′-Oxid mit Nitrit in wassriger Perchlorsaure in Gegenwart von Formaldehyd

Reaktionen wie unter *3.* beschrieben unter Zusatz von 1 ml 37% wässrige Formaldehydlösung.

6. Umsetzung von Nikotin-N′-Oxid mit Nitrit in wassriger Perchlorsäure in Gegenwart von Chlorogensaure

Reaktionen wie unter *3.* beschrieben, aber nur bei 23° und unter Zusatz von 50 mg Chlorogensäure.

ERGEBNISSE UND DISKUSSION

Die Umsetzungen des tertiären Amins Nikotin mit Nitrit sind, wie die Tabelle 1 zeigt, deutlich Zeit- und pH-abhängig. Damit bestätigen sich Befunde verschiedener Arbeitsgruppen,[2,3,11] deren Ausbeute an *N*-Nitroso-Nornikotin z.T. allerdings deutlich höher liegen. Es kann hier nicht endgültig entschieden werden, ob die Reinheit des eingesetzten Nikotins, die Stickstoffbegasung und damit der Ausschluß von Sauerstoff oder die selektivere Bestimmung des NNN nach dünnschichtchromatographischer Tren-

nung zu einer niedrigeren Ausbeute an NNN führen. Auf der Kieselgelplatte lassen sich neben Nikotin (R_f = 0,55) und *N*-Nitroso-Nornikotin (R_f = 0,67) zwei weitere nicht identifizierte Flecken mit R_f = 0,23 und R_f = 0,75 erkennen, so daß mit dem Auftreten anderer Umsetzungsprodukte[2] gerechnet werden muß.

Von mehreren Autoren[7,8,9] ist beobachtet worden, daß eine Nitrosierung tertiärer Amin-*N*-Oxide im Sinne einer Polonovski-Reaktion[12] zu einer höheren Ausbeute an Nitrosaminen führt. Wie ein Vergleich der NNN-Ausbeute der Tabellen 1 und 3 zeigt, liegt auch die Ausbeute bei der Umsetzung mit Nikotin-*N*-Oxid bis zu dreifach höher als beim Einsatz von Nikotin.

Sowohl im Trennsystem auf der Kieselgelplatte als auch auf der etwas schärfer trennenden Polyamidfolie lassen sich aus dem Reaktionsgemisch neben Nikotin-*N*'-Oxid (R_f-Polyamid = 0,13) und *N*-Nitroso-Nornikotin (R_f-Polyamid = 0,63) zwei weitere nicht identifizierte Umsetzungsprodukte (R_f-Polyamid = 0,58 und 0,71) und Nikotin (R_f-Polyamid = 0,24) nachweisen, so daß auch bei diesen Reaktionen mit dem Auftreten weiterer Produkte zu rechnen ist. Da sich bei der Reaktion z.T. beträchtliche Mengen an Nikotin bilden, können Anteile des NNN auch aus der Reaktion zwischen Nikotin und Nitrit entstehen. Die Ausbeuten an NNN liegen bei der Reaktion des Nikotin-*N*'-Oxids aber deutlich höher, so daß eine Bildung des NNN im Sinne einer Polonovsky-Reaktion als sehr wahrscheinlich anzusehen ist.

In letzter Zeit werden verstärkt die katalytischen Einflüsse von Carbonylverbindungen[13] und Polyphenol-Körpern[14] bei der Bildung von Nitrosaminen aus tertiären Aminen und Nitrit diskutiert. Dabei wurden sowohl reaktionsbeschleunigende als auch reaktionshemmende Effekte beobachtet.

Bei der Umsetzung eines tertiären Amins mit Nitrit in Gegenwart von Formaldehyd wird am Beispiel des Nikotins eine Reaktion zum Nitrosamin deutlich gehemmt (Tabelle 2). Im Gegensatz hierzu (Tabelle 3) wird durch Formaldehyd die Umsetzung eines tertiären Amin-*N*-Oxids mit Nitrit zum Nitrosamin katalytisch so beschleunigt, daß selbst bei Raumtemperaturen bereits bemerkenswerte Mengen *N*-Nitroso-Nornikotin nachweisbar sind. Der gleiche Effekt läßt sich bei der Umsetzung in Gegenwart von Chlorogensäure feststellen (Tabelle 3).

Damit kann gezeigt werden, daß eine Entstehung von *N*-Nitroso-Nornikotin in Gegenwart verschiedener Katalysatoren, wie sie auch in der Tabakpflanze in reiner oder derivatisierter Form vorkommen, aus Nikotin-*N*'-Oxid selbst bei niedriger Temperaturen möglich ist. Ob Nikotin-*N*'-Oxid damit als ein Präkursor für *N*-Nitroso-Nornikotin im Tabak anzusehen ist, muß durch weitere Untersuchungen im Tabak wie etwa der Bestimmung des Nikotin-*N*'-Oxid-Gehaltes in Korrelation zum *N*-Nitroso-Nornikotin bei gleichzeitiger Bestimmung ähnlicher Katalysatoren, wie in dieser Arbeit verwendet, geklärt werden.

Wie Klus und Kuhn[1] durch Bestimmung des *N*-Nitroso-Nornikotingehaltes im tabakfreien Filter einer Zigarette diskutieren,[2] sollte NNN zumindest anteilsmäßig ein nativer Rauchbestandteil sein. Ob damit NNN nicht zumindest anteilweise aus dem Tabak in den Rauch übergeht, sollte durch Messungen der Transferrate mit ^{14}C-*N*-Nitroso-Nornikotin bestimmt werden. Hecht und Mitarb.[5] vermerken immerhin eine Rauchübergangsrate um 10%.

ANALYTICAL DATA

EXTRACTION AND PHOTOMETRIC DETERMINATION OF MICROAMOUNTS OF Zn^{2+}, Cd^{2+} AND Hg^{2+} WITH 1-(2-QUINOLYLAZO)-2-ACENAPHTHYLENOL

ISHWAR SINGH, Y. L. MEHTA, B. S. GARG and R. P. SINGH
Department of Chemistry, University of Delhi, Delhi 110007, India

(*Received* 31 *October* 1975 *Accepted* 1 *February* 1976)

The analytical potentialities of 1-(2-quinolylazo)-2-acenaphthylenol (QAAc), already synthesized,[1] for the spectrophotometric determination of Zn^{2+}, Cd^{2+} and Hg^{2+} are reported. They may be compared with those of other heterocyclic azo dyes used for this purpose[2–8]

EXPERIMENTAL

Reagents

Stock solutions of zinc, cadmium and mercury were prepared by dissolving appropriate amounts of analytical-reagent grade ZnO in perchloric acid, $Cd(CH_3COO)_2 \cdot 2H_2O$ in water, and metallic mercury in perchloric acid and were standardized by conventional methods if necessary. A stock solution of QAAc was obtained by dissolving the requisite quantity in pure methanol In no case reagent solutions used were over a week old. The pH was adjusted in the Zn^{2+} and Cd^{2+} systems with a 2*M* solution of sodium acetate, and with 0.5*M* sodium carbonate and 1*M* sodium perchlorate in the Hg^{2+} system. All other reagents used were of the highest purity.

RESULTS AND DISCUSSION

Solvent effect and stability

Red metal–QAAc species precipitate from 50% methanol They are soluble in various organic solvents Carbon tetrachloride, in which the coloured chelates are stable for at least 8 hr, was found to be the most suitable.

The physicochemical characteristics of the metal complexes of QAAc are summarized in Table 1.

Recommended procedures

Zn(II) and Cd(II). To a suitable aliquot containing 2–7 μg of Zn(II) or 4–23 μg of Cd(II) add 5 ml of 10^{-3} *M* QAAc (in methanol), followed by 4 ml of 2 *M* sodium acetate to give the appropriate pH (Table 1). Dilute to 10 ml and extract the complex into 10 ml of carbon tetrachloride.

Hg(II). To a suitable aliquot of solution containing 5–20 μg of Hg(II), add 5 ml of 10^{-3} *M* QAAc (in methanol), followed by the addition of 0.1 ml of 0.5 *M* sodium carbonate and 1 ml of 1 *M* sodium perchlorate (necessary

for complete extraction), dilute to 10 ml and extract the complex into 10 ml of carbon tetrachloride.

Measure the absorbance against a reagent blank.

Effect of foreign ions

The effect of other ions was studied by taking 6.5 μg of Zn^{2+}, 22.4 μg of Cd^{2+} or 20.1 μg of Hg^{2+}, adding different amounts of the ion to be investigated and following the recommended procedure. Table 2 records the results; the tolerance limits are the concentrations which do not cause a deviation of more than ±2% in the absorbance.

Summary—1-(2-Quinolylazo)-2-acenaphthylenol (QAAc) combines with Zn(II), Cd(II) and Hg(II), giving deep red 1:2 complexes which are extractable in CCl_4 and other organic solvents. Spectrophotometric methods based on the reactions are sensitive and fairly selective, the Sandell's sensitivities being 8.8×10^{-4}, 2.4×10^{-3} and 3.3×10^{-3} μg/cm² for Zn(II), Cd(II) and Hg(II) respectively.

ANNOTATIONS

THE RELATIONSHIP BETWEEN THE INFLECTION POINT AND EQUIVALENCE POINT OF A POTENTIOMETRIC TITRATION

WALTER LUND
Department of Chemistry, University of Oslo, Oslo 3, Norway

(*Received* 21 *October* 1975. *Accepted* 26 *November* 1975)

Although the principles of potentiometric titrations are described in some detail in almost every modern textbook of analytical chemistry, it appears that the treatment given in most of these books is incorrect on one particular point, namely the relationship between the equivalence point and the inflection point of the titration curve. In the following discussion a brief outline of this question will be given.

The end-point of a potentiometric titration is usually defined as the inflection point of the titration curve. Moreover, it is usually stated quite categorically that the inflection point will coincide with the equivalence point of the titration, provided that the titration curve is "symmetrical", whereas the inflection point of an "unsymmetrical" curve is said to differ somewhat from the equivalence point. The term "symmetrical" is used to indicate that the reactants combine in a one-to-one stoichiometric ratio. In contrast to these statements a rigorous mathematical treatment reveals that the inflection point and equivalence point of potentiometric titrations will *never* coincide for so-called symmetrical titration curves.[1-3] Only for unsymmetrical reactions may there be conditions under which the inflection point and equivalence point will coincide.[2]

Fortunately, the difference between the inflection point and the equivalence point is usually negligible. However, the categorical form of the statements found in most textbooks could easily lead the reader to the erroneous conclusion that the inflection point of a symmetrical curve coincides with the equivalence point also in a mathematical sense. In this connection it is particularly misleading that attention is frequently drawn to the lack of coincidence for unsymmetrical curves, while at the same time claiming coincidence for symmetrical curves. As already mentioned, the opposite statement is more correct.

The somewhat misleading treatment found in many textbooks concerning this topic may be due to the early results of Roller[4] and Butler.[5] As pointed out by Meites[1] their incorrect results were due to the neglect of dilution in the mathematical treatment of the titration curves. For ion-combination titrations, such as acid–base and precipitation titrations, this neglect results in the coincidence of the inflection point and equivalence point provided that the titration curve is symmetrical. However, for complexometric titration curves the two points in question will never fully coincide, even if volume changes are neglected. This is rather surprising, as complex formation is in some ways the simplest of the common titration reactions. To illustrate this point the difference between the equivalence point and inflection point is calculated below for the complexometric titration of A with B according to the reaction $A + B \rightleftharpoons AB$.

Three equations must be taken into consideration:

$$C_A = [A] + [AB] \tag{1}$$

$$C_B = [B] + [AB] \tag{2}$$

$$[AB] = K[A][B] \tag{3}$$

where C_A and C_B are the total concentrations of A and B respectively, and K is the formation constant for the complex AB. If volume changes are neglected, the equation for the potentiometric titration curve can be obtained by eliminating [B] and [AB] from equations (1), (2) and (3).

$$K[A]^2 + (KC_B - KC_A + 1)[A] - C_A = 0 \tag{4}$$

or written in an explicit form

$$pA = \log(2K) - \log\{[\sqrt{(KC_B - KC_A + 1)^2 + 4KC_A}] - [KC_B - KC_A + 1]\} \tag{5}$$

where pA ($= -\log[A]$) is a function of C_B, the concentration of titrant. The concentration of C_B at the inflection point of the titration curve is calculated by differentiating equation (5) twice with respect to C_B:

$$\frac{d^2(pA)}{dC_B^2} = -(\log e)K^2(KC_B - KC_A + 1) \times \{(KC_B - KC_A + 1)^2 + 4\,KC_A\}^{-3/2} \tag{6}$$

At the inflection point the second derivative is zero, giving

$$C_B = C_A - K^{-1} \tag{7}$$

From equation (7) it is seen that the inflection point does not coincide with the equivalence point ($C_B = C_A$), even though the titration curve is symmetrical, and volume changes are neglected. However, the difference between the inflection point and equivalence point is only K^{-1}, which implies that the difference is quite insignificant. It turns out that the same holds for systems in which volume changes are taken into consideration.

As a conclusion of the discussion above the author would like to point out that it would be wise to avoid too categorical statements when discussing the inflection point of titration curves. In introductory textbooks it seems most appropriate to explain in general terms that the inflection point is usually very close to the equivalence point of the titration, although the two points do not coincide in a mathematical sense.

DETERMINATION OF 14 TRACE ELEMENTS IN COBALT BY PROTON-ACTIVATION ANALYSIS

V. Krivan
Max-Planck-Institut für Metallforschung, Stuttgart, Institut für Werkstoffwissenschaften,
Laboratorium für Reinststoffe, 7070 Schwäbisch Gmünd, Katharinenstrasse 17,
Federal Republic of Germany

(*Received* 31 *December* 1975. *Accepted* 11 *February* 1976)

Summary—Proton-activation analysis has been applied to the determination of 14 trace impurities in cobalt. The method consists of a short (~10 min) and a longer (~2 hr) irradiation of the sample with 13-MeV and 12-MeV protons, respectively, followed by high-resolution γ-ray spectrometry. The elements Ti, Cr, Fe, Ni, Cu, Zn, Nb, Mo, Ru and W have been determined in VP-purity cobalt. In the case of V, Cu, Zr, Pd and Sn, the amounts present were below the limit of detection. In the case of Fe, Ni, and Mo, the results are compared with those obtained by a second independent method. Data on reproducibility, limits of detection and possible interferences are given.

Relatively few trace analytical studies have been performed on cobalt matrices of good and high-purity grades. Optical emission spectrography has been used to determine Si, Mn, Fe, Ni, Cu and Zn,[1] and in addition Al[2] and also As and Sb[3] in cobalt. A spectrographic technique used for the determination of all the above-mentioned elements and, in addition, the alkali metals, Ca, Ti, V, Cr, Nb, Mo, Rh, Pd, Cd, Ag, W and Tl, in cobalt of 99.999% purity has been described by Tombu[4] together with a listing of the different chemical methods for the determination of H, C, N, O, Na, Mg, Al, Si, P, S, K, Ca, Mn, Fe, Ni, Cu, Zn, As, Se, Sn, Sb, W, Tl, Pb and Bi. Unfortunately, neither the concentration intervals to which the individual methods have been applied nor the limits of detection were given. Activation analytical techniques have rarely been applied to the analysis of cobalt matrices.[5,6] In activation analysis with reactor neutrons, there are difficulties with the very high matrix activity due to the high thermal neutron cross-section and the resonance integral for the $^{59}Co(n,\gamma)^{60}Co$ reaction and the long half-life of ^{60}Co. Radiochemical neutron activation analysis has been used for the determination of Cu,[7,8] Mn and Zn.[8]

Recently an article by Benaben, Barrandon and Debrun has appeared[9] in which the application of an instrumental proton-activation technique to multielement analysis of cobalt has been described. However, the experimental conditions and sample types used by these authors differ from those used in the present work. While they irradiated the cobalt samples with 10-MeV protons for 1 hr, in our case the cobalt samples were activated with 13-MeV protons to produce short-lived indicator radionuclides in short irradiations (~10 min), and with 12-MeV protons to produce long-lived indicator radionuclides in longer irradiations (~2 hr). To check the accuracy of the proton-activation technique described here, analytical results for iron, nickel and molybdenum are compared with results obtained by atomic-absorption spectrometry and by X-ray fluorescence spectrometry.

EXPERIMENTAL

Sample and standards

A cobalt sample of VP grade supplied by Material Research, GmbH, Eching bei München, West Germany, was analysed. From the cobalt metal, targets with a thickness of ~0.6 mm were cut. To remove possible surface contamination, a pre-irradiation chemical etch was accomplished with dilute nitric acid (1:1 ultrapure water and nitric acid). Thick metal targets of pure elements, their alloys or pressed powder mixtures were used for the standardization. For the etching of the standards, different solutions were used according to the character of the metal For the measurements of the activation curve of the $^{59}Co(p,pn)^{58}Co$ reaction, stacked foils of VP-purity cobalt were used

Irradiation

Irradiations were performed with 12-MeV and 13-MeV protons at the Karlsruhe isochronous cyclotron. For standardization, the average beam currents were 5–200 nA and the irradiation times were 20–60 sec Cobalt samples were irradiated in a water-cooled target holder for 5–120 min with beam intensities of 3–5 MeV. The activation curve was measured for proton energies up to 25 MeV.

Data acquisition

Gamma-rays were counted with a 55-cm^3 Ge(Li) detector having an energy resolution of 2.1 keV FWHM for the 1.332-MeV γ-ray of ^{60}Co and a peak-to-Compton ratio of 29:1. The detector was coupled with a 4096-channel pulse-height analyser. Computer programs[10] were used to list and plot the spectra and to determine the energies and intensities of the photopeaks. Data on the reaction studied and on the properties of the indicator radionuclides were obtained from recent compilations and tables[11–14]

RESULTS AND DISCUSSION

Selection of activation reactions

Inspection of the nuclear data and preliminary experiments indicated proton-activation analysis to be

Table 1. Proton-induced cobalt reactions producing radionuclides

Reaction	Q-value, MeV	Half-life	γ-Rays, MeV	Intensity, %
^{59}Co(p,n)^{59}Ni	- 1.9	7.5 x 10^{4} yr	-	-
^{59}Co(p,pn)^{58m}Co	-10.5	8.94 hr	0.0249	0.03
^{59}Co(p,pn)^{58}Co	-10.5	70.78 d	0.5110 0.8106 0.8636 1.6748	30.0 99.4 0.7 0.5
^{59}Co(p,p2n)^{57}Co	-19.0	270.0 d	0.0144 0.1221 0.1364 0.5703 0.6921	9.5 85.6 10.6 0.01 0.15
^{59}Co(p,αn)^{55}Fe	- 8.0	2.7 yr	-	-

the most suitable with respect to the instrumental performance and the multi-element character of the cobalt analysis. In activation with thermal neutrons, the matrix is strongly activated through the ^{59}Co(n,γ)^{60}Co reaction, with fast neutrons through the ^{59}Co(n,2n)^{58}Co, ^{59}Co(n,p)^{59}Fe and ^{59}Co(n,α)^{56}Mn reactions, with photons through the ^{59}Co(γ,n)^{58}Co reaction, with deuterons through the ^{59}Co(d,p)^{60}Co reaction, and with ^{3}He and α-particles mainly through ^{59}Co(α,xn) reactions yielding copper nuclides with different half-lives.

Table 1 lists nuclear reactions which can be induced in cobalt when it is bombarded with protons of energy up to 20 MeV. As is evident from the data, the instrumental performance of analysis requires that the ^{59}Co(p,pn)^{58}Co reaction be eliminated or reduced. The activation curve of this reaction is shown in Fig. 1. This activation curve is in good agreement with that obtained by Benaben *et al.*[9] and with the published excitation function.[15] More detailed experiments on this problem showed that a proton energy of 12 MeV can be used even over long irradiation times, *i.e.*, the reaction occurs only to an insignificant extent. Short irradiation times can be used with protons up to an energy of 13 MeV. With use of these proton energies, good sensitivities are obtained as the position of the maximum cross-sections is located in this energy region for most of the analytical reactions. Nuclear data on the analytical reactions used and on the properties of the indicator radionuclides are given in Table 2.

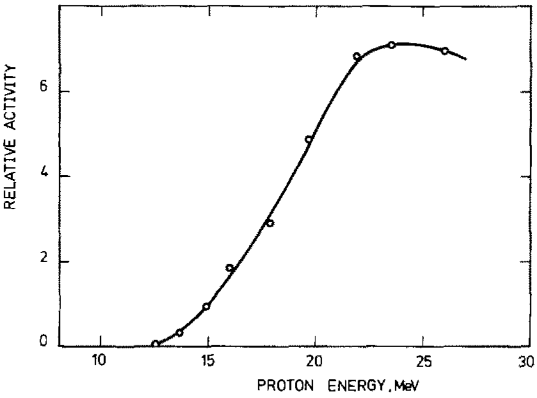

Fig. 1. Activation curve for the ^{59}Co(p,pn)^{58}Co reaction.

Interferences

Primary interference reactions which are energetically possible at the proton energies used are listed in Table 3. No primary interference reactions can occur in the determination of Ti and Cr. By experiment it has already been shown that no measurable interferences occur in the determination of Zr and Nb,[16] V, Fe, Mo and W,[17] and of Ni and Cu,[18] even if the concentrations of the interfering elements are many times those of the elements to be determined. A detailed analysis of the experimental results obtained in the irradiation of cobalt samples has shown that no measurable interferences occurred in the determination of Zn, Ru, Pd and Sn where Ge, Pd, Cd and Te could interfere through nuclear reactions of (p,α) and (p,αn) types. The presence of these interfering elements and the possible extent of their interferences were checked through the corresponding (p,n) reactions, which could yield, at the given proton energy, radioactivities higher by one or two orders of magnitude than those formed in the interfering reactions.

By bombardment of thick targets with protons of medium energy, neutrons can be produced by (p, xn) reactions. The neutron fluxes are considerably lower than the original proton-beam intensities, so the secondary interference reactions induced by neutrons, do not normally occur to a detectable extent if they are induced on the trace elements. However, if such reactions are induced on the main constituents of the sample they must be considered. Secondary interference reactions which can be induced in cobalt are listed in Table 4 together with cross-section data and energies of the γ-rays emitted by the radionuclides produced. None of the radionuclides produced in these reactions is used as an indicator radionuclide

in the analysis, so these reactions cannot act as secondary interference reactions, but the γ-rays of the radionuclides produced in this way have to be considered as instrumental interferences. Possible instrumental interferences which can occur in γ-ray spectrometry using up-to-date Ge(Li) detectors have already been summarized in detail for the analytically relevant γ-ray energies of the indicator radionuclides in the determination of Ti, V, Cr, Fe, Ni, Cu, Zr, Mo and W.[17,18] All instrumental interferences which could occur in the determination of Zn, Nb, Ru, Pd and Sn were also considered. From the many theoretically possible instrumental interferences only those given in Table 5 were actually observed. Also given in this Table are the assumed nuclear reactions yielding radionuclides with the interfering γ-rays. In cases where instrumental interferences occurred, either other lines without interferences (see Tables 2 and 6) were used, or it was possible to count the activated sample after the interferences had decayed, or to eliminate the interferences by analysing the complex decay curves.

Analytical results and their comparison

Typical γ-ray spectra for a proton-irradiated cobalt sample of VP-purity grade, measured after two different irradiation times, are shown in Figs. 2 and 3. Concentrations of trace elements determined in cobalt of VP-purity grade are summarized in Table 6. The results represent averages of three separate determinations, for which average deviations are also given.

Table 4. Possible secondary neutron-induced reactions of cobalt

Reaction	Threshold energy, MeV	E_m, MeV	σ_m, mb	Half-life	Major γ-rays, keV	Intensity, %

[a] average from two determinations by atomic absorption spectrometry

[b] determined by X-ray fluorescence spectrometry

In spite of the fact that attention was paid to the possible nuclear and instrumental interferences, reliable information about the accuracy of the results can be obtained only by checking the accuracy directly on a real sample. The best way of checking the accuracy would be by applying the method to the analysis of Standard Reference Materials, but unfortunately there are no cobalt reference standards available. Therefore, use was made of the opportunity to obtain comparative data for some of the elements determined, *i.e.*, iron, nickel and molybdenum, by two different techniques. Iron and nickel could be determined by atomic-absorption spectrometry and molybdenum by X-ray fluorescence spectrometry performed destructively. The results for the determination of iron and nickel showed that, with both proton-activation analysis and atomic-absorption spectrometry, good agreements were obtained. In the case of molybdenum, the results of proton-activation analysis are on avarage 27% lower than those obtained by X-ray fluorescence spectrometry. Taking into account the deviations of both methods, the lower value differs from the upper by 13%. The agreement is good enough to provide an acceptable measure of certainty about the concentration of these three elements found in cobalt. For information about trace impurities in pure materials, needed by producers and users, this degree of accuracy should be sufficient.

Unfortunately, a similar comparison for other trace elements could not be carried out as the methods still have to be developed, optimized or checked. Because of the need to save costly irradiation time, the reproducibility of the results was obtained in terms of the average deviations for three adjacent samples from the original cobalt material. It varied from element to element and depended mainly on the concentration level above the limit of detection. The reproducibility was poor in the determination of niobium and ruthenium, as these two elements were present at concentrations only slightly above the limits of detection. The average deviation obtained for cop-

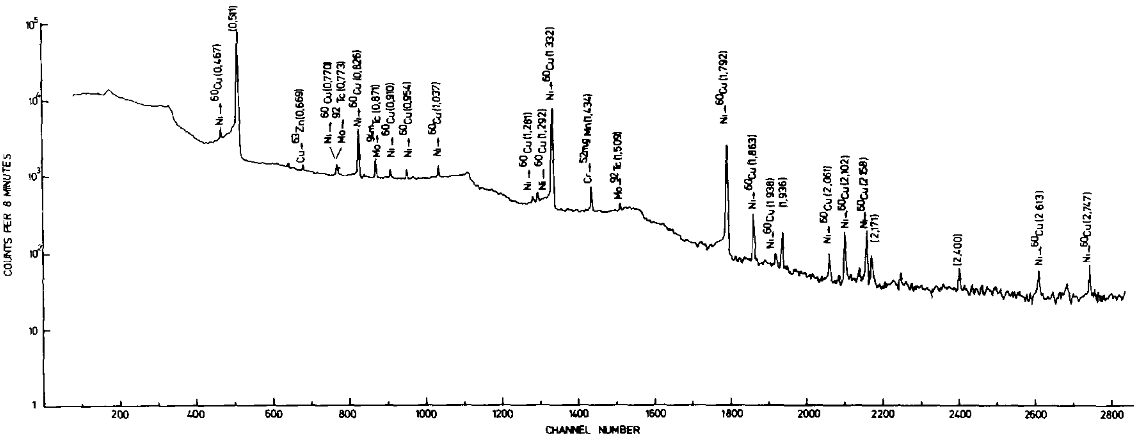

Fig. 2. Gamma-ray spectrum of a proton-irradiated cobalt sample observed 16 min after a 10-min irradiation.

per seems to have been *too* good in view of the high limit of detection. On the other hand, the average deviation for nickel should have been better. The average deviation includes the contribution of any lack of uniformity in the distribution of the trace elements in the sample material.

An irradiation time of 5–10 min is sufficient to determine elements giving rise to short-lived indicator radionuclides, such as Cr, Ni, Cu, Mo, Pd and Sn with ^{52m}Mn, ^{60}Cu, ^{63}Zn, ^{94m}Tc, ^{104m}Ag and ^{116g}Sb, respectively, as indicator radionuclides. In a previous paper,[18] it was shown that the determination of Cr, Ni and Cu by proton-activation analysis is extremely sensitive. However, nickel is present in the sample at higher concentration than all the other impurities. At the same time, the corresponding indicator radionuclide for nickel, ^{60}Cu, emits many high-energy γ-rays, giving a high background affecting the limits of detection for other elements. In addition to Ni, Cr and Cu, Mo can be determined by counting indicator radionuclides with $t_{1/2} < 1$ hr. However, ^{104m,g}Ag and ^{116g}Sb, being indicator radionuclides for the determination of Pd and Sn, respectively, could not be observed, so the limit of detection was taken as the upper concentration limit for these. For counting other than the above-mentioned indicator radionuclides, longer irradiation times, decay times and counting times are more suitable.

Table 7 lists the experimental limits of detection estimated on the basis of the spectral data of the VP-purity grade cobalt. The limits of detection are peak intensities corresponding to three standard deviations of the background at the peak of interest under the given experimental conditions, *i.e.*, irradiation, cooling and counting times. The data given represent the best observed limits of detection. The elements V, Zr, Pd and Sn are present in the sample at such low concentrations that the appropriate indicator radionuclides could not be observed. In these cases, the limits of detection have been estimated from spectra obtained by simultaneous measurement of both the cobalt sample and the pure elements irradiated

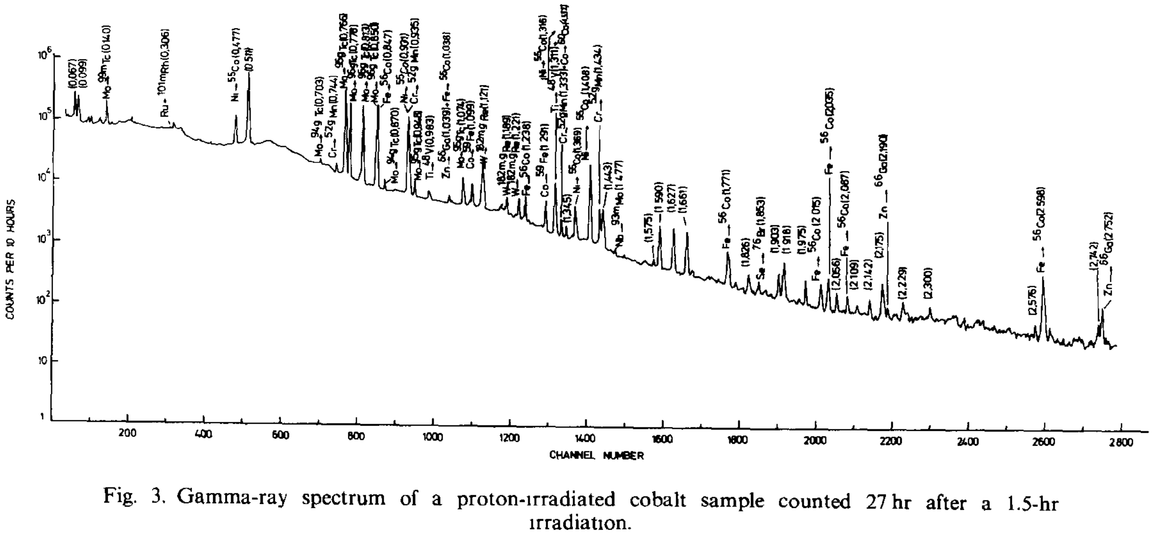

Fig. 3. Gamma-ray spectrum of a proton-irradiated cobalt sample counted 27 hr after a 1.5-hr irradiation.

Table 7. Limits of detection achieved in the analysis of VP-purity grade cobalt, and the appropriate experimental conditions

a) Irradiation conditions assumed: proton energy of 12 MeV, beam intensity of ∼ 4 μA, irradiation time of ∼2 hr

b) proton energy of 13 MeV, beam intensity of ∼4.5 μA, irradiation time of ∼10 min.

separately for shorter irradiation times and at lower beam intensities. After making the appropriate normalization for the different experimental conditions used in processing the cobalt sample and the given element, the limits of detection were estimated by using the same criterion as described above. The limits of detection of the instrumental proton-activation analysis, given in Table 6, are referred to the composition of the cobalt sample analysed and are not generally valid, Since the background may depend on the composition of the cobalt sample. One can assume that the limits of detection listed become better with decreasing concentrations of trace impurities, *i.e.*, with higher purity of the cobalt matrix. A considerable improvement in the limits of detection can be achieved by using high-efficiency γ-ray or β-ray counting. For instance, a measurable radioactivity of 0.5 nCi (1110 dpm) is produced in an activation of a cobalt sample with 12-MeV protons, with a beam intensity of 5 μA and an irradiation time of one half-life (or a maximum of 2 hr) from 3.5 ppM (parts per milliard) chromium, 16 ppM nickel, 3 ppM copper and 90 ppM molybdenum through the reactions ^{52}Cr(p,n)^{52m}Mn, ^{60}Ni(p,n)^{60}Cu, ^{63}Cu(p,n)^{63}Zn and ^{95}Mo(p,n)^{95g}Tc, respectively.

It is possible to compare our technique with that of Benaben *et al.*[9] and from the γ-ray spectra it is evident that, upon activation with 10-MeV protons, much higher relative radioactivities of ^{56}Mn, ^{59}Fe and ^{60}Co in comparison with the indicator radionuclides are produced than with 12-MeV or 13-MeV protons. These radionuclides can be produced only through reactions induced by secondary neutrons on the cobalt matrix. For example, the ratio of the radioactivity of ^{59}Fe produced by the ^{59}Co(n,p)^{59}Fe reaction from the matrix, to the radioactivity of ^{56}Co produced as indicator radionuclide for the determination of iron through the ^{56}Fe(p,n)^{56}Co reaction, is more than twice as high for 10-MeV protons as for 12-MeV protons at the same iron concentration. This is caused by the fact that the activation yield of the ^{56}Fe(p,n)^{56}Co reaction is increased more than the neutron yield by the proton energy, but it may also depend on the thickness of the sample. A similar picture can be expected for all principal reactions for which the maximum cross-section of the excitation function lies above 10 MeV. This is the case with most of the analytical reactions considered. In counting of a number of indicator radionuclides, the radionuclides ^{56}Mn, ^{59}Fe and ^{60}Fe, which emit γ-rays of relatively high energy, contribute to the background.

A direct comparison of the limits of detection for both techniques is unfortunately not possible as the composition of the cobalt samples and the detection conditions were different. A comparison of results obtained for the two samples closest in their composition, indicates that better limits of detection can be obtained by using 12-MeV or 13-MeV proton energy than by using 10-MeV proton energy. For example, the sensitivity (dpm/μA/ppm) in the determination of Cr, Ni and Cu increases by factors of 2, 3 and 4, on increasing the proton energy from 10 MeV to

13 MeV. On increasing the proton energy from 10 MeV to 12 MeV, the sensitivity in the determination of Mo by the reactions Mo + p→ ^{96g}Tc and Mo + p→ ^{95g}Tc is improved by factors of 10 and 15 respectively. Another aspect which should be considered is the range of the protons in cobalt, which is 208 mg/cm^2 at 10 MeV, 284 mg/cm^2 at 12 MeV and 325 mg/cm^2 at 13 MeV. In the case of 12-MeV and 13-MeV proton energies, a larger volume of the cobalt sample is activated and this is of advantage with respect to possible inhomogeneities in the distribution of the trace elements in the sample.

Acknowledgements—Grateful acknowledgement is made to I. Schön, A. Disam and G. Volland who carried out the determination of molybdenum by X-ray fluorescence spectrometry and the determination of iron and nickel by atomic-absorption spectrometry.

(*Received* 31 *December* 1975. *Accepted* 11 *February* 1976)

Summary—Proton-activation analysis has been applied to the determination of 14 trace impurities in cobalt. The method consists of a short (~10 min) and a longer (~2 hr) irradiation of the sample with 13-MeV and 12-MeV protons, respectively, followed by high-resolution γ-ray spectrometry. The elements Ti, Cr, Fe, Ni, Cu, Zn, Nb, Mo, Ru and W have been determined in VP-purity cobalt. In the case of V, Cu, Zr, Pd and Sn, the amounts present were below the limit of detection. In the case of Fe, Ni, and Mo, the results are compared with those obtained by a second independent method. Data on reproducibility, limits of detection and possible interferences are given.

Relatively few trace analytical studies have been performed on cobalt matrices of good and high-purity grades. Optical emission spectrography has been used to determine Si, Mn, Fe, Ni, Cu and Zn,[1] and in addition Al[2] and also As and Sb[3] in cobalt. A spectrographic technique used for the determination of all the above-mentioned elements and, in addition, the alkali metals, Ca, Ti, V, Cr, Nb, Mo, Rh, Pd, Cd, Ag, W and Tl, in cobalt of 99.999% purity has been described by Tombu[4] together with a listing of the different chemical methods for the determination of H, C, N, O, Na, Mg, Al, Si, P, S, K, Ca, Mn, Fe, Ni, Cu, Zn, As, Se, Sn, Sb, W, Tl, Pb and Bi. Unfortunately, neither the concentration intervals to which the individual methods have been applied nor the limits of detection were given. Activation analytical techniques have rarely been applied to the analysis of cobalt matrices.[5,6] In activation analysis with reactor neutrons, there are difficulties with the very high matrix activity due to the high thermal neutron cross-section and the resonance integral for the ^{59}Co(n,γ)^{60}Co reaction and the long half-life of ^{60}Co. Radiochemical neutron activation analysis has been used for the determination of Cu,[7,8] Mn and Zn.[8]

Recently an article by Benaben, Barrandon and Debrun has appeared[9] in which the application of an instrumental proton-activation technique to multi-element analysis of cobalt has been described. However, the experimental conditions and sample types used by these authors differ from those used in the present work. While they irradiated the cobalt samples with 10-MeV protons for 1 hr, in our case the cobalt samples were activated with 13-MeV protons to produce short-lived indicator radionuclides in short irradiations (~10 min), and with 12-MeV protons to produce long-lived indicator radionuclides in longer irradiations (~2 hr). To check the accuracy of the proton-activation technique described here, analytical results for iron, nickel and molybdenum are compared with results obtained by atomic-absorption spectrometry and by X-ray fluorescence spectrometry.

EXPERIMENTAL

Sample and standards

A cobalt sample of VP grade supplied by Material Research, GmbH, Eching bei München, West Germany, was analysed. From the cobalt metal, targets with a thickness of ~0.6 mm were cut. To remove possible surface contamination, a pre-irradiation chemical etch was accomplished with dilute nitric acid (1:1 ultrapure water and nitric acid). Thick metal targets of pure elements, their alloys or pressed powder mixtures were used for the standardization. For the etching of the standards, different solutions were used according to the character of the metal For the measurements of the activation curve of the ^{59}Co(p,pn)^{58}Co reaction, stacked foils of VP-purity cobalt were used

Irradiation

Irradiations were performed with 12-MeV and 13-MeV protons at the Karlsruhe isochronous cyclotron. For standardization, the average beam currents were 5–200 nA and the irradiation times were 20–60 sec Cobalt samples were irradiated in a water-cooled target holder for 5–120 min with beam intensities of 3–5 MeV. The activation curve was measured for proton energies up to 25 MeV.

Data acquisition

Gamma-rays were counted with a 55-cm^3 Ge(Li) detector having an energy resolution of 2.1 keV FWHM for the 1.332-MeV γ-ray of ^{60}Co and a peak-to-Compton ratio of 29:1. The detector was coupled with a 4096-channel pulse-height analyser. Computer programs[10] were used to list and plot the spectra and to determine the energies and intensities of the photopeaks. Data on the reaction studied and on the properties of the indicator radionuclides were obtained from recent compilations and tables[11–14]

RESULTS AND DISCUSSION

Selection of activation reactions

Inspection of the nuclear data and preliminary experiments indicated proton-activation analysis to be

Table 1. Proton-induced cobalt reactions producing radionuclides

Reaction	Q-value, MeV	Half-life	γ-Rays, MeV	Intensity, %
$^{59}Co(p,n)^{59}Ni$	- 1.9	7.5 x 10^4 yr	-	-
$^{59}Co(p,pn)^{58m}Co$	-10.5	8.94 hr	0.0249	0.03
$^{59}Co(p,pn)^{58}Co$	-10.5	70.78 d	0.5110 0.8106 0.8636 1.6748	30.0 99.4 0.7 0.5
$^{59}Co(p,p2n)^{57}Co$	-19.0	270.0 d	0.0144 0.1221 0.1364 0.5703 0.6921	9.5 85.6 10.6 0.01 0.15
$^{59}Co(p,\alpha n)^{55}Fe$	- 8.0	2.7 yr	-	-

the most suitable with respect to the instrumental performance and the multi-element character of the cobalt analysis. In activation with thermal neutrons, the matrix is strongly activated through the $^{59}Co(n,\gamma)^{60}Co$ reaction, with fast neutrons through the $^{59}Co(n,2n)^{58}Co$, $^{59}Co(n,p)^{59}Fe$ and $^{59}Co(n,\alpha)^{56}Mn$ reactions, with photons through the $^{59}Co(\gamma,n)^{58}Co$ reaction, with deuterons through the $^{59}Co(d,p)^{60}Co$ reaction, and with ^3He and α-particles mainly through $^{59}Co(\alpha,xn)$ reactions yielding copper nuclides with different half-lives.

Table 1 lists nuclear reactions which can be induced in cobalt when it is bombarded with protons of energy up to 20 MeV. As is evident from the data, the instrumental performance of analysis requires that the $^{59}Co(p,pn)^{58}Co$ reaction be eliminated or reduced. The activation curve of this reaction is shown in Fig. 1. This activation curve is in good agreement with that obtained by Benaben *et al.*[9] and with the published excitation function.[15] More detailed experiments on this problem showed that a proton energy of 12 MeV can be used even over long irradiation times, *i.e.*, the reaction occurs only to an insignificant extent. Short irradiation times can be used with protons up to an energy of 13 MeV. With use of these proton energies, good sensitivities are obtained as the position of the maximum cross-sections is located in this energy region for most of the analytical reactions. Nuclear data on the analytical reactions used and on the properties of the indicator radionuclides are given in Table 2.

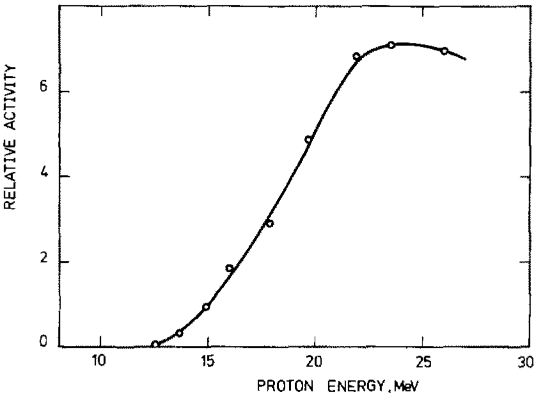

Fig. 1. Activation curve for the $^{59}Co(p,pn)^{58}Co$ reaction.

Interferences

Primary interference reactions which are energetically possible at the proton energies used are listed in Table 3. No primary interference reactions can occur in the determination of Ti and Cr. By experiment it has already been shown that no measurable interferences occur in the determination of Zr and Nb,[16] V, Fe, Mo and W,[17] and of Ni and Cu,[18] even if the concentrations of the interfering elements are many times those of the elements to be determined. A detailed analysis of the experimental results obtained in the irradiation of cobalt samples has shown that no measurable interferences occurred in the determination of Zn, Ru, Pd and Sn where Ge, Pd, Cd and Te could interfere through nuclear reactions of (p,α) and (p,αn) types. The presence of these interfering elements and the possible extent of their interferences were checked through the corresponding (p,n) reactions, which could yield, at the given proton energy, radioactivities higher by one or two orders of magnitude than those formed in the interfering reactions.

By bombardment of thick targets with protons of medium energy, neutrons can be produced by (p, xn) reactions. The neutron fluxes are considerably lower than the original proton-beam intensities, so the secondary interference reactions induced by neutrons, do not normally occur to a detectable extent if they are induced on the trace elements. However, if such reactions are induced on the main constituents of the sample they must be considered. Secondary interference reactions which can be induced in cobalt are listed in Table 4 together with cross-section data and energies of the γ-rays emitted by the radionuclides produced. None of the radionuclides produced in these reactions is used as an indicator radionuclide

in the analysis, so these reactions cannot act as secondary interference reactions, but the γ-rays of the radionuclides produced in this way have to be considered as instrumental interferences. Possible instrumental interferences which can occur in γ-ray spectrometry using up-to-date Ge(Li) detectors have already been summarized in detail for the analytically relevant γ-ray energies of the indicator radionuclides in the determination of Ti, V, Cr, Fe, Ni, Cu, Zr, Mo and W.[17,18] All instrumental interferences which could occur in the determination of Zn, Nb, Ru, Pd and Sn were also considered. From the many theoretically possible instrumental interferences only those given in Table 5 were actually observed. Also given in this Table are the assumed nuclear reactions yielding radionuclides with the interfering γ-rays. In cases where instrumental interferences occurred, either other lines without interferences (see Tables 2 and 6) were used, or it was possible to count the activated sample after the interferences had decayed, or to eliminate the interferences by analysing the complex decay curves.

Analytical results and their comparison

Typical γ-ray spectra for a proton-irradiated cobalt sample of VP-purity grade, measured after two different irradiation times, are shown in Figs. 2 and 3. Concentrations of trace elements determined in cobalt of VP-purity grade are summarized in Table 6. The results represent averages of three separate determinations, for which average deviations are also given.

Table 4. Possible secondary neutron-induced reactions of cobalt

Reaction	Threshold energy, MeV	E_m, MeV	σ_m, mb	Half-life	Major γ-rays, keV	Intensity, %
^{59}Co(n,α)^{56}Mn	0.0	14.5	30	2.58 hr	846.6 1811.2 2112.6	99.0 30.0 15.5

[a] average from two determinations by atomic absorption spectrometry

[b] determined by X-ray fluorescence spectrometry

In spite of the fact that attention was paid to the possible nuclear and instrumental interferences, reliable information about the accuracy of the results can be obtained only by checking the accuracy directly on a real sample. The best way of checking the accuracy would be by applying the method to the analysis of Standard Reference Materials, but unfortunately there are no cobalt reference standards available. Therefore, use was made of the opportunity to obtain comparative data for some of the elements determined, *i.e.*, iron, nickel and molybdenum, by two different techniques. Iron and nickel could be determined by atomic-absorption spectrometry and molybdenum by X-ray fluorescence spectrometry performed destructively. The results for the determination of iron and nickel showed that, with both proton-activation analysis and atomic-absorption spectrometry, good agreements were obtained. In the case of molybdenum, the results of proton-activation analysis are on avarage 27% lower than those obtained by X-ray fluorescence spectrometry. Taking into account the deviations of both methods, the lower value differs from the upper by 13%. The agreement is good enough to provide an acceptable measure of certainty about the concentration of these three elements found in cobalt. For information about trace impurities in pure materials, needed by producers and users, this degree of accuracy should be sufficient.

Unfortunately, a similar comparison for other trace elements could not be carried out as the methods still have to be developed, optimized or checked. Because of the need to save costly irradiation time, the reproducibility of the results was obtained in terms of the average deviations for three adjacent samples from the original cobalt material. It varied from element to element and depended mainly on the concentration level above the limit of detection. The reproducibility was poor in the determination of niobium and ruthenium, as these two elements were present at concentrations only slightly above the limits of detection. The average deviation obtained for cop-

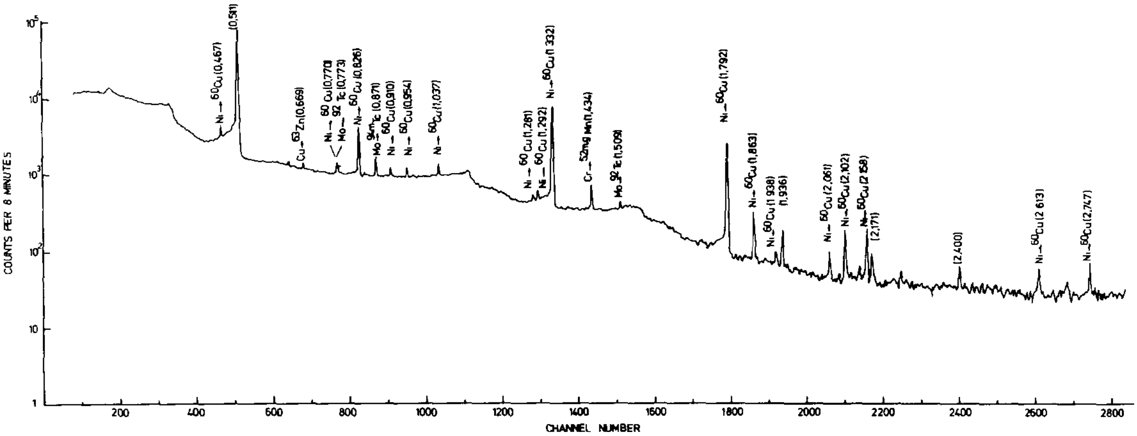

Fig. 2. Gamma-ray spectrum of a proton-irradiated cobalt sample observed 16 min after a 10-min irradiation.

per seems to have been *too* good in view of the high limit of detection. On the other hand, the average deviation for nickel should have been better. The average deviation includes the contribution of any lack of uniformity in the distribution of the trace elements in the sample material.

An irradiation time of 5–10 min is sufficient to determine elements giving rise to short-lived indicator radionuclides, such as Cr, Ni, Cu, Mo, Pd and Sn with ^{52m}Mn, ^{60}Cu, ^{63}Zn, ^{94m}Tc, ^{104m}Ag and ^{116g}Sb, respectively, as indicator radionuclides. In a previous paper,[18] it was shown that the determination of Cr, Ni and Cu by proton-activation analysis is extremely sensitive. However, nickel is present in the sample at higher concentration than all the other impurities. At the same time, the corresponding indicator radionuclide for nickel, ^{60}Cu, emits many high-energy γ-rays, giving a high background affecting the limits of detection for other elements. In addition to Ni, Cr and Cu, Mo can be determined by counting indicator radionuclides with $t_{1/2} < 1$ hr. However, ^{104m,g}Ag and ^{116g}Sb, being indicator radionuclides for the determination of Pd and Sn, respectively, could not be observed, so the limit of detection was taken as the upper concentration limit for these. For counting other than the above-mentioned indicator radionuclides, longer irradiation times, decay times and counting times are more suitable.

Table 7 lists the experimental limits of detection estimated on the basis of the spectral data of the VP-purity grade cobalt. The limits of detection are peak intensities corresponding to three standard deviations of the background at the peak of interest under the given experimental conditions, *i.e.*, irradiation, cooling and counting times. The data given represent the best observed limits of detection. The elements V, Zr, Pd and Sn are present in the sample at such low concentrations that the appropriate indicator radionuclides could not be observed. In these cases, the limits of detection have been estimated from spectra obtained by simultaneous measurement of both the cobalt sample and the pure elements irradiated

separately for shorter irradiation times and at lower beam intensities. After making the appropriate normalization for the different experimental conditions used in processing the cobalt sample and the given element, the limits of detection were estimated by using the same criterion as described above. The limits of detection of the instrumental proton-activation analysis, given in Table 6, are referred to the composition of the cobalt sample analysed and are not generally valid, Since the background may depend on the composition of the cobalt sample. One can assume that the limits of detection listed become better with decreasing concentrations of trace impurities, *i.e.*, with higher purity of the cobalt matrix. A considerable improvement in the limits of detection can be achieved by using high-efficiency γ-ray or β-ray counting. For instance, a measurable radioactivity of 0.5 nCi (1110 dpm) is produced in an activation of a cobalt sample with 12-MeV protons, with a beam intensity of 5 μA and an irradiation time of one half-life (or a maximum of 2 hr) from 3.5 ppM (parts per milliard) chromium, 16 ppM nickel, 3 ppM copper and 90 ppM molybdenum through the reactions ^{52}Cr(p,n)^{52m}Mn, ^{60}Ni(p,n)^{60}Cu, ^{63}Cu(p,n)^{63}Zn and ^{95}Mo(p,n)^{95g}Tc, respectively.

It is possible to compare our technique with that of Benaben *et al.*[9] and from the γ-ray spectra it is evident that, upon activation with 10-MeV protons, much higher relative radioactivities of ^{56}Mn, ^{59}Fe and ^{60}Co in comparison with the indicator radionuclides are produced than with 12-MeV or 13-MeV protons. These radionuclides can be produced only through reactions induced by secondary neutrons on the cobalt matrix. For example, the ratio of the radioactivity of ^{59}Fe produced by the ^{59}Co(n,p)^{59}Fe reaction from the matrix, to the radioactivity of ^{56}Co produced as indicator radionuclide for the determination of iron through the ^{56}Fe(p,n)^{56}Co reaction, is more than twice as high for 10-MeV protons as for 12-MeV protons at the same iron concentration. This is caused by the fact that the activation yield of the ^{56}Fe(p,n)^{56}Co reaction is increased more than the neutron yield by the proton energy, but it may also depend on the thickness of the sample. A similar picture can be expected for all principal reactions for which the maximum cross-section of the excitation function lies above 10 MeV. This is the case with most of the analytical reactions considered. In counting of a number of indicator radionuclides, the radionuclides ^{56}Mn, ^{59}Fe and ^{60}Fe, which emit γ-rays of relatively high energy, contribute to the background.

A direct comparison of the limits of detection for both techniques is unfortunately not possible as the composition of the cobalt samples and the detection conditions were different. A comparison of results obtained for the two samples closest in their composition, indicates that better limits of detection can be obtained by using 12-MeV or 13-MeV proton energy than by using 10-MeV proton energy. For example, the sensitivity (dpm/μA/ppm) in the determination of Cr, Ni and Cu increases by factors of 2, 3 and 4, on increasing the proton energy from 10 MeV to

13 MeV. On increasing the proton energy from 10 MeV to 12 MeV, the sensitivity in the determination of Mo by the reactions Mo + p → ^{96g}Tc and Mo + p → ^{95g}Tc is improved by factors of 10 and 15 respectively. Another aspect which should be considered is the range of the protons in cobalt, which is 208 mg/cm^2 at 10 MeV, 284 mg/cm^2 at 12 MeV and 325 mg/cm^2 at 13 MeV. In the case of 12-MeV and 13-MeV proton energies, a larger volume of the cobalt sample is activated and this is of advantage with respect to possible inhomogeneities in the distribution of the trace elements in the sample.

Acknowledgements—Grateful acknowledgement is made to I. Schön, A. Disam and G. Volland who carried out the determination of molybdenum by X-ray fluorescence spectrometry and the determination of iron and nickel by atomic-absorption spectrometry.

CANDOLUMINESCENCE—A NEW FLAME TECHNIQUE FOR TRACE ANALYSIS—II

DETERMINATION OF NANOGRAM AMOUNTS OF MANGANESE

(*Received* 1 *March* 1976. *Accepted* 17 *March* 1976)

Summary—The yellow candoluminescence of manganese stimulated in a 8:1 w/w calcium oxide–calcium sulphate matrix at the edge of a hydrogen–nitrogen–air flame is used to determine 0.1–3.0 ng of manganese in 1-μl samples. Large amounts of chloride ions enhance the emission, and many transition metals suppress it.

In a previous paper,[1] the candoluminescence spectra of bismuth, manganese, antimony, lead, and a number of lanthanides in a calcium hydroxide–calcium sulphate matrix were reported. A quantitative relationship was established between luminescence emission intensity and the concentration of bismuth activator introduced into the matrix by co-precipitation. In a later paper,[2] the determination of bismuth down to the sub-nanogram level was described. This was made possible by introducing the activator sample directly onto the surface of a matrix, instead of using co-precipitation; with the latter method, most of the activator used is inside the body of the matrix, and is not available for luminescence. The candoluminescence of manganese was first studied by Donau,[3] who found that a bead of calcium carbonate on a platinum wire could be activated by manganese ions to give a yellow emission at the edge of a hydrogen flame. This paper describes the use of the surface-application technique to determine down to sub-ng amounts of manganese, based on this yellow candoluminescence. The lower limit of determination is 0.1 ng, but it could be an order of magnitude lower, except that traces of manganese in the calcium carbonate used as matrix precursor set a practical lower limit.

EXPERIMENTAL

Apparatus

The candoluminescence emission intensity of manganese was measured at 580 nm by using a Unicam SP 900 flame-emission spectrometer, a Servoscribe chart recorder, and sample holder as described previously.[2] The matrix was inlaid into the hexagonal aperture (2 mm deep, 5 mm maximum diagonal) in the head of an Allen screw.[2] The apparatus was used in a dimly illuminated laboratory to eliminate interference from extraneous light sources.

The matrix

The water used should be as pure as possible, and was distilled from an all-glass apparatus and demineralized before use. The primary matrix material was calcium oxide. Because no commercial samples of calcium oxide could be found that had low enough levels of manganese, calcium oxide was prepared by heating analytical-reagent grade calcium carbonate (Fisons) in a muffle furnace at 800° for about 4 hr. After allowing it to cool, an 8:1 w/w calcium oxide.plaster of Paris matrix was prepared as described previously.[2]

The matrix material was inlaid into the cavities of the Allen screws with a clean spatula, and compressed with a clean Allen key that fitted the cavity. This procedure was repeated until the cavity was more than full. Excess of solid was pressed into the cavity by inverting the screw and pressing the head onto a smooth "Perspex" plate whilst sliding it along This left a smooth, hard, but still slightly moist matrix surface which was fractionally higher than the top surface of the screw head. The matrices were dried in an oven at 110° for 10 min, and when cool were stored in a desiccator containing fresh, dry calcium oxide to absorb both water and carbon dioxide Before each matrix was used, excess of matrix material was carefully scraped off with a clean razor blade to leave a smooth clean surface that was level with the top surface of the screw. The activator solution was applied to the centre of the matrix surface as a 1-μl drop from a Hamilton 10-μl syringe. The activated matrix was placed in the flame, and its emission measured as a function of time.

Determination of manganese

A 1000-ppm manganese(II) solution was prepared by dissolving the appropriate quantity of analytical reagent grade manganese(II) sulphate in water. Calibration solutions down to 0.1 ppm were prepared from this solution by dilution in volumetric flasks.

The candoluminescence spectrum of manganese was obtained by scanning a steady emission, the latter being obtained by lowering the flame temperature so that it was only just above the temperature of maximum emission for the activator.[2] In these circumstances a bright steady luminescence can be obtained.

To measure the emission intensities from a prepared set of matrices, the optimal horizontal positioning of the matrix was first determined by carefully adjusting the position of one matrix at the edge of the flame so that the luminescence intensity was maximal. The matrix holder was then kept fixed at this position for the measurement of the succeeding matrices. Graphs of peak luminescence intensity *vs.* quantity of manganese added were obtained.

RESULTS

The candoluminescence spectrum of manganese is shown in Fig. 1. The peak emission intensity is at 580 nm, and all further measurements were made at this wavelength.

Effect of flame conditions and matrix position

The three gases admitted to the pre-mix burner were hydrogen, nitrogen, and air. Under optimal conditions, the part of the flame that stimulated luminescence at the matrix surface was a narrow region at the "edge". Because of this, the lateral positioning of the matrix holder was very critical. Once the optimal position had been found, the holder was left in this position so that the matrices could be positioned reproducibly in the flame by simply rotating the socket.[2] Each matrix–activator pair has a temperature at which maximal luminescence occurs. Thus, if the flame temperature is greater than this, the emission intensity from a matrix at the edge of the flame rises to a maximum, then decreases as the temperature of the surface increases. The emission-time profile of manganese-activated calcium oxide under optimal flame conditions is shown in Fig. 2. The luminescence begins 10 sec after the flame is entered by the matrix and reaches a maximum after 30 sec. The term "optimal flame conditions" implies not only that the emission intensity reached is maximal, but that the, noise, from the flame (principally from dust particles and sodium impurities) is minimal.

Apart from the horizontal distance of the matrix from the flame axis, the four principal flame variables involved are the hydrogen, nitrogen and air flow-rates, and the height of the matrix in the flame above the burner. Each of these was investigated separately. For each study, three of the parameters were fixed at about their optimal value (determined approximately in experiments beforehand), while the fourth was varied. The results are shown in Figs. 3 and 4. The nitrogen flow-rate appeared not to be very critical as far as luminescence intensity was concerned, but was critical for reducing the flame noise, the noise decreasing markedly as the nitrogen flow increased. Variations in hydrogen and air flows were more critical, both with respect to emission intensity and flame noise. This is to be expected, as it is the hydrogen–oxygen interaction in the flame which produces the radicals which stimulate candoluminescence. On the basis of these experiments the optimal gas flow-rates were considered to be: nitrogen 8.0 l./min, hydrogen 2.0 l./min and air 2.5 l./min. The variation of the height of the centre of the matrix above the burner head was not very critical, and 3.0 cm was chosen as suitable.

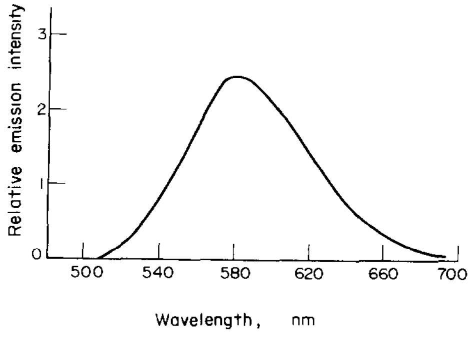

Fig. 1. Candoluminescence spectrum of manganese

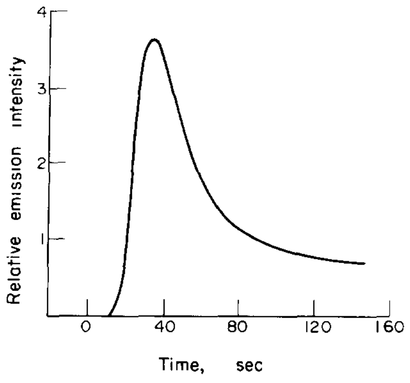

Fig. 2. Change in manganese candoluminescence intensity at 580 nm with time. Matrix inserted into flame at 0 sec

Calibration and reproducibility

Figure 5 shows the calibration curves obtained for 0.1–1.0 and 1.0–5.0 ng of manganese. It was found that, as with other activators,[2,4] there is an upper calibration limit above which the curve levels off or falls. For manganese, this occurs at about 3 ng; for bismuth[2] it had been found to be 2 ng. Below 0.1 ng of manganese the emission becomes difficult to measure because the emission is mainly that of manganese impurity in the matrix. However, it is expected that by utilizing ultrapure calcium carbonate as a matrix material, the calibration range could be extended to well below 0.1 ng.

Good reproducibility in candoluminescence is obtained by exercising precise control over a large number of parameters, including the flame conditions, the sample introduction technique, and above all the

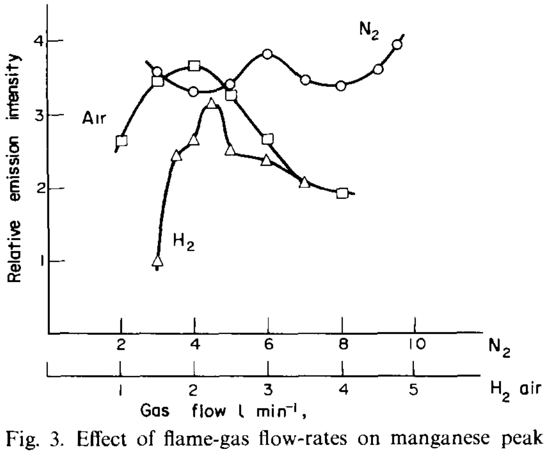

Fig. 3. Effect of flame-gas flow-rates on manganese peak candoluminescence intensity.

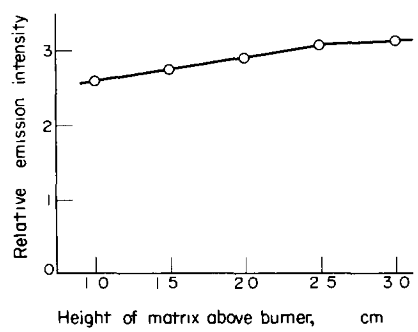

Fig. 4. Effect of height of matrix in flame on manganese peak candoluminescence intensity

matrix preparation technique. With manganese, the reproducibility was ±5%, but could be ±10% or more if the experimental technique was inadequate.

Interferences

Interferences were investigated by preparing solutions containing a standard quantity of manganese together with various quantities of another cation (usually as the sulphate) or of another anion (as its potassium salt). The activator and interferent were applied together in a 1-μl drop of solution.

Cations. Transition metal cations interfered markedly with the luminescence of 10 ng of manganese, causing a gradual decrease in emission intensity, an example of which is shown in Fig. 6. Table 1 shows the degree of interference from various metal ions, when present in a 1:1 and 10:1 w:w ratio to the activator. In most instances, a deposit was visible on the matrix surface after removing it from the flame, and its colour corresponded to that of transition metal oxide. Such a deposit would shield the calcium oxide surface from the flame and thus reduce the luminescence. Zinc, aluminium, bismuth, lead and potassium ions were found to have little effect on the luminescence when present in up to ten times the weight

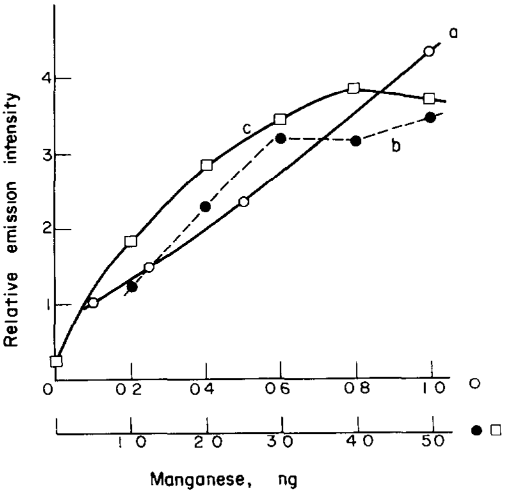

Fig 5. Calibration graphs for (*a*) 0–1.0 ng of Mn; (*b*) 1.0–5.0 ng of Mn; (*c*) 0–5.0 ng of Mn in the presence of 10 μg of Cl⁻.

Bi(III) (as nitrate)	98	84
Al(III)	100	98
Zn(II)	83	100
K(I)	96	88

* Luminescence emission intensity from 10 ng of Mn(II); value = 100 if no interference.

† As sulphate, unless otherwise stated.

of manganese. Of these, bismuth and lead are themselves activators in CaO. Manganese and bismuth have a similar optimal candoluminescence temperature, and thus emit simultaneously in the flame, but the spectra of manganese (peak at 580 nm) and bismuth (400 nm) do not overlap, and the manganese emission can be measured without interference from bismuth. The same considerations apply to lead, with a peak at 390 nm. Moreover, the lead emission occurs at a much lower temperature than that of manganese, and fades to zero before the manganese luminescence starts. The non-luminescing interferents mentioned have white oxides, and so no surface deposit was visible.

Anions. Common anions such as SO_4^{2-}, NO_3^-, NO_2^-, SCN^-, IO_3^- and some organic anions (formate, oxalate) were found to have no effect on the manganese candoluminescence at any concentration. Chloride ions, however, enhanced the luminescence, as shown in Fig. 7. The emission from 10 ng of manganese was found to be twice as intense in the presence of 1 μg of chloride, and was increased 4.2 times by 10 μg of chloride. Bromide had a slight enhancing effect (1.7 times the original intensity, with 10 μg of bromide); fluoride enhanced the emission by about 100% only when present in low concentrations (500 ppm), and had no effect at high concentrations (Fig. 7). Iodide had no effect. The phenomenon of an anion or an acid enhancing the emission from a matrix–activator pair has been termed co-activation, and has been found to occur quite frequently in candoluminescence [4,5] Chloride, for example, co-activates the emissions from lead and antimony in calcium oxide, and from indium in magnesium oxide.[5] Sulphuric acid co-activates cerium and europium candoluminescence in calcium oxide.[4] The emission from co-activated manganese has the same spectrum as that from manganese that has not been co-activated. The presence of a co-activator gives greater sensitivity, as is shown in Fig. 5. However, the calibration range is not extended in the presence of the co-activator, nor is the reproducibility improved.

The only anions that reduced the luminescent intensity were those that contained a transition metal, *viz.* VO_3^- and CrO_4^{2-}.

Acids. As the matrix is mainly calcium oxide, the presence of acids in the sample solution would be expected to interfere chemically with its composition, and thus with the luminescence produced. Increasing concentrations of nitric and sulphuric acids were found to produce a gradual decrease of emission intensity as shown in Fig. 8, the sulphuric acid interference being the greater. Hydrochloric acid was found to cause an initial sharp enhancement of emission, because of chloride co-activation, but with increasing acid concentration, the enhancement fell steadily. However, as shown in Fig. 8, even in the presence of 5 *M* acid, the emission intensity did not fall below that in the absence of co-activation.

Repeated emissions

If, after emission had been obtained from an activated matrix, the matrix was removed from the flame for about a minute to let it cool, and then re-introduced into the flame, the emission intensity obtained was up to three times the initial intensity. Further small enhancements occurred each time the process was repeated, as is shown in Fig. 9. Such a phenomenon does not seem to be exhibited by bismuth, for which repetition of heating gives the same emission from a single matrix.[2]

DISCUSSION

The phenomenon of candoluminescence has been shown to be the basis for a method for the determination of nanogram and sub-nanogram quantities of manganese in aqueous solution. The method is rapid, very sensitive and requires fairly simple apparatus. Co-activation increases the sensitivity of the method.

In the initial quantitative candoluminescence studies of bismuth,[1] the activator was introduced into the matrix by co-precipitating it with the matrix in solution. This gave a calibration range in the microgram region. Much greater sensitivity could be

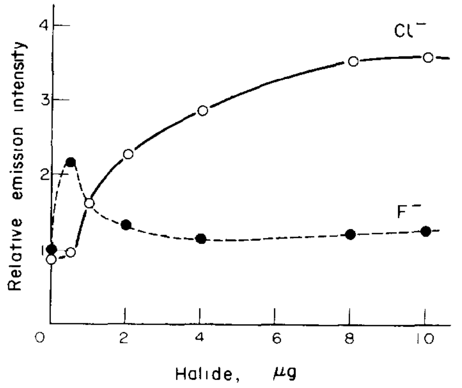

Fig. 7 Effect of chloride and fluoride ions on the peak candoluminescence intensity from 10 ng of manganese.

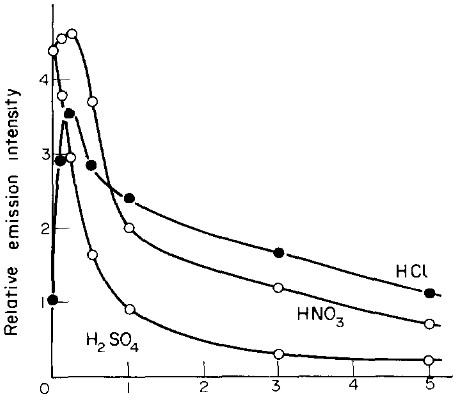

Fig. 8. Effect of some acids on the peak candoluminescence intensity from 10 ng of manganese

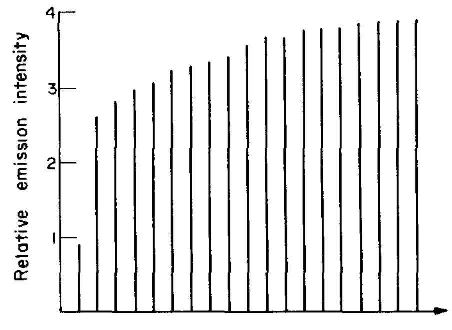

Fig. 9. Peak emission intensities obtained by sequential restimulation of manganese candoluminescence.

obtained by directly adding the activator in solution to the pure matrix surface. With improving techniques, it has been possible to apply a direct-injection method for all activators, including manganese. However, in order to have reasonably reproducible results, it is necessary to have a standardized, reproducible procedure for the preparation of each matrix. This is because the variation of compactness and porosity between matrices is a major cause of poor reproducibility of luminescence emission.

Certain metal ions are found to interfere with the manganese luminescence; thus it is necessary to ensure that these ions are not present in solution with the activator, either by chemically removing them, or by selectively extracting the manganese before determining it.

More matrix–activator pairs are being discovered, and analytical applications of these will be the subject of future papers. With such developments it is apparent that candoluminescence has much potential as a general quantitative trace analytical technique.

After allowing it to cool, an 8:1 w/w calcium oxide:plaster of Paris matrix was prepared as described previously.[2]

The matrix material was inlaid into the cavities of the Allen screws with a clean spatula, and compressed with a clean Allen key that fitted the cavity. This procedure was repeated until the cavity was more than full. Excess of solid was pressed into the cavity by inverting the screw and pressing the head onto a smooth "Perspex" plate whilst sliding it along This left a smooth, hard, but still slightly moist matrix surface which was fractionally higher than the top surface of the screw head. The matrices were dried in an oven at 110° for 10 min, and when cool were stored in a desiccator containing fresh, dry calcium oxide to absorb both water and carbon dioxide Before each matrix was used, excess of matrix material was carefully scraped off with a clean razor blade to leave a smooth clean surface that was level with the top surface of the screw. The activator solution was applied to the centre of the matrix surface as a 1-μl drop from a Hamilton 10-μl syringe. The activated matrix was placed in the flame, and its emission measured as a function of time.

Determination of manganese

A 1000-ppm manganese(II) solution was prepared by dissolving the appropriate quantity of analytical reagent grade manganese(II) sulphate in water. Calibration solutions down to 0.1 ppm were prepared from this solution by dilution in volumetric flasks.

The candoluminescence spectrum of manganese was obtained by scanning a steady emission, the latter being obtained by lowering the flame temperature so that it was only just above the temperature of maximum emission for the activator.[2] In these circumstances a bright steady luminescence can be obtained.

To measure the emission intensities from a prepared set of matrices, the optimal horizontal positioning of the matrix was first determined by carefully adjusting the position of one matrix at the edge of the flame so that the luminescence intensity was maximal. The matrix holder was then kept fixed at this position for the measurement of the succeeding matrices. Graphs of peak luminescence intensity *vs.* quantity of manganese added were obtained.

RESULTS

The candoluminescence spectrum of manganese is shown in Fig. 1. The peak emission intensity is at 580 nm, and all further measurements were made at this wavelength.

Effect of flame conditions and matrix position

The three gases admitted to the pre-mix burner were hydrogen, nitrogen, and air. Under optimal conditions, the part of the flame that stimulated luminescence at the matrix surface was a narrow region at the "edge". Because of this, the lateral positioning of the matrix holder was very critical. Once the optimal position had been found, the holder was left in this position so that the matrices could be positioned reproducibly in the flame by simply rotating the socket.[2] Each matrix–activator pair has a temperature at which maximal luminescence occurs. Thus, if the flame temperature is greater than this, the emission intensity from a matrix at the edge of the flame rises to a maximum, then decreases as the temperature of the surface increases. The emission-time profile of manganese-activated calcium oxide under optimal flame conditions is shown in Fig. 2. The luminescence begins 10 sec after the flame is entered by the matrix and reaches a maximum after 30 sec. The term "optimal flame conditions" implies not only that the emission intensity reached is maximal, but that the, noise, from the flame (principally from dust particles and sodium impurities) is minimal.

Apart from the horizontal distance of the matrix from the flame axis, the four principal flame variables involved are the hydrogen, nitrogen and air flow-rates, and the height of the matrix in the flame above the burner. Each of these was investigated separately. For each study, three of the parameters were fixed at about their optimal value (determined approximately in experiments beforehand), while the fourth was varied. The results are shown in Figs. 3 and 4. The nitrogen flow-rate appeared not to be very critical as far as luminescence intensity was concerned, but was critical for reducing the flame noise, the noise decreasing markedly as the nitrogen flow increased. Variations in hydrogen and air flows were more critical, both with respect to emission intensity and flame noise. This is to be expected, as it is the hydrogen–oxygen interaction in the flame which produces the radicals which stimulate candoluminescence. On the basis of these experiments the optimal gas flow-rates were considered to be: nitrogen 8.0 l./min, hydrogen 2.0 l./min and air 2.5 l./min. The variation of the height of the centre of the matrix above the burner head was not very critical, and 3.0 cm was chosen as suitable.

Calibration and reproducibility

Figure 5 shows the calibration curves obtained for 0.1–1.0 and 1.0–5.0 ng of manganese. It was found that, as with other activators,[2,4] there is an upper calibration limit above which the curve levels off or falls. For manganese, this occurs at about 3 ng; for bismuth[2] it had been found to be 2 ng. Below 0.1 ng of manganese the emission becomes difficult to measure because the emission is mainly that of manganese impurity in the matrix. However, it is expected that by utilizing ultrapure calcium carbonate as a matrix material, the calibration range could be extended to well below 0.1 ng.

Good reproducibility in candoluminescence is obtained by exercising precise control over a large number of parameters, including the flame conditions, the sample introduction technique, and above all the

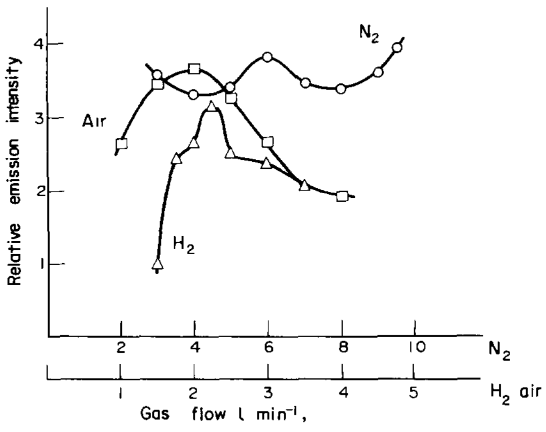

Fig. 3. Effect of flame-gas flow-rates on manganese peak candoluminescence intensity.

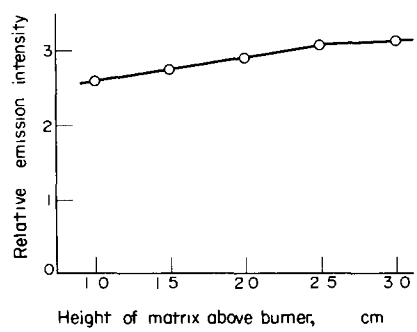

Fig. 4. Effect of height of matrix in flame on manganese peak candoluminescence intensity

matrix preparation technique. With manganese, the reproducibility was ±5%, but could be ±10% or more if the experimental technique was inadequate.

Interferences

Interferences were investigated by preparing solutions containing a standard quantity of manganese together with various quantities of another cation (usually as the sulphate) or of another anion (as its potassium salt). The activator and interferent were applied together in a 1-μl drop of solution.

Cations. Transition metal cations interfered markedly with the luminescence of 10 ng of manganese, causing a gradual decrease in emission intensity, an example of which is shown in Fig. 6. Table 1 shows the degree of interference from various metal ions, when present in a 1:1 and 10:1 w:w ratio to the activator. In most instances, a deposit was visible on the matrix surface after removing it from the flame, and its colour corresponded to that of transition metal oxide. Such a deposit would shield the calcium oxide surface from the flame and thus reduce the luminescence. Zinc, aluminium, bismuth, lead and potassium ions were found to have little effect on the luminescence when present in up to ten times the weight

† As sulphate, unless otherwise stated.

of manganese. Of these, bismuth and lead are themselves activators in CaO. Manganese and bismuth have a similar optimal candoluminescence temperature, and thus emit simultaneously in the flame, but the spectra of manganese (peak at 580 nm) and bismuth (400 nm) do not overlap, and the manganese emission can be measured without interference from bismuth. The same considerations apply to lead, with a peak at 390 nm. Moreover, the lead emission occurs at a much lower temperature than that of manganese, and fades to zero before the manganese luminescence starts. The non-luminescing interferents mentioned have white oxides, and so no surface deposit was visible.

Anions. Common anions such as SO_4^{2-}, NO_3^-, NO_2^-, SCN^-, IO_3^- and some organic anions (formate, oxalate) were found to have no effect on the manganese candoluminescence at any concentration. Chloride ions, however, enhanced the luminescence, as shown in Fig. 7. The emission from 10 ng of manganese was found to be twice as intense in the presence of 1 μg of chloride, and was increased 4.2 times by 10 μg of chloride. Bromide had a slight enhancing effect (1.7 times the original intensity, with 10 μg of bromide); fluoride enhanced the emission by about 100% only when present in low concentrations (500 ppm), and had no effect at high concentrations (Fig. 7). Iodide had no effect. The phenomenon of an anion or an acid enhancing the emission from a matrix–activator pair has been termed co-activation, and has been found to occur quite frequently in candoluminescence [4,5] Chloride, for example, co-activates the emissions from lead and antimony in calcium oxide, and from indium in magnesium oxide.[5] Sulphuric acid co-activates cerium and europium candoluminescence in calcium oxide.[4] The emission from co-activated manganese has the same spectrum as that from manganese that has not been co-activated. The presence of a co-activator gives greater sensitivity, as is shown in Fig. 5. However, the calibration range is not extended in the presence of the co-activator, nor is the reproducibility improved.

The only anions that reduced the luminescent intensity were those that contained a transition metal, *viz.* VO_3^- and CrO_4^{2-}.

Acids. As the matrix is mainly calcium oxide, the presence of acids in the sample solution would be expected to interfere chemically with its composition, and thus with the luminescence produced. Increasing concentrations of nitric and sulphuric acids were found to produce a gradual decrease of emission intensity as shown in Fig. 8, the sulphuric acid interference being the greater. Hydrochloric acid was found to cause an initial sharp enhancement of emission, because of chloride co-activation, but with increasing acid concentration, the enhancement fell steadily. However, as shown in Fig. 8, even in the presence of 5 *M* acid, the emission intensity did not fall below that in the absence of co-activation.

Repeated emissions

If, after emission had been obtained from an activated matrix, the matrix was removed from the flame for about a minute to let it cool, and then re-introduced into the flame, the emission intensity obtained was up to three times the initial intensity. Further small enhancements occurred each time the process was repeated, as is shown in Fig. 9. Such a phenomenon does not seem to be exhibited by bismuth, for which repetition of heating gives the same emission from a single matrix.[2]

DISCUSSION

The phenomenon of candoluminescence has been shown to be the basis for a method for the determination of nanogram and sub-nanogram quantities of manganese in aqueous solution. The method is rapid, very sensitive and requires fairly simple apparatus. Co-activation increases the sensitivity of the method.

In the initial quantitative candoluminescence studies of bismuth,[1] the activator was introduced into the matrix by co-precipitating it with the matrix in solution. This gave a calibration range in the microgram region. Much greater sensitivity could be

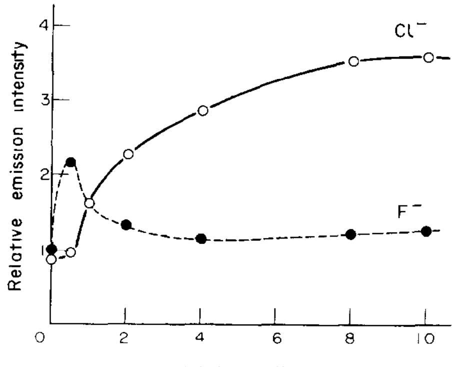

Fig. 7 Effect of chloride and fluoride ions on the peak candoluminescence intensity from 10 ng of manganese.

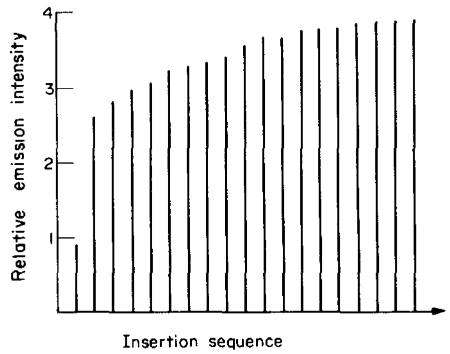

Fig. 9. Peak emission intensities obtained by sequential restimulation of manganese candoluminescence.

obtained by directly adding the activator in solution to the pure matrix surface. With improving techniques, it has been possible to apply a direct-injection method for all activators, including manganese. However, in order to have reasonably reproducible results, it is necessary to have a standardized, reproducible procedure for the preparation of each matrix. This is because the variation of compactness and porosity between matrices is a major cause of poor reproducibility of luminescence emission.

Certain metal ions are found to interfere with the manganese luminescence; thus it is necessary to ensure that these ions are not present in solution with the activator, either by chemically removing them, or by selectively extracting the manganese before determining it.

More matrix–activator pairs are being discovered, and analytical applications of these will be the subject of future papers. With such developments it is apparent that candoluminescence has much potential as a general quantitative trace analytical technique.

A SENSOR FOR HYDROGEN SULPHIDE

NOBUTOSHI KIBA and MOTOHISA FURUSAWA
Laboratory of Chemistry, Faculty of Engineering, Yamanashi University,
Takeda 4-3-11, Kofu-shi, 400, Japan

(*Received* 9 *October* 1975. *Accepted* 8 *March* 1976)

Summary—A sensor for hydrogen sulphide is described. It is based on the catalytic effect of the gas on the iodine–azide reaction. An iodine–azide solution is exuded from a sintered-glass ball (10 mm diameter) at a flow-rate of 3.30 ml/min whilst its potential is monitored by two platinum electrodes, one inside and the other outside the ball. Sample is carried in a gas at a flow-rate of 350 ml/min. Carbon disulphide, methyl mercaptan or sulphur dioxide in amounts up to a hundred times that of the hydrogen sulphide do not interfere. The detection limit is 5 ng and the determination limit is 8 ng, with a relative standard deviation of 10%.

The flame photometric detector has been widely used to monitor sulphur compounds in the atmosphere.[1–4] This detector is selective and sensitive for sulphur, but it does not differentiate one compound of sulphur from another.

The object of this work was to construct a sensor for the sensitive and selective determination of hydrogen sulphide. To achieve this we took advantage of the catalytic effect of hydrogen sulphide. It is well known that the iodine–azide reaction is catalysed by sulphides, thiosulphates, thiocyanates, mercaptans, and thioketones,[5] and this has been used as a basis for the determination of these compounds. For example, metallic sulphides, thiosulphates and thiocyanates have been determined arsenimetrically,[6–11] manometrically,[12–15] amperometrically,[16–20] and photometrically.[21,22] Carbon disulphide has been determined by the chronometric method[23] and arsenimetry.[24] Hydrogen sulphide in the atmosphere was determined manometrically as metallic sulphide,[25] but the direct determination of hydrogen sulphide based on the catalytic reaction has not been reported previously.

Although many sulphur compounds exert a catalytic effect on the reaction, the only gaseous substances able to do so at room temperature are hydrogen sulphide, carbon disulphide, and lower alkyl mercaptans. Further, the mercaptans dissolve in water and react much more slowly than hydrogen sulphide. In our procedure, iodine–azide solution is exuded from a sintered-glass ball at constant flow-rate and the difference in potential between two platinum wire electrodes, one of which is placed in the solution inside the sintered-glass ball and the other outside the ball, is measured. Hydrogen sulphide, which is transported by a carrier gas at constant flow-rate, reacts only with the solution outside the ball. The catalysed reaction results in a variation in composition of the solutions inside and outside the ball and consequently a measurable potential difference across the electrodes.

A device having a sintered-glass ball was devised first by Araki *et al.*,[26] who determined sulphur dioxide at the 0.5–20 ppm level by using an iodine concentration cell.

EXPERIMENTAL

Apparatus

The essential features of the device are shown in Fig. 1. The sintered-glass ball was a glass filter ball 10 mm in diameter. The iodine–azide solution was pumped peristaltically. Potentials were measured with a TOA potentiometer HM-5A connected to a TOA recorder EPR-10A. The platinum wire electrodes were 0.5 mm in diameter and

5 mm long. The electrode outside the ball was placed in contact with the ball as shown in Fig. 2, and the platinum wire (0.5 mm diameter and 100 mm long) was insulated with poly(vinyl chloride). The electrodes were cleaned by electrolysis in 0.2 M sodium acetate for 30 min at 0.0 V *vs.* S.C.E. and stored in 7.0 M nitric acid. This treatment allowed the electrodes to function continuously for about 200 hr

Reagents

A $10^{-3}M$ stock solution of iodine in 0.1M potassium iodide was prepared and standardized by titration with thiosulphate. The sodium azide was checked iodometrically by the method of Feigl *et al.*[27] Solutions were buffered with mixtures of potassium dihydrogen phosphate and sodium hydroxide.

All reagents were analytical-reagent grade and used without further purification.

Procedure

Nitrogen was used as carrier gas, at a constant flow-rate of 350 ml/min. The iodine–azide solution ($3 \times 10^{-5}M$ iodine, 0.02 M sodium azide, 0.02 M potassium iodide, buffered at pH 7.0) was exuded from the sintered-glass ball at a constant flow-rate of 3.3 ml/min by means of the peristaltic pump. When a recorder gave a steady trace, 100 μl of sample were injected with a gas-syringe. A suitable sensitivity was chosen by trial. The recorder was run at a speed of 10 mm/min. All experiments were carried out at room temperature, 25°.

Calibration was made by injecting 5 ml of hydrogen sulphide into a 2250-ml flask, equipped with a rubber stopper coated with silicone grease, and extracting sample from the flask through the rubber stopper with a 500-μl gas-syringe. The amount of hydrogen sulphide injected was determined iodometrically. When the total volume of sample extracted amounted to 2 ml, a fresh sample was prepared.

RESULTS AND DISCUSSION

The pH and flow-rate of the iodine–azide solution

The iodine–azide solution was buffered at pH 5.0, 6.0, 7.0, and 8.0 and the solutions were exuded from the ball at different flow-rates. Typical potential *vs* time (E–t) curves and the results, together with relative standard deviation, are shown in Figs. 3 and 4, respectively. In Fig. 3, the curves rise rapidly and then tail off. The tailing is considerable at the lower flow-rates but, the shapes of the curves do not vary with pH. At the lower flow-rates the base-lines of the curves are very unstable and the curves show several sharp peaks (A, B, E and F in Fig. 3). At higher flow-rates, the base-lines are stable, the curves show a single peak, and the values of the relative standard deviations are more reproducible than those for lower flow-rates. Figure 4 shows that the potential difference is highly dependent on both the pH and the flow-rate of the solution. A slight change of the flow-rate in the range 1.65–4.40 ml/min has a remarkable

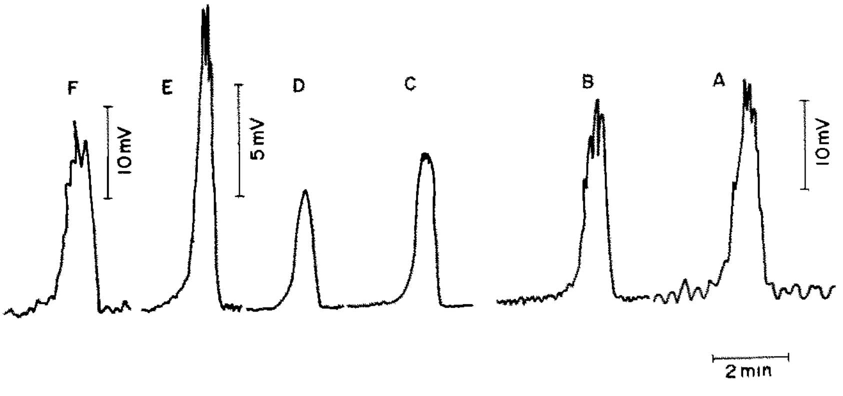

Fig. 3. Potential–time curves. pH and flow-rate of solution, ml/min: A, 7.0, 0.62; B, 7.0, 1.65; C, 7.0, 2.25; D, 7.0, 3.30; E, 8.0, 1.65; F, 6.0, 1.65. Iodine $6.30 \times 10^{-5}M$, sodium azide $1.85 \times 10^{-2}M$, potassium iodide $8.45 \times 10^{-2}M$, gas flow-rate 110 ml/min, hydrogen sulphide 190 ng.

effect on the potential difference, especially at pH 8.0. When the exudation of the solution from the ball was stopped and four separate samples were successively injected at intervals (Fig. 5), a sloping base-line was obtained because of the evaporation of iodine. The curves show that the catalyst is not fully active until a while after the reaction begins. The maximum potentials were obtained at the third injection for all solutions (Fig. 6). The results (Figs. 4 and 6) show that the best compromise between sensitivity and reproducibility is given by using a pH of 7.0 and a flow-rate of about 3.3 ml/min were chosen.

Concentration of the iodine–azide solution

Measurements made on solutions with varied concentrations of iodine, of sodium azide and potassium iodide are shown in Tables 1–3. Plots of potential *vs.* log iodine or azide concentration were linear, whereas the potential was independent of iodide concentration. The results show that the sensitivity of the reaction towards hydrogen sulphide is determined mainly by the azide:iodine ratio. Babko *et al.*,[21] using a photometric method, reported that the sensitivity of the reaction increased with concentration of potassium iodide over the range 0.1–2.8 *M*, concentrations

of the other components being kept constant at 10^{-3} M iodine, 0.011 M sodium azide, and pH 5.2. Such an increase in sensitivity was not observed under the experimental conditions of our study.

The use of lower concentrations of iodine and higher concentrations of azide increases the sensitivity of the reaction, but the base-line drifts when lower iodine concentrations are used, because of the volatility of iodine; reproducible results are also not obtained in the presence of large amounts of sodium azide. Thus, the concentrations of iodine, sodium azide, and potassium iodide were fixed at 3×10^{-5}, 0.02, and 0.02M respectively.

Gas flow-rate

The effect of flow-rate of the carrier gas was examined over the range 75–800 ml/min. Typical E–t curves at different gas flow-rates are shown in Fig. 7, and the results are listed in Table 4. In Fig. 7, the shapes of the curves vary with gas flow-rate, with broad jagged peaks at low flow-rates and single sharp peaks at high. The reproducibilities are better at moderate flow-rates. The potentials are approximately constant in the gas flow-rate range 250–480 ml/min, so a flow-rate of 350 ml/min was chosen.

Working electrode and glass tube

Contact between the platinum electrode and the ball was made in three ways: (*i*) *via* the bottom of the ball as shown in Fig. 2, (*ii*) *via* a platinum wire ring 5 mm in diameter at the bottom of the ball, and (*iii*) *via* a platinum wire 100 mm long wound round

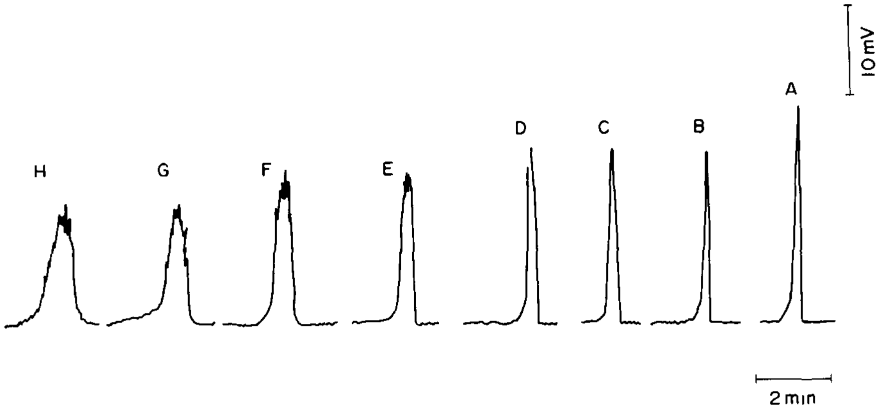

Fig. 7. Potential–time curves at various gas flow-rates. Flow rates, *ml/min*: A, 800; B, 480; C, 330; D, 250; E, 180; F, 130; G, 90; H, 75. Iodine 3.10 × $10^{-5}M$, sodium azide 2.12 × $10^{-2}M$, potassium iodide 2.00 × $10^{-2}M$, solution flow-rate 3.3 ml/min, pH 7.0, hydrogen sulphide 505 ng.

the ball. Method (*i*) gave the most sensitive and reproducible results, the other two giving poor base-lines and variable sensitivities 10–50 times poorer than those obtained by method (*i*).

A change in the linear velocity of the carrier gas in the neighbourhood of the ball made the sensitivity and reproducibility poorer. For example, when a glass tube (20 mm bore) without a bulge was used, the sensitivity was only a third of that for curve C in Fig. 7 and the relative standard deviation was 34% for seven runs, whereas with the glass tube shown in Fig. 2 the deviation was 5.6% under the same conditions. The distance between the gas inlet and the ball also affected the results. A relative standard deviation of 10% or less was obtained with a distance of 20 cm or more.

Interferences

Gaseous reducing substances such as sulphur dioxide and formaldehyde interfered, but the sensitivity towards sulphur dioxide was only about 2%, and that towards formaldehyde only about 0.1% of that towards hydrogen sulphide. The shapes of the E–t curves were symmetric and this could be used to distinguish between other reducing gas (symmetric peaks) and hydrogen sulphide (asymmetric).

Gaseous oxidizing substance such as ozone gave a potential in the opposite direction, with a magnitude similar to that for sulphur dioxide.

Gaseous substances, such as carbon disulphide and methyl mercaptan, having a catalytic effect on the iodine–azide reaction, reacted more slowly, so that a 100-fold amount relative to hydrogen sulphide merely broadened the width of the peak, but left the height unaffected. When there was 200, 300, 400, 500 and 600 times as much carbon disulphide or methyl mercaptan as hydrogen sulphide the error was 2.5, 3.2, 4.3, 7.9 and 12.0% respectively.

Gaseous organic substances which decrease the response of the flame photometric detector[28] did not interfere at any concentration.

Calibration curve

The sensitivity of the sensor to hydrogen sulphide varied somewhat with changes in conditions for electrode treatment such as cleaning time, and concentrations of sodium acetate solution and nitric acid. However, over a period up to 200 hr the following relationship held: $E = 9.61 \log C - 6.0$, where E is the potential in mV and C is the amount of hydrogen sulphide in ng. The slope of the curve varied with electrode treatment by ±0.2. The relative standard deviations (10 runs) were 9.8% for 8 ng of hydrogen sulphide, 9.4% for 10 ng, 7.7% for 50 ng, 5.0% for 100 ng, 3.5% for 500 ng and 2.7% for 1000 ng. When the amount of hydrogen sulphide was greater than 1 μg there was a negative deviation from linearity, amounting to 10% for 10 μg of hydrogen sulphide and 16% for 15 μg. The sensitivity worsened rapidly after 200 hr use of the electrodes.

The lowest detectable potential for the recorder and potentiometer used in this study was 0.7 mV. Therefore, the detection limit was 5 ng.

A SENSOR FOR HYDROGEN SULPHIDE

NOBUTOSHI KIBA and MOTOHISA FURUSAWA
Laboratory of Chemistry, Faculty of Engineering, Yamanashi University,
Takeda 4-3-11, Kofu-shi, 400, Japan

(*Received* 9 *October* 1975. *Accepted* 8 *March* 1976)

Summary—A sensor for hydrogen sulphide is described. It is based on the catalytic effect of the gas on the iodine–azide reaction. An iodine–azide solution is exuded from a sintered-glass ball (10 mm diameter) at a flow-rate of 3.30 ml/min whilst its potential is monitored by two platinum electrodes, one inside and the other outside the ball. Sample is carried in a gas at a flow-rate of 350 ml/min. Carbon disulphide, methyl mercaptan or sulphur dioxide in amounts up to a hundred times that of the hydrogen sulphide do not interfere. The detection limit is 5 ng and the determination limit is 8 ng, with a relative standard deviation of 10%.

The flame photometric detector has been widely used to monitor sulphur compounds in the atmosphere.[1–4] This detector is selective and sensitive for sulphur, but it does not differentiate one compound of sulphur from another.

The object of this work was to construct a sensor for the sensitive and selective determination of hydrogen sulphide. To achieve this we took advantage of the catalytic effect of hydrogen sulphide. It is well known that the iodine–azide reaction is catalysed by sulphides, thiosulphates, thiocyanates, mercaptans, and thioketones,[5] and this has been used as a basis for the determination of these compounds. For example, metallic sulphides, thiosulphates and thiocyanates have been determined arsenimetrically,[6–11] manometrically,[12–15] amperometrically,[16–20] and photometrically.[21,22] Carbon disulphide has been determined by the chronometric method[23] and arsenimetry.[24] Hydrogen sulphide in the atmosphere was determined manometrically as metallic sulphide,[25] but the direct determination of hydrogen sulphide based on the catalytic reaction has not been reported previously.

Although many sulphur compounds exert a catalytic effect on the reaction, the only gaseous substances able to do so at room temperature are hydrogen sulphide, carbon disulphide, and lower alkyl mercaptans. Further, the mercaptans dissolve in water and react much more slowly than hydrogen sulphide. In our procedure, iodine–azide solution is exuded from a sintered-glass ball at constant flow-rate and the difference in potential between two platinum wire electrodes, one of which is placed in the solution inside the sintered-glass ball and the other outside the ball, is measured. Hydrogen sulphide, which is transported by a carrier gas at constant flow-rate, reacts only with the solution outside the ball. The catalysed reaction results in a variation in composition of the solutions inside and outside the ball and consequently a measurable potential difference across the electrodes.

A device having a sintered-glass ball was devised first by Araki *et al.*,[26] who determined sulphur dioxide at the 0.5–20 ppm level by using an iodine concentration cell.

EXPERIMENTAL

Apparatus

The essential features of the device are shown in Fig. 1. The sintered-glass ball was a glass filter ball 10 mm in diameter. The iodine–azide solution was pumped peristaltically. Potentials were measured with a TOA potentiometer HM-5A connected to a TOA recorder EPR-10A. The platinum wire electrodes were 0.5 mm in diameter and

5 mm long. The electrode outside the ball was placed in contact with the ball as shown in Fig. 2, and the platinum wire (0.5 mm diameter and 100 mm long) was insulated with poly(vinyl chloride). The electrodes were cleaned by electrolysis in 0.2 *M* sodium acetate for 30 min at 0.0 V *vs.* S.C.E. and stored in 7.0 *M* nitric acid. This treatment allowed the electrodes to function continuously for about 200 hr

Reagents

A $10^{-3}M$ stock solution of iodine in 0.1*M* potassium iodide was prepared and standardized by titration with thiosulphate. The sodium azide was checked iodometrically by the method of Feigl *et al.*[27] Solutions were buffered with mixtures of potassium dihydrogen phosphate and sodium hydroxide.

All reagents were analytical-reagent grade and used without further purification.

Procedure

Nitrogen was used as carrier gas, at a constant flow-rate of 350 ml/min. The iodine–azide solution ($3 \times 10^{-5}M$ iodine, 0.02 *M* sodium azide, 0.02 *M* potassium iodide, buffered at pH 7.0) was exuded from the sintered-glass ball at a constant flow-rate of 3.3 ml/min by means of the peristaltic pump. When a recorder gave a steady trace, 100 μl of sample were injected with a gas-syringe. A suitable sensitivity was chosen by trial. The recorder was run at a speed of 10 mm/min. All experiments were carried out at room temperature, 25°.

Calibration was made by injecting 5 ml of hydrogen sulphide into a 2250-ml flask, equipped with a rubber stopper coated with silicone grease, and extracting sample from the flask through the rubber stopper with a 500-μl gas-syringe. The amount of hydrogen sulphide injected was determined iodometrically. When the total volume of sample extracted amounted to 2 ml, a fresh sample was prepared.

RESULTS AND DISCUSSION

The pH and flow-rate of the iodine–azide solution

The iodine–azide solution was buffered at pH 5.0, 6.0, 7.0, and 8.0 and the solutions were exuded from the ball at different flow-rates. Typical potential *vs* time (*E–t*) curves and the results, together with relative standard deviation, are shown in Figs. 3 and 4, respectively. In Fig. 3, the curves rise rapidly and then tail off. The tailing is considerable at the lower flow-rates but, the shapes of the curves do not vary with pH. At the lower flow-rates the base-lines of the curves are very unstable and the curves show several sharp peaks (A, B, E and F in Fig. 3). At higher flow-rates, the base-lines are stable, the curves show a single peak, and the values of the relative standard deviations are more reproducible than those for lower flow-rates. Figure 4 shows that the potential difference is highly dependent on both the pH and the flow-rate of the solution. A slight change of the flow-rate in the range 1.65–4.40 ml/min has a remarkable

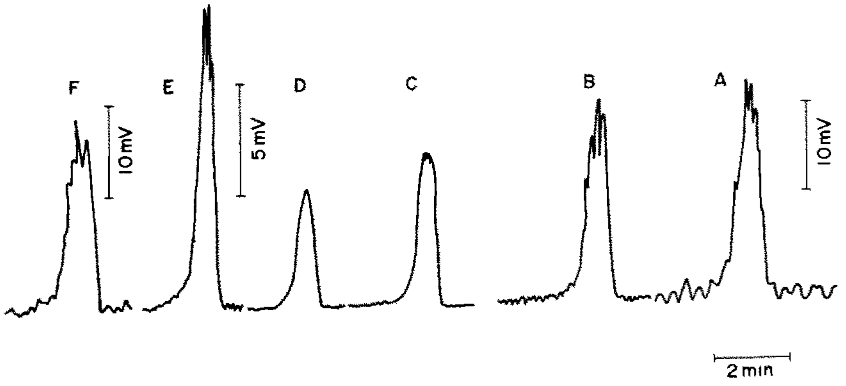

Fig. 3. Potential–time curves. pH and flow-rate of solution, ml/min: A, 7.0, 0.62; B, 7.0, 1.65; C, 7.0, 2.25; D, 7.0, 3.30; E, 8.0, 1.65; F, 6.0, 1.65. Iodine $6.30 \times 10^{-5}M$, sodium azide $1.85 \times 10^{-2}M$, potassium iodide $8.45 \times 10^{-2}M$, gas flow-rate 110 ml/min, hydrogen sulphide 190 ng.

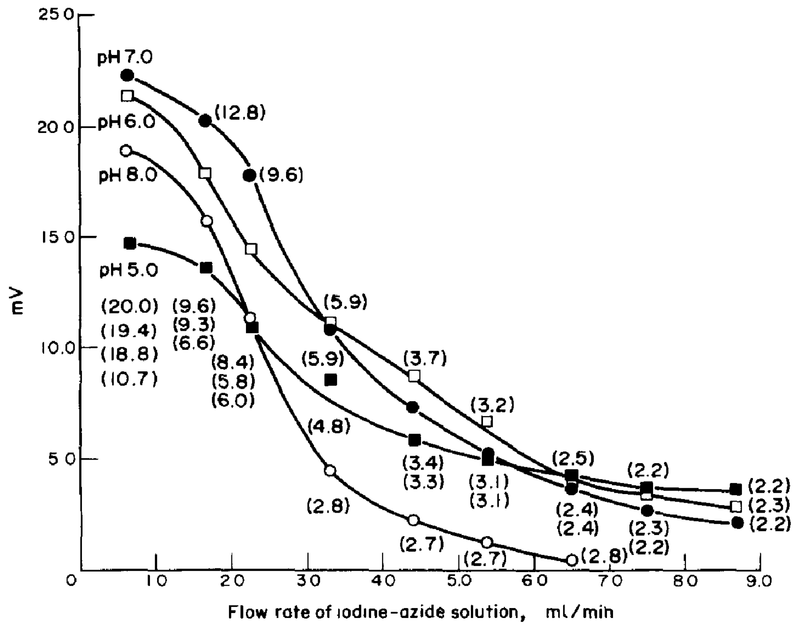

Fig. 4. Relationship between flow-rate of iodine–azide solution and potentials in solutions of different pH. Figures in parentheses represent the relative standard deviations. Each value is the average of 7 runs. Experimental conditions as for Fig. 3.

effect on the potential difference, especially at pH 8.0. When the exudation of the solution from the ball was stopped and four separate samples were successively injected at intervals (Fig. 5), a sloping base-line was obtained because of the evaporation of iodine. The curves show that the catalyst is not fully active until a while after the reaction begins. The maximum potentials were obtained at the third injection for all solutions (Fig. 6). The results (Figs. 4 and 6) show that the best compromise between sensitivity and reproducibility is given by using a pH of 7.0 and a flow-rate of about 3.3 ml/min were chosen.

Concentration of the iodine–azide solution

Measurements made on solutions with varied concentrations of iodine, of sodium azide and potassium iodide are shown in Tables 1–3. Plots of potential *vs.* log iodine or azide concentration were linear, whereas the potential was independent of iodide concentration. The results show that the sensitivity of the reaction towards hydrogen sulphide is determined mainly by the azide:iodine ratio. Babko *et al.*,[21] using a photometric method, reported that the sensitivity of the reaction increased with concentration of potassium iodide over the range 0.1–2.8 *M*, concentrations

of the other components being kept constant at 10^{-3} M iodine, 0.011 M sodium azide, and pH 5.2. Such an increase in sensitivity was not observed under the experimental conditions of our study.

The use of lower concentrations of iodine and higher concentrations of azide increases the sensitivity of the reaction, but the base-line drifts when lower iodine concentrations are used, because of the volatility of iodine; reproducible results are also not obtained in the presence of large amounts of sodium azide. Thus, the concentrations of iodine, sodium azide, and potassium iodide were fixed at 3×10^{-5}, 0.02, and 0.02M respectively.

Gas flow-rate

The effect of flow-rate of the carrier gas was examined over the range 75–800 ml/min. Typical *E–t* curves at different gas flow-rates are shown in Fig. 7, and the results are listed in Table 4. In Fig. 7, the shapes of the curves vary with gas flow-rate, with broad jagged peaks at low flow-rates and single sharp peaks at high. The reproducibilities are better at moderate flow-rates. The potentials are approximately constant in the gas flow-rate range 250–480 ml/min, so a flow-rate of 350 ml/min was chosen.

Working electrode and glass tube

Contact between the platinum electrode and the ball was made in three ways: (*i*) *via* the bottom of the ball as shown in Fig. 2, (*ii*) *via* a platinum wire ring 5 mm in diameter at the bottom of the ball, and (*iii*) *via* a platinum wire 100 mm long wound round

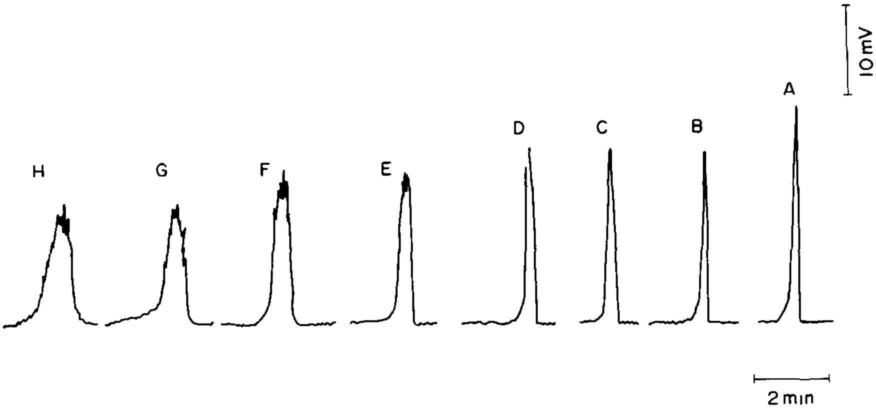

Fig. 7. Potential–time curves at various gas flow-rates. Flow rates, *ml/min*: A, 800; B, 480; C, 330; D, 250; E, 180; F, 130; G, 90; H, 75. Iodine $3.10 \times 10^{-5}M$, sodium azide $2.12 \times 10^{-2}M$, potassium iodide $2.00 \times 10^{-2}M$, solution flow-rate 3.3 ml/min, pH 7.0, hydrogen sulphide 505 ng.

the ball. Method (*i*) gave the most sensitive and reproducible results, the other two giving poor base-lines and variable sensitivities 10–50 times poorer than those obtained by method (*i*).

A change in the linear velocity of the carrier gas in the neighbourhood of the ball made the sensitivity and reproducibility poorer. For example, when a glass tube (20 mm bore) without a bulge was used, the sensitivity was only a third of that for curve C in Fig. 7 and the relative standard deviation was 34% for seven runs, whereas with the glass tube shown in Fig. 2 the deviation was 5.6% under the same conditions. The distance between the gas inlet and the ball also affected the results. A relative standard deviation of 10% or less was obtained with a distance of 20 cm or more.

Interferences

Gaseous reducing substances such as sulphur dioxide and formaldehyde interfered, but the sensitivity towards sulphur dioxide was only about 2%, and that towards formaldehyde only about 0.1% of that towards hydrogen sulphide. The shapes of the E–t curves were symmetric and this could be used to distinguish between other reducing gas (symmetric peaks) and hydrogen sulphide (asymmetric).

Gaseous oxidizing substance such as ozone gave a potential in the opposite direction, with a magnitude similar to that for sulphur dioxide.

Gaseous substances, such as carbon disulphide and methyl mercaptan, having a catalytic effect on the iodine–azide reaction, reacted more slowly, so that a 100-fold amount relative to hydrogen sulphide merely broadened the width of the peak, but left the height unaffected. When there was 200, 300, 400, 500 and 600 times as much carbon disulphide or methyl mercaptan as hydrogen sulphide the error was 2.5, 3.2, 4.3, 7.9 and 12.0% respectively.

Gaseous organic substances which decrease the response of the flame photometric detector[28] did not interfere at any concentration.

Calibration curve

The sensitivity of the sensor to hydrogen sulphide varied somewhat with changes in conditions for electrode treatment such as cleaning time, and concentrations of sodium acetate solution and nitric acid. However, over a period up to 200 hr the following relationship held: $E = 9.61\log C - 6.0$, where E is the potential in mV and C is the amount of hydrogen sulphide in ng. The slope of the curve varied with electrode treatment by ±0.2. The relative standard deviations (10 runs) were 9.8% for 8 ng of hydrogen sulphide, 9.4% for 10 ng, 7.7% for 50 ng, 5.0% for 100 ng, 3.5% for 500 ng and 2.7% for 1000 ng. When the amount of hydrogen sulphide was greater than 1 μg there was a negative deviation from linearity, amounting to 10% for 10 μg of hydrogen sulphide and 16% for 15 μg. The sensitivity worsened rapidly after 200 hr use of the electrodes.

The lowest detectable potential for the recorder and potentiometer used in this study was 0.7 mV. Therefore, the detection limit was 5 ng.

THE STABILITY OF THE CERTIFIED REFERENCE ORES MP-1 KC-1 AND SU-1 TOWARDS AIR OXIDATION

H. F. STEGER
Chemistry Laboratory, Canada Centre for Mineral and Energy Technology,
555 Booth Street, Ottawa, Canada

(*Received* 2 *September* 1975. *Revised* 12 *March* 1976. *Accepted* 30 *March* 1976)

Summary—The stability of three certified reference sulphide ores, MP-1, KC-1 and SU-1, towards air oxidation has been measured at 50° and 40, 62 and 82% relative humidity, and at 62% relative humidity and 34° and 67°. Both the relative humidity and temperature affect the rate of oxidation but their relative importance depends on the mineralogical composition of the ore. Changes in the water-extractable metals and elemental sulphur content on oxidation have been determined. It is concluded that these ores may be stored safely in sealed bottles under normal laboratory conditions.

The susceptibility of sulphide ores and concentrates to air oxidation is widely known. Indeed, it is this phenomenon that can render the storage and transportation of these materials extremely hazardous.[1,2] It is also an awareness of this tendency to oxidize that has caused several enquiries to be made of the Canadian Certified Reference Materials Program concerning the long-term stability of certified reference sulphide ores during storage in the bottle. Accordingly, an investigation was undertaken to ascertain the extent and, if possible, the nature of chemical change in three sulphide reference ores under various conditions of temperature and relative humidity, chosen so as to give accelerated rates of alteration, in order for long-term effects to be predicted early.

It should be noted that these reference ores are very complex materials, both mineralogically and chemically. Further, they have undergone severe treatment during their preparation (drying, grinding *etc.*). The oxidation of the ores studied herein is a composite of the different rates and mechanisms of oxidation of the individual minerals. Accordingly, explanations proposed for trends in the oxidation behaviour of MP-1, KC-1 and SU-1 often cannot be substantiated by experiment and thus are of a speculative nature based on chemical intuition.

EXPERIMENTAL

The preparation, characterization and certification of the reference ores, MP-1,[3] KC-1[4] and SU-1,[5] has already been described. The predominant sulphide minerals present in these ores are summarized in Table 1

The procedure used to study the chemical alteration of these ores was as follows. Approximately 0.5 g of each ore was weighed in duplicate into tared 50-ml beakers. The beakers were placed in a glass tray and inserted into a Controlled Relative Humidity Chamber (Blue M, Electric Co., Blue Island, Illinois, U.S.A.) in which a preselected temperature and relative humidity, RH, was maintained. Air flowed through the system continuously. At the end of one week, the samples (plus beakers) were removed from the chamber, dried over Drierite for 16–24 hr,* weighed, remixed and inserted into the chamber again. This procedure was followed for 7 weeks at 50° and 40, 62 and 82% RH, and at 62% RH and 34° and 67°. One series of samples run at 50° and 62% RH was stopped after 3 weeks.

At the end of 7 weeks, one sample of each ore was transferred to a 200-ml polyethylene bottle, mixed with 30.00-ml of distilled water and shaken for 2 hr. The resultant suspension was centrifuged at 1800 rpm for 30 min and filtered (dry Whatman No. 42 paper) to ensure the removal of solids. A 20.00-ml portion of the filtrate was mixed with 5.00 ml of 10% nitric acid and the Fe, Pb, Cu, Ni and Zn concentrations were measured with a Techtron AA5 atomic-absorption spectro-photometer. The corresponding water-soluble content of these metals in the untreated ores was also measured as above. Originally, the metals in one sample of each ore that had been oxidized at 50° and 62% RH, and of each of the corresponding unoxidized ores, were extracted with 30.00 ml of 5% sodium acetate solution. The sodium acetate solution extracted appreciably

more metal from the treated and untreated ores than did water. However, the difference between the amounts extracted before and after treatment was essentially the same as when water was used. It was decided, therefore, to perform all further extractions with water because the metal concentrations obtained were more amenable to measurement by atomic absorption.

The elemental sulphur content of untreated and treated samples of the reference ores was determined by a method developed in this laboratory.[6]

RESULTS AND DISCUSSION

The values of the gain in weight, Δw, of these reference ores after the 7 weeks treatment are summarized in Table 2. Figure 1, which illustrates the results obtained at 50° and 82% RH is a typical example of Δw as a function of t, the treatment time. The slope of the observed linear functions, $\Delta w/t$, is, of course, the rate of gain in weight. The decrease in $\Delta w/t$ at 3 ± 0.2 weeks was observed in all trials, with the exception of SU-1 at 50° and 40% RH, for which no Δw was detected. The values of $\Delta w/t$ for the time periods of 1–3 and 3–7 weeks are given in Table 3. The cause of the break in $\Delta w/t$ will be discussed below.

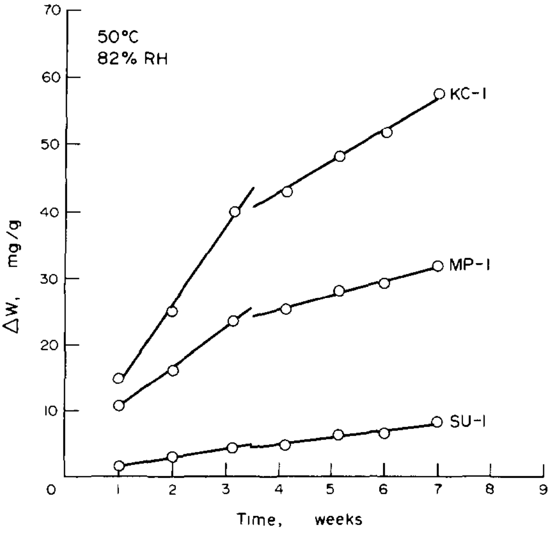

Fig. 1. The gain in weight (as a function of time) due to the treatment of MP-1, KC-1 and SU-1 at 50°C and 82% RH.

The data in Tables 2 and 3 show that RH and temperature are both important parameters in oxidation of the ores. For MP-1 and KC-1, a change in RH from 40 to 82% at 50° results in a larger Δw than does a change in temperature from 34 to 67° at 62% RH, whereas the reverse is observed for SU-1. This difference in behaviour must be a consequence of the mineralogical composition of the ores.

It must be noted that these reference ores, as available in the bottle, cannot really be termed "untreated". They have been subjected to drying, grinding, *etc.*, in their preparation, so oxidation must have occurred to an extent which is unknown but not of interest to the analyst with regard to long-term stability of these ores as reference materials. Because this study was concerned with the stability of the ores as available in the bottle, these ores were labelled as "untreated" and all values of Δw reported refer to them. On this basis, the value of Δw at the beginning of treatment for any RH and temperature should be zero. An examination of Fig. 1, however, illustrates that the linearly extrapolated rate of weight gain does not pass through the origin for MP-1 and KC-1. This behaviour was also observed for all other values of RH and temperature. It must be noted that the rate of a solid–gas reaction where a surface layer of product is formed is often initially quite fast but decreases to become essentially a linear function of time (*i.e.*, diffusion-controlled).[7] In this case, an extrapolation of the linear rate to zero time would not pass through the origin*. This observation for MP-1 and KC-1 suggests that the surface of these ores has not been oxidized completely. That the extrapolation of the linear rate for SU-1 passes through the origin does not necessarily imply that oxidation does not occur quite fast initially, but could simply be a manifestation of a low oxidation rate and the error in the experimental data.

The amounts of water-extractable metals, M_{EXT}, in the untreated reference ores are given in Table 4. MP-1 yields higher values of M_{EXT} although KC-1 has a higher iron, lead and zinc content. Herein such factors as mineralogical composition, particle size distribution and history of the ore play important roles.

---

* The author has considerable data to illustrate that the rate of oxidation of sulphides such as pyrite, pyrrhotite, chalcopyrite, galena and sphalerite does indeed behave as described here.

Table 4. Water-extractable metals in untreated ores

	M_{EXT}, *mg/g*			
Ore	Fe	Pb	Zn	Ni
MP-1	0.42 (0.04)*	0.37 (0.09)	8.6 (0.5)	—
KC-1	0.11 (0.06)	0.29 (0.04)	2.4 (0.2)	—
SU-1	0.0	0.0	0.0	0.0

* Numbers in brackets are the standard deviations of 8 determinations.

Because the tendency to oxidize varies with both the nature and particle size of the minerals in an ore, the resultant water-extractability of a metal is not necessarily related to the total metal content of an ore but instead is related to the mineralogical composition and particle size. Table 5 contains the results of a screening test of MP-1, KC-1 and SU-1 and clearly illustrates the vast difference in the particle size distribution in these ores.

The history of the ores, *i.e.*, the conditions of humidity, moisture content and temperature to which they have been subjected during collection, drying, storage and preparation may differ significantly, so the extent of oxidation also differs.

In general, metal sulphides, both natural and synthetic, are sparingly soluble in water; *e.g.*, the solubility of sphalerite and pyrite is 0.07 and 0.49 mg/100 ml at 20°, respectively.[7] The observation of a water-extractability of certain metals greater than that expected according to the solubility of the sulphide mineral(s) must be attributed to the presence of soluble "thio-salts" such as thiosulphate, sulphite and sulphate.[8–11] It is reasonable to assume therefore, that oxidation of a sulphide mineral which results in "thio-salt" formation should increase the water-extractability of certain metals.[12] Lead sulphite (insoluble) and sulphate (4.3 mg/100 ml) are exceptions, with a lower solubility than galena (12.9 mg/100 ml). Galena is, however, less soluble than lead thiosulphate (30 mg/100 ml).[7] The change in the water-extractability of lead on oxidation of galena therefore depends on the products formed.[9,10]

The values of the difference between M_{EXT} for the untreated and treated ores, ΔM_{EXT}, are given in Table 6. The difference was not considered to be significant if it was less than the standard deviation of M_{EXT} in Table 4. The aqueous extracts were also analysed for copper but none was found.

* No extractable metals were found for SU-1 at any other RH or *T*.

There is a reasonably good correlation between ΔZn_{EXT} and the corresponding value of Δw for MP-1 and KC-1; this reflects oxidation of sphalerite to "thio-salts". The values of ΔZn_{EXT} illustrate the susceptibility of sphalerite to oxidation and its absence is a probable explanation of the relative stability of SU-1. The apparently greater reactivity of the sphalerite in MP-1 compared to that in KC-1 is due to smaller particle size and consequentially larger surface area. The sphalerite gave the following size distribution, measured with an image analyser:[13]

μm	MP-1, %	KC-1, %
2–6	43	0
6–15	32	41
15–32	25	33
32–60	0	26

Although the size distribution was not measured, the particle size of the other sulphide minerals in MP-1 appeared to be similar. The decrease in ΔFe_{EXT} with an increase in the extent of oxidation of MP-1 and KC-1 suggests that iron hydroxide, oxide or basic iron "thio-salts" are formed rather than the soluble "thio-salts" as is observed for zinc. Indeed, it is known that weathering of pyrite and pyrrhotite results in the formation of limonite and/or haematite.[8,11]

The change in the opposite direction for ΔPb_{EXT} suggests the oxidation of galena to $PbSO_4$ for MP-1 but to PbS_2O_3 for KC-1. Although no conclusive explanation can be given here, the difference in the composition of the ores may be important. Sulphide minerals, when mixed as in ores, can often retard or accelerate the oxidation of one another.[14]

The relationships between log $(\Delta w/t)$ and RH at 50° and between log $(\Delta w/t)$ and temperature at 62% RH are linear with slopes *a* and *b* respectively. This dual linearity of log $(\Delta w/t)$ with temperature (T) and RH permits the formulation of a combined relationship

$$\log (\Delta w/t) = a(\mathrm{RH}) + bT + d$$

where RH is in %, *T* in K and *t* in weeks. A plot of log ($\Delta w/t$) against $a(\text{RH}) + bT$ should have unit slope and intercept d. The values of a, b and d, calculated slope and correlation coefficient of this plot for MP-1, KC-1 and SU-1 are summarized in Table 7. Again, it has been necessary to separate the data into those pertaining to 1–3 weeks and to 3–7 weeks.

The parameters a and b are, in effect, a measure of the sensitivity of the rate of gain in weight and, therefore, the rate of oxidation to changes in RH and temperature, respectively. It is tempting to conclude that the order of the values of a and b for the reference ores signifies that the effect of RH on their oxidation decreases in the order KC-1 > MP-1 > SU-1 whereas the effect of temperature decreases in the order SU-1 > KC-1 $\simeq$ MP-1. This, however, would be incorrect. The rate of oxidation depends not only on RH and temperature but also on the surface area, which is, of course, related to particle size. It is a widely accepted phenomenon that the smaller the particle size, the faster a reaction proceeds. Let us suppose that the rate of oxidation of an ore for a particular set of conditions of RH and T was found to be R_i. If, however, this same ore were comminuted to a different particle size distribution, the observed rate of oxidation would differ from R_t by a factor x, i.e., the rate of oxidation for the latter sample of the ore would be xR_i. It has been assumed that a change in particle size distribution has the same proportional effect on the rate of oxidation irrespective of the values of RH and temperature, in which case a and b will also be changed by the factor x. The dependence of a and b on the particle size distribution is evident and a comparison of a and b for different ores is, therefore, meaningless without a thorough understanding of the effect of particle size distribution on the reactivity of an ore.

The values of a/b should, however, be constant for an ore regardless of the state of comminution, provided that all mineral species present are fully liberated. Thus, differences in the values of a/b for a series of ores may be related to differences in their mineralogical composition because it is improbable that the oxidation of all the minerals that comprise an ore would be affected equally by both RH and temperature. The values of a/b for the 1–3 week period for MP-1, KC-1 and SU-1 are 1.38, 1.84 and 0.28, respectively. The difference in a/b illustrates that the influence of RH and temperature on the rate of oxidation of an ore does indeed vary with its mineralogy. For example, the oxidation of nickel-bearing pyrrhotite and pentlandite in SU-1 exhibits a much greater dependence on temperature relative to RH than does the oxidation of MP-1 and KC-1 in which sphalerite must play the dominant role (Table 5). Moreover, the difference between the a/b values for MP-1 and KC-1 indicates that minerals other than sphalerite are oxidized. The abundance of pyrite and galena in KC-1 relative to MP-1 may be the explanation. If so, the larger value of a/b for KC-1 requires that the oxidation of pyrite and/or galena shows a greater dependence on RH relative to temperature than does that of sphalerite.

It is very difficult to assign significance to the intercept d. It is, of course, a concomitant of the linear relationship between log ($\Delta w/t$) and $[a(\text{RH}) + bT]$ and, as such, will vary with the values of both a and b. The main function of d is to permit the calculation of log ($\Delta w/t$) for any value of RH and T.

Some speculations on mechanisms

A satisfactory explanation for the break in $\Delta w/t$ after about 3 weeks' treatment is difficult because of the complexity of the ores. It is improbable that the decrease in $\Delta w/t$ is due to either the complete oxidation of certain minerals in the ore or the formation of an oxidized surface layer sufficiently thick to cause $\Delta w/t$ to become diffusion-controlled. Each of these hypothetical processes would occur at essentially the same extent of oxidation of the ore regardless of T and RH. The change in $\Delta w/t$, however, always occurred at 3 ± 0.2 weeks even though the extent of oxidation as measured by Δw (Table 2) varied appreciably from trial to trial.

Table 7. Relationship of equation parameters

Ore	Time interval *weeks*	$a(10^{-2})$	$b(10^{-2})$	d
MP-1	1–3	2.04* ± 0.05† slope = 1.00	1.47 ± 0.11	−5.56 r = 0.997
	3–7	2.00 ± 0.10 slope = 1.01	1.14 ± 0.03	−4.80 r = 0.972
KC-1	1–3	2.52 ± 0.14 slope = 0.99	1.37 ± 0.10	−5.45 r = 0.984
	3–7	2.54 ± 0.10 slope = 1.00	1.21 ± 0.03	−5.24 r = 1.000
SU-1	1–3	1.48 ± 0.07 slope = 0.99	5.24 ± 0.09	−17.93 r = 0.986
	3–7	1.38 ± 0.16 slope = 0.99	4.21 ± 0.23	−14.52 r = 0.998

* Average of two samples.
† Corresponding deviation.

A comparison of the water-extractable metals (Table 6) for MP-1 and KC-1 for 3 and 7 weeks at 50° and 62% RH clearly illustrates that sphalerite undergoes oxidation throughout the 7 week period but, unfortunately, the results for Fe and Pb are either inconsistent or (because of the zero values) meaningless. The different mineralogical composition of MP-1, KC-1 and SU-1, however, would preclude the change in $\Delta w/t$ being due to the complete oxidation of certain minerals. The magnitude of this change would require that these minerals be present in appreciable quantities.

Although a change in RH or temperature affects the rate of oxidation of an ore, the overall mechanism remains the same, such that the oxidation reaction gives rise to a constant ratio of the amounts of the products. The absolute amount of the products, however, is dependent on the rate of oxidation and, therefore, on RH and temperature. Once formed by oxidation of the ores, the products are themselves subject to further reaction.

A comparison of the a and b values shows that $\Delta w/t$ for the 3–7 week period is affected to a lesser extent by temperature than is $\Delta w/t$ for the 1–3 week period. This does not necessarily mean that the oxidation becomes less sensitive to temperature after 3 weeks, but could indicate the start of some reaction resulting in a loss in weight so that the observed overall $\Delta w/t$ is lower than expected. The ratios of the $\Delta w/t$ values for the first and last periods of exposure (weeks 1–3 and 4–7) at 34, 50 and 67° and 62% RH show that the decrease in $\Delta w/t$ at 3 weeks increases with increasing temperature for all three ores, *i.e.*, the rate of weight loss increases with temperature.

The formation of elemental sulphur during the mild oxidation or weathering of sulphide minerals is well known.[8] This is also illustrated by the sulphur values for the unoxidized and oxidized ores, in Table 8. The results for 50° clearly show that the formation of sulphur increases with RH. The apparent anomaly of a decrease in the formation of sulphur with an increase in temperature is the result of the interplay of two factors. First, an increase in temperature enhances the rate of oxidation of an ore and, therefore, increases the formation of sulphur. Secondly, however, increase in temperature enhances the oxidation and/or volatilization of the sulphur thus formed.

It is reasonable to assume that the quantity of sulphur formed should vary with the extent of oxidation, *i.e.*, with the gain in weight. The quantity of sulphur formed should, therefore, increase with temperature, which is the opposite of what is found experimentally. The quantity of sulphur lost because of oxidation and/or volatilization must therefore also increase with temperature but to a greater extent, which, of course, parallels the magnitude of the decrease in $\Delta w/t$ at 3 weeks. It must be noted that the decomposition of metal thiosulphates or sulphates to the oxide[11,15] will also cause a loss in weight.

Table 8. Elemental sulphur in ores

	S, *mg/g*		
T, °C, RH, %	MP-1	KC-1	SU-1
Untreated	0.09	1.24	0.02
34, 62	0.37	2.94	0.03
50, 40	0.03	0.09	0.02
50, 62	0.22	1.10	0.02
50, 82	0.55	4.29	0.05
67, 62	0.09	0.06	0.63

The decrease in $\Delta w/t$ at 3 weeks can be explained as follows. By their very nature, sulphur and metal thio-salts are less susceptible to air-oxidation than are sulphides. Because sulphur and metal thio-salts are themselves products of oxidation, it is necessary for the oxidation to have proceeded to an extent at which their quantity is sufficiently large to compensate for their lower oxidation/decomposition rate and result in an observable decrease in $\Delta w/t$. In a system where the oxidation yields sulphur and metal thio-salts regardless of the RH and temperature, the decrease in the rate of gain in weight should be detected at approximately the same time, which is ~3 wk for MP-1, KC-1 and SU-1. The cause of the break in $\Delta w/t$ at 3 weeks can only be determined from a study of the mechanism of oxidation. Such a study, which is now under way, requires use of the pure minerals and the identification and determination of the oxidation products.

Stability of MP-1, KC-1 and SU-1 as reference ores

The stability of MP-1, KC-1 and SU-1 towards oxidation under laboratory conditions is readily calculated by extrapolation* of the data in Table 7. For example, when exposed to the atmosphere at 20° and 40% RH, MP-1 and KC-1 would undergo a 1% change in weight in about 45 weeks. SU-1 is stable. It can, therefore, be concluded that these certified reference ores should undergo no significant alteration at normal laboratory temperature and RH when stored in tightly sealed bottles.

Acknowledgement—The author wishes to thank Mr. R. G. Pinard, Mineral Sciences Laboratories, for his assistance in the mineralogical assessment of these ores.

THE STABILITY OF THE CERTIFIED REFERENCE ORES MP-1 KC-1 AND SU-1 TOWARDS AIR OXIDATION

H. F. STEGER
Chemistry Laboratory, Canada Centre for Mineral and Energy Technology,
555 Booth Street, Ottawa, Canada

(*Received* 2 *September* 1975. *Revised* 12 *March* 1976. *Accepted* 30 *March* 1976)

Summary—The stability of three certified reference sulphide ores, MP-1, KC-1 and SU-1, towards air oxidation has been measured at 50° and 40, 62 and 82% relative humidity, and at 62% relative humidity and 34° and 67°. Both the relative humidity and temperature affect the rate of oxidation but their relative importance depends on the mineralogical composition of the ore. Changes in the water-extractable metals and elemental sulphur content on oxidation have been determined. It is concluded that these ores may be stored safely in sealed bottles under normal laboratory conditions.

The susceptibility of sulphide ores and concentrates to air oxidation is widely known. Indeed, it is this phenomenon that can render the storage and transportation of these materials extremely hazardous.[1,2] It is also an awareness of this tendency to oxidize that has caused several enquiries to be made of the Canadian Certified Reference Materials Program concerning the long-term stability of certified reference sulphide ores during storage in the bottle. Accordingly, an investigation was undertaken to ascertain the extent and, if possible, the nature of chemical change in three sulphide reference ores under various conditions of temperature and relative humidity, chosen so as to give accelerated rates of alteration, in order for long-term effects to be predicted early.

It should be noted that these reference ores are very complex materials, both mineralogically and chemically. Further, they have undergone severe treatment during their preparation (drying, grinding *etc.*). The oxidation of the ores studied herein is a composite of the different rates and mechanisms of oxidation of the individual minerals. Accordingly, explanations proposed for trends in the oxidation behaviour of MP-1, KC-1 and SU-1 often cannot be substantiated by experiment and thus are of a speculative nature based on chemical intuition.

EXPERIMENTAL

The preparation, characterization and certification of the reference ores, MP-1,[3] KC-1[4] and SU-1,[5] has already been described. The predominant sulphide minerals present in these ores are summarized in Table 1

The procedure used to study the chemical alteration of these ores was as follows. Approximately 0.5 g of each ore was weighed in duplicate into tared 50-ml beakers. The beakers were placed in a glass tray and inserted into a Controlled Relative Humidity Chamber (Blue M, Electric Co., Blue Island, Illinois, U.S.A.) in which a preselected temperature and relative humidity, RH, was maintained. Air flowed through the system continuously. At the end of one week, the samples (plus beakers) were removed from the chamber, dried over Drierite for 16–24 hr,* weighed, remixed and inserted into the chamber again. This procedure was followed for 7 weeks at 50° and 40, 62 and 82% RH, and at 62% RH and 34° and 67°. One series of samples run at 50° and 62% RH was stopped after 3 weeks.

At the end of 7 weeks, one sample of each ore was transferred to a 200-ml polyethylene bottle, mixed with 30.00-ml of distilled water and shaken for 2 hr. The resultant suspension was centrifuged at 1800 rpm for 30 min and filtered (dry Whatman No. 42 paper) to ensure the removal of solids. A 20.00-ml portion of the filtrate was mixed with 5.00 ml of 10% nitric acid and the Fe, Pb, Cu, Ni and Zn concentrations were measured with a Techtron AA5 atomic-absorption spectro-photometer. The corresponding water-soluble content of these metals in the untreated ores was also measured as above. Originally, the metals in one sample of each ore that had been oxidized at 50° and 62% RH, and of each of the corresponding unoxidized ores, were extracted with 30.00 ml of 5% sodium acetate solution. The sodium acetate solution extracted appreciably

Table 1. Predominant sulphide minerals

* These minerals were indistinguishable in SU-1 by image analysis.

---

* This 16–24 hr drying period corresponds to overnight drying. Several simple tests indicated that there was no further change in weight of the sample after 8 hr drying. It must be noted that this drying period was not included in the one-week treatment period.

Table 2. Gain in weight after 7 weeks

		Gain in weight, *mg/g*		
Temp., °C	RH, %	MP-1	KC-1	SU-1
34	62	9.9	12.6	1.5
50	40	3.2	2.2	0.0
50	62	15.7	18.6	4.0
50	82	32.2	58.2	8.4
67	62	21.6	24.7	35.9

more metal from the treated and untreated ores than did water. However, the difference between the amounts extracted before and after treatment was essentially the same as when water was used. It was decided, therefore, to perform all further extractions with water because the metal concentrations obtained were more amenable to measurement by atomic absorption.

The elemental sulphur content of untreated and treated samples of the reference ores was determined by a method developed in this laboratory.[6]

RESULTS AND DISCUSSION

The values of the gain in weight, Δw, of these reference ores after the 7 weeks treatment are summarized in Table 2. Figure 1, which illustrates the results obtained at 50° and 82% RH is a typical example of Δw as a function of t, the treatment time. The slope of the observed linear functions, $\Delta w/t$, is, of course, the rate of gain in weight. The decrease in $\Delta w/t$ at 3 ± 0.2 weeks was observed in all trials, with the exception of SU-1 at 50° and 40% RH, for which no Δw was detected. The values of $\Delta w/t$ for the time periods of 1–3 and 3–7 weeks are given in Table 3. The cause of the break in $\Delta w/t$ will be discussed below.

Table 3. Rate of gain in weight

		Rate of gain in weight, $mg . g^{-1} . weeks^{-1}$

67	62	3.85	1.96	4.52	2.33	8.65	3.49

* Weeks.

The data in Tables 2 and 3 show that RH and temperature are both important parameters in oxidation of the ores. For MP-1 and KC-1, a change in RH from 40 to 82% at 50° results in a larger Δw than does a change in temperature from 34 to 67° at 62% RH, whereas the reverse is observed for SU-1. This difference in behaviour must be a consequence of the mineralogical composition of the ores.

It must be noted that these reference ores, as available in the bottle, cannot really be termed "untreated". They have been subjected to drying, grinding, *etc.*, in their preparation, so oxidation must have occurred to an extent which is unknown but not of interest to the analyst with regard to long-term stability of these ores as reference materials. Because this study was concerned with the stability of the ores as available in the bottle, these ores were labelled as "untreated" and all values of Δw reported refer to them. On this basis, the value of Δw at the beginning of treatment for any RH and temperature should be zero. An examination of Fig. 1, however, illustrates that the linearly extrapolated rate of weight gain does not pass through the origin for MP-1 and KC-1. This behaviour was also observed for all other values of RH and temperature. It must be noted that the rate of a solid–gas reaction where a surface layer of product is formed is often initially quite fast but decreases to become essentially a linear function of time (*i.e.*, diffusion-controlled).[7] In this case, an extrapolation of the linear rate to zero time would not pass through the origin*. This observation for MP-1 and KC-1 suggests that the surface of these ores has not been oxidized completely. That the extrapolation of the linear rate for SU-1 passes through the origin does not necessarily imply that oxidation does not occur quite fast initially, but could simply be a manifestation of a low oxidation rate and the error in the experimental data.

The amounts of water-extractable metals, M_{EXT}, in the untreated reference ores are given in Table 4. MP-1 yields higher values of M_{EXT} although KC-1 has a higher iron, lead and zinc content. Herein such factors as mineralogical composition, particle size distribution and history of the ore play important roles.

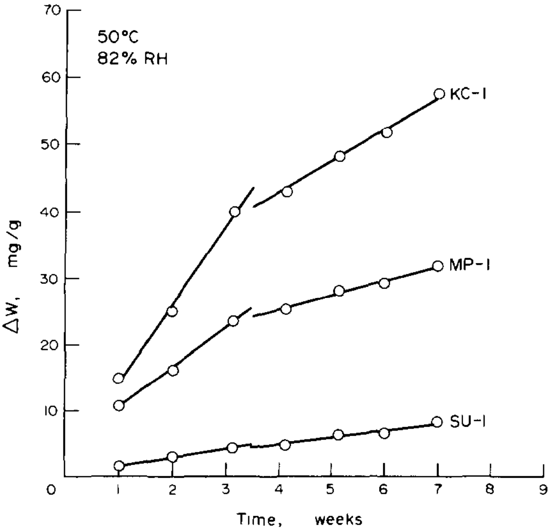

Fig. 1. The gain in weight (as a function of time) due to the treatment of MP-1, KC-1 and SU-1 at 50°C and 82% RH.

---

* The author has considerable data to illustrate that the rate of oxidation of sulphides such as pyrite, pyrrhotite, chalcopyrite, galena and sphalerite does indeed behave as described here.

Table 4. Water-extractable metals in untreated ores

	M_{EXT}, *mg/g*			
Ore	Fe	Pb	Zn	Ni
MP-1	0.42 (0.04)*	0.37 (0.09)	8.6 (0.5)	—
KC-1	0.11 (0.06)	0.29 (0.04)	2.4 (0.2)	—
SU-1	0.0	0.0	0.0	0.0

* Numbers in brackets are the standard deviations of 8 determinations.

Because the tendency to oxidize varies with both the nature and particle size of the minerals in an ore, the resultant water-extractability of a metal is not necessarily related to the total metal content of an ore but instead is related to the mineralogical composition and particle size. Table 5 contains the results of a screening test of MP-1, KC-1 and SU-1 and clearly illustrates the vast difference in the particle size distribution in these ores.

The history of the ores, *i.e.*, the conditions of humidity, moisture content and temperature to which they have been subjected during collection, drying, storage and preparation may differ significantly, so the extent of oxidation also differs.

In general, metal sulphides, both natural and synthetic, are sparingly soluble in water; *e.g.*, the solubility of sphalerite and pyrite is 0.07 and 0.49 mg/100 ml at 20°, respectively.[7] The observation of a water-extractability of certain metals greater than that expected according to the solubility of the sulphide mineral(s) must be attributed to the presence of soluble "thio-salts" such as thiosulphate, sulphite and sulphate.[8–11] It is reasonable to assume therefore, that oxidation of a sulphide mineral which results in "thio-salt" formation should increase the water-extractability of certain metals.[12] Lead sulphite (insoluble) and sulphate (4.3 mg/100 ml) are exceptions, with a lower solubility than galena (12.9 mg/100 ml). Galena is, however, less soluble than lead thiosulphate (30 mg/100 ml).[7] The change in the water-extractability of lead on oxidation of galena therefore depends on the products formed.[9,10]

The values of the difference between M_{EXT} for the untreated and treated ores, ΔM_{EXT}, are given in Table 6. The difference was not considered to be significant if it was less than the standard deviation of M_{EXT} in Table 4. The aqueous extracts were also analysed for copper but none was found.

Table 5. Particle size distribution of MP-1, KC-1 and SU-1 (screening test)

	%		
Mesh range (Tyler)	MP-1	KC-1	SU-1
<200	0.4	1.7	34.3
200–325	10.7	62.4	65.7
325–400	8.1	11.8	
>400	80.8	24.1	

Table 6. Difference between extractable metal values of untreated and treated ores

Ore	*T*, °*C* RH, %	ΔM_{EXT} *mg/g* Fe	Pb	Zn	Ni
MP-1 (7 weeks)	34, 62	−0.25	0.0	3.59	—
	50, 40	−0.19	0.0	1.89	—
	50, 62	−0.33	0.0	4.92	—
	50, 82	−0.42	−0.18	18.5	—
	67, 62	−0.39	−0.14	16.3	—
MP-1 (3 weeks)	50, 62	−0.23	0.0	2.54	—
KC-1 (7 weeks)	34, 62	0.0	−0.12	1.76	—
	50, 40	0.0	0.0	1.70	—
	50, 62	0.0	0.06	4.00	—
	50, 82	−0.08	0.13	13.3	—
	67, 62	0.0	0.12	8.86	—
KC-1 (3 weeks)	50, 62	0.0	0.08	1.80	—
SU-1*	67, 62	0.0	0.0	0.0	1.39

* No extractable metals were found for SU-1 at any other RH or *T*.

There is a reasonably good correlation between ΔZn_{EXT} and the corresponding value of Δw for MP-1 and KC-1; this reflects oxidation of sphalerite to "thio-salts". The values of ΔZn_{EXT} illustrate the susceptibility of sphalerite to oxidation and its absence is a probable explanation of the relative stability of SU-1. The apparently greater reactivity of the sphalerite in MP-1 compared to that in KC-1 is due to smaller particle size and consequentially larger surface area. The sphalerite gave the following size distribution, measured with an image analyser:[13]

μm	MP-1, %	KC-1, %
2–6	43	0
6–15	32	41
15–32	25	33
32–60	0	26

Although the size distribution was not measured, the particle size of the other sulphide minerals in MP-1 appeared to be similar. The decrease in ΔFe_{EXT} with an increase in the extent of oxidation of MP-1 and KC-1 suggests that iron hydroxide, oxide or basic iron "thio-salts" are formed rather than the soluble "thio-salts" as is observed for zinc. Indeed, it is known that weathering of pyrite and pyrrhotite results in the formation of limonite and/or haematite.[8,11]

The change in the opposite direction for ΔPb_{EXT} suggests the oxidation of galena to $PbSO_4$ for MP-1 but to PbS_2O_3 for KC-1. Although no conclusive explanation can be given here, the difference in the composition of the ores may be important. Sulphide minerals, when mixed as in ores, can often retard or accelerate the oxidation of one another.[14]

The relationships between log $(\Delta w/t)$ and RH at 50° and between log $(\Delta w/t)$ and temperature at 62% RH are linear with slopes *a* and *b* respectively. This dual linearity of log $(\Delta w/t)$ with temperature (*T*) and RH permits the formulation of a combined relationship

$$\log(\Delta w/t) = a(\text{RH}) + bT + d$$

where RH is in %, *T* in K and *t* in weeks. A plot of log $(\Delta w/t)$ against $a(\mathrm{RH}) + bT$ should have unit slope and intercept d. The values of a, b and d, calculated slope and correlation coefficient of this plot for MP-1, KC-1 and SU-1 are summarized in Table 7. Again, it has been necessary to separate the data into those pertaining to 1–3 weeks and to 3–7 weeks.

The parameters a and b are, in effect, a measure of the sensitivity of the rate of gain in weight and, therefore, the rate of oxidation to changes in RH and temperature, respectively. It is tempting to conclude that the order of the values of a and b for the reference ores signifies that the effect of RH on their oxidation decreases in the order KC-1 > MP-1 > SU-1 whereas the effect of temperature decreases in the order SU-1 > KC-1 $\simeq$ MP-1. This, however, would be incorrect. The rate of oxidation depends not only on RH and temperature but also on the surface area, which is, of course, related to particle size. It is a widely accepted phenomenon that the smaller the particle size, the faster a reaction proceeds. Let us suppose that the rate of oxidation of an ore for a particular set of conditions of RH and T was found to be R_i. If, however, this same ore were comminuted to a different particle size distribution, the observed rate of oxidation would differ from R_t by a factor x, i.e., the rate of oxidation for the latter sample of the ore would be xR_i. It has been assumed that a change in particle size distribution has the same proportional effect on the rate of oxidation irrespective of the values of RH and temperature, in which case a and b will also be changed by the factor x. The dependence of a and b on the particle size distribution is evident and a comparison of a and b for different ores is, therefore, meaningless without a thorough understanding of the effect of particle size distribution on the reactivity of an ore.

The values of a/b should, however, be constant for an ore regardless of the state of comminution, provided that all mineral species present are fully liberated. Thus, differences in the values of a/b for a series of ores may be related to differences in their mineralogical composition because it is improbable that the oxidation of all the minerals that comprise an ore would be affected equally by both RH and temperature. The values of a/b for the 1–3 week period for MP-1, KC-1 and SU-1 are 1.38, 1.84 and 0.28, respectively. The difference in a/b illustrates that the influence of RH and temperature on the rate of oxidation of an ore does indeed vary with its mineralogy. For example, the oxidation of nickel-bearing pyrrhotite and pentlandite in SU-1 exhibits a much greater dependence on temperature relative to RH than does the oxidation of MP-1 and KC-1 in which sphalerite must play the dominant role (Table 5). Moreover, the difference between the a/b values for MP-1 and KC-1 indicates that minerals other than sphalerite are oxidized. The abundance of pyrite and galena in KC-1 relative to MP-1 may be the explanation. If so, the larger value of a/b for KC-1 requires that the oxidation of pyrite and/or galena shows a greater dependence on RH relative to temperature than does that of sphalerite.

It is very difficult to assign significance to the intercept d. It is, of course, a concomitant of the linear relationship between log $(\Delta w/t)$ and $[a(\mathrm{RH}) + bT]$ and, as such, will vary with the values of both a and b. The main function of d is to permit the calculation of log $(\Delta w/t)$ for any value of RH and T.

Some speculations on mechanisms

A satisfactory explanation for the break in $\Delta w/t$ after about 3 weeks' treatment is difficult because of the complexity of the ores. It is improbable that the decrease in $\Delta w/t$ is due to either the complete oxidation of certain minerals in the ore or the formation of an oxidized surface layer sufficiently thick to cause $\Delta w/t$ to become diffusion-controlled. Each of these hypothetical processes would occur at essentially the same extent of oxidation of the ore regardless of T and RH. The change in $\Delta w/t$, however, always occurred at 3 ± 0.2 weeks even though the extent of oxidation as measured by Δw (Table 2) varied appreciably from trial to trial.

Table 7. Relationship of equation parameters

Ore	Time interval *weeks*	$a(10^{-2})$	$b(10^{-2})$	d
MP-1	1–3	2.04* ± 0.05† slope = 1.00	1.47 ± 0.11	−5.56 r = 0.997
	3–7	2.00 ± 0.10 slope = 1.01	1.14 ± 0.03	−4.80 r = 0.972
KC-1	1–3	2.52 ± 0.14 slope = 0.99	1.37 ± 0.10	−5.45 r = 0.984
	3–7	2.54 ± 0.10 slope = 1.00	1.21 ± 0.03	−5.24 r = 1.000
SU-1	1–3	1.48 ± 0.07 slope = 0.99	5.24 ± 0.09	−17.93 r = 0.986
	3–7	1.38 ± 0.16 slope = 0.99	4.21 ± 0.23	−14.52 r = 0.998

* Average of two samples.
† Corresponding deviation.

A comparison of the water-extractable metals (Table 6) for MP-1 and KC-1 for 3 and 7 weeks at 50° and 62% RH clearly illustrates that sphalerite undergoes oxidation throughout the 7 week period but, unfortunately, the results for Fe and Pb are either inconsistent or (because of the zero values) meaningless. The different mineralogical composition of MP-1, KC-1 and SU-1, however, would preclude the change in $\Delta w/t$ being due to the complete oxidation of certain minerals. The magnitude of this change would require that these minerals be present in appreciable quantities.

Although a change in RH or temperature affects the rate of oxidation of an ore, the overall mechanism remains the same, such that the oxidation reaction gives rise to a constant ratio of the amounts of the products. The absolute amount of the products, however, is dependent on the rate of oxidation and, therefore, on RH and temperature. Once formed by oxidation of the ores, the products are themselves subject to further reaction.

A comparison of the a and b values shows that $\Delta w/t$ for the 3–7 week period is affected to a lesser extent by temperature than is $\Delta w/t$ for the 1–3 week period. This does not necessarily mean that the oxidation becomes less sensitive to temperature after 3 weeks, but could indicate the start of some reaction resulting in a loss in weight so that the observed overall $\Delta w/t$ is lower than expected. The ratios of the $\Delta w/t$ values for the first and last periods of exposure (weeks 1–3 and 4–7) at 34, 50 and 67° and 62% RH show that the decrease in $\Delta w/t$ at 3 weeks increases with increasing temperature for all three ores, *i.e.*, the rate of weight loss increases with temperature.

The formation of elemental sulphur during the mild oxidation or weathering of sulphide minerals is well known.[8] This is also illustrated by the sulphur values for the unoxidized and oxidized ores, in Table 8. The results for 50° clearly show that the formation of sulphur increases with RH. The apparent anomaly of a decrease in the formation of sulphur with an increase in temperature is the result of the interplay of two factors. First, an increase in temperature enhances the rate of oxidation of an ore and, therefore, increases the formation of sulphur. Secondly, however, increase in temperature enhances the oxidation and/or volatilization of the sulphur thus formed.

It is reasonable to assume that the quantity of sulphur formed should vary with the extent of oxidation, *i.e.*, with the gain in weight. The quantity of sulphur formed should, therefore, increase with temperature, which is the opposite of what is found experimentally. The quantity of sulphur lost because of oxidation and/or volatilization must therefore also increase with temperature but to a greater extent, which, of course, parallels the magnitude of the decrease in $\Delta w/t$ at 3 weeks. It must be noted that the decomposition of metal thiosulphates or sulphates to the oxide[11,15] will also cause a loss in weight.

Table 8. Elemental sulphur in ores

	S, *mg/g*		
T, °C, RH, %	MP-1	KC-1	SU-1
Untreated	0.09	1.24	0.02
34, 62	0.37	2.94	0.03
50, 40	0.03	0.09	0.02
50, 62	0.22	1.10	0.02
50, 82	0.55	4.29	0.05
67, 62	0.09	0.06	0.63

The decrease in $\Delta w/t$ at 3 weeks can be explained as follows. By their very nature, sulphur and metal thio-salts are less susceptible to air-oxidation than are sulphides. Because sulphur and metal thio-salts are themselves products of oxidation, it is necessary for the oxidation to have proceeded to an extent at which their quantity is sufficiently large to compensate for their lower oxidation/decomposition rate and result in an observable decrease in $\Delta w/t$. In a system where the oxidation yields sulphur and metal thio-salts regardless of the RH and temperature, the decrease in the rate of gain in weight should be detected at approximately the same time, which is ~3 wk for MP-1, KC-1 and SU-1. The cause of the break in $\Delta w/t$ at 3 weeks can only be determined from a study of the mechanism of oxidation. Such a study, which is now under way, requires use of the pure minerals and the identification and determination of the oxidation products.

Stability of MP-1, KC-1 and SU-1 as reference ores

The stability of MP-1, KC-1 and SU-1 towards oxidation under laboratory conditions is readily calculated by extrapolation* of the data in Table 7. For example, when exposed to the atmosphere at 20° and 40% RH, MP-1 and KC-1 would undergo a 1% change in weight in about 45 weeks. SU-1 is stable. It can, therefore, be concluded that these certified reference ores should undergo no significant alteration at normal laboratory temperature and RH when stored in tightly sealed bottles.

Acknowledgement—The author wishes to thank Mr. R. G. Pinard, Mineral Sciences Laboratories, for his assistance in the mineralogical assessment of these ores.

QUANTITATIVE NMR-SPEKTROSKOPISCHE SIMULTANANALYSE VON MEHRKOMPONENTENGEMISCHEN UNTER EINSATZ EINES RECHNERS IM ON-LINE-BETRIEB

Werner Storek
Akademie der Wissenschaften der DDR, Zentralinstitut für physikalische Chemie,
DDR-1199 Berlin, Rudower Chaussee 5

(*Eingegangen am* 9. *Juni* 1975. *Angenommen am* 15. *Dezember* 1975)

Zusammenfassung—Die Voraussetzungen und der Algorithmus des on-line-Verfahrens zur quantitativen NMR-Analyse von Mehrkomponentensystemen, deren NMR-Spektren sich vollständig überlagern, werden vorgestellt. Am Beispiel der ^{1}H-NMR-Analyse einer 3-Komponentenmischung von isomeren Heptylsulfochloriden werden die Vor- und Nachteile dieser Methode diskutiert.

Mit der hochauflösenden NMR-Spektroskopie steht dem Chemiker eine zerstörungsfreie Analysenmethode für flüssige und gelöste Stoffe zur Verfügung, die in bestimmten Anwendungsfällen, ähnlich wie z.B. die UV-[1,2] oder IR-[3,4] Spektroskopie zur Konzentrationsbestimmung von Komponenten in Gemischen, deren Spektren sich vollständig überlagern*, eingesetzt werden kann.

Als nachteilig erweist sich bei der hochauflösenden NMR-Spektroskopie die gegenüber anderen Verfahren vergleichsweise geringe Nachweisempfindlichkeit, deren starke Abhängigkeit vom dem zur Analyse ausgewählten Resonanzkern (z.B. ^{1}H, ^{13}C, ^{19}F, ^{31}P) und der damit verbundene relativ hohe Substanzeinsatz†.

Die wesentlichen methodenspezifischen Voraussetzungen‡ zur Durchführung einer zuverlässigen quantitativen Analyse, die heute ein breites Anwendungsgebiet der hochauflösenden NMR-Spektroskopie bildet,[6–11] sind in zahlreichen Veröffentlichungen dargestellt worden. Zusätzlich zu diesen Voraussetzungen müssen für das hier vorgestellte Verfahren der Mehrkomponentenanalyse folgende Bedingungen erfüllt sein.

(1) Die Spektren der k reinen Komponenten müssen bekannt sein.

(2) Es existieren genau k Komponenten in der Mischung, deren Signale sich nur additiv in Abhängigkeit von ihren relativen Konzentrationen überlagern, d.h. nichtadditive Mischungseffekte dürfen nicht auftreten.

(3) Es müssen mindestens k signifikante Unterschiede bezüglich Linienlage bzw. Linienprofil zwischen den Spektren der reinen Komponenten existieren (lineare Unabhängigkeit der Spektren voneinander).

(4) Es müssen mindestens $n = k + 1$ geeignete Samplingpunkte unter reproduzierbaren Bedingungen bezüglich der Stabilität der Geräteparameter (wie Auflösung, Phase, Probentemperatur, Hochfrequenzmagnetfeldstärke, Abtastgeschwindigkeit, Lock usw.) ausgewählt werden können.

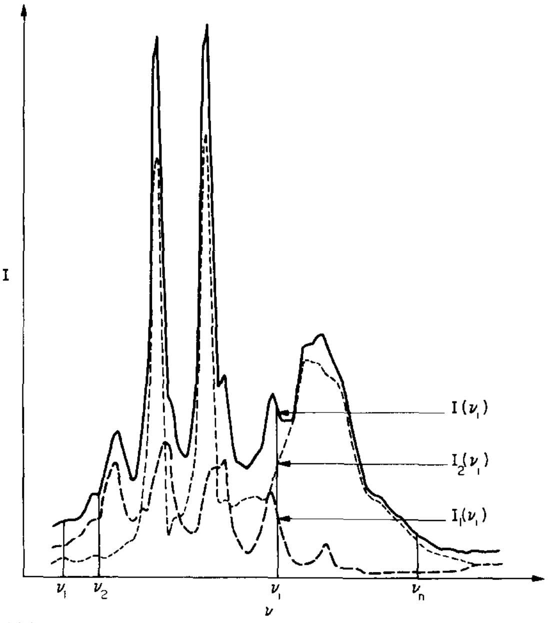

Abb. 1. Prinzip der Datenerfassung im NMR-Spektrum eines 2-Komponentengemisches. —— NMR-Spektrum der Mischung; – – – NMR-Spektrum der Komponente 1; - - NMR-Spektrum der Komponente 2.

---

* Damit ist die vom Analytiker angestrebte Selektivität bzw. Spezifität des Analysenverfahrens[5] aufgehoben, die sonst eine möglichst hohe Analysengenauigkeit bei relativ geringem Aufwand erlaubt.

† So beträgt z.B. die Nachweisgrenze für die ^{1}H-NMR (CW-Betrieb bei 100 MHz) *ca.* 10^{18}–10^{17} Protonen. Das entspricht einem Substanzeinsatz von einigen hundert Mikrogramm für eine Substanz mit dem Molekulargewicht 100 und 10 Wasserstoffatomen im Molekül, wobei das Signal eines isolierten Protons im Spektrum nicht aufspalten darf.

‡ Z.B. müssen die Hochfrequenzmagnetfeldstärke und die Spektrenabtastgeschwindigkeit optimiert werden, um den Einfluß von Sättigungs- und Relaxationseffekten, die die Signalintensität verfälschen, möglichst zu vermeiden, bzw. über Eichkurven korrigieren zu können.

Unter diesen Bedingungen folgt für den Intensitätswert $I(v_i)$ im Samplingpunkt v_i des k-Komponentengemisches

$$I(v_i) = \sum_{j=1}^{k} X_j I_j(v_i) \qquad (1)$$

mit

X_j = Regressionskonstante, die der Konzentration der Komponente j direkt proportional ist.
$I_j(v_i)$ = Intensität der j-ten Komponente im Samplingpunkt v_i.
v_i = Chemische Verschiebung in ppm oder Hz bezüglich eines Referenzsignals.

Zur Bestimmung der Konzentrationswerte x_j wird das Verfahren der mehrfachen linearen Regression[12–14] herangezogen. Die Regressionskonstanten X_j ergeben sich aus der Forderung

$$\sum_{i=1}^{n} \sum_{j=1}^{k} [X_j I_j(v_i) - I(v_i)]^2 = [\mathrm{vv}] \rightarrow \mathrm{Min} \qquad (2)$$

bzw. für alle $j = 1, 2, \ldots, k$

$$\frac{\partial[\mathrm{vv}]}{\partial X_j} = 0 \qquad (3)$$

worin [vv] die Summe der Fehlerquadrate bedeutet. Daraus folgt in bekannter Weise ein lineares Gleichungssystem zur Bestimmung der X_j, dessen Lösung sich nach den Methoden der linearen Algebra in Matrizenschreibweise zu

$$\bar{\mathrm{X}} = \bar{\mathrm{B}} \cdot \bar{\mathrm{Y}} \qquad (4)$$

ergibt.

Die Elemente des Lösungsvektors $\bar{\mathrm{X}}$ sind die gesuchten Regressionskonstanten X_j. $\bar{\mathrm{B}}$ ist die inverse Matrix zur sogenannten Kovarianzmatrix, deren Elemente nur aus den Summen von Produkten der Intensitätswerte $I_j(v_i)$ der reinen Komponenten gebildet werden. Deshalb kann man sie als "Eichmatrix" für das zu untersuchende Mischungssystem bezeichnen. $\bar{\mathrm{Y}}$ ist ebenfalls ein Spaltenvektor, wie der Lösungsvektor, dessen Elemente aus Summen von Produkten der Intensitätswerte der Mischung $I(v_i)$ und denen der reinen Komponenten zusammengesetzt sind.

Der Zusammenhang zwischen den gesuchten Molenbruchkonzentrationen x_j der k Mischungskomponenten und den entsprechenden k Regressionskonstanten X_j wird noch durch Einführen von k Korrekturfaktoren F_j modifiziert.

Dann gilt:

$$x_j = \frac{F_j X_j x_k}{X_k} \qquad (5)$$

und wegen

$$\sum_{j=1}^{k} x_j = 1 \qquad (6)$$

wird $F_k = 1$ gesetzt.

Auf diese Weise können mögliche systematische Fehler bei der Konzentrationsbestimmung in Mehrkomponentengemischen eingeschränkt werden. So lassen sich z.B. unterschiedliche Verstärkungs- oder Akkumulationsgrade bei der Aufnahme der reinen Komponenten korrigieren.

Die Nützlichkeit dieser Faktoren sollte sich auch bei der Eichung der durch Relaxationsprozesse und den Kern-Overhauser-Effekt (NOE)[15,16] beeinflußten Signalintensitäten in der ^{13}C-Fourier-Transform-NMR-Spektroskopie mit Protonenrauschentkopplung erweisen.

Unter Einhaltung einer hohen Reproduzierbarkeit der apparativen Einstellungen könnten mit der ^{13}C-NMR ebenfalls derartige quantitative Analysen durchgeführt werden, wie sie sich z.B. für bestimmte Fragestellungen der Polymeren- oder Kohlenwasserstoffanalytik ergeben.

In Abb. 2 ist der Programmablaufplan skizziert. Die mit "Eichen" bezeichnete Programmverzweigung erlaubt die Bestimmung der Korrekturfaktoren F_j mittels vorgegebenen Testgemischen. Größen, wie die Standardabweichungen $m(I)$ der Einzelmessung und $m(X_k)$ der Regressionskonstanten, die Summe der Fehlerquadrate [vv] und das Bestimmtheitsmaß *BM*, dessen Betrag bei fehlerfreier Regression den Wert 1 annimmt und der F(Test)-Wert* nach Fisher dienen zur Beurteilung der Güte der Regression.

Die Mehrkomponentenanalyse nach dem vorgestellten Verfahren wurde für 2- bzw. 3-Komponenten-

Abb. 3. ^{1}H-NMR-Spektren der reinen Komponenten A, B und C. 2-HSCl: n-Heptylsulfochlorid (2); 3-HSCl: n-Heptylsulfochlorid (3); 4-HSCl: n-Heptylsulfochlorid (4).

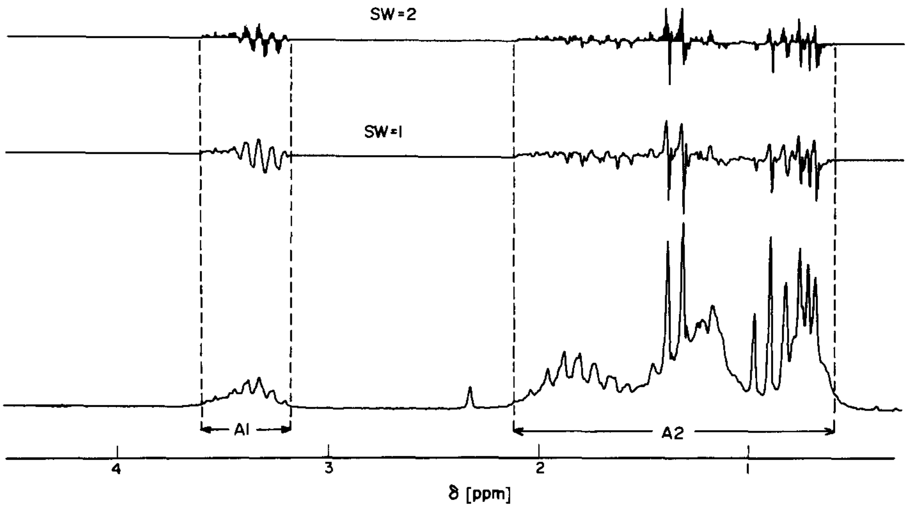

Abb. 4. ^{1}H-NMR-Spektrum der 3-Komponentenmischung I mit den in zwei aktuellen Auswertebereichen (*A*1, *A*2) erhaltenen Fehlerkurven für eine Samplingweite $SW = 1$ ($n = 462$ Samplingpunkte) bzw. $SW = 2$ ($n = 231$).

gemische mit einem hochauflösenden NMR-Spektrometer Typ JNM-PS-100/PFT-100 der Fa. JEOL, Tokio (Japan) mit dem "dedicated" Computersystem NICOLET-1085* der Fa. Nicolet, Madison (USA) erprobt. Der in Abb. 2 skizzierte Programmablauf wurde in der NIC-Assembler-Sprache programmiert, wobei für die 3-Komponentenanalyse *ca.* 2K (1K = 1024) Speicherplätze belegt wurden. Abbildung 3 zeigt die ^{1}H-NMR-Spektren der drei reinen Komponenten.

Die Spektren wurden in jeweils 1K Datenspeicherplätze über den AD-Wandler des Rechners mit 2 Scans (CW-Akkumulation) im Bereich von $\delta = 0{,}292$–$4{,}542$ ppm (entsprechend einem Frequenzbereich von 425 Hz bei einer Protonenresonanzfrequenz von 100 MHz) abgespeichert. Somit betrug die minimal mögliche Samplingweite ($SW = 1$) bei 1024 Datenpunkten 0,415 Hz. Die gewählte Abtastgeschwindigkeit von 540 Hz/250 s bei 10 Hz Filterbreite ergab eine Abtastzeit von *ca.* 3,3 min/Scan.

Aus praktischen Gründen wurden sowohl die reinen Komponenten als auch die zu untersuchenden Gemische derselben in etwa 60% (Vol.) CCl_4, in dem etwas Hexamethyldisiloxan für den internen Probenlock enthalten war, gelöst.

---

* Das NICOLET-1085 Datenerfassungs- und Verarbeitungssystem (Zykluszeit: 2 µs, 20 Bit Wortlänge) ist mit einer für die moderne NMR-Spektroskopie zweckmäßigen Peripherie, wie z. B. AD- und DA-Wandler, Filter, Teletype und Datensichtgerät (Display) ausgestattet.

	e	0,101	0,326	0,572

In Tabelle 1 sind die Analysenergebnisse für drei Testgemische isomerer n-Heptylsulfochloride angegeben.

Mit einer Absolutabweichung von maximal ± 0,04 (Molenbruch) sind die Konzentrationsbestimmungen der Mischungskomponenten zufriedenstellend.

Mit Hilfe des auf dem Oszillograph angezeigten Signalpegels im Lock-Kanal des Spektrometers wurde die Auflösung (*ca.* $5 \cdot 10^{-9}$) eingestellt und deren Stabilität während des Meßvorganges überwacht. Der abgetastete Frequenzbereich wurde mit dem im Spektrometer eingebauten Frequenzzähler (auf ± 0,1 Hz genau) ständig kontrolliert. Es wurden sowohl der Signalbereich der Methyl- und Methylengruppen ($A2$) als auch der Bereich der den Substituenten $-SO_2Cl$ tragenen CH-Gruppe ($A1$) zur Auswertung herangezogen, wie aus Abb. 4 hervorgeht. Für eine Samplingweite von $SW = 1$ umfaßt der Bereich $A1$ 101 Kanäle und der Bereich $A2$ 361 Kanäle.

Gleiche Erfahrungen bezüglich der erzielbaren Analysengenauigkeit wurden bei der ^{1}H-NMR-spektroskopischen Untersuchung von Testgemischen (2 bzw. 3 Komponenten) aus Alkanen gemacht. Allerdings konnte wegen Verstoßes gegen die Bedingung 3) des Verfahrens ein Gemisch aus n-Hexan, n-Oktan und n-Undekan nicht analysiert werden.

Die Abbildungen 5 und 6 zeigen die NMR-Spektren der Mischungen II und III und die Teletype-Protokolle der Analyse nebst den in den zwei Auswertebereichen dargestellten Fehlerkurven der für SW = 1 in insgesamt N = 462 Samplingpunkten durchgeführten Regressionsrechnung.*

Bei der Analyse dieser drei Testgemische wurde so verfahren, daß nach Analyse der Mischung I die Programmverzweigung "Routine" bejaht wurde (s. Abb. 2), damit ist für die getroffene Auswahl der Samplingbereiche und der Samplingpunkte die "systemcharakteristische" Matrix $\bar{B}$ fixiert und in allen weiteren Analysenfällen sind nur noch die Spektren der zu analysierenden Gemische dieser Komponenten aufzunehmen. Somit ist im Routinebetrieb eine quantitative Analyse in etwa 5–10 min—vom Einbringen der Probe bis zum Ergebnisausdruck—zu erhalten.

Die wesentlichen Vorteile des on-line-Verfahrens kann man in folgenden Punkten erkennen:

—die zeitaufwendige und fehleranfällige manuelle Datenerfassung entfällt;

—durch die Möglichkeit der Spektrenakkumulation ist eine Erhöhung der Nachweisempfindlichkeit bzw. eine Herabsetzung des statistischen Fehlers bei der Analyse zu erreichen;

—Nachteile der off-line-Verarbeitung, wie z.B. Datenträgertransporte oder Wartezeiten, entfallen;

—es können die Samplingweiten und die Auswertebereiche beliebig variiert werden und damit das Analysenverfahren optimiert werden. Durch Zugabe einer Referenzsubstanz zu allen reinen Komponenten und deren Gemischen, deren Signal ebenfalls erfaßt wird, lassen sich Drift- oder Lösungsmitteleinflüsse korrigieren.

—der Datenspeicherinhalt des Computers kann jederzeit auf dem Display visuell kontrolliert werden, so daß z.B. systematische Fehler oder das Vorliegen von Verunreinigungen in der Fehlerkurve der Analyse des *k*-Komponentengemisches erkannt werden können.

In Abb. 7 (Oben) ist das ^{1}H-NMR-Spektrum des n-Undekans dargestellt, dessen Signale ebenfalls im

Abb 7. Oben: ^{1}H-NMR-Spektrum des n-Undekans. Mitte: ^{1}H-NMR-Spektrum der mit n-Undekan verunreinigten Mischung II; Unten: Fehlerkurve dieser in zwei Auswertebereichen analysierten Mischung mit den durch die Störkomponente verursachten systematischen Abweichungen; Oben links: Analysenprotokoll der mit n-Undekan verunreinigten Mischung II.

aktuellen Auswertebereich $A2$ der isomeren Heptylsulfochloride liegen. Durch Spektrenaddition mittels des Rechners wurde die Mischung II mit n-Undekan als Störkomponente "verunreinigt", wie aus Abb. 7 (Mitte) hervorgeht. Die Fehlerkurve dieses analysierten Systems zeigt deutlich die durch die Störkomponente im Bereich der Methylengruppen des n-Undekans hervorgerufene systematische Abweichung [Abb. 7 (Unten)]. Aus diesem Beispiel geht hervor, daß aus der Fehlerkurve nur bei einer sehr hohen Störkomponentenkonzentration ein identifizierbares Spektrum der verursachenden Substanz zu erhalten sein wird.

Verunreinigungen verschlechtern sofort das Analysenergebnis, da diese aufgrund der Voraussetzungen nicht erkannt und auf die k Komponenten "aufgeteilt" werden, wie z.B. das Analysenprotokoll in Abb. 7 für die "verunreinigte" Mischung II zeigt.

Äußerst empfindlich reagiert das Verfahren auf systematische Fehler, wo die Voraussetzung der strengen additiven Überlagerung der Spektren verletzt wird. Derartige Fehler liegen bei Abweichungen von der Phase des reinen Absorptionssignals vor oder bei geringfügigen Änderungen der chemischen Verschiebung (Größenordnung von einigen 10^{-3} ppm) infolge von Drift- oder Lösungsmitteleffekten.

Der erforderliche Speicherplatzbedarf steigt mit der Zahl der zu analysierenden Komponenten schnell an. So werden in der Regel pro reine Komponente und das Gemisch derselben 1K Speicherplätze reserviert und für $n \geqslant k + 1$ Samplingpunkte werden $2n(k + 1)$ weitere Speicherplätze belegt, da die Werte $I_j(v_i)$ und $I(v_i)$ als Gleitkommazahlen abgespeichert werden und somit jeweils zwei Speicherplätze beanspruchen. Für die Darstellung der Fehlerkurve werden ebenfalls 1K Speicherplätze reserviert. Zusammen mit dem eigentlichen Programm werden somit für $n = 500$ Samplingpunkte im Fall einer 3-Komponentenanalyse etwa 11K Speicherplätze benötigt. Nach der Festlegung der Matrix $\bar{\text{B}}$ (Routinebetrieb) werden noch 8K Speicherplätze benötigt.

Dagegen fallen Rechenzeiten kaum ins Gewicht, da z.B. nach der Datenerfassung für das vorgestellte Beispiel der 3-Komponentenanalyse mit 462 Samplingpunkten für die Regressionsrechnung nur *ca.* 15 s erforderlich waren und die restliche Zeit des Ergebnisausdruckes durch die Druckgeschwindigkeit des benutzten Teletype bedingt war.

Eine Verbesserung des Verfahrens sollte noch unter Einbeziehung von Gewichtsfaktoren möglich sein,[17,18] während Bemühungen zur Optimierung der Zahl der Samplingpunkte[19] aufgrund der hohen Rechengeschwindigkeit nicht so wesentlich erscheinen.

Eine weitere Anwendungsmöglichkeit ist dadurch gegeben, daß es z.B. möglich ist, die Konzentration einer Komponente in einem k-Komponentengemisch relativ gegenüber allen anderen zu bestimmen, d.h. durch Zusammenfassen der restlichen $(k - 1)$ zu einer "Komponente". Damit ist dieser Spezialfall auf die Analyse einer 2-Komponentenmischung zurückgeführt.

Die Grenzen der hier beschriebenen Methode dürften im Rahmen einer vertretbaren Analysengenauigkeit (Molenbruch ± 0,07) und Eindeutigkeit für die Analyse eines Systems mit 5–8 Komponenten erreicht sein. Die Nützlichkeit des relativ aufwendigen Verfahrens kommt erst bei einer hohen Wiederholrate der Analysen (Routinebetrieb)—wie sie z.B. bei der Produktkontrolle in der chemischen oder pharmazeutischen Industrie erforderlich sein kann—voll zur Geltung.

Die Substanzen wurden von Herrn Dr. Ch. Duschek von der Sektion Verfahrenschemie der TH Leuna-Merseburg zur Verfügung gestellt, wofür auch an dieser Stelle nochmals gedankt werden soll.

(*Eingegangen am* 9. *Juni* 1975. *Angenommen am* 15. *Dezember* 1975)

Zusammenfassung—Die Voraussetzungen und der Algorithmus des on-line-Verfahrens zur quantitativen NMR-Analyse von Mehrkomponentensystemen, deren NMR-Spektren sich vollständig überlagern, werden vorgestellt. Am Beispiel der ^{1}H-NMR-Analyse einer 3-Komponentenmischung von isomeren Heptylsulfochloriden werden die Vor- und Nachteile dieser Methode diskutiert.

Mit der hochauflösenden NMR-Spektroskopie steht dem Chemiker eine zerstörungsfreie Analysenmethode für flüssige und gelöste Stoffe zur Verfügung, die in bestimmten Anwendungsfällen, ähnlich wie z.B. die UV-[1,2] oder IR-[3,4] Spektroskopie zur Konzentrationsbestimmung von Komponenten in Gemischen, deren Spektren sich vollständig überlagern*, eingesetzt werden kann.

Als nachteilig erweist sich bei der hochauflösenden NMR-Spektroskopie die gegenüber anderen Verfahren vergleichsweise geringe Nachweisempfindlichkeit, deren starke Abhängigkeit vom dem zur Analyse ausgewählten Resonanzkern (z.B. ^{1}H, ^{13}C, ^{19}F, ^{31}P) und der damit verbundene relativ hohe Substanzeinsatz†.

Die wesentlichen methodenspezifischen Voraussetzungen‡ zur Durchführung einer zuverlässigen quantitativen Analyse, die heute ein breites Anwendungsgebiet der hochauflösenden NMR-Spektroskopie bildet,[6-11] sind in zahlreichen Veröffentlichungen dargestellt worden. Zusätzlich zu diesen Voraussetzungen müssen für das hier vorgestellte Verfahren der Mehrkomponentenanalyse folgende Bedingungen erfüllt sein.

(1) Die Spektren der k reinen Komponenten müssen bekannt sein.

(2) Es existieren genau k Komponenten in der Mischung, deren Signale sich nur additiv in Abhängigkeit von ihren relativen Konzentrationen überlagern, d.h. nichtadditive Mischungseffekte dürfen nicht auftreten.

(3) Es müssen mindestens k signifikante Unterschiede bezüglich Linienlage bzw. Linienprofil zwischen den Spektren der reinen Komponenten existieren (lineare Unabhängigkeit der Spektren voneinander).

(4) Es müssen mindestens $n = k + 1$ geeignete Samplingpunkte unter reproduzierbaren Bedingungen bezüglich der Stabilität der Geräteparameter (wie Auflösung, Phase, Probentemperatur, Hochfrequenzmagnetfeldstärke, Abtastgeschwindigkeit, Lock usw.) ausgewählt werden können.

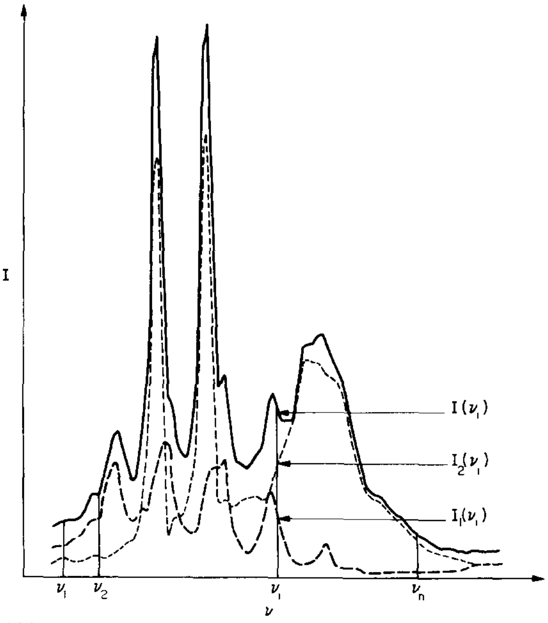

Abb. 1. Prinzip der Datenerfassung im NMR-Spektrum eines 2-Komponentengemisches. —— NMR-Spektrum der Mischung; – – – NMR-Spektrum der Komponente 1; -- NMR-Spektrum der Komponente 2.

---

* Damit ist die vom Analytiker angestrebte Selektivität bzw. Spezifität des Analysenverfahrens[5] aufgehoben, die sonst eine möglichst hohe Analysengenauigkeit bei relativ geringem Aufwand erlaubt.

† So beträgt z.B. die Nachweisgrenze für die ^{1}H-NMR (CW-Betrieb bei 100 MHz) *ca.* 10^{18}–10^{17} Protonen. Das entspricht einem Substanzeinsatz von einigen hundert Mikrogramm für eine Substanz mit dem Molekulargewicht 100 und 10 Wasserstoffatomen im Molekül, wobei das Signal eines isolierten Protons im Spektrum nicht aufspalten darf.

‡ Z.B. müssen die Hochfrequenzmagnetfeldstärke und die Spektrenabtastgeschwindigkeit optimiert werden, um den Einfluß von Sättigungs- und Relaxationseffekten, die die Signalintensität verfälschen, möglichst zu vermeiden, bzw. über Eichkurven korrigieren zu können.

Unter diesen Bedingungen folgt für den Intensitätswert $I(v_i)$ im Samplingpunkt v_i des k-Komponentengemisches

$$I(v_i) = \sum_{j=1}^{k} X_j I_j(v_i) \tag{1}$$

mit

X_j = Regressionskonstante, die der Konzentration der Komponente j direkt proportional ist.

$I_j(v_i)$ = Intensität der j-ten Komponente im Samplingpunkt v_i.

v_i = Chemische Verschiebung in ppm oder Hz bezüglich eines Referenzsignals.

Zur Bestimmung der Konzentrationswerte x_j wird das Verfahren der mehrfachen linearen Regression[12–14] herangezogen. Die Regressionskonstanten X_j ergeben sich aus der Forderung

$$\sum_{i=1}^{n} \sum_{j=1}^{k} [X_j I_j(v_i) - I(v_i)]^2 = [\mathrm{vv}] \rightarrow \mathrm{Min} \tag{2}$$

bzw. für alle $j = 1, 2, \ldots, k$

$$\frac{\partial[\mathrm{vv}]}{\partial X_j} = 0 \tag{3}$$

worin [vv] die Summe der Fehlerquadrate bedeutet. Daraus folgt in bekannter Weise ein lineares Gleichungssystem zur Bestimmung der X_j, dessen Lösung sich nach den Methoden der linearen Algebra in Matrizenschreibweise zu

$$\bar{\mathrm{X}} = \bar{\mathrm{B}} \cdot \bar{\mathrm{Y}} \tag{4}$$

ergibt.

Die Elemente des Lösungsvektors $\bar{\mathrm{X}}$ sind die gesuchten Regressionskonstanten X_j. $\bar{\mathrm{B}}$ ist die inverse Matrix zur sogenannten Kovarianzmatrix, deren Elemente nur aus den Summen von Produkten der Intensitätswerte $I_j(v_i)$ der reinen Komponenten gebildet werden. Deshalb kann man sie als "Eichmatrix" für das zu untersuchende Mischungssystem bezeichnen.

$\bar{\mathrm{Y}}$ ist ebenfalls ein Spaltenvektor, wie der Lösungsvektor, dessen Elemente aus Summen von Produkten der Intensitätswerte der Mischung $I(v_i)$ und denen der reinen Komponenten zusammengesetzt sind.

Der Zusammenhang zwischen den gesuchten Molenbruchkonzentrationen x_j der k Mischungskomponenten und den entsprechenden k Regressionskonstanten X_j wird noch durch Einführen von k Korrekturfaktoren F_j modifiziert.

Dann gilt:

$$x_j = \frac{F_j X_j x_k}{X_k} \tag{5}$$

und wegen

$$\sum_{j=1}^{k} x_j = 1 \tag{6}$$

wird $F_k = 1$ gesetzt.

Auf diese Weise können mögliche systematische Fehler bei der Konzentrationsbestimmung in Mehrkomponentengemischen eingeschränkt werden. So lassen sich z.B. unterschiedliche Verstärkungs- oder Akkumulationsgrade bei der Aufnahme der reinen Komponenten korrigieren.

Die Nützlichkeit dieser Faktoren sollte sich auch bei der Eichung der durch Relaxationsprozesse und den Kern-Overhauser-Effekt (NOE)[15,16] beeinflußten Signalintensitäten in der ^{13}C-Fourier-Transform-NMR-Spektroskopie mit Protonenrauschentkopplung erweisen.

Unter Einhaltung einer hohen Reproduzierbarkeit der apparativen Einstellungen könnten mit der ^{13}C-NMR ebenfalls derartige quantitative Analysen durchgeführt werden, wie sie sich z.B. für bestimmte Fragestellungen der Polymeren- oder Kohlenwasserstoffanalytik ergeben.

In Abb. 2 ist der Programmablaufplan skizziert. Die mit "Eichen" bezeichnete Programmverzweigung erlaubt die Bestimmung der Korrekturfaktoren F_j mittels vorgegebenen Testgemischen. Größen, wie die Standardabweichungen $m(I)$ der Einzelmessung und $m(X_k)$ der Regressionskonstanten, die Summe der Fehlerquadrate [vv] und das Bestimmtheitsmaß BM, dessen Betrag bei fehlerfreier Regression den Wert 1 annimmt und der F(Test)-Wert* nach Fisher dienen zur Beurteilung der Güte der Regression.

Die Mehrkomponentenanalyse nach dem vorgestellten Verfahren wurde für 2- bzw. 3-Komponenten-

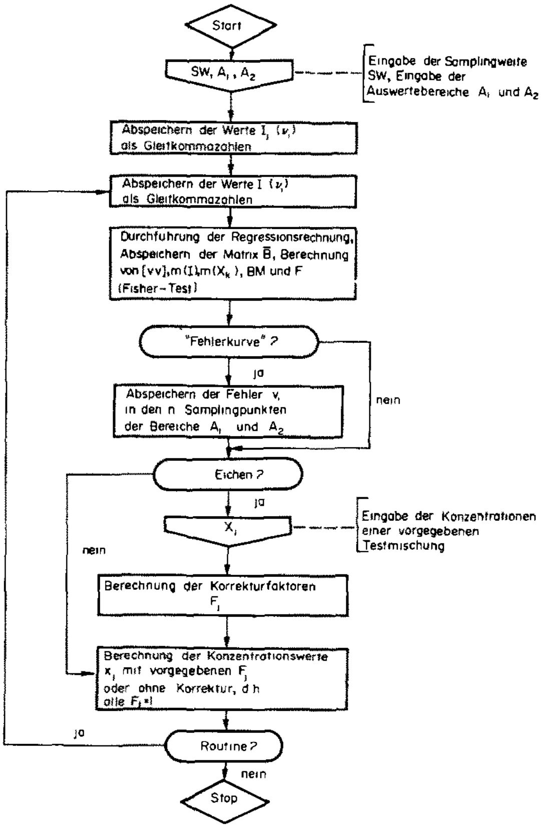

Abb. 2. Programmablaufplan (Skizze).

Abb. 3. ¹H-NMR-Spektren der reinen Komponenten A, B und C. 2-HSCl: n-Heptylsulfochlorid (2); 3-HSCl: n-Heptylsulfochlorid (3); 4-HSCl: n-Heptylsulfochlorid (4).

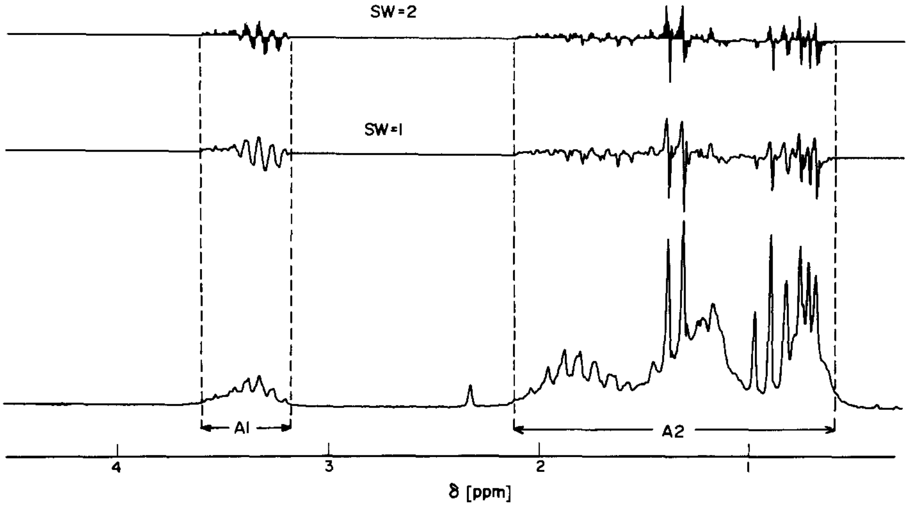

Abb. 4. ¹H-NMR-Spektrum der 3-Komponentenmischung I mit den in zwei aktuellen Auswertebereichen (*A*1, *A*2) erhaltenen Fehlerkurven für eine Samplingweite *SW* = 1 (*n* = 462 Samplingpunkte) bzw. *SW* = 2 (*n* = 231).

gemische mit einem hochauflösenden NMR-Spektrometer Typ JNM-PS-100/PFT-100 der Fa. JEOL, Tokio (Japan) mit dem "dedicated" Computersystem NICOLET-1085* der Fa. Nicolet, Madison (USA) erprobt. Der in Abb. 2 skizzierte Programmablauf wurde in der NIC-Assembler-Sprache programmiert, wobei für die 3-Komponentenanalyse *ca.* 2K (1K = 1024) Speicherplätze belegt wurden. Abbildung 3 zeigt die ¹H-NMR-Spektren der drei reinen Komponenten.

Die Spektren wurden in jeweils 1K Datenspeicherplätze über den AD-Wandler des Rechners mit 2 Scans (CW-Akkumulation) im Bereich von δ = 0,292–4,542 ppm (entsprechend einem Frequenzbereich von 425 Hz bei einer Protonenresonanzfrequenz von 100 MHz) abgespeichert. Somit betrug die minimal mögliche Samplingweite (*SW* = 1) bei 1024 Datenpunkten 0,415 Hz. Die gewählte Abtastgeschwindigkeit von 540 Hz/250 s bei 10 Hz Filterbreite ergab eine Abtastzeit von *ca.* 3,3 min/Scan.

Aus praktischen Gründen wurden sowohl die reinen Komponenten als auch die zu untersuchenden Gemische derselben in etwa 60% (Vol.) CCl_4, in dem etwas Hexamethyldisiloxan für den internen Probenlock enthalten war, gelöst.

---

* Das NICOLET-1085 Datenerfassungs- und Verarbeitungssystem (Zykluszeit: 2 μs, 20 Bit Wortlänge) ist mit einer für die moderne NMR-Spektroskopie zweckmäßigen Peripherie, wie z. B. AD- und DA-Wandler, Filter, Teletype und Datensichtgerät (Display) ausgestattet.

Tabelle 1. Gegenüberstellung der durch Einwaage vorgegebenen (v) und der mittels des on-line-Verfahrens erhaltenen (e) Analysenergebnisse für drei 3-Komponentensysteme unterschiedlicher Zusammensetzung

Mischung		Zusammensetzung (Molenbrüche) x(A)	x(B)	x(C)
I	v	0,328	0,461	0,211
	e	0,300	0,461	0,237
II	v	0,155	0,614	0,231
	e	0,154	0,602	0,242
III	v	0,074	0,313	0,612
	e	0,101	0,326	0,572

In Tabelle 1 sind die Analysenergebnisse für drei Testgemische isomerer n-Heptylsulfochloride angegeben.

Mit einer Absolutabweichung von maximal ± 0,04 (Molenbruch) sind die Konzentrationsbestimmungen der Mischungskomponenten zufriedenstellend.

Mit Hilfe des auf dem Oszillograph angezeigten Signalpegels im Lock-Kanal des Spektrometers wurde die Auflösung (*ca.* $5 \cdot 10^{-9}$) eingestellt und deren Stabilität während des Meßvorganges überwacht. Der abgetastete Frequenzbereich wurde mit dem im Spektrometer eingebauten Frequenzzähler (auf ± 0,1 Hz genau) ständig kontrolliert. Es wurden sowohl der Signalbereich der Methyl- und Methylengruppen ($A2$) als auch der Bereich der den Substituenten $-SO_2Cl$ tragenen CH-Gruppe ($A1$) zur Auswertung herangezogen, wie aus Abb. 4 hervorgeht. Für eine Samplingweite von $SW = 1$ umfaßt der Bereich $A1$ 101 Kanäle und der Bereich $A2$ 361 Kanäle.

Gleiche Erfahrungen bezüglich der erzielbaren Analysengenauigkeit wurden bei der ^{1}H-NMR-spektroskopischen Untersuchung von Testgemischen (2 bzw. 3 Komponenten) aus Alkanen gemacht. Allerdings konnte wegen Verstoßes gegen die Bedingung 3) des Verfahrens ein Gemisch aus n-Hexan, n-Oktan und n-Undekan nicht analysiert werden.

Die Abbildungen 5 und 6 zeigen die NMR-Spektren der Mischungen II und III und die Teletype-Protokolle der Analyse nebst den in den zwei Auswertebereichen dargestellten Fehlerkurven der für SW = 1 in insgesamt N = 462 Samplingpunkten durchgeführten Regressionsrechnung.*

Bei der Analyse dieser drei Testgemische wurde so verfahren, daß nach Analyse der Mischung I die Programmverzweigung "Routine" bejaht wurde (s. Abb. 2), damit ist für die getroffene Auswahl der Samplingbereiche und der Samplingpunkte die "systemcharakteristische" Matrix $\bar{B}$ fixiert und in allen weiteren Analysenfällen sind nur noch die Spektren der zu analysierenden Gemische dieser Komponenten aufzunehmen. Somit ist im Routinebetrieb eine quantitative Analyse in etwa 5–10 min—vom Einbringen der Probe bis zum Ergebnisausdruck—zu erhalten.

Die Fehlerkurve dieses analysierten Systems zeigt deutlich die durch die Störkomponente im Bereich der Methylengruppen des n-Undekans hervorgerufene systematische Abweichung [Abb. 7 (Unten)]. Aus diesem Beispiel geht hervor, daß aus der Fehlerkurve nur bei einer sehr hohen Störkomponentenkonzentration ein identifizierbares Spektrum der verursachenden Substanz zu erhalten sein wird.

Verunreinigungen verschlechtern sofort das Analysenergebnis, da diese aufgrund der Voraussetzungen nicht erkannt und auf die k Komponenten "aufgeteilt" werden, wie z.B. das Analysenprotokoll in Abb. 7 für die "verunreinigte" Mischung II zeigt.

Äußerst empfindlich reagiert das Verfahren auf systematische Fehler, wo die Voraussetzung der strengen additiven Überlagerung der Spektren verletzt wird. Derartige Fehler liegen bei Abweichungen von der Phase des reinen Absorptionssignals vor oder bei geringfügigen Änderungen der chemischen Verschiebung (Größenordnung von einigen 10^{-3} ppm) infolge von Drift- oder Lösungsmitteleffekten.

Der erforderliche Speicherplatzbedarf steigt mit der Zahl der zu analysierenden Komponenten schnell an. So werden in der Regel pro reine Komponente und das Gemisch derselben 1K Speicherplätze reserviert und für $n \geqslant k + 1$ Samplingpunkte werden $2n(k + 1)$ weitere Speicherplätze belegt, da die Werte $I_j(v_i)$ und $I(v_i)$ als Gleitkommazahlen abgespeichert werden und somit jeweils zwei Speicherplätze beanspruchen. Für die Darstellung der Fehlerkurve werden ebenfalls 1K Speicherplätze reserviert. Zusammen mit dem eigentlichen Programm werden somit für $n = 500$ Samplingpunkte im Fall einer 3-Komponentenanalyse etwa 11K Speicherplätze benötigt. Nach der Festlegung der Matrix $\bar{B}$ (Routinebetrieb) werden noch 8K Speicherplätze benötigt.

Dagegen fallen Rechenzeiten kaum ins Gewicht, da z.B. nach der Datenerfassung für das vorgestellte Beispiel der 3-Komponentenanalyse mit 462 Samplingpunkten für die Regressionsrechnung nur *ca.* 15 s erforderlich waren und die restliche Zeit des Ergebnisausdruckes durch die Druckgeschwindigkeit des benutzten Teletype bedingt war.

Eine Verbesserung des Verfahrens sollte noch unter Einbeziehung von Gewichtsfaktoren möglich sein,[17,18] während Bemühungen zur Optimierung der Zahl der Samplingpunkte[19] aufgrund der hohen Rechengeschwindigkeit nicht so wesentlich erscheinen.

Eine weitere Anwendungsmöglichkeit ist dadurch gegeben, daß es z.B. möglich ist, die Konzentration einer Komponente in einem k-Komponentengemisch relativ gegenüber allen anderen zu bestimmen, d.h. durch Zusammenfassen der restlichen $(k - 1)$ zu einer "Komponente". Damit ist dieser Spezialfall auf die Analyse einer 2-Komponentenmischung zurückgeführt.

Die Grenzen der hier beschriebenen Methode dürften im Rahmen einer vertretbaren Analysengenauigkeit (Molenbruch ± 0,07) und Eindeutigkeit für die Analyse eines Systems mit 5–8 Komponenten erreicht sein. Die Nützlichkeit des relativ aufwendigen Verfahrens kommt erst bei einer hohen Wiederholrate der Analysen (Routinebetrieb)—wie sie z.B. bei der Produktkontrolle in der chemischen oder pharmazeutischen Industrie erforderlich sein kann—voll zur Geltung.

Die Substanzen wurden von Herrn Dr. Ch. Duschek von der Sektion Verfahrenschemie der TH Leuna-Merseburg zur Verfügung gestellt, wofür auch an dieser Stelle nochmals gedankt werden soll.

STÖRENDE EINFLÜSSE VON BORSÄURE UND KOHLENDIOXID BEI DER MASSANALYTISCHEN AMMONIAKBESTIMMUNG

JOSEF MALÝ
Wasserwirtschaftsverwaltung, Brno, Tshechoslowakei

(*Eingegangen am* 2. *April* 1975. *Revidiert am* 20. *November* 1975. *Angenommen am* 24. *Februar* 1976)

Zusammenfassung—Die erreichbare Genauigkeit der maßanalytischen Ammoniakbestimmung mit potentiometrischer oder visueller Indikation bei Anwesenheit von Fremdstoffen (Borsäure und Kohlendioxid) wurde auf Grund des Verlaufes der Ammoniaktitrationskurven festgelegt und die Fehler dieses Verfahrens ausgewertet.

Die Mehrzahl der Verfahren für die Ammoniakbestimmung beruhen in seiner vorherigen Überführung durch Destillation, Diffusion oder Belüftung in eine starke Mineralsäure, in der es indirekt alkalimetrisch bestimmt wird, oder in eine Lösung der Borsäure mit anschließender azidimetrischer Bestimmung.[1,2] Im Verlaufe des Prozesses, bei dem Ammoniak in gasförmiger Zustand aus der analysierten Lösung ausgetrieben wird, können die in der Probe enthaltenden Fremdstoffe unter den gegebenen Bedingungen in die Absorptionslösung überführt werden und die nachfolgende Ammoniakbestimmung stören.

Handelt es sich um Basen (z.B. Pyridin), die mit Ammoniak aus alkalischen Lösungen freigemacht werden, läßt sich ihr Einfluß auf die Titrationsbedingungen aus den in der Literatur angeführten Diagrammen bestimmen.[3] In der vorliegenden Arbeit ist vor allem die Aufmerksammkeit den sauren Komponenten—der Borsäure und Kohlensäure—gewidmet. Der Einfluß der Borsäure wird deshalb untersucht, weil ihre Lösung oft zur Absorption des Ammoniaks nach seiner Abtrennung verwendet wird. Kohlensäure (bzw. Karbonate) ist ein üblicher Bestandteil der analysierten Lösungen und es kann während der Destillation eine Beträchtliche Menge von CO_2 in die Vorlage überführt werden.

Ableitung der Titrationskurven

Der Verlauf der Ammoniaktitrationskurve läßt sich aus den Gleichgewichtsbedingungen der beteiligten Ionen und aus den Elektroneutralitätsbedingungen in der Lösung berechnen. Bei der vereinfachten Voraussetzung der Volumenunveränderlichkeit der titrierten Lösung wird er durch die Gleichung (1) ausgedrückt:

$$c_t = [H^+] + \frac{c_a \cdot K_a \cdot [H^+]}{K_a \cdot [H^+] + K_w} - \frac{K_w}{[H^+]} \qquad (1)$$

worin K_a und K_w die Dissoziationskonstanten der Ammoniumionen und des Wassers, c_a und c_t die analytischen Konzentrationen des Ammoniaks und der Normallösung (starken Säure), die in Äquivalenten pro Liter in der titrierten Lösung ausgedrückt werden, bedeuten. Anstatt von der jetzt üblichen Bezeichnung der Wasserstoffionen H_3O^+ wird im Text der Einfachheit wegen die ältere Bezeichnung H^+ verwendet.

Die Gleichung (1) kann man auch zur Ermittlung der Titrationskurve verwenden, die die Rücktitration einer starken Säure bei Anwesenheit des Ammoniumsalzes mit einer starken Base darstellt. In diesem Falle entspricht c_t der Differenz zwischen der Äquivalenzkonzentration der starken Säure und Base.

Enthält die titrierte Lösung einige weitere sauer oder basisch reagierende Bestandteile, geht die Gleichung (1) in die folgende Form über:

$$c_t + \Sigma[A] - \Sigma[B] = [H^+] + \frac{c_a \cdot K_a [H^+]}{K_a \cdot [H^+] + K_w} - \frac{K_w}{[H^+]} \qquad (2)$$

Hier entspricht $\Sigma[A]$ der Summe von sauer- und $\Sigma[B]$ von alkalisch reagierenden Komponenten. Handelt es sich um eine Säure H_nA, die in n Stufen dissoziiert, gilt:

$$[A] = c_A \cdot \frac{K_{A1}[H^+]^{n-1} + 2K_{A1}K_{A2}[H^+]^{n-2} + \ldots + nK_{A1}K_{A2}\ldots K_{An}}{[H^+]^n + K_{A1}[H^+]^{n-1} + K_{A1}K_{A2}[H^+]^{n-2} + \ldots + K_{A1}K_{A2}\ldots K_{An}} \qquad (3)$$

Analogisch, wenn eine in m Stufen dissoziierte Base vorliegt, gilt:

$$[B] = c_B \cdot \frac{K_{B1}K_w^{m-1}[H^+] + 2K_{B1}K_{B2}K_w^{m-2}[H^+]^2 + \ldots + mK_{B1}K_{B2}\ldots K_{Bm}[H^+]^m}{K_w^m + K_{B1}K_w^{m-1}[H^+] + K_{B1}K_{B2}K_w^{m-2}[H^+]^2 + \ldots + K_{B1}K_{B2}\ldots K_{Bm}[H^+]^m} \qquad (4)$$

Darin bedeuten K_{A1}, K_{A2} ... K_{An} bzw. K_{B1}, K_{B2} ... K_{Bm} die Dissoziationskonstanten der Säure bzw. Base, c_A und c_B ihre analytischen Konzentrationen, die in Äquivalenten pro Liter ausgedrückt werden. Sind die angeführten Bestandteile Borsäure und Kohlensäure, gilt:

$$\Sigma[\mathrm{B}] = 0$$

$$\Sigma[\mathrm{A}] = \frac{c_b K_b}{K_b + [\mathrm{H}^+]} + c_k \frac{K_{k1}[\mathrm{H}^+] + 2K_{k1}K_{k2}}{[\mathrm{H}^+]^2 + K_{k1}[\mathrm{H}^+] + K_{k1}K_{k2}} \qquad (5)$$

In diesen Ausdrücken bedeuten K_b, K_{k1}, K_{k2} die Dissoziationskonstanten der Borsäure und Kohlensäure (beide Stufen), c_b und c_k ihre molare Konzentration.

Der pH-Wert des Äquivalenzpunktes der Ammoniaktitrationskurve bzw. bei Anwesenheit von Borsäure und Kohlensäure wird aus den Gleichungen (2) und (5) nach der Einsetzung $c_t = c_a$ ermittelt. Nach Fortlassung einiger vernachlässigbaren kleinen Gliedern bekommt man:

$$\mathrm{pH} = -\tfrac{1}{2}\log\left(\frac{c_a \cdot K_w}{K_a} + c_b \cdot K_b + c_k \cdot K_{k1}\right) \qquad (6)$$

Für die Beurteilung der Genauigkeit der Titrationsmethode ist es wichtig die Steigerung der Titrationskurve im Äquivalenzpunkt, die durch den Richtungskoeffizient der Tangente in diesem Punkt ermittelt wird, zu kennen. Er wird aus der zugehörigen Funktionsabhängigkeit zwischen pH und c_t durch Differenzieren berechnet. Diese Abhängigkeit wird für Ammoniak und Borsäure durch die Gleichung (2), in der für die $[\mathrm{H}^+]$-Werte ein äquivalenter Ausdruck $10^{-\mathrm{pH}}$ eingesetzt wird, dargestellt. Der Differenzialquotient wird aus dem implizierten Ausdruck der Funktion $F(c_t, \mathrm{pH})$ ermittelt:

$$-\frac{\mathrm{d}c_t}{\mathrm{dpH}} = \frac{\partial F(c_t, \mathrm{pH})/\partial \mathrm{pH}}{\partial F(c_t, \mathrm{pH})/\partial c_t} \qquad (7)$$

Aus den Gleichungen (7) und (2) bzw. (5) bekommt man für den Äquivalenzpunkt ($c_t = c_a$) nach der Vereinfachung durch Fortlassung der vernachlässigbaren kleinen Gliedern (siehe Appendix):

$$-\frac{\mathrm{d}c_t}{\mathrm{dpH}} = \frac{2\ln 10(2K_a \cdot 10^{-2\mathrm{pH}} - c_a K_w - c_b K_a K_b)}{K_a 10^{-\mathrm{pH}}} \qquad (8)$$

Ermittlung der Titrationskurven

Nach den oben angeführten Beziehungen wird die Berechnung der Ammoniaktitrationskurven auch bei Anwesenheit von Borsäure und Kohlensäure durchgeführt. Wie erwähnt, wird dabei eine Volumenveränderung während der Titration nicht errechnet.

Die für sehr verdünnte Lösungen gültigen Tabellenwerte der Dissoziationskonstanten wurden mit Rücksicht auf die Ionenstärke der Lösung (im Äquivalenzpunkt) umgerechnet—Tabelle 1.

$$-\log f_i = i^2 \frac{0{,}511\sqrt{J}}{(1 + 1{,}5\sqrt{J})} - 0{,}2\,J \qquad (9)$$

$$K'_1 = f_1^2 \cdot K_1 \qquad (10)$$

$$K'_2 = f_2 \cdot K_2 \qquad (10a)$$

In diesen Gleichungen bedeuten K' die Tabellenwerte der Dissoziationskonstanten der unendlich verdünnten Lösungen, K die Dissoziationskonstanten der Lösungen mit der Ionenstärke J, f_i sind die Aktivitätskoeffizienten der i-Wertigen Ionen. Für die Berechnung der Ionenstärke wird die Ammoniumchlorid konzentration (im Äquivalenzpunkt) in Betracht genommen, während Borsäure und Kohlensäure wegen ihrer vernachlässigbarer Dissoziation unbeachtet bleiben.

Bei der hier verwendeten Konzentration der Borsäure (0,1*M*) ist nur die Ionenstärke der Lösung bei Berechnung der Dissoziationskonstante K_b in Betracht zu ziehen. Wenn die Borsäurekonzentration höher als 0,1*M* vorliegt, werden stärkere Polyborsäuren gebildet. Der K_b-Wert verändert sich dann mehr als der erhöhten Ionenstärke entspricht, und er muß aus der empirisch bestimmten Abhängigkeit pH von der Borsäurekonzentration abgeleitet werden.[4]

Der untersuchte Ammoniakkonzentrationsbereich war 10^{-4} bis $10^{-2}M$. Der Konzentrationsbegrenzung der Borsäure wurde die Anforderung für die quantitative Absorption des Ammoniaks im Verlaufe seiner Abtrennung aus der analysierten Lösung in Betracht gezogen. Die erforderliche Menge der Borsäure und ihre Konzentration in der Vorlage hängt von der Menge des Destillierten Ammoniaks ab. Zur Absorption von 20 mg Ammoniak sind 25 ml 2%iger Borsäure hinreichend. Nach Abdestillieren des erforderlichen Volumens wird die Lösung in der Vorlage verdünnt und die resultierende Borsäurekonzentration ist dann ungefähr 0,1*M*.

Tabelle 1. Die für die Berechnung verwendeten Dissoziationskonstanten (für 18°C)

		Ionenstärke der Lösung			
Komponente		0	10^{-4}	10^{-3}	10^{-2}
Wasser	K_w	$0{,}74 \cdot 10^{-14}$	$0{,}75 \cdot 10^{-14}$	$0{,}79 \cdot 10^{-14}$	$0{,}90 \cdot 10^{-14}$
Ammoniak	K_a	$1{,}75 \cdot 10^{-5}$	$1{,}76 \cdot 10^{-5}$	$1{,}88\ 10^{-5}$	$2{,}13 \cdot 10^{-5}$
Borsäure	K_b	$7{,}3 \cdot 10^{-10}$	$7{,}4 \cdot 10^{-10}$	$7{,}8 \cdot 10^{-10}$	$8{,}9\ 10^{-10}$
Kohlensäure	K_{k1}	$4{,}01 \cdot 10^{-7}$	$4{,}07 \cdot 10^{-7}$	$4{,}30 \cdot 10^{-7}$	$4{,}87 \cdot 10^{-7}$
Kohlensäure	K_{k2}	$5{,}2 \cdot 10^{-11}$	$5{,}4 \cdot 10^{-11}$	$6{,}0 \cdot 10^{-11}$	$7{,}8 \cdot 10^{-11}$

Tabelle 2. Die Richtungskoeffizienten der Tangente im Wendepunkt der Titrationskurve

$[NH_3]$, *M*	$[H_3BO_3]$, *M*	$-dc_t/d$ pH *Äquiv/l.*
10^{-4}	0	$1{,}1 \cdot 10^{-6}$
10^{-3}	0	$3{,}1 \cdot 10^{-6}$
10^{-2}	0	$9{,}3 \cdot 10^{-6}$
10^{-4}	10^{-2}	$1{,}3 \cdot 10^{-5}$
10^{-3}	10^{-2}	$1{,}3 \cdot 10^{-5}$
10^{-2}	10^{-2}	$1{,}9 \cdot 10^{-5}$
10^{-4}	10^{-1}	$3{,}9 \cdot 10^{-5}$
10^{-3}	10^{-1}	$4{,}3 \cdot 10^{-5}$

Bei den Titrationskurven des Ammoniaks, auch in Anwesenheit von Borsäure, werden die Richtungskoeffizienten der Tangenten im Wendepunkt nach der Gleichung (8) berechnet und die Ergebnisse in Tabelle 2 zusammengefaßt.

Karbonate liegen in verschiedenen Materialen häufig vor. Zum Beispiel in Naturwässern sind sie in einer Konzentration bis $10^{-2}M$ und ausnahmsweise noch höher enthalten. Bei der Destillation aus gepufferten Lösungen von pH 7,4, der bei der Wasseranalyse vorgeschrieben wird,[5] geht ein beträchtlicher Anteil von CO_2 in die Vorlage über. Kohlendioxid, als Bestandteil der Luft, kann in die Maßlösung oder in das zur Analyse verwendete redestillierte Wasser eindringen. Deshalb wird sein Einfluß schon von sehr niedrigen Mengen, die ihren Ursprung in der atmosphärischen Verunreinigungen haben können, untersucht.

Die charakteristischen Angaben der Titrationskurven-pH im Äquivalenzpunkt [berechnet aus der Gleichung (6)], pH im Wendepunkt (graphisch aus der berechneten Titrationskurve ermittelt) und die Differenz des Normallösungsverbrauches zwischen dem Äquivalentspunkt und dem Wendepunkt [aus den Gleichungen (2) und (5) berechnet], sind in Tabelle 3 verzeichnet. Einige ausgewählte Titrationskürven sind in Abb. 1 und 2 wiedergegeben.

Der berechnete Verlauf von Titrationskurven wurde experimentell mit Hilfe des pH-meters Radelkis OP-206 überprüft, wobei eine gute Übereinstimmung erreicht wurde (siehe Abbildungen 1 und 2).

Die Lösungen wurden aus redestilliertem, von CO_2 durch Auskochen befreitem Wasser, vorbereitet. Nach Herstellung der einzelnen Lösungen durch Vermischung der Grundlösungen ($0{,}01M$ NH_3, $0{,}01M$ HCl, $0{,}4M$ H_3BO_3 und $2{,}1 \times 10^{-3}M$ CO_2) wurde der

pH-Wert bestimmt. Die gewünschte CO_2-Konzentration wurde durch Zugabe von kohlendioxidgesättigtem redistilliertem Wasser, in dem CO_2 gleich vor Verwendung alkalimetrisch bestimmt wurde, hergestellt.

Diskussion der Ergebnisse

Die pH-Werte im Äquivalenzpunkt der Ammoniaktitrationskurven sind eine logarithmische Funktion der NH_3-Konzentration [siehe Gleichung (6)], die auch ihren Verlauf als Folge der Hydrolyse des Ammoniumsalzes beeinflußt. Äquivalenz- und Wendepunkte der Ammoniaktitrationskurven unterscheiden sich durch nicht mehr als 0,01 pH (Tabelle 3).

Aus dem Richtungskoeffizient dc_t/dpH in der Nähe des Äquivalenzpunktes (der in diesem Falle mit dem Wendepunkt identisch ist) läßt sich ableiten, daß eine Konzentrationsänderung der starken Säure in der titrierten Lösung (für $[NH_3] < 0{,}01M$) um 10^{-7} bis 10^{-8} Äquivalent pro Liter den pH-Wert nur um ein Hundertstel ändert (Tabelle 2). Bei der pH-Ablesung mit einer Genauigkeit von einem Hundertstel kann die Ammoniakkonzentration unter Verwendung der maßanalytischen, potentiometrisch indizierten Methode mit der theoretisch maximal erreichbaren Genauigkeit auf $10^{-7}M$ bestimmt werden. Bei der pH-Ablesung auf Zehntel, ist die erreichbare Genauigkeit der Ammoniakbestimmung zehnmal kleiner. Bei diesen extrem genauen Bestimmungen ist es nötig, die Volumsänderungen der Lösung während der Titration, und besonders die Anwesenheit von Kohlendioxid zu beachten. Es ist außerdem notwendig, daß die Maßlösung in die Probelösung mit entsprechender Genauigkeit zugesetzt werden kann.

Die Beeinflußung des Verlaufes von Ammoniaktitrationskurven durch schwache Säuren ist aus den Abb. 1 und 2 für Borsäure und Kohlendioxid ersichtlich. Da Säuren die Titrationskurven im alkalischen Gebiete deformieren, verschiebt sich der Äquivalenzpunkt zu niedrigen pH-Werten. Diese Wirkung ist von der Säurekonzentration und von der Größe ihrer Dissoziationskonstante abhängig. Die Identität des Aquivalenzpunktes mit dem Wendepunkt der Titrationskurve von Ammoniak bei Anwesenheit der Borsäure stimmt mit einer Genauigkeit auf Hundertstel pH-Wert (Tabelle 3).

Der Richtungskoeffizient der Tangente im Äquivalenzpunkt wird durch eine Borsäurezugabe auf Werte von 10^{-5} bis 5×10^{-5} Äquivalent pro Liter erhöht. Die Änderung der Säurekonzentration c_t um etwa 10^{-6} Äquivalent pro Liter bewirkt in der Umgebung dieses Punktes eine pH-Änderung von 0,01. Deshalb ist bei Anwesenheit der Borsäure die theoretisch erreichbare Genauigkeit der Ammoniakbestimmung $10^{-6}M$ unter Verwendung der potentiometrischen Indikation bei pH-Ablesung auf Hundertstel. Bei pH-Ablesung auf Zehntel ist die erreichbare Genauigkeit $10^{-5}M$.

Ähnlich wie Borsäure verhält sich auch Kohlensäure, deren Wirkung aber deutlicher in Übereinstimmung mit der Größe ihrer Dissoziationskonstante ist. Bei dieser Säure ist ihre zweite Dissoziationsstufe zu beachten, erkennbar durch einen zweiten Wendepunkt, besonders eindeutig bei höheren CO_2-Konzentrationen. Bei niedrigen CO_2-Konzentrationen ist nur ein Wendepunkt deutlich, der aber stark vom Äquivalenzpunkt abweicht (Tabelle 3). Bei einer Kohlensäurekonzentration höher als $3 \times 10^{-4}M$,

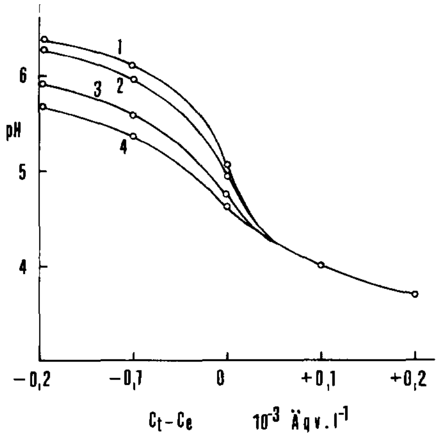

Abb. 2. Ammoniaktitrationskurven bei Anwesenheit von Borsäure und Kohlensäure $[NH_3] = 10^{-3}M$; $[H_3BO_3] = 10^{-1}M$

Kurve Nr.	$[CO_2]$	Kurve Nr.	$[CO_2]$
1	0	3	$5 \cdot 10^{-4}M$
2	$10^{-4}M$	4	$10^{-3}M$

Tabelle 4. Die maximal zulässige CO_2-Konzentrationen (M) für die massanalytische Ammoniakbestimmung der verlangten Genauigkeit

	verlangte Genauigkeit der Bestimmung (in Mol NH_3 pro Liter)			
$[NH_3]$, M	10^{-4}	10^{-5}	10^{-6}	10^{-7}
(a) potentiometrische Indikation:				
für $[H_3BO_3] = 0$				
10^{-4}	10^{-3}	$2\cdot10^{-5}$	$2\cdot10^{-6}$	$2\cdot10^{-7}$
10^{-3}	10^{-3}	$3\cdot10^{-5}$	$3\cdot10^{-6}$	$3\cdot10^{-7}$
10^{-2}	10^{-3}	10^{-3}	10^{-5}	10^{-6}
für $[H_3BO_3] = 10^{-2}$–$10^{-1}M$				
10^{-4}–10^{-2}	10^{-3}	10^{-3}	$5\cdot10^{-5}$	—
(b) visuelle Indikation (im pH-Bereiche 5,7–4,1):				
für $[H_3BO_3] = 0$–$10^{-1}M$				
10^{-4}–10^{-2}	10^{-4}	—	—	—
(c) visuelle Indikation (im pH-Bereiche 5,0–4,8):				
für $[H_3BO_3] = 0$–$10^{-1}M$				
10^{-4}–10^{-2}	10^{-3}	10^{-4}	—	—

oder in Anwesenheit von Borsäure kann man den Wendepunkt der ersten Stufe, dessen Abweichung vom Äquivalenzpunkt kleiner ist, bestimmen. Liegt die CO_2-Konzentration höher als $10^{-3}M$ vor, wird die Titrationskurve so flach, daß die Ammoniakbestimmung sich nur mit einer Genauigkeit von $10^{-3}M$ durchführen läßt.

Die Angaben über den zulässigen CO_2-Konzentrationen bei der maßanalytischen Ammoniakbestimmung mit der verlangten Genauigkeit sind in Tabelle 4 verzeichnet. Sie gehen aus dem Verlauf der Titrationskurven und aus den in Tabellen 3 und 5 angeführten Werten hervor. Diese Angaben dokumentieren die Abhängigkeit der angeführten Grenzwerte von der Ammoniak- und Borsäurekonzentration in der analysierten Probe.

Von den azidobasischen Indikatoren, die bei der maßanalytischen Ammoniakbestimmung am häufig-

stens verwendet werden, ist Methylrot oder seine Mischung mit Methylenblau (Indikator nach Taschiro) zu nennen. Die Indikatorkonstante ($pK_i = 4{,}9$) ist durch den ersten Bestandteil bestimmt. Methylenblau macht nur den Farbumschlag für das menschliche Auge deutlicher. Die Farbänderung des Indikators wird durch den Bereich von 10 bis 90% aus der erreichbaren Intensität der roten Farbe, die in diesem Falle maßgebend ist, bestimmt. Das entspricht dem pH-Bereiche 4,1–5,7. Eine genauere Unterscheidung kann man durch Verwendung einer auf den pH-Wert 4,9 gepufferten Vergleichslösung erreichen, In diesem Falle läßt sich in der Nähe von pK_{i1} die Farbintensität mit Genauigkeit auf ± 6% gegenüber ihrer maximaler Intensität, die bei einer extremen Azidität erreicht wird, zuverlässig unterscheiden. Dieses Farbintervall entspricht dem pH-Bereich 4,8–5,0.

Die Differenzen des Verbrauches an Normallösung der Säure beim Erreichen des gewünschten pH-Wertes und Äquivalenzpunktes im Verlaufe der Ammoniaktitration sind in Tabelle 5 angegeben. Diese Differenzen sind für die Beurteilung der erreichbaren Genauigkeit entscheidend.

Im ersten Falle, d.h. für den Farbumschlag, der durch den pH-Bereich 5,7–4,1 bestimmt wird, ist bei der Ammoniaktitration, auch in Anwesenheit der Borsäure, die maximal erreichbare Genauigkeit der Ammoniakbestimmung $10^{-4}M$. Durch das Verengen des pH-Intervalls, in dem der Farbumschlag wahrnehmbar ist, auf 5,0 bis 4,8, wird die Genauigkeit auf $10^{-5}M$ erhöht.

Bei Anwesenheit von Kohlendioxid wird die Titrationskurve flacher, wodurch die Indikation erschwert wird. Die erreichbare Genauigkeit der Ammoniakbestimmung ist bei der Indikation mit Methylrot $10^{-4}M$ unter Voraussetzung, daß die CO_2-Konzentration $10^{-4}M$ nicht übersteigt. Unter den gleichen Bedingungen kann man durch die Verwendung von Indikatorvergleichslösung eine Genauigkeit von $10^{-5}M$ erzielen. Liegt die CO_2-Konzentration höher als $10^{-4}M$ vor (bis ungefähr $2 \cdot 10^{-3}M$), läßt sich bei visueller Indikation nur eine Genauigkeit von $10^{-3}M$. bzw. unter Verwendung von Vergleichslösung $10^{-4}M$ erreichen.

Bei der genauen maßanalytischen Bestimmung muß man aber berücksichtigen, daß auch der Indikator beim Übergang von einer Form in die andere einen gewissen Verbrauch an Normallösung aufweist. Methylrot in der Menge von 0,1 ml 0,1%iger Lösung verbraucht bei dieser Umwandlung 0,003 ml 0,1*N* Normallösung.[2] Diese Tatsache wurde bei den in Tabelle 5 angegebenen Werten außer Acht gelassen.

APPENDIX

Berechnung der Gleichung (8) aus der Gleichung (2): $c_t + \dfrac{c_b K_b}{K_b + [H^+]} = [H^+] + \dfrac{c_a K_a [H^+]}{K_a[H^+] + K_w} - \dfrac{K_w}{[H^+]}$

oder $F'(c_t, [H^+]) \equiv [H^+]^4 A + [H^+]^3 B + [H^+]^3 c_t D + [H^+]^2 E + [H^+]^2 c_t L + [H^+] P + [H^+] c_t S + T = 0$

wo $A = K_a$, $B = K_a K_b + K_a c_a + K_w$; $D = -K_a$; $E = K_a K_b c_a - K_a K_b c_b + K_b K_w - K_a K_w$, $L = -K_a K_b - K_w$. $P = -K_a K_b K_w - K_b K_w c_b - K_w^2$; $S = -K_b K_w$; $T = -K_b K_w^2$

$$F'(c_t, 10^{-pH}) = F(c_t, pH)$$

$$\frac{\partial F(c_t, pH)}{\partial c_t} = 10^{-3pH} D + 10^{-2pH} L + 10^{-pH} S$$

$$\frac{\partial F(c_t, pH)}{\partial pH} = -\ln 10 \{4 \cdot 10^{-4pH} A + 3 \cdot 10^{-3pH}(B + c_t D) + 2 \cdot 10^{-2pH}(E + c_t L) + 10^{-pH}(P + c_t S)\}$$

aus der Gleichung (7):

$$-\frac{dc_t}{dpH} = \frac{\ln 10 \{4\ 10^{-3pH} A + 3 \cdot 10^{-2pH}(B + c_t D) + 2 \cdot 10^{-pH}(E + c_t L) + (P + c_t S)\}}{10^{-2pH} D + 10^{-pH} L + S}$$

für $c_t = c_a$ (Äquivalenzpunkt):

$$-\frac{dc_t}{dpH} = \frac{\ln 10 \{4\ 10^{-3pH} K_a + 3 \cdot 10^{-2pH}(K_a K_b + K_w) + 2\ 10^{-pH}(K_b K_w - K_a K_w - K_a K_b c_b - K_w c_a) - K_a K_b K_w - K_w^2 - K_b K_w c_b - K_b K_w c_a\}}{10^{-2pH} K_a + 10^{-pH} K_a K_b + 10^{-pH} K_w + K_b K_w}$$

vereinfacht durch Vernachlässigung der kleinen Gliedern:

$$-\frac{dc_t}{dpH} = \frac{\ln 10 \{4\ 10^{-3pH} K_a - 2\ 10^{-pH}(K_a K_b c_b + K_w c_a)\}}{10^{-2pH} K_a}$$

daraus läßt sich schon leicht die Gleichung (8) ableiten.

STÖRENDE EINFLÜSSE VON BORSÄURE UND KOHLENDIOXID BEI DER MASSANALYTISCHEN AMMONIAKBESTIMMUNG

JOSEF MALÝ
Wasserwirtschaftsverwaltung, Brno, Tshechoslowakei

(*Eingegangen am* 2. *April* 1975. *Revidiert am* 20. *November* 1975. *Angenommen am* 24. *Februar* 1976)

Zusammenfassung—Die erreichbare Genauigkeit der maßanalytischen Ammoniakbestimmung mit potentiometrischer oder visueller Indikation bei Anwesenheit von Fremdstoffen (Borsäure und Kohlendioxid) wurde auf Grund des Verlaufes der Ammoniaktitrationskurven festgelegt und die Fehler dieses Verfahrens ausgewertet.

Die Mehrzahl der Verfahren für die Ammoniakbestimmung beruhen in seiner vorherigen Überführung durch Destillation, Diffusion oder Belüftung in eine starke Mineralsäure, in der es indirekt alkalimetrisch bestimmt wird, oder in eine Lösung der Borsäure mit anschließender azidimetrischer Bestimmung.[1,2] Im Verlaufe des Prozesses, bei dem Ammoniak in gasförmiger Zustand aus der analysierten Lösung ausgetrieben wird, können die in der Probe enthaltenden Fremdstoffe unter den gegebenen Bedingungen in die Absorptionslösung überführt werden und die nachfolgende Ammoniakbestimmung stören.

Handelt es sich um Basen (z.B. Pyridin), die mit Ammoniak aus alkalischen Lösungen freigemacht werden, läßt sich ihr Einfluß auf die Titrationsbedingungen aus den in der Literatur angeführten Diagrammen bestimmen.[3] In der vorliegenden Arbeit ist vor allem die Aufmerksammkeit den sauren Komponenten—der Borsäure und Kohlensäure—gewidmet. Der Einfluß der Borsäure wird deshalb untersucht, weil ihre Lösung oft zur Absorption des Ammoniaks nach seiner Abtrennung verwendet wird. Kohlensäure (bzw. Karbonate) ist ein üblicher Bestandteil der analysierten Lösungen und es kann während der Destillation eine Beträchtliche Menge von CO_2 in die Vorlage überführt werden.

Ableitung der Titrationskurven

Der Verlauf der Ammoniaktitrationskurve läßt sich aus den Gleichgewichtsbedingungen der beteiligten Ionen und aus den Elektroneutralitätsbedingungen in der Lösung berechnen. Bei der vereinfachten Voraussetzung der Volumenunveränderlichkeit der titrierten Lösung wird er durch die Gleichung (1) ausgedrückt:

$$c_t = [H^+] + \frac{c_a \cdot K_a \cdot [H^+]}{K_a \cdot [H^+] + K_w} - \frac{K_w}{[H^+]} \qquad (1)$$

worin K_a und K_w die Dissoziationskonstanten der Ammoniumionen und des Wassers, c_a und c_t die analytischen Konzentrationen des Ammoniaks und der Normallösung (starken Säure), die in Äquivalenten pro Liter in der titrierten Lösung ausgedrückt werden, bedeuten. Anstatt von der jetzt üblichen Bezeichnung der Wasserstoffionen H_3O^+ wird im Text der Einfachheit wegen die ältere Bezeichnung H^+ verwendet.

Die Gleichung (1) kann man auch zur Ermittlung der Titrationskurve verwenden, die die Rücktitration einer starken Säure bei Anwesenheit des Ammoniumsalzes mit einer starken Base darstellt. In diesem Falle entspricht c_t der Differenz zwischen der Äquivalenzkonzentration der starken Säure und Base.

Enthält die titrierte Lösung einige weitere sauer oder basisch reagierende Bestandteile, geht die Gleichung (1) in die folgende Form über:

$$c_t + \Sigma[A] - \Sigma[B] = [H^+] + \frac{c_a \cdot K_a [H^+]}{K_a \cdot [H^+] + K_w} - \frac{K_w}{[H^+]} \qquad (2)$$

Hier entspricht $\Sigma[A]$ der Summe von sauer- und $\Sigma[B]$ von alkalisch reagierenden Komponenten. Handelt es sich um eine Säure H_nA, die in n Stufen dissoziiert, gilt:

$$[A] = c_A \cdot \frac{K_{A1}[H^+]^{n-1} + 2K_{A1}K_{A2}[H^+]^{n-2} + \ldots + nK_{A1}K_{A2}\ldots K_{An}}{[H^+]^n + K_{A1}[H^+]^{n-1} + K_{A1}K_{A2}[H^+]^{n-2} + \ldots + K_{A1}K_{A2}\ldots K_{An}} \qquad (3)$$

Analogisch, wenn eine in m Stufen dissoziierte Base vorliegt, gilt:

$$[B] = c_B \cdot \frac{K_{B1}K_w^{m-1}[H^+] + 2K_{B1}K_{B2}K_w^{m-2}[H^+]^2 + \ldots + mK_{B1}K_{B2}\ldots K_{Bm}[H^+]^m}{K_w^m + K_{B1}K_w^{m-1}[H^+] + K_{B1}K_{B2}K_w^{m-2}[H^+]^2 + \ldots + K_{B1}K_{B2}\ldots K_{Bm}[H^+]^m} \qquad (4)$$

Darin bedeuten $K_{A1}, K_{A2} \ldots K_{An}$ bzw. $K_{B1}, K_{B2} \ldots K_{Bm}$ die Dissoziationskonstanten der Säure bzw. Base, c_A und c_B ihre analytischen Konzentrationen, die in Äquivalenten pro Liter ausgedrückt werden. Sind die angeführten Bestandteile Borsäure und Kohlensäure, gilt:

$$\Sigma[\mathrm{B}] = 0$$

$$\Sigma[\mathrm{A}] = \frac{c_b K_b}{K_b + [\mathrm{H}^+]} + c_k \frac{K_{k1}[\mathrm{H}^+] + 2K_{k1}K_{k2}}{[\mathrm{H}^+]^2 + K_{k1}[\mathrm{H}^+] + K_{k1}K_{k2}} \qquad (5)$$

In diesen Ausdrücken bedeuten K_b, K_{k1}, K_{k2} die Dissoziationskonstanten der Borsäure und Kohlensäure (beide Stufen), c_b und c_k ihre molare Konzentration.

Der pH-Wert des Äquivalenzpunktes der Ammoniaktitrationskurve bzw. bei Anwesenheit von Borsäure und Kohlensäure wird aus den Gleichungen (2) und (5) nach der Einsetzung $c_t = c_a$ ermittelt. Nach Fortlassung einiger vernachlässigbaren kleinen Gliedern bekommt man:

$$\mathrm{pH} = -\tfrac{1}{2}\log\left(\frac{c_a \cdot K_w}{K_a} + c_b \cdot K_b + c_k \cdot K_{k1}\right) \qquad (6)$$

Für die Beurteilung der Genauigkeit der Titrationsmethode ist es wichtig die Steigerung der Titrationskurve im Äquivalenzpunkt, die durch den Richtungskoeffizient der Tangente in diesem Punkt ermittelt wird, zu kennen. Er wird aus der zugehörigen Funktionsabhängigkeit zwischen pH und c_t durch Differenzieren berechnet. Diese Abhängigkeit wird für Ammoniak und Borsäure durch die Gleichung (2), in der für die $[\mathrm{H}^+]$-Werte ein äquivalenter Ausdruck $10^{-\mathrm{pH}}$ eingesetzt wird, dargestellt. Der Differenzialquotient wird aus dem implizierten Ausdruck der Funktion $F(c_t, \mathrm{pH})$ ermittelt:

$$-\frac{\mathrm{d}c_t}{\mathrm{dpH}} = \frac{\partial F(c_t, \mathrm{pH})/\partial \mathrm{pH}}{\partial F(c_t, \mathrm{pH})/\partial c_t} \qquad (7)$$

Aus den Gleichungen (7) und (2) bzw. (5) bekommt man für den Äquivalenzpunkt ($c_t = c_a$) nach der Vereinfachung durch Fortlassung der vernachlässigbaren kleinen Gliedern (siehe Appendix):

$$-\frac{\mathrm{d}c_t}{\mathrm{dpH}} = \frac{2\ln 10(2K_a \cdot 10^{-2\mathrm{pH}} - c_a K_w - c_b K_a K_b)}{K_a 10^{-\mathrm{pH}}} \qquad (8)$$

Ermittlung der Titrationskurven

Nach den oben angeführten Beziehungen wird die Berechnung der Ammoniaktitrationskurven auch bei Anwesenheit von Borsäure und Kohlensäure durchgeführt. Wie erwähnt, wird dabei eine Volumenveränderung während der Titration nicht errechnet.

Die für sehr verdünnte Lösungen gültigen Tabellenwerte der Dissoziationskonstanten wurden mit Rücksicht auf die Ionenstärke der Lösung (im Äquivalenzpunkt) umgerechnet—Tabelle 1.

$$-\log f_i = i^2 \frac{0{,}511\sqrt{J}}{(1 + 1{,}5\sqrt{J})} - 0{,}2\,J \qquad (9)$$

$$K'_1 = f_1^2 \cdot K_1 \qquad (10)$$

$$K'_2 = f_2 \cdot K_2 \qquad (10a)$$

In diesen Gleichungen bedeuten K' die Tabellenwerte der Dissoziationskonstanten der unendlich verdünnten Lösungen, K die Dissoziationskonstanten der Lösungen mit der Ionenstärke J, f_i sind die Aktivitätskoeffizienten der i-Wertigen Ionen. Für die Berechnung der Ionenstärke wird die Ammoniumchlorid konzentration (im Äquivalenzpunkt) in Betracht genommen, während Borsäure und Kohlensäure wegen ihrer vernachlässigbarer Dissoziation unbeachtet bleiben.

Bei der hier verwendeten Konzentration der Borsäure (0,1*M*) ist nur die Ionenstärke der Lösung bei Berechnung der Dissoziationskonstante K_b in Betracht zu ziehen. Wenn die Borsäurekonzentration höher als 0,1*M* vorliegt, werden stärkere Polyborsäuren gebildet. Der K_b-Wert verändert sich dann mehr als der erhöhten Ionenstärke entspricht, und er muß aus der empirisch bestimmten Abhängigkeit pH von der Borsäurekonzentration abgeleitet werden.[4]

Der untersuchte Ammoniakkonzentrationsbereich war 10^{-4} bis $10^{-2}M$. Der Konzentrationsbegrenzung der Borsäure wurde die Anforderung für die quantitative Absorption des Ammoniaks im Verlaufe seiner Abtrennung aus der analysierten Lösung in Betracht gezogen. Die erforderliche Menge der Borsäure und ihre Konzentration in der Vorlage hängt von der Menge des Destillierten Ammoniaks ab. Zur Absorption von 20 mg Ammoniak sind 25 ml 2%iger Borsäure hinreichend. Nach Abdestillieren des erforderlichen Volumens wird die Lösung in der Vorlage verdünnt und die resultierende Borsäurekonzentration ist dann ungefähr 0,1*M*.

Tabelle 1. Die für die Berechnung verwendeten Dissoziationskonstanten (für 18°C)

		Ionenstärke der Lösung			
Komponente		0	10^{-4}	10^{-3}	10^{-2}
Wasser	K_w	$0{,}74 \cdot 10^{-14}$	$0{,}75 \cdot 10^{-14}$	$0{,}79 \cdot 10^{-14}$	$0{,}90 \cdot 10^{-14}$
Ammoniak	K_a	$1{,}75 \cdot 10^{-5}$	$1{,}76 \cdot 10^{-5}$	$1{,}88\ 10^{-5}$	$2{,}13 \cdot 10^{-5}$
Borsäure	K_b	$7{,}3 \cdot 10^{-10}$	$7{,}4 \cdot 10^{-10}$	$7{,}8 \cdot 10^{-10}$	$8{,}9\ 10^{-10}$
Kohlensäure	K_{k1}	$4{,}01 \cdot 10^{-7}$	$4{,}07 \cdot 10^{-7}$	$4{,}30 \cdot 10^{-7}$	$4{,}87 \cdot 10^{-7}$
Kohlensäure	K_{k2}	$5{,}2 \cdot 10^{-11}$	$5{,}4 \cdot 10^{-11}$	$6{,}0 \cdot 10^{-11}$	$7{,}8 \cdot 10^{-11}$

Tabelle 2. Die Richtungskoeffizienten der Tangente im Wendepunkt der Titrationskurve

$[NH_3]$, *M*	$[H_3BO_3]$, *M*	$-dc_t/d$ pH *Äquiv/l.*
10^{-4}	0	$1{,}1 \cdot 10^{-6}$
10^{-3}	0	$3{,}1 \cdot 10^{-6}$
10^{-2}	0	$9{,}3 \cdot 10^{-6}$
10^{-4}	10^{-2}	$1{,}3 \cdot 10^{-5}$
10^{-3}	10^{-2}	$1{,}3 \cdot 10^{-5}$
10^{-2}	10^{-2}	$1{,}9 \cdot 10^{-5}$
10^{-4}	10^{-1}	$3{,}9 \cdot 10^{-5}$
10^{-3}	10^{-1}	$4{,}3 \cdot 10^{-5}$

Bei den Titrationskurven des Ammoniaks, auch in Anwesenheit von Borsäure, werden die Richtungskoeffizienten der Tangenten im Wendepunkt nach der Gleichung (8) berechnet und die Ergebnisse in Tabelle 2 zusammengefaßt.

Karbonate liegen in verschiedenen Materialen häufig vor. Zum Beispiel in Naturwässern sind sie in einer Konzentration bis $10^{-2}M$ und ausnahmsweise noch höher enthalten. Bei der Destillation aus gepufferten Lösungen von pH 7,4, der bei der Wasseranalyse vorgeschrieben wird,[5] geht ein beträchtlicher Anteil von CO_2 in die Vorlage über. Kohlendioxid, als Bestandteil der Luft, kann in die Maßlösung oder in das zur Analyse verwendete redestillierte Wasser eindringen. Deshalb wird sein Einfluß schon von sehr niedrigen Mengen, die ihren Ursprung in der atmosphärischen Verunreinigungen haben können, untersucht.

Die charakteristischen Angaben der Titrationskurven-pH im Äquivalenzpunkt [berechnet aus der Gleichung (6)], pH im Wendepunkt (graphisch aus der berechneten Titrationskurve ermittelt) und die Differenz des Normallösungsverbrauches zwischen dem Äquivalentspunkt und dem Wendepunkt [aus den Gleichungen (2) und (5) berechnet], sind in Tabelle 3 verzeichnet. Einige ausgewählte Titrationskürven sind in Abb. 1 und 2 wiedergegeben.

Der berechnete Verlauf von Titrationskurven wurde experimentell mit Hilfe des pH-meters Radelkis OP-206 überprüft, wobei eine gute Übereinstimmung erreicht wurde (siehe Abbildungen 1 und 2).

Die Lösungen wurden aus redestilliertem, von CO_2 durch Auskochen befreitem Wasser, vorbereitet. Nach Herstellung der einzelnen Lösungen durch Vermischung der Grundlösungen ($0{,}01M$ NH_3, $0{,}01M$ HCl, $0{,}4M$ H_3BO_3 und $2{,}1 \times 10^{-3}M$ CO_2) wurde der

pH-Wert bestimmt. Die gewünschte CO_2-Konzentration wurde durch Zugabe von kohlendioxidgesättigtem redistilliertem Wasser, in dem CO_2 gleich vor Verwendung alkalimetrisch bestimmt wurde, hergestellt.

Diskussion der Ergebnisse

Die pH-Werte im Äquivalenzpunkt der Ammoniaktitrationskurven sind eine logarithmische Funktion der NH_3-Konzentration [siehe Gleichung (6)], die auch ihren Verlauf als Folge der Hydrolyse des Ammoniumsalzes beeinflußt. Äquivalenz- und Wendepunkte der Ammoniaktitrationskurven unterscheiden sich durch nicht mehr als 0,01 pH (Tabelle 3).

Aus dem Richtungskoeffizient dc_t/dpH in der Nähe des Äquivalenzpunktes (der in diesem Falle mit dem Wendepunkt identisch ist) läßt sich ableiten, daß eine Konzentrationsänderung der starken Säure in der titrierten Lösung (für $[NH_3] < 0{,}01M$) um 10^{-7} bis 10^{-8} Äquivalent pro Liter den pH-Wert nur um ein Hundertstel ändert (Tabelle 2). Bei der pH-Ablesung mit einer Genauigkeit von einem Hundertstel kann die Ammoniakkonzentration unter Verwendung der maßanalytischen, potentiometrisch indizierten Methode mit der theoretisch maximal erreichbaren Genauigkeit auf $10^{-7}M$ bestimmt werden. Bei der pH-Ablesung auf Zehntel, ist die erreichbare Genauigkeit der Ammoniakbestimmung zehnmal kleiner. Bei diesen extrem genauen Bestimmungen ist es nötig, die Volumsänderungen der Lösung während der Titration, und besonders die Anwesenheit von Kohlendioxid zu beachten. Es ist außerdem notwendig, daß die Maßlösung in die Probelösung mit entsprechender Genauigkeit zugesetzt werden kann.

Die Beeinflußung des Verlaufes von Ammoniaktitrationskurven durch schwache Säuren ist aus den Abb. 1 und 2 für Borsäure und Kohlendioxid ersichtlich. Da Säuren die Titrationskurven im alkalischen Gebiete deformieren, verschiebt sich der Äquivalenzpunkt zu niedrigen pH-Werten. Diese Wirkung ist von der Säurekonzentration und von der Größe ihrer Dissoziationskonstante abhängig. Die Identität des Aquivalenzpunktes mit dem Wendepunkt der Titrationskurve von Ammoniak bei Anwesenheit der Borsäure stimmt mit einer Genauigkeit auf Hundertstel pH-Wert (Tabelle 3).

Der Richtungskoeffizient der Tangente im Äquivalenzpunkt wird durch eine Borsäurezugabe auf Werte von 10^{-5} bis 5×10^{-5} Äquivalent pro Liter erhöht. Die Änderung der Säurekonzentration c_t um etwa 10^{-6} Äquivalent pro Liter bewirkt in der Umgebung dieses Punktes eine pH-Änderung von 0,01. Deshalb ist bei Anwesenheit der Borsäure die theoretisch erreichbare Genauigkeit der Ammoniakbestimmung $10^{-6}M$ unter Verwendung der potentiometrischen Indikation bei pH-Ablesung auf Hundertstel. Bei pH-Ablesung auf Zehntel ist die erreichbare Genauigkeit $10^{-5}M$.

Ähnlich wie Borsäure verhält sich auch Kohlensäure, deren Wirkung aber deutlicher in Übereinstimmung mit der Größe ihrer Dissoziationskonstante ist. Bei dieser Säure ist ihre zweite Dissoziationsstufe zu beachten, erkennbar durch einen zweiten Wendepunkt, besonders eindeutig bei höheren CO_2-Konzentrationen. Bei niedrigen CO_2-Konzentrationen ist nur ein Wendepunkt deutlich, der aber stark vom Äquivalenzpunkt abweicht (Tabelle 3). Bei einer Kohlensäurekonzentration höher als $3 \times 10^{-4}M$,

10^{-4}–10^{-2}	10^{-4}	—	—	—
(c) visuelle Indikation (im pH-Bereiche 5,0–4,8):				
für $[H_3BO_3] = 0$–$10^{-1}M$				
10^{-4}–10^{-2}	10^{-3}	10^{-4}	—	—

oder in Anwesenheit von Borsäure kann man den Wendepunkt der ersten Stufe, dessen Abweichung vom Äquivalenzpunkt kleiner ist, bestimmen. Liegt die CO_2-Konzentration höher als $10^{-3}M$ vor, wird die Titrationskurve so flach, daß die Ammoniakbestimmung sich nur mit einer Genauigkeit von $10^{-3}M$ durchführen läßt.

Die Angaben über den zulässigen CO_2-Konzentrationen bei der maßanalytischen Ammoniakbestimmung mit der verlangten Genauigkeit sind in Tabelle 4 verzeichnet. Sie gehen aus dem Verlauf der Titrationskurven und aus den in Tabellen 3 und 5 angeführten Werten hervor. Diese Angaben dokumentieren die Abhängigkeit der angeführten Grenzwerte von der Ammoniak- und Borsäurekonzentration in der analysierten Probe.

Von den azidobasischen Indikatoren, die bei der maßanalytischen Ammoniakbestimmung am häufig-

stens verwendet werden, ist Methylrot oder seine Mischung mit Methylenblau (Indikator nach Taschiro) zu nennen. Die Indikatorkonstante ($pK_i = 4{,}9$) ist durch den ersten Bestandteil bestimmt. Methylenblau macht nur den Farbumschlag für das menschliche Auge deutlicher. Die Farbänderung des Indikators wird durch den Bereich von 10 bis 90% aus der erreichbaren Intensität der roten Farbe, die in diesem Falle maßgebend ist, bestimmt. Das entspricht dem pH-Bereiche 4,1–5,7. Eine genauere Unterscheidung kann man durch Verwendung einer auf den pH-Wert 4,9 gepufferten Vergleichslösung erreichen, In diesem Falle läßt sich in der Nähe von pK_{i1} die Farbintensität mit Genauigkeit auf ± 6% gegenüber ihrer maximaler Intensität, die bei einer extremen Azidität erreicht wird, zuverlässig unterscheiden. Dieses Farbintervall entspricht dem pH-Bereich 4,8–5,0.

Die Differenzen des Verbrauches an Normallösung der Säure beim Erreichen des gewünschten pH-Wertes und Äquivalenzpunktes im Verlaufe der Ammoniaktitration sind in Tabelle 5 angegeben. Diese Differenzen sind für die Beurteilung der erreichbaren Genauigkeit entscheidend.

Im ersten Falle, d.h. für den Farbumschlag, der durch den pH-Bereich 5,7–4,1 bestimmt wird, ist bei der Ammoniaktitration, auch in Anwesenheit der Borsäure, die maximal erreichbare Genauigkeit der Ammoniakbestimmung $10^{-4}M$. Durch das Verengen des pH-Intervalls, in dem der Farbumschlag wahrnehmbar ist, auf 5,0 bis 4,8, wird die Genauigkeit auf $10^{-5}M$ erhöht.

Bei Anwesenheit von Kohlendioxid wird die Titrationskurve flacher, wodurch die Indikation erschwert wird. Die erreichbare Genauigkeit der Ammoniakbestimmung ist bei der Indikation mit Methylrot $10^{-4}M$ unter Voraussetzung, daß die CO_2-Konzentration $10^{-4}M$ nicht übersteigt. Unter den gleichen Bedingungen kann man durch die Verwendung von Indikatorvergleichslösung eine Genauigkeit von $10^{-5}M$ erzielen. Liegt die CO_2-Konzentration höher als $10^{-4}M$ vor (bis ungefähr $2 \cdot 10^{-3}M$), läßt sich bei visueller Indikation nur eine Genauigkeit von $10^{-3}M$. bzw. unter Verwendung von Vergleichslösung $10^{-4}M$ erreichen.

Bei der genauen maßanalytischen Bestimmung muß man aber berücksichtigen, daß auch der Indikator beim Übergang von einer Form in die andere einen gewissen Verbrauch an Normallösung aufweist. Methylrot in der Menge von 0,1 ml 0,1%iger Lösung verbraucht bei dieser Umwandlung 0,003 ml 0,1N Normallösung.[2] Diese Tatsache wurde bei den in Tabelle 5 angegebenen Werten außer Acht gelassen.

APPENDIX

Berechnung der Gleichung (8) aus der Gleichung (2): $c_t + \dfrac{c_b K_b}{K_b + [H^+]} = [H^+] + \dfrac{c_a K_a [H^+]}{K_a[H^+] + K_w} - \dfrac{K_w}{[H^+]}$

oder $F'(c_t, [H^+]) \equiv [H^+]^4 A + [H^+]^3 B + [H^+]^3 c_t D + [H^+]^2 E + [H^+]^2 c_t L + [H^+]P + [H^+] c_t S + T = 0$

wo $A = K_a$, $B = K_a K_b + K_a c_a + K_w$; $D = -K_a$; $E = K_a K_b c_a - K_a K_b c_b + K_b K_w - K_a K_w$, $L = -K_a K_b - K_w$.
$P = -K_a K_b K_w - K_b K_w c_b - K_w^2$; $S = -K_b K_w$; $T = -K_b K_w^2$

$$F'(c_t, 10^{-pH}) = F(c_t, pH)$$

$$\frac{\partial F(c_t, pH)}{\partial c_t} = 10^{-3pH} D + 10^{-2pH} L + 10^{-pH} S$$

$$\frac{\partial F(c_t, pH)}{\partial pH} = -\ln 10 \{4 \cdot 10^{-4pH} A + 3 \cdot 10^{-3pH}(B + c_t D) + 2 \cdot 10^{-2pH}(E + c_t L) + 10^{-pH}(P + c_t S)\}$$

aus der Gleichung (7):

$$-\frac{dc_t}{dpH} = \frac{\ln 10 \{4\; 10^{-3pH} A + 3 \cdot 10^{-2pH}(B + c_t D) + 2 \cdot 10^{-pH}(E + c_t L) + (P + c_t S)\}}{10^{-2pH} D + 10^{-pH} L + S}$$

für $c_t = c_a$ (Äquivalenzpunkt):

$$-\frac{dc_t}{dpH} = \frac{\begin{array}{r}\ln 10 \{4\; 10^{-3pH} K_a + 3 \cdot 10^{-2pH}(K_a K_b + K_w) + 2\; 10^{-pH}(K_b K_w - K_a K_w - K_a K_b c_b - K_w c_a) \\ - K_a K_b K_w - K_w^2 - K_b K_w c_b - K_b K_w c_a\}\end{array}}{10^{-2pH} K_a + 10^{-pH} K_a K_b + 10^{-pH} K_w + K_b K_w}$$

vereinfacht durch Vernachlässigung der kleinen Gliedern:

$$-\frac{dc_t}{dpH} = \frac{\ln 10 \{4\; 10^{-3pH} K_a - 2\; 10^{-pH}(K_a K_b c_b + K_w c_a)\}}{10^{-2pH} K_a}$$

daraus läßt sich schon leicht die Gleichung (8) ableiten.

DIFFUSION-LAYER MODEL FOR COPPER SOLID-STATE CHALCOCITE MEMBRANE ELECTRODE; SENSITIVITY TO COPPER(II) IONS

ADAM HULANICKI and ANDRZEJ LEWENSTAM
Institute of Fundamental Problems in Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 22 *July* 1975. *Revised* 20 *November* 1975. *Accepted* 29 *January* 1976)

Summary—The diffusion-layer model for the chalcocite (Cu_2S) membrane electrode is discussed. It is equivalent to a simpler model based on exchange reactions at the electrode surface. The chalcocite is sensitive to copper(I) and copper(II) ions and the theoretically predicted response is in good agreement with experimental data. The membrane is a conductor, but this does not significantly affect its function as an ion detector. The limitation of the electrode is the membrane solubility as shown when Cu(II) ions in contrast to copper(I) ions are strongly complexed.

The reason for the sensitivity to copper(II) ions of solid-state electrodes based on copper(I) chalcogenides[1–7] is not fully understood. Heerman and Rechnitz[6] have stated that the copper(I) ions should be considered as the significant ions for the copper(I) sulphide electrode and Hansen *et al.*[8] agree that the contribution of Cu(I) ions to the mechanism should be taken into account.

This paper proposes a model for the function of the chalcocite (Cu_2S) membrane electrode and its sensitivity to copper(II) ions.

EXPERIMENTAL

The indicator electrode with an internal solution containing copper(II) chloride was prepared as described previously.[7] The potential was measured with an N-512 meter (ELPO-Wrocław) and potentiograph E-336 (Metrohm). The saturated calomel electrode used as reference was connected through a salt bridge. The copper(I) solution was obtained by coulometric generation from the copper electrode in a chloride medium. The solutions were prepared from analytical grade reagents and doubly distilled water.

THEORETICAL

In various models of electrode action given by several authors[9–13] the potential E of the half-cell formed by the membrane electrode is given by

$$E = E_M + E_R \qquad (1)$$

where E_M is the membrane potential and E_R the internal reference potential.

Eisenman[9] and Buck[11] describe the membrane potential as the sum of the diffusion potential E_D in the membrane and the potential E_B on the phase boundaries, while the membrane is considered as an ionic conductor. In the Pungor and Tóth[12] model only the potential E_R is taken into account, while the condition concerning ionic conductance is not irremissible. Both models result in formally analogous equations relating the potential of the electrode to the ionic activity (where admissible, concentrations are used instead of activities). For the chalcocite electrode this may be expressed as

$$E = \text{const.} + \frac{RT}{F}\ln([Cu^+] + K^{pot}_{Cu^+,M_i}[M_i^{2+}]^{1/2}) \qquad (2)$$

where $[Cu^+]$, and $[M_i^{2+}]$ are the actual concentrations of the main (Cu^+) and interfering (M^{2+}) ions, and $K^{pot}_{Cu^+,M_i}$ is the corresponding potentiometric selectivity coefficient.

In the Eisenman[9] and Buck[11] models (for miscible salts) the selectivity coefficient is equal to the product of the ratio of the ionic mobilities U_{Cu^+}/U_{M_i} in the membrane and the equilibrium constant K of the exchange reaction

$$M^{2+} + Cu_2S \rightleftharpoons MS + 2Cu^+ \qquad (3)$$

In the Pungor–Tóth[12] and Buck[11] models (for immiscible salts) the selectivity coefficient is directly related to the same equilibrium constant, and equal to the ratio of the solubility products K_{so} of the corresponding sulphides (with an exponent which follows from the stoichiometry): $K_{so(Cu_2S)}/K_{so(MS)}$. When no other mechanism of interference is assumed, the exchange reaction provides some of the concentration of the main ion causing the electrode response.

In the electrode model discussed here we assume that the electrode response is caused by the main ion concentration at the electrode surface. Three contributions may be discussed: the first is due to the analytical concentration in solution $[Cu^+]^A$, the second to the finite solubility of the membrane $[Cu^+]^L$, and the last to the exchange reaction with interfering ions $[Cu^+]^I$. This is represented as:

$$[Cu^+]_0 = [Cu^+]_0^A + [Cu^+]_0^L + [Cu^+]_0^I \qquad (4)$$

where the suffix indicates concentrations at the electrode surface, in contrast to bulk concentrations.

The concentration $[Cu^+]_0^L$ is directly related to the conditional solubility product

$$K'_{so(Cu_2S)} = K_{so(Cu_2S)}\alpha_{S(H)}\alpha^2_{Cu^+} = [Cu(I)']^2\,[S']$$

of the electrode-active substance, *i.e.*, Cu_2S, where the α values represent the side-reaction coefficients. The $\alpha_{S(H)}$ and α_{Cu^+} values depend on pH and the chloride concentration, respectively. Since

$$[S'] = \tfrac{1}{2}[Cu(I)']$$

we obtain

$$[Cu^+]_0^L = \left[\frac{2K_{so(Cu_2S)}\alpha_{S(H)}}{\alpha_{Cu^+}}\right]^{1/3} \tag{5}$$

Perhaps in the limit the concentration of interstitial copper(I) ions may become important, as found by Morf, Kahr and Simon[14] for silver(I) and the Ag_2S electrode. In the present discussion this factor is not considered, but from our experiments its value is about $10^{-10}M$.

The relation (5) as a function of pH for two different chloride concentrations is graphically presented in Fig. 1. It can be seen that the value of $[Cu^+]_0^L$ is mostly well below $10^{-12}M$ and therefore this contribution is small compared to the others.

The concentration $[Cu^+]_0^E$ represents the contribution to the electrode response caused by the presence of interfering ions having particular selectivity coefficients. The coefficients are expected to be larger than unity for Ag^+ and Hg^{2+}, which interfere even in small concentrations by covering the membrane with their sulphides, preventing further contact of the chalcocite membrane with the solution. For other common ions, including Cu^{2+}, the selectivity coefficients are significantly less than unity.

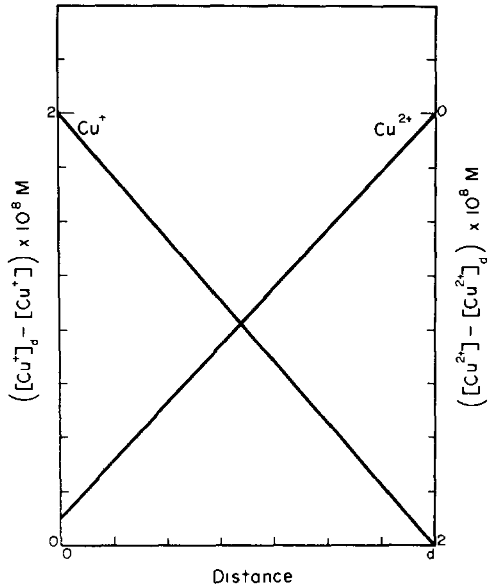

Fig. 2. Scheme for the diffusion layer $[Cu^+] = 1.6 \times 10^{-10}M$, $[Cu^{2+}] = 1.0 \times 10^{-3}M$ in bulk solution. $A = 2$, $K = 4 \times 10^{-13}$. [Calculated from equations (8) and (9).]

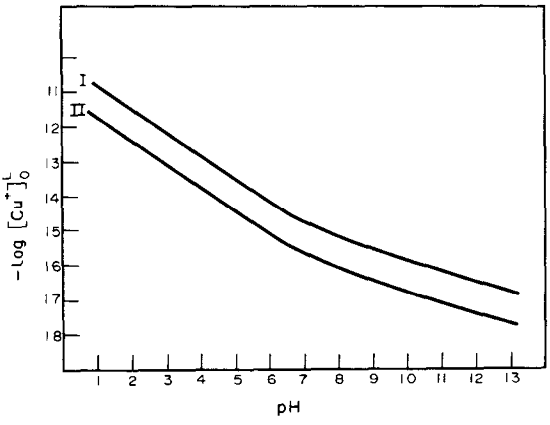

Fig. 1. Concentration of free copper(I) in equilibrium with the chalcocite membrane as a function of pH. Curve I—in 0.1*M* KCl, curve II—in 1*M* KCl.

For the equilibrium constant, K, of the reaction

$$Cu_2S + Cu^{2+} \rightleftharpoons CuS + 2Cu^+ \tag{6}$$

which is equal to the ratio of the solubility products, we obtain

$$K = ([Cu^+]_0)^2/[Cu^{2+}]_0 \tag{7}$$

where the concentrations are those at the electrode surface. When the reaction is sufficiently rapid and reversible a diffusion layer is formed, shown schematically in Fig. 2. Assuming diffusive transport at the electrode surface, linearity of the concentration gradients and independence of the diffusion coefficients on the diffusion layer thickness, we obtain from the mass balance

$$D_{Cu^+}([Cu^+]_0 - [Cu^+]) = 2D_{Cu^{2+}}([Cu^{2+}] - [Cu^{2+}]_0) \tag{8}$$

where D represents the diffusion coefficient of the ion indicated. From equations (7) and (8) the value of $[Cu^+]_0$ may be calculated as a function of the Cu^+ and Cu^{2+} concentrations:

$$[Cu^+]_0 = -\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[Cu^+] + 4K[Cu^{2+}]\right)^{1/2} \tag{9}$$

where $A = D_{Cu^+}/D_{Cu^{2+}}$, which has a numerical value of approximately 2, if the diffusion coefficient of Cu^+ (not reported in the literature) is taken as slightly smaller than that of Ag^+.

The value of $[Cu^+]_0$ should really be indicated as $[Cu^+]_0^E$, because it represents the contribution of the exchange reaction (interference) when the membrane solubility and analytical concentration contributions may be neglected. When the other contributions should be taken into account then the total concentration may be represented as:

$$[\mathrm{Cu}^+]_0 = [\mathrm{Cu}^+]_0^{\mathrm{A}} + [\mathrm{Cu}^+]_0^{\mathrm{L}} + \left\{ -\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[\mathrm{Cu}^+] + 4K[\mathrm{Cu}^{2+}] \right)^{1/2} \right\} \tag{10}$$

which enters into the equation for the potential:

$$E = \text{const.} + \frac{RT}{F}\ln[\mathrm{Cu}^+]_0. \tag{11}$$

This equation is valid for the intermediate range but no precise derivation of this equation can be presented. Nevertheless, from measurements in the concentration ranges used in our experiments, it evidently describes the behaviour of the electrode with enough accuracy for its practical use.

RESULTS AND DISCUSSION

The model described, in which the surface concentrations are different from those in the bulk of the solution, is similar to that given for the cyanide electrode.[13,15] The expanded form of equation (11):

$$E = \text{const.} + \frac{RT}{F}\ln\left\{ [\mathrm{Cu}^+]_0^{\mathrm{A}} + [\mathrm{Cu}^+]_0^{\mathrm{L}} + \left[-\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[\mathrm{Cu}^+] + 4K[\mathrm{Cu}^{2+}] \right)^{1/2} \right] \right\}, \tag{12}$$

may be simplified when some justifiable approximations are introduced. When $[\mathrm{Cu}^{2+}]$ is significantly greater than $4 \times 10^{-13}M$, *i.e.* $[\mathrm{Cu}^{2+}] \gg K$, then in equation (12) the total term corresponding to the exchange reaction is simplified to $K^{1/2}[\mathrm{Cu}^{2+}]^{1/2}$, and the equation is the same as given previously [(2)] on the basis of the Pungor–Tóth model.[12] The value of the constant $K = 4 \times 10^{-13}$ for reaction (6) is based on the solubility products,[19] and is an idealized approach. In real conditions the side-reaction coefficient effect of Cu^+ with chloride ions is much stronger than that of Cu^{2+}, shifting the reaction (6) towards the right-hand side. The dependence of pK' on the chloride concentration is shown in Fig. 3.

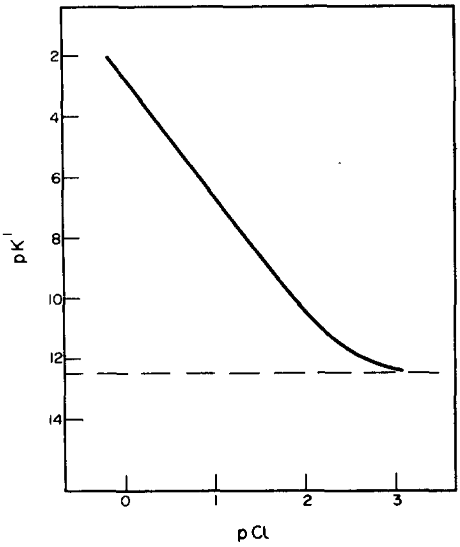

Fig. 3. Conditional constant of the exchange reaction $\mathrm{Cu}^{2+} + \mathrm{Cu_2S} \rightleftharpoons 2\mathrm{Cu}^+ + \mathrm{CuS}$ as a function of chloride concentration.

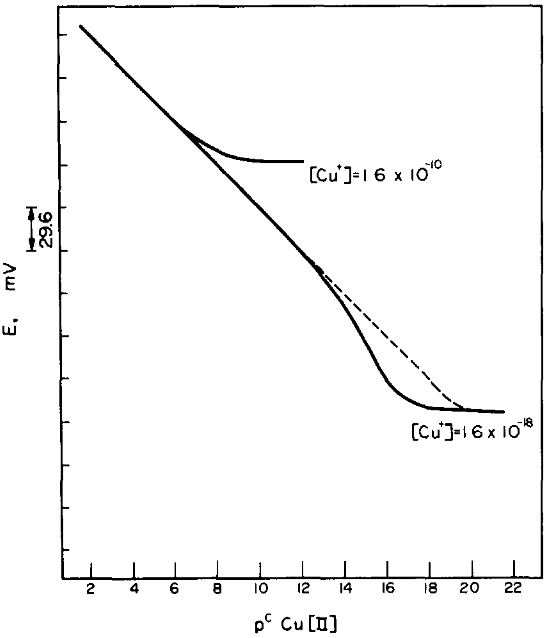

Fig. 4. Theoretical potential response curves calculated on the basis of the diffusion barrier model—solid line, and on the basis of the Pungor–Tóth model—dashed line.

For low concentrations of copper(I), *i.e.*, when $[\mathrm{Cu}^+] \ll K[\mathrm{Cu}^{2+}]^{1/2}$ the electrodes become sensitive to copper(II). In such conditions the chalcocite electrode may be treated as a copper(II) electrode, for which the copper(II) ions are the main ions. In this case the simplified model may be treated as a special case of the diffusion layer model. The potential response curves $E = f([\mathrm{Cu}^{2+}])$ have been calculated for several levels of concentration of copper(I) ions in solution (Fig. 4). It can be seen that only at the lowest levels is there departure from linearity.

The value of the selectivity coefficient of the chalcocite electrode is 4×10^{-13}, which is the equilibrium constant of the exchange reaction. The potentiometric selectivity coefficient, determined experimentally, $K^{\mathrm{pot}}_{\mathrm{Cu^+,Cu^{2+}}} = K^{1/2} = 6.3 \times 10^{-7}$, as described previously.[7] The magnitude of these values suggests that the extent of the exchange reaction is not large enough to allow the electrode to function according to the scheme $\mathrm{Cu_2S/CuS/Cu^{2+}}$ (external solution).

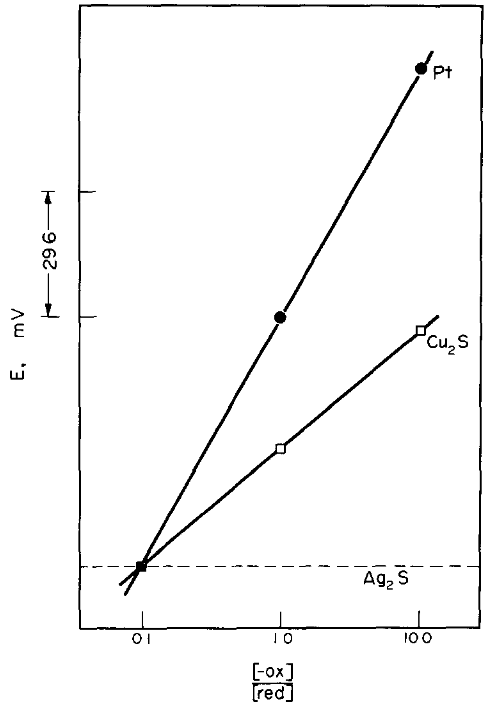

Fig. 5 Dependence of the electrode potential on the $[Fe(CN)_6^{3-}]$:$[Fe(CN)_6^{4-}]$ ratio at pH 5 The Ag_2S relationship is given according to Weser and Pungor [17]

It must be mentioned that the diffusion layer model does not specify the type of conductivity in the membrane. Because of the absence of β-Ag_2S, as the ionic conductor, one can expect for the chalcocite electrode a significant contribution of electron conductivity.[16] This has been confirmed experimentally by measuring the redox response of the electrode in comparison with that of the platinum electrode (Fig. 5).

Experimental potential response curves have been prepared for the chalcocite electrode in solutions containing both copper(I) and copper(II) ions. In the case of the copper(II) response (Fig. 6, curve I) the medium used was 1*M* potassium nitrate. The experimental points obtained by successive dilutions agree with those calculated on the assumption that $[Cu^+]$ is not greater than $1.6 \times 10^{-10}M$. As can be seen by comparison with Fig. 4 the curve is linear with the theoretical slope of 29.6 mV per decade. The slight curvature at low concentrations is due to $[Cu^+]_0^L$.

The response curve for copper(I) ions (Fig. 6, curve II) has been prepared on the basis of the analytical concentration of copper(I), generated coulometrically at pH 3 in 1*M* potassium chloride. The concentration of free (hydrated) Cu^+ ions is significantly lower. The constant degree of complexation due to the constant concentration of Cl^- as the predominant ligand, ensures that the slope has the theoretical value of 59.2 mV per decade, which is in good agreement with the calculated curve. Under these conditions the concentration of Cu^{2+} is insufficient for the formation of a CuS layer at the electrode surface. Therefore the contribution of the exchange concentration$[Cu^+]_0^L$ is negligible and except in a very low concentration range only the term $[Cu^+]_0^A$ is significant in equation (11).

In the presence of both copper(I) and copper(II) ions, at equal analytical concentrations, the potential response curve is influenced by both ions. The extent of complexation of copper(I) in 1*M* chloride solution is significantly greater ($\alpha_{Cu^+(Cl)} = 8.5 \times 10^4$)[18] than that of the copper(II). Therefore the α-value compensates partially for the small value of selectivity coefficient $K^{pot}_{Cu^+,Cu^{2+}}$. Both types of ion contribute to the slope, which in the range of concentrations indicated is approximately 55 mV per decade (Fig. 6, curve III).

The electrode limit, defined by $[Cu^+]_0^L$, may be reached under conditions where the copper(II) ions are more strongly complexed that the copper(I) ions. This happens, for example, in the potentiometric titration of copper(II) with EDTA. Because the copper(II) concentration drops significantly after the end-point, $[Cu^+]_0^L$ becomes the decisive factor influencing the potential response. From the potential limit the value of $[Cu^+]_0^L$ may be estimated and the α_{Cu} value calculated from equation (5). This makes it possible to estimate the stability constants of copper(I) complexes. In the case of the TETREN titration of copper it may be expected that both copper ions are complexed, therefore the limit is strongly suppressed, and the potentials after the end-point are much lower.[7]

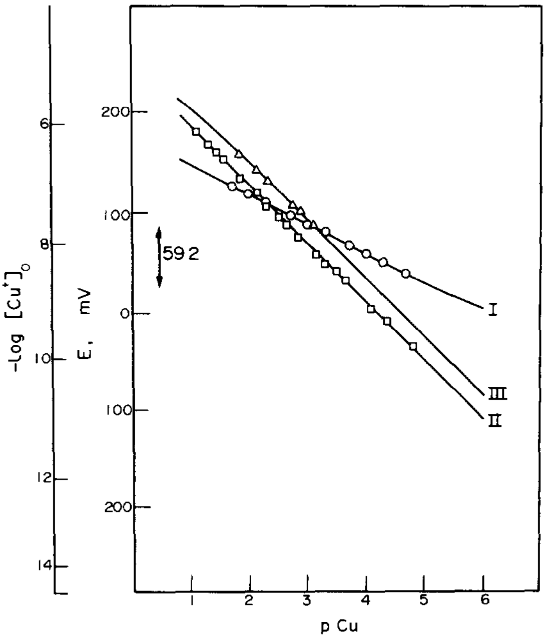

Fig. 6. Potential response curves of the chalcocite membrane electrode, in copper(II) solution (in 1*M* KNO_3). Curve I, Copper(II) solution in 1*M* KNO_3. Curve II, copper(I) solution in 1*M* KCl. Curve III, equivalent amounts of copper(I) and copper(II) in 1*M* KCl Experimental points are indicated on the theoretically calculated curves (solid lines).

The value of the stability constant of the copper(I)-TETREN complex calculated on this basis is approximately 10^8.

DIFFUSION-LAYER MODEL FOR COPPER SOLID-STATE CHALCOCITE MEMBRANE ELECTRODE; SENSITIVITY TO COPPER(II) IONS

ADAM HULANICKI and ANDRZEJ LEWENSTAM
Institute of Fundamental Problems in Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 22 *July* 1975. *Revised* 20 *November* 1975. *Accepted* 29 *January* 1976)

Summary—The diffusion-layer model for the chalcocite (Cu_2S) membrane electrode is discussed. It is equivalent to a simpler model based on exchange reactions at the electrode surface. The chalcocite is sensitive to copper(I) and copper(II) ions and the theoretically predicted response is in good agreement with experimental data. The membrane is a conductor, but this does not significantly affect its function as an ion detector. The limitation of the electrode is the membrane solubility as shown when Cu(II) ions in contrast to copper(I) ions are strongly complexed.

The reason for the sensitivity to copper(II) ions of solid-state electrodes based on copper(I) chalcogenides[1-7] is not fully understood. Heerman and Rechnitz[6] have stated that the copper(I) ions should be considered as the significant ions for the copper(I) sulphide electrode and Hansen *et al.*[8] agree that the contribution of Cu(I) ions to the mechanism should be taken into account.

This paper proposes a model for the function of the chalcocite (Cu_2S) membrane electrode and its sensitivity to copper(II) ions.

EXPERIMENTAL

The indicator electrode with an internal solution containing copper(II) chloride was prepared as described previously.[7] The potential was measured with an N-512 meter (ELPO-Wrocław) and potentiograph E-336 (Metrohm). The saturated calomel electrode used as reference was connected through a salt bridge. The copper(I) solution was obtained by coulometric generation from the copper electrode in a chloride medium. The solutions were prepared from analytical grade reagents and doubly distilled water.

THEORETICAL

In various models of electrode action given by several authors[9-13] the potential E of the half-cell formed by the membrane electrode is given by

$$E = E_M + E_R \tag{1}$$

where E_M is the membrane potential and E_R the internal reference potential.

Eisenman[9] and Buck[11] describe the membrane potential as the sum of the diffusion potential E_D in the membrane and the potential E_B on the phase boundaries, while the membrane is considered as an ionic conductor. In the Pungor and Tóth[12] model only the potential E_R is taken into account, while the condition concerning ionic conductance is not irremissible. Both models result in formally analogous equations relating the potential of the electrode to the ionic activity (where admissible, concentrations are used instead of activities). For the chalcocite electrode this may be expressed as

$$E = \text{const.} + \frac{RT}{F}\ln([\mathrm{Cu}^+] + K^{\mathrm{pot}}_{\mathrm{Cu}^+,\mathrm{M}_i}[\mathrm{M}_i^{2+}]^{1/2}) \tag{2}$$

where $[Cu^+]$, and $[M_i^{2+}]$ are the actual concentrations of the main (Cu^+) and interfering (M^{2+}) ions, and $K^{pot}_{Cu^+,M_i}$ is the corresponding potentiometric selectivity coefficient.

In the Eisenman[9] and Buck[11] models (for miscible salts) the selectivity coefficient is equal to the product of the ratio of the ionic mobilities U_{Cu^+}/U_{M_i} in the membrane and the equilibrium constant K of the exchange reaction

$$\mathrm{M}^{2+} + \mathrm{Cu_2S} \rightleftharpoons \mathrm{MS} + 2\mathrm{Cu}^+ \tag{3}$$

In the Pungor–Tóth[12] and Buck[11] models (for immiscible salts) the selectivity coefficient is directly related to the same equilibrium constant, and equal to the ratio of the solubility products K_{s0} of the corresponding sulphides (with an exponent which follows from the stoichiometry): $K_{s0(Cu_2S)}/K_{s0(MS)}$. When no other mechanism of interference is assumed, the exchange reaction provides some of the concentration of the main ion causing the electrode response.

In the electrode model discussed here we assume that the electrode response is caused by the main ion concentration at the electrode surface. Three contributions may be discussed: the first is due to the analytical concentration in solution $[Cu^+]^A$, the second to the finite solubility of the membrane $[Cu^+]^L$, and the last to the exchange reaction with interfering ions $[Cu^+]^I$. This is represented as:

$$[\mathrm{Cu}^+]_0 = [\mathrm{Cu}^+]_0^A + [\mathrm{Cu}^+]_0^L + [\mathrm{Cu}^+]_0^I \tag{4}$$

where the suffix indicates concentrations at the electrode surface, in contrast to bulk concentrations.

The concentration $[Cu^+]_0^L$ is directly related to the conditional solubility product

$$K'_{so(Cu_2S)} = K_{so(Cu_2S)}\alpha_{S(H)}\alpha^2_{Cu^+} = [Cu(I)']^2\,[S']$$

of the electrode-active substance, *i.e.*, Cu_2S, where the α values represent the side-reaction coefficients. The $\alpha_{S(H)}$ and α_{Cu^+} values depend on pH and the chloride concentration, respectively. Since

$$[S'] = \tfrac{1}{2}[Cu(I)']$$

we obtain

$$[Cu^+]_0^L = \left[\frac{2K_{so(Cu_2S)}\alpha_{S(H)}}{\alpha_{Cu^+}}\right]^{1/3} \qquad (5)$$

Perhaps in the limit the concentration of interstitial copper(I) ions may become important, as found by Morf, Kahr and Simon[14] for silver(I) and the Ag_2S electrode. In the present discussion this factor is not considered, but from our experiments its value is about $10^{-10}M$.

The relation (5) as a function of pH for two different chloride concentrations is graphically presented in Fig. 1. It can be seen that the value of $[Cu^+]_0^L$ is mostly well below $10^{-12}M$ and therefore this contribution is small compared to the others.

The concentration $[Cu^+]_0^E$ represents the contribution to the electrode response caused by the presence of interfering ions having particular selectivity coefficients. The coefficients are expected to be larger than unity for Ag^+ and Hg^{2+}, which interfere even in small concentrations by covering the membrane with their sulphides, preventing further contact of the chalcocite membrane with the solution. For other common ions, including Cu^{2+}, the selectivity coefficients are significantly less than unity.

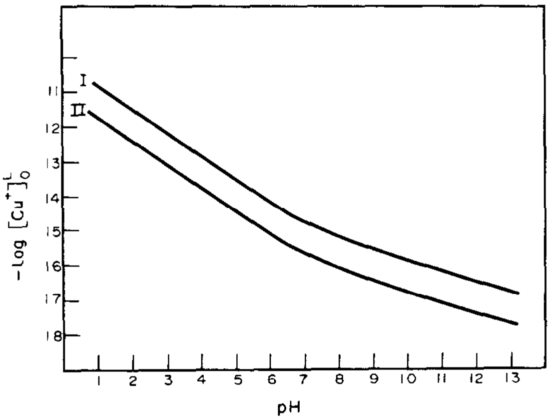

Fig. 1. Concentration of free copper(I) in equilibrium with the chalcocite membrane as a function of pH. Curve I—in 0.1*M* KCl, curve II—in 1*M* KCl.

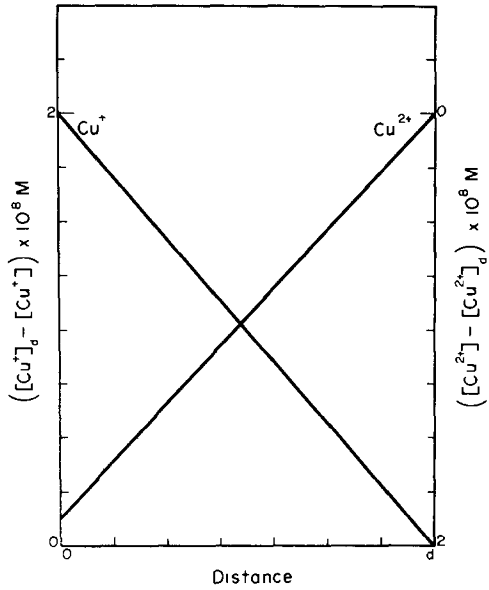

Fig. 2. Scheme for the diffusion layer $[Cu^+] = 1.6 \times 10^{-10}M$, $[Cu^{2+}] = 1.0 \times 10^{-3}M$ in bulk solution. $A = 2$, $K = 4 \times 10^{-13}$. [Calculated from equations (8) and (9).]

For the equilibrium constant, K, of the reaction

$$Cu_2S + Cu^{2+} \rightleftharpoons CuS + 2Cu^+ \qquad (6)$$

which is equal to the ratio of the solubility products, we obtain

$$K = ([Cu^+]_0)^2/[Cu^{2+}]_0 \qquad (7)$$

where the concentrations are those at the electrode surface. When the reaction is sufficiently rapid and reversible a diffusion layer is formed, shown schematically in Fig. 2. Assuming diffusive transport at the electrode surface, linearity of the concentration gradients and independence of the diffusion coefficients on the diffusion layer thickness, we obtain from the mass balance

$$D_{Cu^+}([Cu^+]_0 - [Cu^+]) = 2D_{Cu^{2+}}([Cu^{2+}] - [Cu^{2+}]_0) \qquad (8)$$

where D represents the diffusion coefficient of the ion indicated. From equations (7) and (8) the value of $[Cu^+]_0$ may be calculated as a function of the Cu^+ and Cu^{2+} concentrations:

$$[Cu^+]_0 = -\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[Cu^+] + 4K[Cu^{2+}]\right)^{1/2} \qquad (9)$$

where $A = D_{Cu^+}/D_{Cu^{2+}}$, which has a numerical value of approximately 2, if the diffusion coefficient of Cu^+ (not reported in the literature) is taken as slightly smaller than that of Ag^+.

The value of $[Cu^+]_0$ should really be indicated as $[Cu^+]_0^E$, because it represents the contribution of the exchange reaction (interference) when the membrane solubility and analytical concentration contributions may be neglected. When the other contributions should be taken into account then the total concentration may be represented as:

$$[\mathrm{Cu}^+]_0 = [\mathrm{Cu}^+]_0^{\mathrm{A}} + [\mathrm{Cu}^+]_0^{\mathrm{L}} + \left\{-\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[\mathrm{Cu}^+] + 4K[\mathrm{Cu}^{2+}]\right)^{1/2}\right\} \qquad (10)$$

which enters into the equation for the potential:

$$E = \mathrm{const.} + \frac{RT}{F}\ln[\mathrm{Cu}^+]_0. \qquad (11)$$

This equation is valid for the intermediate range but no precise derivation of this equation can be presented. Nevertheless, from measurements in the concentration ranges used in our experiments, it evidently describes the behaviour of the electrode with enough accuracy for its practical use.

RESULTS AND DISCUSSION

The model described, in which the surface concentrations are different from those in the bulk of the solution, is similar to that given for the cyanide electrode.[13,15] The expanded form of equation (11):

$$E = \mathrm{const.} + \frac{RT}{F}\ln\left\{[\mathrm{Cu}^+]_0^{\mathrm{A}} + [\mathrm{Cu}^+]_0^{\mathrm{L}} + \left[-\frac{AK}{4} + \frac{1}{2}\left(\frac{A^2K^2}{4} + 2AK[\mathrm{Cu}^+] + 4K[\mathrm{Cu}^{2+}]\right)^{1/2}\right]\right\}, \qquad (12)$$

may be simplified when some justifiable approximations are introduced. When $[\mathrm{Cu}^{2+}]$ is significantly greater than $4 \times 10^{-13}M$, *i.e.* $[\mathrm{Cu}^{2+}] \gg K$, then in equation (12) the total term corresponding to the exchange reaction is simplified to $K^{1/2}[\mathrm{Cu}^{2+}]^{1/2}$, and the equation is the same as given previously [(2)] on the basis of the Pungor–Tóth model.[12] The value of the constant $K = 4 \times 10^{-13}$ for reaction (6) is based on the solubility products,[19] and is an idealized approach. In real conditions the side-reaction coefficient effect of Cu^+ with chloride ions is much stronger than that of Cu^{2+}, shifting the reaction (6) towards the right-hand side. The dependence of pK' on the chloride concentration is shown in Fig. 3.

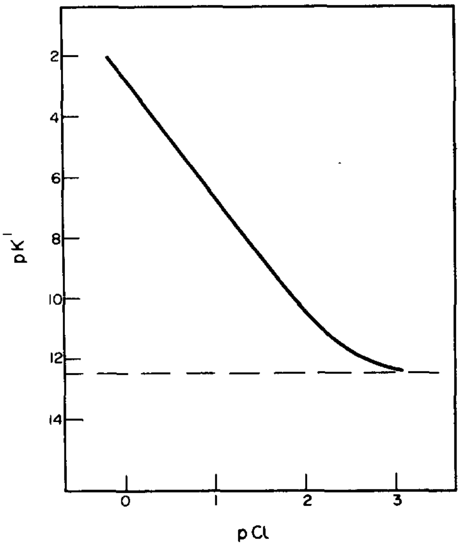

Fig. 3. Conditional constant of the exchange reaction $\mathrm{Cu}^{2+} + \mathrm{Cu_2S} \rightleftharpoons 2\mathrm{Cu}^+ + \mathrm{CuS}$ as a function of chloride concentration.

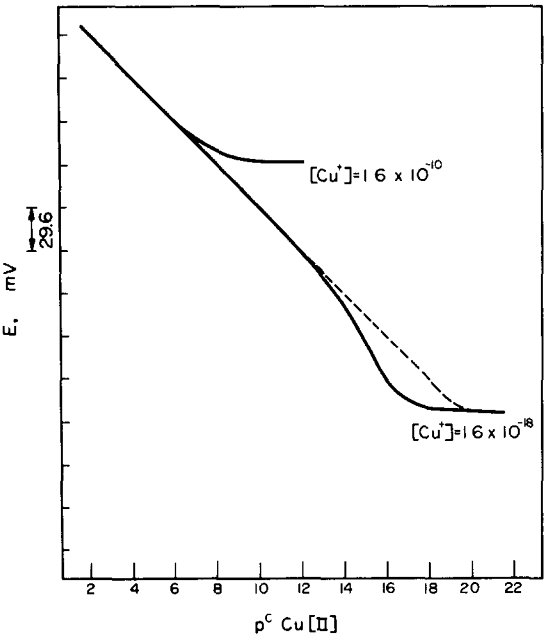

Fig. 4. Theoretical potential response curves calculated on the basis of the diffusion barrier model—solid line, and on the basis of the Pungor–Tóth model—dashed line.

For low concentrations of copper(I), *i.e.*, when $[\mathrm{Cu}^+] \ll K[\mathrm{Cu}^{2+}]^{1/2}$ the electrodes become sensitive to copper(II). In such conditions the chalcocite electrode may be treated as a copper(II) electrode, for which the copper(II) ions are the main ions. In this case the simplified model may be treated as a special case of the diffusion layer model. The potential response curves $E = f([\mathrm{Cu}^{2+}])$ have been calculated for several levels of concentration of copper(I) ions in solution (Fig. 4). It can be seen that only at the lowest levels is there departure from linearity.

The value of the selectivity coefficient of the chalcocite electrode is 4×10^{-13}, which is the equilibrium constant of the exchange reaction. The potentiometric selectivity coefficient, determined experimentally, $K^{\mathrm{pot}}_{\mathrm{Cu}^+,\mathrm{Cu}^{2+}} = K^{1/2} = 6.3 \times 10^{-7}$, as described previously.[7] The magnitude of these values suggests that the extent of the exchange reaction is not large enough to allow the electrode to function according to the scheme $\mathrm{Cu_2S/CuS/Cu}^{2+}$ (external solution).

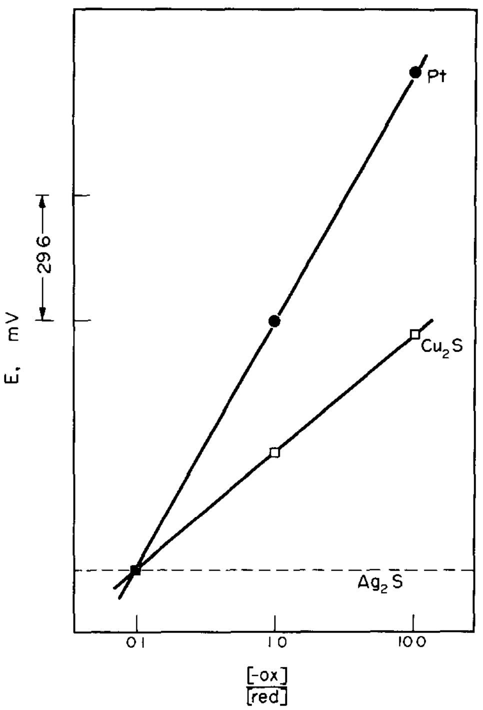

Fig. 5 Dependence of the electrode potential on the $[Fe(CN)_6^{3-}]:[Fe(CN)_6^{4-}]$ ratio at pH 5 The Ag_2S relationship is given according to Weser and Pungor[17]

It must be mentioned that the diffusion layer model does not specify the type of conductivity in the membrane. Because of the absence of β-Ag_2S, as the ionic conductor, one can expect for the chalcocite electrode a significant contribution of electron conductivity.[16] This has been confirmed experimentally by measuring the redox response of the electrode in comparison with that of the platinum electrode (Fig. 5).

Experimental potential response curves have been prepared for the chalcocite electrode in solutions containing both copper(I) and copper(II) ions. In the case of the copper(II) response (Fig. 6, curve I) the medium used was 1*M* potassium nitrate. The experimental points obtained by successive dilutions agree with those calculated on the assumption that $[Cu^+]$ is not greater than $1.6 \times 10^{-10}M$. As can be seen by comparison with Fig. 4 the curve is linear with the theoretical slope of 29.6 mV per decade. The slight curvature at low concentrations is due to $[Cu^+]_0^L$.

The response curve for copper(I) ions (Fig. 6, curve II) has been prepared on the basis of the analytical concentration of copper(I), generated coulometrically at pH 3 in 1*M* potassium chloride. The concentration of free (hydrated) Cu^+ ions is significantly lower. The constant degree of complexation due to the constant concentration of Cl^- as the predominant ligand, ensures that the slope has the theoretical value of 59.2 mV per decade, which is in good agreement with the calculated curve. Under these conditions the concentration of Cu^{2+} is insufficient for the formation of a CuS layer at the electrode surface. Therefore the contribution of the exchange concentration $[Cu^+]_0^L$ is negligible and except in a very low concentration range only the term $[Cu^+]_0^A$ is significant in equation (11).

In the presence of both copper(I) and copper(II) ions, at equal analytical concentrations, the potential response curve is influenced by both ions. The extent of complexation of copper(I) in 1*M* chloride solution is significantly greater ($\alpha_{Cu^+(Cl)} = 8.5 \times 10^4$)[18] than that of the copper(II). Therefore the α-value compensates partially for the small value of selectivity coefficient $K^{pot}_{Cu^+,Cu^{2+}}$. Both types of ion contribute to the slope, which in the range of concentrations indicated is approximately 55 mV per decade (Fig. 6, curve III).

The electrode limit, defined by $[Cu^+]_0^L$, may be reached under conditions where the copper(II) ions are more strongly complexed that the copper(I) ions. This happens, for example, in the potentiometric titration of copper(II) with EDTA. Because the copper(II) concentration drops significantly after the end-point, $[Cu^+]_0^L$ becomes the decisive factor influencing the potential response. From the potential limit the value of $[Cu^+]_0^L$ may be estimated and the α_{Cu} value calculated from equation (5). This makes it possible to estimate the stability constants of copper(I) complexes. In the case of the TETREN titration of copper it may be expected that both copper ions are complexed, therefore the limit is strongly suppressed, and the potentials after the end-point are much lower.[7]

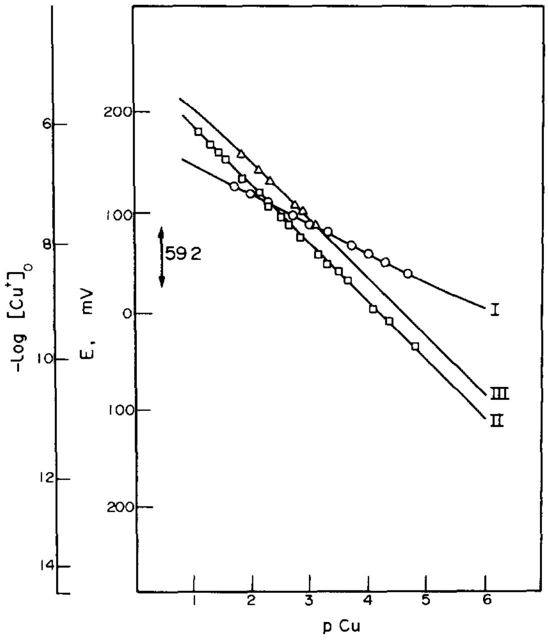

Fig. 6. Potential response curves of the chalcocite membrane electrode, in copper(II) solution (in 1*M* KNO_3). Curve I, Copper(II) solution in 1*M* KNO_3. Curve II, copper(I) solution in 1*M* KCl. Curve III, equivalent amounts of copper(I) and copper(II) in 1*M* KCl Experimental points are indicated on the theoretically calculated curves (solid lines).

The value of the stability constant of the copper(I)-TETREN complex calculated on this basis is approximately 10^8.

SHORT COMMUNICATIONS

STUDIES ON THE ELECTROCAPILLARY CURVES OF ANIONIC SURFACTANTS IN PRESENCE OF NON-IONIC SURFACTANTS

RAMESH BEMBI, R. N. GOYAL and WAHID U. MALIK
Chemistry Department, University of Roorkee, Roorkee, India

(*Received* 1 *October* 1975. *Revised* 19 *January* 1976. *Accepted* 27 *January* 1976)

Polarographic maxima of simple and complex metal ions have been effectively suppressed by the use of surfactants[1–3]. In most cases, cationic soaps suppress the negative maxima while anionic soaps suppress the positive maxima.[1] However no such simple relation has been found for non-ionic surfactants. Studies have shown that weak positive charges may be associated with the micelles of polyoxyethyl non-ionic surfactants, but the sign of these charges is not definite. The changes in the electrocapillary curves of ionic surfactants on addition of non-ionic surfactants provide a means to assess the nature of the net effective charge on the latter (and hence their effectiveness in suppressing positive and/or negative polarographic maxima). Studies have, therefore, been carried out on the effect of four such non-ionic surfactants, *viz.* Tween 20, Tween 40, Nonidet P40, and Nonex 501 on the electrocapillary curves of three anionic surfactants, *viz.* Aerosol IB (di-isobutyl sodium sulphosuccinate, c.m.c. 0.20 *M*), Manaxol OT (dioctyl sodium sulphosuccinate, c.m.c. 6.8×10^{-4} *M*) and SLS (sodium lauryl sulphate, c.m.c. 8.2×10^{-3} *M*).

EXPERIMENTAL

The surfactants were B.D.H. products. Other reagents used were of analytical-reagent grade. All solutions were prepared in doubly-distilled water

A Cambridge pen-recording polarograph was used for electrocapillary measurements The solutions were deaerated by bubbling purified nitrogen through them in H-type polarographic cells. At least 20 drops were counted and the drop-time was measured with a precision stop-watch, each reading being repeated at least three times. The electrocapillary measurements were carried out from 0.0 to −1.4 V at constant temperature (25 ± 1°). The concentration of the anionic surfactants was kept below their respective c m c's.

RESULTS AND DISCUSSION

Polyoxyethyl non-ionic surfactants may have cationic character. Chwala and Martina[4] have proposed the existence of anionic character for the ethylene oxide adducts. However, Wurzschmitt,[5] who studied the analytical behaviour of ethylene oxide adducts, concluded that in aqueous solutions they are present as cationic polyoxonium compounds

Wurzschmitt assumes that only a few of the ether oxygen atoms form oxonium ions and this fraction has been termed the degree of oxonium formation. Hsiao[6] and Scholler[7 8] have supported these views The present studies further confirm the existence of cation-active characteristics in these non-ionic surfactants.

Typical electrocapillary curves obtained by plotting drop-time against applied potential are depicted in Fig. 1. These curves, although parabolic, are marked by a lack of symmetry, indicating adsorption of the surfactant on the mercury–solution interface. Lipmann[9] has shown that mercury carries the positive charge (when the applied potential is zero), as a result of which the interfacial tension is decreased and a lower drop-time is observed. As the mercury is polarized to more negative potentials, the positive charge decreases and at a certain potential it disappears. At this point the interfacial tension is maximum and hence a maximum drop-time is recorded Further negative polarization results in a drop of interfacial tension and hence lower drop-times. An examination of the electrocapillary curves shows that the non-ionic surfactants, Tween 20, Tween 40, Nonidet P40 and Nonex 501 influence the electrocapillary curve of the anionic surfactants Aerosol IB, Manaxol OT and SLS in more or less the same manner The curves are shifted downwards and towards more positive potentials with increasing concentration of the non-ionic surfactant and they progressively lose their symmetry

The values of the electrocapillary maxima in the presence of the various anionic surfactants used (Table 1) show that their adsorbability at the mercury–solution interface follows the order: SLS > Manaxol OT > Aerosol IB.

The gradual shift in the electrocapillary maxima towards more positive potentials on addition of the non-ionic surfactants indicates neutralization of the adsorbed surface-active agent by the added non-ionic surfactant and its subsequent adsorption at the mercury–solution interface. The shift in electrocapillary maxima is then in the order. Aerosol IB ~ Manaxol OT > SLS. Thus the least shift occurs in the case of SLS which is the most strongly adsorbed anionic surfactant. These data provide evidence that the micelles of the polyoxyethylated non-ionic surfactants are associated with a net positive charge. The values of the electrocapillary maxima in presence of added non-ionic surfactants (Table 1) show that the shift caused by these surfactants follows the order: Nonex 501 > Nonidet P40 > Tween 20 > Tween 40. This may well be the order of the magnitude of positive charge carried by the micelles of these non-ionic surfactants.

Summary—Polyoxyethylated non-ionic surfactants such as Tween 20, Tween 40, Nonidet P40 and Nonex 501 have been supposed to be associated with cationic characteristics. Studies on the effect of these surfactants on the electrocapillary curves of the anionic surfactants Aerosol IB, Manaxol OT and sodium lauryl sulphate (SLS), show that the electrocapillary maxima shift towards positive potentials. The order of adsorption of the anionic surfactants is SLS $>$ Manaxol OT $>$ Aerosol IB while the shift in maxima is in the order Aerosol IB $\sim$ Manaxol OT $>$ SLS which confirms association of cationic characteristics with the micelles of these non-ionic surfactants. The magnitude of the shift in electrocapillary maxima is Nonex 501 $>$ Nonidet P40 $>$ Tween 20 $>$ Tween 40 which may be the order of magnitude of the positive charge carried by these non-ionic surfactants.

(*Received* 12 *March* 1976. *Accepted* 18 *March* 1976)

In the copper(II)–EDTA titration with Xylenol Orange (XO) as indicator, hexamine slows down the rate of colour change of XO.[1,2] In the work described here, the rate of the substitution reaction of the copper(II)–XO chelate with EDTA was determined in MES buffer [2-(*N*-morpholino)ethanesulphonic acid] and in hexamine buffer, and the mechanism of the disturbing effect of hexamine on the colour change of the indicator discussed.

EXPERIMENTAL

XO was synthesized and purified in a manner similar to that in the literature.[3] The free acid form (H_6XO) was dissolved in water, and the solution stored in a refrigerator. Dissociation constants of XO determined by spectrophotometry and pH-titration were in good agreement with the values given by Murakami *et al.*[3]

A copper(II) solution was prepared from the reagent-grade nitrate.

Reagent-grade hexamine dried over phosphorus pentoxide was used without further purification. The purity was established as 99.0% by means of pH-titration with sodium hydroxide in the presence of excess of hydrochloric acid.

Other reagents and apparatus employed were the same as those reported previously.[4]

All experiments were carried out at 25 ± 1° and at ionic strength of 0.1 (KNO_3).

RESULTS AND DISCUSSION

The composition of copper(II)–XO chelates

From the results of the continuous variation method, the molar-ratio method by spectrophotometry and the potentiometric titration with use of a copper(II) ion-selective electrode, the ratio of copper to XO was essentially 2:1 in MES buffer. The pH-titration of a solution $3.76 \times 10^{-3}M$ in Cu and $0.934 \times 10^{-3}M$ in H_6XO with $0.198M$ sodium hydroxide shows the formation of Cu_2HXO^- at pH 2, and further release of one proton, which corresponds to the sixth proton of H_6XO, takes place in the pH-range from 3.5 to 5.5. In this pH-range the absorption maximum shifts from 440 to 574 nm, and an isosbestic point occurs at 487 nm. From these results the following equilibrium exists: $Cu_2XO^{2-} + H^+ \rightleftharpoons Cu_2HXO^-$. The equilibrium constant, $K^{H}_{Cu_2HXO} = [Cu_2HXO^-]/[Cu_2XO^{2-}][H^+]$, was evaluated as $10^{4.55}$ by spectrophotometry and pH-titration.

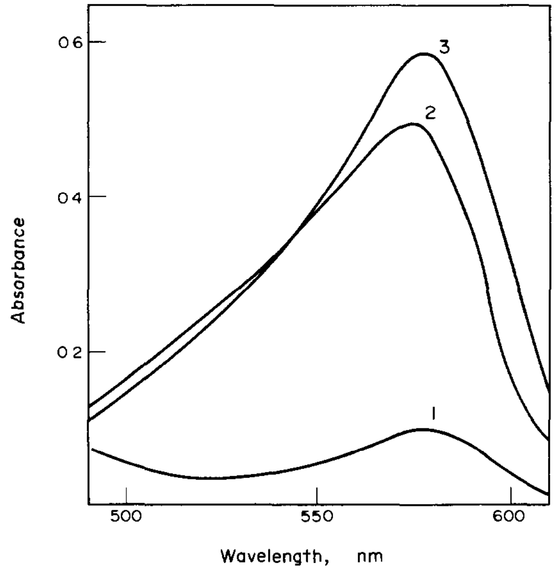

Fig. 1. Spectra of Cu–XO chelates. C_{Cu} $1.6 \times 10^{-4}M$, C_{XO} $1.1 \times 10^{-5}M$. 1, XO blank; 2, Cu_2XO^{2-}; 3, Cu_2XOL^{2-}, C_{hex} $2.0 \times 10^{-1}M$, pH 6.0.

STUDIES ON THE ELECTROCAPILLARY CURVES OF ANIONIC SURFACTANTS IN PRESENCE OF NON-IONIC SURFACTANTS

RAMESH BEMBI, R. N. GOYAL and WAHID U. MALIK
Chemistry Department, University of Roorkee, Roorkee, India

(*Received* 1 *October* 1975. *Revised* 19 *January* 1976. *Accepted* 27 *January* 1976)

Polarographic maxima of simple and complex metal ions have been effectively suppressed by the use of surfactants[1-3]. In most cases, cationic soaps suppress the negative maxima while anionic soaps suppress the positive maxima.[1] However no such simple relation has been found for non-ionic surfactants. Studies have shown that weak positive charges may be associated with the micelles of polyoxyethyl non-ionic surfactants, but the sign of these charges is not definite. The changes in the electrocapillary curves of ionic surfactants on addition of non-ionic surfactants provide a means to assess the nature of the net effective charge on the latter (and hence their effectiveness in suppressing positive and/or negative polarographic maxima). Studies have, therefore, been carried out on the effect of four such non-ionic surfactants, *viz.* Tween 20, Tween 40, Nonidet P40, and Nonex 501 on the electrocapillary curves of three anionic surfactants, *viz.* Aerosol IB (di-isobutyl sodium sulphosuccinate, c.m.c. 0.20 *M*), Manaxol OT (dioctyl sodium sulphosuccinate, c.m.c. 6.8×10^{-4} *M*) and SLS (sodium lauryl sulphate, c.m.c. 8.2×10^{-3} *M*).

EXPERIMENTAL

The surfactants were B.D.H. products. Other reagents used were of analytical-reagent grade. All solutions were prepared in doubly-distilled water

A Cambridge pen-recording polarograph was used for electrocapillary measurements The solutions were deaerated by bubbling purified nitrogen through them in H-type polarographic cells. At least 20 drops were counted and the drop-time was measured with a precision stop-watch, each reading being repeated at least three times. The electrocapillary measurements were carried out from 0.0 to −1.4 V at constant temperature (25 ± 1°). The concentration of the anionic surfactants was kept below their respective c m c's.

RESULTS AND DISCUSSION

Polyoxyethyl non-ionic surfactants may have cationic character. Chwala and Martina[4] have proposed the existence of anionic character for the ethylene oxide adducts. However, Wurzschmitt,[5] who studied the analytical behaviour of ethylene oxide adducts, concluded that in aqueous solutions they are present as cationic polyoxonium compounds

Wurzschmitt assumes that only a few of the ether oxygen atoms form oxonium ions and this fraction has been termed the degree of oxonium formation. Hsiao[6] and Scholler[7, 8] have supported these views The present studies further confirm the existence of cation-active characteristics in these non-ionic surfactants.

Typical electrocapillary curves obtained by plotting drop-time against applied potential are depicted in Fig. 1. These curves, although parabolic, are marked by a lack of symmetry, indicating adsorption of the surfactant on the mercury–solution interface. Lipmann[9] has shown that mercury carries the positive charge (when the applied potential is zero), as a result of which the interfacial tension is decreased and a lower drop-time is observed. As the mercury is polarized to more negative potentials, the positive charge decreases and at a certain potential it disappears. At this point the interfacial tension is maximum and hence a maximum drop-time is recorded Further negative polarization results in a drop of interfacial tension and hence lower drop-times. An examination of the electrocapillary curves shows that the non-ionic surfactants, Tween 20, Tween 40, Nonidet P40 and Nonex 501 influence the electrocapillary curve of the anionic surfactants Aerosol IB, Manaxol OT and SLS in more or less the same manner The curves are shifted downwards and towards more positive potentials with increasing concentration of the non-ionic surfactant and they progressively lose their symmetry

The values of the electrocapillary maxima in the presence of the various anionic surfactants used (Table 1) show that their adsorbability at the mercury–solution interface follows the order: SLS > Manaxol OT > Aerosol IB.

The gradual shift in the electrocapillary maxima towards more positive potentials on addition of the non-ionic surfactants indicates neutralization of the adsorbed surface-active agent by the added non-ionic surfactant and its subsequent adsorption at the mercury–solution interface. The shift in electrocapillary maxima is then in the order. Aerosol IB ~ Manaxol OT > SLS. Thus the least shift occurs in the case of SLS which is the most strongly adsorbed anionic surfactant. These data provide evidence that the micelles of the polyoxyethylated non-ionic surfactants are associated with a net positive charge. The values of the electrocapillary maxima in presence of added non-ionic surfactants (Table 1) show that the shift caused by these surfactants follows the order: Nonex 501 > Nonidet P40 > Tween 20 > Tween 40. This may well be the order of the magnitude of positive charge carried by the micelles of these non-ionic surfactants.

RESULTS AND DISCUSSION

The composition of copper(II)–XO chelates

From the results of the continuous variation method, the molar-ratio method by spectrophotometry and the potentiometric titration with use of a copper(II) ion-selective electrode, the ratio of copper to XO was essentially 2:1 in MES buffer. The pH-titration of a solution $3.76 \times 10^{-3}M$ in Cu and $0.934 \times 10^{-3}M$ in H_6XO with $0.198M$ sodium hydroxide shows the formation of Cu_2HXO^- at pH 2, and further release of one proton, which corresponds to the sixth proton of H_6XO, takes place in the pH-range from 3.5 to 5.5. In this pH-range the absorption maximum shifts from 440 to 574 nm, and an isosbestic point occurs at 487 nm. From these results the following equilibrium exists: $Cu_2XO^{2-} + H^+ \rightleftharpoons Cu_2HXO^-$. The equilibrium constant, $K^H_{Cu_2HXO} = [Cu_2HXO^-]/[Cu_2XO^{2-}][H^+]$, was evaluated as $10^{4.55}$ by spectrophotometry and pH-titration.

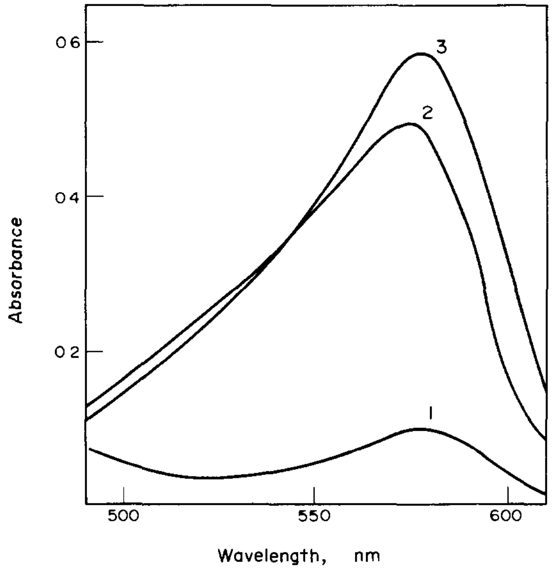

Fig. 1. Spectra of Cu–XO chelates. C_{Cu} $1.6 \times 10^{-4}M$, C_{XO} $1.1 \times 10^{-5}M$. 1, XO blank; 2, Cu_2XO^{2-}; 3, Cu_2XOL^{2-}, C_{hex} $2.0 \times 10^{-1}M$, pH 6.0.

---

* Part III: *Talanta*, 1976, **23**, 155.

At pH 6 in the presence of hexamine the absorption spectrum of Cu_2XO^{2-} shifts to longer wavelengths ($\lambda_{max} = 578$ nm) and the molar absorptivity increases with increase in the hexamine concentration (Fig. 1). This indicates the formation of a mixed-ligand complex of the copper–XO chelate with hexamine.

The formation constant of the mixed-ligand complex is defined as:

$$K^{nL}_{Cu_2XOL_n} = \frac{[Cu_2XOL_n^{2-}]}{[Cu_2XO^{2-}][L]^n} \qquad (1)$$

where L represents free hexamine. The absorbances of $Cu_2XOL_n^{2-}$ at 578 nm were measured for varying hexamine concentration from 10^{-3} to $10^{-1}M$ at pH 6.00–6.30. A plot of $\log[Cu_2XOL_n^{2-}]/[Cu_2XO^{2-}]$ *vs.* log[L] yielded a straight line with slope of 1. Therefore, one molecule of hexamine co-ordinates with Cu_2XO^{2-}. The value of $K^{L}_{Cu_2XOL}$ was evaluated as $10^{2.14}$. The dissociation constant of HL^+ was taken as $10^{-4.98}$.

The rate of substitution of Cu_2XO with EDTA

In MES buffer. A solution 2.10–5.25 × $10^{-5}M$ in XO, 3.87–7.74 × $10^{-5}M$ in Cu and 0.02*M* in MES–NaOH buffer (pH 4.82–6.00) and a solution 3.56–14.25 × $10^{-4}M$ in EDTA and 0.02*M* in MES–NaOH buffer (pH 4.82–6.00) were mixed, and the absorbance at 574 nm was measured as a function of the reaction time by the stopped-flow method.

Under these experimental conditions the substitution reaction of the Cu_2XO^{2-} chelate with EDTA proceeds to completion·

$$Cu_2XO + 2EDTA = 2Cu(EDTA) + XO \qquad (2)$$

The rate-law is expressed by

$$-\frac{d[Cu_2XO^{2-}]}{dt} = k_{0(H,R,M,Y)}[Cu_2XO^{2-}] \qquad (3)$$

where $k_{0(H,R,M,Y)}$ is the conditional rate-constant involving the concentrations of hydrogen ion, XO, Cu and EDTA. From equation (3) we obtain

$$\log(A_t - A_\infty) = -\frac{k_{0(H,R,M,Y)}}{2.303}t + \log(A_0 - A_\infty) \qquad (4)$$

where A_0, A_t and A_∞ represent the absorbances of the reaction system at $t = 0$, t and ∞, respectively. The plots of $\log(A_t - A_\infty)$ *vs.* t yielded straight lines up to 90% of the total reaction, and the conditional rate-constants $k_{0(H,R,M,Y)}$ were obtained from the slopes of the straight lines. The data in Table 1 indicate that the values of k_0 are proportional to the concentration of EDTA but are independent of hydrogen ion, XO and Cu concentrations. Hence,

$$-\frac{d[Cu_2XO^{2-}]}{dt} = k_1[Y'][Cu_2XO^{2-}] \qquad (5)$$

where [Y′] is the total concentration of EDTA ($[H_2Y^{2-}] + [HY^{3-}]$) not combined with copper ion, and the rate-constant k_1 was evaluated as 7.84 × 10^2 l.mole.sec^{-1}. The following reaction mechanism may be proposed.

$$Cu_2XO^{2-} + Y' \rightleftharpoons YCu(XO)Cu \xrightarrow{r\,d\,s}$$
$$CuY^{2-} + CuHXO^{3-} \quad \text{or} \quad CuH_2XO^{2-} \qquad (6)$$
$$CuHXO^{3-} \quad \text{or} \quad CuH_2XO^{2-} + Y' \xrightarrow{\text{fast}}$$
$$CuY^{2-} + H_3XO^{3-} \qquad (7)$$

The release of the first copper ion from the Cu_2XO^{2-} chelate may be the rate-determining step (r.d.s.). From the results of potentiometry with a copper(II) ion-selective electrode the resulting 1:1 chelate is in the form of $CuHXO^{3-}$ or CuH_2XO^{2-}, and the protonation of the 1:1 chelate may weaken the Cu–XO bonds. The high stability of the 2:1 chelate (Cu_2XO^{2-}) may support the mechanism proposed in equations (6) and (7).

In the presence of hexamine. A solution containing XO, Cu and hexamine (2.83 × 10^{-4}–2.19 × $10^{-1}M$) was mixed with a solution containing EDTA, and the absorbance at 578 nm was measured in the pH range from 5.77 to 6.24 (MES buffer) in the same way as for the MES buffer system.

The substitution reaction is written as:

$$Cu_2XOL + EDTA \rightleftharpoons 2Cu(EDTA) + XO + L \qquad (8)$$

The rate-law is

$$-\frac{d[Cu_2XOL^{2-}]}{dt} = k_{0(H,R,M,Y,L)}[Cu_2XOL^{2-}] \qquad (9)$$

The results are shown in Table 2. No dependence of $k_{0(H,R,M,Y,L)}$ on the concentrations of XO, Cu and hydrogen ion was observed, but there was a linear relation to EDTA concentration. With increasing concentration of hexamine the rate of the substitution reaction decreased. In the hexamine concentration range from 3.00 × 10^{-2} to 2.19 × $10^{-1}M$, where the mixed-ligand complex Cu_2XOL^{2-} forms quantitatively, k_0 was proportional to the reciprocal of the concentration of hexamine. Thus, the rate-law may be rewritten as

$$-\frac{d[Cu_2XOL^{2-}]}{dt} = k_2\frac{[Y'][Cu_2XOL^{2-}]}{[L']} \qquad (10)$$

The value of k_2 was evaluated as 5.39 sec^{-1}.

Therefore, the dissociation of hexamine from Cu_2XOL^{2-} takes place first:

$$Cu_2XOL^{2-} = Cu_2XO^{2-} + L \qquad (11)$$

The substitution mechanism of Cu_2XO^{2-} with EDTA may be the same as that in the absence of hexamine. From equations (1), (5) and (10):

$$k_1 = k_2K^{L}_{Cu_2XOL} = 5.39 \times 10^{2.14}$$
$$= 7.44 \times 10^2 \text{ l.mole}^{-1}.\text{sec}^{-1}$$

This value is in good agreement with that obtained in the absence of hexamine. This fact supports the reaction mechanism described above.

At lower concentrations of hexamine Cu_2XO^{2-} and Cu_2XOL^{2-} complexes exist. Thus, the rate law can be expressed as

$$-\frac{d[(Cu_2XO)']}{dt} = k[Y'][(Cu_2XO)']$$

$$= \left(\frac{k_1}{1 + K^L_{Cu_2XOL}[L]}\right)[Y'][(Cu_2XO)'] \quad (12)$$

where $[(Cu_2XO)']$ represents the total concentration of Cu–XO chelates. The plot of log k *vs.* log[L] is shown in Fig. 2. The values of $K^L_{Cu_2XOL}$, k_1 and k_2 obtained by a curve-fitting method were $10^{2\ 18}$, 7.76×10^2 l.mole^{-1}.sec^{-1} and 5.13 sec^{-1}, respectively. These values agree well with those obtained above. The curve shows that the presence of more than $10^{-2}M$ hexamine markedly slows down the rate of colour change of the indicator.

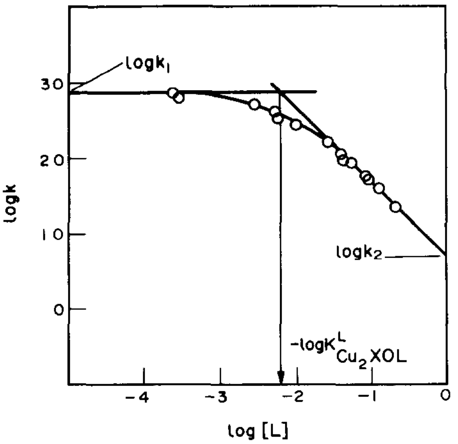

Fig. 2. Plot of log$k$ *vs.* log[L]. Solid line is the theoretical curve.

Summary—The rate of ligand substitution of copper(II)-Xylenol Orange (XO) with EDTA (Y) has been determined spectrophotometrically over the pH range 4.8–6.0 at $\mu = 0.1$ (KNO_3) and at 25°. In 2-(*N*-morpholino)ethane sulphonic acid buffer, copper forms a 2:1 chelate (Cu_2XO^{2-}) with XO, and the rate-law is expressed as $-d[Cu_2XO^{2-}]/dt = 10^{2.89}[Cu_2XO^{2-}][Y']$. The release of the first copper ion from Cu_2XO^{2-} is the rate-determining step. The resulting $CuHXO^{3-}$ or CuH_2XO^{2-} may undergo fast substitution with EDTA. In the presence of hexamine, the copper(II)–XO chelate forms a mixed-ligand complex with hexamine (L). The formation constant $K^L_{Cu_2XOL} = [Cu_2XOL^{2-}]/[Cu_2XO^{2-}][L] = 10^{2\ 14}$ ($\mu = 0.1$, 25°). At 3×10^{-2}–$2 \times 10^{-1}M$ hexamine the rate-law is expressed as $-d[Cu_2XOL^{2-}]/dt = 5.39[Cu_2XOL^{2-}][Y']/[L']$. The dissociation of hexamine from Cu_2XOL^{2-} has to precede the substitution reaction of Cu_2XO^{2-} with EDTA. Hence, hexamine at higher concentrations than $10^{-3}M$ slows down the rate of colour change of XO in the copper–EDTA titration.

Summary—Polyoxyethylated non-ionic surfactants such as Tween 20, Tween 40, Nonidet P40 and Nonex 501 have been supposed to be associated with cationic characteristics. Studies on the effect of these surfactants on the electrocapillary curves of the anionic surfactants Aerosol IB, Manaxol OT and sodium lauryl sulphate (SLS), show that the electrocapillary maxima shift towards positive potentials. The order of adsorption of the anionic surfactants is SLS > Manaxol OT > Aerosol IB while the shift in maxima is in the order Aerosol IB ~ Manaxol OT > SLS which confirms association of cationic characteristics with the micelles of these non-ionic surfactants. The magnitude of the shift in electrocapillary maxima is Nonex 501 > Nonidet P40 > Tween 20 > Tween 40 which may be the order of magnitude of the positive charge carried by these non-ionic surfactants.

EFFECTS OF AUXILIARY COMPLEX-FORMING AGENTS ON THE RATE OF METALLOCHROMIC INDICATOR COLOUR CHANGE—IV*

MECHANISM OF THE COLOUR CHANGE OF XYLENOL ORANGE IN COPPER(II)—EDTA TITRATIONS

Hiroko Wada, Tomosuke Ishizuki and Genkichi Nakagawa

Laboratory of Analytical Chemistry, Nagoya Institute of Technology,
Gokiso-cho, Showa-ku, Nagoya, 466, Japan

(*Received* 12 *March* 1976. *Accepted* 18 *March* 1976)

In the copper(II)–EDTA titration with Xylenol Orange (XO) as indicator, hexamine slows down the rate of colour change of XO.[1,2] In the work described here, the rate of the substitution reaction of the copper(II)–XO chelate with EDTA was determined in MES buffer [2-(*N*-morpholino)ethanesulphonic acid] and in hexamine buffer, and the mechanism of the disturbing effect of hexamine on the colour change of the indicator discussed.

EXPERIMENTAL

XO was synthesized and purified in a manner similar to that in the literature.[3] The free acid form (H_6XO) was dissolved in water, and the solution stored in a refrigerator. Dissociation constants of XO determined by spectrophotometry and pH-titration were in good agreement with the values given by Murakami *et al.*[3]

A copper(II) solution was prepared from the reagent-grade nitrate.

Reagent-grade hexamine dried over phosphorus pentoxide was used without further purification. The purity was established as 99.0% by means of pH-titration with sodium hydroxide in the presence of excess of hydrochloric acid.

Other reagents and apparatus employed were the same as those reported previously.[4]

All experiments were carried out at 25 ± 1° and at ionic strength of 0.1 (KNO_3).

RESULTS AND DISCUSSION

The composition of copper(II)–XO chelates

From the results of the continuous variation method, the molar-ratio method by spectrophotometry and the potentiometric titration with use of a copper(II) ion-selective electrode, the ratio of copper to XO was essentially 2:1 in MES buffer. The pH-titration of a solution $3.76 \times 10^{-3}M$ in Cu and $0.934 \times 10^{-3}M$ in H_6XO with $0.198M$ sodium hydroxide shows the formation of Cu_2HXO^- at pH 2, and further release of one proton, which corresponds to the sixth proton of H_6XO, takes place in the pH-range from 3.5 to 5.5. In this pH-range the absorption maximum shifts from 440 to 574 nm, and an isosbestic point occurs at 487 nm. From these results the following equilibrium exists: $Cu_2XO^{2-} + H^+ \rightleftharpoons Cu_2HXO^-$. The equilibrium constant, $K^{H}_{Cu_2HXO} = [Cu_2HXO^-]/[Cu_2XO^{2-}][H^+]$, was evaluated as $10^{4.55}$ by spectrophotometry and pH-titration.

* Part III: *Talanta*, 1976, **23**, 155.

At pH 6 in the presence of hexamine the absorption spectrum of $\mathrm{Cu_2XO^{2-}}$ shifts to longer wavelengths ($\lambda_{\max} = 578$ nm) and the molar absorptivity increases with increase in the hexamine concentration (Fig. 1). This indicates the formation of a mixed-ligand complex of the copper–XO chelate with hexamine.

The formation constant of the mixed-ligand complex is defined as:

$$K^{nL}_{\mathrm{Cu_2XOL}_n} = \frac{[\mathrm{Cu_2XOL}_n^{2-}]}{[\mathrm{Cu_2XO^{2-}}][\mathrm{L}]^n} \qquad (1)$$

where L represents free hexamine. The absorbances of $\mathrm{Cu_2XOL}_n^{2-}$ at 578 nm were measured for varying hexamine concentration from 10^{-3} to $10^{-1}M$ at pH 6.00–6.30. A plot of $\log[\mathrm{Cu_2XOL}_n^{2-}]/[\mathrm{Cu_2XO^{2-}}]$ *vs.* $\log[\mathrm{L}]$ yielded a straight line with slope of 1. Therefore, one molecule of hexamine co-ordinates with $\mathrm{Cu_2XO^{2-}}$. The value of $K^{\mathrm{L}}_{\mathrm{Cu_2XOL}}$ was evaluated as $10^{2.14}$. The dissociation constant of $\mathrm{HL^+}$ was taken as $10^{-4.98}$.

The rate of substitution of Cu₂XO with EDTA

In MES buffer. A solution 2.10–5.25 × $10^{-5}M$ in XO, 3.87–7.74 × $10^{-5}M$ in Cu and 0.02*M* in MES–NaOH buffer (pH 4.82–6.00) and a solution 3.56–14.25 × $10^{-4}M$ in EDTA and 0.02*M* in MES–NaOH buffer (pH 4.82–6.00) were mixed, and the absorbance at 574 nm was measured as a function of the reaction time by the stopped-flow method.

Under these experimental conditions the substitution reaction of the $\mathrm{Cu_2XO^{2-}}$ chelate with EDTA proceeds to completion:

$$\mathrm{Cu_2XO + 2EDTA = 2Cu(EDTA) + XO} \qquad (2)$$

The rate-law is expressed by

$$-\frac{d[\mathrm{Cu_2XO^{2-}}]}{dt} = k_{0(\mathrm{H,R,M,Y})}[\mathrm{Cu_2XO^{2-}}] \qquad (3)$$

where $k_{0(\mathrm{H,R,M,Y})}$ is the conditional rate-constant involving the concentrations of hydrogen ion, XO, Cu and EDTA. From equation (3) we obtain

$$\log(A_t - A_\infty) = -\frac{k_{0(\mathrm{H,R,M,Y})}}{2.303}t + \log(A_0 - A_\infty) \qquad (4)$$

where A_0, A_t and A_∞ represent the absorbances of the reaction system at $t = 0$, t and ∞, respectively. The plots of $\log(A_t - A_\infty)$ *vs.* t yielded straight lines up to 90% of the total reaction, and the conditional rate-constants $k_{0(\mathrm{H,R,M,Y})}$ were obtained from the slopes of the straight lines. The data in Table 1 indicate that the values of k_0 are proportional to the concentration of EDTA but are independent of hydrogen ion, XO and Cu concentrations. Hence,

$$-\frac{d[\mathrm{Cu_2XO^{2-}}]}{dt} = k_1[\mathrm{Y'}][\mathrm{Cu_2XO^{2-}}] \qquad (5)$$

where [Y′] is the total concentration of EDTA ($[\mathrm{H_2Y^{2-}}] + [\mathrm{HY^{3-}}]$) not combined with copper ion, and the rate-constant k_1 was evaluated as 7.84 × 10^2 l.mole.sec^{-1}. The following reaction mechanism may be proposed.

$$\mathrm{Cu_2XO^{2-}} + \mathrm{Y'} \rightleftharpoons \mathrm{YCu(XO)Cu} \xrightarrow{\mathrm{r\,d\,s}}$$
$$\mathrm{CuY^{2-}} + \mathrm{CuHXO^{3-}} \text{ or } \mathrm{CuH_2XO^{2-}} \qquad (6)$$
$$\mathrm{CuHXO^{3-}} \text{ or } \mathrm{CuH_2XO^{2-}} + \mathrm{Y'} \xrightarrow{\mathrm{fast}}$$
$$\mathrm{CuY^{2-}} + \mathrm{H_3XO^{3-}} \qquad (7)$$

The release of the first copper ion from the $\mathrm{Cu_2XO^{2-}}$ chelate may be the rate-determining step (r.d.s.). From the results of potentiometry with a copper(II) ion-selective electrode the resulting 1:1 chelate is in the form of $\mathrm{CuHXO^{3-}}$ or $\mathrm{CuH_2XO^{2-}}$, and the protonation of the 1:1 chelate may weaken the Cu–XO bonds. The high stability of the 2:1 chelate ($\mathrm{Cu_2XO^{2-}}$) may support the mechanism proposed in equations (6) and (7).

In the presence of hexamine. A solution containing XO, Cu and hexamine (2.83 × 10^{-4}–2.19 × $10^{-1}M$) was mixed with a solution containing EDTA, and the absorbance at 578 nm was measured in the pH range from 5.77 to 6.24 (MES buffer) in the same way as for the MES buffer system.

The substitution reaction is written as:

$$\mathrm{Cu_2XOL + EDTA \rightleftharpoons 2Cu(EDTA) + XO + L} \qquad (8)$$

The rate-law is

$$-\frac{d[\mathrm{Cu_2XOL^{2-}}]}{dt} = k_{0(\mathrm{H,R,M,Y,L})}[\mathrm{Cu_2XOL^{2-}}] \qquad (9)$$

The results are shown in Table 2. No dependence of $k_{0(\mathrm{H,R,M,Y,L})}$ on the concentrations of XO, Cu and hydrogen ion was observed, but there was a linear relation to EDTA concentration. With increasing concentration of hexamine the rate of the substitution reaction decreased. In the hexamine concentration range from 3.00 × 10^{-2} to 2.19 × $10^{-1}M$, where the mixed-ligand complex $\mathrm{Cu_2XOL^{2-}}$ forms quantitatively, k_0 was proportional to the reciprocal of the concentration of hexamine. Thus, the rate-law may be rewritten as

$$-\frac{d[\mathrm{Cu_2XOL^{2-}}]}{dt} = k_2\frac{[\mathrm{Y'}][\mathrm{Cu_2XOL^{2-}}]}{[\mathrm{L'}]} \qquad (10)$$

The value of k_2 was evaluated as 5.39 sec^{-1}.

Therefore, the dissociation of hexamine from $\mathrm{Cu_2XOL^{2-}}$ takes place first:

$$\mathrm{Cu_2XOL^{2-} = Cu_2XO^{2-} + L} \qquad (11)$$

The substitution mechanism of $\mathrm{Cu_2XO^{2-}}$ with EDTA may be the same as that in the absence of hexamine. From equations (1), (5) and (10):

$$k_1 = k_2K^{\mathrm{L}}_{\mathrm{Cu_2XOL}} = 5.39 \times 10^{2.14}$$
$$= 7.44 \times 10^2\ \mathrm{l.mole^{-1}.sec^{-1}}$$

This value is in good agreement with that obtained in the absence of hexamine. This fact supports the reaction mechanism described above.

CONTROLLED POTENTIAL IODOMETRIC DETERMINATION OF IRON AFTER EXTRACTION WITH DI-ISOPROPYL ETHER

RONALD KARLSSON* and LO GORTON
Department of Analytical Chemistry, Chemical Center, University of Lund,
S-220 07 Lund 7, Sweden

(*Received* 23 *December* 1975. *Accepted* 1 *February* 1976)

The main difficulty arising in the determination of the iron in samples with complex matrices, is the separation of the iron from the other constituents in the sample. This is necessary to prevent any interference with the analysis. The lower the concentration of iron in the sample the better the separation required for its accurate determination.

Solvent extraction has been found to be one of the most efficient ways of separating iron from other constituents and several papers have described analytical applications of such methods.[1–3] The ferric chloride–hydrochloric acid–ether system is probably the most studied, and according to Dodson *et al.*[4] the use of di-isopropyl ether offers the greatest advantages. Nachtrieb *et al.*[5–6] have investigated this system and have stated the optimal conditions for such extractions.

An iodometric method for the determination of iron (III), based on the reaction

$$2Fe^{3+} + 2I^- \rightarrow 2Fe^{2+} + I_2 \qquad (1)$$

was originally proposed by Mohr,[7] and later Kolthoff[8] and Swift[9] worked out the best conditions for its analytical application.

The extraction procedures outlined in the methods above will give a tetrachloroferrate(III) complex in acid solution and an acidic ferric chloride solution is to be preferred for the iodometric determination of iron(III). Consequently, a combination of the extraction procedure and iodometric analysis seems rather attractive. The present work describes the development of a di-isopropyl ether extraction procedure for micro amounts of iron(III) and an iodometric method for the determination of the iron(III), based on a modification of the apparatus used previously for the investigation of controlled potential coulometry in the iodine–iodide system [10,11]

EXPERIMENTAL

Apparatus

The controlled-potential coulometric circuit and the electrolysis cell used were constructed on the principles applied for the apparatus used in our laboratory and described previously.[10,11] However, the recent rapid development in electronic components has made it possible to choose better components and modify the circuit to achieve 100% higher current capacity in the controlled-potential apparatus used in this study.

Separatory funnel. The separatory funnel is made of Pyrex glass and connected to a Teflon tube (see Fig. 1) which can be pushed up and down, and is closed by the sealed-in glass plug when pushed up. A series of five identical funnels was used during the analyses.

Reagents

Cell solutions. The counter-electrode compartment and the bridge compartment are filled with 1*M* sodium perchlorate and the working electrode compartment with equal volumes of 1*M* sodium iodide and 1*M* sodium perchlorate.

Ether for extraction. Di-isopropyl ether of *p.a.* quality was used. Redistillation of this ether did not give significantly better results. The ether was treated before use by shaking with appropriate concentrations of hydrochloric acid (usually 8*M*). The occurrence of peroxide in the ether will interfere with the iodometric analysis and therefore the ether was regularly tested for peroxide content by the method proposed by Fiedler.[12]

Iron stock solutions. Stock solutions of ferrous and ferric iron were prepared from ferrous and ferric ammonium sulphate of p.a. quality. All solutions were prepared with distilled water that had been boiled and then cooled under nitrogen. The solutions were standardized with 1,10-phenanthroline (Fe^{2+}) and EDTA with sulphosalicylic acid as indicator (Fe^{3+}).

Extraction

A suitable aliquot of the sample was made to be 8*M* in hydrochloric acid, placed in the separatory funnel, and shaken with di-isopropyl ether (generally 2.0 ml), pre-equilibrated with hydrochloric acid. After the phases had separated the aqueous phase was discarded and the ether phase shaken with three 1-ml portions of distilled water. The

aqueous fractions were retained for further analysis in the electrolysis cell, the ether phase was discarded. For more complex samples it is recommended that the first aqueous fraction is re-extracted by the same procedure, but generally, this step has been found to be unnecessary. The volume of the extraction solutions used can be varied, within rather wide limits, in order to obtain suitable concentrations of iron(III) for the coulometric step. However, from a practical point of view, volumes in the range 1–5 ml are preferred.

Preparation of sample

Blood serum. Serum sample (1–4 ml) was mixed with an equal amount of 10% trichloroacetic acid solution in a 10-ml test-tube. The test-tube was then covered, shaken and centrifuged. As much as possible of the clear supernatant was then transferred with a graduated pipette to a second test-tube, and the solution made 8*M* in hydrochloric acid.

Tablets. An appropriate number of tablets, depending on their iron content, was powdered in a mortar and dissolved in 8*M* hydrochloric acid.

Cocoa powder The sample was heated in a furnace at 600° for 2 hr and then the residue was dissolved in 8*M* hydrochloric acid. This method may also be used for analysis of tablets.

After the samples have been prepared, all the iron present must be oxidized to the ferric state before the extraction step. Either oxygen can be bubbled through the sample solution for 30 min, or an excess of bromine can be added and the excess reduced with formic acid.

Procedure

After the electrolysis cell had been filled with the appropriate solutions, a stream of nitrogen (15 ml/min) was allowed to pass through the solution in the working compartment for 10 min, after which the coulometric system was checked. The system was standardized with reagent blank solutions. A suitable amount of iodine was generated coulometrically at 350 mV *vs.* SCE and then immediately reduced at 0 mV *vs.* SCE and any discrepancies arising from the calculated blank value, background current or time of analysis were corrected for before the analyses of iron. After this standardization a sample containing iron(III) was added and the iodine formed according to reaction (1) reduced, and from the integrator read-out the iron content in the sample was calculated.

RESULTS AND DISCUSSION

The extraction procedure is critically dependent on the concentration of hydrochloric acid used and to some extent on the concentration of iron to be extracted. Therefore it was necessary to determine the best conditions for quantitative extraction of iron.

From a 0.050*M* stock solution of Fe(III) in 12*M* hydrochloric acid, 1.0-ml aliquots were pipetted into each of 15 volumetric flasks (10 ml) and made up to volume with 2.5–12*M* hydrochloric acid. With an Agla microsyringe, a 0.5-ml portion was then transferred from each flask to different separatory funnels and extracted with 2.0 ml of di-isopropyl ether which had previously been shaken once with the corresponding concentration of hydrochloric acid. The extraction procedure and coulometric analysis steps described above were then performed, and the results are shown in Fig. 2. It can be seen that in order to obtain quantitative extraction, the concentration of the acid must be within the limits 7.5–8.5*M*.

The method investigated is only valid for ferric iron, and any ferrous iron must be oxidized if the total iron concentration is to be determined. This can very easily be done by means of the two methods outlined above.

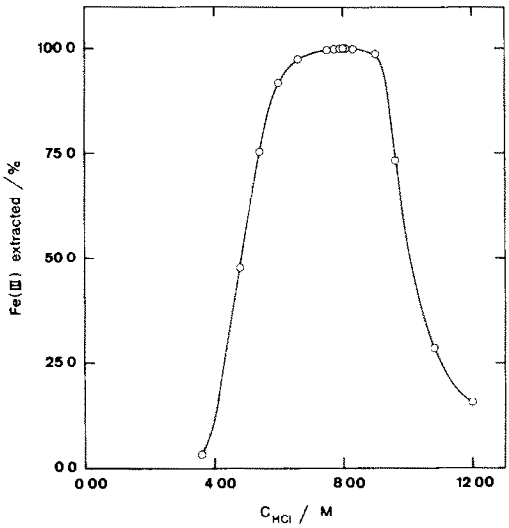

Fig. 2. Extraction of Fe(III) from hydrochloric acid by di-isopropyl ether.

The dependence of the oxidation of ferrous to ferric iron on the hydrochloric acid concentration is shown in Fig. 3. In this experiment a 0.005*M* ferrous solution was oxidized by allowing oxygen to bubble through the solution for 30 min. The higher the concentration of the hydrochloric acid the more efficient was the oxidation, because the formation of ferric chloride complexes decreases the formal potential for the ferrous–ferric couple, and the oxidizing power of oxygen increases with increasing acidity. However, with a hydrochloric acid concentration of just over 8*M* the oxidation is quantitative, as can be seen from Fig. 3, and this concentration has also been shown to be the most favourable for the extraction procedure. Thus dilution of the sample is not necessary. A drawback is the rather time-consuming oxidation procedure. The bromine–formic acid method of oxidation is rapid and does not interfere with either the extraction or the coulometric steps, but the concomitant dilution of the sample may be a source of error when only small samples are available for analysis.

The iron contents of several different samples have been determined and in Tables 1 and 2 some of the more interesting results are collected. Because both the extraction and the coulometric steps are quite selective for ferric iron,

the distribution between ferrous and ferric iron in a sample can be readily determined (see Table 2, tablet B[3]). Analyses before and after oxidation will give the amount of ferric iron and the total amount of iron in the sample, and from these results the amount of ferrous iron can be readily determined.

Summary—A selective method for the determination of small amounts of iron in different kinds of samples with complex matrices has been developed. The iron in a sample is converted into the ferric state and after extraction with di-isopropyl ether the ferric iron is iodometrically determined with a controlled-potential apparatus previously described. Iron concentrations lower than 1 ppm can be determined.

IRON(II)-INDUCED OXIDATION OF HYPOPHOSPHITE BY PEROXYDIPHOSPHATE IN ACID MEDIUM

SURINDER KAPOOR and Y. K. GUPTA
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 11 *December* 1975. *Accepted* 10 *February* 1976)

An induced reaction was discovered while attempting to determine peroxydiphosphate cerimetrically in the presence of hypophosphite. Peroxydiphosphate is added to excess of iron(II), the surplus of which is back-titrated with cerium(IV) However, in the presence of hypophosphite the method fails. The reaction of peroxydiphosphate with iron(II) is fast, but with hypophosphite[1] it is slow. However, if iron(II) and hypophosphite are present together, both are oxidized comparably. Peroxydiphosphate, iron(II) and hypophosphite are respectively the *actor*, *inductor* and *acceptor*. The induced reaction suggests an intermediate species derived from peroxydiphosphate, possibly a free radical HPO_4^-:

$$H_4P_2O_8 + Fe(II) \rightarrow H_3PO_4 + HPO_4^- + Fe(III) \quad (1)$$

$$HPO_4^- + Fe(II) \rightarrow HPO_4^{2-} + Fe(III) \quad (2)$$

$$2HPO_4^- + H_3PO_2 + H_2O \rightarrow 2H_2PO_4^{2-} + H_3PO_3 \quad (3)$$

The limiting value of the induction factor, the ratio of the number of equivalents of H_3PO_2 oxidized to the number of equivalents of iron(II) oxidized, was found to be one,

CONTROLLED POTENTIAL IODOMETRIC DETERMINATION OF IRON AFTER EXTRACTION WITH DI-ISOPROPYL ETHER

RONALD KARLSSON* and LO GORTON
Department of Analytical Chemistry, Chemical Center, University of Lund,
S-220 07 Lund 7, Sweden

(*Received* 23 *December* 1975. *Accepted* 1 *February* 1976)

The main difficulty arising in the determination of the iron in samples with complex matrices, is the separation of the iron from the other constituents in the sample. This is necessary to prevent any interference with the analysis. The lower the concentration of iron in the sample the better the separation required for its accurate determination.

Solvent extraction has been found to be one of the most efficient ways of separating iron from other constituents and several papers have described analytical applications of such methods.[1–3] The ferric chloride–hydrochloric acid–ether system is probably the most studied, and according to Dodson *et al.*[4] the use of di-isopropyl ether offers the greatest advantages. Nachtrieb *et al.*[5–6] have investigated this system and have stated the optimal conditions for such extractions.

An iodometric method for the determination of iron (III), based on the reaction

$$2Fe^{3+} + 2I^- \rightarrow 2Fe^{2+} + I_2 \qquad (1)$$

was originally proposed by Mohr,[7] and later Kolthoff[8] and Swift[9] worked out the best conditions for its analytical application.

The extraction procedures outlined in the methods above will give a tetrachloroferrate(III) complex in acid solution and an acidic ferric chloride solution is to be preferred for the iodometric determination of iron(III). Consequently, a combination of the extraction procedure and iodometric analysis seems rather attractive. The present work describes the development of a di-isopropyl ether extraction procedure for micro amounts of iron(III) and an iodometric method for the determination of the iron(III), based on a modification of the apparatus used previously for the investigation of controlled potential coulometry in the iodine–iodide system.[10,11]

EXPERIMENTAL

Apparatus

The controlled-potential coulometric circuit and the electrolysis cell used were constructed on the principles applied for the apparatus used in our laboratory and described previously.[10,11] However, the recent rapid development in electronic components has made it possible to choose better components and modify the circuit to achieve 100% higher current capacity in the controlled-potential apparatus used in this study.

Separatory funnel. The separatory funnel is made of Pyrex glass and connected to a Teflon tube (see Fig. 1) which can be pushed up and down, and is closed by the sealed-in glass plug when pushed up. A series of five identical funnels was used during the analyses.

Reagents

Cell solutions. The counter-electrode compartment and the bridge compartment are filled with 1*M* sodium perchlorate and the working electrode compartment with equal volumes of 1*M* sodium iodide and 1*M* sodium perchlorate.

Ether for extraction. Di-isopropyl ether of *p.a.* quality was used. Redistillation of this ether did not give significantly better results. The ether was treated before use by shaking with appropriate concentrations of hydrochloric acid (usually 8*M*). The occurrence of peroxide in the ether will interfere with the iodometric analysis and therefore the ether was regularly tested for peroxide content by the method proposed by Fiedler.[12]

Iron stock solutions. Stock solutions of ferrous and ferric iron were prepared from ferrous and ferric ammonium sulphate of p.a. quality. All solutions were prepared with distilled water that had been boiled and then cooled under nitrogen. The solutions were standardized with 1,10-phenanthroline (Fe^{2+}) and EDTA with sulphosalicylic acid as indicator (Fe^{3+}).

Extraction

A suitable aliquot of the sample was made to be 8*M* in hydrochloric acid, placed in the separatory funnel, and shaken with di-isopropyl ether (generally 2.0 ml), pre-equilibrated with hydrochloric acid. After the phases had separated the aqueous phase was discarded and the ether phase shaken with three 1-ml portions of distilled water. The

aqueous fractions were retained for further analysis in the electrolysis cell, the ether phase was discarded. For more complex samples it is recommended that the first aqueous fraction is re-extracted by the same procedure, but generally, this step has been found to be unnecessary. The volume of the extraction solutions used can be varied, within rather wide limits, in order to obtain suitable concentrations of iron(III) for the coulometric step. However, from a practical point of view, volumes in the range 1–5 ml are preferred.

Preparation of sample

Blood serum. Serum sample (1–4 ml) was mixed with an equal amount of 10% trichloroacetic acid solution in a 10-ml test-tube. The test-tube was then covered, shaken and centrifuged. As much as possible of the clear supernatant was then transferred with a graduated pipette to a second test-tube, and the solution made 8*M* in hydrochloric acid.

Tablets. An appropriate number of tablets, depending on their iron content, was powdered in a mortar and dissolved in 8*M* hydrochloric acid.

Cocoa powder The sample was heated in a furnace at 600° for 2 hr and then the residue was dissolved in 8*M* hydrochloric acid. This method may also be used for analysis of tablets.

After the samples have been prepared, all the iron present must be oxidized to the ferric state before the extraction step. Either oxygen can be bubbled through the sample solution for 30 min, or an excess of bromine can be added and the excess reduced with formic acid.

Procedure

After the electrolysis cell had been filled with the appropriate solutions, a stream of nitrogen (15 ml/min) was allowed to pass through the solution in the working compartment for 10 min, after which the coulometric system was checked. The system was standardized with reagent blank solutions. A suitable amount of iodine was generated coulometrically at 350 mV *vs.* SCE and then immediately reduced at 0 mV *vs.* SCE and any discrepancies arising from the calculated blank value, background current or time of analysis were corrected for before the analyses of iron. After this standardization a sample containing iron(III) was added and the iodine formed according to reaction (1) reduced, and from the integrator read-out the iron content in the sample was calculated.

RESULTS AND DISCUSSION

The extraction procedure is critically dependent on the concentration of hydrochloric acid used and to some extent on the concentration of iron to be extracted. Therefore it was necessary to determine the best conditions for quantitative extraction of iron.

From a 0.050*M* stock solution of Fe (III) in 12*M* hydrochloric acid, 1.0-ml aliquots were pipetted into each of 15 volumetric flasks (10 ml) and made up to volume with 2.5–12*M* hydrochloric acid. With an Agla microsyringe, a 0.5-ml portion was then transferred from each flask to different separatory funnels and extracted with 2.0 ml of di-isopropyl ether which had previously been shaken once with the corresponding concentration of hydrochloric acid. The extraction procedure and coulometric analysis steps described above were then performed, and the results are shown in Fig. 2. It can be seen that in order to obtain quantitative extraction, the concentration of the acid must be within the limits 7.5–8.5*M*.

The method investigated is only valid for ferric iron, and any ferrous iron must be oxidized if the total iron concentration is to be determined. This can very easily be done by means of the two methods outlined above.

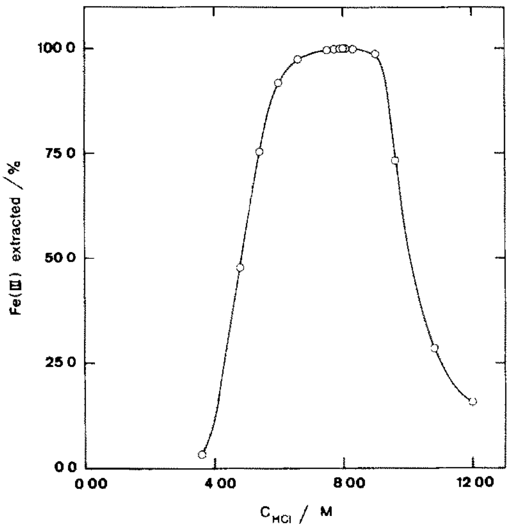

Fig. 2. Extraction of Fe(III) from hydrochloric acid by di-isopropyl ether.

The dependence of the oxidation of ferrous to ferric iron on the hydrochloric acid concentration is shown in Fig. 3. In this experiment a 0.005*M* ferrous solution was oxidized by allowing oxygen to bubble through the solution for 30 min. The higher the concentration of the hydrochloric acid the more efficient was the oxidation, because the formation of ferric chloride complexes decreases the formal potential for the ferrous–ferric couple, and the oxidizing power of oxygen increases with increasing acidity. However, with a hydrochloric acid concentration of just over 8*M* the oxidation is quantitative, as can be seen from Fig. 3, and this concentration has also been shown to be the most favourable for the extraction procedure. Thus dilution of the sample is not necessary. A drawback is the rather time-consuming oxidation procedure. The bromine–formic acid method of oxidation is rapid and does not interfere with either the extraction or the coulometric steps, but the concomitant dilution of the sample may be a source of error when only small samples are available for analysis.

The iron contents of several different samples have been determined and in Tables 1 and 2 some of the more interesting results are collected. Because both the extraction and the coulometric steps are quite selective for ferric iron,

3	20 ml Fe(II)	A + 10 ml $K_4P_2O_8$	B + excess H_3PO_2 (>40 ml)	$K_4P_2O_8$, A − B	Oxidation of H_3PO_2, A − C	
	14.85	2.05	8.40	12.8	6.45	1.01

consistent with a two electron-change of the peroxydiphosphate.

Stock solutions of 0 0083M $K_4P_2O_8$, 0.01M iron(II) ammonium sulphate, 0.1M sodium hypophosphite, 0.4M iron(III) sulphate, and *ca* 0.01M cerium(IV) nitrate were prepared. Sulphuric acid was added wherever necessary to check hydrolysis of the solution. The indicator was *N*-phenylanthranilic acid.

Ten ml of iron(II) solution were titrated with cerium(IV). Next 5 ml of $K_4P_2O_8$ solution were added to 10 ml of iron(II) solution and the excess of the latter was titrated with cerium(IV). Then 10 ml of iron(II) solution were mixed with 25 ml of iron(III) solution and varying amounts of hypophosphite, 10 ml of peroxydiphosphate solution were added, and the whole was titrated with cerium(IV). The iron(III) solution was added to remove interference[2] of hypophosphite in the cerimetric determination of excess of iron(II).

These sets of titrations were repeated with 5 ml of iron(II) solution and 2.5 ml of $K_4P_2O_8$ solution, and with 20 ml of iron(II) solution and 10 ml of $K_4P_2O_8$ solution. All the results are shown in Fig. 1. It is obvious from the limiting titration values that when excess of hypophosphite is present, half the amount of peroxydiphosphate is consumed by iron(II) and half by hypophosphite (Table 1). Although it has been possible to identify this induced reaction by the titration of iron(II) with Ce(IV), it is not possible to determine hypophosphite or phosphite under the conditions of the experiment.

La demande croissante de dosage du sélénium dans les composés organiques nous a conduit à éprouver différentes méthodes en vue de leur application dans le domaine microanalytique et à choisir, entre elles, la plus appropriée. Cette étude est l'objet de la présente note.

PARTIE EXPERIMENTALE

Le microdosage du sélénium dans les composés organiques par iodométrie après combustion dans l'oxygène en fiole de Schöniger d'après Ihn *et al.*[1] (méthode A) est satisfaisant pour des masses de prélèvements de 2 à 3 mg. Il est toutefois possible d'utiliser une fiole avec panier et fil de platine de 0,5 mm de diamètre,[2] plus simple et moins fragile.

Le platine, attaqué peu à peu, peut être nettoyé par immersion de 2 ou 3 mn dans l'eau régale. Les échantillons sont enveloppés de façon classique dans du papier filtre.[1] L'emploi d'un sachet de terphane[3,4] enveloppé dans le papier filtre habituel permet le dosage de nombreux liquides et de substances instables à l'air.

Il est recommandable d'utiliser 20 gouttes d'eau de brome plutôt que 10.[1] L'oxydation par le brome conduit à la formation quantitative d'ions SeO_4^{2-} qui sont ensuite

[2] Fe^{2+} as the only active substance.
[3] Analysed before oxidation.
* According to the manufacturer.

the distribution between ferrous and ferric iron in a sample can be readily determined (see Table 2, tablet B[3]). Analyses before and after oxidation will give the amount of ferric iron and the total amount of iron in the sample, and from these results the amount of ferrous iron can be readily determined.

Acknowledgements—The authors wish to express their appreciation to Mr. Alf Lundberg, glassblowers' workshop of the Chemical Center of Lund, for constructing the separatory funnels.

Summary—A selective method for the determination of small amounts of iron in different kinds of samples with complex matrices has been developed. The iron in a sample is converted into the ferric state and after extraction with di-isopropyl ether the ferric iron is iodometrically determined with a controlled-potential apparatus previously described. Iron concentrations lower than 1 ppm can be determined.

IRON(II)-INDUCED OXIDATION OF HYPOPHOSPHITE BY PEROXYDIPHOSPHATE IN ACID MEDIUM

SURINDER KAPOOR and Y. K. GUPTA
Department of Chemistry, University of Rajasthan, Jaipur, India

(*Received* 11 *December* 1975. *Accepted* 10 *February* 1976)

An induced reaction was discovered while attempting to determine peroxydiphosphate cerimetrically in the presence of hypophosphite. Peroxydiphosphate is added to excess of iron(II), the surplus of which is back-titrated with cerium(IV) However, in the presence of hypophosphite the method fails. The reaction of peroxydiphosphate with iron(II) is fast, but with hypophosphite[1] it is slow. However, if iron(II) and hypophosphite are present together, both are oxidized comparably. Peroxydiphosphate, iron(II) and hypophosphite are respectively the *actor*, *inductor* and *acceptor*. The induced reaction suggests an intermediate species derived from peroxydiphosphate, possibly a free radical HPO_4^-:

$$H_4P_2O_8 + Fe(II) \rightarrow H_3PO_4 + HPO_4^- + Fe(III) \quad (1)$$

$$HPO_4^- + Fe(II) \rightarrow HPO_4^{2-} + Fe(III) \quad (2)$$

$$2HPO_4^- + H_3PO_2 + H_2O \rightarrow 2H_2PO_4^{2-} + H_3PO_3 \quad (3)$$

The limiting value of the induction factor, the ratio of the number of equivalents of H_3PO_2 oxidized to the number of equivalents of iron(II) oxidized, was found to be one,

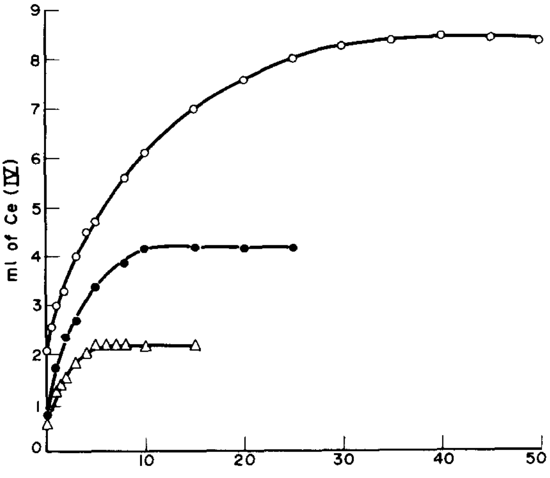

Fig. 1.

Table 1. $[Fe(II)] = 1.0 \times 10^{-2}M; [K_4P_2O_8] = 8.53 \times 10^{-3}M; [H_3PO_2] = 1.0 \times 10^{-1}M$

Service Central de Microanalyse du Centre National de la Recherche Scientifique,
2 rue Henry Dunant, 94320 Thiais, France

(*Reçu le* 28 *novembre* 1975. *Accepté le* 11 *janvier* 1976)

La demande croissante de dosage du sélénium dans les composés organiques nous a conduit à éprouver différentes méthodes en vue de leur application dans le domaine microanalytique et à choisir, entre elles, la plus appropriée. Cette étude est l'objet de la présente note.

PARTIE EXPERIMENTALE

Le microdosage du sélénium dans les composés organiques par iodométrie après combustion dans l'oxygène en fiole de Schöniger d'après Ihn *et al.*[1] (méthode A) est satisfaisant pour des masses de prélèvements de 2 à 3 mg. Il est toutefois possible d'utiliser une fiole avec panier et fil de platine de 0,5 mm de diamètre,[2] plus simple et moins fragile.

Le platine, attaqué peu à peu, peut être nettoyé par immersion de 2 ou 3 mn dans l'eau régale. Les échantillons sont enveloppés de façon classique dans du papier filtre.[1] L'emploi d'un sachet de terphane[3,4] enveloppé dans le papier filtre habituel permet le dosage de nombreux liquides et de substances instables à l'air.

Il est recommandable d'utiliser 20 gouttes d'eau de brome plutôt que 10.[1] L'oxydation par le brome conduit à la formation quantitative d'ions SeO_4^{2-} qui sont ensuite

réduits par de l'acide chlorhydrique en ions SeO_3^{2-} lesquels sont dosés par iodométrie. Il ne se forme pas de sélénium élémentaire.

Deux conditions sont très importantes en vue de l'obtention de résultats corrects : la destruction totale du brome résiduel et la limitation du volume de solution à titrer. Un trop grand excès de brome, s'il est mal détruit, donne lieu à l'obtention de résultats erronés par excès. Le volume total de solution obtenu après rinçage de la fiole ne doit pas dépasser 21 ml (10 ml de solution absorbante + 11 ml d'eau de rinçage) afin que la concentration d'acide chlorhydrique reste appropriée.

Les sélénites ou séléniates trouvés dans le commerce ne possèdent pas, en général, les caractéristiques requises pour préparer une solution de titre exactement connu par simple pesage de ces produits; il est possible de préparer une solution de séléniate de sodium approximativement titrée et de déterminer son titre exact par réduction du séléniate en sélénium rouge par l'acide chlorhydrique et l'iodure de potassium. La distillation de l'iode libéré et son titrage permettent d'obtenir la titre exact du séléniate.[5] Le titre de thiosulfate utilisé pour le titrage après minéralisation en fiole de Schöniger est alors déterminé par rapport au séléniate dans les conditions décrites pour ce titrage (méthode A).

RESULTATS ET DISCUSSION

Quelques résultats significatifs obtenus par la méthode préconisée sont reportés dans le tableau ci-dessous.

De nombreux hétéroéléments métalliques tels que Co, Cr, *etc.* sont souvent responsables d'une combustion et mise en solution du sélénium incomplètes.

Des essais de minéralisation en bombe par le peroxyde de sodium[5] n'ont pas conduit à des résultats corrects même pour des composés organiques séléniés ne contenant pas d'hétéroéléments métalliques.

Une minéralisation sulfonitrique[6] du type micro-Lorenz[7, 8] effectuée en micromatras du type "Kjeldahl" semble susceptible de convenir mais l'acide nitreux formé ou l'eau oxygénée susceptible d'être utilisée pour détruire les produits nitreux, gênent l'iodométrie.

Des essais d'emploi de l'urée,[9] à cette fin, n'ont pas conduit à l'obtention de résultats iodométriques reproductibles.

Tableau 1

Composé de recherche*	Masse du prélèvement, *mg*	Teneur en élément, %	
		trouvée	calculée

	2,960	$27{,}2_3$	—
B	3,104	$32{,}5_6$	32,61
	2,252	$32{,}2_0$	—
	2,987	$32{,}4_0$	—
C	1,260	$33{,}9_3$	33,60
	3,816	$33{,}1_8$	—
	3,008	$33{,}7_2$	—

* Il est difficile de se procurer dans le commerce des substances pures et stables. La composé A est un dérivé de l'α sélénonaphtol , le composé B est un dérivé du sélénacyclopentadiène ; le composé C est un dérivé du diséléniure de diphényle

Conclusion

La méthode retenue pour la mise en oeuvre du microdosage du sélénium est la combustion en fiole de Schöniger associée à une iodométrie.

	14.85	2.05	8.40	12.8	6.45	1.01

consistent with a two electron-change of the peroxydiphosphate.

Stock solutions of $0.0083M$ $K_4P_2O_8$, $0.01M$ iron(II) ammonium sulphate, $0.1M$ sodium hypophosphite, $0.4M$ iron(III) sulphate, and *ca* $0.01M$ cerium(IV) nitrate were prepared. Sulphuric acid was added wherever necessary to check hydrolysis of the solution. The indicator was *N*-phenylanthranilic acid.

Ten ml of iron(II) solution were titrated with cerium(IV). Next 5 ml of $K_4P_2O_8$ solution were added to 10 ml of iron(II) solution and the excess of the latter was titrated with cerium(IV). Then 10 ml of iron(II) solution were mixed with 25 ml of iron(III) solution and varying amounts of hypophosphite, 10 ml of peroxydiphosphate solution were added, and the whole was titrated with cerium(IV). The iron(III) solution was added to remove interference[2] of hypophosphite in the cerimetric determination of excess of iron(II).

These sets of titrations were repeated with 5 ml of iron(II) solution and 2.5 ml of $K_4P_2O_8$ solution, and with 20 ml of iron(II) solution and 10 ml of $K_4P_2O_8$ solution. All the results are shown in Fig. 1. It is obvious from the limiting titration values that when excess of hypophosphite is present, half the amount of peroxydiphosphate is consumed by iron(II) and half by hypophosphite (Table 1). Although it has been possible to identify this induced reaction by the titration of iron(II) with Ce(IV), it is not possible to determine hypophosphite or phosphite under the conditions of the experiment.

Le platine, attaqué peu à peu, peut être nettoyé par immersion de 2 ou 3 mn dans l'eau régale. Les échantillons sont enveloppés de façon classique dans du papier filtre.[1] L'emploi d'un sachet de terphane[3,4] enveloppé dans le papier filtre habituel permet le dosage de nombreux liquides et de substances instables à l'air.

Il est recommandable d'utiliser 20 gouttes d'eau de brome plutôt que 10.[1] L'oxydation par le brome conduit à la formation quantitative d'ions SeO_4^{2-} qui sont ensuite

réduits par de l'acide chlorhydrique en ions SeO_3^{2-} lesquels sont dosés par iodométrie. Il ne se forme pas de sélénium élémentaire.

Deux conditions sont très importantes en vue de l'obtention de résultats corrects : la destruction totale du brome résiduel et la limitation du volume de solution à titrer. Un trop grand excès de brome, s'il est mal détruit, donne lieu à l'obtention de résultats erronés par excès. Le volume total de solution obtenu après rinçage de la fiole ne doit pas dépasser 21 ml (10 ml de solution absorbante + 11 ml d'eau de rinçage) afin que la concentration d'acide chlorhydrique reste appropriée.

Les sélénites ou séléniates trouvés dans le commerce ne possèdent pas, en général, les caractéristiques requises pour préparer une solution de titre exactement connu par simple pesage de ces produits; il est possible de préparer une solution de séléniate de sodium approximativement titrée et de déterminer son titre exact par réduction du séléniate en sélénium rouge par l'acide chlorhydrique et l'iodure de potassium. La distillation de l'iode libéré et son titrage permettent d'obtenir la titre exact du séléniate.[5] Le titre de thiosulfate utilisé pour le titrage après minéralisation en fiole de Schöniger est alors déterminé par rapport au séléniate dans les conditions décrites pour ce titrage (méthode A).

RESULTATS ET DISCUSSION

Quelques résultats significatifs obtenus par la méthode préconisée sont reportés dans le tableau ci-dessous.

De nombreux hétéroéléments métalliques tels que Co, Cr, *etc.* sont souvent responsables d'une combustion et mise en solution du sélénium incomplètes.

Des essais de minéralisation en bombe par le peroxyde de sodium[5] n'ont pas conduit à des résultats corrects même pour des composés organiques séléniés ne contenant pas d'hétéroéléments métalliques.

Une minéralisation sulfonitrique[6] du type micro-Lorenz[7] [8] effectuée en micromatras du type "Kjeldahl" semble susceptible de convenir mais l'acide nitreux formé ou l'eau oxygénée susceptible d'être utilisée pour détruire les produits nitreux, gênent l'iodométrie.

Des essais d'emploi de l'urée,[9] à cette fin, n'ont pas conduit à l'obtention de résultats iodométriques reproductibles.

Tableau 1

Composé de recherche*	Masse du prélèvement, *mg*	Teneur en élément, % trouvée	Teneur en élément, % calculée
A	2,693	27,3$_7$	26,93
	3,077	26,6$_5$	—
	2,960	27,2$_3$	—
B	3,104	32,5$_6$	32,61
	2,252	32,2$_0$	—
	2,987	32,4$_0$	—
C	1,260	33,9$_3$	33,60
	3,816	33,1$_8$	—
	3,008	33,7$_2$	—

* Il est difficile de se procurer dans le commerce des substances pures et stables. La composé A est un dérivé de l'α sélénonaphtol , le composé B est un dérivé du sélénacyclopentadiène ; le composé C est un dérivé du diséléniure de diphényle

Conclusion

La méthode retenue pour la mise en oeuvre du microdosage du sélénium est la combustion en fiole de Schöniger associée à une iodométrie.

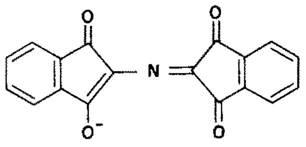
(*Received* 21 *November* 1975. *Accepted* 8 *March* 1976)

Following on the recent descriptions[1,2] of liquid-membrane ion-selective electrodes based on metal chelates dissolved in organic solvents, we now describe the construction and evaluation of a new liquid-state Hg^{2+}-sensitive electrode. Our liquid membrane consisted of the Hg(II) chelate of diketohydrindylidene-diketohydrindamine (DYDA).

DYDA is formed in the reaction between ninhydrin (triketohydrindene hydrate) with amino-acids[3] and is more commonly known under the name of "Ruhemann's Purple":



DYDA

This reaction has been studied from the mechanistic point of view by many authors, starting with Ruhemann. On the basis of this reaction some methods were developed for the determination of amino-acids.[4–8]

EXPERIMENTAL

Preparation of the electroactive substance (the liquid membrane)

In order to obtain the liquid membrane, the procedure is as follows: 10 ml of $10^{-2}M$ glycine and 10 ml of $5 \times 10^{-2}M$ ninhydrin are introduced into a U-shaped glass tube with stop-cocks at both ends. One of the stop-cocks is kept closed, while the other is connected with a rubber tube to a water-filled graduated cylinder. The U-tube is placed in a bath of boiling water. The reaction is finished when no more CO_2 evolves from the U-shaped tube. The product is a solution of the ammonium salt of DYDA. It is transferred to a 100-ml separating funnel, then 3 ml of $0{\cdot}1M$ nitric acid are added. DYDA (the free acid) is precipitated and is extracted with 25 ml of chloroform by shaking for 2 min. The organic layer (solution A) is transferred to another separating funnel containing 25 ml of $10^{-2}M$ mercuric nitrate. The acidity of the solution is adjusted to pH 6 with hexamine and the two phases are shaken for 2 min. The aqueous phase is transferred to another separating funnel and shaken with 25 ml of chloroform The organic phases are combined, dried by passage through anhydrous sodium sulphate and transferred to a 100-ml flask. This is solution B, the liquid membrane with a mercury(II) concentration of $5 \times 10^{-4}M$. The absorption spectra of solutions A and B have peaks at 480 and 520 nm respectively.

Construction of the electrode

This is done as described previously[9–11] by impregnating the support material (a hydrophobized graphite rod) with solution B. The internal reference electrode is eliminated by use of a stainless-steel wire introduced into the graphite rod. The electrode is stored in solution B.

RESULTS AND DISCUSSIONS

The electrode function

The emf measurements were made with the electrochemical cell

$$\begin{array}{c|c|c|c} \text{Hg}^{2+}\text{-sensitive electrode} & \text{Hg}^{2+}(C_{\text{Hg}^{2+}}),\ \mu = 0.4\ (\text{KNO}_3) & \text{KNO}_3\ \text{std.} & \text{SCE} \end{array} \qquad \text{(I)}$$

where $C_{Hg^{2+}}$ represents the Hg^{2+} concentration, varying from 10^{-1} to $10^{-6}M$. The emf of cell (I) is given by

$$E_1 = E'_0 + 0.031 \log [\text{Hg}^{2+}] \qquad (1)$$

in the range 10^{-1}–$10^{-5}M$ Hg^{2+} concentration; E'_0 represents the conditional standard potential of the electrode. The measurements were carried out at constant ionic strength ($\mu = 0.4$, KNO_3), and the junction potential was kept constant.

The fact that we cannot obtain better sensitivities for this electrode is probably due to the absorption of Hg^{2+} at the end of the electrolyte bridge and on the surface of the glass vessel.

Influence of pH

In Fig. 1 we show the effect of pH on the response of the electrode at different mercury(II) concentrations.

The pH range in which the potential remains constant is relatively narrow because of the hydrolysis of Hg^{2+}. The direct potential measurements for calibration of the electrode were done at pH 1 (adjusted with nitric acid).

Response time of the electrode

The response characteristics of the electrode were evaluated by introducing the electrode into mercuric nitrate solutions of different concentrations but of identical acidity (pH 1) and noting the emf values as a function of time. A Servogor^S potentiometric recorder (Goerz Electro, Vienna) was used. The response time of the electrode is

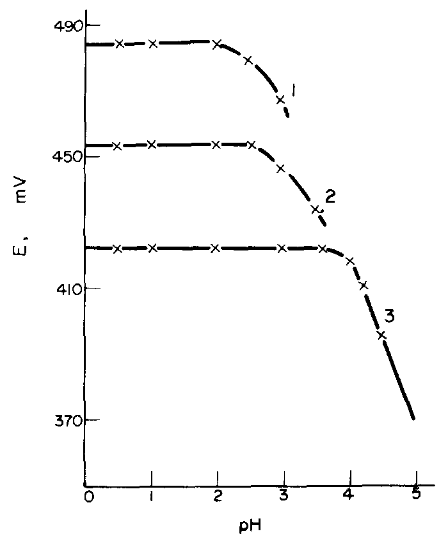


Fig 1. Influence of pH on the response of the electrode for different $Hg(NO_3)_2$ concentrations ($\mu = 0.4$, KNO_3) 1—$10^{-1}M$, 2—$10^{-2}M$, 3—$10^{-3}M$.

Table 1. Selectivity coefficients, $K_{\mathrm{Hg}^{2+},\mathrm{M}^{z+},\mathrm{M}_{z+}}$. [The nitrates of the respective metals at a concentration of 0.1*M*, pH = 1.0 and $\mu = 0.4(KNO_3)$]

Interferent cation (M^{z+})	$K_{\mathrm{Hg}^{2+},\mathrm{M}^{z+},\mathrm{M}_{z+}}$
Bi^{3+}	1.52×10^{-4}
Cd^{2+}	2.30×10^{-4}
Pb^{2+}	3.81×10^{-4}
Ni^{2+}	5.63×10^{-4}
Co^{2+}	6.46×10^{-4}
Zn^{2+}	1.00×10^{-3}
Cu^{2+}	1.35×10^{-2}
Ag^{+}	1.82

Table 2. Reproducibility of potential measurements (tested during 5 weeks). The values represent the average of 15 measurements

$[Hg^{2+}]$,*M*	10^{-5}	10^{-4}	10^{-3}	10^{-2}	10^{-1}
E, *mV*	364 ± 6	392 ± 4	423 ± 3	454 ± 3	485 ± 3

longest in the $10^{-5}M$ (*ca.* 4 min) and $10^{-4}M$ (*ca.* 1 min) solutions. In the concentrated solutions the response times of the electrode are of the order of a few seconds.

Selectivity

Selectivity coefficients ($K_{\mathrm{Hg}^{2+}}$, M^{z+}) were calculated by the method of Srinivasan and Rechnitz,[12] using the relation:

$$\log K_{\mathrm{Hg}^{2+},\mathrm{M}^{z+},\mathrm{M}_{z+}} = (E_{\mathrm{II}} - E_{\mathrm{I}})/0.031 + \log[\mathrm{Hg}^{2+}] - \log[\mathrm{M}^{z+}]^{2/z} \quad (2)$$

where E_I is the emf of cell I for $C_{\mathrm{Hg}^{2+}} = 10^{-1}M$, and E_{II} is the emf of an electrochemical cell of type (II):

Hg^{2+}-sensitive electrode	$M^{z+}(C_{M^{z+}} = 10^{-1}M)$, $\mu = 0.4(KNO_3)$	KNO_3 std.	SCE (II)

where M^{z+} represents the main metallic cations that form more or less stable chelates with DYDA. In all cases the nitrates were used at pH 1 The values of the selectivity coefficients may be seen in Table 1.

Reproducibility of potential measurements

The reproducibility was tested in the 10^{-1}–$10^{-5}M$ $Hg(NO_3)_2$ range during a five-week period. The values in Table 2 are the average of 15 measurements, and prove the excellent stability of the electrode.

ANALYTICAL USE

The electrode was used with good results as an indicator electrode for complexing and precipitation potentiometric titrations with mercuric ions. In our experiments we used a TTT2 pH/mV meter with an ABU 12 Autoburette and Titrigraph SBR 2 C recorder (Radiometer).

The potentiometric titration curves for EDTA titration of mercury(II) gave potential breaks of about 70 mV for $10^{-3}M$ mercury and 120 mV for $10^{-2}M$ solution. The acidity was adjusted to pH 6 with hexamine, but because of pH interference, the emf readings are not typical of the overall Hg(II) concentration.

In potentiometric titration of potassium iodide with mercuric nitrate solutions ten times as concentrated, at pH 1.0, the potential breaks ranged from about 50 mV for $10^{-4}M$ iodide to 110 mV for $10^{-2}M$ iodide. The mean error was 0.4% for both types of titration.

The electrode was used with good results as indicator electrode in the potentiometric titration of $10^{-3}M$ Cl^-, Br^- and SCN^-, the potential breaks being 170, 260 and 200 mV respectively.

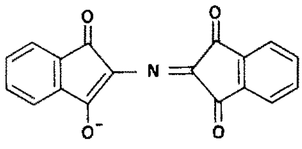
Following on the recent descriptions[1,2] of liquid-membrane ion-selective electrodes based on metal chelates dissolved in organic solvents, we now describe the construction and evaluation of a new liquid-state Hg^{2+}-sensitive electrode. Our liquid membrane consisted of the Hg(II) chelate of diketohydrindylidene-diketohydrindamine (DYDA).

DYDA is formed in the reaction between ninhydrin (triketohydrindene hydrate) with amino-acids[3] and is more commonly known under the name of "Ruhemann's Purple":



DYDA

This reaction has been studied from the mechanistic point of view by many authors, starting with Ruhemann. On the basis of this reaction some methods were developed for the determination of amino-acids.[4–8]

EXPERIMENTAL

Preparation of the electroactive substance (the liquid membrane)

In order to obtain the liquid membrane, the procedure is as follows: 10 ml of $10^{-2}M$ glycine and 10 ml of $5 \times 10^{-2}M$ ninhydrin are introduced into a U-shaped glass tube with stop-cocks at both ends. One of the stop-cocks is kept closed, while the other is connected with a rubber tube to a water-filled graduated cylinder. The U-tube is placed in a bath of boiling water. The reaction is finished when no more CO_2 evolves from the U-shaped tube. The product is a solution of the ammonium salt of DYDA. It is transferred to a 100-ml separating funnel, then 3 ml of $0{\cdot}1M$ nitric acid are added. DYDA (the free acid) is precipitated and is extracted with 25 ml of chloroform by shaking for 2 min. The organic layer (solution A) is transferred to another separating funnel containing 25 ml of $10^{-2}M$ mercuric nitrate. The acidity of the solution is adjusted to pH 6 with hexamine and the two phases are shaken for 2 min. The aqueous phase is transferred to another separating funnel and shaken with 25 ml of chloroform The organic phases are combined, dried by passage through anhydrous sodium sulphate and transferred to a 100-ml flask. This is solution B, the liquid membrane with a mercury(II) concentration of $5 \times 10^{-4}M$. The absorption spectra of solutions A and B have peaks at 480 and 520 nm respectively.

Construction of the electrode

This is done as described previously[9–11] by impregnating the support material (a hydrophobized graphite rod) with solution B. The internal reference electrode is eliminated by use of a stainless-steel wire introduced into the graphite rod. The electrode is stored in solution B.

RESULTS AND DISCUSSIONS

The electrode function

The emf measurements were made with the electrochemical cell

$$\begin{array}{c|c|c|c} \text{Hg}^{2+}\text{-sensitive electrode} & \text{Hg}^{2+}(C_{\text{Hg}^{2+}}),\ \mu = 0.4\ (\text{KNO}_3) & \begin{array}{c}\text{KNO}_3\\ \text{std.}\end{array} & \text{SCE} \end{array} \qquad (\text{I})$$

where $C_{Hg^{2+}}$ represents the Hg^{2+} concentration, varying from 10^{-1} to $10^{-6}M$. The emf of cell (I) is given by

$$E_I = E'_0 + 0.031 \log [\mathrm{Hg}^{2+}] \qquad (1)$$

in the range 10^{-1}–$10^{-5}M$ Hg^{2+} concentration; E'_0 represents the conditional standard potential of the electrode. The measurements were carried out at constant ionic strength ($\mu = 0.4$, KNO_3), and the junction potential was kept constant.

The fact that we cannot obtain better sensitivities for this electrode is probably due to the absorption of Hg^{2+} at the end of the electrolyte bridge and on the surface of the glass vessel.

Influence of pH

In Fig. 1 we show the effect of pH on the response of the electrode at different mercury(II) concentrations.

The pH range in which the potential remains constant is relatively narrow because of the hydrolysis of Hg^{2+}. The direct potential measurements for calibration of the electrode were done at pH 1 (adjusted with nitric acid).

Response time of the electrode

The response characteristics of the electrode were evaluated by introducing the electrode into mercuric nitrate solutions of different concentrations but of identical acidity (pH 1) and noting the emf values as a function of time. A Servogor^{S} potentiometric recorder (Goerz Electro, Vienna) was used. The response time of the electrode is

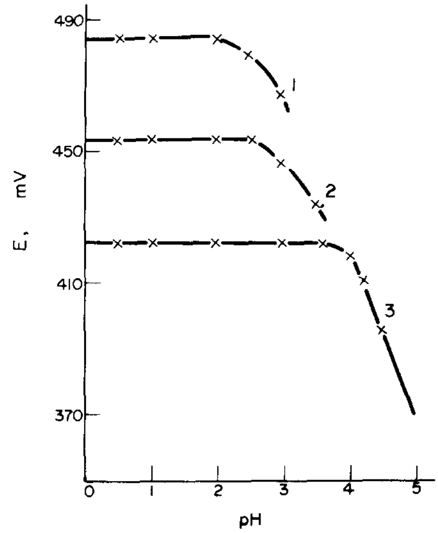


Fig 1. Influence of pH on the response of the electrode for different Hg(NO$_3$)$_2$ concentrations ($\mu = 0.4$, KNO$_3$) *1*—10^{-1}*M*, *2*—10^{-2}*M*, *3*—10^{-3}*M*.

EXTRACTION-SPECTROPHOTOMETRIC DETERMINATION OF ZINC(II) WITH 4-(2-PYRIDYLAZO)-RESORCINOL AND A QUATERNARY AMMONIUM SALT

D. Nonova, V. Nenov and N. Lihareva
Department of Analytical Chemistry, University of Sofia, 1 Anton Ivanov Avenue, Sofia 26, Bulgaria

(*Received* 19 *November* 1975. *Accepted* 23 *February* 1976)

The object of this study was to develop a new, simple and highly sensitive spectrophotometric method for zinc determination. Recent studies have shown that the quaternary ammonium salts, when used to extract chelates in the form of an ion-association complex, improve the quality of spectrophotometric methods.[1–7] Accordingly we decided to investigate whether the sensitive reaction between zinc(II) and 4-(2-pyridylazo)-resorcinol (PAR),[8] could be enhanced by extraction in the presence of cetyldimethylbenzylammonium chloride (CDBA), just as the determination of zinc with PAN is improved by addition of the surfactant Triton-X-100.[9]

EXPERIMENTAL

Apparatus

A Carl Zeiss VSU-1 universal spectrophotometer was used for the accurate absorbance measurements and a Zeiss SPECORD-UV-VIS spectrophotometer for recording the spectra.

The precise pH values were measured with a digital Radiometer pH-meter PHM 52; A Seibold pH-meter, type GLD was used for analytical purposes.

Reagents

Standard zinc solution A known weight of pure zinc was dissolved in hydrochloric acid[10] or 0.1*M* perchloric acid and diluted to known volume.

4-(2-Pyridylazo)-resorcinol, monosodium salt. A $10^{-4}M$ solution was standardized by spectrophotometric titration with copper(II) nitrate solution at pH 5 and 520 nm.[11] More dilute solutions ($10^{-5}M$) were also used. An aqueous 0.01% (w/v) solution was used for the analytical studies.

Cetyldimethylbenzylammonium chloride. A 0.002*M* solution was prepared by dissolving 0.082 g of the quaternary salt in 100 ml of distilled water

Buffer solutions pH 9.5–11.5. Mixtures of 0.2*M* sodium bicarbonate and 0 2*M* sodium carbonate[12] were used. At pH above, 11.5, 0.1*M* sodium hydroxide was used.

Standard cadmium solution. A 0.01*M* stock solution was standardized complexometrically and diluted as required.

Sodium diethyldithiocarbamate. A 0.1% (w/v) aqueous solution.

All other chemicals used were of analytical-reagent grade.

Extraction procedure

Place an aliquot of the sample solution containing not more than 50 μg of zinc in a 50-ml volumetric flask, add 10 ml of 0.01% PAR solution, 5 ml of bicarbonate–carbonate buffer solution (pH 9.7) and dilute to the mark. Pipette into a 100-ml separatory funnel an aliquot of this solution containing up to 5 μg of zinc. Add 1 ml of 0.002*M* CDBA solution and 5.00 ml of chloroform. Dilute with a little water (5–6 ml) and shake for about 1 min. Allow the layers to separate and run the pink chloroform extract into a 10-mm glass cell containing, if necessary, a small amount of anhydrous sodium sulphate crystals to remove the droplets of water. Measure the absorbance at 505 nm against a reagent blank as reference solution (the excess of PAR is also extracted).

RESULTS AND DISCUSSION

Absorption spectra sensitivity and accuracy

The absorption spectra of the zinc(II)–PAR complex and PAR in water, as well as their ion-association compounds in chloroform, were recorded. The extraction with the quaternary ammonium salt produces a small bathochromic shift for the metal complex (10 nm) and a hypsochromic shift for the chromogenic reagent (15 nm) but otherwise the spectra in the two phases are virtually identical. Thus the long-chain cation favourably influences the optical characteristics of the analytical system.

The colour appears immediately after shaking and the absorbance remains constant for at least 1 hr. Beer's law is valid up to an absorbance of 1.4, corresponding to a range of 0.2–1.2 ppm zinc. Two quite different standard zinc solutions ($10^{-5}M$ and 1 ppm) were used to calculate the conditional molar absorptivity, giving $9.14 \pm 0.21 \times 10^4$ and $9.21 \pm 0.26 \times 10^4$ $\text{l.mole}^{-1}.\text{cm}^{-1}$ respectively compared with 8.68×10^4 and 8.3×10^4 for aqueous solutions. This is an improvement over the dithizone procedure.

A series of solutions containing 0.129–0.645 ppm zinc were subjected to the procedure. Recoveries ranged from 99.2 to 101.1% with a standard deviation[13] of 0.0056 ppm.

Nature of the reaction

The reaction between zinc(II) and PAR in aqueous solution has been investigated in detail by several workers.[14–18] Kitano and Ueda[8] have discussed the analytical aspects of the reaction, and confirmed the composition of the chelate in alkaline medium to be Zn.PAR = 1:2. We verified the anionic nature of the chelate complex by determining the number of protons released during the complexation in equimolar solutions, using the following equation[19,20]

$$\log \beta_2' = \log K_{eq} + n\text{pH} \qquad (1)$$

The conditional stability constants β_2' were calculated and plotted against corresponding pH values. The plot gave a straight line with a slope $n = 2$ which led to $\log \beta_2 = 21.7 \pm 0.3$. This is in agreement with the results of Tanaka *et al.*[18] ($\log \beta_2 = 22.2 \pm 0.2$) and Corsini *et al.*[16] ($n = 2$), so in the pH range studied the reaction is

$$Zn^{2+} + 2HL^- = ZnL_2^{2-} + 2H^+ \qquad (2)$$

where L denotes PAR.

Effect of pH, and concentrations of PAR and CDBA

The absorbance depends on pH, but is constant over the range 9.5–11.5 (Fig. 1). Several standard buffer solutions were examined, but only with carbonate/bicarbonate was a clean separation of the layers obtained.

The amount of PAR added in aqueous solution was varied and the absorbance of the organic phase measured

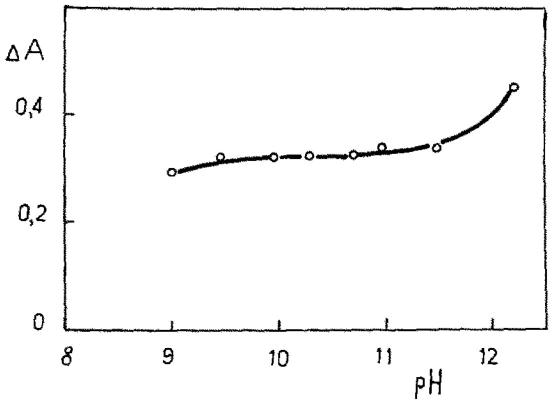

Fig. 1. Effect of pH (series of bicarbonate-carbonate buffer solutions). $C_{Zn} = 0.3$ ppm.

The results obtained are shown in Fig. 2. The absorbance increases rapidly on addition of the reagent to a mole-ratio of Zn:PAR = 1:4, whereas beyond this value the colour intensity is independent of the reagent concentration.

In the presence of a quaternary ammonium salt PAR is also extracted. Thus, the excess of both PAR and CDBA needed to ensure that PAR will always be extracted and transferred completely into the chloroform layer, must be established.

The extraction also depends on the excess of cationic surfactant, which affects the rate at which the two phases separate and remain clear. A very large excess of CDBA produces a stable emulsion on shaking so that the two liquids do not separate quickly. One ml of $2 \times 10^{-3}M$ CDBA solution proved adequate for the extraction and permitted satisfactory separation (Fig. 3).

Composition of the ion-association complexes

(*a*) The composition of the zinc(II)-PAR chelate in the organic phase was determined by the Job method.[21] This was done by extracting into the same volume of chloroform (5 ml) various ratios of the two equimolar solutions ($1.01 \times 10^{-5}M$) added to the aqueous phase in presence of a small excess of the quaternary ammonium salt and a buffer solution, which also kept the ionic strength constant. The molar ratio thus found was the same as in aqueous solution, 1:2.

(*b*) The composition of the Zn-PAR-CDBA ion-association compound was determined by extracting the three-component isomolar series prepared by varying the volumes of the three equimolar solutions ($1.01 \times 10^{-5}M$) of zinc, PAR and CDBA in such a way that the molar ratio of zinc:PAR was always 1:2 and the total volume was always the same (20 ml). The results obtained show that the stoichiometry of the complex is Zn:PAR:CDBA = 1:2:2, suggesting that the extracted species is $[Zn(PAR)_2](CDBA)_2$. The results were confirmed by other standard methods.

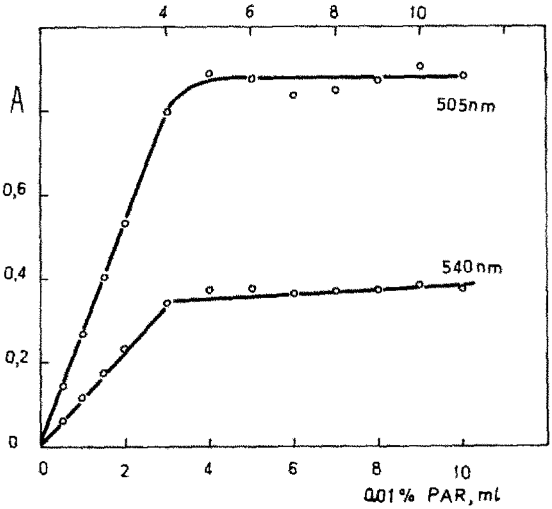

Fig. 2. Effect of PAR concentration on the absorbance of the complex in chloroform. $C_{Zn} = 0.5$ ppm (*vs.* water).

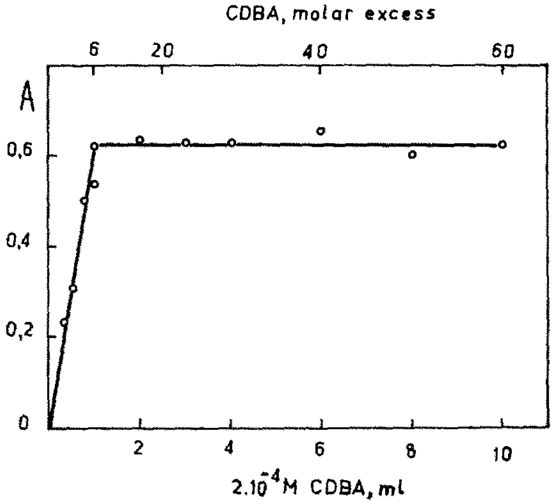

Fig. 3. Effect of CDBA concentration on the extractability of the system $C_{Zn} = 0.4$ ppm (*vs* water)

Effect of cadmium

Preliminary tests with several kinds of masking reagents for cadmium showed that only sodium diethyldithiocarbamate (DDTC) was satisfactory. In order to find the optimum conditions for determination of zinc without cadmium being simultaneously extracted, the mutual dependence of the DDTC and CDBA concentrations was studied. For these experiments [Cd] = [Zn] = 0.26 ppm. First [CDBA] was held constant (1 ml of $2 \times 10^{-3}M$ solution) and the volume of 0.01% DDTC varied, with the following results:

DDTC, *ml*:	0	0.1	0.25	0.5	1.0	1.5
Absorbance.	0.364	0.352	0.365	0.345	0.348	0.327

Then the level of DDTC was fixed at 0.25 ml whilst the volume of CDBA was varied:

CDBA, *ml*.	0	0.1	0.25	0.5	1.0
Absorbance:	0.364	0.269	0.353	0.372	0.365

These results enable optimum concentrations of DDTC and CDBA to be selected. The zinc solution should be diluted to at least 20 ml before the extraction, otherwise zinc will be partially masked, and the buffer solution should be added after the reagent to prevent the precipitation of cadmium. The results obtained by the modified procedure are given in Table 1.

It is evident that cadmium can be tolerated in up to 50-fold w/w ratio. This is a better selectivity than that of the dithizone method.

Preliminary investigations on the influence of DDTC on strongly interfering cations such as cobalt(II), nickel and copper(II) were also performed It was found that these metals are masked when present in the same amount as the zinc Cobalt and nickel can be tolerated up to a weight ratio Zn:Me = 1:10, while copper is tolerated at a ratio 1:2.5. These investigations will be extended to other interfering ions. Further work on the analytical application of the method will also be carried out and presented later

Table 1. Effect of cadmium(II) on the determination of zinc(II) with DDTC as masking agent (0.26 ppm Zn, 505 nm, 10-mm cell)

Weight ratio Zn:Cd	Absorbance	Zn found, *ppm*
1:0	0.364	
1:1	0.364	0.260

Summary—A simple and selective extraction spectrophotometric determination of zinc is described. The complex $[Zn(PAR)_2](CDBA)_2$, where PAR is the 4-(2-pyridylazo)resorcinol anion and CDBA is cetyldimethylbenzylammonium ion, is extracted from a solution buffered at pH 9.7 with carbonate/bicarbonate. Beer's law is obeyed over the range 0.2–1.2 ppm zinc, the molar absorptivity being 9.2×10^4 $l.mole^{-1}.cm^{-1}$. The precision in this range is 0.0056 ppm. Cadmium in up to a 50-fold w/w ratio may be masked with diethyldithiocarbamate.

DETERMINATION OF BARIUM AND STRONTIUM PEROXIDES (ACTIVE OXYGEN) IN IGNITERS IN SMALL-ARMS TRACER AMMUNITION

George Norwitz and Michael Galan
Frankford Arsenal, Philadelphia, PA 19137, U.S.A.

(*Received* 24 *October* 1975. *Accepted* 15 *December* 1975)

Tracer ammunition for both small arms and artillery is used for determining range and for directing fire. The tracer compositions in such ammunition are set off by igniters which may contain barium or strontium peroxide (oxidizers), calcium resinate, "Parlon" and zinc stearate (binders and fuels), magnesium powder (fuel), and Toluidine Red toner (identifying colouring agent and fuel). It has been noted by ammunition experts for many years that the igniters (and consequently the rounds of tracer ammunition) are inclined to lose their effectiveness with time and it has been suggested that this deterioration is caused by decomposition of the peroxide. However, this has never been proved, because of the lack of satisfactory analytical methods.

In view of the need, this arsenal undertook an investigation to develop a method for determining peroxide (active oxygen) in igniters in small-arms tracer ammunition. Many methods that had been previously used for determining peroxide in various materials were considered. The most common method for determining peroxide is the titrimetric permanganate method.[1–5] Other titrimetric methods that have been used involve ceric sulphate, potassium iodide, sodium thiosulphate, titanous chloride, and sodium nitrite.[1,5,6] Another method for peroxide is the eudiometric method whereby the volume of oxygen generated on decomposition is measured.[6] Spectrophotometric methods that have been proposed include the use of the titanium–peroxide complex,[5–9] permanganate decolorization,[5,6] ferric thiocyanate,[6] starch–iodide,[6–10] and ferroin[11] reactions.

The permanganate titrimetric method was found to be unreliable for the determination of peroxides in igniters because of interference from organic matter and magnesium powder. It is possible that some other titrimetric reagent could be used, but this approach was not pursued because a titrimetric method would not be applicable in any case to the accurate determination of the small amount of igniter to be found in ammunition. The eudiometer method was not applicable because of interference from hydrogen generated by the magnesium. It seemed, therefore, that a spectrophotometric technique would be the most feasible means for determining peroxide in igniters. The titanium–peroxide method was selected as the most useful.

EXTRACTION-SPECTROPHOTOMETRIC DETERMINATION OF ZINC(II) WITH 4-(2-PYRIDYLAZO)-RESORCINOL AND A QUATERNARY AMMONIUM SALT

D. NONOVA, V. NENOV and N. LIHAREVA
Department of Analytical Chemistry, University of Sofia, 1 Anton Ivanov Avenue, Sofia 26, Bulgaria

(*Received* 19 *November* 1975. *Accepted* 23 *February* 1976)

The object of this study was to develop a new, simple and highly sensitive spectrophotometric method for zinc determination. Recent studies have shown that the quaternary ammonium salts, when used to extract chelates in the form of an ion-association complex, improve the quality of spectrophotometric methods.[1–7] Accordingly we decided to investigate whether the sensitive reaction between zinc(II) and 4-(2-pyridylazo)-resorcinol (PAR),[8] could be enhanced by extraction in the presence of cetyldimethylbenzylammonium chloride (CDBA), just as the determination of zinc with PAN is improved by addition of the surfactant Triton-X-100.[9]

EXPERIMENTAL

Apparatus

A Carl Zeiss VSU-1 universal spectrophotometer was used for the accurate absorbance measurements and a Zeiss SPECORD-UV-VIS spectrophotometer for recording the spectra.

The precise pH values were measured with a digital Radiometer pH-meter PHM 52; A Seibold pH-meter, type GLD was used for analytical purposes.

Reagents

Standard zinc solution A known weight of pure zinc was dissolved in hydrochloric acid[10] or $0.1M$ perchloric acid and diluted to known volume.

4-(2-Pyridylazo)-resorcinol, monosodium salt. A $10^{-4}M$ solution was standardized by spectrophotometric titration with copper(II) nitrate solution at pH 5 and 520 nm.[11] More dilute solutions ($10^{-5}M$) were also used. An aqueous 0.01% (w/v) solution was used for the analytical studies.

Cetyldimethylbenzylammonium chloride. A $0.002M$ solution was prepared by dissolving 0.082 g of the quaternary salt in 100 ml of distilled water

Buffer solutions pH 9.5–11.5. Mixtures of $0.2M$ sodium bicarbonate and $0.2M$ sodium carbonate[12] were used. At pH above, 11.5, $0.1M$ sodium hydroxide was used.

Standard cadmium solution. A $0.01M$ stock solution was standardized complexometrically and diluted as required.

Sodium diethyldithiocarbamate. A 0.1% (w/v) aqueous solution.

All other chemicals used were of analytical-reagent grade.

Extraction procedure

Place an aliquot of the sample solution containing not more than 50 μg of zinc in a 50-ml volumetric flask, add 10 ml of 0.01% PAR solution, 5 ml of bicarbonate–carbonate buffer solution (pH 9.7) and dilute to the mark. Pipette into a 100-ml separatory funnel an aliquot of this solution containing up to 5 μg of zinc. Add 1 ml of $0.002M$ CDBA solution and 5.00 ml of chloroform. Dilute with a little water (5–6 ml) and shake for about 1 min. Allow the layers to separate and run the pink chloroform extract into a 10-mm glass cell containing, if necessary, a small amount of anhydrous sodium sulphate crystals to remove the droplets of water. Measure the absorbance at 505 nm against a reagent blank as reference solution (the excess of PAR is also extracted).

RESULTS AND DISCUSSION

Absorption spectra sensitivity and accuracy

The absorption spectra of the zinc(II)–PAR complex and PAR in water, as well as their ion-association compounds in chloroform, were recorded. The extraction with the quaternary ammonium salt produces a small bathochromic shift for the metal complex (10 nm) and a hypsochromic shift for the chromogenic reagent (15 nm) but otherwise the spectra in the two phases are virtually identical. Thus the long-chain cation favourably influences the optical characteristics of the analytical system.

The colour appears immediately after shaking and the absorbance remains constant for at least 1 hr. Beer's law is valid up to an absorbance of 1.4, corresponding to a range of 0.2–1.2 ppm zinc. Two quite different standard zinc solutions ($10^{-5}M$ and 1 ppm) were used to calculate the conditional molar absorptivity, giving $9.14 \pm 0.21 \times 10^4$ and $9.21 \pm 0.26 \times 10^4$ $l.mole^{-1}.cm^{-1}$ respectively compared with 8.68×10^4 and 8.3×10^4 for aqueous solutions. This is an improvement over the dithizone procedure.

A series of solutions containing 0.129–0.645 ppm zinc were subjected to the procedure. Recoveries ranged from 99.2 to 101.1% with a standard deviation[13] of 0.0056 ppm.

Nature of the reaction

The reaction between zinc(II) and PAR in aqueous solution has been investigated in detail by several workers.[14–18] Kitano and Ueda[8] have discussed the analytical aspects of the reaction, and confirmed the composition of the chelate in alkaline medium to be Zn.PAR = 1:2. We verified the anionic nature of the chelate complex by determining the number of protons released during the complexation in equimolar solutions, using the following equation[19,20]

$$\log \beta'_2 = \log K_{eq} + n\text{pH} \qquad (1)$$

The conditional stability constants β'_2 were calculated and plotted against corresponding pH values. The plot gave a straight line with a slope $n = 2$ which led to $\log \beta_2 = 21.7 \pm 0.3$. This is in agreement with the results of Tanaka *et al.*[18] ($\log \beta_2 = 22.2 \pm 0.2$) and Corsini *et al.*[16] ($n = 2$), so in the pH range studied the reaction is

$$Zn^{2+} + 2HL^- = ZnL_2^{2-} + 2H^+ \qquad (2)$$

where L denotes PAR.

Effect of pH, and concentrations of PAR and CDBA

The absorbance depends on pH, but is constant over the range 9.5–11.5 (Fig. 1). Several standard buffer solutions were examined, but only with carbonate/bicarbonate was a clean separation of the layers obtained.

The amount of PAR added in aqueous solution was varied and the absorbance of the organic phase measured

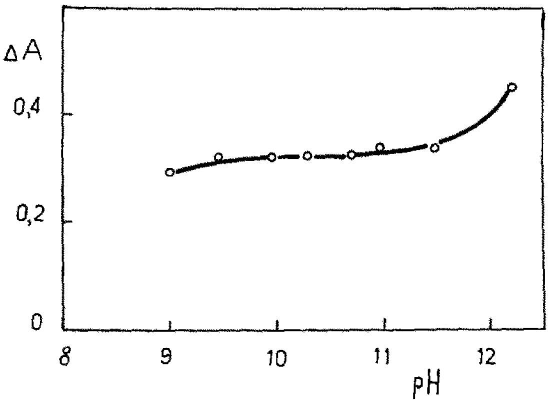

Fig. 1. Effect of pH (series of bicarbonate-carbonate buffer solutions). $C_{Zn} = 0.3$ ppm.

The results obtained are shown in Fig. 2. The absorbance increases rapidly on addition of the reagent to a mole-ratio of Zn:PAR = 1:4, whereas beyond this value the colour intensity is independent of the reagent concentration.

In the presence of a quaternary ammonium salt PAR is also extracted. Thus, the excess of both PAR and CDBA needed to ensure that PAR will always be extracted and transferred completely into the chloroform layer, must be established.

The extraction also depends on the excess of cationic surfactant, which affects the rate at which the two phases separate and remain clear. A very large excess of CDBA produces a stable emulsion on shaking so that the two liquids do not separate quickly. One ml of $2 \times 10^{-3}M$ CDBA solution proved adequate for the extraction and permitted satisfactory separation (Fig. 3).

Composition of the ion-association complexes

(*a*) The composition of the zinc(II)–PAR chelate in the organic phase was determined by the Job method.[21] This was done by extracting into the same volume of chloroform (5 ml) various ratios of the two equimolar solutions ($1.01 \times 10^{-5}M$) added to the aqueous phase in presence of a small excess of the quaternary ammonium salt and a buffer solution, which also kept the ionic strength constant. The molar ratio thus found was the same as in aqueous solution, 1:2.

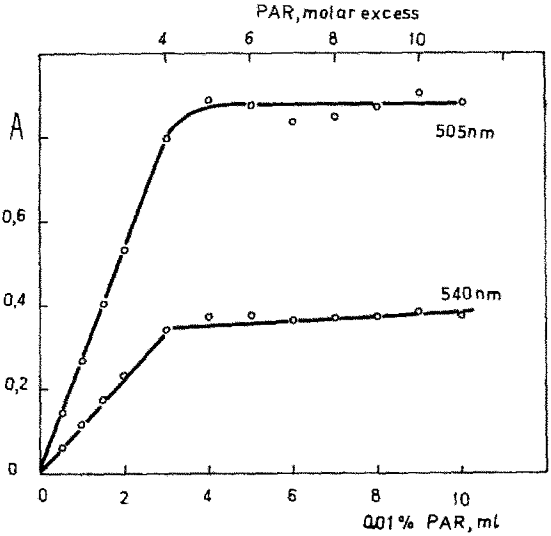

Fig. 2. Effect of PAR concentration on the absorbance of the complex in chloroform. $C_{Zn} = 0.5$ ppm (*vs.* water).

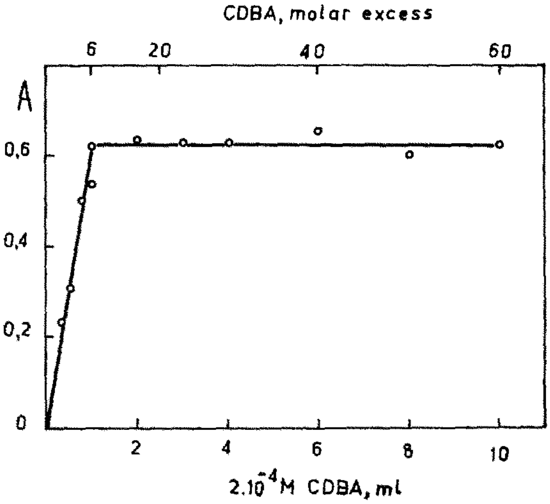

Fig. 3. Effect of CDBA concentration on the extractability of the system $C_{Zn} = 0.4$ ppm (*vs* water)

(*b*) The composition of the Zn–PAR–CDBA ion-association compound was determined by extracting the three-component isomolar series prepared by varying the volumes of the three equimolar solutions ($1.01 \times 10^{-5}M$) of zinc, PAR and CDBA in such a way that the molar ratio of zinc:PAR was always 1:2 and the total volume was always the same (20 ml). The results obtained show that the stoichiometry of the complex is Zn:PAR:CDBA = 1:2:2, suggesting that the extracted species is $[Zn(PAR)_2](CDBA)_2$. The results were confirmed by other standard methods.

Effect of cadmium

Preliminary tests with several kinds of masking reagents for cadmium showed that only sodium diethyldithiocarbamate (DDTC) was satisfactory. In order to find the optimum conditions for determination of zinc without cadmium being simultaneously extracted, the mutual dependence of the DDTC and CDBA concentrations was studied. For these experiments [Cd] = [Zn] = 0.26 ppm. First [CDBA] was held constant (1 ml of $2 \times 10^{-3}M$ solution) and the volume of 0.01% DDTC varied, with the following results:

DDTC, *ml*:	0	0.1	0.25	0.5	1.0	1.5
Absorbance.	0.364	0.352	0.365	0.345	0.348	0.327

Then the level of DDTC was fixed at 0.25 ml whilst the volume of CDBA was varied:

CDBA, *ml*.	0	0.1	0.25	0.5	1.0
Absorbance:	0.364	0.269	0.353	0.372	0.365

These results enable optimum concentrations of DDTC and CDBA to be selected. The zinc solution should be diluted to at least 20 ml before the extraction, otherwise zinc will be partially masked, and the buffer solution should be added after the reagent to prevent the precipitation of cadmium. The results obtained by the modified procedure are given in Table 1.

It is evident that cadmium can be tolerated in up to 50-fold w/w ratio. This is a better selectivity than that of the dithizone method.

Preliminary investigations on the influence of DDTC on strongly interfering cations such as cobalt(II), nickel and copper(II) were also performed. It was found that these metals are masked when present in the same amount as the zinc. Cobalt and nickel can be tolerated up to a weight ratio Zn:Me = 1:10, while copper is tolerated at a ratio 1:2.5. These investigations will be extended to other interfering ions. Further work on the analytical application of the method will also be carried out and presented later

Table 1. Effect of cadmium(II) on the determination of zinc(II) with DDTC as masking agent (0.26 ppm Zn, 505 nm, 10-mm cell)

DETERMINATION OF BARIUM AND STRONTIUM PEROXIDES (ACTIVE OXYGEN) IN IGNITERS IN SMALL-ARMS TRACER AMMUNITION

George Norwitz and Michael Galan
Frankford Arsenal, Philadelphia, PA 19137, U.S.A.

(*Received* 24 *October* 1975. *Accepted* 15 *December* 1975)

Tracer ammunition for both small arms and artillery is used for determining range and for directing fire. The tracer compositions in such ammunition are set off by igniters which may contain barium or strontium peroxide (oxidizers), calcium resinate, "Parlon" and zinc stearate (binders and fuels), magnesium powder (fuel), and Toluidine Red toner (identifying colouring agent and fuel). It has been noted by ammunition experts for many years that the igniters (and consequently the rounds of tracer ammunition) are inclined to lose their effectiveness with time and it has been suggested that this deterioration is caused by decomposition of the peroxide. However, this has never been proved, because of the lack of satisfactory analytical methods.

In view of the need, this arsenal undertook an investigation to develop a method for determining peroxide (active oxygen) in igniters in small-arms tracer ammunition. Many methods that had been previously used for determining peroxide in various materials were considered. The most common method for determining peroxide is the titrimetric permanganate method.[1–5] Other titrimetric methods that have been used involve ceric sulphate, potassium iodide, sodium thiosulphate, titanous chloride, and sodium nitrite.[1,5,6] Another method for peroxide is the eudiometric method whereby the volume of oxygen generated on decomposition is measured.[6] Spectrophotometric methods that have been proposed include the use of the titanium–peroxide complex,[5–9] permanganate decolorization,[5,6] ferric thiocyanate,[6] starch–iodide,[6–10] and ferroin[11] reactions.

The permanganate titrimetric method was found to be unreliable for the determination of peroxides in igniters because of interference from organic matter and magnesium powder. It is possible that some other titrimetric reagent could be used, but this approach was not pursued because a titrimetric method would not be applicable in any case to the accurate determination of the small amount of igniter to be found in ammunition. The eudiometer method was not applicable because of interference from hydrogen generated by the magnesium. It seemed, therefore, that a spectrophotometric technique would be the most feasible means for determining peroxide in igniters. The titanium–peroxide method was selected as the most useful.

Summary—A simple and selective extraction spectrophotometric determination of zinc is described. The complex $[Zn(PAR)_2](CDBA)_2$, where PAR is the 4-(2-pyridylazo)resorcinol anion and CDBA is cetyldimethylbenzylammonium ion, is extracted from a solution buffered at pH 9.7 with carbonate/bicarbonate. Beer's law is obeyed over the range 0.2–1.2 ppm zinc, the molar absorptivity being 9.2×10^4 l.mole^{-1}.cm^{-1}. The precision in this range is 0.0056 ppm. Cadmium in up to a 50-fold w/w ratio may be masked with diethyldithiocarbamate.

DETERMINATION OF BARIUM AND STRONTIUM PEROXIDES (ACTIVE OXYGEN) IN IGNITERS IN SMALL-ARMS TRACER AMMUNITION

George Norwitz and Michael Galan
Frankford Arsenal, Philadelphia, PA 19137, U.S.A.

(*Received* 24 *October* 1975. *Accepted* 15 *December* 1975)

Tracer ammunition for both small arms and artillery is used for determining range and for directing fire. The tracer compositions in such ammunition are set off by igniters which may contain barium or strontium peroxide (oxidizers), calcium resinate, "Parlon" and zinc stearate (binders and fuels), magnesium powder (fuel), and Toluidine Red toner (identifying colouring agent and fuel). It has been noted by ammunition experts for many years that the igniters (and consequently the rounds of tracer ammunition) are inclined to lose their effectiveness with time and it has been suggested that this deterioration is caused by decomposition of the peroxide. However, this has never been proved, because of the lack of satisfactory analytical methods.

In view of the need, this arsenal undertook an investigation to develop a method for determining peroxide (active oxygen) in igniters in small-arms tracer ammunition. Many methods that had been previously used for determining peroxide in various materials were considered. The most common method for determining peroxide is the titrimetric permanganate method.[1–5] Other titrimetric methods that have been used involve ceric sulphate, potassium iodide, sodium thiosulphate, titanous chloride, and sodium nitrite.[1,5,6] Another method for peroxide is the eudiometric method whereby the volume of oxygen generated on decomposition is measured.[6] Spectrophotometric methods that have been proposed include the use of the titanium–peroxide complex,[5–9] permanganate decolorization,[5,6] ferric thiocyanate,[6] starch–iodide,[6–10] and ferroin[11] reactions.

The permanganate titrimetric method was found to be unreliable for the determination of peroxides in igniters because of interference from organic matter and magnesium powder. It is possible that some other titrimetric reagent could be used, but this approach was not pursued because a titrimetric method would not be applicable in any case to the accurate determination of the small amount of igniter to be found in ammunition. The eudiometer method was not applicable because of interference from hydrogen generated by the magnesium. It seemed, therefore, that a spectrophotometric technique would be the most feasible means for determining peroxide in igniters. The titanium–peroxide method was selected as the most useful.

EXPERIMENTAL

Reagents

Titanium solution. Weigh 2.00 g of titanium sponge into

a 250-ml beaker, add 90 ml of concentrated hydrochloric acid, cover with a watch-glass, and warm on the hot-plate to dissolve. Maintain the volume of hydrochloric acid at 75–90 ml during the dissolution process. After the metal has completely dissolved, add 1 ml of concentrated nitric acid and boil for 1 min Cool and dilute to 200 ml in a volumetric flask

Barium peroxide, MIL-B-153A, Grade B,[2] or equivalent (the sample used in this work contained 8.9% active oxygen).

Strontium peroxide, MIL-S-612B, Grade B,[3] or equivalent (the sample used in this work contained 12.7% active oxygen).

Magnesium powder, MIL-M-382B, Type III, Granulation 12, nominal mesh size 120–200,[12] or equivalent.

Calcium resinate, MIL-C-20470A, Type II.[13]

"Parlon" (chlorinated rubber), MIL-R-60671 [14]

Zinc stearate, USP [15]

Toluidine Red toner, TT-P-445.[16]

Preparation of calibration curves

Barium peroxide. Transfer 0.20–0 21 g of barium peroxide (weighed to 0.1 mg) to a 150-ml beaker. Add 100 ml of dilute hydrochloric acid (1 + 9) and allow to stand with occasional stirring until the sample has dissolved (10–30 min) Dilute to 250 ml in a volumetric flask. Transfer 5.0, 10 0, 15.0, 20.0, and 25.0-ml aliquots to 100-ml volumetric flasks and dilute to about 35 ml with water. Add sufficient concentrated hydrochloric acid to bring its total content in each flask to 5 ml Dilute to about 75 ml with water and add 5.0 ml of titanium solution. Dilute to the mark and within 1 hr measure the absorbance at 410 nm against the reagent blank. Plot mg of barium peroxide (per 100 ml) against absorbance.

Strontium peroxide. Transfer 0.15–0.16 g of strontium peroxide (weighed to 0.1 mg) to a 150-ml beaker and proceed as described for the calibration curve for barium peroxide, but use 5.0, 10.0, 15.0, 17.5, and 20.0-ml aliquots. Plot mg of strontium peroxide (per 100 ml) against absorbance

Procedure

Igniter mixes. Transfer about 0.20 g of sample (weighed to 0 1 mg) to a 150-ml beaker. Add 100 ml of dilute hydrochloric acid (1 + 9) all at once. Allow to stand with occasional stirring until the barium or strontium peroxide has dissolved (10–30 min). Within 30 min after dissolution, filter through a Whatman No. 41 filter paper, wash with water, and dilute to the mark in a 250 ml volumetric flask. Transfer an aliquot, containing 13–20 mg of barium peroxide or 10–15 mg of strontium peroxide, to a 100-ml volumetric flask and dilute to about 35 ml. Add sufficient concentrated hydrochloric acid to bring its total content in the flask to 5 ml, dilute to about 75 ml with water, add 5 ml of titanium solution, dilute to the mark, and within 1 hr measure the absorbance at 410 nm against a reagent blank Find the number of mg of barium or strontium peroxide from the calibration curve and calculate the barium or strontium peroxide content as follows:

$$\% \, BaO_2 \text{ or } SrO_2 = \frac{\text{mg of } BaO_2 \text{ or } SrO_2 \text{ read from curve}}{\text{g of sample in aliquot}} \times 0{\cdot}101$$

Igniters contained in small-arms tracer ammunition. Remove the bullet from the round Working behind a safety shield, cut through the exterior of the bullet jacket lengthwise on both sides with a handsaw to just sufficient depth to be able to reach the tracer and igniter. Take care not to overheat the bullet during cutting, since overheating might cause some decomposition of the peroxide and constitute a hazard. Pull off one side of the jacket with a suitable instrument. Remove the igniter mix and store it in a closed bottle. Transfer a weighed sample to a 150-ml beaker, add 35–100 ml of dilute hydrochloric acid (1 + 9), allow to stand until the barium or strontium peroxide has dissolved, filter, wash, and dilute to volume in a volumetric flask (the amount of hydrochloric acid and the volume of the flask will depend on the amount of sample). Transfer an appropriate aliquot to a 100-ml volumetric flask and proceed as described for barium and strontium peroxides in igniter mixes.

DISCUSSION AND RESULTS

The magnesium metal dissolves almost instantaneously on adding 100 ml of hydrochloric acid (1 + 9) at room temperature and all at once; then the barium or strontium peroxide dissolves slowly in 10–30 min The extremely rapid dissolution of the magnesium minimizes the interference of magnesium If a more concentrated hydrochloric acid solution were used, the barium and strontium peroxides would dissolve simultaneously with the magnesium, causing lower results. The acid dissolution process must be conducted at room temperature. If the solutions were cooled, the magnesium would not dissolve instantly, causing lower results. The organic matter contained in the igniters does not dissolve in the acid and is filtered off and does not seem to interfere. In spite of all precautions, however, preliminary work with synthetic samples showed that the recoveries for peroxides were slightly low; therefore, it was decided on the basis of the preliminary work to multiply the calculated result by the empirical factor 1·01.

Hydrochloric acid is used rather than sulphuric acid because the latter would precipitate barium and strontium sulphates.

The acidity of the solution in which the titanium peroxide colour is developed is about 1.8*N*. This acidity is not critical since the permissible range is about 1·5–3·5*N* [17]

Full colour development was achieved with 5 ml of the titanium solution. Our titanium solution was prepared from the metal because that could be readily obtained in high purity. Nitric acid must be used in oxidizing Ti(III) to Ti(IV); oxidizing with hydrogen peroxide and subsequent boiling to destroy the peroxide caused hydrolysis of the titanium. The calibration curves followed Beer's law.

All the calculations for the barium and strontium peroxides in igniters were relative to the original barium and strontium peroxides which were arbitrarily taken to be 100% pure. This mode of calculation was chosen because the prime aim of the investigation was to determine whether there had been degradation of the barium or strontium peroxide in the igniters

If it were desired to make the calculation for the igniters in terms of active oxygen it would first be necessary to determine the active oxygen content of the barium and strontium peroxides used for preparing the calibration curves and then plot mg of active oxygen (per 100 ml) against absorbance. This would be a relatively simple matter.

The active oxygen of barium and strontium peroxide can be defined as the per cent oxygen (by weight) released when the peroxide reverts to the simple oxide (*e.g.*, $2BaO_2 \rightarrow 2BaO + O_2$). The active oxygen content of these materials is best determined by titration with permanganate in a perchloric–phosphoric acid medium.[2,3] The theoretical oxygen contents of barium and strontium peroxide are 9.45% and 13.38%, respectively The military specifications for barium and strontium peroxides[2,3] call for a minimum active oxygen content of 8.5% and 12 3%, respectively. However, according to the experience of this arsenal over many years, the active oxygen content of the barium peroxide and strontium peroxide used in the preparation of igniters varies from 8.8 to 9.0% for barium peroxide and from 12 5 to 12.8% for strontium peroxide (and does not change significantly for 2 or 3 years if the two

Table 1. Nominal composition of igniters used in small-arms tracer ammunition

Igniter	Nominal composition
I-280	76.5 SrO_2, 15.0 Mg, 8.5 Ca resinate
I-276	83.5 BaO_2, 15.0 Mg, 1.0 Zn stearate, 0.5 Toluidine Red toner
I-508	79.0 BaO_2, 14.1 Mg, 5.5 "Parlon", 0.9 Zn stearate, 0.5 Toluidine Red toner

materials are stored in air-tight containers). The cited ranges for active oxygen are equivalent to 93.1–95.2% pure barium peroxide and 93.4–95.7% pure strontium peroxide, respectively. Rosin[4] and the Fisher Scientific Co.[18] specify a minimum barium peroxide content of 88% and 85%, respectively, for reagent-grade barium peroxide. There is no specification for reagent-grade strontium peroxide.

The nominal compositions of the common igniter mixes used in small-arms tracer ammunition by the U.S. Army are shown in Table 1.

The results obtained for barium and strontium peroxides in synthetic igniter mixes are shown in Table 2. The recoveries were satisfactory (the average for all the runs was 100.2%).

The results obtained for peroxide in three actual production igniter mixes stored in closed containers for about a year are shown in Table 3. The results obtained for an igniter in a batch of ammunition several years old were 57.0, 49.0 and 53.3% BaO_2, the nominal content being 79.0% BaO_2 (each result represents an individual round). It is seen that two of three actual igniter mixes showed some deterioration while the igniter in the ammunition showed marked deterioration.

Summary—A method is proposed for the determination of barium and strontium peroxides (active oxygen) in igniters in small-arms tracer ammunition. The sample is treated with dilute hydrochloric acid (1 + 9) which dissolves the magnesium powder almost instantaneously and then dissolves the barium or strontium peroxides within 10–30 min. The solution is then filtered to remove the organic substances (calcium resinate, "Parlon". Toluidine Red toner, and zinc stearate) and the peroxide is determined by means of the colour of the titanium–peroxide complex. It is shown that igniter mixes and igniters used in small-arms tracer ammunition deteriorate on storage.

DETERMINATION OF BARIUM AND STRONTIUM PEROXIDES (ACTIVE OXYGEN) IN IGNITERS IN SMALL-ARMS TRACER AMMUNITION

George Norwitz and Michael Galan
Frankford Arsenal, Philadelphia, PA 19137, U.S.A.

(*Received* 24 *October* 1975. *Accepted* 15 *December* 1975)

Tracer ammunition for both small arms and artillery is used for determining range and for directing fire. The tracer compositions in such ammunition are set off by igniters which may contain barium or strontium peroxide (oxidizers), calcium resinate, "Parlon" and zinc stearate (binders and fuels), magnesium powder (fuel), and Toluidine Red toner (identifying colouring agent and fuel). It has been noted by ammunition experts for many years that the igniters (and consequently the rounds of tracer ammunition) are inclined to lose their effectiveness with time and it has been suggested that this deterioration is caused by decomposition of the peroxide. However, this has never been proved, because of the lack of satisfactory analytical methods.

In view of the need, this arsenal undertook an investigation to develop a method for determining peroxide (active oxygen) in igniters in small-arms tracer ammunition. Many methods that had been previously used for determining peroxide in various materials were considered. The most common method for determining peroxide is the titrimetric permanganate method.[1–5] Other titrimetric methods that have been used involve ceric sulphate, potassium iodide, sodium thiosulphate, titanous chloride, and sodium nitrite.[1,5,6] Another method for peroxide is the eudiometric method whereby the volume of oxygen generated on decomposition is measured.[6] Spectrophotometric methods that have been proposed include the use of the titanium–peroxide complex,[5–9] permanganate decolorization,[5,6] ferric thiocyanate,[6] starch–iodide,[6–10] and ferroin[11] reactions.

The permanganate titrimetric method was found to be unreliable for the determination of peroxides in igniters because of interference from organic matter and magnesium powder. It is possible that some other titrimetric reagent could be used, but this approach was not pursued because a titrimetric method would not be applicable in any case to the accurate determination of the small amount of igniter to be found in ammunition. The eudiometer method was not applicable because of interference from hydrogen generated by the magnesium. It seemed, therefore, that a spectrophotometric technique would be the most feasible means for determining peroxide in igniters. The titanium–peroxide method was selected as the most useful.

Titanium solution. Weigh 2.00 g of titanium sponge into

a 250-ml beaker, add 90 ml of concentrated hydrochloric acid, cover with a watch-glass, and warm on the hot-plate to dissolve. Maintain the volume of hydrochloric acid at 75–90 ml during the dissolution process. After the metal has completely dissolved, add 1 ml of concentrated nitric acid and boil for 1 min Cool and dilute to 200 ml in a volumetric flask

Barium peroxide, MIL-B-153A, Grade B,[2] or equivalent (the sample used in this work contained 8.9% active oxygen).

Strontium peroxide, MIL-S-612B, Grade B,[3] or equivalent (the sample used in this work contained 12.7% active oxygen).

Magnesium powder, MIL-M-382B, Type III, Granulation 12, nominal mesh size 120–200,[12] or equivalent.

Calcium resinate, MIL-C-20470A, Type II.[13]

"Parlon" (chlorinated rubber), MIL-R-60671 [14]

Zinc stearate, USP [15]

Toluidine Red toner, TT-P-445.[16]

Preparation of calibration curves

Barium peroxide. Transfer 0.20–0.21 g of barium peroxide (weighed to 0.1 mg) to a 150-ml beaker. Add 100 ml of dilute hydrochloric acid (1 + 9) and allow to stand with occasional stirring until the sample has dissolved (10–30 min) Dilute to 250 ml in a volumetric flask. Transfer 5.0, 10.0, 15.0, 20.0, and 25.0-ml aliquots to 100-ml volumetric flasks and dilute to about 35 ml with water. Add sufficient concentrated hydrochloric acid to bring its total content in each flask to 5 ml Dilute to about 75 ml with water and add 5.0 ml of titanium solution. Dilute to the mark and within 1 hr measure the absorbance at 410 nm against the reagent blank. Plot mg of barium peroxide (per 100 ml) against absorbance.

Strontium peroxide. Transfer 0.15–0.16 g of strontium peroxide (weighed to 0.1 mg) to a 150-ml beaker and proceed as described for the calibration curve for barium peroxide, but use 5.0, 10.0, 15.0, 17.5, and 20.0-ml aliquots. Plot mg of strontium peroxide (per 100 ml) against absorbance

Procedure

Igniter mixes. Transfer about 0.20 g of sample (weighed to 0.1 mg) to a 150-ml beaker. Add 100 ml of dilute hydrochloric acid (1 + 9) all at once. Allow to stand with occasional stirring until the barium or strontium peroxide has dissolved (10–30 min). Within 30 min after dissolution, filter through a Whatman No. 41 filter paper, wash with water, and dilute to the mark in a 250 ml volumetric flask. Transfer an aliquot, containing 13–20 mg of barium peroxide or 10–15 mg of strontium peroxide, to a 100-ml volumetric flask and dilute to about 35 ml. Add sufficient concentrated hydrochloric acid to bring its total content in the flask to 5 ml, dilute to about 75 ml with water, add 5 ml of titanium solution, dilute to the mark, and within 1 hr measure the absorbance at 410 nm against a reagent blank Find the number of mg of barium or strontium peroxide from the calibration curve and calculate the barium or strontium peroxide content as follows:

$$\% \text{ BaO}_2 \text{ or SrO}_2 = \frac{\text{mg of BaO}_2 \text{ or SrO}_2 \text{ read from curve}}{\text{g of sample in aliquot}} \times 0{\cdot}101$$

Igniters contained in small-arms tracer ammunition. Remove the bullet from the round Working behind a safety shield, cut through the exterior of the bullet jacket lengthwise on both sides with a handsaw to just sufficient depth to be able to reach the tracer and igniter. Take care not to overheat the bullet during cutting, since overheating might cause some decomposition of the peroxide and constitute a hazard. Pull off one side of the jacket with a suitable instrument. Remove the igniter mix and store it in a closed bottle. Transfer a weighed sample to a 150-ml beaker, add 35–100 ml of dilute hydrochloric acid (1 + 9), allow to stand until the barium or strontium peroxide has dissolved, filter, wash, and dilute to volume in a volumetric flask (the amount of hydrochloric acid and the volume of the flask will depend on the amount of sample). Transfer an appropriate aliquot to a 100-ml volumetric flask and proceed as described for barium and strontium peroxides in igniter mixes.

DISCUSSION AND RESULTS

The magnesium metal dissolves almost instantaneously on adding 100 ml of hydrochloric acid (1 + 9) at room temperature and all at once; then the barium or strontium peroxide dissolves slowly in 10–30 min The extremely rapid dissolution of the magnesium minimizes the interference of magnesium If a more concentrated hydrochloric acid solution were used, the barium and strontium peroxides would dissolve simultaneously with the magnesium, causing lower results. The acid dissolution process must be conducted at room temperature. If the solutions were cooled, the magnesium would not dissolve instantly, causing lower results. The organic matter contained in the igniters does not dissolve in the acid and is filtered off and does not seem to interfere. In spite of all precautions, however, preliminary work with synthetic samples showed that the recoveries for peroxides were slightly low; therefore, it was decided on the basis of the preliminary work to multiply the calculated result by the empirical factor 1.01.

Hydrochloric acid is used rather than sulphuric acid because the latter would precipitate barium and strontium sulphates.

The acidity of the solution in which the titanium peroxide colour is developed is about 1.8*N*. This acidity is not critical since the permissible range is about 1.5–3.5*N* [17]

Full colour development was achieved with 5 ml of the titanium solution. Our titanium solution was prepared from the metal because that could be readily obtained in high purity. Nitric acid must be used in oxidizing Ti(III) to Ti(IV); oxidizing with hydrogen peroxide and subsequent boiling to destroy the peroxide caused hydrolysis of the titanium. The calibration curves followed Beer's law.

All the calculations for the barium and strontium peroxides in igniters were relative to the original barium and strontium peroxides which were arbitrarily taken to be 100% pure. This mode of calculation was chosen because the prime aim of the investigation was to determine whether there had been degradation of the barium or strontium peroxide in the igniters

If it were desired to make the calculation for the igniters in terms of active oxygen it would first be necessary to determine the active oxygen content of the barium and strontium peroxides used for preparing the calibration curves and then plot mg of active oxygen (per 100 ml) against absorbance. This would be a relatively simple matter.

The active oxygen of barium and strontium peroxide can be defined as the per cent oxygen (by weight) released when the peroxide reverts to the simple oxide (*e.g.*, $2BaO_2 \rightarrow 2BaO + O_2$). The active oxygen content of these materials is best determined by titration with permanganate in a perchloric–phosphoric acid medium.[2,3] The theoretical oxygen contents of barium and strontium peroxide are 9.45% and 13.38%, respectively The military specifications for barium and strontium peroxides[2,3] call for a minimum active oxygen content of 8.5% and 12.3%, respectively. However, according to the experience of this arsenal over many years, the active oxygen content of the barium peroxide and strontium peroxide used in the preparation of igniters varies from 8.8 to 9.0% for barium peroxide and from 12.5 to 12.8% for strontium peroxide (and does not change significantly for 2 or 3 years if the two

Table 1. Nominal composition of igniters used in small-arms tracer ammunition

Igniter	Nominal composition
I-280	76.5 SrO_2, 15.0 Mg, 8.5 Ca resinate
I-276	83.5 BaO_2, 15.0 Mg, 1.0 Zn stearate, 0.5 Toluidine Red toner
I-508	79.0 BaO_2, 14.1 Mg, 5.5 "Parlon", 0.9 Zn stearate, 0.5 Toluidine Red toner

materials are stored in air-tight containers). The cited ranges for active oxygen are equivalent to 93.1–95.2% pure barium peroxide and 93.4–95.7% pure strontium peroxide, respectively. Rosin[4] and the Fisher Scientific Co.[18] specify a minimum barium peroxide content of 88% and 85%, respectively, for reagent-grade barium peroxide. There is no specification for reagent-grade strontium peroxide.

The nominal compositions of the common igniter mixes used in small-arms tracer ammunition by the U.S. Army are shown in Table 1.

The results obtained for barium and strontium peroxides in synthetic igniter mixes are shown in Table 2. The recoveries were satisfactory (the average for all the runs was 100.2%).

The results obtained for peroxide in three actual production igniter mixes stored in closed containers for about a year are shown in Table 3. The results obtained for an igniter in a batch of ammunition several years old were 57.0, 49.0 and 53.3% BaO_2, the nominal content being 79.0% BaO_2 (each result represents an individual round). It is seen that two of three actual igniter mixes showed some deterioration while the igniter in the ammunition showed marked deterioration.

Summary—A method is proposed for the determination of barium and strontium peroxides (active oxygen) in igniters in small-arms tracer ammunition. The sample is treated with dilute hydrochloric acid (1 + 9) which dissolves the magnesium powder almost instantaneously and then dissolves the barium or strontium peroxides within 10–30 min. The solution is then filtered to remove the organic substances (calcium resinate, "Parlon", Toluidine Red toner, and zinc stearate) and the peroxide is determined by means of the colour of the titanium–peroxide complex. It is shown that igniter mixes and igniters used in small-arms tracer ammunition deteriorate on storage.

DOSAGE PAR SPECTROMETRIE GAMMA NON DESTRUCTIVE DU MERCURE ET DE L'OR DANS L'EAU DE MER APRES PRECONCENTRATION PAR LE SULFURE DE PLOMB

S. ALEXANDROV
Faculté de Chimie, Université de Sofia, Bulgarie

(*Reçu le* 14 *octobre* 1975. *Accepté le* 28 *janvier* 1976)

A l'heure actuelle, le dosage du mercure dans l'eau est un problème étroitement lié au problème de la pollution de l'environnement. Par exemple, le mercure s'accumule dans le corps des poissons et peut mener à des empoisonnements graves. Dans une revue récente, Chilov[1] discute les méthodes de détermination de petites quantités de mercure. Quelques recherches importantes ont été consacrées au dosage du mercure dans l'eau.[2–6]

L'intérêt du dosage de l'or dans l'eau de mer provient des nombreuses tentatives d'extraction industrielle. Différentes méthodes de dosage de petites quantités d'or dans l'eau de mer sont connues.[7–26]

L'application des sorbants inorganiques dans la radiochimie analytique, en particulier dans l'analyse par activation, devient de plus en plus fréquente. Nous présentons ci-dessous nos résultats sur la rétention du mercure et de l'or de l'eau de mer par le sulfure de plomb en colonne, ainsi qu'une nouvelle méthode de dosage de ces éléments par analyse par activation sans séparation radiochimique.

PARTIE EXPERIMENTALE

Colonne

La colonne consiste en un tube de verre, dont la partie inférieure est rétrécie (0,3 cm de diamètre et 3 cm de hauteur). On y introduit 0,5 g de PbS sur un tampon de laine de verre. Le PbS est d'abord dégazé dans 25 ml de HNO_3 0,1 *N* à la température de 20 ± 2° pendant 15 mn, puis versé dans la colonne qu'on relie à un récipient contenant l'eau de mer (Fig. 1).

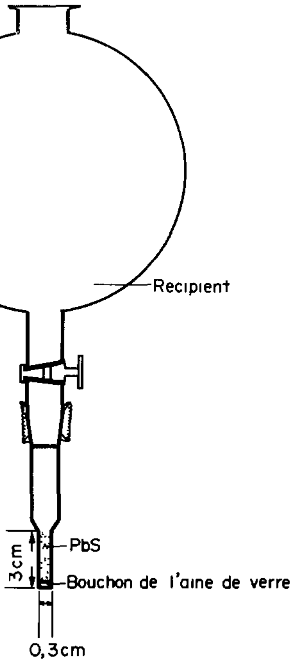

Fig. 1. Appareil utilisé pour la rétention du mercure et de l'or de l'eau de mer sur le PbS.

Reactifs et solutions

Le sulfure de plomb utilisé a été préparé à partir de plomb 99,9999% (Lead-Zinc Plant, Kirdzali, Bulgaria) ne contenant pas de mercure, d'argent et d'or en quantités détectables par radioactivation par neutrons thermiques. Le plomb a été dissous à l'aide de HNO_3 *p.a.* (2 + 1), puis PbS a été précipité par chauffage lent en présence de thioacétamide. Après 24 h de repos et centrifugation, le PbS a été seché a 50°. Le spectre de diffraction X a montré que le produit a la même structure que la galène. Il présente une granulométrie de l'ordre de 0,1 à 0,4 mm, permettant l'emploi facile en colonne. L'analyse par radioactivation par neutrons thermiques a indiqué que, dans le spectre gamma du PbS irradié pendant 6 h et mesuré 6 jours après la fin de l'irradiation, il n'y a pas de pics photoélectriques du mercure et de l'or (Fig. 2*a*).

La solution étalon de mercure a été preparée à partir de $Hg(NO_3)_2$, *p a.* La concentration précise a été déterminée par la méthode gravimétrique après précipitation du HgS[27]

La solution étalon d'or a été préparée par dissolution d'or métallique, *p.a.*

Les deux solutions étalons contenaient 10^{-3} g/ml de mercure et d'or. Les solutions diluées—$1 \cdot 10^{-6}$–$1 \cdot 10^{-8}$ g/ml de mercure et $1 \cdot 10^{-8}$–$1 \cdot 10^{-10}$ g/ml d'or—ont été préparées le jour de l'utilisation. Les solutions des traceurs ^{203}Hg et ^{198}Au ont été obtenues par radioactivation d'or en poudre et de $HgCl_2$ au réacteur suivie de la dissolution de l'or dans l'eau régale et du $HgCl_2$ dans l'eau. La concentration des solutions utilisées était de $1 \cdot 10^{-8}$–$1 \cdot 10^{-9}$ g/ml pour Au et de $1 \cdot 10^{-6}$–$1 \cdot 10^{-8}$ g/ml pour Hg.

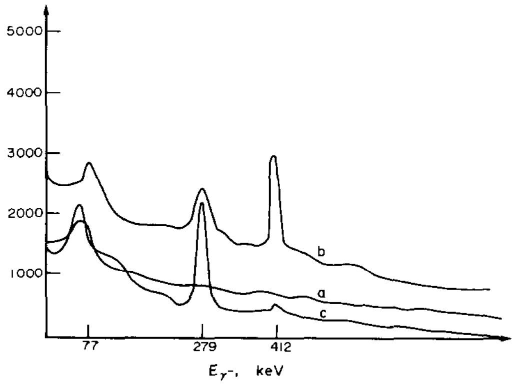

Fig. 2. Spectres gamma: (*a*) de 0,5 g du précipité de PbS irradié pendant 6 h dans un flux de $1{,}2 \cdot 10^{12}$ $n.cm^{-2}.sec^{-1}$, mesuré 6 jours après la fin de l'irradiation; (*b*) de l'étalon (0,5 g PbS + $1 \cdot 10^{-6}$ g Hg + $1 \cdot 10^{-8}$ g Au) irradié pendant 6 h, mesuré 6 jours après la fin de l'irradiation; (*c*) du même étalon, mesuré 15 jours après la fin de l'irradiation. Temps de comptage 15 mn

Irradiation des echantillons

Les échantillons ont été irradiés au réacteur IRT-2000 de FI ANEB, Sofia (Bulgarie) dans un flux de l'ordre de 10^{12} n.cm^{-2}.sec^{-1}. On a mis les échantillons dans de petits cachets de polyéthylène et ceux-ci dans de petites boites de polyéthylène. L'irradiation de PbS, contenant Hg et Au, donne ^{197}Hg, ^{203}Hg et ^{198}Au selon les réactions ^{196}Hg (n,γ) ^{197}Hg, ^{202}Hg (n,γ) ^{203}Hg, ^{197}Au (n,γ) ^{198}Au. Les pics photoélectriques ont des énergies de 77, 288, et 412 keV respectivement et des périodes de 2,7, 47 et 2,7 jours.

Moyens de mesure

Les activités gamma tant en phase solide (PbS) qu'en phase liquide ont été mesurées au moyen d'un analyseur à 100 canaux équipé d'une sonde NaI (Tl) 4,5 × 4,5 cm. Les activités mises en jeu assurent une précision statistique des comptages de ^{203}Hg et ^{198}Au de l'ordre de $\pm 2\%$ (temps de comptage 15 mn).

Mode opératoire

Pour étudier la rétention du mercure et de l'or contenus dans l'eau de mer sur PbS en colonne, on a utilisé les traceurs ^{203}Hg et ^{198}Au. On a fait d'abord des essais pour déterminer le rendement (R) de fixation sur PbS du mercure et de l'or. A un litre d'eau de mer, on ajoute $HNO_3 + H_2SO_4$ (1:1) pour obtenir le pH désiré et 1 ml de la solution contenant les traceurs Après une semaine, on fait passer cet échantillon d'eau de mer sur la colonne. La vitesse d'écoulement (0,2–0,5 ml/mn) dépend des dimensions des grains On lave le PbS sur la colonne avec 100 ml de la solution $HNO_3 + H_2SO_4$, ayant la même valeur de pH que la solution étudiée. On sèche doucement le PbS dans la colonne, puis on le récupère. On mesure la radioactivité gamma du PbS. On mesure aussi la radioactivité des étalons qui representent 0,5 g PbS sur lequel on a séché 1 ml de la solution des traceurs. On calcule $R\%$.

$$R\% = (A_e/A_0)\cdot 100$$

ou A_e = l'activité (cpm) de PbS en colonne, A_0 = l'activité de l'étalon.

Aux échantillons d'eau de mer qu'on utilise pour le dosage de l'or et du mercure, on ajoute $HNO_3 + H_2SO_4$ (1:1) au moment même où l'on prélève les échantillons de la mer, jusqu'a ce qu'on obtienne pH = 1. Après passage de la solution à travers la colonne, le PbS est lavé avec 100 ml de la solution $HNO_3 + H_2SO_4$ à pH = 1, séché à 50° et transféré dans un cachet de polyéthylène. On prépare deux étalons en séchant à 50° 1 ml de la solution étalon de mercure et d'or sur 0,5 g de PbS. L'un des étalons contient $1\cdot10^{-6}$ g Hg et $1\cdot10^{-8}$ g Au et l'autre $1\cdot10^{-8}$ g Hg et $1\cdot10^{-10}$ g Au.

Trois des échantillons et les deux étalons sont irradiés simultanément pendant 6 h au réacteur dans une boîte de polyéthylène. Après 6 jours, le pic photoélectrique du ^{198}Au est mesuré. On procède de même avec de ^{203}Hg, mais après 15 jours. On mesure des étalons dans les mêmes conditions.

RESULTATS ET DISCUSSION

A l'aide des traceurs ^{203}Hg et ^{198}Au, on a constaté que la quantité de PbS dans la colonne doit être d'environ 0,5 g. Cette quantité assure la rétention complète du mercure et de l'or contenus en petites quantités dans les solutions. Si la quantité du PbS est inférieure à 0,4 g, la vitesse d'écoulement est élevée et le temps de contact n'est pas suffisant pour la rétention complète du mercure et de l'or. Si la quantité est supérieure à 0,5 g la vitesse d'écoulement est très lente. A l'aide de ^{203}Hg et ^{198}Au, on a constaté aussi que le séchage à 50° n'entraine pas de pertes notables de Hg et Au par suite de l'évaporation.

Tableau 1.

pH	R, % Hg	Au
0	87	86
0,5	91	94
1	98	97
1,5	98	96
2	91	88

Les résultats, présentés dans le Tableau 1, indiquent que dans l'intervalle de pH 0,5–1,5 et à la température de 20 ± 2°, le rendement de la fixation du mercure et de l'or sur le PbS dépasse 90% (les chiffres donnés sont des valeurs moyennes pour trois essais).

On peut supposer que, après une semaine, les traceurs ^{203}Hg et ^{198}Au ajoutés à l'échantillon d'eau de mer sont dans le même état que le mercure et l'or contenus dans l'eau des mers et des océans. (A pH 1, la fixation du mercure et de l'or sur le verre est insignifiante.)[28–30] Des études antérieures[31–34] ont permis de constater que l'or est fixé au mieux sur le PbS en milieu acide sulfurique à pH 0,5–1,5 et le mercure en acide nitrique a pH = 1. Dans le mélange $H_2SO_4 + HNO_3$ a pH 1, les rendements de fixation sont de 98 et 97% pour le mercure et l'or respectivement (Tableau 1).

La Fig. 2*a* présente le spectre gamma de 0,5 g de PbS irradié pendant 6 h et mesuré 6 jours après la fin de l'irradiation. On n'y voit pas de pics photoélectriques gênants. La Fig. 2 présente aussi le spectre gamma de l'étalon, mesuré 6 jours (2*b*) et 15 jours (2*c*) après la fin de l'irradiation. La Fig. 3 montre le spectre gamma de 0,5 g de PbS utilisé en colonne pour retenir le mercure et l'or d'un échantillon d'un litre d'eau de la Mer Noire. Le PbS est irradié dans les conditions mentionnées ci-dessus; ^{198}Au est mesuré 6 jours après la fin de l'irradiation (3*a*) et ^{203}Hg 15 jours après la fin de l'irradiation (3*b*).

Après 6 jours, le bruit de fond provenant du PbS et la radioactivité-gamma des éléments à courte durée de vie qui se trouvent sur le PbS diminuent. Les éléments les plus gênants sont ^{24}Na et ^{64}Cu. Leurs quantités dans le PbS sont telles que les pics photoélectriques de ^{203}Hg et de ^{198}Au sont à peine visibles dans leur "compton". Après 15 jours, le pic de ^{198}Au n'empêche plus la mesure de ^{203}Hg. Le pic photoélectrique de ^{197}Hg ne convient pas pour le dosage, car le bruit de fond provenant du PbS est très élevé. Les spectres gamma ont été traités par la méthode de Covell.[35]

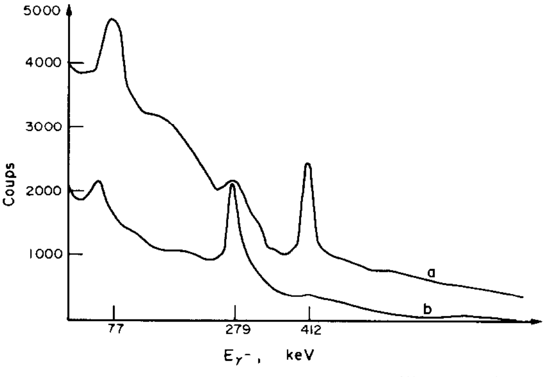

Fig. 3. Spectres gamma de 0,5 g de PbS utilisé en colonne pour retenir Hg et Au dans l'eau de la Mer Noire, irradié pendant 6 h et mesuré (*a*) 6 jours après la fin de l'irradiation; (*b*) 15 jours après la fin de l'irradiation. Temps de comptage 15 mn.

La Fig. 3 indique aussi qu'il suffit d'irradier les échantillons pendant 6 h pour déterminer avec une précision suffisante le mercure et l'or contenus dans 1 litre d'eau de la Mer Noire. Une série de mesures effectuées sur 10 échantillons de 1 litre de la même region de la Mer Noire a donné les résultats suivants: $(8 \pm 2)\cdot 10^{-7}$ g/l. Hg et $(6 \pm 3)\cdot 10^{-9}$ g/l. Au avec un écart-type de ±12% pour Hg et ±23% pour Au.

Ce résultat pour le mercure est en accord avec les résultats qu'on trouve dans la littérature.[36] Malheureusement il n'y a pas d'autres études sur la teneur en or de l'eau de la Mer Noire, auxquelles nous pourrions comparer nos résultats.

Nous avons obtenu les mêmes résultats après un traitement préalable d'un échantillon d'eau de la Mer Noire par le Cl_2 à température elevée, d'un autre avec $H_2SO_4 + HNO_3$, et d'un troisième par ultra-sons.

La limite de détection absolue de dosage par la méthode présentée atteint $1\cdot 10^{-7}$ g pour le mercure et $1\cdot 10^{-10}$ g pour l'or, calculée sur la base du critérium 3σ. Pour atteindre une limite de détection plus faible, le dosage pourrait s'effectuer par irradiation pendant une periode plus longue.

En ce qui concerne le mécanisme de fixation du mercure et de l'or, on peut supposer qu'il s'agit d'une réaction du type suivant:

$$PbS + Hg^{2+} \rightarrow HgS + Pb^{2+}$$

$$3PbS + 2Au^{3+} \rightarrow Au_2S_3 + 3Pb^{2+}$$

Il est cependant impossible, à cause de la concentration très faible du mercure et de l'or, de constater la formation d'une phase de HgS ou de Au_2S_3. Les ions du mercure et de l'or sont fixés sur la surface du sulfure de plomb en déplaçant les ions du plomb.

La méthode présentée ci-dessus, comparée aux autres méthodes décrites dans la littérature, offre les avantages suivants: simplicité du procédé de rétention du mercure et de l'or de l'eau de mer sur le PbS, suppression de la nécessité de séparation radiochimique après l'irradiation des échantillons, simplicité de la mesure par spectrométrie gamma non destructive.

Résumé—On décrit une méthode pour le dosage du mercure et de l'or dans l'eau de mer, basée sur la préconcentration de ces éléments par rétention sur le sulfure du plomb en colonne à pH 1 ($HNO_3 + H_2SO_4$). L'analyse est effectúee par spectrométrie gamma non destructive. On a détermíné $0{,}8 \pm 0{,}2$ µg/l. de mercure et 6 ± 3 ng/l. d'or dans un échantillon d'eau de la Mer Noire aux environs de Varna.

Talanta, Vol 23, pp 684–686 Pergamon Press, 1976 Printed in Great Britain

DOSAGE PAR SPECTROMETRIE GAMMA NON DESTRUCTIVE DU MERCURE ET DE L'OR DANS L'EAU DE MER APRES PRECONCENTRATION PAR LE SULFURE DE PLOMB

S. ALEXANDROV
Faculté de Chimie, Université de Sofia, Bulgarie

(*Reçu le* 14 *octobre* 1975. *Accepté le* 28 *janvier* 1976)

A l'heure actuelle, le dosage du mercure dans l'eau est un problème étroitement lié au problème de la pollution de l'environnement. Par exemple, le mercure s'accumule dans le corps des poissons et peut mener à des empoisonnements graves. Dans une revue récente, Chilov[1] discute les méthodes de détermination de petites quantités de mercure. Quelques recherches importantes ont été consacrées au dosage du mercure dans l'eau.[2–6]

L'intérêt du dosage de l'or dans l'eau de mer provient des nombreuses tentatives d'extraction industrielle. Différentes méthodes de dosage de petites quantités d'or dans l'eau de mer sont connues.[7–26]

L'application des sorbants inorganiques dans la radiochimie analytique, en particulier dans l'analyse par activation, devient de plus en plus fréquente. Nous présentons ci-dessous nos résultats sur la rétention du mercure et de l'or de l'eau de mer par le sulfure de plomb en colonne, ainsi qu'une nouvelle méthode de dosage de ces éléments par analyse par activation sans séparation radiochimique.

PARTIE EXPERIMENTALE

Colonne

La colonne consiste en un tube de verre, dont la partie inférieure est rétrécie (0,3 cm de diamètre et 3 cm de hauteur). On y introduit 0,5 g de PbS sur un tampon de laine de verre. Le PbS est d'abord dégazé dans 25 ml de HNO_3 0,1 *N* à la température de 20 ± 2° pendant 15 mn, puis versé dans la colonne qu'on relie à un récipient contenant l'eau de mer (Fig. 1).

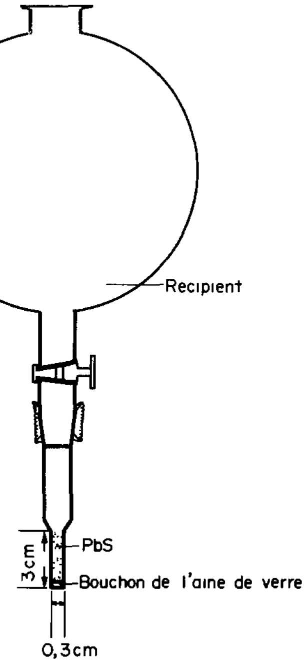

Fig. 1. Appareil utilisé pour la rétention du mercure et de l'or de l'eau de mer sur le PbS.

Reactifs et solutions

Le sulfure de plomb utilisé a été préparé à partir de plomb 99,9999% (Lead-Zinc Plant, Kirdzali, Bulgaria) ne contenant pas de mercure, d'argent et d'or en quantités détectables par radioactivation par neutrons thermiques. Le plomb a été dissous à l'aide de HNO_3 *p.a.* (2 + 1), puis PbS a été précipité par chauffage lent en présence de thioacétamide. Après 24 h de repos et centrifugation, le PbS a été seché a 50°. Le spectre de diffraction X a montré que le produit a la même structure que la galène. Il présente une granulométrie de l'ordre de 0,1 à 0,4 mm, permettant l'emploi facile en colonne. L'analyse par radioactivation par neutrons thermiques a indiqué que, dans le spectre gamma du PbS irradié pendant 6 h et mesuré 6 jours après la fin de l'irradiation, il n'y a pas de pics photoélectriques du mercure et de l'or (Fig. 2*a*).

La solution étalon de mercure a été preparée à partir de $Hg(NO_3)_2$, *p.a.* La concentration précise a été déterminée par la méthode gravimétrique après précipitation du HgS[27]

La solution étalon d'or a été préparée par dissolution d'or métallique, *p.a.*

Les deux solutions étalons contenaient 10^{-3} g/ml de mercure et d'or. Les solutions diluées—$1 \cdot 10^{-6}$–$1 \cdot 10^{-8}$ g/ml de mercure et $1 \cdot 10^{-8}$–$1 \cdot 10^{-10}$ g/ml d'or—ont été préparées le jour de l'utilisation. Les solutions des traceurs ^{203}Hg et ^{198}Au ont été obtenues par radioactivation d'or en poudre et de $HgCl_2$ au réacteur suivie de la dissolution de l'or dans l'eau régale et du $HgCl_2$ dans l'eau. La concentration des solutions utilisées était de $1 \cdot 10^{-8}$–$1 \cdot 10^{-9}$ g/ml pour Au et de $1 \cdot 10^{-6}$–$1 \cdot 10^{-8}$ g/ml pour Hg.

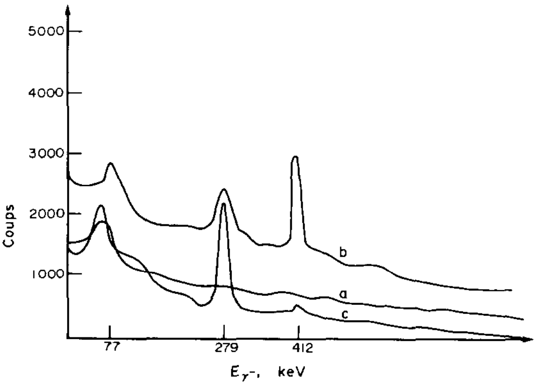

Fig. 2. Spectres gamma: (*a*) de 0,5 g du précipité de PbS irradié pendant 6 h dans un flux de $1{,}2 \cdot 10^{12}$ $n.cm^{-2}.sec^{-1}$, mesuré 6 jours après la fin de l'irradiation; (*b*) de l'étalon (0,5 g PbS + $1 \cdot 10^{-6}$ g Hg + $1 \cdot 10^{-8}$ g Au) irradié pendant 6 h, mesuré 6 jours après la fin de l'irradiation; (*c*) du même étalon, mesuré 15 jours après la fin de l'irradiation. Temps de comptage 15 mn

Irradiation des echantillons

Les échantillons ont été irradiés au réacteur IRT-2000 de FI ANEB, Sofia (Bulgarie) dans un flux de l'ordre de 10^{12} n.cm^{-2}.sec^{-1}. On a mis les échantillons dans de petits cachets de polyéthylène et ceux-ci dans de petites boites de polyéthylène. L'irradiation de PbS, contenant Hg et Au, donne ^{197}Hg, ^{203}Hg et ^{198}Au selon les réactions ^{196}Hg (n,γ) ^{197}Hg, ^{202}Hg (n,γ) ^{203}Hg, ^{197}Au (n,γ) ^{198}Au. Les pics photoélectriques ont des énergies de 77, 288, et 412 keV respectivement et des périodes de 2,7, 47 et 2,7 jours.

Moyens de mesure

Les activités gamma tant en phase solide (PbS) qu'en phase liquide ont été mesurées au moyen d'un analyseur à 100 canaux équipé d'une sonde NaI (Tl) 4,5 × 4,5 cm. Les activités mises en jeu assurent une précision statistique des comptages de ^{203}Hg et ^{198}Au de l'ordre de $\pm 2\%$ (temps de comptage 15 mn).

Mode opératoire

Pour étudier la rétention du mercure et de l'or contenus dans l'eau de mer sur PbS en colonne, on a utilisé les traceurs ^{203}Hg et ^{198}Au. On a fait d'abord des essais pour déterminer le rendement (R) de fixation sur PbS du mercure et de l'or. A un litre d'eau de mer, on ajoute $HNO_3 + H_2SO_4$ (1:1) pour obtenir le pH désiré et 1 ml de la solution contenant les traceurs Après une semaine, on fait passer cet échantillon d'eau de mer sur la colonne. La vitesse d'écoulement (0,2–0,5 ml/mn) dépend des dimensions des grains On lave le PbS sur la colonne avec 100 ml de la solution $HNO_3 + H_2SO_4$, ayant la même valeur de pH que la solution étudiée. On sèche doucement le PbS dans la colonne, puis on le récupère. On mesure la radioactivité gamma du PbS. On mesure aussi la radioactivité des étalons qui représentent 0,5 g PbS sur lequel on a séché 1 ml de la solution des traceurs. On calcule $R\%$.

$$R\% = (A_e/A_0)\cdot 100$$

ou A_e = l'activité (cpm) de PbS en colonne, A_0 = l'activité de l'étalon.

Aux échantillons d'eau de mer qu'on utilise pour le dosage de l'or et du mercure, on ajoute $HNO_3 + H_2SO_4$ (1:1) au moment même où l'on prélève les échantillons de la mer, jusqu'a ce qu'on obtienne pH = 1. Après passage de la solution à travers la colonne, le PbS est lavé avec 100 ml de la solution $HNO_3 + H_2SO_4$ à pH = 1, séché à 50° et transféré dans un cachet de polyéthylène. On prépare deux étalons en séchant à 50° 1 ml de la solution étalon de mercure et d'or sur 0,5 g de PbS. L'un des étalons contient $1\cdot10^{-6}$ g Hg et $1\cdot10^{-8}$ g Au et l'autre $1\cdot10^{-8}$ g Hg et $1\cdot10^{-10}$ g Au.

Trois des échantillons et les deux étalons sont irradiés simultanément pendant 6 h au réacteur dans une boîte de polyéthylène. Après 6 jours, le pic photoélectrique du ^{198}Au est mesuré. On procède de même avec de ^{203}Hg, mais après 15 jours. On mesure des étalons dans les mêmes conditions.

RESULTATS ET DISCUSSION

A l'aide des traceurs ^{203}Hg et ^{198}Au, on a constaté que la quantité de PbS dans la colonne doit être d'environ 0,5 g. Cette quantité assure la rétention complète du mercure et de l'or contenus en petites quantités dans les solutions. Si la quantité du PbS est inférieure à 0,4 g, la vitesse d'écoulement est élevée et le temps de contact n'est pas suffisant pour la rétention complète du mercure et de l'or. Si la quantité est supérieure à 0,5 g la vitesse d'écoulement est très lente. A l'aide de ^{203}Hg et ^{198}Au, on a constaté aussi que le séchage à 50° n'entraine pas de pertes notables de Hg et Au par suite de l'évaporation.

Tableau 1.

	R, %	
pH	Hg	Au
0	87	86
0,5	91	94
1	98	97
1,5	98	96
2	91	88

Les résultats, présentés dans le Tableau 1, indiquent que dans l'intervalle de pH 0,5–1,5 et à la température de 20 ± 2°, le rendement de la fixation du mercure et de l'or sur le PbS dépasse 90% (les chiffres donnés sont des valeurs moyennes pour trois essais).

On peut supposer que, après une semaine, les traceurs ^{203}Hg et ^{198}Au ajoutés à l'échantillon d'eau de mer sont dans le même état que le mercure et l'or contenus dans l'eau des mers et des océans. (A pH 1, la fixation du mercure et de l'or sur le verre est insignifiante.)[28–30] Des études antérieures[31–34] ont permis de constater que l'or est fixé au mieux sur le PbS en milieu acide sulfurique à pH 0,5–1,5 et le mercure en acide nitrique a pH = 1. Dans le mélange $H_2SO_4 + HNO_3$ a pH 1, les rendements de fixation sont de 98 et 97% pour le mercure et l'or respectivement (Tableau 1).

La Fig. 2*a* présente le spectre gamma de 0,5 g de PbS irradié pendant 6 h et mesuré 6 jours après la fin de l'irradiation. On n'y voit pas de pics photoélectriques gênants. La Fig. 2 présente aussi le spectre gamma de l'étalon, mesuré 6 jours (2*b*) et 15 jours (2*c*) après la fin de l'irradiation. La Fig. 3 montre le spectre gamma de 0,5 g de PbS utilisé en colonne pour retenir le mercure et l'or d'un échantillon d'un litre d'eau de la Mer Noire. Le PbS est irradié dans les conditions mentionnées ci-dessus; ^{198}Au est mesuré 6 jours après la fin de l'irradiation (3*a*) et ^{203}Hg 15 jours après la fin de l'irradiation (3*b*).

Après 6 jours, le bruit de fond provenant du PbS et la radioactivité-gamma des éléments à courte durée de vie qui se trouvent sur le PbS diminuent. Les éléments les plus gênants sont ^{24}Na et ^{64}Cu. Leurs quantités dans le PbS sont telles que les pics photoélectriques de ^{203}Hg et de ^{198}Au sont à peine visibles dans leur "compton". Après 15 jours, le pic de ^{198}Au n'empêche plus la mesure de ^{203}Hg. Le pic photoélectrique de ^{197}Hg ne convient pas pour le dosage, car le bruit de fond provenant du PbS est très élevé. Les spectres gamma ont été traités par la méthode de Covell.[35]

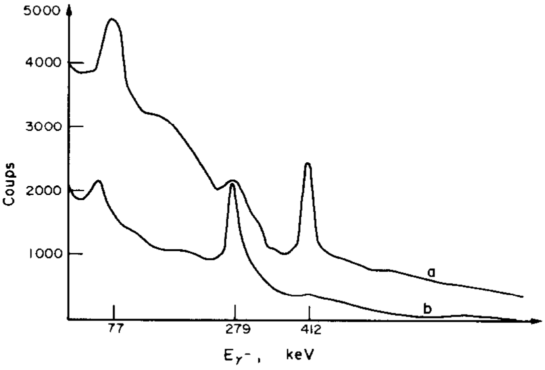

Fig. 3. Spectres gamma de 0,5 g de PbS utilisé en colonne pour retenir Hg et Au dans l'eau de la Mer Noire, irradié pendant 6 h et mesuré (*a*) 6 jours après la fin de l'irradiation; (*b*) 15 jours après la fin de l'irradiation. Temps de comptage 15 mn.

La Fig. 3 indique aussi qu'il suffit d'irradier les échantillons pendant 6 h pour déterminer avec une précision suffisante le mercure et l'or contenus dans 1 litre d'eau de la Mer Noire. Une série de mesures effectuées sur 10 échantillons de 1 litre de la même region de la Mer Noire a donné les résultats suivants: $(8 \pm 2) \cdot 10^{-7}$ g/l. Hg et $(6 \pm 3) \cdot 10^{-9}$ g/l. Au avec un écart-type de ±12% pour Hg et ±23% pour Au.

Ce résultat pour le mercure est en accord avec les résultats qu'on trouve dans la littérature.[36] Malheureusement il n'y a pas d'autres études sur la teneur en or de l'eau de la Mer Noire, auxquelles nous pourrions comparer nos résultats.

Nous avons obtenu les mêmes résultats après un traitement préalable d'un échantillon d'eau de la Mer Noire par le Cl_2 à température elevée, d'un autre avec $H_2SO_4 + HNO_3$, et d'un troisième par ultra-sons.

La limite de détection absolue de dosage par la méthode présentée atteint $1 \cdot 10^{-7}$ g pour le mercure et $1 \cdot 10^{-10}$ g pour l'or, calculée sur la base du critérium 3σ. Pour atteindre une limite de détection plus faible, le dosage pourrait s'effectuer par irradiation pendant une periode plus longue.

En ce qui concerne le mécanisme de fixation du mercure et de l'or, on peut supposer qu'il s'agit d'une réaction du type suivant:

$$PbS + Hg^{2+} \rightarrow HgS + Pb^{2+}$$

$$3PbS + 2Au^{3+} \rightarrow Au_2S_3 + 3Pb^{2+}$$

Il est cependant impossible, à cause de la concentration très faible du mercure et de l'or, de constater la formation d'une phase de HgS ou de Au_2S_3. Les ions du mercure et de l'or sont fixés sur la surface du sulfure de plomb en déplaçant les ions du plomb.

La méthode présentée ci-dessus, comparée aux autres méthodes décrites dans la littérature, offre les avantages suivants: simplicité du procédé de rétention du mercure et de l'or de l'eau de mer sur le PbS, suppression de la nécessité de séparation radiochimique après l'irradiation des échantillons, simplicité de la mesure par spectrométrie gamma non destructive.

NON-AQUEOUS QUANTITATIVE DETERMINATION OF THE CARBONYL FUNCTIONAL GROUP BY CONSTANT-CURRENT POTENTIOMETRIC TITRATION

J. F. Remark*® and C. A. Reynolds
Department of Chemistry, The University of Kansas, Lawrence, Kansas 66045, U.S.A.

(*Received* 29 *September* 1975. *Accepted* 13 *January* 1976)

There is a significant lack of rapid and accurate methods for determination of carbonyl groups. Most of those available involve a back-titration. A direct titration method would be a useful innovation. This paper reports such a procedure.[1] The titrant, sodium fluorenyl, is a strong base[2] as well as a very potent reducing agent, especially towards oxygen and oxygen-containing compounds. In this work its reduction properties were utilized. The titrant and titrands exhibit irreversible electrochemical behaviour; therefore, in the potentiometric titrations two platinum-wire electrodes are used at a small constant current of ~0.5 μA.

EXPERIMENTAL

Reagents

Sodium fluorenyl titrant is prepared by letting an excess of sodium metal shavings (5 g) react with 11 g of recrystallized fluorene in 100 ml of distilled 1,2-dimethoxyethane,[3] which is a 3:1 molar ratio, over a period of 24 hr in a sealed 250-ml round-bottomed flask in an inert atmosphere. It is then filtered through glass wool and diluted with 350 ml of distilled tetrahydrofuran (THF) to yield a final sodium fluorenyl concentration of approximately 0 1*M* The titrant is standardized against freshly distilled 2,4-pentanedione by the procedure described below. The titrant is stored under dry pure argon, the inlet to the titrant reservoir being connected to an argon bubbler which allows the inert gas over the titrant to be kept at atmospheric pressure. A balloon system fails to work properly because of diffusion of oxygen through the walls of the balloon. The THF is stored over sodium metal and under argon to inhibit diffusion of oxygen and water vapour into the system. The titrant is stable for at least a day and it should be noted that the method is not very practical unless a large number of samples is available for analysis on the same day.

The tetrahydrofuran and 1,2-dimethoxyethane are distilled twice under nitrogen, first from lithium aluminium hydride and then from sodium metal. All other compounds were purified by normal laboratory procedures.

Apparatus

A Metrohm potentiograph Model E436, Series 14, was used together with a Model E436D automatic titrator. The potentiograph also supplies the constant current for the electrodes. A simplified circuit diagram is shown in Fig. 1.

Electrode pretreatment

The pretreatment involves the procedures developed by Ashworth and Walisch[4] and by van Name and Fenwick.[5] The platinum electrodes are cleaned by submersion for 5 min in potassium dichromate–sulphuric acid solution, then thoroughly rinsed with distilled, deoxygenated water, and allowed to stand for 12 hr in 2*M* sulphuric acid–0.15*M* ferrous ammonium sulphate solution. Immediately before use the electrodes are heated to a dull red in a burner flame, then plunged into a crystal of sodium bisulphite, care being taken not to amass any bisulphite on the glass around the platinum wire. The electrodes are then heated again to a dull red, allowed to cool for 90–120 sec, and used immediately to measure the potential of the solution being titrated.

This pretreatment procedure produces reproducible electrode surfaces, as indicated by reproducibility of the potentiometric titration curves. The pretreatment procedure is not time-consuming, requiring less than 2 min before each titration.

Cell and apparatus pretreatment

Before each titration the pipette and titration vessel are thoroughly rinsed with acetone and then flushed with nitrogen to remove the acetone. They are then flamed-out to remove any traces of moisture, and allowed to cool under nitrogen. If these procedures are not properly applied, the concentration of water and reducible substances, approximately 0.025*M*, interferes The acetone wash is necessary to remove the reaction product, which is insoluble in water.

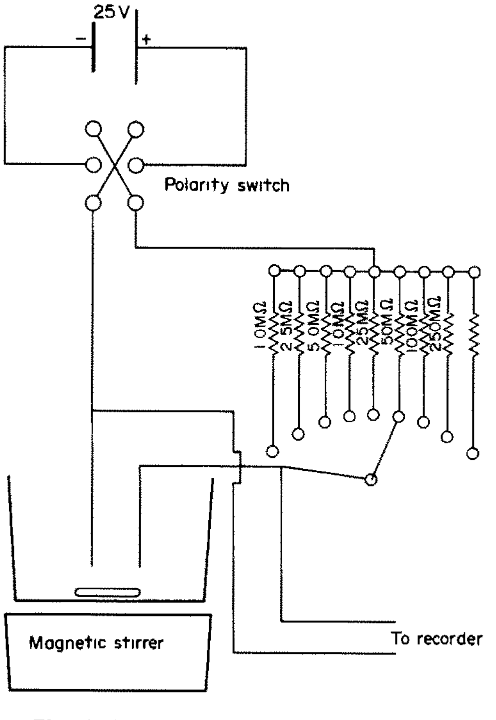

Fig. 1. Electrical circuit employed for use in constant-current titrations. The double-pole, double-throw switch is used to change the polarity of the electrodes.

Titration procedure

Fifteen ml of 0.15*M* sodium perchlorate in tetrahydrofuran, employed as supporting electrolyte, are introduced into the dry titration vessel which has been purged with nitrogen, and deaerated with dry nitrogen for 90–120 sec. The 0.5-μA electrode current is switched on and the titrant added continuously at the optimum flow-rate of 0.85 ml/min. If the flow-rate is faster, slow reaction kinetics cause a false end-point to be obtained for certain carbonyls. Once the titrant flow starts, the nitrogen flow is transferred from the bubbler to an orifice which permits the nitrogen to sweep out the volume above the reaction medium.

The potential of the two indicator electrodes is monitored until a derivative end-point is observed, which corresponds to the reducible impurities originally present in the purified tetrahydrofuran (their concentration is usually 2.5–4.5 × $10^{-3}M$). Immediately afterwards, 2 ml of the carbonyl sample are added, containing approximately 0.2 mmole of carbonyl, and the titration is continued until just after the carbonyl derivative end-point is reached.

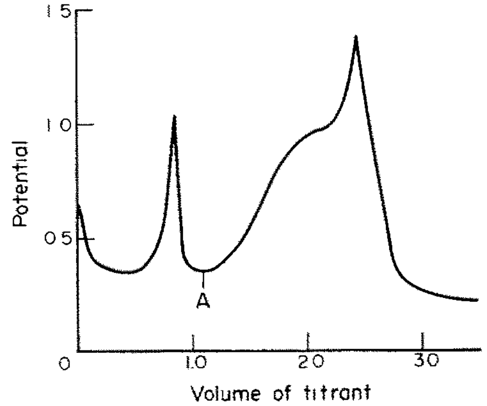

Fig. 2. Typical derivative-type titration curve for a carbonyl with sodium fluorenyl as a titrant. A denotes the point at which the butyraldehyde is injected. The difference between the end-points corresponds to the butyraldehyde and impurities injected.

RESULTS AND DISCUSSION

Aliphatic, aromatic and cyclic ketones, and aliphatic and aromatic aldehydes were investigated in this research and the carbonyls listed in Table 1 were chosen to represent a wide range of steric, configurational, and electronic effects. As can be seen, all types of carbonyl compounds lend themselves to analysis by this procedure.

Steric hindrance, as might be expected from the large size of the fluorenyl anion, plays a major role in the reactivity of certain carbonyls. Three carbonyl compounds investigated were found not to react: 9-fluorenone, benzophenone, and DL-camphor. This inertness most likely results from the bulkiness of the attacking fluorenyl anion and of the compound being attacked. However, 9-anthraldehyde, which was expected to be inert, was found to react rapidly. It is believed that the carbonyl carbon in 9-anthraldehyde, being positioned one carbon atom away from the bulky anthracene moiety, allows the fluorenyl anion the spatial orientation required to make attack possible, whereas in benzophenone and 9-fluorenone the carbonyl carbon is positioned in the 2- and 3-ring moiety, respectively. The carbonyl solution in THF must be freshly prepared so as to avoid build-up of peroxide contaminants. Table 1 shows that when a cyclohexanone solution was examined 6 days after it was prepared, the amount of reducible species corresponded to 129% of the amount originally introduced.

The minimum concentration of carbonyl that can be determined with acceptable accuracy and precision depends on the concentration of the titrant. We used 0.1*M* titrant and the minimum concentration of carbonyl determinable was 7.5 × $10^{-3}M$. Storrs[6] found sodium fluorenyl to be stable at a concentration as low as 0.02*M*. With this titrant concentration, the determination limit might be lowered to 1.2 × $10^{-3}M$.

The accuracy is reasonable, the error being mainly positive, which may be explained by the introduction of impurities during injection of the carbonyl sample. The 2 ml of added tetrahydrofuran solution contains 3–15 × 10^{-3} mmole of reducible impurities. These impurities govern the minimum amount of carbonyl that can be determined. Naturally, the smaller the carbonyl concentration and the larger the concentration of impurities, the larger will be the error in this method.

The poor precision for *p*-methoxybenzaldehyde, *p*-aminoacetophenone and 2-butanone is due to the poor derivative end-points obtained. In most cases the end-point is sharp and easily measured (Fig. 2). The first derivative end-point corresponds to the reducible impurities in the tetrahydrofuran solvent. The carbonyl-tetrahydrofuran solution is added to the reaction vessel at point *A* just after this first end-point. The second derivative end-point is that for the sample titration and the amount of titrant used to titrate the carbonyl and the small amount of reducible substances introduced with the carbonyl corresponds to the distance between the two derivative end-points.

Interferences

A wide variety of compounds was investigated for their ability to react with the titrant. Aliphatic and aromatic alcohols and nitro-compounds, acid chlorides, peroxides, acids and water interfered (Table 2). Acetonitrile, aniline, n-butylamine, diethylamine, dimethylformamide, ethyl acetate and triethylamine did not interfere. Ethers were not tested, but the tetrahydrofuran and 1,2-dimethoxyethane used as solvents did not react with the sodium fluorenyl.

Table 2. Compounds that react with the titrant

Compound	Average found, %
Acetyl chloride	110.0
Benzoic acid	99.5
Hydrogen peroxide	101.0
Nitrobenzene	96.0
Nitromethane	104.0
Phenol	99.9
1,3-Propanediol	119.0
Propanol	78.0
Water	100.0

The interferences occur by an oxidation–reduction or an acid–base mechanism, depending on the particular functional group. All the interferents react quantitatively save for the aliphatic alcohols. The instability of the alcohol carbonium ion is believed to cause the slow reaction of the nucleophilic attack on the alcohol by the sodium fluorenyl. All these interferents react in a 1:1 ratio with sodium fluorenyl except for nitro-groups, which require two equivalents of sodium fluorenyl per mole.

The method could obviously be extended to determination of other reducible functional groups. Indeed, preliminary investigations into other functional groups, namely nitro-groups and acid chlorides, have been performed in the study of interferences in this work. Further investigation could lead to a direct, non-aqueous, analytical titration procedure for other reducible functional groups.

Summary—A non-aqueous direct titration procedure has been developed for the determination of aldehydes and ketones. It uses two platinum-wire indicating electrodes with a constant current of ~0.5 μA. The solvent medium is 0.15*M* sodium perchlorate in tetrahydrofuran The titrant is sodium fluorenyl in a mixture of 1,2-dimethoxyethane and tetrahydrofuran. All types of carbonyl compounds react with the sodium fluorenyl, but steric hindrance prevents complete reaction with certain ketones containing bulky groups. The lowest concentration of carbonyl that can be determined with acceptable accuracy and precision is $7.5 \times 10^{-3}M$, the error being <3% and the precision better than ±2.5%. Most reducible compounds interfere, *e.g.*, peroxides, acid halides, nitro-compounds, acids, and water, and cannot be differentiated potentiometrically. The method can be extended to other reducible functional groups, *e.g.*, nitro groups and acid chlorides.

GRAVIMETRIC DETERMINATION OF IODINE AS TETRAPHENYLARSONIUM TRI-IODIDE

N. Gantchev and A. Kireva
Department of Analytical Chemistry, Institute of Chemical Technology and Metallurgy,
Sofia, Bulgaria

(*Received* 20 *August* 1975. *Revised* 7 *October* 1975. *Accepted* 31 *January* 1976)

Besides the classical gravimetric methods[1,2] for the determination of iodine, there are a few that use organic reagents.[3,4,5] One of these[5] is based on precipitation of ICl_2^- with the tetraphenylarsonium cation (Ph_4As^+). In view of the properties of Ph_4As^+, the tri-iodide ion would be expected to form an ion-association compound with it. Our investigations confirm this, and we have used the compound for the gravimetric determination of iodine.

EXPERIMENTAL

Composition and properties of tetraphenylarsonium tri-iodide

Tetraphenylarsonium tri-iodide (Ph_4AsI_3) was prepared by mixing solutions of Ph_4AsCl and I_3^-. It is a stable yellowish brown crystalline precipitate, m.p. 165°. It is practically insoluble in water: $K_{sp} = 2.0 \times 10^{-11}$. It is more soluble in polar solvents (CH_3COCH_3, $3 \times 10^{-2}M$; $C_2H_4Cl_2$, $6.6 \times 10^{-2}M$; $CHCl_3$, $7.6 \times 10^{-3}M$; C_2H_5OH, $5.7 \times 10^{-3}M$), giving yellow solutions. In non-polar solvents Ph_4AsI_3 is sparingly soluble (C_6H_6, $1.8 \times 10^{-4}M$; $C_6H_5CH_3$, $6 \times 10^{-5}M$).

Conditions for quantitative precipitation

Iodide is readily converted into iodate.[4] The iodate can then be changed into the equivalent amount of I_3^- if about

NON-AQUEOUS QUANTITATIVE DETERMINATION OF THE CARBONYL FUNCTIONAL GROUP BY CONSTANT-CURRENT POTENTIOMETRIC TITRATION

J. F. REMARK*® and C. A. REYNOLDS
Department of Chemistry, The University of Kansas, Lawrence, Kansas 66045, U.S.A.

(*Received* 29 *September* 1975. *Accepted* 13 *January* 1976)

There is a significant lack of rapid and accurate methods for determination of carbonyl groups. Most of those available involve a back-titration. A direct titration method would be a useful innovation. This paper reports such a procedure.[1] The titrant, sodium fluorenyl, is a strong base[2] as well as a very potent reducing agent, especially towards oxygen and oxygen-containing compounds. In this work its reduction properties were utilized. The titrant and titrands exhibit irreversible electrochemical behaviour; therefore, in the potentiometric titrations two platinum-wire electrodes are used at a small constant current of ~0.5 μA.

EXPERIMENTAL

Reagents

Sodium fluorenyl titrant is prepared by letting an excess of sodium metal shavings (5 g) react with 11 g of recrystallized fluorene in 100 ml of distilled 1,2-dimethoxyethane,[3] which is a 3:1 molar ratio, over a period of 24 hr in a sealed 250-ml round-bottomed flask in an inert atmosphere. It is then filtered through glass wool and diluted with 350 ml of distilled tetrahydrofuran (THF) to yield a final sodium fluorenyl concentration of approximately 0 1*M* The titrant is standardized against freshly distilled 2,4-pentanedione by the procedure described below. The titrant is stored under dry pure argon, the inlet to the titrant reservoir being connected to an argon bubbler which allows the inert gas over the titrant to be kept at atmospheric pressure. A balloon system fails to work properly because of diffusion of oxygen through the walls of the balloon. The THF is stored over sodium metal and under argon to inhibit diffusion of oxygen and water vapour into the system. The titrant is stable for at least a day and it should be noted that the method is not very practical unless a large number of samples is available for analysis on the same day.

The tetrahydrofuran and 1,2-dimethoxyethane are distilled twice under nitrogen, first from lithium aluminium hydride and then from sodium metal. All other compounds were purified by normal laboratory procedures.

Apparatus

A Metrohm potentiograph Model E436, Series 14, was used together with a Model E436D automatic titrator. The potentiograph also supplies the constant current for the electrodes. A simplified circuit diagram is shown in Fig. 1.

Electrode pretreatment

The pretreatment involves the procedures developed by Ashworth and Walisch[4] and by van Name and Fenwick.[5] The platinum electrodes are cleaned by submersion for 5 min in potassium dichromate–sulphuric acid solution, then thoroughly rinsed with distilled, deoxygenated water, and allowed to stand for 12 hr in 2*M* sulphuric acid–0.15*M* ferrous ammonium sulphate solution. Immediately before use the electrodes are heated to a dull red in a burner flame, then plunged into a crystal of sodium bisulphite, care being taken not to amass any bisulphite on the glass around the platinum wire. The electrodes are then heated again to a dull red, allowed to cool for 90–120 sec, and used immediately to measure the potential of the solution being titrated.

This pretreatment procedure produces reproducible electrode surfaces, as indicated by reproducibility of the potentiometric titration curves. The pretreatment procedure is not time-consuming, requiring less than 2 min before each titration.

Cell and apparatus pretreatment

Before each titration the pipette and titration vessel are thoroughly rinsed with acetone and then flushed with nitrogen to remove the acetone. They are then flamed-out to remove any traces of moisture, and allowed to cool under nitrogen. If these procedures are not properly applied, the concentration of water and reducible substances, approximately 0.025*M*, interferes The acetone wash is necessary to remove the reaction product, which is insoluble in water.

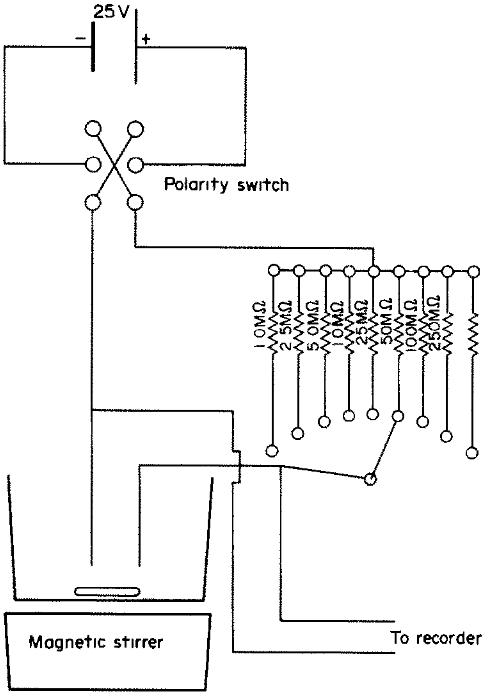

Fig. 1. Electrical circuit employed for use in constant-current titrations. The double-pole, double-throw switch is used to change the polarity of the electrodes.

Tetraphenylarsonium tri-iodide (Ph_4AsI_3) was prepared by mixing solutions of Ph_4AsCl and I_3^-. It is a stable yellowish brown crystalline precipitate, m.p. 165°. It is practically insoluble in water: $K_{sp} = 2.0 \times 10^{-11}$. It is more soluble in polar solvents (CH_3COCH_3, $3 \times 10^{-2}M$; $C_2H_4Cl_2$, $6.6 \times 10^{-2}M$; $CHCl_3$, $7.6 \times 10^{-3}M$; C_2H_5OH, $5.7 \times 10^{-3}M$), giving yellow solutions. In non-polar solvents Ph_4AsI_3 is sparingly soluble (C_6H_6, $1.8 \times 10^{-4}M$; $C_6H_5CH_3$, $6 \times 10^{-5}M$).

Conditions for quantitative precipitation

Iodide is readily converted into iodate.[4] The iodate can then be changed into the equivalent amount of I_3^- if about

1000	1000	±0.0	6000	5994	+0.1

10% more than the theoretical amount of iodide is added. Experiment shows that 50% excess of iodide is needed to precipitate Ph_4AsI_3 quantitatively. This excess of I^-, however, could also be precipitated as Ph_4AsI. To avoid this, the difference between the solubilities of tetraphenylarsonium tri-iodide and tetraphenylarsonium iodide at higher temperatures can be utilized. Table 1 shows that when, after the precipitation, the mixture is heated to 100° and filtered at >60°, correct results are obtained.

The precipitation cannot be done at high temperatures because low values are obtained owing to the volatilization of elementary iodine. However, in the preparation of the I_3^- there may also be loss of iodine. For this reason, a special precipitation procedure is used. To a solution containing Ph_4AsCl and I^-, the acid solution of IO_3^- to be determined is added drop by drop. Under these conditions, Ph_4AsI_3 forms immediately as the I_3^- is produced.

EXPERIMENTAL

Reagents

Hydrochloric acid, 2M.

Chlorine water, saturated and freshly prepared.

Potassium iodide solution. Iodide concentration 5 *mg/ml.*

Ph_4AsCl solution, 0.01M.

Procedure

Place 20–25 ml of a solution containing 1–6 mg of iodide in a flat-bottomed flask marked at a volume of 10 ml. Add 5 ml of chlorine water, 2.5 ml of 2*M* hydrochloric acid and water to 45–50 ml, and evaporate the mixture to a volume of 10 ml. Cool, and add this solution dropwise to a mixture of the 0.01*M* Ph_4AsCl (15 ml) and potassium iodide solution (10 ml) previously placed in a 150-ml beaker, rinsing the flask with three 10 ml portions of water. After the precipitation, stir the mixture for about 2 min, dilute with water to 100 ml, heat to 100°, and filter off the precipitate when the temperature has fallen to 50°. Use the filtrate to transfer the precipitate, wash it twice with 4 ml of warm water and dry it for 1 hr at 120°. Table 2 shows results for the determination of 1 and 6 mg of iodide.

The relative standard deviation for 6 mg of iodide (reliability coefficient 95%) is 0.9% (10 results) and that for 1 mg is 2.5%. NO_3^-, CO_3^{2-}, SO_4^{2-}, Cl^- and Br^- do not interfere. If the sample contains cations with a higher oxidation potential than that of iodine (*e.g.*, Fe^{3+}), these should be removed first in the form of the hydroxides or other insoluble compounds.

Summary—Tetraphenylarsonium tri-iodide has been prepared and its properties studied. On the basis of its stability and very low solubility a gravimetric method for the determination of mg amounts of iodine has been developed. The mean relative error for amounts of 1–6 mg is about +0.3%. CO_3^{2-}, SO_4^{2-}, NO_3^-, Cl^- and Br^- do not interfere.

Table 2. Compounds that react with the titrant

Compound	Average found, %
Acetyl chloride	110.0
Benzoic acid	99.5
Hydrogen peroxide	101.0
Nitrobenzene	96.0
Nitromethane	104.0
Phenol	99.9
1,3-Propanediol	119.0
Propanol	78.0
Water	100.0

The interferences occur by an oxidation–reduction or an acid–base mechanism, depending on the particular functional group. All the interferents react quantitatively save for the aliphatic alcohols. The instability of the alcohol carbonium ion is believed to cause the slow reaction of the nucleophilic attack on the alcohol by the sodium fluorenyl. All these interferents react in a 1:1 ratio with sodium fluorenyl except for nitro-groups, which require two equivalents of sodium fluorenyl per mole.

The method could obviously be extended to determination of other reducible functional groups. Indeed, preliminary investigations into other functional groups, namely nitro-groups and acid chlorides, have been performed in the study of interferences in this work. Further investigation could lead to a direct, non-aqueous, analytical titration procedure for other reducible functional groups.

Summary—A non-aqueous direct titration procedure has been developed for the determination of aldehydes and ketones. It uses two platinum-wire indicating electrodes with a constant current of ~0.5 μA. The solvent medium is 0.15*M* sodium perchlorate in tetrahydrofuran The titrant is sodium fluorenyl in a mixture of 1,2-dimethoxyethane and tetrahydrofuran. All types of carbonyl compounds react with the sodium fluorenyl, but steric hindrance prevents complete reaction with certain ketones containing bulky groups. The lowest concentration of carbonyl that can be determined with acceptable accuracy and precision is $7.5 \times 10^{-3}M$, the error being <3% and the precision better than ±2.5%. Most reducible compounds interfere, *e.g.*, peroxides, acid halides, nitro-compounds, acids, and water, and cannot be differentiated potentiometrically. The method can be extended to other reducible functional groups, *e.g.*, nitro groups and acid chlorides.

GRAVIMETRIC DETERMINATION OF IODINE AS TETRAPHENYLARSONIUM TRI-IODIDE

N. Gantchev and A. Kireva
Department of Analytical Chemistry, Institute of Chemical Technology and Metallurgy,
Sofia, Bulgaria

(*Received* 20 *August* 1975. *Revised* 7 *October* 1975. *Accepted* 31 *January* 1976)

Besides the classical gravimetric methods[1,2] for the determination of iodine, there are a few that use organic reagents.[3,4,5] One of these[5] is based on precipitation of ICl_2^- with the tetraphenylarsonium cation (Ph_4As^+). In view of the properties of Ph_4As^+, the tri-iodide ion would be expected to form an ion-association compound with it. Our investigations confirm this, and we have used the compound for the gravimetric determination of iodine.

EXPERIMENTAL

ANNOTATION

THE EFFECT OF LOW-TEMPERATURE ASHING ON THE STRUCTURE AND COMPOSITION OF MINERAL COMPONENTS

Y. Michotte and D. L. Massart
Pharmaceutical Institute, Vrije Universiteit Brussel, Paardenstraat 67, B-1640. Sint Genesius Rhode, Belgium

and

J. Pelsmaekers
S.C.K./C.E.N. Boeretang 200, B-2400 Mol, Belgium

(*Received* 20 *February* 1976. *Accepted* 16 *March* 1976)

Low-temperature ashing (LTA) is used in analytical chemistry as one of the methods of decomposing samples containing carbon or organic material. LTA has several advantages. The most cited are as follows:

(*a*) There is less chance of losing trace elements by volatilization than with the classical dry ashing technique. Most published work on the use of LTA is concerned with trace element analysis and therefore there is a not inconsiderable body of data available concerning losses of trace elements by LTA.

(*b*) The structure of the mineral component is left unaltered. By structure is meant the microscopic as well as the crystalline structure, and the composition of the mineral residue. Although this has been said by several authors, this statement has not been systematically checked.

Apart from work by Gluskoter[1] and Estep *et al.*,[2] who investigated the changes of a few minerals present in coal, there appears to be no study available on the effect of LTA on the structure of minerals. During an investigation on the composition and structure of small brain calcifications,[3] we developed a procedure in which, after LTA, the inorganic composition (matrix elements and trace elements) was determined, usually by atomic absorption, the mineralogical identity by infrared spectrophotometry and X-ray diffraction, and the microscopic morphology by microscan electron microscopy. Excellent results were obtained. A study on the validity of the results obtained led us to investigate, in a more systematic way than seems to have been done until now, whether LTA indeed leaves the crystalline structure and composition of the inorganic residue unaltered. We wish to report these results here, because we think that they can be valuable for several applications such as the analysis of the minerals present in coal, calcifications in animal and plant tissue, the identification or determination of minerals collected on filters in air pollution studies, the identification of inorganic fibres in lung tissue, *etc.*

EXPERIMENTAL

Apparatus

LTA-505 (Tracerlab). Unicam SP-1000 I.R. spectrophotometer (Pye Unicam). Philips Norelco X-ray diffractometer (with goniometer and Geiger-Müller counter).

Samples

All salts were *p.a.* products. Mineral samples were obtained from Prof. P. Pasteels (Vrije Universiteit Brussel, Belgium).

Procedures

LTA. Samples of about 10–20 mg were ashed during 24 hr at 250 W.

Infrared. A 1–2 mg portion of sample was mixed with 150 mg of KBr and pressed into a pellet.

X-Ray diffraction. Diffractograms were taken, using the Cu $K_{\alpha 1}$-line.

RESULTS AND DISCUSSION

Two kinds of sample were investigated, namely a number of minerals (Table 1) and salts (Table 2). Before

Table 1. Minerals investigated

1. Aragonite ($CaCO_3$)	11. Apatite [$Ca_5(PO_4)_3(OH)$]
2. Calcite ($CaCO_3$)	12. Brucite [$Mg(OH)_2$]
3. Kaolinite [$Al_4Si_4O_{10}(OH)_8$]	13. Dolomite [$CaMg(CO_3)_2$]
4. α-Quartz (SiO_2)	14. Diopside ($CaMgSi_2O_6$)
5. Anhydrite ($CaSO_4$)	15. Orthoclase ($KAlSi_3O_8$)
6. Epsomite ($MgSO_4 \cdot 7H_2O$)	16. Chalcantite ($CuSO_4 \cdot 5H_2O$)
7. Leucite ($KAlSi_2O_6$)	17. Chalcopyrite ($CuFeS_2$)
8 Olivine (Mg_2SiO_4)	18. Pyrite (FeS_2)
9. Talcum [$Mg_6Si_8O_2(OH)_4$]	19. Gypsum ($CaSO_4 \cdot 7H_2O$)
10. Malachite [$Cu_2CO_3(OH)_2$]	20. Fluorite (CaF_2)

Table 2. Salts investigated

1. $FeSO_4\ 7H_2O$
2. $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$
3. $CaSO_4 \cdot 2H_2O$
4. K_2SO_4
5. Na_2SO_4
6. $(NH_4)_2SO_4$
7. $Fe_2(SO_4)_3 \cdot H_2O$
8. $KHSO_4$
9. $CaCO_3$
10. Li_2CO_3
11. K_2CO_3
12. $MgCO_3$
13. Na_2CO_3
14. $(NH_4)_2CO_3$
15. $NaHCO_3$
16. K_2HPO_4
17. $Ca(H_2PO_4)_2 \cdot H_2O$
18. $CaHPO_4 \cdot 2H_2O$
19. $MgHPO_4 \cdot 3H_2O$
20. Na_2HPO_4
21. $(NH_4)_2HPO_4$
22. $NaH_2PO_4 \cdot 2H_2O$
23. $Na_3PO_4 \cdot 12H_2O$
24. $Ca_3(PO_4)_2$
25. $Na_2SiO_3\ 9H_2O$

and after LTA, the infrared spectra and the X-ray diffractograms of the minerals were obtained. For the salts only the infrared spectra were measured.

The LTA treatment has no effect on most of the minerals investigated. Changes were detected in only one X-ray diffractogram. It was found that gypsum is converted into the monohydrate $CaSO_4 \cdot H_2O$, so that the effect of the LTA treatment was to remove one of the two molecules of water of crystallization. Changes were also detected in the infrared spectra of pyrite, chalcopyrite, gypsum and chalcanthite. These are due to oxidation and/or dehydration. It is evident that oxidation must have a marked effect on the infrared spectrum since new chemical groups are formed. This is also true for dehydration. This is due[4] either to the formation of another crystalline species (as in the case of gypsum) or because water molecules forming hydrogen bonds with anions and thereby changing their vibration frequency, are eliminated.

Results from classical thermogravimetry, such as those summarized by Duval[5] can help to explain the changes. However, it should be kept in mind that classical thermogravimetry is carried out at normal pressure (while LTA is carried out at very low pressures) and in a much less oxidizing atmosphere.

Pyrite and chalcopyrite are oxidized in part with the formation of SO_4^{2-}, since a sulphate peak was detected in the infrared spectra after LTA It is interesting that no change is found in the X-ray diffractograms of these minerals. This can be explained by assuming that only a rather small part of the sulphide is oxidized, with the formation of an amorphous sulphate. In the chalcanthite infrared spectrum no new bands are formed after LTA, but their relative importance changes drastically. A possible explanation is that some of the water of crystallization has been lost. Classical thermogravimetry[5] shows that chalcanthite loses four molecules of water between 67° and 153°.

For the salts, more changes were observed. We will not try to discuss and explain these systematically, since our principal intention is to see whether LTA causes changes or not. No effects were observed for most sulphates (Nos. 4–8 in Table 2), carbonates (Nos. 10–14), the silicate (No. 25) and some phosphates (Nos. 16–18). The most drastic change is found for $NaHCO_3$ which is entirely converted into Na_2CO_3. The ferrous sulphate (No. 1) is converted into a basic ferric sulphate. This is in agreement with the findings of classical thermogravimetry, since Duval[5] states that partial oxidation and dehydration occur for this salt between 23° and 96° and that complete dehydration with the formation of a basic sulphate occurs at 140°. The spectrum of Mohr's salt (No. 2) still contains sulphate and ammonium bands after LTA This could be interpreted as due to the formation of $NH_4Fe(SO_4)_2$ (*i.e.*, an oxidation of Fe^{2+}). Most phosphates show changes. These are, no doubt, due to dehydration, formation of polymeric phosphates and pyrophosphates. The effect of such changes on the infrared spectra has been discussed by Corbridge[6] and by Bellamy and Beecher[7].

In general, we conclude that in many cases, LTA can be used without changing the composition and the crystalline structure of the inorganic residues. In particular, X-ray diffraction identification of the mineral originally present is possible in almost all cases investigated, even if some change is detected by infrared spectrometry. This is also true for the application which is of the greatest interest to us, namely the study of brain microcalcifications However, it is clear that changes do occur quite often and that, therefore, the often-made statement that LTA leaves the mineral component unaltered, is misleading.

Acknowledgements—The authors thank P. Pasteels for the mineral samples and FGWO for financial assistance.

Two kinds of sample were investigated, namely a number of minerals (Table 1) and salts (Table 2). Before

Table 1. Minerals investigated

1. Aragonite ($CaCO_3$)
2. Calcite ($CaCO_3$)
3. Kaolinite [$Al_4Si_4O_{10}(OH)_8$]
4. α-Quartz (SiO_2)
5. Anhydrite ($CaSO_4$)
6. Epsomite ($MgSO_4 \cdot 7H_2O$)
7. Leucite ($KAlSi_2O_6$)
8. Olivine (Mg_2SiO_4)
9. Talcum [$Mg_6Si_8O_2(OH)_4$]
10. Malachite [$Cu_2CO_3(OH)_2$]
11. Apatite [$Ca_5(PO_4)_3(OH)$]
12. Brucite [$Mg(OH)_2$]
13. Dolomite [$CaMg(CO_3)_2$]
14. Diopside ($CaMgSi_2O_6$)
15. Orthoclase ($KAlSi_3O_8$)
16. Chalcantite ($CuSO_4 \cdot 5H_2O$)
17. Chalcopyrite ($CuFeS_2$)
18. Pyrite (FeS_2)
19. Gypsum ($CaSO_4 \cdot 7H_2O$)
20. Fluorite (CaF_2)

Table 2. Salts investigated

1. $FeSO_4 \cdot 7H_2O$
2. $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$
3. $CaSO_4 \cdot 2H_2O$
4. K_2SO_4
5. Na_2SO_4
6. $(NH_4)_2SO_4$
7. $Fe_2(SO_4)_3 \cdot H_2O$
8. $KHSO_4$
9. $CaCO_3$
10. Li_2CO_3
11. K_2CO_3
12. $MgCO_3$
13. Na_2CO_3
14. $(NH_4)_2CO_3$
15. $NaHCO_3$
16. K_2HPO_4
17. $Ca(H_2PO_4)_2 \cdot H_2O$
18. $CaHPO_4 \cdot 2H_2O$
19. $MgHPO_4 \cdot 3H_2O$
20. Na_2HPO_4
21. $(NH_4)_2HPO_4$
22. $NaH_2PO_4 \cdot 2H_2O$
23. $Na_3PO_4 \cdot 12H_2O$
24. $Ca_3(PO_4)_2$
25. $Na_2SiO_3 \cdot 9H_2O$

and after LTA, the infrared spectra and the X-ray diffractograms of the minerals were obtained. For the salts only the infrared spectra were measured.

The LTA treatment has no effect on most of the minerals investigated. Changes were detected in only one X-ray diffractogram. It was found that gypsum is converted into the monohydrate $CaSO_4 \cdot H_2O$, so that the effect of the LTA treatment was to remove one of the two molecules of water of crystallization. Changes were also detected in the infrared spectra of pyrite, chalcopyrite, gypsum and chalcanthite. These are due to oxidation and/or dehydration. It is evident that oxidation must have a marked effect on the infrared spectrum since new chemical groups are formed. This is also true for dehydration. This is due[4] either to the formation of another crystalline species (as in the case of gypsum) or because water molecules forming hydrogen bonds with anions and thereby changing their vibration frequency, are eliminated.

Results from classical thermogravimetry, such as those summarized by Duval[5] can help to explain the changes. However, it should be kept in mind that classical thermogravimetry is carried out at normal pressure (while LTA is carried out at very low pressures) and in a much less oxidizing atmosphere.

Pyrite and chalcopyrite are oxidized in part with the formation of SO_4^{2-}, since a sulphate peak was detected in the infrared spectra after LTA It is interesting that no change is found in the X-ray diffractograms of these minerals. This can be explained by assuming that only a rather small part of the sulphide is oxidized, with the formation of an amorphous sulphate. In the chalcanthite infrared spectrum no new bands are formed after LTA, but their relative importance changes drastically. A possible explanation is that some of the water of crystallization has been lost. Classical thermogravimetry[5] shows that chalcanthite loses four molecules of water between 67° and 153°.

For the salts, more changes were observed. We will not try to discuss and explain these systematically, since our principal intention is to see whether LTA causes changes or not. No effects were observed for most sulphates (Nos. 4–8 in Table 2), carbonates (Nos. 10–14), the silicate (No. 25) and some phosphates (Nos. 16–18). The most drastic change is found for $NaHCO_3$ which is entirely converted into Na_2CO_3. The ferrous sulphate (No. 1) is converted into a basic ferric sulphate. This is in agreement with the findings of classical thermogravimetry, since Duval[5] states that partial oxidation and dehydration occur for this salt between 23° and 96° and that complete dehydration with the formation of a basic sulphate occurs at 140°. The spectrum of Mohr's salt (No. 2) still contains sulphate and ammonium bands after LTA This could be interpreted as due to the formation of $NH_4Fe(SO_4)_2$ (*i.e.*, an oxidation of Fe^{2+}). Most phosphates show changes. These are, no doubt, due to dehydration, formation of polymeric phosphates and pyrophosphates. The effect of such changes on the infrared spectra has been discussed by Corbridge[6] and by Bellamy and Beecher[7].

In general, we conclude that in many cases, LTA can be used without changing the composition and the crystalline structure of the inorganic residues. In particular, X-ray diffraction identification of the mineral originally present is possible in almost all cases investigated, even if some change is detected by infrared spectrometry. This is also true for the application which is of the greatest interest to us, namely the study of brain microcalcifications However, it is clear that changes do occur quite often and that, therefore, the often-made statement that LTA leaves the mineral component unaltered, is misleading.

Acknowledgements—The authors thank P. Pasteels for the mineral samples and FGWO for financial assistance.

Summary—To investigate the often-made statement that low-temperature ashing leaves the structure and composition of the mineral residue unaltered, 25 salts and 20 minerals were studied by X-ray diffractometry and infrared spectrophotometry It is concluded that many substances remain unaltered, but some do not, so the statement is misleading.

EINFLUSS VON VERSCHIEDENEN PARAMETERN UND MESSBEDINGUNGEN AUF DIE ANFÄNGLICHE NEIGUNG VON ATOMABSORPTIOMETRISCHEN EICHKURVEN

B. MAGYAR und G. WIDMER
Laboratorium für Anorganische Chemie, Eidg. Techn. Hochschule, Zürich, Schweiz

(*Eingegangen am* 3. *Februar* 1976. *Angenommen am* 31. *März* 1976)

Zusammenfassung—Die anfängliche Neigung a_0 von atomabsorptiometrischen Eichkurven wird durch die gewählten Meßbedingungen und spektroskopischen Kenngrößen des zu bestimmenden Elementes A beeinflußt. In dieser Arbeit wurde eine Beziehung abgeleitet, mit deren Hilfe die Größenordnung von a_0 für verschiedene Meßbedingungen vorausgesagt werden kann. Insbesondere werden die Beeinflussungen von a_0 durch spektroskopische Daten der betreffenden Linie, Erniedrigung der Konzentration von A infolge seiner Ionisation und Verbindung, Konstruktion und Temperatur des Atomreservoirs und durch die spektrale Bandbreite des Monochromators diskutiert. Der Einfluß der Stromstärke von Spektrallampen auf die anfängliche Neigung der Eichkurven wurde ebenfalls untersucht. Ein sog. "Lampenstromeffekt" wurde bei Elementen gefunden, deren Dampfdruck bei 400 K größer als 10^{-14} mmHg ist. Schließlich wurden die Elektronenkonzentrationen bzw. Elektronenpartialdrücke p_e in der Flamme unter Anwendung der Saha-Gleichung aus den atomabsorptiometrisch ermittelten Ionisationsgraden vom Barium berechnet. Man erhielt einen p_e-Wert von $1{,}21 \cdot 10^{-7}$ bzw. $1{,}3 \cdot 10^{-7}$ atm für die metallfreie N_2O/C_2H_2- bzw. Luft/C_2H_2-Flamme.

Bei der atomabsorptiometrischen Bestimmung eines Elementes wird bekanntlich die optische Dichte D gemessen, welche gewöhnlich nur in einem engen optischen Dichtebereich von der Konzentration w_A [Gewichtsbruch, ppm] des zu bestimmenden Elementes A in der untersuchten Lösung linear abhängt. Die anfängliche Neigung a_0 der Funktion (D, w_A) hängt von vielen Faktoren ab:

(1) von spektralen Größen

(2) von der Konstruktion und der Temperatur T des Atomreservoirs (Flamme, Graphitrohrküvette)

(3) von der Elektronik der Signalpräsentation.

Die Elektronik eines Atomabsorptions Spektrophotometers soll hier nicht diskutiert werden. Wir nehmen eine ideale elektronische Signalverarbeitung an, so daß die optische Dichte D immer exakt angezeigt wird:

$$D = \log I_0/I = 0{,}434\, k_\lambda L = a_0 w_A \qquad (1)$$

Hier bedeuten I_0 bzw. I die Intensität [W/cm^2] einer schmalen Resonanzlinie vor bzw. nach dem Atomreservoir der Länge L und k_λ den linearen natürlichen Absorptionskoeffizienten.

k_λ hat einen maximalen Wert k_{λ_0} in der Mitte (bei λ_0) des Absorptionsprofils k_λ,λ. Hat k_λ,λ die Form einer Gauss'schen Normalverteilung, so beträgt[1] k_{λ_0}:

$$k_{\lambda_0} = f_G \cdot \frac{\pi \cdot e^2}{m \cdot c^2} \cdot \frac{\lambda_0^2}{\Delta\lambda_{ab}} \cdot N_j f_{ji} \qquad (2)$$

Hier bedeuten f_G das Verhältnis des Produktes aus der Peakhöhe und der Halbwertsbreite zu der Peakfläche einer Gauss'schen Glockenkurve ($f_G = 2[(\ln 2)/\pi]^{1/2}$), e die Ladung und m die Ruhemasse des Elektrons, c die Lichtgeschwindigkeit, $\Delta\lambda_{ab}$ die Halbwertsbreite der Absorptionslinie, N_j die Anzahl der absorbierenden Atome pro cm^3 und f_{ji} die Oszillatorenstärke, d.h. die effektive Anzahl der Oszillatoren pro Atom. Walsh hat gezeigt,[2] daß k_{λ_0} aus der Gleichung (1) erhalten wird, falls zur Messung der optischen Dichte eine Strahlungsquelle benutzt wird, deren emittierte Resonanzlinie viel schmäler als das Absorptionsprofil ist. In diesem Fall sollte D in einem großen Bereich zu der Konzentration N_j direkt proportional sein, wie man durch Einsetzen von k_{λ_0} anstelle von k_λ in der Gleichung (1) zeigen kann. In der analytischen Praxis findet man gewöhnlich eine Proportionalität zwischen D und w_A bis zu D-Werten von *ca.* 0,2. In dieser Arbeit soll die Beeinflussung der Proportionalitätskonstante durch experimentelle Meßbedingungen diskutiert werden. Insbesondere sollen dabei die Selbstabsorptionsverbreiterung der Emissionslinie (Linien-Selbstumkehr), die Ionisation gewisser Metalle und nicht absorbierbare Störstrahlungen berücksichtigt werden.

EXPERIMENTELLER TEIL

Geräte und Aufnahme der Eichkurven

Man verwendete die Perkin-Elmer Atomabsorptions-Spektrophotometer Modell 303 bzw. 300 für die Flammentechnik bzw. Graphitrohr-Küvettentechnik (HGA 72). Alle Stammlösungen wurden aus analysenreinen Präparaten hergestellt und mit chemischen Analysenmethoden kontrolliert. Durch Verdünnen mit verdünnten Mineralsäuren (s. Tabelle 1) wurden die Eichlösungen erhalten, welche je zweimal in die Flamme bzw. Küvette eingespritzt wurden. Um kleine systematische Fehler zu kompensieren, welche infolge langzeitiger Instabilität des Meßsystems manchmal auftraten, wurden die Lösungen in umgekehrter Reihenfolge ein zweites Mal gemessen. Man verwendete den Mittelwert beider D-Werte. Im allgemeinen wurde bei der Aufnahme der Eichkurven nach der entsprechenden Vorschrift des Geräteherstellers vorgegangen. Wesentliche Abweichungen sind an der entsprechenden Stelle vermerkt.

Bestimmung und Rolle der spektralen Bandbreite

Zur Abschätzung der Störintensität einer nicht absorbierten Strahlung muß die spektrale Bandbreite $\Delta\lambda_M$ bekannt sein. Ihre experimentelle Bestimmung soll nun kurz beschrieben werden.

Jeder Spektrallinie λ_0 entspricht eine Stelle λ_0^* an der Wellenlängenskala, wo das Detektor-Signal S_D seinen Maximalwert $S_{D,max}$ hat. Ein Monochromator ist dann richtig justiert, wenn λ_0 und λ_0^* zahlenmäßig übereinstimmen. Wird nun der Monochromator in Richtung von kleineren oder größeren λ^*-Werten verstellt, so nimmt S_D im Bereich von $\lambda^* \pm \Delta\lambda_M$ linear ab, da sich der Lichtleitwert[3] des Monochromators ändert. Bei den meisten Spektrophotometern sind Eintritts- und Austrittsspalt gekoppelt und haben die gleiche Breite B und Höhe H. Mit dem optischen System wird der Eintrittsspalt auf den Austrittspalt scharf abgebildet.[4,5] Ist zudem das Signal S_D zur der empfangenen Strahlungsleistung proportional, so kann für eine scharfe Spektrallinie die folgende Beziehung abgeleitet werden:

$$S_D = k_D f_{SV} I \frac{BHF}{f^2}\left(1 - \frac{|\lambda_0^* - \lambda^*|}{BR}\right) \qquad (3)$$

Hier bedeuten k_D die Detektorkonstante (Größe des unverstärkten Signals pro Watt Strahlungsleistung), f_{SV} den Signalverstärkungsfaktor, F die Oberfläche des optischen Gitters, R die Lineardispersion am Ort des Austrittsspaltes und f die Brennweite des optischen Abbildungssystems.

Das Produkt BR entspricht bei vollständiger Abbildung der instrumentellen Verbreiterung der durchgelassenen schmalen Spektrallinie λ_0 d.h. der spektralen Bandbreite $\Delta\lambda_M$. Das Verhältnis von S_D bei falscher Einstellung λ^* zu $S_{D,max}$ bei richtiger Einstellung λ_0^* des Monochromators auf die Spektrallinie λ_0 beträgt, nach Gleichung (3):

$$S_D^{rel} = S_D/S_{D,max} = f_S = \left(1 - \frac{|\lambda_0^* - \lambda^*|}{\Delta\lambda_M}\right) \qquad (4)$$

f_S wird als Spaltfunktion bezeichnet, und kann entweder durch Messung von $S_D/S_{D,max}$ für eine scharfe Emissionslinie (s. Kreise in Abb. 1) oder durch Messung der relativen Absorption (% ABS)/(% ABS)$_{max}$ einer polychromatischen Strahlung in einem atomaren Absorber (s. Dreiecke in Abb. 1) in Abhängigkeit von λ^* erhalten werden. Emissions- und Absorptions-Messungen müssen für die gleiche mechanische Spaltbreite B die gleiche Spaltfunktion ergeben, falls $\Delta\lambda_M$ viel größer als $\Delta\lambda_{em}$ bzw. $\Delta\lambda_{ab}$ ist ($\Delta\lambda_{em}$ ist die Halbwertsbreite der Emissionslinie).

Die $\Delta\lambda_M$-Werte wurden als Kehrwerte der Neigungen von f_S, λ^* im Bereich (λ_0^*-$\Delta\lambda_M$) bzw. als absolute Kehrwerte der Neigungen von f_S, λ^* im Bereich (λ_0^* + $\Delta\lambda_M$) und durch Abmessen des Abstandes zwischen beiden Schenkeln der dreieckförmigen Spaltfunktionen bei der halben Höhe der Dreiecke ermittelt [s. Gleichung (4) und Abb.1]. Aus Messungen der Emissions-Intensität der Resonanzlinie des Cadmiums ($\lambda_0 = 228{,}80$ nm) erhielt man daher je 3 Werte für eine bestimmte Spaltbreite des Monochromators. In zwei Fällen wurde zusätzlich auch noch die Absorption einer polychromatischen Strahlung durch Cadmiumatome in der Graphitrohrküvette gemessen, so daß 6 $\Delta\lambda_M$-Werte erhalten wurden. Die Mittelwerte betragen $0{,}17 \pm 0{,}02_6$, $0{,}59 \pm 0{,}08_6$ und $1{,}60 \pm 0{,}13_3$ nm, bei den Spaltpositionen 2, 7 und 20 des Gerätes PE 300. Hierbei ist die Anzahl der Einzelwerte der einfachen Standardabweichung als ein Index zugefügt. Bei den Spaltpositionen 3, 4 und 5 des Gerätes 303 wurden die $\Delta\lambda_M$-Werte von $0{,}29 \pm 0{,}02_3$, $0{,}97 \pm 0{,}12_3$ und $3{,}41 \pm 0{,}53_3$ nm gefunden. Die für das Gerät 300 geltenden Nominalwerte sind im Durchschnitt 1,2-mal größer als die gemessenen Werte. Demgegenüber wurden beim Gerät 303—allerdings nach 7-jährigem Gebrauch—1,4-mal größere Bandbreiten als die Nominalwerte gefunden. Der Justierungsfehler ($\lambda_0^* - \lambda_0$) und die instrumentelle Unsicherheit der Position λ_0^* der Resonanzlinie können aus der Abb. 1 ebenfalls entnommen werden.

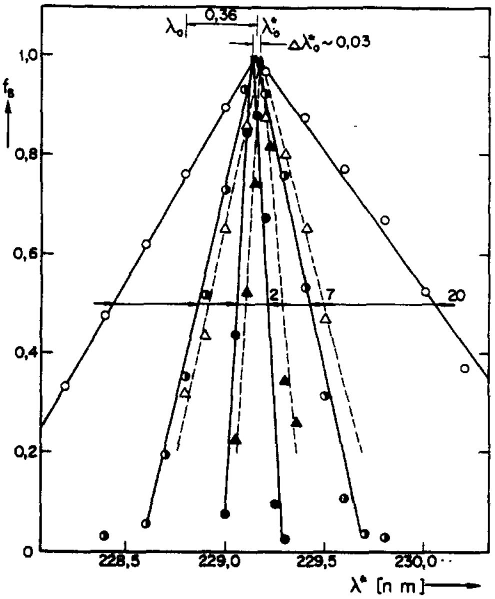

Abb. 1. Mit der Cd-Resonanzlinie (228,8 nm) aufgenommen Spaltfunktionen f_S eines Atomabsorptions-Spektrophotometers (Perkin Elmer 300) bei den Spaltpositionen 2, 7 und 20. Kreise: S_D^{rel}-Werte. Dreiecke: (% ABS)/(% ABS)$_{max}$-Werte, welche mit einer Wasserstofflampe als Strahlungsquelle und 2,2 μg Cd als atomarer Absorber in der Graphitrohrküvette erhalten wurden.

Die wichtigste Konsequenz einer dreieckförmigen Spaltfunktion besteht für die analytische Praxis darin, daß alle Störlinien λ^S im Bereich von $\lambda_0^* \pm \Delta\lambda_M$ einen Einfluß auf meßbare optische Dichte haben. Allerdings beträgt die an der Stelle λ_0^* registrierte Störintensität $I^s_{\lambda^*_0}$ nicht $I^s_{\lambda^*_s}$ sondern nur $f^s_S I^s_{\lambda^*_s}$. Eine polychromatische Störstrahlung mit der Intensitätsdichte

J_λ [$W \cdot cm^{-2} \cdot nm^{-1}$] liefert dagegen den Beitrag von $J_{\lambda_S^*}\Delta\lambda_M$ da J_λ im engen Bereich von $\Delta\lambda_M$ praktisch konstant ist. Lässt nun der Monochromator außer der Hauptresonanzlinie λ_0 mit der Intensität I_0 die schwächer absorbierten Linien $\lambda_1^a \ldots \lambda_m^a$ und die nicht absorbierten Störlinien $\lambda_1^s \ldots \lambda_m^s$ mit den relativen Intensitäten $I_1^a/I_0 \ldots I_m^a/I_0$, und $I_1^s/I_0 \ldots I_m^s/I_0$ durch, so wird die folgende optische Dichte gemessen:

$$D = \log \frac{1 + \Sigma f_{Sm}^a(I_m^a/I_0) + \Sigma f_{Sm}^s(I_m^s/I_0) + J_{\lambda_0^*}^q \Delta\lambda_M/I_0}{\exp[-a_0 w_A] + \Sigma f_{Sm}^a(I_m^a/I_0)] \exp[-a_m w_A + \Sigma f_{Sm}^s(I_m^s/I_0) + (J_{\lambda_0^*}^q + J_{\lambda_0^*}^r)\Delta\lambda_M/I_0} \tag{5}$$

Die Intensität von polychromatischen Störstrahlungen der Quelle q und des Atomreservoirs r können gewöhnlich vernachläßigt werden. Ihr Beitrag ist aber bei großen Spaltbreiten und schwachen Intensitäten der Resonanzlinien zu berücksichtigen. Die anfänglichen Neigungen der Eichkurven für die Linien λ_0, $\lambda_1, \ldots \lambda_m$ wurden in dieser Gleichung mit a_0, $a_1, \ldots a_m$ bezeichnet. Sie müssen mit einer derart engen Bandbreite bestimmt werden, daß keine Störlinien und nur unwesentliche polychromatische Strahlung in den Detektor gelangen.

Ermittlung des Ionisationsgrades von Ba, Na und Li und der freien Elektronenkonzentration in der Flamme

Bariumeichlösungen mit je $5 \cdot 10^{-4}M$ Bariumchlorid bzw. Bariumnitrat und 0,1*M* Perchlorsaüre bzw. Salpetersaüre sowie mit verschiedenen Kaliumchlorid- bzw. Kaliumnitrat-Konzentrationen wurden in die N_2O/C_2H_2- bzw. Luft/C_2H_2-Flamme eingespritzt. Aus den gemessenen optischen Dichten D_I (bei der Resonanzlinie von Ba, 553,6 nm) und D_{II} (bei der Resonanzlinie von Ba^+, 455,4 nm) wurden der Ionisationsgrad f_I^0 von Barium und die Konzentration N_e^0 der freien Elektronen in der Flamme ohne Kaliumzusatz (Index "o" oben rechts) nach den folgenden Beziehungen berechnet:

$$\frac{1 - D_I/D_I^0}{D_{II}/D_{II}^0 - D_I/D_I^0} = f_I^0 = \frac{1}{1 + N_e^0/K_{I_{Ba}}} \tag{6}$$

Man erhielt f_I^0-Werte für Barium von 0,916 ± 0,009 in der N_2O/C_2H_2-Flamme bzw. 0,10 ± 0,02 in der Luft/C_2H_2-Flamme. Diese entsprechen einer Elektronenkonzentration von $2{,}97 \cdot 10^{11}$ bzw. $3{,}9 \cdot 10^{11}$ cm^{-3} oder einem Elektronpartialdruck von $1{,}21 \cdot 10^{-7}$ bzw. $1{,}3 \cdot 10^{-7}$ atm. Die zur Berechnung von N_e^0 benötigte Ionisationskonstante $K_{I_{Ba}}$ von Barium wurde aus der Saha-Gleichung[6] berechnet. Sie beträgt $10^{12{,}51}\,cm^{-3}$ bei 3000 K bzw. $10^{10{,}64}\,cm^{-3}$ bei 2500 K.

Mit den f_I^0-Werten wurde nun der chemischen Ionisationsgrad f_I^K von Barium und die Elektronenkonzentration N_e^K in Gegenwart von Kalium aus der folgenden Beziehung berechnet:

$$f_I^0 \frac{D_{II}}{D_{II}^0} = f_I^K = \frac{1}{1 + N_e^K/K_{I_{Ba}}} \tag{7}$$

In Abb. 2 sind f_I^K und N_e^K gegen die Molarität [K] des Kaliums in der eingespritzten Lösung graphisch aufgetragen. Zur Berechnung der N_e^K-Werte wurden die Mittelwerte der beiden f_I^K-Werte eingesetzt.

Die Elektronenkonzentration N_e^K nimmt mit zunehmender [K] langsamer zu als die berechnete Elektronenkonzentration N_e^*. Letztere kann unter der Annahme erhalten werden, daß die Flammengase das Ionisationsgleichgewicht

$$K \rightleftharpoons K^+ + e^-; K_{I_K} = N_{K^+} \cdot N_e^*/N_K \tag{8}$$

nicht stören. N_e^* bedeutet also die Elektronenkonzentration in einem hypothetischen Atomreservoir, welches nur K, K^+ und e^- enthält, sonst aber die gleichen Kenngrößen wie die Flamme aufweist. In diesem Reservoir sind N_{K^+} und N_e^* immer gleich groß, so daß die Auflösung von Gleichung (8) nach N_e^* bei gleichzeitiger Elimination der unbekannten Konzentration N_K ergibt:

$$N_e^* = \tfrac{1}{2}[-K_{I_K} + (K_{I_K}^2 + 4\,K_{I_K}[K] \cdot 6{,}02 \cdot 10^{20}/f_{VF})^{1/2}] \tag{9}$$

Bei der Herleitung dieser Beziehung wurde angenommen, daß die Verdünnung f_{VF} des Kaliums beim überführen aus der Lösung in die Flamme bzw. in das hypothetische Atomreservoir dieselbe ist, so daß N_K durch Subtraktion von N_e^* ($= N_{K^+}$) von der Totalkonzentration $[K] \cdot 6{,}02 \cdot 10^{20}/f_{VF}$ erhalten wird. Die Verdünnung f_{VF} beim Uberführen des Kaliums aus der Lösung in die N_2O/C_2H_2-Flamme betrug $6{,}23 \cdot 10^5$ [s. auch Gleichung (12)]. Die N_e^*-Werte ergeben eine leicht gekrümmte Kurve (s. Abb. 2), welche *ca.* 2-mal steiler ist als die experimentelle N_e^K-Gerade. Offensichtlich geben die K-Atome ihre Elektronen zum Teil an die Komponenten des Flammengases ab.

Das Barium erwies sich als ein guter Indikator für die freie Elektronenkonzentration N_e^K bei verschiedenen Kalium-konzentrationen in der N_2O/C_2H_2-Flamme. In der kälteren Luft/C_2H_2-Flamme liegt alles Barium in Form von Ba und BaO vor, falls [K] größer als *ca.* 0,002 *M* ist. Das Verhältnis D_{II}/D_{II}^0 kann daher nicht genügend genau bestimmt werden und kann nicht als Maß für N_e^K dienen. Ein geeignetes Indikatorelement wäre das Cäsium, welches in der Luft/C_2H_2-Flamme in Abwesenheit leicht ionisierbarer Elemente eine Ionisation von 92% erleidet. Cs^+ hat leider keine Resonanzlinie im Spektralbereich von 200 bis 900 nm. Aus der Messung von D_I in Abhängigkeit von [K] kann f_I^{Cs} nur mit gewissen Annahmen berechnet werden, worauf hier verzichtet wird.

Unter den untersuchten Metallen haben außer Barium und Cäsium noch Lithium und Natrium

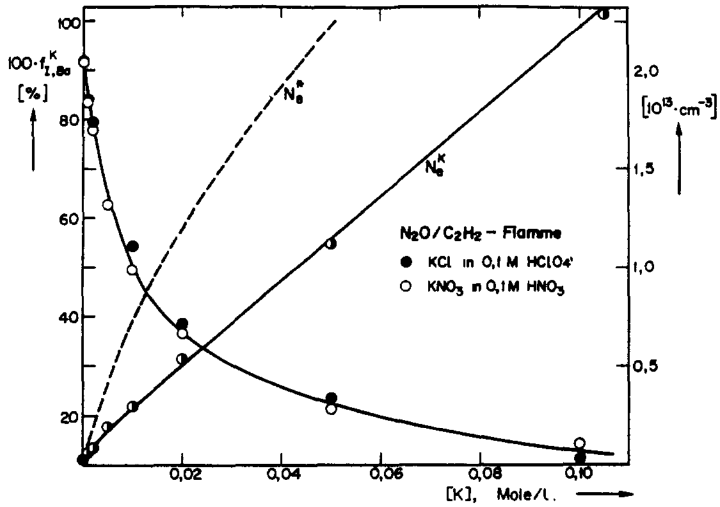

Abb. 2. Ionisationsgrad $f^{K}_{I,Ba}$ von Barium und Konzentration N_e^K der freien Elektronen in der C_2H_2/N_2O-Flamme bei verschiedenen Kaliumkonzentrationen in der eingespritzten Lösung. ($Q_{bg} = 8{,}4$, $Q_{ox} = 17{,}1$ l./min $T = 3000$ K, Beobachtung *ca.* 10 mm über der Austrittsöffnung).

kleine Ionisationsenergien und somit große Ionisationskonstanten K_I von $10^{9,61}$ und $10^{10,12}\,cm^{-3}$ bei 2500 K. Setzt man diese Werte und die mit Barium als Indikator ermittelte Elektronenkonzentration N_e^0 von $3{,}9 \cdot 10^{11}$ in die Gleichung (6) ein, so erhält man einen Ionisationsgrad von 1,0% bzw. 3,3% für Lithium bzw. Natrium.

RESULTATE UND DISKUSSION

Zur Diskussion der Empfindlichkeit von atomabsorptiometrischen Bestimmungen muß N_j in der Gleichung (2) mit der experimentell zugänglichen Konzentration w_A der Lösung in Zusammenhang gebracht werden. Dabei muß berücksichtigt werden, daß ein Teil der Atome eventuell chemisch gebunden (N_C) oder ionisiert (N_I) ist. Die freien Atome befinden sich in verschiedenen energetischen Zuständen, 0, 1,...*j*,...*i*,...*m*, wobei 0 den Grundzustand, *j* das untere Niveau (meistens $j = 0$) und *i* das obere Niveau des Überganges *ij* und *m* die Termlaufzahl bezeichnen.

$$N_t = N_C + N_I + N_0 + N_1 + \dots + N_j + \dots + N_i + \dots + N_m = N_A/f_C(1 - f_I) \quad (10)$$

Hier bedeuten $f_C = (N_A + N_I)/N_t$ den Dissoziationsgrad, $f_I = N_I/(N_A + N_I)$ den Ionisationsgrad und N_A die Summe von N_0 bis N_m.

Die totale Konzentration N_t aller A-Spezies kann aus der Konzentration w_A [μg A/g der Lösung] der in das Atomreservoir (r, d.h. die Flamme bzw. Küvette) eingespritzten Lösung berechnet werden:

$$N_t = 6{,}022 \cdot 10^{17} \cdot d\, w_A/f_V\, M \quad (11)$$

In dieser Gleichung bedeuten *d* die Dichte der eingespritzten Lösung, *M* die relative Molmasse und f_V die Verdünnung ($= N_{t,L_g}/N_{t,r}$). Wenn das Atomreservoir eine Flamme (F) ist, kann f_{VF} der eingestellten Strömungsgeschwindigkeit [ml/min] des Brenngases Q_{bg} und des Oxidants Q_{ox} berechnet werden. Nimmt man an, daß sich sowohl die Flamme mit der Temperatur T_F als auch die Brennmischung bei der Raumtemperatur T_R ideal verhalten, erhält man für f_{VF}:

$$f_{VF} = \frac{(Q_{bg} + Q_{ox})(T_F/T_R)(n_F/n_R)}{Q_{L_g} f_Z} \quad (12)$$

Das Verhältnis n_F/n_R der Molzahlen nach und vor Ablauf der Verbrennungsreaktion[7] berücksichtigt die durch die Teilchenzahlerhöhung bedingte Ausdehnung der Flamme. Q_{L_g} bezeichnet die Geschwindigkeit der Lösungszufuhr [ml/min], von welcher nur der Anteil $f_Z Q_{L_g}$ in die Flamme gelangt.

Die Verdünnung in der Küvette kann nur näherungsweise berechnet werden, da im Gegensatz zur Flamme keine stationäre Zu- und Abfuhr der Atome erfolgt. Man atomisiert den A-Gehalt einer Lösungsmenge *V* von 5 bis 50 μl während einer kurzen Zeit[8] (z.B. 0,5 bzw. 2 s im Falle von Cadmium bzw. Kupfer). Wenn wir annehmen, daß die Atomwolke die Küvette mit dem Radius *r* und der Länge L_K beim Erscheinen des Absorptionsmaximums gleichmäßig ausfüllt, erhalten wir:

$$f_{V_K} \simeq r^2 \pi L_K/V \quad (13)$$

In Kenntnis von N_A kann nun der Anteil N_j der absorbierenden Atome berechnet werden. In einer laminaren Flamme und in einer Graphitrohrküvette herrscht zwischen den verschiedenen Zuständen 0, 1,...*j*...*i*...*m* mit den Energien E_0, E_1,...E_j...E_i...E_m ein thermodynamisches Gleichgewicht, so daß diese Zustände nach der Boltzmann-Verteilung populiert sind:

$$N_j = (2\,J_j + 1)\frac{\exp[-(E_j - E_0)/kT]}{F_A(T)} \cdot N_A = g_j f_A N_A \quad (14)$$

Hierbei bedeuten J_j die Gesamtdrehimpulsquantenzahl, k die Boltzmann-Konstante und $F_A(T)$ die atomare, innere Zustandsumme:

$$F_A(T) \equiv \sum_{0}^{m^*} g_m \exp\left[-(E_m - E_0)/kT\right] = g_0 \sum_{0}^{m^*} N_m/N_0 \tag{15}$$

Die Summierung kann bei demjenigen Grenzterm m^* abgebrochen werden, dessen Beitrag kleiner als die gewünschte Genauigkeit (z.B. 0,002 in dieser Arbeit) ist.

Schließlich muß man noch berücksichtigen, daß die Halbwertsbreite $\Delta\lambda_{em}$ der Emissionslinie in Wirklichkeit nicht vernachlässigbar klein ist. Wenn das Profil der Emmisionslinie ebenfalls der Form einer Gauss'schen Glockenkurve entspricht, kann[9] dieses dadurch geschehen, daß man $\Delta\lambda_{ab}$ in der Gleichung (2) einfach durch $(\Delta\lambda_{ab}^2 + \Delta\lambda_{em}^2)^{1/2}$ ersetzt. Berechnet man gleichzeitig das Produkt der Konstanten, so ergibt die Kombination der Gleichungen (1), (2), (10), (11) und (14) die folgende Beziehung zwischen D und w_A:

$$D = (2{,}175 \cdot 10^5\ \mathrm{cm \cdot mole^{-1}}) \frac{f_C(1 - f_I)dL}{M f_V} \times \frac{\lambda_0^2 (gf) f_A}{(\Delta\lambda_{ab}^2 + \Delta\lambda_{em}^2)^{1/2}} \cdot w_A = a_0 w_A \tag{16}$$

a_0 kann als die anfängliche Neigung der Eichkurven D, w_A experimentell bestimmt werden. Bei g und f wurden die Indizies weggelassen, da $g_j f_{ji} = g_i f_{ij}$.

Von den zur Berechnung der a_0-Werte benötigten Daten sind d, L, M, und f_V leicht zu ermitteln. f_A kann gemäß der Definitionsgleichung (14) aus dem Termschema[10] des betreffenden Atoms beliebig genau berechnet werden. Der Ionisationsgrad f_I hängt bei einer bestimmten Temperatur des Atomreservoirs nur von der Konzentration der freien Elektronen ab [s. auch Gleichungen (6) und (7)]. Gewöhnlich ist die totale Konzentration N_t des zu bestimmenden Elementes viel kleiner als die Elektronenkonzentration N_e^0 der Flamme selbst, so daß f_I im ganzen Meßbereich von w_A konstant ist und nur die anfängliche Neigung von D, w_A beeinflußt sonst aber keine Krümmung der Eichkurven verursacht.

Die emissionspektroskopisch ermittelten (gf)-Werte[11] sind nicht besonders präzise. Die in der Tabelle 1 angegebenen Halbwertsbreiten $\Delta\lambda_{ab}$ der Absorptionslinien sind Mittelwerte von berechneten Grenzwerten[12] und weisen daher eine recht große Unsicherheit auf. Ebenfalls sind die chemischen Dissoziationsgrade sehr schwierig zu ermitteln. Für die Halbwertsbreiten $\Delta\lambda_{em}$ der Emissionslinien stehen nur vereinzelt Daten zur Verfügung. Daher wurden alle Abschätzungen mit der Annahme von $f_C = 1$ und $\Delta\lambda_{em} = 0$ berechnet (a_0^*-Werte in der Tabelle 2). Für das Cäsium wurde kein a_0^*-Wert abgeschätzt, da der Ionisationsgrad f_I in Gegenwart von 0,01M Kaliumchlorid in der eingespritzten Lösung (s. Tabelle 1) nicht bestimmt wurde. Bei der Berechnung der a_0^*-Werte wurde bei allen Messungen mit der Luft/C_2H_2-Flamme die gleiche Verdünnung f_{VF} angenommen, was ebenfalls nur näherungsweise zutrifft.

Aus den erwähnten Gründen erwartet man, daß die abgeschätzten Neigungen a_0^* nur näherungsweise mit den anfänglichen Neigungen a_0 der Eichkruven D, w_A übereinstimmen. Dabei muß ein Verhältnis $a_0/a_0^* \geq 0{,}2$ bereits als eine gute Voraussage für die Größenordnung der meßbaren optischen Dichte betrachtet werden. Im Falle von $Cd_{a,b,c}$, Zn, Pd, Ni, Fe und Na trifft dies zu. Barium und Indium bzw. Lithium liegen zum Teil als Oxide bzw. als Hydroxid in der Flamme vor und ergeben daher eine kleinere Empfindlichkeit als man unter der Annahme von $f_C = 1$ erwartet. Das Platin atomisiert vermutlich un-

* Bei allen diesen Linien ($\lambda_0 = hc/(E_i - E_j)$) ist das zugehörige untere Niveau j mit dem Grundzustand 0 identisch so daß $f_A = 1/F_A(T)$ ist (wegen T s. folgende Bemerkung.)

† Ba wurde in der Acetylen/Lachgas-Flamme (T = 3000 K) und die übrigen Elemente wurden in der Acetylen/Luft-Flamme (T = 2500 K) bestimmt.

vollständig, was die Unempfindlichkeit der Platinbestimmung erklärt.

Die Gleichung (16) erklärt die Befunde bei Änderungen wichtiger experimenteller Parameter in befriedigendem Maße.

1. Eine empfindliche Bestimmung ist nur bei Wellenlängen des betreffenden Elementes möglich, welche dem Übergang des Atoms aus dem Grundzustand oder aus einem dem Grundzustand 0 energetisch nahe liegenden Zustand j in den angeregten Zustand i angehören. Der Faktor f_{A} nimmt nämlich mit $(E_j - E_0)$ exponentiell ab.

2. Die Ionisation von Metallen mit niedrigen Ionisationsenergien muß durch Erhöhung der Konzentration der freien Elektronen in der Flamme zurückgedrängt werden. Die maximale Empfindlichkeit wird natürlich bei $f_{\mathrm{I}} = 0$ erreicht. Bei der Bestimmung des Bariums in der N_2O/C_2H_2-Flamme wird dieses nur erreicht, wenn die Konzentration vom Kaliumchlorid in der eingespritzten Lösung mehr als $0.1M$ beträgt. Solche Lösungen sind jedoch für die analytische Praxis nicht gut geeignet, da sich Störungen infolge Kaliumchlorid-Abscheidung an der Austrittsöffnung des Brenners einstellen. Eine Kaliumchlorid-Konzentration von $0{,}01M$ stellt eine gute Kompromißlösung betreffend Empfindlichkeit und Präzision dar. In Abwesenheit leicht ionisierbarer Begleitstoffe kann natürlich auch die Resonanzlinie von Ba^+ benutzt werden.

3. Damit keine systematischen Eichfehler entstehen, muß f_{VF} beim Einspritzen von Eichlösungen und der zu analysierenden Lösungen dieselbe sein. Gemäß der Definitionsgleichung (12) müssen daher alle Lösungen dieselbe Temperatur haben, und müssen alle drei Flüsse Q_{bg}, Q_{ox} und Q_{Lg} konstant bleiben. Damit alle Lösungen gleich schnell angesaugt und mit dem gleichen Wirkungsgrad f_{Z} zerstäubt werden, müssen alle Lösungen ungefähr die gleiche Viskosität haben. Das wird praktisch der Fall sein, wenn die Konzentrationen der Begleitstoffe in allen Lösungen auf mindestens 10% übereinstimmen.

Die Größenordnung der Erhöhung der Empfindlichkeit beim Übergang von der Flammen- zu der Küvettentechnik kann mit der kleineren Verdünnung in der Küvette in befriedigender Weise erklärt werden. Während die gemessene Empfindlichkeitszunahme $a_{0,\mathrm{K}}/a_{0,\mathrm{F}}$ für die Resonanzlinie (228,8 nm) des Cadmiums 1620 betrug, ergibt Gleichung (16) für $a^{\bullet}_{0,\mathrm{K}}/a^{\bullet}_{0,\mathrm{F}}$ einen Wert von 4400, wenn f_{VK} 40 beträgt, d.h. wenn in der Küvette je 100 μl von Cadmiumlösungen verschiedener Konzentration atomisiert werden. Bei der Küvettentechnik ist die in die Küvette eingebrachte Menge q_{A} des zu bestimmenden Elementes A maßgebend, so daß die Eichkurven meistens in der Form D, q_{A} dargestellt werden. Aus der anfänglichen Neigung $b_{0,\mathrm{K}}$ dieser Eichkurve kann $a_{0,\mathrm{K}}$ leicht berechnet werden: $a_{0,\mathrm{K}} = b_{0,\mathrm{K}} V d$. Nach unserer Erfahrung sind die Eichkurven D, w_{A} bei konstantem Einspritz-Volumen V der Eichlösungen verschiedener Konzentration w_{A} besser reproduzierbar als die Eichkurven D, q_{A} bei variablen Mengen einer einzigen Eichlösung. Im letzten Fall beeinflussen nämlich die Benetzung der Graphitoberfläche durch die Lösung und die Verteilung der Atomwolke in der Küvette die meßbare optische Dichte, wobei aber diese Beeinflussung vom V in schlecht kontrollierbarer Weise abhängt.

4. Gemäß Gleichung (16) beträgt das Verhältnis $a^{\bullet}_0/a^{\bullet}_1$ der Neigung der Hauptresonanzlinie λ_0 zu der Neigung der Negenresonanzlinie λ_1, $(\lambda^2 gf/\Delta\lambda_{\mathrm{ab}})_0/(\lambda^2\, gf/\Delta\lambda_{\mathrm{ab}})_1$. Dieses entspricht bei den Linien des Cadmiums einem theoretischen Verhältnis von 510. Die Messungen ergaben den beinahe gleichen Wert von 475.

5. Verwendet man eine polychromatische Strahlungsquelle PQ anstelle einer Spektrallampe SL, so muß $\Delta\lambda_{\mathrm{em}}$ in der Gleichung (16) durch $\Delta\lambda_{\mathrm{M}}$ ($\gg \Delta\lambda_{\mathrm{ab}}$) ersetzt werden. Unter Vernachlässigung des kleinen Formfaktors f_{G} erhält man für dieselbe Linie des betreffenden Elementes: $a_0^{\mathrm{SL}}/a_0^{\mathrm{PQ}} = \Delta\lambda_{\mathrm{M}}/\Delta\lambda_{\mathrm{ab}}$. Nach dieser Beziehung liegen die Verhältnisse der anfänglichen Neigungen beider Eichkurven $(D, w_{\mathrm{A}})_{\mathrm{SL}}$ und $(D, w_{\mathrm{A}})_{\mathrm{PQ}}$ in der Größenordnung von 10 bis 100 falls eine spektrale Bandbreite von 0,1 nm benutzt wird. Die $\Delta\lambda_{\mathrm{ab}}$-Werte liegen nämlich im Bereich von 10^{-2} bis 10^{-3} nm (s. Tabelle 1).

6. Irgendwelche Voraussagen der Gleichung (16) treffen nur dann zu, wenn der Monochromator nur die gewünschte Linie durchläßt. Bei der Erhöhung der spektralen Bandbreite fallen eventuell mehrere Linien in den Detektor, was die meßbare optische Dichte beeinflußt. Dieses kann experimentell am einfachsten durch Aufnahme der Kurve D, $\Delta\lambda_{\mathrm{M}}$ beim Konstanthalten der Konzentration w_{A} in der eingespritzten Lösung geprüft werden (s. Kurven für Li, K und Fe in Abb. 3).

Die beiden Komponenten des Resonanzdoubletts von Lithium sind auch bei der kleinsten spektralen Bandbreite nicht aufgelöst. In dem Spektralbereich von 670,8 ± 20 nm befinden sich keine Störlinien. Zudem ist hier auch die polychromatische Störstrah-

lung sehr schwach. In diesem Idealfall ist D gemäß Gleichung (5) von $\Delta\lambda_M$ unabhängig (s. Gerade "Li" in Abb. 3). Im Falle von Kalium beträgt die Resonanzaufspaltung 3,4 nm. Dementsprechend sinkt die optische Dichte bei $\Delta\lambda_M > 3$ nm entsprechend der Voraussage von Gleichung (5). Nach dieser muß nämlich bei größeren Bandbreiten neben der Hauptresonanzlinie λ_0 (= 766,5 nm) auch noch die schwächer absorbierte Komponente λ_1^a (= 769,9 nm) des Resonanzdubletts berücksichtigt werden. Das Eisenatom hat mehrere Linien in der Umgebung der Hautresonanzlinie. Bei Öffnen des Spaltes müssen sukzessive immer mehr Linien λ^a und λ^a berücksichtigt werden, so daß sich D mit zunehmender $\Delta\lambda_M$ auf einen Viertel reduziert. Merkwürdigerweise wird eine maximale optische Dichte nicht bei dem engsten Spalt erhalten. Das kann nur mit starker polychromatischer Störstrahlung erklärt werden. Diese konnte quantitativ nicht ermittelt werden, so daß auf die Berechnung der Kurve D, $\Delta\lambda_M$ mit Hilfe der Gleichung (5) verzichtet wird. Mit Hilfe der Kurven D,$\Delta\lambda_M$ kann die optimale Spaltbreite leicht ermittelt werden. Da das elektronische Rauschen des Detektorsignals mit zunehmender Strahlungsintensität abnimmt, muß die größte spektrale Bandbreite, bei welcher noch keine wesentliche Abnahme der meßbaren optischen Dichte auftrifft, als optimal angesehen werden.

7. Schließlich soll noch der Einfluß des Lampenstromes LS der Spektrallampe auf die meßbare Intensität kurz diskutiert werden. Dieser Effekt wurde im Falle von Cadmium bei Messungen sowohl mit der Flamme[13] als auch mit der Graphitrohrküvette[14] als Atomreservoir beobachtet. Wir haben diesen Effekt systematisch untersucht, wobei Eichkurven für mehrere Metalle mit unterschiedlichem Dampfdruck bei zwei möglichst verschiedenen Stromstärken aufgenommen wurden. Diese Metalle sind in der ersten Kolonne der Tabelle 2 in der Reihenfolge ihres abnehmenden Dampfdruckes[15] bei 400 K angeführt. Log p_A wurde für diese Temperatur berechnet, da in der Hohlkathode ungefähr diese Temperatur[16] herrschen soll. Als maximale Stromstärke (max. LS) wählte man den vom Hersteller empfohlene Maximalwert (100%). Als möglichst kleine Stromstärke wurde 60% des Maximalwertes gewählt, da eine weitere Stromreduktion Schwankungen der Linienintensitäten zur Folge hatte. Das Verhältnis $a_0(60\%)/a_0(100\%)$ der anfänglichen Neigungen beider Eichkurven erwies sich als eine geeignete Kenngröße für den "Lampenstromeffekt". Die Fehlerangaben für diese Kenngröße bedeuten den Vertrauensbereich für 95%-ige statistische Sicherheit und wurde durch Fehlerfortpflanzung aus den Fehlern beider a_0-Werte ermittelt. Wenn der Dampfdruck p_A des Hohlkathodenelementes größer als 10^{-15} mmHg bei der betreffenden Hohlkathodentemperatur beträgt, wird die anfängliche Neigung und auch die Form der Eichkurven D, w_A eine Stromabhängigkeit zeigen. Den größten Lampenstromeffekt zeigt das Cadmium mit besonders hohem Dampfdruck. Cadmium hat zugleich einen tiefen Schmelzpunkt, welcher zur Erklärung des Lampenstromeffektes herangezogen wurde.[13] Indium schmilzt jedoch viel tiefer als Cadmium und zeigt einen kleinen, eher umgekehrten Lampenstromeffekt, was eine Korrelation zwischen dem Schmelzpunkt und Stromabhängigkeit der Neigung nicht zuläßt. Bei der Bestimmung von Cäsium und Natrium wurden Gasentladungsröhren verwendet. Bei diesen kann eine Entladungsstromeffekt ebenfalls beobachtet werden. Der Effekt ist jedoch viel

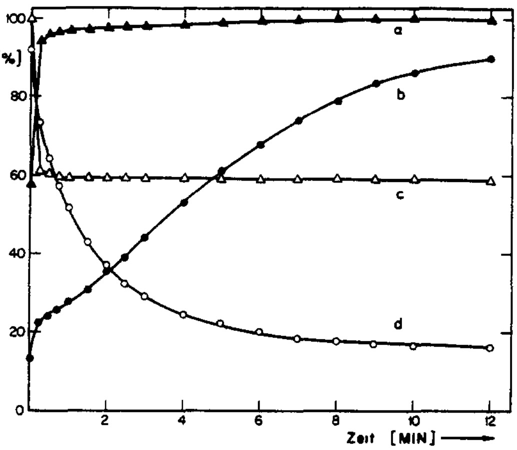

Abb. 4. Zeitlicher Verlauf der relativen Intensität der Resonanzlinie (228,8 nm) einer handelsüblichen Cd-Hohlkathodenlampe (HLK) und einer Cd-HKL mit thermostatisierter Hohlkathode nach plötzlicher Änderung des Lampenstromes um 25%. Dreiecke: thermostatisierte Cd-HKL, 1,2 mmHg Ar, 28°C. *a*: Erhöhung der Stromstärke von 28 auf 32 mA *c*: Verminderung der Stromstärke von 32 auf 24 mA Kreise: käufliche HKL, Ar *b*: Erhöhung der Stromstärke von 6 auf 8 mA *d*: Verminderung der Stromstärke von 8 auf 6 mA

weniger ausgeprägt da sich der Dampfdruck in diesen Lampen bei Erhöhung des Entladungsstromes nur wenig erhöht.

Um einen direkteren Beweis für den Zusammenhang zwischen dem Dampfdruck p_{Cd} und dem großen Lampenstromeffekt von 3,6 zu erbringen, wurde eine Hohlkathodenlampe mit thermostatisierter Kathode gebaut. Der Lampenstrom-Effekt für diese Lampe ist kaum nachweisbar (s. Tabelle 2). Für die analytische Praxis bringt die Thermostatierung der Hohlkathode einen bemerkenswerten Vorteil: nach einer Veränderung des Lampenstromes stellt sich die relative Emissionsintensität sehr rasch auf einen neuen Wert ein (s. Kurven *a* und *c* in Abb. 4). Die relative Intensität I_{rel} einer käuflichen Lampe mit nicht thermostatierter Hohlkathode nimmt dagegen erst nach 15 Minuten einen einigermassen konstanten Wert an. Der Verlauf der Kurven *b* bzw. *d* entspricht einer typischen Aufheiz- bzw. Abkühlkurve. Dieses unterschiedliche Verhalten beider Cadmium-Lampen und die Tatsache, daß die Hohlkathodenlampen mit schwerflüchtigen Elementen keinen Lampenstromeffekt zeigen, beweisen eindeutig, daß es sich bei der Verbreiterung der Emissionslinie um Linienumkehr handelt. Bei dieser Art Linienverbreiterung besitzt die Emissionslinie der Hohlkathodenlampe kein glockenförmiges Profil. Aus diesem Grunde würde die Auflösung von Gleichung (16) nach $\Delta\lambda_{em}$ nur eine hypothetische Halbwertsbreite ergeben.

Die Bedeutung der analytischen Form der Funktion D, w_A (Gleichungen (5) und (16)), besteht ganz allgemein nicht in zahlenmäßigen Voraussagen, sondern in komprimierter Darstellung aller atomabsorptiometrisch wichtigen Faktoren.

Anerkennungen—Der Eidg. Stiftung zur Förderung Schweizerischer Volkswirtschaft durch wissenschaftliche Forschung danken wir für die finanzielle Unterstützung.

Summary—The application of secondary-electron capture negative-ion (SECNI) mass spectrometry to the analysis of metal-organic compounds is described and typical examples are discussed. Negative-ion mass spectra are simple, molecular anions and ligand ions being the predominant species. Metallic or ligand impurities are readily identified by this technique, which makes it extremely useful for the determination of purity and formulation of metal-organic compounds. Because of its sensitivity, the technique is also valuable for trace metal analysis.

Positive-ion electron-impact mass spectrometry is a useful analytical tool for both inorganic and organic compounds and the applications of this technique have been reviewed comprehensively.[1,2] The possibility of using chemical ionization mass spectrometry for the analysis and study of metal-organic compounds has been proposed, but this application has so far been restricted.[3–5]

For the analysis of metal-organic compounds, and particularly metal chelates, both of these techniques have limitations. The disadvantages of conventional mass spectrometry as an analytical tool for metal-organic compounds are twofold. Interaction of a 70-eV electron beam with a metal-organic molecule frequently produces excessive fragmentation, yielding a complex mass spectrum (especially for mixtures of species containing different polyisotopic metal atoms). Further, the absence of intense peaks due to metal cations in the spectra of many metal-organic compounds can lead to erroneous analytical conclusions. The chemical ionization technique is limited for general use because of the need for high-pressure source and reagent-gas facilities.

The application of secondary-electron capture negative-ion (SECNI) mass spectrometry to the analysis of metal-organic compounds overcomes many of these difficulties. Although this technique is also, in principle, applicable to the analysis of organic compounds it would have less versatility in this field. The number of organic compounds amenable to the capture of secondary or thermal electrons with the formation of molecular anions is very limited unless appropriate derivatives are first synthesized.[6–9] The main value of the SECNI technique is in the analysis of metal-organic compounds, since either the metal or the ligand may act as a site for electron capture. With polyisotopic metals, ready identification of both molecular and fragment anions can be achieved.[10–12] The present paper gives examples of the application of this new technique to the analysis of metal-organic compounds.

EXPERIMENTAL

The instrument used was a modified Hitachi Perkin-Elmer RMU-6L single focusing mass spectrometer, capable of operating in both the positive and negative ion modes. Instrumental parameters used for SECNI spectra were as follows: electron energy 70 eV, filament current 3.2 A, target voltage 100 V, target current 40 μA, total emission 50 μA, ion accelerating voltage 3.2 kV, repeller voltage zero and ion-source pressures $<5 \times 10^{-6}$ mmHg. Total negative-ion currents, measured with a retractable probe placed after the ion-exit of the source, were commonly 1–10% of those obtained for positive ions for the same samples, although with some samples this value may reach approximately 50%. Thus, with an electron-multiplier detector with a gain of $>10^6$, ample sensitivity for the detection of negative ions was available. Spectra were obtained at the lowest possible sample and ionization-chamber temperatures. Additional characterization of each compound was obtained by recording its positive-ion mass spectrum within minutes of its negative-ion spectrum, the same temperature and ion-source conditions being maintained. Care was taken to show that pyrolysis, followed by electron impact, was not the route to the production of the significant ions in the spectra. All spectra were checked for reproducibility. Mass-marking was accomplished by running a duplicate spectrum in the presence of perfluorokerosene. Ion identification was assisted by comparing the spectrum with a computer simulation based on known isotopic abundances.[11] All compounds were prepared by standard published methods and were recrystallized or sublimed before use.

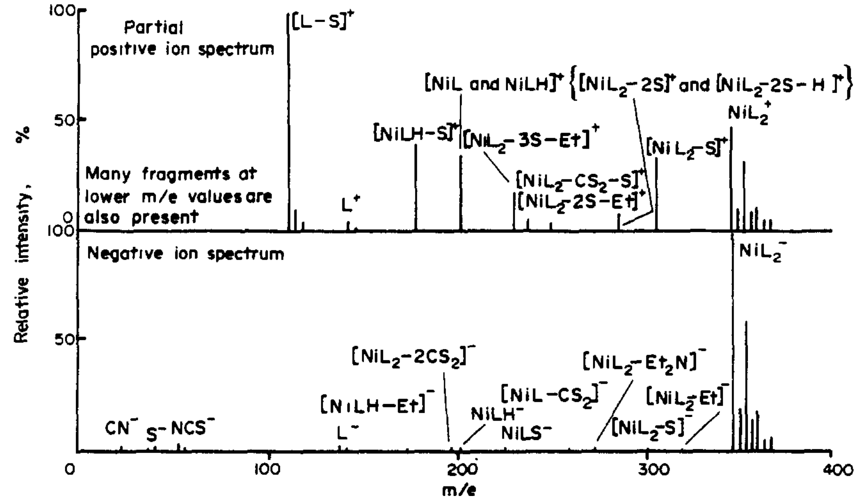

Fig. 1. 70-eV positive- and negative-ion mass spectra of bis(diethyldithiocarbamato)nickel(II) (NiL_2), where $L = (S_2CNEt_2)^-$. For clarity only complete clusters are shown for the molecular ions (with the *m/e* scale expanded); other fragment ions are shown in terms of ^{58}Ni (or ^{32}S for species containing no metal ion).

RESULTS AND DISCUSSION

The following examples have been chosen to illustrate the advantages of secondary-electron capture negative-ion mass spectrometry as an analytical tool for metal-organic compounds. The most important features of negative-ion mass spectra of metal-organic compounds are their extreme simplicity and absence of instrumental background. These features are demonstrated in Fig. 1 where the complete negative-ion and partial positive-ion mass spectra of bis(diethyldithiocarbamato)nickel(II) are compared. Significantly, 97% of the total negative-ion current is carried by the molecular anion. Virtually all bivalent metal dialkyldithiocarbamate compounds of this type give similar simple negative-ion mass spectra[13] and these ligands are useful chelating reagents for quantitative trace metal analysis[14] by this technique. Inclusion of an aromatic ring in the dithiocarbamate ligand leads to a greater degree of fragmentation of the complex as shown by the SECNI spectrum of bis(ethylphenyldithiocarbamato)nickel(II).[13] Even so, this fragmentation is not extensive enough to preclude the use of this ligand for analytical purposes.

The advantages of such simple spectra for analytical work are obvious since both identification of complexes and determination of particular metals in mixtures may be readily achieved. An additional example is provided by the metal hexafluoroacetylacetonates;[15] in Fig. 2 the positive- and negative-ion mass spectra of the aluminium complex are illustrated. Again, the negative-ion spectrum is much the simpler and the dominant negative ions are the molecular ion and the ligand fragment ion formed from it in the process $[Al(CF_3COCHCOCF_3)_3]^- \xrightarrow{*} (CF_3COCHCOCF_3)^-$. Similar negative-ion mass

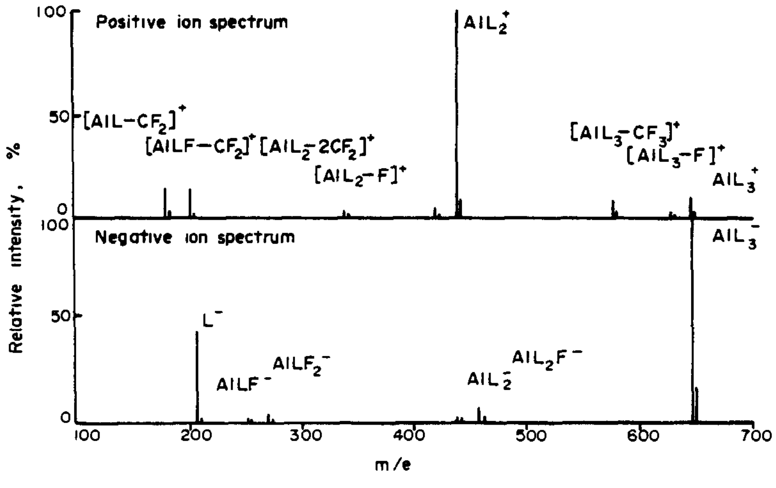

Fig. 2. 70-eV positive- and negative-ion mass spectra of tris(hexafluoroacetylacetonato)aluminium(III) (AlL_3), where $L = (CF_3COCHCOCF_3)^-$.

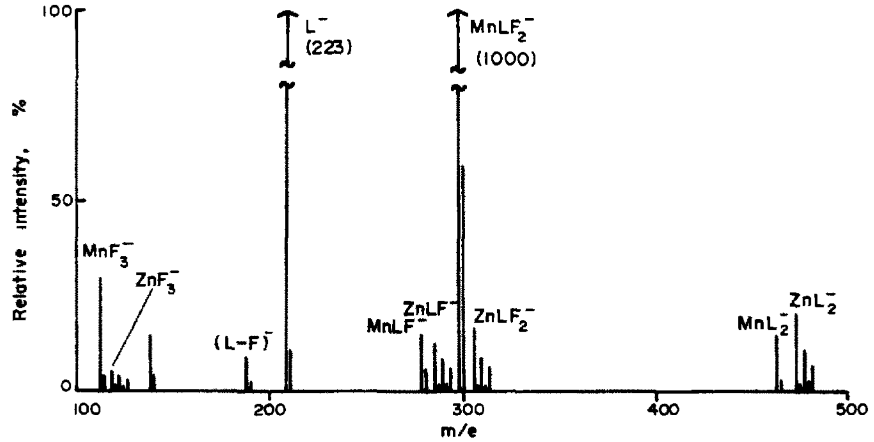

Fig. 3. 70-eV negative-ion mass spectrum of a sample of bis(hexafluoroacetylacetonato)manganese(II), (MnL$_2$), which contained the analogous zinc(II) complex as an impurity, (ZnL$_2$), where L = (CF$_3$COCHCOCF$_3$)$^-$.

spectra are obtained for metal complexes of other fluorinated β-diketones.[16]

The SECNI technique is also useful for the detection of trace metal impurities in complexes because of the ease of assignment[11,12] of peaks. In particular, the presence of characteristic clusters of peaks due to polyisotopic metals facilitates the identification of these impurities.[11] In Fig. 3, a sample of bis(hexafluoroacetylacetonato)manganese(II) is shown to contain the analogous zinc(II) complex as an impurity even though the manganese complex was prepared from "pure" reagents. The use of positive-ion mass spectrometry is not satisfactory for this purpose because neither metal complex gives a relatively intense molecular cation peak and the spectra are further complicated by extensive fragmentation peaks.

An additional advantage is in the detection of ligand impurities in a metal complex. A sample of bis-(1,1,1-trifluoro-7-methyl-2,4-octanedionato)copper(II), prepared from copper(II) acetate and the ligand, sublimed and having a satisfactory elemental analysis, was analysed by its SECNI spectrum, illustrated in Fig. 4. This spectrum revealed the presence of the complex bis(1,1,1-trifluoro-5-methyl-2,4-hexanedionato)copper(II) as an impurity. SECNI mass spectral analysis of the ligand used for the original synthesis confirmed the presence of 1,1,1-trifluoro-5-methyl-2,4-hexanedione as an impurity.

The technique can also be used for detection of mixed-ligand complexes, *e.g.*, thio-β-diketone complexes. Dimerization usually prevents isolation of pure thio-β-diketones and hence the metal complexes must be prepared *in situ*[17] in the presence of the appropriate metal salt.

Figure 5 shows the negative-ion mass spectrum of a sample of the mixed-ligand nickel(II) complex which gave elemental analyses consistent with the formula Ni(CH$_3$CSCHCSCH$_3$)(CH$_3$CSCHCOCH$_3$). It is obvious from this spectrum that the method of synthesis we have used[17] has led to a sample

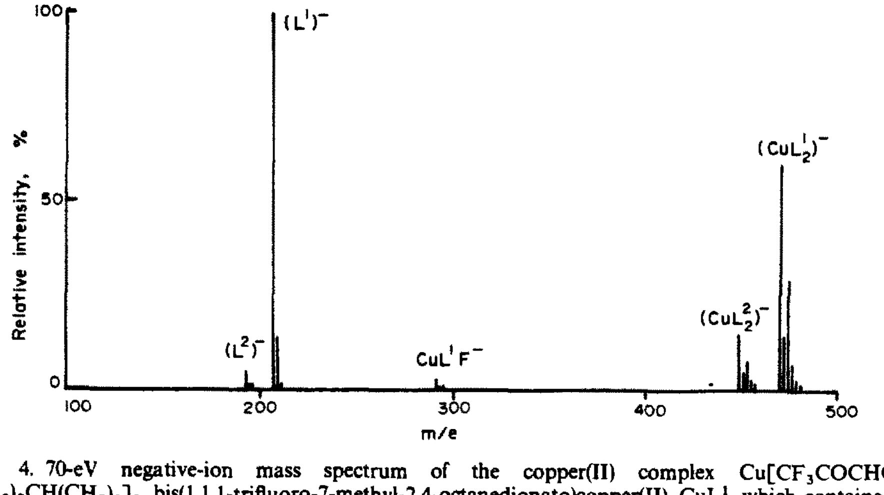

Fig. 4. 70-eV negative-ion mass spectrum of the copper(II) complex Cu[CF$_3$COCHCO(CH$_2$)$_2$CH(CH$_3$)$_2$]$_2$, bis(1,1,1-trifluoro-7-methyl-2,4-octanedionato)copper(II), CuL$^1_2$, which contained as an impurity the complex Cu[CF$_3$COCHCOCH$_2$CH(CH$_3$)$_2$]$_2$, bis(1,1,1-trifluoro-5-methyl-2,4-hexanedionato)copper(II), CuL$^2_2$.

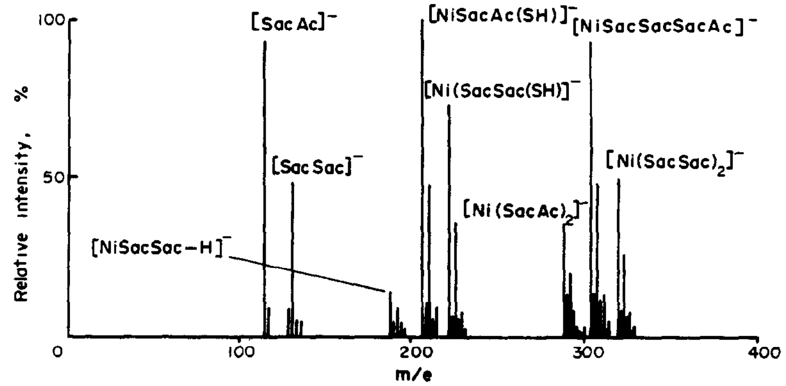

Fig. 5. 70-eV negative-ion mass spectrum of a sample of Ni(SacSac) (SacAc), 4-thiolopent-3-ene-2-thione-4-thiolopent-3-en-2-one nickel(II), which also contained $Ni(SacSac)_2$ and $Ni(SacAc)_2$, where SacSac = $(CH_3CSCHCSCH_3)^-$ and SacAc = $(CH_3CSCHCOCH_3)^-$.

Table 1. Temperature, pressure, and relative ion abundance for bis(hexafluoroacetylacetonato)copper(II)

Pressure, 10^{-6} *mmHg*	2.2	2.2	2.3
Temperature, °C	100	150	200
$Cu(CF_3COCHCOCF_3)_2^-$, %	100	45	17
$(CF_3COCHCOCF_3)^-$, %	56	100	100

containing virtually all combinations of the dithio- and monothio-β-diketone ligands, a conclusion substantiated by the presence in high abundance of the $(CH_3CSCHCSCH_3)^-$ and $(CH_3CSCHCOCH_3)^-$ species.

A final example concerns the thermal stabilities of metal complexes, which can be established from the simple negative ion spectra. In Table 1 are listed relative abundances for the predominant negative ions given by bis(hexafluoroacetylacetonato)copper(II) at similar source pressures but at different temperatures. Even though the process $Cu(CF_3COCHCOCF_3)_2^- \xrightarrow{*} (CF_3COCHCOCF_3)^-$ occurs in the field-free region, it is apparent that thermolysis contributes to the increased abundance of ligand ions observed as the ion-source temperature is increased. The complexity of positive-ion spectra makes the presence of any thermolysis process difficult to detect. However, because of the greater simplicity of negative-ion mass spectra, thermal processes leading to the rupture of metal–ligand bonds are readily detected by means of the resultant increase in intensity of the ligand-ion peaks at higher temperatures. In this respect the facility to use the mass spectrometer in both the positive- and negative-ion modes within minutes under the same ion-source conditions is of great value. SECNI mass spectra have been obtained for other types of metal-organic compounds[18,19] and the results are similar to those described here.

POLAROGRAPHIC REDUCTION OF SOME POTENTIAL ANTIDIABETIC COMPOUNDS WITH MORE THAN ONE REDUCTION SITE

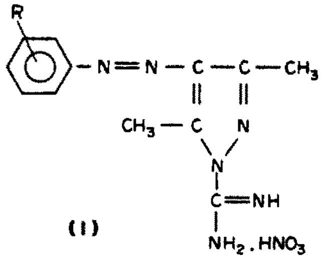
Wahid U. Malik* and R. N. Goyal
Chemistry Department, University of Roorkee, Roorkee, India

(*Received* 22 *October* 1975. *Accepted* 19 *January* 1976)

Summary—The polarographic reduction of a number of *N*′-guanylarylazopyrazole nitrates has been studied over a range of concentration and pH values. The effect of substituent groups on the value of the half wave potential has been determined.

In recent years, interest in the electrochemical behaviour of biologically important compounds[1–3] has increased. However, as few organic redox systems behave reversibly, valid potentiometric data have been obtained for only a few compounds. As most organic compounds behave in an irreversible manner, studies of their redox behaviour have been based on polarography.

The present paper summarizes the results of polarographic examination of 4-arylazo-*N*′-guanyl-3,5-dimethylpyrazole nitrates (I), well known for their antidiabetic activity.[4]



(I)

In these compounds the possible reduction sites are the C=C and C=N groups of the pyrazole ring and the –N=N– and –C=N– extra-nuclear groups. As extranuclear sites are more susceptible to reduction,[5] it can be assumed that the reduction takes place at the extranuclear –N=N– and –C=N– sites. This view is supported by the fact that simple pyrazoles are not electroactive, while guanine is electroreducible.

EXPERIMENTAL

Reagents and solutions

Substituted phenylazo-*N*′-guanyl-3,5-dimethylpyrazole nitrates having as substituents hydrogen, 2-nitro, 3-nitro, 4-nitro, 3-chloro, 4-chloro, 2-bromo, 4-bromo, 3-methyl and 4-methyl groups were synthesized.[6] In order to study the effect of substituents at positions 3 and 5, two more compounds, 4-phenylazo-*N*′-guanyl-3-methyl-5-phenylpyrazole nitrate and 4-phenylazo-*N*′-guanyl-3,5-diphenylpyrazole nitrate were synthesized. All the compounds were purified by recrystallization from ethanol and their purity was checked by nitrogen estimation. Britton–Robinson buffers[7] in the pH range 2.0–11.0 were prepared. Solutions ($1 \times 10^{-3}M$) of all the pyrazoles were prepared in pure methanol.

Apparatus

A Cambridge pen-recording polarograph was used. The capillary characteristics were 3.75 $mg^{2/3}\,s^{-1/2}$ at $h = 50$ cm. Triply distilled mercury was used and the temperature of the solution was maintained at 30 ± 0.1°.

Procedure

Working solutions were prepared by taking the appropriate buffer (8 ml) and a fixed amount of pyrazole solution (1 ml). The ionic strength was kept constant by adding 1.0 ml of 1*M* potassium chloride. An inert atmosphere was maintained by passing purified nitrogen for about 15 min. Corrections for residual current were made in all cases. The value of *n*, the number of electrons involved in the reduction, was determined by controlled potential electrolysis as recommended by DeVries and Kroon,[8] with a platinum wire as the anode and the mercury pool as the cathode. Values of *n* are given in Table 1.

RESULTS AND DISCUSSION

All the arylazopyrazoles are reduced in two 2-electron reduction waves. The nitro-substituted pyrazoles exhibit a further reduction wave at a less negative potential. Some typical polarograms are shown in Fig. 1.

Reduction of the azo group

As the –N=N– group is more susceptible to reduction than the –C=N– group, the former is reduced at a less negative potential than the latter. The first

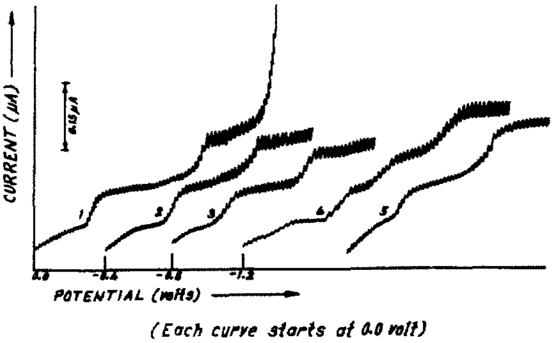

Fig. 1. Typical polarograms of pyrazoles (1) R = 4-Cl, $c = 1.0 \times 10^{-4}M$, pH = 3.8 (2) R = 4-CH_3, $c = 1.0 \times 10^{-4}M$, pH = 3.8. (3) R = 3-Cl, $c = 1.0 \times 10^{-4}M$, pH = 3.8. (4) R = 4-NO_2, $c = 1.5 \times 10^{-4}M$, pH = 8.9. (5) R = 2-Br, $c = 1.0 \times 10^{-4}M$, pH = 3.8.

wave is therefore assigned to the reduction of the –N=N– group. The limiting current was diffusion-controlled, as can be deduced from plots of i against $h^{\frac{1}{2}}$. The wave-heights are independent of pH (2.0–11.0) and the temperature coefficient is in the range 1.5–1.6% per deg. The concentration of the depolarizer influences the electrode process and shifts the $E_{\frac{1}{2}}$ towards a more negative potential. The $E_{\frac{1}{2}}$ of the wave is dependent on pH and shifts towards a more negative value with increase in pH. The plots of $E_{\frac{1}{2}}$ against pH give straight lines with a slope of 0.06.

To obtain an indication of the reversibility, various concentrations of these pyrazoles were polarographed and it was found that the half-wave potential shifts to a more negative potential, revealing the irreversible nature of the waves (Table 2).

Azo compounds are reduced in a two-electron step to hydrazo derivatives,[9–11] the overall process being

$$\text{R–N=N–R}' \xrightarrow{2e+2H^+} \text{R–NH–NH–R}'$$

As the nature of R and R′ will alter the electron density at the –N=N– group, electron-donating groups will facilitate the reduction and electron-withdrawing groups will make reduction more difficult.[12] This behaviour is observed with the present compounds (Table 3).

Reduction of the azomethine group

It may be seen from Fig. 1 that the second wave is well-defined and well-separated from the first wave. This wave may be assigned to the reduction of the extranuclear azomethine (–C=N–) group. It is interesting to note that the half-wave potential of all these waves becomes more negative with increase in pH. However, unlike the case of the azo group, the half-wave potential for the reduction of –C=N– fails to give a linear relationship with pH. A similar nonlinearity has been reported by other workers.[13] The shift of $E_{\frac{1}{2}}$ with increasing pH indicates the involvement of the hydrogen ion in the electrode reaction. Zuman[14] and other workers[15] have reported that plots of $E_{\frac{1}{2}}$ against pH can be represented by extrapolation as sets of linear segments of different slopes (*cf.* Fig. 2). The intersections of the linear segments give the values of pK for the oxidized or reduced species. The pK values calculated from these plots are given in Table 3 and all lie in the same range.

The behaviour of the wave at various concentrations gives an idea of the reversibility or irreversibility of the electrode process. For a reversible process $E_{\frac{1}{2}}$ is independent of concentration, whereas in the case of an irreversible process $E_{\frac{1}{2}}$ shifts to a more negative value.[16] The concentration was varied from

† Slight maxima observed.

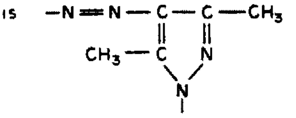
0.5×10^{-4} to $4 \times 10^{-4}M$ and it was found that $E_{\frac{1}{2}}$ varied with concentration (Table 2), revealing the irreversible nature of the electrode process. The diffusion currents increase linearly with concentration and the temperature coefficients are below 1.6% per deg in all cases. The diffusion currents (i_d) for all the waves are constant at different values of pH. The plots of i_d against $h^{\frac{1}{2}}$ are linear, indicating the diffusion-controlled nature of the waves.

The value of n, the number of electrons involved in the reduction of the azomethine group, was determined by the millicoulometric method and found to be 2, suggesting the following mechanism:

$$RR'C{=}NH \xrightarrow{2H^+ + 2e} RR'CH{-}NH_2$$

where

R is



R′ is $-NH_2.HNO_3$

Similar reduction steps have also been proposed by Kastening,[17] Zuman[18] and others.[19]

Reduction of the nitro group

In the case of nitro-substituted arylazopyrazoles, such as N'-guanyl-3,5-dimethyl-4-(2-nitrophenylazo)-pyrazole nitrate, and the 3-nitro and 4-nitro analogues, an additional wave appeared at a less negative potential. Since the nitro group in both aliphatic and aromatic compounds is easily reducible at a dropping mercury electrode, this behaviour is understandable.[20] The reduction takes place by a 4-electron process in the pH range 2.0–11.0. The waves are diffusion-controlled, as shown by the plots of i against $h^{\frac{1}{2}}$ and of i against concentration of depolarizer, which were linear. The half-wave potential shifts to a more negative potential with increase in pH, but the limiting current is almost independent of pH. The plots of $E_{\frac{1}{2}}$ against pH are linear. These waves were found to be irreversible as the plot of $E_{d.e.}$ against $\log i/(i_d - i)$ showed a higher slope and $E_{\frac{1}{2}}$ shifted to a more negative potential with increase in concentration (Table 2).

In the case of m-nitro-substituted arylazopyrazoles and p-nitro-substituted pyrazoles, the reduction waves of the nitro group merge with those of the –N=N– group in the pH range 2.0–6.2. At higher pH, the two waves separate, giving two well-defined waves (Fig. 3).

A mechanism for the reduction of the nitro group, similar to that suggested by Fields[21] and other workers,[22] can be proposed for these compounds.

Effect of substituents on the half-wave potential

Table 3 gives the values of $E_{\frac{1}{2}}$ for substituted arylazopyrazoles. These values become more positive for electron-donating substituent groups, except in the case of 4-methylphenylazopyrazole, where the value shifts to a more negative potential. This behaviour may be due to the *ortho* effect,[5] while the shift to

1.	CH_3	CH_3	0.360	0.820	—	—
2.	CH_3	C_6H_5	0.365	0.800	0.005	0.020
3.	C_6H_5	C_6H_5	0.370	0.760	0.010	0.040

$(-E_{\frac{1}{2}})_1$ and $(-E_{\frac{1}{2}})_2$ are for the reduction of the azo group and azomethine group respectively.

a more positive potential is explained by assuming an increase of electron density at the site of reduction (–N=N–). The 3-Cl, 4-Cl, 2-Br, 4-Br and $3\text{-}CH_3$ substituents shift the half-wave potential to a more positive value (with respect to the parent compound). Electron-withdrawing substituents, $2\text{-}NO_2$, $3\text{-}NO_2$ and $4\text{-}NO_2$, give half-wave potentials more negative than that of the unsubstituted pyrazole by decreasing the electron density at the reduction site. Bromo and nitro substituents show positive polarographic *ortho* shifts (Δ_o), indicating that *o*-substituted arylazopyrazoles undergo reduction more easily than the corresponding *p*-substituted analogues.

$$(E_{\frac{1}{2}})_{o\text{-Nitro}} = (E_{\frac{1}{2}})_{p\text{-Nitro}} = -0.02\ \text{V at pH 3.8}$$

$$(E_{\frac{1}{2}})_{o\text{-Bromo}} - (E_{\frac{1}{2}})_{p\text{-Bromo}} = -0.02\ \text{V at pH 3.8}$$

In the case of azomethine group reduction, the substituents are remote from the reaction site and hence no systematic change in $E_{\frac{1}{2}}$ was observed. A change in the $E_{\frac{1}{2}}$ value with various substituents may be attributed to the conjugated double bond in (I). It was also found that substituents at positions 3 and 5 appreciably affect the $E_{\frac{1}{2}}$ value for this reduction site (–C=N–). Thus the introduction of an electron-withdrawing C_6H_5 group at position 3 shifts the $E_{\frac{1}{2}}$ value to a more positive potential (Table 4) and this shift is greater if a second C_6H_5 group is introduced at position 5. Similar behaviour has been reported for the case of substituted benzalanilines.[23]

A COULOMETRIC METHOD FOR THE ASSAY OF SOME EASILY OXIDIZED ORGANIC SUBSTANCES WITH IODINE AS AN OXIDIZING AGENT

L. E. Edholm
Department of Technical Analytical Chemistry, Chemical Center, Lund, Sweden

(*Received* 29 *December* 1975. *Accepted* 21 *March* 1976)

Summary—A coulometric method for the assay of easily oxidized organic substances, using iodine as an oxidizing agent, has been developed. The principle of the method is to oxidize the substance with an excess of iodine in a water–acetic acid medium and then titrate the iodide formed, with anodically generated silver ion. The titration is followed by dead-stop indication using two platinum electrodes. The method has been applied to the assay of dihydric phenols with hydroxyl groups in the *ortho* or *para* positions and to the determination of ascorbic acid in various pharmaceutical preparations. The absolute relative error varied between 0.2 and 2.8% for the 8 phenols investigated and the relative standard deviation between 0.2 and 1%. For standard solutions of ascorbic acid the absolute relative error was 0.9% and for the 6 pharmaceutical preparations investigated the relative standard deviation lay in the range 0.3–0.9%. The method is easy to apply and has a number of advantages over current iodimetric methods.

Iodine and other halogens are frequently used as oxidizing agents. Iodine is often preferred because it gives rise to fewer side-reactions than do bromine and chlorine. The reaction between iodine and a dihydric phenol with hydroxyl groups in the 1,2- or 1,4-positions furnishes the corresponding quinones and iodide ion, *e.g.*, for hydroquinone

$$\text{Hydroquinone} + I_2 \rightleftharpoons p\text{-Benzoquinone} + 2I^- + 2H^+ \quad (1)$$

Kolthoff[1] titrated hydroquinone with iodine, both directly with potentiometric indication of the end-point and indirectly with back-titration of the excess of iodine with thiosulphate or arsenic trioxide and end-point indication with starch. Kolthoff also studied the influence of the pH on the result. He calculated that for a quantitative reaction the pH must be 6 or higher as the equilibrium in equation (1) lies too far to the left at lower pH. Another fact which may complicate a determination is that some dihydric phenols are easily oxidized by air at higher pH. Thus Preiss[2] got erroneous results when titrating hydroquinone with iodine in sodium hydrogen carbonate solution at pH 8–9 and Ashworth *et al.*[3] had the same experience with hydroquinone in $1M$ sodium acetate solution. There is also a tendency for iodine solutions to produce iodide at higher pH, in a slow reaction which is difficult to control.[4]

Some attempts to apply coulometric methods to the oxidation of dihydric phenols, using anodically generated iodine, have been made. Bajalovic and Nikolic[5] titrated hydroquinone amperometrically in phosphate buffer at pH 8, and Čůta and Kučera[6] titrated hydroquinone at pH 7–8 and pyrocatechol at pH > 7. The amount of hydroquinone titrated was in the range 110–1100 μg and the results were given as 99.00 ± 0.36%. For pyrocatechol no quantitative result was obtained at pH above 7.

As mentioned above, there is a lower pH-limit for the quantitative oxidation of a 1,2- or 1,4-dihydric phenol by iodine. On the other hand too high a pH can cause low results because of interference from aerial oxidation of the phenol. Hence it is desirable to perform the oxidation at the lowest possible pH which is compatible with quantitative oxidation. When performing the titration in the conventional way, *i.e.*, either directly by adding iodine up to the end-point or indirectly with back-titration of the excess of iodine, the assay is based on a determination of the iodine consumed. However, equation (1) suggests that there should be another way of evaluating the result of the oxidation, namely by determining the iodide formed.

This procedure should have a number of advantages over the methods currently in use. Thus the equilibrium in equation (1) will be displaced to the right by the consumption of iodide ion and the displacement can be further enhanced by using a large excess of iodine. Because of this the titration can be performed at a lower pH than when the assay is based on the iodine consumption, with decreased risk of aerial oxidation. Losses of iodine during the titration are also unimportant in this case. In our method the iodide formed is determined by constant-current coulometry using anodically generated silver ion. Accordingly, the method has the general advantage of coulometric methods, *i.e.*, no titrants are necessary. The titration can also be performed with rather simple and inexpensive equipment found in most laboratories. As will be discussed in more detail later in this paper, the appearance of the titration curve gives an indication of the reliability of the assay. Hence there are a number of advantages associated with this method which should make it an attractive competitor to existing iodimetric methods.

Methods used for the assay of ascorbic acid (vitamin C) have been discussed by Hashmi[7] and Hajratwala.[8] They can be divided into two main groups, *viz.* spectrophotometric methods and redox methods. The former, although generally specific, are often time-consuming. The latter are based on the reducing properties of ascorbic acid and are subject to interference from other reducing substances present. One of the most frequently used methods was originally proposed by Tillmans *et al.*[9] and is based on the use of 2,6-dichlorophenolindophenol as an oxidation agent. Its reaction with ascorbic acid is accompanied by a colour change which can be followed visually, photometrically or electrometrically. Although it has been adopted as an official method for the assay of ascorbic acid in pharmaceutical products[10] it is often not usable because of interfering reducing substances present. It is also time-consuming and demands considerable experimental skill for good results to be obtained.[11]

Iodine oxidation of ascorbic acid has also been recommended and exploited a good deal for its determination.[12] It is used as an official method for pharmaceutical preparations.[10] The usual way is to add iodine solution in excess and back-titrate the excess with thiosulphate, using starch as an indicator. This procedure is reported to be time-consuming, owing to slow equilibration near the equivalence point.[13] However, improved indication methods have been developed, utilizing polarized platinum electrodes[14] or platinum–tungsten electrodes[15] to follow the progress of the titration.

An elegant method for the assay of ascorbic acid, based on controlled potential coulometry, has recently been described by Karlsson.[16] Iodine in slight excess is generated at a platinum anode and allowed to react with the ascorbic acid. After the reaction is finished the excess of iodine is reduced, and the result obtained on an electronic integrator can be related to the amount of ascorbic acid. The greatest disadvantage of this method seems to be the need for expensive, specialized apparatus, not available in most laboratories. The advantages of the method developed in this work were previously outlined in connection with the discussion of the iodine oxidation of dihydric phenols. The conclusions then drawn are applicable also to the constant-current coulometric assay of ascorbic acid, using iodine as oxidizing agent.

EXPERIMENTAL

Apparatus

The oxidation was performed in a Metrohm titration vessel EA 875-20 as described below and the amount of iodide ion formed titrated with silver ion, generated from a 0.1-mm thick 20 × 10 mm rectangular silver plate (see Fig. 1). A constant current of 1 mA was taken from a Knick "Präzision Stromgeber". The counter-electrode was a platinum plate placed in 2*M* sulphuric acid. This electrode was made by modifying a Metrohm EA 247 electrode according to Fig. 1. The fritted glass disc was of porosity D3, and 10 mm in diameter. Replacement of the original fritted glass disc was necessary to increase the electrical conductance. The titration was followed by means of an indicating double platinum point electrode (Metrohm EA 235) through which a constant current of 1 μA passed, taken from a Knick constant-current generator. The electrode polarization was measured by registering the potential drop between the electrodes. This method of indication was preferred to the one used in previous work where a constant polarization voltage was applied to the double platinum point electrode and the current registered,[17] which gave rise to currents of 7 μA in the depolarized state, which might adversely affect the titration results in the present case.

Reagents

Phenols. The dihydroxybenzenes were of the best grade commercially available and were used without further purification.

Vitamin preparations. The vitamin preparations analysed were obtained from Ferrosan AB, Sweden. For their content of various vitamins see Table 2.

Ascorbic acid. Merck PA.
Acetic acid. Merck 99–100%.
Sodium acetate. Merck PA.
Iodine. Mallinckrodt AR, resublimed.

Oxidation and titration procedure

A standard solution of iodine was prepared by dissolving iodine in glacial acetic acid to give a concentration of 40m*M*. This solution was stable for several months if protected from water. A reaction solution was prepared by adding 2 ml of this solution to the titration vessel, followed by 10 ml of glacial acetic acid and 8 ml of water in that order to prevent precipitation of iodine. In one case the composition of the reaction solution had to be changed

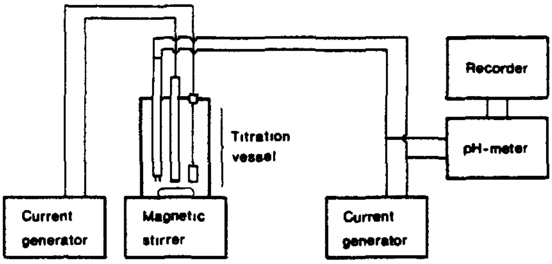

Fig. 2. Schematic diagram showing the connections in the coulometric apparatus.

(see Table 1). The compound to be oxidized was then added to the reaction solution.

The phenols were weighed, and dissolved in glacial acetic acid in a 50-ml volumetric flask to give a concentration of 0.001–0.01*M*. From this solution a volume containing about 4 μmoles of phenol was dispensed into the titration vessel by means of an Agla micrometer syringe.

In the case of ascorbic acid, standard solutions as well as various vitamin preparations were analysed. The standard solutions (0.005–0.01*M*) were prepared by dissolving ascorbic acid in deaerated 8% v/v acetic acid in water. The liquid vitamin preparation ABCDin was dispensed as such into the reaction solution by means of the Agla syringe. The remainder of the vitamin preparations, which were tablets, were treated in the following way. Five vitamin tablets were crushed in an agate mortar and an amount of the powder calculated to give 100 ml of an approximately 0.01*M* solution of ascorbic acid when dissolved, was weighed out. The powder was leached with deaerated 8% v/v acetic acid–water and the solution filtered into a 100-ml volumetric flask and made up to the mark with more of the leaching solution. The vitamin preparation Multiplex Comp N contains Fe^{2+} which was removed by pouring the filtered solution through a tube containing a 2-cm thick layer of Amberlite CG 120, 400–600 mesh, cation-exchanger in acid form. All volumetric flasks containing ascorbic acid were wrapped in aluminium foil in order to prevent decomposition by light during storage. An exact volume, containing about 4 μmoles of ascorbic acid, was transferred from the volumetric flask to the reaction solution in the usual way by an Agla syringe.

The electrodes were inserted and connected to their electric circuits (see Fig. 2). The magnetic stirrer was set at a relatively high speed and the pH-meter set to READ. The silver-ion generator current was adjusted to 1.000 mA, the indicator generator current to 1 μA, the recorder speed to 30 mm/min and the measuring range set to MILLIVOLT. The silver-ion generation and the indication circuit were started simultaneously as the recorder pen crossed a vertical line on the chart after a stable base-line had been achieved. The generation of silver ion was continued until the second polarization of the indicator electrode. The appearance of the titration curve as well as the method for determining the end-point are shown in Fig. 3. A blank containing only the reaction solution was titrated in the same way and the iodide ion formed is equivalent to the distance A–B in Fig. 3. Generally the blank consumption was very small or negligible. Increased blank consumption can result from deterioration of the indicator electrode or be caused by the reaction solution being kept for a long time before addition of the determinand. The indicator electrode should be washed with demineralized water after each titration and if there is any sign of contamination it should also be wiped with wet filter paper. Contamination generally affects the blank titration curve, which assumes a different appearance from the normal one shown in Fig. 3. The amount of oxidized substance (in μmoles) is calculated from

$$m/M = 1000tI/Fn \qquad (2)$$

where m = the amount titrated in μg; t = the time in sec (= twice the distance A–B in mm); I = generating current, in mA; M = molecular weight of oxidized substance; F = Faraday constant = 96487 C/eq; n = number of electrons transferred per mole of oxidized substance.

RESULTS AND DISCUSSION

Appearance of titration curve

A typical titration curve is shown in Fig. 3. It consists of two regions corresponding to depolarization, connected by a section corresponding to polarization. At the beginning of the titration the indicator electrode is depolarized, probably by the I_2/I_3^- couple. As the iodide ion is consumed by the silver ion a polarization takes place and the electrode is polarized to a level dependent on the concentration of acetate ion, since addition of sodium acetate decreases it. This can be explained by the formation of silver acetate complexes, AgOAc and $Ag(OAc)_2^-$, which reduces the concentration of silver ion, controlling the level to which the electrode is polarized. When the production of silver ion is continued the indicator electrode becomes depolarized again. For this depolarization to take place the presence of Ag^+ as well as I_2 seems to be necessary. There is at present no obvious explanation of this behaviour. It might be that the couple I_2/AgI_2^+ is responsible for the depolarization. Arotsky *et al.*[18] have assumed the AgI_2^+ complex to be formed when silver sulphate is added to a solution of iodine in sulphuric acid. In the present investigation it was found that when ultraviolet spectra were run for successive portions taken during a blank titration, a new absorption band appeared as a shoulder at 430 nm. As Arotsky *et al.* have reported that the AgI_2^+ complex absorbs at 520 nm with a weak shoulder at 420 nm, there seems to be some justification for the assumption made above. The main absorption band for AgI_2^+ at 520 nm cannot be observed in the present case as iodine has a strong absorption band in the same region.

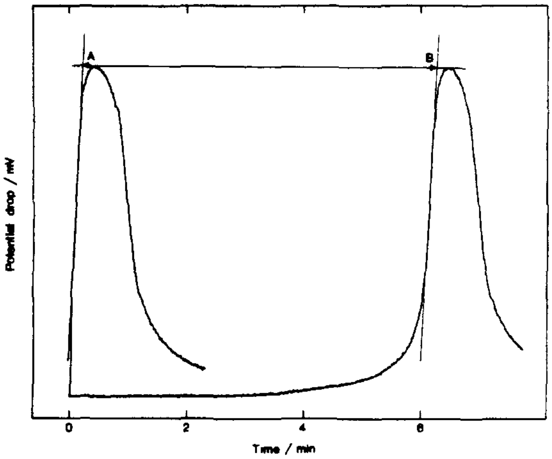

Fig. 3. Titration curve with construction for evaluating the end-point.

The width and height of the polarization part of the curve give some indication of the reliability of the titration. Ideally the width and height should be the same as in the blank titration. Increased width is a sign of disturbing reactions and, if the widening is considerable, the result should be discarded. The Fe^{2+} in Multiplex Comp N reacts with iodine, causing a broadening of the polarization part of the titration curve. This interference can be remedied by removing the iron on a cation-exchanger as described in the experimental part. Turbid solutions can also give rise to a broadening, *e.g.*, when assaying vitamin C in fruit juices. For the vitamin preparation ABCDin a slight broadening is observed, which contributes to the somewhat high results obtained for this preparation.

Reaction and titration medium

It has been shown that no oxidation takes place when ascorbic acid is added to iodine in glacial acetic acid,[19] and that iodide cannot be titrated with silver ion in this medium either. Experiments with aqueous acetic acid indicated that a water content of 40% v/v was suitable and this mixture has been used throughout as reaction and titration medium. The measured pH of this medium is 1.6 when compared with standard buffer solutions. This value is not directly comparable with Kolthoff's pH 6 which refers to aqueous solution, but, in the medium chosen, quantitative results were obtained for all but one of the phenols investigated. The exception was 1,2-dihydroxy-4-methylbenzene in which case the pH had to be raised to 2.9 by making the reaction medium 0.25*M* with respect to sodium acetate. The fact that the titration can be carried out at a relatively low pH diminishes the risk of losses of dihydric phenols by aerial oxidation. Substitution reactions due to iodination are also less likely to interfere at low pH.

Stability of solutions

Glacial acetic acid is a suitable solvent for dihydric phenols, their solutions being stable for several days. For ascorbic acid, aqueous acetic acid containing 8% v/v acetic acid has been recommended as an appropriate extraction medium.[16] Ascorbic acid is not stable in this medium, the decomposition amounting to about 10% after 10 hr. A solution of ascorbic acid in aqueous acetic acid of the prescribed composition should therefore not be kept for more than 1–2 hr before analysis. The presence of B-vitamins in several of the vitamin preparations could, however, contribute to decreased decomposition of ascorbic acid in their solutions.[7]

Interfering substances

The vitamin preparations investigated contain other compounds besides ascorbic acid, *e.g.*, sugars of various kinds, chloride, and iron in the form of Fe^{2+}. Of these, iron in Multiplex Comp N has already been discussed. It might be expected that chloride would interfere with the determination of iodide. However, the presence of chloride up to 5% of the amount of iodide did not influence the results. This can be explained by the difference in solubility between the silver halides. Various kinds of sugars used in tablet formulations were tested, but none of them was found to interfere significantly, nor have we encountered any sign of interference from other kinds of vitamins present in the preparations. It thus appears that the method proposed for the assay of ascorbic acid is comparatively free from interferences by other substances compounded in the vitamin preparations.

Results

The results of the assay of dihydric phenols and ascorbic acid have been collected in Tables 1–3. The mean relative error is ±1.0% for the 8 phenols listed in Table 1 and the relative standard deviation lies in the range 0.2–1%. These results must be considered satisfactory, taking into account that the phenols are not 100% pure but contain impurities of unknown composition.

As the purity of the ascorbic acid used for preparing the standard solution was better than 99.5%, the results given in Table 3 seem to indicate that the method gives somewhat low results. However, as certain losses due to aerial oxidation cannot be avoided,

Table 1. Determination of dihydroxybenzenes

* mg/100 ml.

the method should in fact be more exact than is indicated by these figures. In the case of the vitamin preparations two figures are given in Table 2 for the content of ascorbic acid. The first one is the result obtained by a pharmaceutical laboratory using official methods and the second the result given by the present iodimetric method. The agreement is surprisingly good considering the errors inherent in the two methods and the statistical error accompanying the tablet analyses. A more exact comparison could be made if the assays in the two cases were made on a solution prepared from the same five tablets. However, as this could not be realized, the comparison in Table 2 refers only to the same batch of tablets, which causes an additional uncertainty due to the variation in the content of ascorbic acid from tablet to tablet. The relatively large error for Multiplex Comp N might be expected to be caused by the ion-exchange treatment to remove Fe^{2+} from the solution. However, when solutions of ascorbic acid were subjected to the same treatment, no losses of ascorbic acid were observed.

CONCLUSIONS

The iodimetric method proposed in this paper for the assay of easily oxidized organic substances has been shown to function well for dihydric phenols with hydroxyl groups at the *ortho* or *para* positions and for ascorbic acid in various pharmaceutical preparations. The special advantages of the method are the elimination of titrant solutions, easy evaluation of the end-point, and the possibility of performing the oxidation at a relatively low pH, thereby decreasing the risk of aerial oxidation. It is concluded that it should be possible to apply the method to numerous other substances which can be quantitatively oxidized by iodine.

SHORT COMMUNICATIONS

QUANTITATIVE REFLECTOMETRY—III*. DETERMINATION OF PROTEIN IN AQUEOUS MEDIA

DAVID KEALEY
School of Chemical and Physical Sciences, Kingston Polytechnic, Kingston-upon-Thames, Surrey, U.K.

(*Received* 30 *July* 1975. *Revised* 7 *April* 1976. *Accepted* 15 *April* 1976)

The first two papers in this series demonstrated the principles of direct reflectance measurements,[1] established the precision that can reasonably be expected, and discussed the nature of interferences.[2] The work described in this paper is concerned with test-strips for the determination of protein in aqueous media and with comparisons between commercially available and laboratory-prepared strips. The commercial protein strips are similar to those available for nickel, consisting of a plastic backing (0.5 × 8.0 cm) to which is attached a 0.5-cm square of reagent-impregnated absorbent paper at one end. The reagent used is Tetrabromophenol Blue, which is yellow under slightly acid conditions and turns green–blue on immersion in protein-containing solutions. Colour charts provided with the commercial product cover the range from 5 to >1000 mg of albumin per 100 ml of solution and the strips are intended for the semi-quantitative determination of protein in urine samples.

EXPERIMENTAL

Reagents and apparatus

Standard protein solution. Bovine serum albumin (30% aqueous solution), Ortho Pharmaceuticals Ltd. Additional standards to cover the range 0.25–10 mg/ml were prepared by dilution with distilled water.

Urine control sample. "UR-Sure Urinalysis Control", Travenol Laboratories, protein level 1.30 ± 0.1 mg/ml.

Protein test-strips. "Albustix", Ames Company.

Tetrabromophenolphthalein, ethyl ester, sodium salt.

Aerosol contact adhesive. "Photomount", 3M Company.

Preparation of protein test-strips

Chromatographic paper (Whatman 3 mm) was cut into strips (10 × 2.5 cm) which were impregnated with reagent by immersing them for 1 min in a 0.1% methanolic solution of tetrabromophenolphthalein ethyl ester buffered to pH 2.8 with 0.05*M* citric acid/sodium citrate. Excess of reagent solution was removed by shaking, and the strips were dried in a horizontal position, with a hot-air blower (5 min). Smaller pieces (3 × 1.5 cm) were cut from the prepared strips and attached to one end of plastic backing material (3 × 10 cm) with an aerosol contact adhesive.

Visible reflectance spectra of the protein test-strips

All reflectance measurements were made on the Unicam SP 8000 spectrophotometer fitted with an SP 890 diffuse-reflectance attachment, with freshly prepared magnesium oxide as reference standard (made by burning magnesium ribbon beneath a brass disc, on which the magnesium oxide vapour condenses to give a uniform layer). Strips prepared in the laboratory or the commercially available "Albustix" were immersed for 3 sec in a series of freshly-diluted and unstirred solutions of bovine serum albumin (0.25–10 mg/ml). Each strip was shaken to remove excess of protein solution and dried horizontally for 4 min with a hot-air blower. As the size of the "Albustix" test area is only 0.5 × 0.5 cm, six strips were immersed in each test solution to provide an adequate area for subsequent measurement. These were mounted on a card as described previously.[1] Reflectance spectra are shown in Fig. 1.

Optimization of conditions for quantitative measurements

All measurements were made on laboratory-prepared test-strips.

Immersion time. Strips were immersed in a 5-mg/ml solution of protein for 2 sec and 10 sec respectively. After shaking to remove excess of protein solution, they were dried in a horizontal position with a hot-air blower for 4 min. Reflectance measurements are given in Table 1.

Drying conditions. Strips were immersed in a 5-mg/ml protein solution for 2 sec, shaken, and dried in either a vertical or a horizontal position for 2–6 min. The position of the hot-air blower was varied so as to alter both the temperature at the surface of the strip and the degree of disturbance of the surface moisture by the air stream. Reflectance measurements are given in Table 1.

Buffer efficiency. Separate portions of a 5-mg/ml protein solution were adjusted to pH 4 and 9 and test-strips immersed in each solution for 2 sec. After shaking and drying in a horizontal position for 4 min, the reflectance of each was measured (Table 1).

Precision of quantitative measurements

Groups of five test-strips were immersed for 2 sec in standard protein solutions covering the range 0–10.0 mg/ml. Each was dried for 4 min in a horizontal position with a hot-air blower. Reflectance measurements and relative precisions are given in Table 2.

Determination of protein in urine

Protein-free urine was spiked with bovine serum albumin to give protein concentrations of up to 10.0 mg/ml. Groups of five test-strips were immersed in each sample solution and dried for 4 min as before. Reflectance measurements were recorded and the precision at several concentration levels calculated (Table 2). Standards were also prepared in the range 0.80–2.00 mg/ml protein and the level of protein in two urine control samples measured from a calibration curve.

RESULTS AND DISCUSSION

Adsorption indicators such as Bromophenol Blue (tetrabromophenolsulphonephthalein) are used extensively for

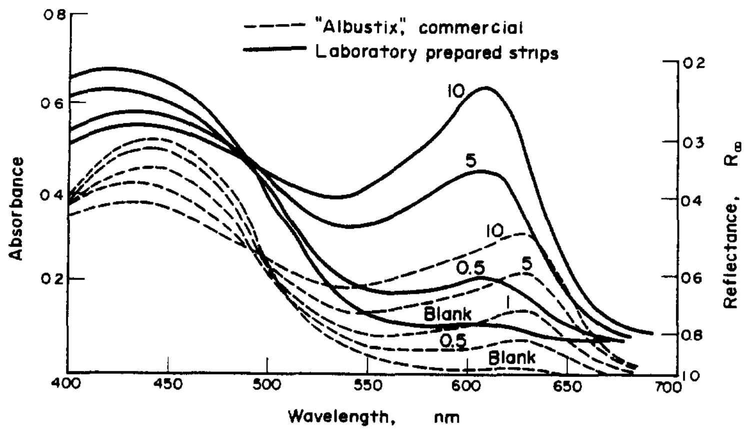

Fig. 1. Reflectance spectra of protein test-strips (reference MgO, numbers by the curves refer to albumin concentration, mg/ml).

the detection of proteins separated by electrophoresis.[3] They are acid–base indicators, the colour transition range of which is modified by the formation of a salt-like adsorption product with the protein molecules. The colour reaction may be observed in solution or at the surface of reagent-impregnated absorbent paper after immersion in a protein-containing solution. Commercially available test-strips for protein in urine ("Albustix") employ Tetrabromophenol Blue as the chromogenic reagent. During preliminary work with laboratory-prepared test-strips impregnated with the same reagent, rapid bleeding of the indicator into the test solution was observed. As this did not occur with "Albustix" it was assumed that they must be specially treated during manufacture to render them resistant to bleeding. A similar indicator, tetrabromophenolphthalein ethyl ester, which has been recommended by Feigl[4] as a spot-test reagent for proteins, bled much more slowly and was used for all subsequent work. The observed colour transition range for this reagent is pH 3.2–6.4, the change being from yellow to blue. Below pH 3.2 and in the presence of protein, a proton is displaced from the indicator molecule, which assumes a blue salt-like form according to the equation:

$$\underset{\text{yellow}}{\mathrm{HIn}} + \text{protein} = \underset{\text{blue}}{\mathrm{In^{-}\text{-}protein}} + \mathrm{H^{+}}$$

Protein hydrolysis products, including amino-acids, di- and tripeptides and peptones do not cause a colour change.[4] As the indicator is normally present in considerable excess, the observed final colour is generally between yellowish-green and greenish-blue, depending on the level of protein present. The laboratory-prepared strips were buffered to pH 2.8 with citric acid ($pK_a = 3.1$) and sodium citrate to provide a stable and reproducible pH at the surface and to allow for some variation in the pH of the sample solutions.

Table 1. Effect of immersion time, drying procedure and pH of sample solution on the reflectance function $F(R_\infty)$ of protein test-strips (5.00 mg/ml protein)

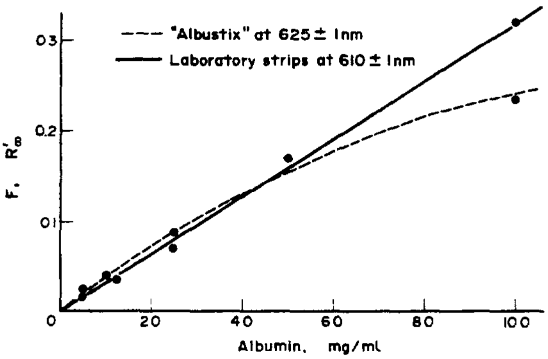

Fig. 2. Kubelka–Munk plot for albumin in water, 2-sec immersion (reference MgO).

Visible reflectance spectra of commercial and laboratory-produced test-strips (Fig. 1) show two fairly broad maxima. The one between 425 and 440 nm corresponds to the yellow acid form of the indicator and that between 610 and 625 nm to the blue indicator–protein adsorption product. The slightly shorter wavelengths of maximum absorbance observed for the laboratory test-strips may arise from the change of indicator. Alternatively, the commercial strips may be manufactured from paper with a somewhat coarser fibrous structure than those prepared in the laboratory. An interesting feature of the spectra is the occurrence of an isosbestic point in the region of 500 nm, confirming that the two maxima are derived from a single species existing in two distinct forms.

Kubelka–Munk plots for the commercial and laboratory-prepared test-strips are shown in Fig. 2. The difference in the range of reflectance function values $F(R_\infty)$ (where R'_∞ is the reflectance measured relative to a blank) for identical concentration ranges is again indicative of the different indicators used in the two types of strip, although differences in paper quality or reagent concentrations may also be contributory factors. The better linearity and wider range of $F(R'_\infty)$ values found for the laboratory-prepared strips would be an advantage where quantitative rather than semi-quantitative information is required. An upper protein concentration limit of 10 mg/ml was selected as levels of clinical interest are largely below this value.

Quantitative measurements

For quantitative measurements an immersion time of 2 sec is considered preferable to 10 sec in the interests of speed and to minimize the risk of the indicator–protein complex dispersing into the sample solution. This was observed in exploratory work for strips immersed for more than 10 sec. Drying conditions must be such as to avoid redistribution of the complex on the surface of the strips while excess of moisture is present. This was achieved by shaking the strips to remove excess of sample solution and by laying them horizontally 3–4 ft beneath a hot-air blower. Reflectance readings were found to be stable and reproducible after a minimum of 4 min drying in this manner. The buffer capacity of the strips was found to be adequate to cope with sample solutions with pH as high as 9. This is considerably above that normally encountered in urine samples, which range in pH between 5.5 and 7.0.

A statistical assessment of the data has established that relative precisions of 1.7–5.7% over the protein concentration range 0.5–10 mg/ml in both water and urine (Table 2) can be expected. This is in agreement with an estimated value of 2.9% derived from Ringbom curves, assuming an instrumental reading error of 0.5%. The individual Ringbom plots did not show the full extent of the normal S-shaped curves as concentrations exceeding 10 mg/ml were not examined. This is particularly noticeable for the commercial strips, where reflectances are generally higher than those of the laboratory-prepared strips for reasons already discussed. Precision is unaffected by storage for at least three months, as evidenced by a comparison of stored strips with those which provided the data in Table 2. The accuracy of the method was assessed by analysing two urine control samples, each containing 1.30 ± 0.10 mg/ml protein, as determined by the biuret method. The results were 1.17, 1.29, 1.22 (mean 1.23) and 1.18, 1.12, 1.28 (mean 1.19) mg/ml, and demonstrate an acceptable accuracy for the proposed method. The slightly lower figures suggest that the urine samples may have contained some protein hydrolysis products which would react with the biuret reagent but not with the test strips.

CONCLUSIONS

A method for the determination of protein in aqueous media has been described and shown to have a relative precision of between 1.7 and 5.7% over the concentration range 0.5–10 mg/ml. Results for the analysis of urine control samples show good agreement with figures obtained by the biuret method. All experimental work was done using bovine serum albumin but the reagent will also react with other native proteins. The method has a potential application in clinical analysis where quantitative rather than semi-quantitative data are required. It would be suitable for the determination of protein in urine, as in cases of proteinurea, and in cerebrospinal fluids. In conjunction with a portable reflectance meter the method could provide data quickly and cheaply.

Acknowledgement—I am grateful to Mr. P. W. Dalton of the New Charing Cross Hospital who was responsible for some of the experimental work described in this paper.

Summary—The determination of protein in aqueous media by using commercial and laboratory-prepared test-strips has been investigated. Adsorption indicators of the Bromophenol Blue type form the basis of the colour-forming reaction, which is selective for natural protein. The relative precision of reflectance measurements is 1.7–5.7% over the concentration range 0.5–10 mg/ml, for bovine serum albumin. The method would be suitable for the rapid determination of protein in urine and other body fluids.

ANALYTISCHE ASPEKTE DER KOORDINATIONSREAKTIONEN DES HEXAMETHYLPHOSPHORSÄURETRIAMIDS IN WÄSSRIGEN LÖSUNGEN

MAX ZIEGLER, HELMUT ROSEMEYER, HORST WINKLER und GÜNTER MODZEL
Anorganisch-Chemisches Institut der Universität Göttingen, 3400 Göttingen, Tammannstraße 4, BRD

(*Eingegangen am* 27. *Oktober* 1975. *Angenommen am* 12. *Februar* 1976)

Nach ersten Arbeiten von Donoghue und Drago[1] über die Darstellung von Koordinationsverbindungen des Hexamethylphosphorsäuretriamids (HMPT) mit Kobalt-, Nickel-, Kupfer- und Zinksalzen wurde von den Unterzeichnern über Komplexverbindungen des HMPT sowie des Octamethylpyrophosphorsäuretetramids (OMPA) und des Diisopropylfluorophosphats (DFP) mit Salzen des Eisens-(III), Wismuts, Urans, Thoriums, Vanadiums, Zinns(II) und (IV), des Goldes sowie des Zinks berichtet.[2] Ebenso waren Verbindungen des HMPT mit verschiedenen Übergangsmetall-Cyano- und Rhodanosäuren, sowie mit der Säure $H[B(C_6H_5)_4]$ Gegenstand unserer Untersuchungen. Ferner wurden extraktiv-analytische Methoden erstellt für die selektive Erfassung von Eisen(III),[3] Gold[4] und von Zink.[5] Ab 1967 haben daraufhin zahlreiche Autoren weit über 100 Verbindungen des Typs $(HMPT)_m[MeX_n]$ (I) beschrieben.[6] Über Darstellungsmöglichkeiten von komplexen Säuren $H[MeX_n(HMPT)_m]$ (II) unter Erhöhung der Koordinationszahl, wie in $H[BiX_4(HMPT)_2]$ bzw. $H[AuX_4(HMPT)_2]$ ($\delta^1H = 13{,}67$ ppm für den Chlorokomplex in D_2O; $\Delta\nu = -28\,cm^{-1}$) wie auch über Verbindungen des Typs $(HMPTH)_mH_2[MeX_n]$ (III), wie $(HMPTH)_2H_2[Fe(CN)_6]$, sagt die Literatur nichts Weiteres aus. Diese Verbindungen wurden erstmals von den Autoren dargestellt.

Bei der Darstellung des Verbindungstyps (I), z.B. von $[Fe(SCN)_3(HMPT)_3]$ ist eine geringe Acidität der Probelösung erforderlich, um die Bildung der komplexen Säure $H_3[(Fe(SCN)_6)]$ hintan zu halten. Die quantitativ eintretende Fällung des Eisens erfolgt hier auch aus verdünnten Lösungen des Eisens unter vollständigem Ligandenaustausch des in wässrigen Lösungen am Eisen-ion koordinierten Wassers. Erst durch diese vollständige Ligandenhydrophobierung wird eine Extraktion mit chlorierten Kohlenwasserstoffen möglich. Diese selektive Extrahierbarkeit z.B.[3] des Eisens als $[FeCl_3(HMPT)]$ aus vorzugsweise chloridhaltigen Lösungen ist somit auf die Bildung von nicht extrahierbaren Mischkomplexen von H_2O und HMPT an den anderen vorhandenen Übergangsmetallen zurückführbar. Erkennbar wird dies bei späteren Darstellungsmethoden für Übergangsmetall–HMPT-Komplexe, bei denen auf größtmögliche Wasserfreiheit in den Ansätzen geachtet werden mußte, da die unvollständige Entfernung koordinierten Wassers zu wasserlöslichen Verbindungen führte und Fällungen verhinderte.[6]

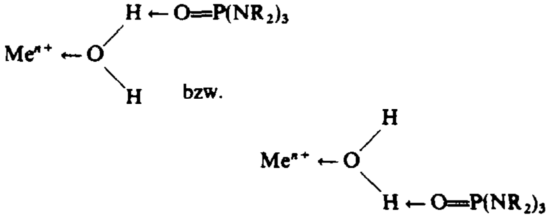
Tabelle 1 zeigt 14 neue HMPT-Komplexe mit Alkali- und Erdalkalimetallen. Erstgenannte Verbindungen fallen nur aus wasserfreiem Medium, denn Wasser verhindert durch seine koordinative Bindung die vollständige Koordination des HMPT. An Erdalkalimetallen kann Wasser gleichzeitig koordinieren. Da, wie weiter unten näher beschrieben, das HMPT nicht nur am Metall koordiniert, sondern auch mit den Wasserprotonen reagiert, wird die Koordination überschüssigen HMPT's am Metallkation noch erleichtert:



Es handelt sich also bei den beschriebenen Reaktionen um Ligandenaustauschreaktionen, bei denen die Liganden auch miteinander eine Reaktion eingehen.

EXPERIMENTELLER TEIL

Darstellung der Verbindungen der Tabelle 1

Die Alkalimetall-Verbindungen sind darstellbar durch Lösen der entwässerten Halogenide in HMPT, das auf 70–100° erhitzt ist. Nach dem Auskristallisieren in der Kälte wird zweimal mit je 5 ml Petroläther (Kp 130°) gewaschen und im Vakuum über Kaliumhydroxid getrocknet.

Die Erdalkalimetall-Verbindungen werden dargestellt durch Suspendieren von 3–5 g der Erdalkalihalogenid-hydrate in 15 ml Methylenchlorid, und Auflösen durch Zusatz von 8–10 ml HMPT. Man kristallisiert im Vakuum, wäscht mit Petroläther und trocknet im Vakuum über Kaliumhydroxid.

Geräte

IR-Aufnahmen: Hitachi Perkin-Elmer, Typ 180; ^1H-NMR-Aufnahmen: Hitachi Perkin-Elmer, Typ R 24 A; ^{31}P-NMR-Aufnahmen: Bruker, Typ RM 504.

Die Widerstandsmessungen wurden mit einem Instrument der Firma WTW durchgeführt. Bei der benutzten Elektrode handelte es sich um platinierte Platinbleche. (Gerätekonstante: $K = 0{,}582\,cm^{-1}$).

Physikalische Untersuchungen am System HMPT–H_2O

Est ist seit längerer Zeit bekannt, daß HMPT auf Grund seiner außerordentlich hohen Donor-Eigenschaft mit prak-

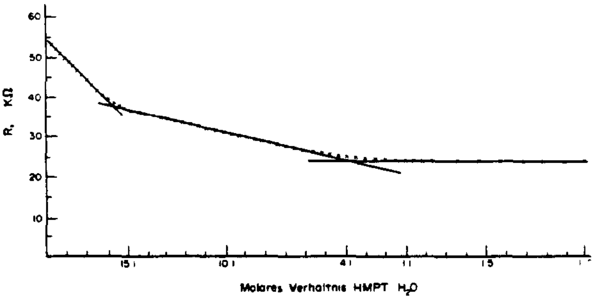


Abb. 1. Widerstand von Mischungen des HMPT mit Wasser.

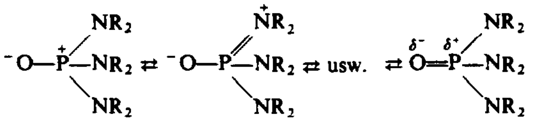
tisch allen protischen Substanzen über den Phosphorylsauerstoff reagiert.[7] Die große Koordinationsfähigkeit ist auf die hohe Mesomeriemöglichkeit der positiven Partialladung des Phosphors zurückzuführen:[7]



Aus ramanspektroskopischen Untersuchungen ist nachgewiesen worden, daß die P=O-Bindung zu 50% Ionencharakter besitzt.[7] Als Beispiel für eine Reaktion des HMPT mit einer protischen Substanz wurde aus den oben dargelegten Gründen die Reaktion

$$(H_2O)_m + n\mathrm{HMPT} \rightarrow [(\mathrm{HMPT})_n(\mathrm{HOH})_m]$$

untersucht. Diese Reaktion wurde durch Messung der Leitfähigkeit, der ^{1}H-NMR, der ^{31}P-NMR und der IR-Spektroskopie verfolgt.

Leitfähigkeitsmessungen. Durch Zugabe von doppeltdestilliertem Wasser zu reinem HMPT wird eine Zunahme der Leitfähigkeit erreicht. Eine konduktometrische Mikrotitration einer bekannten, vorgegebenen Menge HMPT mit Wasser ist in Abb. 1 dargestellt. Hierbei wurde das Titrationsgefäß auf 53° thermostatiert und die Mischung nach jedem Zutropfen *ca.* eine Minute gerührt. Während der anschließenden Widerstandsmessung wurde der Magnetrührer abgestellt. Die Widerstandsmessung wurde mit Hilfe einer Wheatstoneschen Brücke durchgeführt, die zur Vermeidung störender Polarisationseffekte mit einer Wechselspannung von 3 kHz betrieben wurde. Analoge Titrationen mit anderen Ausgangsmengen an HMPT oder anderen Temperaturen (20–60°) zeigen der Abb. 1 analoge Kurvenverläufe. Aus der Kurve sind zwei Knickpunkte bei den molaren Verhältnissen HMPT: H_2O = 16:1 und 4:1 abzulesen. Ab dem molaren Verhältnis 1:1 bis in das Gebiet großer Verdünnungen bleibt der Widerstand weitgehend konstant.

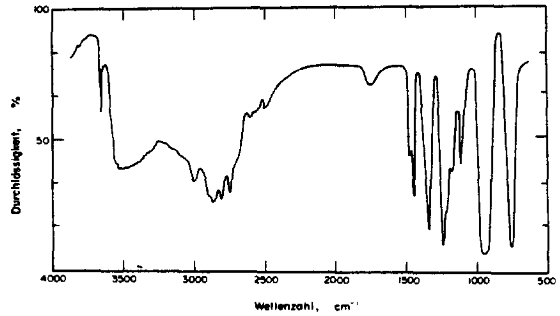


Abb. 2. IR-Spektrum der Mischung HMPT:H_2O = 6:1.

IR-spektroskopische Untersuchungen. Abbildung 2 zeigt ein typisches IR-Spektrum einer HMPT-H_2O-Mischung innerhalb des Bereiches 10:1–4:1 (hier als Beispiel 6:1). Neben den zu erwartenden, auf das HMPT zurückführbaren Banden, tritt bei 3680 cm^{-1} ein scharfer Peak auf, der einem OH^--Ion in festen Hydroxyden entspricht.[8] Weiterhin tritt zum Unterschied zum reinem HMPT eine sehr breite Bande von 3000 cm^{-1} bis 3600 cm^{-1} auf, die einer Wasserstoffbrückenbindung P=O···H···O=P zugeordnet werden muß.

Aus den bisherigen Untersuchungen können folgende Schlüsse gezogen werden: bei dem Molverhältnis HMPT:H_2O = 4:1 liegt eine Koordination von vier Phosphorylsauerstoffen des HMPT an einem Wasserproton vor, gemäß einer Verbindung $[H(HMPT)_4^+]OH^-$. Die Existenz von Hydroxylionen ist durch die IR-Spektren nachgewiesen. Der Knickpunkt der Titrationskurve beim molaren Verhältnis HMPT:H_2O = 4:1 zeigt, daß das Wassermolekül vollständig dissoziiert ist. Dem Molverhältnis 16:1 entspricht eine in zweiter Sphäre noch vorhandene zusätzliche Koordination durch weitere zwölf HMPT-Moleküle.

^{1}H-NMR-Messungen. Bestätigungen der gemachten Angaben über die Koordinationsspezies des HMPT-Sauerstoffs an einem Wasserproton ergeben sich durch die Messung der ^{1}H-NMR des "Wassers" in Abhängigkeit von dessen molarer Konzentration in HMPT. Hierzu wurden Verdünnungsstufen HMPT-H_2O im molaren Bereich 10:1 bis 1:20 hergestellt und von jeder Mischung sowie von reinem Wasser als auch von reinem HMPT ^{1}H-NMR-Aufnahmen gemacht (ext. Standart TMS, 0 ppm). Das ^{1}H-NMR-Spektrum von reinem HMPT zeigt zwei Methylbanden bei 2,55 und 2,37 ppm. Der Grund für die Aufspaltung in zwei Peaks ist die Kopplung der Methylprotonen mit dem ^{31}P-Kern (Abb. 3).

Reines, doppeltdestilliertes Wasser zeigt einen Peak bei 4,80 ppm. Abbildung 4 zeigt die chemische Verschiebung des Wasserprotons in Abhängigkeit vom molaren Verhältnis HMPT:H_2O. Man erkennt, daß im Bereich 10:1–4:1 die chemische Verschiebung und damit gleichbedeutend die Elektronendichte am komplexierten Proton gleichbleibt. Bei dem Verhältnis 4:1 werden δ = 3,45 ppm gemessen. Dies bedeutet einen Unterschied von 1,35 ppm

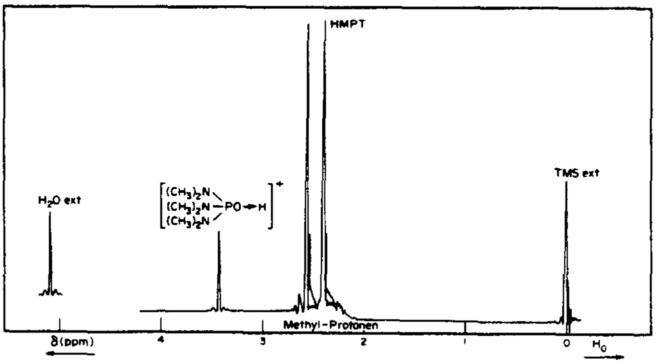

Abb. 3. ^{1}H-NMR-Spektrum der Mischung HMPT:H_2O = 4:1.

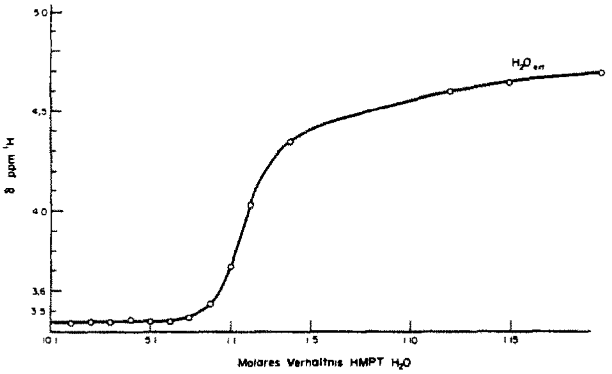

Abb. 4. ^{1}H-NMR-Verschiebungen von HMPT-Wasser-Mischungen.

gegenüber reinem Wasser. Es ist also ersichtlich, daß bei einer Komplexzusammensetzung $[H(HMPT)_4^+]OH^-$ die maximale Elektronendichte am zentralen Proton erreicht ist. Komplexe der Zusammensetzung $[H(HMPT)_x^+]OH^-$ mit $x > 4$ existieren nicht. Weiter zugefügtes HMPT baut, wie die konduktometrische Titration zeigt, eine zweite Koordinationssphäre auf. Im Bereich größerer Verdünnungen (HMPT:H_2O wie 4:1 bis 1:10 usw.) nähert sich der Peak mehr und mehr dem des reinen Wassers bei 4,8 ppm.

^{31}P-NMR-Messungen. Von den bereits unter ^{1}H-NMR erwähnten Verdünnungsstufen sowie von reinem HMPT wurden ^{31}P-NMR-Spektren angefertigt. Als externer Standart diente konz. H_3PO_4 (Abb. 5). Es wurde jeweils der höchste Peak eines HMPT-Signals ausgemessen und die δ^{31}P-Werte gegen das molare Verhältnis wie oben aufgetragen. Die Kurve zeigt den gleichen Sachverhalt wie bei Abb. 4. Auch hier ist ein deutlicher Knickpunkt beim molaren Verhältnis HMPT:H_2O = 4:1 erkennbar. Im Bereich 10:1–4:1 erfolgt keine wesentliche Änderung der Elektronendichte am Phosphor. Erst ab dem Verhältnis 4:1 greift eine zunehmend stärker werdende Entschirmung des ^{31}P-Kerns Platz.

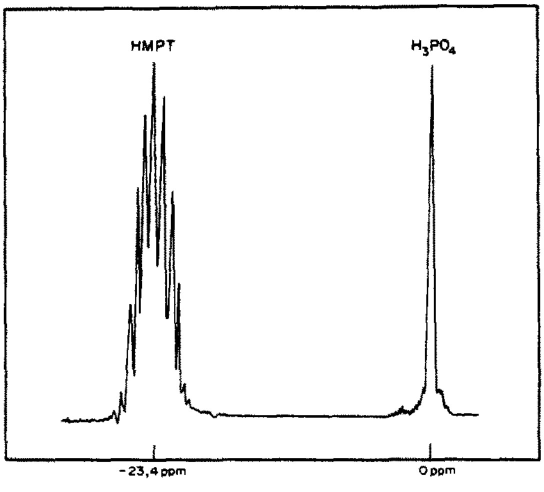

Abb. 5. ^{31}P-NMR-Spektrum des HMPT.

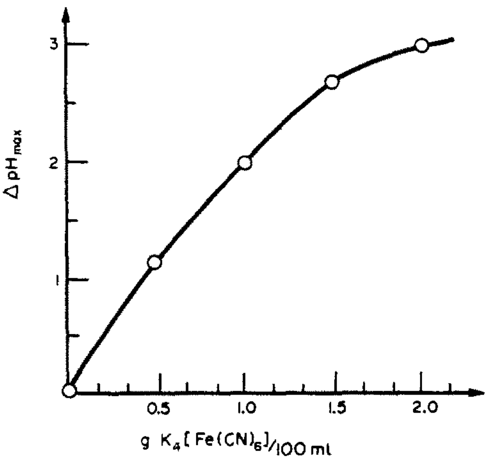

Abb. 6. Maximale pH-Wert-Erhöhungen durch Zusatz von HMPT und $K_4[Fe(CN)_6]$zu Probelösungen.

Als Interpretationsmöglichkeit dieses und des analogen Verhaltens in Abb. 4 ist ein stufenweiser Abbau des Komplexes $[H(HMPT)_4^+]OH^-$ bis zur Verbindung H–O–H···O=$P(NR_2)_3$ denkbar. Weitere Überlegungen sowie experimentelle Untersuchungen, insbesondere über die strukturellen Gegebenheiten bei hohen Wassergehalten in HMPT, sind im Gange. Hierüber wird berichtet werden.

Verbindungstyp $(HMPT)_mH_k[1MeX_n)]$

Die Verbindungen des Typs (III), in denen wie eingangs erwähnt, der Phosphorylsauerstoff des HMPT mit den Protonen schwacher komplexer Metallsäuren (z.B. $H_4[(Fe(CN)_6)]$) reagiert, erweisen sich insbesondere dann als in Wasser schwerlöslich, wenn sich die Protonen bereits in einer intramolekularen Wasserstoffbrücke mit den Liganden des Metalls befinden.[9] Unter diesen (Tabelle 2) ist die Verbindung $(HMPTH)_2H_2[(Fe(CN)_6)]$ auch in organischen Solventien der verschiedensten Art praktisch unlöslich. Hieraus ergeben sich Schwierigkeiten für die Strukturaufklärung mittels ^{1}H-NMR-Spektroskopie. Die zunächst überraschende Tatsache, daß sich die Vertreter dieses Verbindungstyps jedoch in überschüssigem HMPT lösen, ist durch die gewonnenen Erkenntnisse über die Reaktionen des HMPT mit Protonen erklärbar. Beispiel:

$$(HMPT)H[B(C_6H_5)_4] + 3HMPT \rightarrow H(HMPT)_4^+ + [B(C_6H_5)_4]^-$$

Tabelle 2. HMPT-Komplexe des Typs (HMPTH) $n(MeX_m)$

Nr.	Substanz	Smpt., °C	$\Delta\nu_{PO}$* cm^{-1}
1	$[\{(CH_3)_2\ N\}_3PO\ H][(C_6H_5)_4B]$	176	−16
2	$[\{(CH_3)_2N\}_3PO\ H][Cr(SCN)_4(NH_3)]$	150 Zers.	−33
3	$[\langle\{(CH_3)_2N\}_3PO\rangle_2H_2][Fe(CN)_5NO]$	103 Zers.	−32
4	$[\langle\{(CH_3)_2N\}_3PO\rangle_2H_2]H_2[Fe(CN)_6]$	170 Zers.	−33

* Bezogen auf freies HMPT.

Bestimmung der "sauren" Protonen: 1,2,3, direkt und indirekt; 4, indirekt. Löslichkeit: in Wasser, 1,4 sehr schwer löslich; 2,3 schwer löslich; in Alkoholen, 1,23 leicht löslich, 4 sehr schwer löslich.

Das Auftreten des Kations ist durch ^{1}H-NMR-Spektroskopie nachgewiesen.

Trotz der außerordentlichen Schwerlöslichkeit der Verbindung $(HMPTH)_2H_2[Fe(CN)_6]$ in allen gängigen Lösungsmitteln läßt sich die Protonenzahl indirekt durch Messung der Differenz der Aciditäten vor und nach der Ausfällung bestimmen. Sofern die betreffenden Verbindungen in Wasser–Alkohol–Gemischen löslich sind, kann ihr Gehalt an Protonen auch direkt durch Titration mit Natriumhydroxid ermittelt werden.

Durch Zufügen von $K_4[Fe(CN)_6]$ zu verdünnten Mineralsäuren bei Gegenwart von HMPT lassen sich durch "Protonenfällung" auch bestimmte pH-Werte im Bereich 0–4 einstellen. Abbildung 6 zeigt die mögliche pH-Wert-Steigerung von Lösungen, deren Anfangs-pH-Wert zwischen 0,5 und 3 lag.

$$4HCl + K_4[Fe(CN)_6] + 2HMPT \rightarrow (HMPTH)_2H_2[Fe(CN)_6] + 4KCl$$

Aus dieser Gleichung ist ersichtlich, daß die Protonen in der Lösung durch Kalium-Ionen ersetzt werden. Dies hat gegenüber dem Einsatz von Puffern, deren Anionen Metalle komplexieren Vorteile (hierüber wird berichtet werden).

Der Deutschen Forschungsgemeinschaft, Bonn-Bad Godesberg und dem Fond der Chemischen Industrie danken wir für die Unterstützung der vorliegenden Arbeit.

Zusammenfassung—Es wird die Erklärung für die erreichten Spezifitäten bei der Selektivierung von Übergangsmetallen unter Verwendung von Hexamethylphosphorsäuretriamid gegeben. Sie liegt in der Bildung nicht extrahierbarer Mischkomplexe des HMPT und des Wassers an den Fremdmetallionen. Eine gleichzeitige Reaktion des HMPT mit Wasser unter Bildung der Verbindung $[H(HMPT)_4]^+OH^-$ läuft den ebengenannten Koordinationsreaktionen parallel. Die Bildung diskreter Komplexe des HMPT mit H_2O wurde ausgewiesen durch Konduktometrie, IR-, ^{1}H-NMR- und ^{31}P-NMR-spektroskopische Untersuchungen. Innerhalb des Verbindungstyps $(HMPTH)_mH_k(MeX_n)$ eröffnet die Verbindung $(HMPTH)_2H_2[Fe(CN)_6]$ die Möglichkeit der Protonenfällung an Stelle der Pufferung.

ANALYTICAL APPLICATIONS OF COMPLEX FORMATION IN NON-AQUEOUS SOLUTIONS—I

COMPLEXES OF BISMUTH(III) WITH POTASSIUM DIPHENYLDISELENOPHOSPHATE IN ORGANIC SOLVENTS

N. T. YATSIMIRSKAYA, ARAIN RAFEE and A. I. BUSEV
Department of Analytical Chemistry, Moscow State University, Moscow, USSR

(*Received* 15 *January* 1976. *Accepted* 18 *February* 1976)

Reactions in non-aqueous solution are used in analytical chemistry mainly in electrochemical and titrimetric methods,[1,2] but are also promising for development of spectrophotometric methods based on complex formation.[3,4] The stability constants, composition and spectral properties of the complexes are obviously of importance in this connection.

This report is concerned with the complex formed by Bi(III) with potassium diphenyldiselenophosphate in a number of non-aqueous solvents with various physical and chemical properties. The diphenyldiselenophosphate is a new analytical reagent, an analogue of the dialkyldithiophosphoric acids used for extraction–photometric determination of bismuth and other elements.[5,6] Its usefulness as a ligand in complex formation is as yet unknown and awaits special study.

EXPERIMENTAL

Reagents

Anhydrous $BiCl_3$ was purified by distillation in quartz apparatus at 447°. Its solutions were standardized complexometrically, with Xylenol Orange as indicator. Solvents were freed from water according to Weissberger.[7] Potassium diphenyldiselenophosphate was synthesized in the Department of Organic Chemistry of the Lvov State University, by interaction of diphenylchloroselenophosphate with potassium hydroselenide (recrystallized from benzene/acetone, m.p. 172°, decomp.). The PMR spectrum of potassium diphenyldiselenophosphate in D_2O at 90 MHz was a singlet at $\delta = 2.6$ ppm with respect to H_2O and 7.6 ppm with respect to tetramethylsilane. This absorption is due to the protons of the phenyl ring (characterized by a resonance signal in the region $\delta = 6.5$–8.0 ppm.[8]

Apparatus

Absorbances were measured on Hitachi EPS-3 and SP-4A spectrophotometers at 25 ± 0.1°. Infrared spectra were taken on an IR-10 spectrometer, with KBr pellets. PMR spectra were recorded on a WH-90 spectrometer.

RESULTS AND DISCUSSION

Potassium diphenyldiselenophosphate absorbs in the infrared at 610 cm^{-1} (ν_1) and 510 cm^{-1} (ν_2). The two absorption bands can be accounted for by asymmetric (ν_1) and symmetric (ν_2) stretching frequencies of the diphenyldiselenophosphate P(Se)Se group.[9] Complex formation leads to a decrease in both frequencies ν_1 and ν_2 and to ν_1 splitting into a doublet. For Bi(III) diphenyldiselenophosphate isolated from methanol ν_1 is 510 cm^{-1} and ν_2 450 cm^{-1}, showing that the diphenyldiselenophosphate is attached to the Bi(III) through both selenium atoms. Figures 1 and 2 show the absorption spectra of solutions of bismuth(III) chloride, potassium diphenyldiselenophosphate and the bismuth complex, in acetonitrile, ethanol, dimethylformamide, dimethylsulphoxide, acetone, methanol and carbon tetrachloride. The complex can be obtained in carbon tetrachloride medium by extraction from 0.3*M* hydrochloric acid. It is seen from Figs. 1 and 2 that the spectrum is rather similar whatever the solvent, being characterized (just as in carbon tetrachloride with minimum solvation) by a more intense short-wave band at 350–370 nm and a less intense waveband forming a shoulder at 390–450 nm. The two absorption bands can be accounted for by singlet–singlet and singlet–triplet transitions respectively, with charge transfer, by analogy with the dialkyldithiophosphate and bromide complexes of Bi(III).[10]

Changing from bromide as ligand to sulphur- and selenium-containing ligands gives rise to shifts of the Bi(III)-complex absorption bands to longer wavelengths. Thus the bromide, dithiophosphate and diselenophosphate complexes have singlet–triplet transitions at 373, 395[10] and 370 nm and singlet–singlet transitions at 260, 329[10] and 370 nm, respectively. Such a shift might be explained by the decreasing electronegativity of the co-ordinating atoms in the series H_2O; Cl^-; Br^-; $(RO)_2P(S)S^-$; $(RO)_2P(Se)Se^-$.[11]

The positions of the absorption bands of the bismuth diphenyldiselenophosphate complex depend on the solvent used, the shift to longer wavelength increasing in the order DMF < acetone < acetonitrile < DMSO < ethanol < methanol ~ carbon tetrachloride. In the electronic spectra

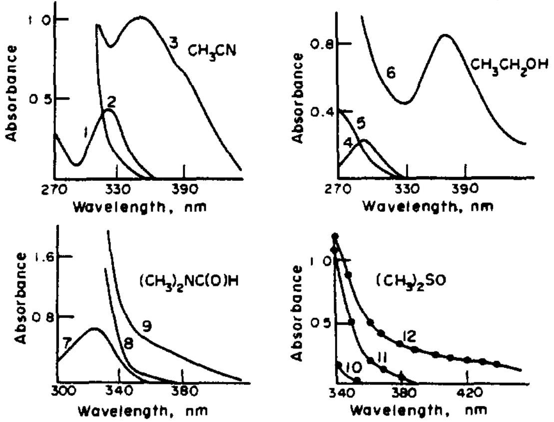

Fig. 1. Absorption spectra: 1—Bi $8 \times 10^{-5}M$; 2—L $1 \times 10^{-3}M$; 3—Bi $8 \times 10^{-5}M$ and L $1 \times 10^{-3}M$; 4—Bi $5 \times 10^{-5}M$; 5—L $1.5 \times 10^{-4}M$; 6—Bi $5 \times 10^{-5}M$ and L $1.5 \times 10^{-4}M$; 7—Bi $8 \times 10^{-5}M$; 8—L $1 \times 10^{-2}M$; 9—Bi $8 \times 10^{-5}M$ and L $1 \times 10^{-2}M$; 10—Bi $4 \times 10^{-4}M$; 11—L 1.13*M*; 12—Bi $4 \times 10^{-4}M$ and L 1.13*M*; (1—9, $l = 1$ cm; 10–12, $l = 0.1$ cm).

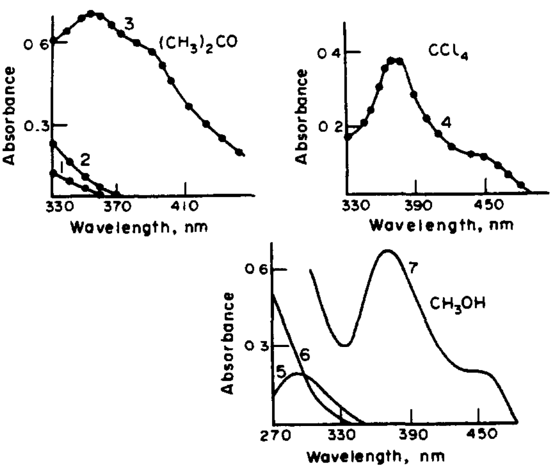

Fig. 2. Absorption spectra: 1—L $9 \times 10^{-4}M$; 2—Bi $4 \times 10^{-5}M$; 3—Bi $4 \times 10^{-5}M$ and L $9 \times 10^{-4}M$; 4—Bi $2 \times 10^{-5}M$ and L $5 \times 10^{-3}M$ (in aqueous phase); 5—Bi $4 \times 10^{-5}M$; 6—L $1.8 \times 10^{-4}M$; 7—Bi $4 \times 10^{-5}M$ and L $1.8 \times 10^{-4}M$; ($l = 1$ cm).

of the bismuth chloride solutions, the absorption maximum is also shifted depending on the solvent, but in the opposite direction. These changes are likely to be caused by different degrees of solvation in the ground and excited states of the Bi(III) compounds involved. The dependence of the wavelength of maximum absorption in the bismuth chloride and diphenyldiselenophosphate spectra on the chemical nature of the solvent was estimated by means of the Kosower *Z* parameter that characterizes the solvating ability of solvents[3] in terms of the electronic transition energy corresponding to the charge-transfer band of 1-ethyl-4-carbomethoxypyridine iodine in the particular solvent (Table 1).

For bismuth chloride a plot of the transition energy at 280–320 nm *vs.* *Z* is linear with slope close to unity (Fig. 3). This points to the excited state being more ionic than the ground state, which is in accord with the interpretation of these bands as those of charge transfer from the Cl^--ion to vacant bismuth(III) 6*d* orbitals. For the bismuth diphenyldiselenophosphate complex the charge-transfer band is almost unaffected by *Z* (Fig. 3), possibly because of screening of the bismuth ion from the solvent. On the other hand, the negative, though slight, slope of the graph shows the excited state to be more ionic than the ground state. This might be explained by the Bi–Se bond being more covalent than the Bi–Cl bond, which would make the excited state more ionic than the ground one on charge transfer (the covalent nature of the Bi–Se bond follows from comparison of the electronegativity of the atoms[12]).

Stability constants and composition of the bismuth(III) diphenyldiselenophosphate complexes were determined by the molar ratio method, with measurement at 370 nm and constant chloride concentration of 0.01*M*. Continuous-variations studies showed the complexes to contain bismuth and diphenyldiselenophosphate in 1:3 ratio. The stability constants calculated according to Schaeppi and Treadwell,[13] are shown in Table 2.

It will be seen from Table 2 that the stability constants change by about 12 orders of magnitude when the solvent is changed from ethanol to DMSO. These constants are affected both by physical characteristics, primarily the dielectric permeability, and the chemical characteristics of the solvent. The constants reported here do not correlate with the dielectric permeability of the solvents under study, presented in Table 1. The solvent effect cannot be explained, then, in terms of elementary electrostatic concepts. It might be supposed that the stability constants are mainly affected by the chemical nature of the solvent, especially by its donor strength, which is estimated from the enthalpy of formation of the iodine and phenol adducts with the particular solvent ($-\Delta H_{I_2}$, $-\Delta H_{PhOH}$), and from the donor number (DN) of the solvent, proposed by Gutmann[4] as involving the enthalpy of solvate formation between a donor solvent and a standard acceptor such as $SbCl_5$. The solvents under study cover a wide donicity range (Table 1). If the donating effect plays a dominant role there should be a correlation between the stability constants and the donor strengths of the solvents. This is because the molecules of such solvents undergo stronger

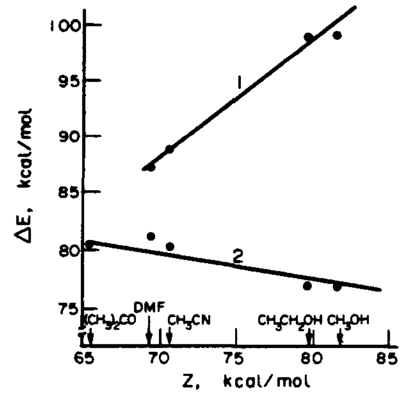

Fig. 3. Dependence (upon *Z*) of electronic transition energy corresponding to maximum absorption bands of (1) bismuth chloride and (2) bismuth diphenyldiselenophosphate complex in DMF, CH_3CN, CH_3OH, C_2H_5OH and $(CH_3)_2CO$.

Table 1. Parameters for the solvents studied

Solvent	Dielectric constant (25°C)	*Z*, *kcal/mole*	$\Delta H_{I_2\text{—adduct}}$ *kcal/mole*	DN_{SbCl_5}
Acetonitrile	36.2	71.3	2.4	14.1
Acetone	20.7	65.7	3.3	17.0
Methanol	32.6	83.6	1.9	18.9
Ethanol	24.3	79.6	2.1	17.9
DMF	36.1	68.5	3.7	26.6
DMSO	46.1	71.7	4.4	29.8

Table 2. Stability constants of bismuth(III) diphenyldiselenophosphate complexes in different solvents

	CH_3CN	$(CH_3)_2CO$	CH_3CH_2OH	CH_3OH	$(CH_3)_2NC(O)H$	$(CH_3)_2SO$
log β_3	13.11	10.50	14.40	14.30	5.20	2.22

co-ordination by the bismuth chloride, thus decreasing its ability to accept diphenyldiselenophosphate. It is seen from Figs. 4 and 5 that the logarithms of the stability constants of the bismuth(III) diphenyldiselenophosphate complex decrease linearly with increased donicity of the solvent and more negative enthalpy of iodine adduct formation with the solvent.

Our results show that all the solvents tested can be used for developing spectrophotometric methods of bismuth determination, the molar absorptivities of the complex being in the range $1.0–1.8 \times 10^4 \, \mathrm{l.mole^{-1}.cm^{-1}}$, which allows bismuth(III) to be determined over the $4 \times 10^{-6}–5 \times 10^{-5}M$ concentration range. The solvents with minimum solvating ability are preferred because of the shift of the maximum-absorption bands to longer wavelengths, which eliminates interference by ions absorbing in the near ultraviolet. Similarly, preference is given to the solvents with small donor numbers (or low enthalpy of iodine-adduct formation) because the stability constants of the Bi(III) complexes are highest in these solvents, increasing the selectivity. Thus methanol, ethanol and acetonitrile are the most useful of the solvents studied. Calibration graphs for methanol and ethanol media at potassium diphenyldiselenophosphate concentration of $5 \times 10^{-4}M$, (370 nm, 1-cm cuvettes, LiCl concentration constant at 0.01M) are described by the equations $A = (1.85 \pm 0.01) \times 10^4[\mathrm{Bi(III)}]$ and $A = (1.79 \pm 0.01) \times 10^4[\mathrm{Bi(III)}]$, respectively, over the bismuth concentration range $4 \times 10^{-6}–4 \times 10^{-5}M$. The equation for acetonitrile medium is $A = (1.51 \pm 0.02) \times 10^4[\mathrm{Bi(III)}]$ (=350 nm) for $4 \times 10^{-6}–8 \times 10^{-5}M$ bismuth. In all the solvents there is no interference from 100 times as much Pb(II), Sb(III), Cd(II) or Sn(II) as Bi(III), in contrast to the extraction–photometric method with bismuth(III) dialkyldithiophosphate.

Our suggestions about choice of the optimum solvent for the spectrophotometric determination are of a general nature, and based on the known physico-chemical properties of the solvents and their correlation with the spectral and thermodynamic properties of the complex, which is valid for a rather wide range of solvents with different chemical nature.

Summary—Complex formation between bismuth(III) chloride and potassium diphenyldiselenophosphate has been studied spectrophotometrically in acetronitrile, dimethylformamide, acetone, methanol, ethanol and dimethylsulphoxide media. Increased solvation ability is found to shift the maximum absorption band of the complex to longer wavelengths and there is a correlation between the stability constants and the solvent donor strength. Spectrophotometric methods for bismuth(III) determination are proposed, in methanol, ethanol and acetonitrile as media.

SEMIMICRO DETERMINATION OF MERCAPTANS WITH COPPER(II)

SAMEER BOSE
Department of Chemistry, University of Jabalpur, Jabalpur 482001, India

M. P. SAHASRABUDDHEY and KRISHNA K. VERMA
Department of Chemistry, Government Science College, Jabalpur 482001, India

(*Received* 17 *February* 1976. *Accepted* 23 *February* 1976)

Copper(II) reacts with many mercapto compounds to yield simultaneously the cuprous mercaptide and a disulphide according to the reaction

$$4RSH + 2Cu^{2+} \rightarrow 2RSCu + RSSR + 4H^+$$

Cupric oleate,[1] acetate[2] and alkyl phthalate[3] solutions have been used as titrants on the macro-scale. The end-point is shown by the blue colour of the excess of reagent. Mercaptoacetic acid cannot be determined by this method because the deep violet cupric–cuprous mercaptide obscures the end-point,[3] but at the end-point in the reverse titration[4] the deep violet precipitate first formed changes to a permanent yellow precipitate of cuprous mercaptide.

Roth[5] suggested an indirect micro-method in which the sample is treated with an excess of cupric butylphthalate. After 5 min, the residual cupric ions are determined iodimetrically. Ellis,[2] however, says that a part of the iodine that is liberated oxidizes the mercaptide to disulphide and introduces error.

The general applicability of the reaction of mercaptans with cupric ion led us to evolve a convenient semi-micro method. Mercaptans can be determined by treating a solution of them in water, methanol, dimethylformamide or acetonitrile with an excess of cupric sulphate solution in water. After 1 min, the residual copper(II) is titrated with mercaptoacetic acid solution.

EXPERIMENTAL

Reagents

Standardized 0.1*M* copper sulphate and 0.1*M* mercaptoacetic acid standardized[6] by treatment with excess of iodine and thiosulphate back-titration.

Procedure

Weigh a sample containing 0.3–1.0 meq of mercaptan into a 150-ml Erlenmeyer flask and dissolve it in 20 ml of water, methanol, dimethylformamide or acetonitrile. Add a measured excess of 0.1*M* cupric sulphate solution and swirl for 1 min. Titrate with 0.1*M* mercaptoacetic acid from a 10-ml burette until the deep violet precipitate first formed changes to a permanent yellow. Near the end-point titrate slowly with vigorous swirling. Run a blank determination on the same volume of cupric sulphate solution.

RESULTS AND DISCUSSION

A wide variety of mercaptans, including primary, secondary and tertiary compounds, was examined. In all cases, the reaction was rapid and complete and the end-point was unaffected. Table 1 gives a comparison of results obtained by the present method and independent methods.

Table 1. Determination of mercaptans with copper(II)

	Purity, %	
Compound	Present method[a]	Comparison method
1-Dodecanethiol	98.1	98.2[b]
o-Mercaptobenzoic acid	96.6	96.5[c]
2-Mercaptoethanol	99.1	99.3[c]
p-Chlorobenzenethiol	99.3	99.5[d]
1-Butanethiol	91.0	90.8[e]
Toluene-α-thiol	98.6	98.4[f]
Allylthiol	93.5	93.6[c]
3-Mercaptopropionic acid	100.0	99.8[c]
Mercaptosuccinic acid	96.7	96.5[b]
2-Mercaptopropionic acid	95.9	95.7[e]
2-Methylpropane-2-thiol	99.0	98.9[f]
2-Naphthalenethiol	98.2	98.0[d]
p-Toluenethiol	97.6	97.6[d]
2-Diethylaminoethanethiol	98.6	98.4[e]
2-Mercaptobenzothiazole	99.2	99.0[d]
2-Mercaptobenzimidazole	97.8	97.6[d]
2-Mercaptobenzoxazole	98.9	98.8[d]
2-Butanethiol	97.9	97.8[b]
Cyclohexanethiol	95.3	95.6[c]

[a] Average of 10 determinations; average deviation in the range 0.2–0.3%.
[b] Hg^{2+} titration[9].
[c] Pb^{4+} titration[10].
[d] alkalimetry[11].
[e] iodimetry[6].
[f] acetylation[12].

The advantages of the present method over methods involving precipitation with silver or mercuric ion are its fixed stoichiometry and its simplicity. Although the iodimetric method yields more accurate results, the number of mercaptans to which it can be applied is limited, and it is reported to give over-oxidation of compounds such as 3-mercaptopropionic, mercaptosuccinic and *o*-mercaptobenzoic acid,[7] and non-stoichiometric or slow reactions with secondary, tertiary and long-chain aliphatic mercaptans,[8] all of which can be determined accurately by the present method.

Organic sulphides, disulphides, thiocyanates and unsaturated compound do not interfere. Chloride, bromide and sulphite also do not interfere. Serious interference is caused by thiourea and ions such as sulphide, thiosulphate, thiocyanate and cyanide. Like ethylenedithiol, *o*-aminobenzenethiol does not reduce copper(II), but forms a cupric mercaptide.

Acknowledgements—Thanks are due to Evans Chemetics, Inc., New York, U.S.A., for gifts of mercaptan samples and to University Grants Commission, New Delhi, for financial assistance to one of us (K.K.V.).

Summary—A rapid and precise titrimetric method for the determination of mercaptans on the semimicro scale is described. Samples dissolved in water, methanol, dimethylformamide or acetonitrile are treated with a measured excess of cupric sulphate. After 1 min, the excess of copper(II) is back-titrated with standard mercaptoacetic acid solution. At the end-point the violet complex first formed changes to a permanent yellow. The method is applicable to a variety of mercaptans and accurate to 0.2%. It is relatively free from interferences.

RAPID POLAROGRAPHIC METHOD FOR DETERMINING ARSENIC IN STEEL

N. G. ELENKOVA, R. A. TCONEVA and TC. K. NEDELTCHEVA
Department of Analytical Chemistry, Higher Institute of Chemical Technology, Sofia 56, Bulgaria

(*Received* 24 *June* 1975. *Accepted* 7 *March* 1976)

Many polarographic methods have been reported for determining micro- or macroamounts of arsenic in steel. They are usually based on three stages: oxidative decomposition of the sample, quantitative separation of the arsenic by extraction,[1,2] distillation[3,4] or co-precipitation[5] and subsequent determination of arsenic by a polarographic method. But none of them is sufficiently rapid, accurate and sensitive for routine analysis.

The Russian Standard Method[6] for determining arsenic in steel involves oxidative attack of the sample with *aqua regia*, treatment with $Ca(H_2PO_2)_2$ in the presence of CuCl and $CuCl_2$ to separate the arsenic in an elementary state, and its subsequent iodometric determination. With arsenic contents of 0.01–0.1% the precision of the method is about 15%.

The British Standard Method[7] is based on the evolution of AsH_3 and its absorption in silver diethyldithiocarbamate–pyridine solution. The precision is 50% and 3% for contents of 0.003% and 0.15% arsenic respectively.

This paper describes a sensitive and accurate polarographic method for determining arsenic in steel, suitable for routine control analysis.

EXPERIMENTAL

Apparatus

Polarograms were recorded with an electronic polarograph model LP-60, using a mercury electrode with a drop-time of 2.97 sec in 0.1*M* potassium chloride and a drop-rate of 4.65 mg/sec. A saturated calomel reference electrode was used for all measurements, in conjunction with a 0.033*M* sodium sulphate bridge.

Reagents and solutions

Concentrated nitric, formic and sulphuric acids; 0.1 g/ml sodium metabisulphite solution; 1% potassium iodide solution; 8% ascorbic acid solution; 0.1% Methyl Orange solution; 0.1*M* manganese sulphate; citrate buffer (1.25*M*) prepared by dissolving 53 g of citric acid monohydrate in hot distilled water, cooling and diluting to 200 ml, neutralizing with 5 g of sodium hydroxide and adjusting to pH 3.0; 40% and 20% sodium hydroxide solutions; arsenic-free iron (less than 0.0005% arsenic). Standard arsenic solution (0.1 mg/ml) was prepared by dissolving 0.132 g of arsenic trioxide in 5 ml of 5% sodium hydroxide solution, diluting to 200 ml with redistilled water and neutralizing carefully with sulphuric acid (1 + 1) (indicator litmus); the solution was then diluted to the mark in a 1000-ml volumetric flask, and standardized by the bromate method.[8]

All reagents used were analytical-reagent grade and were used without further purification.

Procedure

Weigh 0.25–1 g of steel into a 150-ml beaker, add 5 ml of nitric acid (1 + 1) and cover with a watch-glass. When the violent reaction is over, heat on a sand-bath (<200°) to complete decomposition of the sample. Add about 10–15 ml of formic acid dropwise, gradually, and heat carefully to fully expel the nitrogen oxides. Wash the watch-glass with water, cool to room temperature. Add 5 ml of concentrated sulphuric acid and heat gently almost to dryness. Then add 10–20 ml of water, heat to boiling to dissolve the salts and add 20 ml of 0.1 g/ml sodium metabisulphite solution and 1 ml of 1% potassium iodide solution. Cover with the watch-glass, wait for 15 min and

RAPID POLAROGRAPHIC METHOD FOR DETERMINING ARSENIC IN STEEL

N. G. Elenkova, R. A. Tconeva and Tc. K. Nedeltcheva
Department of Analytical Chemistry, Higher Institute of Chemical Technology, Sofia 56, Bulgaria

(*Received* 24 *June* 1975. *Accepted* 7 *March* 1976)

Many polarographic methods have been reported for determining micro- or macroamounts of arsenic in steel. They are usually based on three stages: oxidative decomposition of the sample, quantitative separation of the arsenic by extraction,[1,2] distillation[3,4] or co-precipitation[5] and subsequent determination of arsenic by a polarographic method. But none of them is sufficiently rapid, accurate and sensitive for routine analysis.

The Russian Standard Method[6] for determining arsenic in steel involves oxidative attack of the sample with *aqua regia*, treatment with $Ca(H_2PO_2)_2$ in the presence of $CuCl$ and $CuCl_2$ to separate the arsenic in an elementary state, and its subsequent iodometric determination. With arsenic contents of 0.01–0.1% the precision of the method is about 15%.

The British Standard Method[7] is based on the evolution of AsH_3 and its absorption in silver diethyldithiocarbamate–pyridine solution. The precision is 50% and 3% for contents of 0.003% and 0.15% arsenic respectively.

This paper describes a sensitive and accurate polarographic method for determining arsenic in steel, suitable for routine control analysis.

EXPERIMENTAL

Apparatus

Polarograms were recorded with an electronic polarograph model LP-60, using a mercury electrode with a drop-time of 2.97 sec in $0.1M$ potassium chloride and a drop-rate of 4.65 mg/sec. A saturated calomel reference electrode was used for all measurements, in conjunction with a $0.033M$ sodium sulphate bridge.

Reagents and solutions

Concentrated nitric, formic and sulphuric acids; 0.1 g/ml sodium metabisulphite solution; 1% potassium iodide solution; 8% ascorbic acid solution; 0.1% Methyl Orange solution; $0.1M$ manganese sulphate; citrate buffer ($1.25M$) prepared by dissolving 53 g of citric acid monohydrate in hot distilled water, cooling and diluting to 200 ml, neutralizing with 5 g of sodium hydroxide and adjusting to pH 3.0; 40% and 20% sodium hydroxide solutions; arsenic-free iron (less than 0.0005% arsenic). Standard arsenic solution (0.1 mg/ml) was prepared by dissolving 0.132 g of arsenic trioxide in 5 ml of 5% sodium hydroxide solution, diluting to 200 ml with redistilled water and neutralizing carefully with sulphuric acid (1 + 1) (indicator litmus); the solution was then diluted to the mark in a 1000-ml volumetric flask, and standardized by the bromate method.[8]

All reagents used were analytical-reagent grade and were used without further purification.

Procedure

Weigh 0.25–1 g of steel into a 150-ml beaker, add 5 ml of nitric acid (1 + 1) and cover with a watch-glass. When the violent reaction is over, heat on a sand-bath (<200°) to complete decomposition of the sample. Add about 10–15 ml of formic acid dropwise, gradually, and heat carefully to fully expel the nitrogen oxides. Wash the watch-glass with water, cool to room temperature. Add 5 ml of concentrated sulphuric acid and heat gently almost to dryness. Then add 10–20 ml of water, heat to boiling to dissolve the salts and add 20 ml of 0.1 g/ml sodium metabisulphite solution and 1 ml of 1% potassium iodide solution. Cover with the watch-glass, wait for 15 min and boil on a hot-plate to reduce As(V) to As(III) (until the solution becomes pale green in colour) and to remove SO_2 completely (test by smell). Cool, wash the watch-glass with water, transfer the sample into a 100-ml volumetric flask and dilute to the mark. Mix well and take three 25-ml aliquots in three 50-ml volumetric flasks. Add to each flask 2 ml of 0.1*M* manganese sulphate solution, 5 ml of 8% ascorbic acid solution, 1 or 2 drops of Methyl Orange solution and neutralize with 40% sodium hydroxide solution. When the colour of the solution is bleaching, add 1 or 2 more drops of indicator and continue the neutralization with 20% sodium hydroxide solution till the solution becomes orange in colour. Add 5 ml of citrate buffer and dilute to the mark with distilled water. Record the polarograms from −0.4 to −1.6 V *vs.* SCE without removal of oxygen. Measure the current at the middle of the maximum, and take the mean for the three aliquots.

Preparation of calibration graph

The calibration graphs are prepared by using the same quantity of pure iron as the weight of the sample of steel. The iron is dissolved and treated by the proposed procedure. Then 3.00; 2.00; 1.00; 0.50 and 0.25 ml of the standard arsenic solution are added to 25-ml aliquots in 50-ml volumetric flasks and the solutions are treated according to the procedure described above.

RESULTS AND DISCUSSION

The method is based on an oxidative decomposition of the sample to prevent loss of arsenic as arsine, followed by a reduction of As(V) and Fe(III) with sodium metabisulphite ($Na_2S_2O_5$) and potassium iodide, and subsequent polarographic determination of arsenic (III). This method is sensitive and less tedious than the other methods, and there is no interference from Fe, Si, P, Sn, Sb, Pb, Bi and Cu.

Accuracy and precision

To estimate the possible sources of errors [loss of arsenic during decomposition of the sample, incompleteness of reduction of As(V) and Fe(III), effect of supporting electrolyte composition, *etc.*] samples were prepared from high-purity iron (0.5 g), and different amounts of arsenic(III) were added before and after the dissolution, and arsenic was determined by the procedure described. Table 1 gives the currents obtained on addition of arsenic before (I) and after (II) the decomposition of the samples, for three individual measurements on separately prepared solutions. The equations of both linear calibration curves, calculated by the method of least squares,[9] were $i_I = 0.434 + 0.773C_{As}$ and $i_{II} = 0.432 + 0.799C_{As}$ where i is the current in μA and C_{As} the arsenic concentration in μg/ml. The slopes of the two lines were compared by the Student-t criterion[10] [$t = 1.1 < t(95\%, f = 7) = 2.36$]. The difference between them was found to be determined only by random errors. In addition the mean currents of the two lines at a given arsenic concentration were compared by the F- and t-tests.[9] The values of t and F (see Table 1) indicate that there is no significant difference between the two currents and consequently the dissolution process and the conditions of the reduction have no effect on the accuracy of the arsenic determination. Accordingly the two calibration graphs are identical and can be combined into $i = (0.43 \pm 0.14) + (0.79 \pm 0.06)C_{As}$. The coefficient a of the regression line was tested by the F-criterion.[9] The test $F = 115 > F(95\%, f_1 = 1, f_2 = 3) = 10.13$ shows that the intercept is not zero.

The accuracy and precision of the method were studied with samples of standard steel, containing: As 0.182%, Si 0.37%, Mn 1.68%, P 1.66%, S 0.68%. The results of the arsenic determination by the proposed method and their statistical analysis are given in Table 2.

The accuracy of the method was also studied by fitting the line $y_i = a + bx_i$ to the data, where x_i stands for the arsenic contents, y_i for the amounts found by the proposed method, and a for the initial content of arsenic in the steel (see Table 3). To 0.5-g samples of steel, containing 0.137 ± 0.008% As, 0.22% C, 0.30% Si, 0.65% Mn, 0.045% P, 0.055% S, were added different amounts of standard As(III) solution before the decomposition of the samples (x_i) and they were determined by the polarographic method (y_i = As found). The results are given in Table 3. It was found that the line $y_i = 0.133 + 1.06x_i$ fitted the data: the intercept $a = 0.133$ corresponded to the original arsenic content of the steel, the slope b of the line was unity and therefore, except for random errors, the amounts found were equal to the amounts taken. In Fig. 1 is given the statistical ellipse to test the systematic errors.[11,12]

Tables 4 and 5 consist of data for polarographic determination of arsenic in two different steels, as well as the dispersion analysis, testing possible sources of errors.[9] To

* As = 0.5(i-0.43)/0.79%.

estimate the precision of the method the coefficient of variation ($V\%$) is also used. The dispersion analysis of the data in Tables 4 and 5 showed equal random errors in groups A, B, C (three 25-ml aliquots of a sample of steel):

Table 4

$$\chi^2 = 2.303(f_{ji}\log S^2 - \Sigma f_i \log S_i^2)$$
$$= 2.31 < \chi^2(99\%, f = 5) = 15.1$$
$$F = \frac{S_2^2}{S_1^2} = 1.57 < F(99\%, f_1 = 2, f_2 = 17) = 6.11$$
$$\sqrt{S_1^2} = 0.0077\%; \quad \sqrt{S_2^2} = 0.0097\%$$

Table 5

$$\chi^2 = 3{\cdot}67 < \chi^2(99\%, f = 3) = 11.3$$
$$F = 2.78 < F(99\%, f_1 = 2, f_2 = 11) = 7.20$$
$$\sqrt{S_1^2} = 0.0042\%; \quad \sqrt{S_2^2} = 0.0071\%$$

Consequently the random errors of comparison $\sqrt{S_1^2}$ and of the reproducibility $\sqrt{S_2^2}$ do not differ statistically.

Selectivity

The influence of pH and the interference of some elements (Cu, Mn, Sn, Sb, Bi, Pb, Fe) have been investigated in another work.[13] It was found that Fe(II) and Mn(II) and pH affect the shape and the height of the arsenic wave. On the basis of these results we recorded all polarograms of arsenic at given Fe(II) and Mn(II) concentrations, under the following conditions: $0.045M$ ascorbic acid, $0.125M$ citric acid, $0.004M$ $MnSO_4$, $0.009M$ Fe(II). All statistical tests for systematic errors also proved that the different

elements contained in steel do not interfere with the arsenic polarographic determination. Consequently, the proposed method, without preliminary separation of arsenic, is sufficiently sensitive, much more rapid and convenient for routine control analysis (the time of analysis is 20–30 min after the decomposition of the sample).

Sensitivity

The fact that Fe(II) and Mn(II) considerably increase the limiting current of arsenic had a favourable effect on increasing the sensitivity of polarographic As(III) determination. As a rule in the other supporting electrolytes the determination of As concentrations less than $10^{-4}M$ is difficult. The maximum on the arsenic wave in the presence of Fe(II), Mn(II) and citric acid at pH 3.0 enables us to determine As(III) at concentrations of about 10^{-7}–$10^{-6}M$ by the classical polarographic method with sufficient accuracy and precision.

The lower limit of determination was found from the equation of the calibration curve[9]

$$\mathrm{As}_{\min} = \frac{t(P,f)[S_a + \bar{x}S_b]}{b + t(P,f)\cdot S_b} = 0.311\ \mu g/\mathrm{ml}$$

where S_a and S_b are the mean-square errors of the coefficients a and b of the regression line. This lower limit corresponds to an As content of 0.0015% if a sample is dissolved and made up to 50 ml and analysed polarographically directly. For fourfold dilution and 0.5 g of steel the lower limit of determination is 0.012% As, which corresponds to the lowest measurable signal ($i_{\min} = 0.21\ \mu A$).

Summary—A simple and sensitive polarographic method for determining arsenic in steel is presented. The steel is dissolved in HNO_3, and arsenic reduced with $Na_2S_2O_5$–KI. The polarographic wave is recorded for an electrolyte at pH 3.0 and containing Fe(II), Mn(II), citric and ascorbic acids. Levels of 0.2% and 0.003% As can be determined with a coefficient of variation of ± 6%.

INTERFERENCES IN THE ATOMIC-ABSORPTION DETERMINATION OF SILICON

J. Musil and Marie Nehasilová
Development Laboratory Kovohutě, Z.C. 262 01 Mníšek pod Brdy, Czechoslovakia

(*Received* 29 *September* 1975. *Accepted* 16 *March* 1976)

In recent years much interest has been expressed in interferences in atomic-absorption spectroscopy (AAS) determination of Si.[1–6] Enhancement by sodium was observed[1] as well as some general enhancement effects.[3–6] There is a suggestion that the effects may be dependent on the nebulizer and/or spray chamber arrangement.[6]

The present investigation was made in an attempt to establish the effects of possible interferents in amounts up to 10 mg/ml on the absorption of Si (50 μg/ml).

EXPERIMENTAL

The measurements were performed on a Perkin–Elmer Model 303 atomic-absorption spectrometer with the burner assembly from the Model 403 and a standard N_2O burner (slot 0.48 × 50 mm). The flow-rate of N_2O was 12 l./min. The flow-rate of acetylene (about 7.5 l./min) was adjusted in such a way that the upper edge of the "red feather" was 30 mm above the burner slot when water was

INTERFERENCES IN THE ATOMIC-ABSORPTION DETERMINATION OF SILICON

J. Musil and Marie Nehasilová
Development Laboratory Kovohutě, Z.C. 262 01 Mníšek pod Brdy, Czechoslovakia

(*Received* 29 *September* 1975. *Accepted* 16 *March* 1976)

In recent years much interest has been expressed in interferences in atomic-absorption spectroscopy (AAS) determination of Si.[1–6] Enhancement by sodium was observed[1] as well as some general enhancement effects.[3–6] There is a suggestion that the effects may be dependent on the nebulizer and/or spray chamber arrangement.[6]

The present investigation was made in an attempt to establish the effects of possible interferents in amounts up to 10 mg/ml on the absorption of Si (50 µg/ml).

EXPERIMENTAL

The measurements were performed on a Perkin-Elmer Model 303 atomic-absorption spectrometer with the burner assembly from the Model 403 and a standard N_2O burner (slot 0.48 × 50 mm). The flow-rate of N_2O was 12 l./min. The flow-rate of acetylene (about 7.5 l./min) was adjusted in such a way that the upper edge of the "red feather" was 30 mm above the burner slot when water was being nebulized. The position of the burner was adjusted to give maximum absorption (light-beam 8 mm above the burner slot), see Fig. 1. A Perkin–Elmer silicon hollow-cathode lamp was employed and the measurements were made at 251.6 nm with band-width 0.23 nm. The interferent solutions did not absorb at this wave-length.

The 5000-ppm silicon stock solution was prepared by dissolving silica in sodium hydroxide solution. The 10-mg/ml stock solutions of interferents other than vanadium were prepared by dissolving the high-purity metals in hydrochloric acid. The vanadium solution was made by dissolving V_2O_5 in the acid. The silicon stock solution was found to be stable for several months; the solutions measured, prepared by dilution, contained 50 ppm Si, 100 ppm Na and any interferents added. They were acidified with 4 ml of 6 *M* hydrochloric acid per 100 ml and measured within 8 hr of preparation. The silicon calibration curve was linear up to 150 ppm Si under these conditions. Non-selective absorption at the Si 243.5 nm line was tested and found negligible in all cases.

RESULTS AND DISCUSSION

Effects of acids (Fig. 2)

The acids were always added after dilution of the silicon solution to 500–1000 ppm; the addition of acids to more concentrated silicon solutions may cause the polymerization of $SiO_2 . xH_2O$. The depressive effect of sulphuric acid is not in correlation with the change in viscosity.

Effect of alkali metals (Fig. 3)

There is an inverse correlation between atomic number of the elements and the enhancement effects. Silicon is unlikely to be ionized, so the effect is most likely caused by formation of more easily volatilized mixed oxides. There is no plateau on the enhancement curve, so it is very important to keep the alkali metal concentration strictly constant in practical analysis (or below $10^{-2}M$ for Na and K). This factor may explain the somewhat higher precision of Si determination by Teflon bomb decomposition than by alkali fusion, which was recently reported.[6] However, the interference can be reduced by dilution, at the expense of sensitivity.

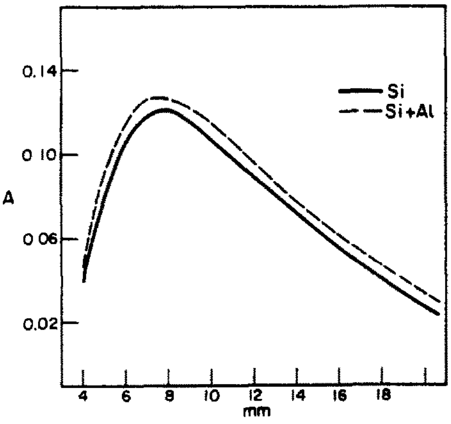

Fig. 1. Flame profile (50 ppm Si; ditto + 1000 ppm Al).

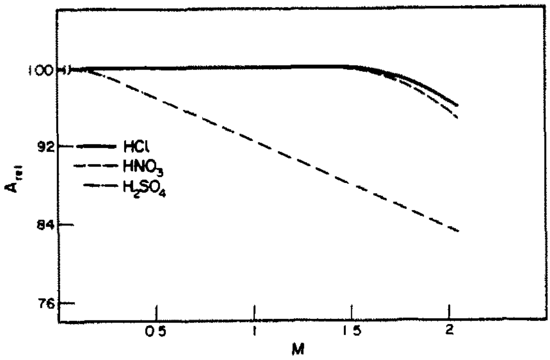

Fig. 2. Effect of acids on the absorbance of 50 ppm Si.

Effect of aluminium (Fig. 4)

This effect cannot be explained by a change in the lateral diffusion in the flame (see Fig. 5); with the same experimental arrangement a clear lateral diffusion effect by sulphuric acid was observed earlier.[7] Also the flame-height profile in presence of Al^{3+} is not changed except for a constant

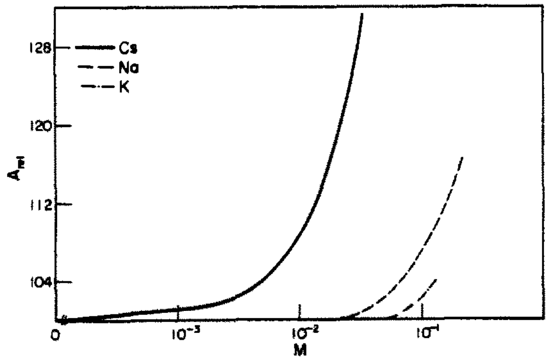

Fig. 3. Effect of alkali metals on the absorbance of 50 ppm Si.

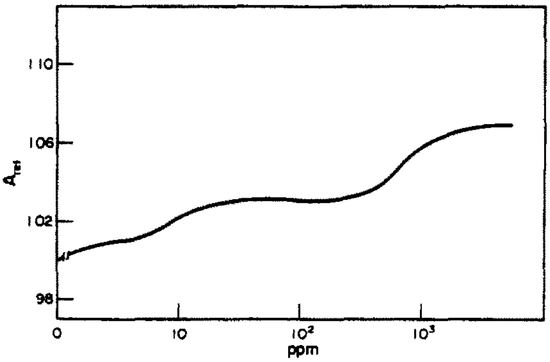

Fig. 4. Effect of Al on the absorbance of 50 ppm Si.

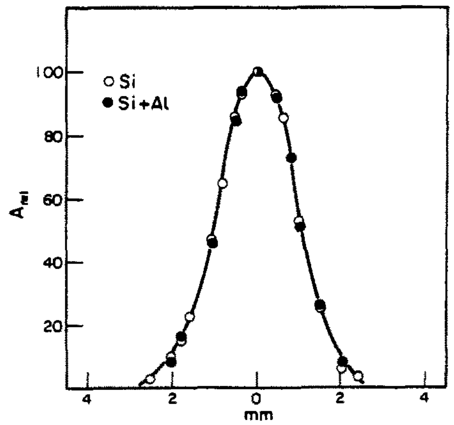

Fig. 5. Distribution of Al atoms in the flame cross-section 8 mm above the burner slot (50 ppm Si; ditto + 1000 ppm Al).

signal enhancement (Fig. 1). Thus, the enhancement effect probably takes place in the first steps of the atomization process. The two plateaux on the curve (Fig. 4) may be due to two different mechanisms.

The effect of iron, nickel, manganese (Fig. 6)

The effects of Al and Fe or Ni are additive.

The effect of vanadium (Fig. 7)

This depends on the oxidation state of the vanadium, the depression being greater with V(V) than with V(IV). The simultaneous influence of V and Fe is constant over a wide range of V:Fe ratios (7% enhancement for V:Fe < 9, falling to 2% for V alone). This situation is analytically favourable, as observed earlier in the good precision of Si determination in ferrovanadium.[8]

The effect of magnesium, etc.

The plateaux on the Mg interference curve depend on the Si:Mg ratio (Fig. 8), and the effects of Al and Mg are practically additive.

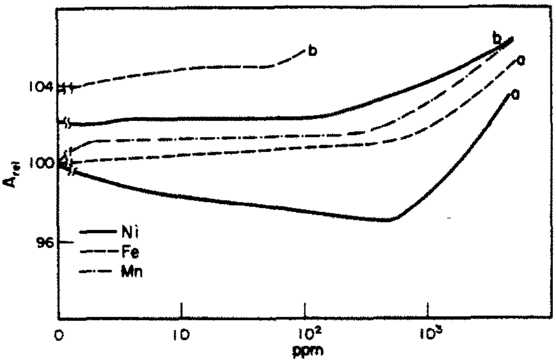

Fig. 6. Effect of Ni, Mn, Fe (curves *a*) and Ni, Fe simultaneously with 500 ppm Al (curves *b*) on the absorbance of 50 ppm Si.

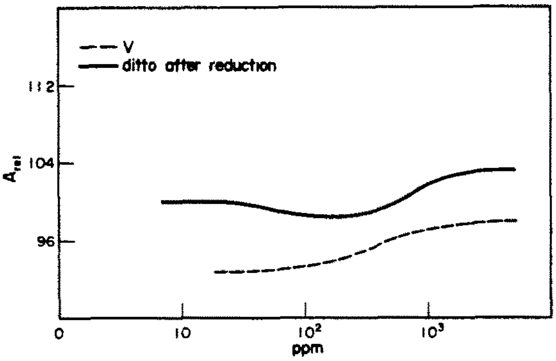

Fig. 7. Effect of V on the absorbance of 50 ppm Si (reduction with $NH_2OH.HCl$).

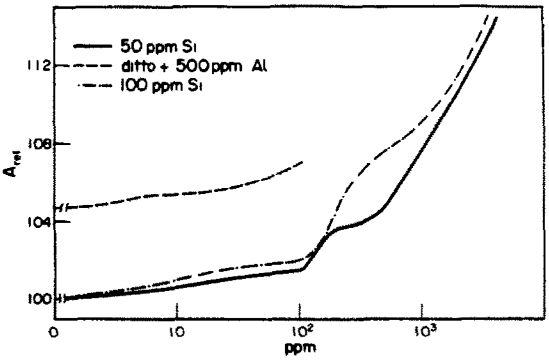

Fig. 8. Effect of Mg on the absorbance of 50 and 100 ppm Si and effect of Mg in presence of 500 ppm Al on the absorbance of 50 ppm Si.

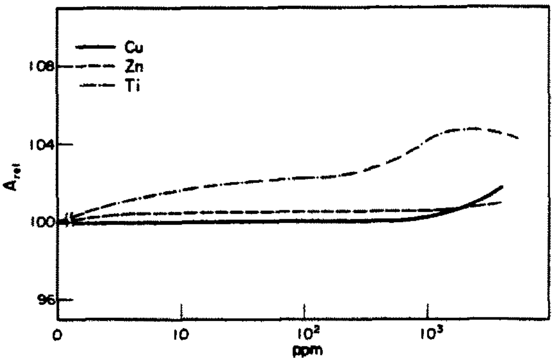

Fig. 9. Effect of Cu, Zn and Ti on the absorbance of 50 ppm Si.

In the case of Ti (Fig. 9) a higher acidity was used to prevent hydrolysis, so the decrease in interference at higher concentrations may be caused by the depressive effect of the acid. Both Ti(III) and Ti(IV) were tested, and the enhancement effect was somewhat higher with Ti(III).

The actual magnitude of the effects depends on the nebulizer and spray chamber arrangements, but the form of the interference curves is not usually changed.

Summary—The following substances have been investigated with regard to their interfering effect in the determination of silicon by AAS: HCl, HNO_3, H_2SO_4, Na^+, K^+, Cs^+, Al^{3+}, Ni^{2+}, Mn^{2+}, Fe^{3+}, V^{5+}, Mg^{2+}, Cu^{2+}, Zn^{2+} and Ti^{4+}. Some ternary systems with aluminium have been studied to examine the additive effects. Most of the interferents enhance the silicon absorption; only nickel and the acids exert depressive effects; the interference of copper and zinc is negligible.

FORMATION OF Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Ag(I) AND Cd(II) HEXACYANOCOBALTATES

Alessandro De Robertis, Athos Bellomo and Domenico De Marco
Institute of Analytical Chemistry, University of Messina, Messina, Italy

(*Received* 15 *January* 1976. *Accepted* 16 *March* 1976)

Some authors[1–7] have considered the reactions occurring in aqueous solution between $K_3Co(CN)_6$ and uni-, bi- and tervalent cations, but it appears that so far the reaction stoichiometries at various reagent concentrations have not been determined. We therefore decided to investigate the precipitation reactions of $K_3Co(CN)_6$ (hereafter referred to as An) with various cations Me [Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Ag(I) and Cd(II)] by means of direct and reverse titrations. The reagent concentration range examined was the widest possible, ranging from the reagent solubility down to the lowest limit detectable with the instruments used.

EXPERIMENTAL

The Me solutions were prepared from analytically pure salts, and standardized according to the usual techniques.[8]

The $K_3Co(CN)_6$ solutions were made by direct weighing of the analytically pure salt that had been dried over P_2O_5, and were stored in the dark to avoid photoreactions;[9] they were periodically checked spectrophotometrically in the 300–400 nm range, a single maximum at 310 nm confirming the exclusive presence of the hexacyanocobaltate species.[9]

The precipitations of Me with An and *vice versa* were followed by a conductometric high-frequency apparatus with digital read-out.[10] This technique was preferred because (*a*) it eliminated difficulty in choosing electrodes (an advantage over the potentiometric method), (*b*) readings could be taken immediately (zero equilibration time), (*c*) in the case of cation-exchange in the precipitates there would be a change in the solution conductivity, which could be detected even if the precipitates had similar K_{sp} values.

For each titration, the ratio between the analytical concentrations of Me and An at the equivalence point was calculated: $R = [Me]/[An]$. The volume titrated was always 100 ml, and the Me and An concentrations were allowed to vary.

Me titrations with An

Reactions occurring on addition of An to the solutions of Me always produce only $Me_3[Co(CN)_6]_n$ (n = charge on Me) except for Cd(II), for which, by further addition of An beyond the first equivalence point with $R = 1.5$, a precipitate with $R = 1.0$, corresponding to $CdKCo(CN)_6$, is obtained.

Table 1 reports the Me concentration range, R values, formulae and colours of the precipitates obtained. Titrations of 0.05–25 mmole of the cations gave results with errors ranging from −0.5 to +0.6%, average 0.3%.

Titrations of An with Me

In the reverse titrations, the stoichiometry of the precipitates was variable, depending on the nature of the precipitating cation and on the An concentration (Table 2).

Titration of 0.1–22 mmole of An with the various Me solutions gave errors ranging from −0.8 to +0.8%, average 0.2%, except for two results with zinc as titrant (± 1.2%).

DISCUSSION OF RESULTS

The interpretation of the stoichiometry of the reactions is based on the possibility of ion-pair formation between $Co(CN)_6^{3-}$ and K^+,[11,12] the concentration of the latter being three times that of the former. K_{eq} for $KCo(CN)_6^{2-}$ formation is between 17 and 30,[11,12] so ion-pairs should be the predominant species in solution and their degree

Table 1. Concentration ranges, R values, formulae and colour of compounds obtained by precipitating Me with $K_3Co(CN)_6$

Cation precipitated	Me concentration range	R value	Formula	Colour
Fe(II)	$0.90 \le pFe \le 2.92$	$1.50 \begin{vmatrix} +0.004 \\ -0.006 \end{vmatrix}$	$Fe_3[Co(CN)_6]_2$	Ivory-yellow

§ Transformation from R = 1.00 to R = 1.50 occurred in the solid phase.

of formation should increase with increasing $K_3Co(CN)_6$ concentration.

On these premises, we can assume that in all the titrations considered, the first stage consists of the reaction of Me with $KCo(CN)_6^{2-}$ species:

$$2Me^{n+} + nKCo(CN)_6^{2-} = Me_2[KCo(CN)_6]_n \qquad (1)$$

Factors such as the nature of Me, concentration of An, order of addition of reagents, may then favour a solid phase transformation:

$$Me_2[KCo(CN)_6]_n + Me^{n+} \rightleftharpoons Me_3[Co(CN)_6]_n + nK^+ \qquad (2)$$

or, over a narrow concentration range for Ni(II) added to An, the formation of $Ni_4K[Co(CN)_6]_3$:

$$3NiKCo(CN)_6 + Ni^{2+} = Ni_4K[Co(CN)_6]_3 + 2K^+ \qquad (3)$$

In the titrations of Me with An, only the $Me_3[Co(CN)_6]_n$ species were obtained [reactions (1) and (2)] except for Me = Cd(II) where further addition of $K_3Co(CN)_6$ after the first equivalence point ($R = 1.50$) leads to formation of $CdKCo(CN)_6$ ($R = 1.00$).

In titrations of An with Me, the behaviour can be classified according to the atomic number of the metal and its position in the periodic table. For the group Fe(II), Co(II) and Ni(II), whereas Fe(II) gives exclusively $Fe_3[Co(CN)_6]_2$, Co(II) first forms the compound with $R = 1.00$ [$CoKCo(CN)_6$], which transforms into $Co_3[Co(CN)_6]_2$, and Ni(II) behaves like Co(II) with dilute An solution, but at pAn ≤ 1.26 gives a single compound with $R = 1.33$, having the formula $Ni_4K[Co(CN)_6]_3$ and being stoichiometrically equivalent to $NiKCo(CN)_6 + Ni_3[Co(CN)_6]_2$; for pAn values lower than 1.00, a trend towards quantitative precipitation of $NiKCo(CN)_6$ is observed. The stability of the compounds of $Me_3[Co(CN)_6]_2$ type, with respect to addition of potassium ions, is Fe(II) > Co(II) > Ni(II). Cu(II) and Ag(I) show identical behaviour, since they form exclusively the $Me_3[Co(CN)_6]_n$ species. Zn(II) and Cd(II) react almost identically, both forming the $MeKCo(CN)_6$ and $Me_3[Co(CN)_6]_2$ types of compounds.

The titration errors are fairly small, and the reactions can be exploited analytically for the frequentometric determination of these metal ions or, more usefully, of $K_3Co(CN)_6$, since no valid methods have hitherto been proposed for the latter.

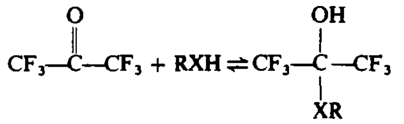
FLUORINE-19 MAGNETIC RESONANCE IN MEASUREMENT OF THE THERMODYNAMICS OF THE REACTION OF *o*-ALKYLPHENOLS WITH HEXAFLUOROACETONE[*]

Floyd F.-L. Ho
Research Center, Hercules Incorporated, Wilmington, Delaware 19899, U.S.A.

(*Received* 23 *February* 1976. *Accepted* 31 *March* 1976)

Hexafluoroacetone (HFA) has been used advantageously as a sensitive probe in the analysis of compounds containing active hydrogen. Leader[1,2] has examined HFA adducts of various alcohols, amines, mercaptans, oximes, *etc.* and found that the fluorine magnetic resonance (FMR) signals of the adducts are generally sharp and characteristic of the compounds being investigated. These signals spread over a 10-ppm range. Different functional groups in multifunctional compounds can be conveniently examined at the same time. Owing to the relatively high sensitivity of FMR (exceeded only by proton magnetic resonance, PMR) and the presence of six fluorine nuclei in each functional adduct, small samples of a few μl or mg can be easily studied. Also, use of expensive deuterated solvents is avoided.

However, the adduct reaction is an equilibrium:



$$CF_3-\overset{\overset{\displaystyle O}{\|}}{C}-CF_3 + RXH \rightleftharpoons CF_3-\underset{\underset{\displaystyle XR}{|}}{\overset{\overset{\displaystyle OH}{|}}{C}}-CF_3 \qquad (1)$$

where X is O, S, NH, or NR′, *etc.* Although this equilibrium generally lies far to the right,[3,4] incomplete reaction at room temperature has been observed.[2,5] Therefore thermodynamic data for it would be useful in devising analytical procedures based on it. Such data could also readily be correlated with reactivity of functional compounds, and therefore useful in correlation of reactivity parameters with structural influences or solvent effects. In this work, the equilibria of HFA with a series of *o*-alkylphenols are examined at several temperatures, and correlation of the thermodynamic data with other structural parameters is discussed.

EXPERIMENTAL

The phenols studied were reagent grade chemicals, and were further purified by fractional distillation. HFA was purchased from Pierce Chemical Co. Reagent grade ethyl acetate was dried by a Soxhlet extraction using activated 4A molecular sieves and used immediately; this procedure removed any ethanol completely and reduced the water content to below 50 ppm. It is a more effective way of removing these impurities than the alumina column reported earlier.[5] The HFA reagent in ethyl acetate was prepared in a plastic bag filled with dried nitrogen, and the general procedure in handling the reagent was as described by Leader.[1,2] The reaction in equation (1) was carried out *in situ* in a 1-ml volumetric flask. Small quantities of hexafluorobenzene were added to provide the instrument lock signal. 1,2-Difluorotetrachloroethane, obtained from PCR, Inc., and further purified by fractional distillation, was used as internal standard for integral calibration. This signal is observed 96.07 ppm downfield from that of C_6F_6.

The FMR spectra were obtained on a Bruker HFX-90 spectrometer, operated at 84.67 MHz and equipped with a variable temperature probe. The probe temperature was measured with a calibrated copper–constantan thermocouple and checked with a thin thermometer held in the spinning sample holder. The temperature was controlled within ± 1° during the measurement. Sealed tubes were used in all measurements. The equilibrium constant of equation (1) was calculated from

$$K = [c/a(b - c)] \qquad (2)$$

where a is the molar concentration of the excess of HFA (which gives a sharp peak 88.6 ppm downfield from that of C_6F_6), c is that of the phenolic adduct, measured by integration of the spectra; b is the initial molar concentration of the phenol. The adduct signals generally occurred in a region a few ppm upfield from the HFA peak and were slightly temperature-dependent.

RESULTS AND DISCUSSION

The equilibrium constants of the HFA adducts of several *o*-alkylphenols (listed in Table 1) were measured at 0–68° in ethyl acetate as solvent. The reaction was found to be truly reversible and thermodynamically controlled. Equilibrium was reached in a few minutes except in the case of *o*-tert-butylphenol at 0°, for which 1 hr was necessary. Ample time should be allowed for equilibrium to be reached before measurements are taken.

The signal from the excess of HFA increased with increasing temperature and that from the adduct decreased.

The logarithms of the equilibrium constants measured at 25° are listed in Table 1, together with several other constants reported in the literature. The enthalpies and entropies of the reaction, derived from the variation of the equilibrium constant with temperature, are summarized in Table 2.

In quantitative analyses of such functional compounds by use of FMR and HFA, knowledge of the chemical equilibrium is important. For example, the ΔH and ΔS values of *o*-ethylphenol, Table 2, show that the reaction at 40° is only 92.5% complete if $b = 0.05M$ and $a = 0.5M$. However, if the same measurement were made at 0°, the reaction would be 99.6% complete. Because the precision of the NMR integral is generally about ±2%, the reaction at 0° under these conditions can be considered virtually quantitative.

The log K values reported in Table 1 correlate fairly linearly with the apparent σ_{ortho} obtained from the pK_a values for the phenols in water at 25°,[6] and change in the same direction as those of Taft's constants within the series. However, no apparent correlation was found between log K and σ^- measured from the phenolic proton shift;[7] this can be partly attributed to the dissimilarity of the properties measured. For example, the chemical shift of *ortho*-substituted phenols in dimethyl sulphoxide was shown to be influenced by the substituents mainly through electronic effects,[7] whereas the substituent constant based on reactivity measurements includes contributions from both electronic and steric effects, as well as resonance effects. In addition, –OH chemical shifts are known to be greatly influenced by intermolecular interactions, such as hydrogen bonding and magnetic shielding by solvent molecules.

Table 2. Enthalpies and entropies of reaction of *o*-alkylphenols with HFA in ethyl acetate

ortho-substituent	ΔH, *kcal/mole*	ΔS, *cal. mole^{-1}.deg^{-1}*
$—CH_3$	-15 ± 1	-41 ± 2
$—CH_2CH_3$	-14	-38
$—CH(CH_3)_2$	-13.5	-37
$—C(CH_3)_3$	-5	-14

As expected, the thermodynamic data shown in Table 2 indicate that the reaction becomes less exothermic as the size of the *ortho*-substituent increases, suggesting the importance of steric interaction. This steric effect is very pronounced in the case of *o*-tert-butyl substituent. It is also interesting to note that within the series ΔH changes roughly linearly with ΔS, indicating the existence of an isokinetic relationship.[8]

The main attraction of the method is that it provides direct measurement of two of the parameters needed for determining equilibrium constants, but the error is about 5%.

Summary—The reaction of several *o*-alkylphenols with hexafluoroacetone at 0–68° was followed by measuring the fluorine magnetic resonance. A knowledge of the equilibrium of the hemiacetal formation is useful in devising schemes for determination of these compounds. The enthalpy and entropy changes for the equilibrium were found to become less negative with increasing size of the *ortho*-substituents, indicating the importance of steric interaction. The equilibrium data correlate well with Taft's constant and σ_{ortho} from pK_a values, but deviate from σ^- derived from measurements of phenolic proton chemical shifts.

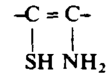
SOLVENT EXTRACTION AND PHOTOMETRIC DETERMINATION OF MOLYBDENUM (VI) WITH 2-AMINOBENZENETHIOL*

Anil K. Chakrabarti and Saswati P. Bag®
Department of Chemistry, Jadavpur University, Calcutta-700032, India

(*Received* 14 *May* 1975. *Revised* 16 *March* 1976. *Accepted* 15 *April* 1976)

In our search for sensitive reagents containing sulphur as a donor atom for molybdenum, 2-aminobenzenethiol[1] was found to be a good colour-forming reagent. There are only a few chelating agents with the



$$\begin{array}{cc} -C = & C- \\ | & | \\ SH & NH_2 \end{array}$$

grouping that form stable complexes with metal oxo-cations such as VO_2^+, WO_2^{2+}, TiO^{2+} and MoO_2^{2+}.[2] Molybdenum usually forms stable oxo-species, *e.g.*, MoO_2^{2+}, MoO^{4+}, $MoO(OH)^{3+}$, in combination with various chelating agents in the acidic pH range. Except for instances where ligands such as dithiocarbamates reduce Mo(VI) to Mo(V), the stable chelates of oxo-molybdenum ions are reported to be formed from Mo(VI).

The present investigation shows that with 2-aminobenzenethiol, molybdenum forms a green complex which is quantitatively extractable into chloroform at pH 1.4–2.8. The colour is stable for 2 hr at room temperature and the molar absorptivity is 7.08×10^4 l.mole^{-1}.cm^{-1}. The reagent has been applied to the estimation of Mo in high-speed alloy steel containing Cr, Mo, W and V.

EXPERIMENTAL

Reagents

Ammonium heptamolybdate octahydrate was dissolved in water containing a few drops of ammonia and the solution standardized gravimetrically by the 8-hydroxyquinoline method.[3] Working solutions were prepared by appropriate dilution of the stock solution.

Chloroform was freed from alcohol by washing with dilute sulphuric acid, dilute ammonia and then twice-distilled water. Anhydrous sodium sulphate was used to free the organic phase from water.

Purification of 2-aminobenzenethiol. The reagent was fractionally distilled under reduced pressure. Because the compound is sensitive to atmospheric oxidation the distillation system was saturated with nitrogen. The product distilling at 88–91°/1 mmHg was kept frozen under nitrogen. The pure liquid is almost colourless at room temperature.

A 2% w/v solution of reagent was freshly prepared in pure chloroform before use.

Procedure

Adjust the pH of the aqueous molybdenum solution (10 ml) to 2.0. Add 5 ml of 2% reagent solution and 1 ml of pure chloroform, shake the mixture thoroughly for 5 min in a 50-ml separatory funnel, collect the chloroform layer in a 50-ml beaker and dry it over anhydrous sodium sulphate. Extract the aqueous phase with further 5-ml portions of chloroform. Transfer the combined extracts quantitatively to a 25-ml volumetric flask and dilute to volume with chloroform. Measure the absorbance at 700 nm in 1-cm cells. Construct a calibration curve similarly.

Procedure for steel analysis

Dissolve an appropriate weight of sample (1 g for 0.2% of Mo, 0.1 g for 6% Mo) in 50 ml of 3*M* sulphuric acid in a 150-ml Erlenmeyer flask and oxidize with concentrated nitric acid. Place a small funnel in the neck of the flask. Boil to reduce the volume to about 20 ml; cool, add 30 ml of water and boil for a few minutes. Cool, filter if necessary, add 0.5 g of ferrous sulphate to reduce vanadium(V) and chromium(VI), transfer to a 100-ml volumetric flask and dilute to volume. Take 5 ml of this solution, add 1 ml of saturated ascorbic acid solution and determine the molybdenum content by the procedure described above. Table 2 summarizes the results for two BAS standard steels.

RESULTS AND DISCUSSION

Characteristics of the complex

The absorption spectrum of the molybdenum–thiol complex in chloroform, extracted at pH 2.0 according to the general procedure, is reproducible for different concentrations of the metal, and has its absorbance maximum at 700 nm. The reagent does not absorb at wavelengths longer than 500 nm at the concentrations used. The system obeys Beer's law from 0.25 to 10 ppm molybdenum and a Ringbom plot[4] shows the optimum range to be 0.5–4.5 ppm. The relative error per 1% absolute photometric error for this range is 2.5%. The molar absorptivity and Sandell sensitivity of the complex were found to be 7.08×10^4 l.mole^{-1}.cm^{-1} and 0.0075 μg/cm^2 respectively.

Sufficient colour intensity is observed between pH 0.6 and 4.2, but the optimum range for the quantitative extraction of the chelate is pH 1.4–2.8. The amount of reagent necessary is at least 3 ml of 2% w/v solution for 4 ppm Mo, and 5 ml is recommended.

The optimum extraction time for 99.9% extraction is 5 min. If shaking is continued for more than 15 min the colour intensity decreases. The extracted chelate is stable for at least 2 hr at room temperature, but changes rapidly to a brown complex in presence of oxidizing agents.

Effect of other ions

The effect of diverse ions on the molybdenum determination was studied by adding 200 ppm of the ion in question to a solution containing 4 ppm of molybdenum and applying the recommended procedure. Ba, Ca, Mg, Sr, Al, Ti(IV), Sn(IV) and Sb(III) do not interfere. Tolerance limits for other ions are given in Table 1. The interference due to V(V) and Fe(III) can be eliminated by addition of hydroxylamine hydrochloride and ascorbic acid respectively. Bi(III), Sn(II), and Re(V) obtained by reduction with stannous chloride, interfere seriously.

Composition of the complex

The composition of the complex was determined by Job's method of continuous variations and was reproducible at different molybdenum concentrations.

The Job plot (Fig. 1) showed some unusual features. At the mole ratio corresponding to the MR_2 species there

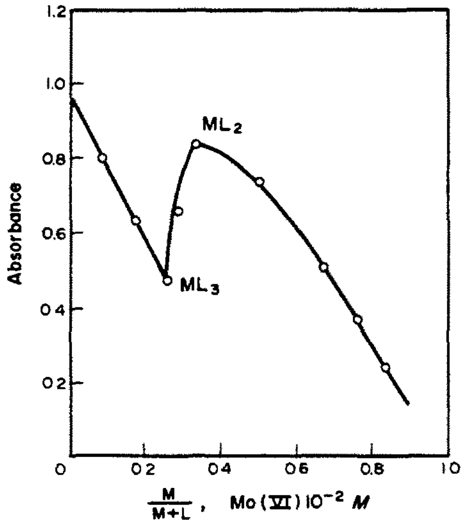

Fig. 1. Job plot, $[M] = [R] = 1.042 \times 10^{-2} M$.

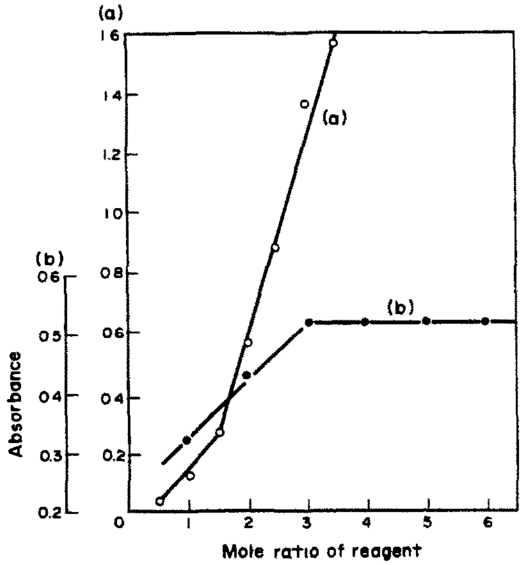

Fig. 2. Mole-ratio plots: (*a*) $[M] = [R] = 2.084 \times 10^{-2} M$; (*b*) $[M] = 1.402 \times 10^{-3} M$, $[R] = 7.01 \times 10^{-2} M$.

was a maximum in the absorbance and a sharp minimum at the ratio corresponding to MR_3. A mole-ratio plot (Fig. 2) gave a non-linear increase in absorbance up to an R:M ratio of about 3, then a steeper and linear increase followed by a maximum and constant absorbance when an R:M ratio of at least 500 was reached. This formation can be interpreted as indicating first an MR_2 complex of low molar absorptivity (2.0×10^4 $l.mole^{-1}.cm^{-1}$) followed by formation of an MR_3 complex of low stability but high molar absorptivity (found by the Bag and Chakrabarti method[5] to be 7.08×10^4 $l.mole^{-1}.cm^{-1}$). The stability constant of the MR_3 complex was evaluated as 2.0×10^8 at 25 ± 1° by Yatsimirskii's method.[6] The reaction can be interpreted as

$$MoO_2L_2 + HL \rightleftharpoons MoO(OH)L_3$$

where HL = 2-aminobenzenethiol.

The MR_3 complex was isolated for verification of its composition. Elemental analysis supported the formula $MoO(OH)L_3$. The complex gave negative tests for chloride. The infrared spectrum of the isolated complex showed a sharp absorption peak in the 3100 cm^{-1} region, suggesting the presence of an O—H stretching band. The compound also showed an Mo=O absorption band at 920 cm^{-1} (s). This again supports the existence of the $MoO(OH)^{3+}$ species. The complexes MoO_2L_2 in presence of a stoichiometric amount of ligand and $MoO(OH)L_3$ in presence of a large excess of ligand are both extractable into chloroform.

ION-SELECTIVE ELECTRODES IN ORGANIC FUNCTIONAL GROUP ANALYSIS MICRODETERMINATION OF NITRATES AND NITRAMINES WITH USE OF THE IODIDE ELECTRODE

SAAD S. M. HASSAN
Research Microanalytical Laboratory, Department of Chemistry, Faculty of Science
Ain Shams University, Cairo, Egypt

(*Received* 20 *February* 1976. *Accepted* 12 *April* 1976)

Organic nitrates and nitramines have been determined by titration with various reductants.[1] However, these methods suffer from the defect that many nitrogenous and non-nitrogenous compounds interfere and the titrants need special precautions during preparation, storage and use.[2] Methods based on spectrophotometric[3] and gravimetric[4] procedures are usually time-consuming and unreliable when used on a routine basis. Gasometric reactions using inorganic[5–9] and organic[10,11] reagents have also been suggested.

Recently, the development of the nitrate-responsive electrodes[12–14] has made possible substantial improvement in the analysis of inorganic nitrates. Reduction of the nitrate ion followed by measurement of the liberated ammonia by means of the ammonium-responsive electrode has also been reported.[15] The use of both electrodes for the analysis of the nitrates by direct potential measurements requires careful adjustment of many variables and the resulting precision is not better than ± 2%.[12–15] Potentiometric titration is more accurate provided that the titrant forms either a stable complex or a precipitate, but unfortunately not many such titrants are available for nitrate or ammonia. However, diphenylthallium(III) sulphate has been applied for the titration of the nitrate ion, on the semi-micro scale only, with use of the nitrate electrode.[16]

On the other hand, the nitrate electrode is inapplicable to the determination of organic nitrates, and prior conversion of the organic nitrate or nitramine into inorganic nitrate by acid or alkaline hydrolysis is not quantitative.[17,18] The organic moiety of these compounds partially reduces the nitrate to various products such as ammonia and nitrogen oxides.

The present work describes a new finish to the determination of organic nitrates and nitramines by reaction with mercury–sulphuric acid mixture, the mercurous ions released being titrated with iodide, and an iodide electrode used to detect the end-point. Several compounds used as high explosives, industrial intermediates and vasodilators have been analysed and the results obtained are accurate.

EXPERIMENTAL

Reagents and materials

All reagents were analytical grade except where stated. Doubly-distilled water was used throughout. The nitrate and nitramine samples used were of purity not less than 99% as confirmed by the gasometric method.[5]

Apparatus

A Pye Unicam 292 MK2 pH-meter, an Orion 94-53 solid-state iodide-selective electrode and an Orion 90-02 double-junction reference electrode were used.

Procedure

Weigh accurately 2–5 mg of the ground dried nitrate, nitrite or nitramine sample and transfer it to a test-tube (10 × 21 cm). For smaller samples, transfer to the tube a portion of solution containing 0.1–1.0 mg of the sample and evaporate to complete dryness. Add 2–3 ml of 96% sulphuric acid and displace the air in the tube with pure nitrogen. Add 3 drops of mercury and shake the tube for 5–7 min at room temperature, with a continuous flow of nitrogen. Transfer the contents of the tube to a 250-ml beaker, rinsing with *ca.* 50 ml of doubly-distilled water, and stir. Insert the iodide and reference electrodes, titrate with 0.02*M* potassium iodide for sample sizes above 2 mg and with 0.002*M* solution for sample sizes below 2 mg and monitor the e.m.f. As the end-point is approached add the titrant in 0.01-ml increments. For sample sizes above 5 mg, the titration has to be conducted slowly, with efficient stirring from the beginning of the titration, since the equilibrium is reached slowly. Run a blank in the same manner.

RESULTS AND DISCUSSION

Nature of the reaction

Mercury in presence of concentrated sulphuric acid quantitatively reduces nitrates to nitric oxide,[5–9] and is itself converted into mercurous and/or mercuric ions. It is found experimentally that three moles of potassium

20	0.4
30	0.6
40	1.6
60	3.6
80	6.4
100	90.0

iodide are required to titrate quantitatively the mercury ions produced by reaction of one mole of the nitrate or nitramine group. Consequently, the reactions of nitrates and nitramines with mercury may be

$$2\,R{-}O{-}NO_2 + 3H_2SO_4 + 6Hg = 3Hg_2SO_4 + 2NO + 2R{-}OH + 2H_2O \quad (1)$$

$$2\,R{-}NH{-}NO_2 + 3H_2SO_4 + 6Hg = 3Hg_2SO_4 + 2NO + 2R{-}NH_2 + 2H_2O \quad (2)$$

The possibility of formation of mercuric ions as shown by equation (3) leads to the same overall stoichiometry $2NO_3^- \equiv 3Hg_2^{2+} \equiv 3Hg^{2+} \equiv 6I^-$.

$$2\,R{-}O{-}NO_2 + 3H_2SO_4 + 3Hg = 3HgSO_4 + 2NO + 2R{-}OH + 2H_2O \quad (3)$$

However, qualitative identification of the inorganic reaction products, by addition of dilute hydrochloric acid and enough ethanol to give a concentration of 75% v/v, removal of Hg_2Cl_2 by filtration, then passage of hydrogen sulphide, showed that mercurous ions were the sole product.

Reaction conditions

Reaction of organic nitrates and nitramines with mercury and sulphuric acid is fast enough to ensure quantitative reduction within 5 min at 20°. Table 1 shows the blank values obtained by reaction of mercury with 96% sulphuric acid for 15 min at temperatures ranging from 20° up to 100°. Reaction at temperatures above 40° is not recommended, since the blank values tend to increase and affect the results, especially with sample sizes in the range between 100 μg and 1 mg.

Study of the effect of the sulphuric acid concentration shows that 85% v/v is the minimum concentration permissible for quantitative reduction (Fig. 1). The amount of acid actually required is determined not only by the amount needed for the reduction but also by the amount needed to give maximum solubility of mercurous sulphate during the titration. Measurements on mercurous sulphate in various concentrations of sulphuric acid show that the solubility of mercurous sulphate is maximal in the 1.5–3 *N* acid (Table 2). Consequently, the optimum volume of 96% sulphuric acid required for the reaction is 2–3 ml, which on dilution with water to *ca.* 50 ml gives a 1.5–3 *N* solution which will completely dissolve up to 33 mg of mercurous sulphate (equivalent to about 4 mg of nitrate sample containing 15% nitrogen).

It is necessary to carry out the reaction under a flow of nitrogen to remove the nitric oxide produced, because in presence of air or oxygen some nitric oxide will be oxidized, dissolve in the acid and cause oxidation of some of the mercurous ions, and possibly dissolve a little additional mercury, resulting in erratic positive errors.

Determination of mercurous ions, by using the ion-selective electrode

It has been reported that the solid-state iodide-sensitive electrode (Orion 94-53) responds to mercuric ions [20] down to 10^{-8} *M* and is useful as end-point detector in the titration of mercuric ions with potassium iodide. [21] The behaviour of this electrode towards mercurous ions has not been explored. In the present work, attempts were made to use it to determine mercurous ions by both direct potentiometry and potentiometric titration.

A test of the potential response of the iodide electrode (Orion 94-53) in conjunction with a double-junction reference electrode (Orion 90-02) at pH 2–4 in 0.1 *M* sodium perchlorate shows a more or less linear relation between the logarithm of mercurous ion concentration in the range 10^{-2}–10^{-6} *M* and the potential, but the slope is less than Nernstian, being about 45 mV/decade. Direct measurement

of the mercurous ion concentration by using a calibration graph gives unsatisfactory results.

The use of the iodide electrode as indicator for the potentiometric titration was therefore tried. The titration curves show a sharp inflection (~400 mV) at the equivalence point. The relative standard deviation for 1 mg of mercurous ion is 0.2% and the reaction follows a 1:2 ($Hg_2^{2+}:I^-$) stoichiometry down to mercurous ion concentrations of 10^{-5} *M*.

Determination of organic nitrates and nitramines

The results obtained (Table 3) for the analysis of some nitrate esters, nitrate salts of organic bases and nitramines in the range 0.1–50 μmole show an average recovery of 99.0% and a mean relative standard deviation of 0.2%. A series of 10 replicate analysis of pentaerythritol tetranitrate and of nitroguanidine in the range 100–1000 μg showed a mean relative standard deviation of 0.3% and an average recovery of 98.3%.

The response of many nitrogenous groups to the reaction was tested. Mono-, di- and tri-nitro compounds (*e.g.*, *p*-nitrophenol, *m*-dinitrobenzene, 2,4,6-trinitrobenzoic acid and 2,4,6-trinitrophenol) as well as amides, anilides, oximes and hydrazides (*e.g.*, benzamide, benzanilide, dimethylglyoxime, sulphanilic acid and hydrazobenzene) were checked and none of these compounds responded to the reaction.

Determination of inorganic nitrates and nitrites

The applicability of the reaction to the analysis of inorganic nitrates and nitrites was also tested. The results obtained, based on the consumption of three and one equivalents of potassium iodide per nitrate and nitrite group, respectively, according to equations (4) and (5), show an average recovery of 99% for the nitrates and 97.5% for the nitrites (Table 4). The quantitative liberation of one mole of nitric oxide gas per nitrate and nitrite group[5,9] is in a good agreement with these data.

$$2NO_3^- + 4H_2SO_4 + 6Hg = 3Hg_2SO_4 + 4H_2O + 2NO + SO_4^{2-} \quad (4)$$

$$2NO_2^- + 2H_2SO_4 + 2Hg = Hg_2SO_4 + 2H_2O + 2NO + SO_4^{2-} \quad (5)$$

Advantages

The proposed procedure has advantages on the score of sensitivity, selectivity and simplicity over many of the methods used for analysis of the nitrates.[1,2] It is more than 60 times as sensitive as the micro-gasometric methods, since it is applicable to the analysis of 100 μg of the nitrates, an amount which are totally inadequate for many gasometric and titrimetric procedures: 10 μg of nitrate-nitrogen ≡ 1.07 ml of 0.002 *M* KI ≡ 0.0160 ml of NO at NTP.

It is not affected by environmental conditions such as pressure, temperature, solubility, and vapour-pressure factors, which have a direct effect on the measurement by the gasometric procedures. Also, the reagents are stable and require no special precautions such as those needed with the reductants used in the titrimetric methods. Finally, it avoids the difficulties and errors arising from the time-consuming reduction[15] and hydrolysis[22] procedures.

Summary—A simple, selective and accurate method has been described for the rapid micro and submicro determination of organic nitrates and nitramines. It is based on reaction with mercury–sulphuric acid mixture for 5 min at room temperature followed by potentiometric titration of the mercurous ions released, a solid-state iodide-sensitive electrode being used. Three equivalents of potassium iodide as titrant are consumed per mole of nitrate or nitramine group. The results obtained, with sample sizes ranging from 1.0 to 50 μmole, are precise to ± 0.2% and the average recovery is 99%. None of the other nitrogenous functional groups responds to this reaction.

ANALYTICAL DATA

DISSOCIATION OF THE AMMONIUM ION IN WATER–UREA AND WATER–tert-BUTYL ALCOHOL MIXTURES

Yvon Pointud, Henri Gillet and Jean Juillard
Laboratoire d'Etude des Interactions Solutés-Solvants, Université de Clermont, BP 45, 63170 Aubière, France

(*Received* 17 *March* 1976. *Accepted* 31 *March* 1976)

In the course of a continuing study of ion solvation in the two series of media[1] named in the title it seemed appropriate to evaluate the dissociation of the ammonium ion in order to appreciate the meaning of the thermodynamic properties of this ion, measured in those solutions.

This has been done through potentiometric measurements of the potential difference of a galvanic cell such as:

$$\text{Ag, AgCl}\left|\begin{array}{c}\text{NH}_4^+, \text{Cl}^-, \text{NH}_3\\ \text{water} + \text{solvent S}\end{array}\right|\text{H}^+, \text{glass electrode}$$

Aqueous solutions approximately equimolal in NH_3 and NH_4Cl were prepared by adding to water weighed amounts of hydrochloric acid and ammonia stock solutions of accurately known concentration. The variations δU of the potential difference U of the galvanic cell were then recorded when weighed amounts of co-solvent S were added, a Radiometer pH-meter 4, reading to 0.2 mV, being used. The solutions were kept at 25.0°; the addition of urea considerably lowered the temperature, so the measurements were taken only when the temperature had been restored to 25.0°.

The dissociation constants were calculated from δU, δU^0 (which is the change of the standard potential of the cell) and the pK_a of NH_4^+ in water (9.245).[4] Activity coefficients were estimated by using the extended Debye–Hückel equation with coefficients A and B appropriate to the media, and Bjerrum's q as distance parameter. Association of ammonium chloride was neglected and the pK_a values in mixed solvents were then obtained by using the equations

$$\mathrm{p}^{s}K_a = \frac{F(\delta U^0 - \delta U)}{RT\ln 10} + \mathrm{p}^{w}K_a + {}^{s}\Omega - {}^{w}\Omega \qquad (1)$$

where the superscript s stands for the aqueous organic mixture and w for water, and for both solvent media

$$\Omega = \log\frac{(m_s + m_{\mathrm{OH}^-})m_s}{m_b - m_{\mathrm{OH}^-}} + \frac{2A\sqrt{(m_s + m_{\mathrm{OH}^-})\rho}}{1 + Bq\sqrt{(m_s + m_{\mathrm{OH}^-})\rho}}$$

where m_b and m_s are the molal analytical concentrations of base and salt respectively (m_s = molality of acid added to the solution, $m_b + m_s$ = molality of ammonia added to the solution) and ρ is the density of the solvent medium.

The value of m_{OH^-} in water was calculated from the pK_a of NH_4^+, the ionic product of water and the analytical molality of base and salt, by using classical treatment of ionic equilibria; δU^0 was obtained by measuring the variations of the potential of the cell when co-solvent was added to pure aqueous hydrochloric acid of various concentrations. There are, then, two non-independent unknown quantities in equation (1): $\mathrm{p}^{s}K_a$ and ${}^{s}m_{\mathrm{OH}^-}$. Therefore calculations are made through successive approximations. The ionic product values used for solvent mixtures were taken from the literature.[5]

With urea, it has been observed that, taking into account the possible hydrolyses which can produce ammonium and cyanate ions, it is best to work only with fresh solutions and high enough electrolyte concentrations. With analytical salt concentrations between 5×10^{-3} and $10^{-2}\,m$,

Table 1. Molal dissociation constant of ammonium ion (pK_a) in water–urea mixtures at 25°C (pK_a in water = 9.245)[4]

m_b*	10†	20†	30†	40†
1.004×10^{-2}	8.72_6	8.43_0	8.20_7	8.02_0
9.05×10^{-3}	8.73_1	8.43_8	8.21_4	8.02_7
8.14×10^{-3}	8.72_4	8.43_3	8.20_8	8.02_1
7.07×10^{-3}	8.72_3	8.42_7	8.20_7	8.01_8
6.2×10^{-3}	8.72_5	8.42_9	8.20_1	8.01_5
Mean	8.72_6	8.43_1	8.20_7	8.02_0

* Molality of initial solution of NH_3 in water.
† Urea, % w/w.

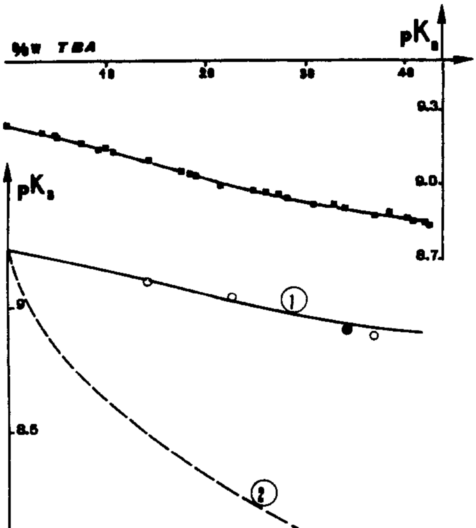

Fig. 1. Variation of the molal dissociation constant of the ammonium ion with: ■ % w/w TBA. — volume fraction of TBA, ϕ. --- volume fraction of urea, ϕ. ● volume fraction of MeOH according to ref. 6 and ○ volume fraction of EtOH according to ref. 7.

Table 2. Molal dissociation constant of ammonium ion in water–TBA mixtures at 25°C

TBA, % w/w	pK_a	TBA, % w/w	pK_a
5	9.20	25	8.97
10	9.15	30	8.94
15	9.09	35	8.90
20	9.03	40	8.87

good reproducibility of the results has been obtained (Table 1). Data concerning water–tert-butyl alcohol media are shown in Fig. 1; extrapolated data for exact concentrations of the alcohol are reported in Table 2.

It is worth noting (Fig. 1) that changes of pK_a with *volume fraction of alcohol* (ϕ) *are identical* for methanol,[6] ethanol,[7] and tert-butyl alcohol (TBA), at least in water-rich media, as if they were determined only by the actual volume of water. The same situation has been encountered for the ΔG of transfer of RbCl from water to aqueous organic media:[8] for most of the co-solvents, the variations observed are related only to the volume fraction, whereas urea produces quite different effects.

ANNOTATION

SOME COMMENTS ON "THE PROGRESS OF ANALYTICAL CHEMISTRY 1910–1970"

T. Braun
Institute of Inorganic and Analytical Chemistry, L. Eötvös University,
1443 Budapest, P.O.B. 123, Hungary

(*Received* 28 *November* 1975. *Accepted* 29 *March* 1976)

The paper by Brooks and Smythe[1] of the title above has initiated some thoughts I consider worth while to add as comments.

The authors of this paper have tried to approach a very much up-to-date problem with methods and means applied only in very few cases to analytical chemistry. To follow the progress of analytical chemistry between 1910 and 1970, they consider the number of publications, its time-dependent growth and the distribution of publications with respect to various factors (country, language, sub-fields, elements), "in order to evaluate some of the long-term trends of this century". Now the statistical distribution and growth of scientific publications, citations and manpower has been dealt with in detail in some basic works,[2–4] and it has been shown in these that the statistical data on the number of scientific publications can be correlated to the data on new scientific achievements, although scientific achievement and scientific information are different concepts. The study of this "indicator", supplemented by several others (number of citations, number of scientists, number of institutions, funds, equipments, *etc.*) drawn from various sources (e.g., bibliographies, abstract journals, progress reviews, *etc.*) can reveal many interesting conclusions. However, one should avoid the misjudgment that the number of publications is the only and fundamental measure ("indicator") of the "size of science" or its "development" or "progress". Thus, as a title, "Progress of the literature of analytical chemistry, 1910–1970" would have been more relevant.

The growth of the number of scientific publications is exponential, as has been shown both for all science[2–4] and for several individual fields.[5] It is usual to characterize further the exponential increase by a growth rate that can be compared with the growth rate of chemistry in general or with that of some other fields.[5] A very convenient, simple, way to compare various rates of exponential growth is by means of the doubling time, the length of time required for the literature to double in size, when growing at constant rate. The problems in attempting to assess the total volume of analytical literature are so great and diverse as to cast doubts on the value of any such estimate. It seems that it is more reliable to look at and compare the rates of growth of the various techniques (see Fig. 3).

It is well known that the whole scientific literature doubles within about 15 years,[3] the literature of chemistry within 8–10 years,[6] and that of analytical chemistry within about 5–7 years[7] (for the period 1956–1972).

Another question worth consideration is whether the ranking of the countries in which analytical chemistry was carried out (*cf.* ref. 1, p. 497) is of help in the study of the general progress of analytical chemistry. It seems that a transformation of the data into a correlation with some specific factor would be more useful. If, for example, the number of publications in analytical chemistry (or its logarithm) from a given country is plotted *vs.* some indicator representing the general stage of scientific development in the country (*e.g.*, the total number of scientists or scientific authors in the country[8]), it would perhaps provide a picture of the weight of analytical chemistry within the general scientific capacity of the country. A preliminary plot of this sort is given in Fig. 1, showing data for 1970 (number of analytical publications from ref. 1, number of authors from ref. 8).

On page 500 in ref. 1, "the major (analytical) journals (each containing more than 1.0% of the world total)" are listed, based on calculations for the year 1970. The Polish nuclear journal *Nukleonika* is also mentioned. The 1% means that each listed journal published at least 184 analytical papers in 1970. Going through the 1970 issues of *Nukleonika*, it can be established that they contain *a total of 82 papers* (including nuclear physics, chemistry, biology and analytical chemistry) out of which there are only 13 dealing or related with analytical chemistry. From this it seems that this nuclear journal, excellent as it is, cannot be included in the list of major analytical journals.*

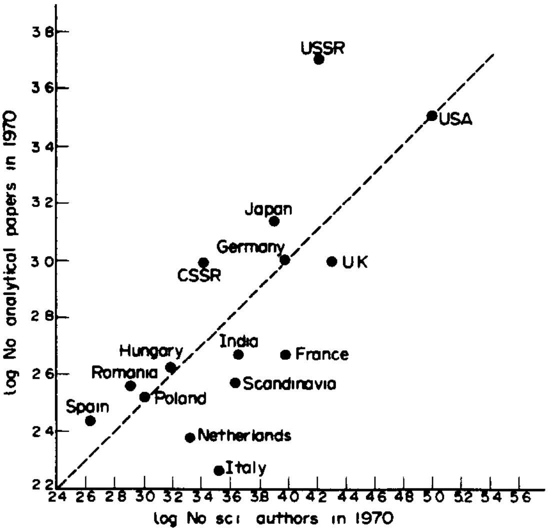

Fig. 1. Log–log scatter plot of output of analytical papers by various countries for 1970 as a function of total number of scientific authors in these countries for 1970 (slope of the regression line 1.09).

---

* The authors of the original paper wish to apologise for this error; the journal itself was not available to them [Editor].

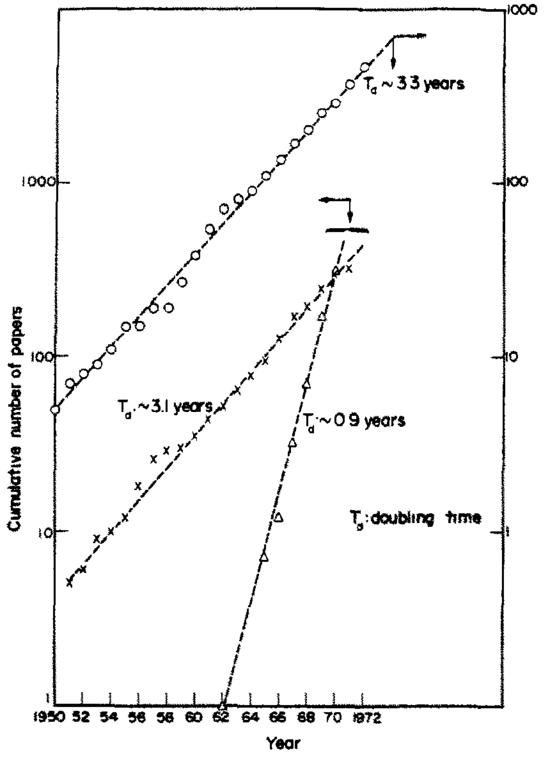

Fig. 2. Growth of papers in some sub-fields of radioanalytical chemistry. Adapted from refs. 9 and 11. ○ Prompt nuclear analysis, × Charged-particle activation analysis, △ Solid-state gamma-spectrometry.

Finally, I would like to mention that I am not convinced that "the main source for the (statistical) evaluation of methods used in analytical chemistry is the biennial reviews in Analytical Chemistry" (ref. 1. p. 500).

As a matter of fact, the basis of preparation of these reviews is not uniform and both their qualitative and quantitative contents vary over a wide range. There are some very selective critical reviews among them, and others can be considered rather as bibliographies. The latter might serve the purpose of ref. 1 but the former do not.

I have the notion that more useful data could be obtained if true bibliographies or abstract journals were used as a source, and if the number of papers published in the analytical sub-fields were plotted cumulatively as a function of time. Figures 2 and 3 shows such two illustrations from the field of radioanalytical chemistry and electroanalytical chemistry.

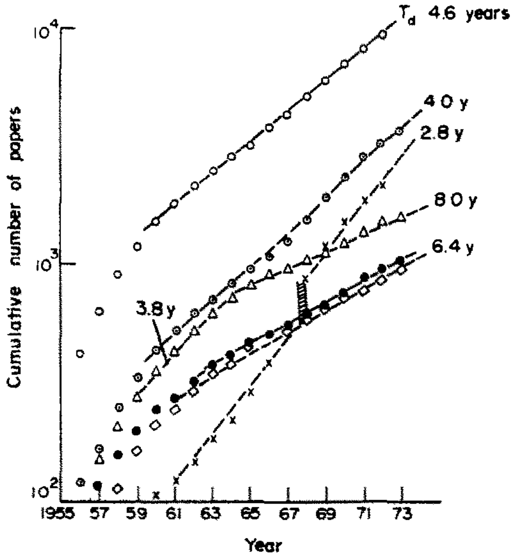

Fig. 3. Growth of papers on electroanalytical chemistry of inorganic compounds. Adapted from ref. 10. ○ Electroanalytical chemistry, total, ● Conductometry, × Voltammetry, ⊙ Potentiometry, ◇ Coulometry, △ Amperometry.

LETTER TO THE EDITOR

Manganese in serum

SIR,

We have read the short communication by Muzzarelli and Rocchetti[1] on the atomic-absorption determination of manganese, cobalt and copper in whole blood and serum. In it they refer three times to our publications[2,3] in a wrong manner.

First. We have never stated that a high serum manganese concentration is one of the most accurate indicators of myocardial infarction as they suggest in their introduction. We have in fact examined patients with the disease but our results show that the difference in the mean serum manganese concentration between normal controls (0.57 ng/ml) and patients with acute myocardial infarction (0.64 ng/ml) is not significant ($t = 1.89$; $0.05<P<0.10$).[4] Thus, in our experience, serum manganese values do not provide an indication of myocardial damage. To the best of our knowledge, there is one publication[5] claiming that the serum manganese concentration increases after myocardial infarction, but it is apparently based on analyses of contaminated samples.[4] We found that the serum manganese concentration increases during the active phase of acute viral hepatitis (mean ± standard deviation = 2.32 ± 0.96 ng/ml), chronic aggressive hepatitis (0.84 ± 0.24 ng/ml) and posthepatitic cirrhosis (0.84 ± 0.20 ng/ml)[6] as well as in some other hepatobiliary disorders, *e.g.*, liver cirrhosis of different aetiology (0.78 ± 0.30 ng/ml) and liver metastases (1.08 ± 0.50 ng/ml).[7]

Second. In their discussion Muzzarelli and Rocchetti erroneously assert that the serum manganese concentrations they found (mean ± standard deviation = 9 ± 4.3 ng/ml; range = 5 - 16 ng/ml)[1] are in agreement with those described by us (0.57 ± 0.13 ng/ml; range = 0.38 - 1.04 ng/ml).[2]

Third. Muzzarelli and Rocchetti mention that the serum cobalt levels they determined (mean ± standard deviation = 7.7 ± 1.9 ng/ml; range = 5.6 - 9.8 ng/ml)[1] correspond to those reported by us.[3] Our paper dealt with the preparation of a multi-element serum standard. We added cobalt to give a final concentration of 6.46 ppm (μg/ml) in lyophilized serum, *i.e.*, three orders of magnitude higher than their result. The alleged agreement thus arises from a fundamental misunderstanding of the facts.

INSTRUMENTS IN ANALYSIS—CRITICAL REVIEWS

DEVELOPMENT OF THE DIFFERENTIAL REFRACTOMETER

J. R. MAJER
Chemistry Department, The University, P.O. Box 363, Birmingham 15, U.K.

When the refractive index of a solute differs from that of a solvent, then if the solution is of low absorbance and contains no suspended matter, it is possible to determine the concentration of the solute by measuring the refractive index of the solution and comparing it with those of a set of standard solutions. To take a trivial but biologically important example, the refractive index of pure water at 20° and 589 nm is 1.33299, while that of sodium chloride is 1.5442. The refractive index difference of approximately 0.22 is therefore sufficiently large to make the determination of the concentration of saline solutions by refractometry a practical proposition. A linear correlation of refractive index and concentration would be expected and solutions containing more than 1% w/v of sodium chloride can be analysed with simple apparatus.

When a solution contains more than one species having a refractive index which differs from the solvent, it may still be possible to analyse the solutions by making a pair of measurements at different dilutions or at different wavelengths. The refractive index of many substances varies substantially with wavelength and this variation is not the same for substances of different composition. Shippy and Burrows[1] derived the following equation for the calculation of the concentration of solutions containing two solutes A and B

$$\frac{\%\mathrm{A}}{100} = \frac{n(X\%\mathrm{B}) - n(\mathrm{mixture})}{n(X\%\mathrm{B}) - n(X\%\mathrm{A})}$$

where n is the refractive index and X is a concentration at which the refractive index is known for each solute in separate solutions. The same authors were the first to publish accurate values of the refractive indices of sodium chloride solutions in the concentration range 5–20% w/v. Later Brodskii and Shershever[2] analysed solutions of potassium chloride in the range 0.03–0.75% by measuring the refractive index with an interferometer. Tables of the refractive indices of dilute salt solutions have since been published by Kruis[3] and Stamm.[4]

Recently,[5] a precise study of the variation of refractive index with concentration (dn/dC) has been made for aqueous solutions of sodium chloride, potassium chloride and ammonium nitrate. The high precision made possible by the use of a helium–neon laser as a light-source revealed that the relationship was not strictly linear, but could be fitted to a polynomial. Although solutions of substances in solvents other than water do not have linear relationships between refractive index and concentration, nevertheless a wide range of solutions in organic solvents has been analysed refractometrically. Most simple refractometers rely on the critical angle principle and the Abbé refractometer is probably the most familiar. It can be used with liquids of refractive index between 1.300 and 1.700 and requires only a small sample. It can measure accurately to the third decimal place and when the temperature is kept constant to 0.2°, reliable measurements may be made to 4 decimal places. Other models such as the Pulfrich and immersion types require much larger samples and have a restricted refractive index range. Comparisons of refractive indices may sometimes be made to the fifth decimal place.

With such instruments it is thus possible to analyse solutions with a refractive index difference of 0.1 between the solute and solvent and a concentration of down to 1% w/v, with an error of 10% or better. When it is required to analyse solutions with a smaller refractive index difference between the solute and solvent, or with a lower concentration of solute, then a more sensitive instrument must be used. In many cases it is not necessary to make an absolute measurement of the refractive index with an expensive instrument such as an interferometer, but to make only a precise comparison of two similar refractive indices such as that of the pure solvent and the solution. In such cases the measurements may be made with a differential refractometer.

The principle of the differential refractometer is extremely simple. If a ray of light passes through a hollow prism which contains a liquid, the ray will be deflected (Fig. 1). If now a second identical prism is placed close to the first, thus creating a cube, the ray will now suffer no deflection if it strikes the face of the first prism normally, for any deflection experienced in the first prism will be cancelled by a deflection in the opposite direction. This condition is only fulfilled when the refractive indices of the liquids in both prisms are equal. If the refractive index of the liquid in the second prism changes by a small

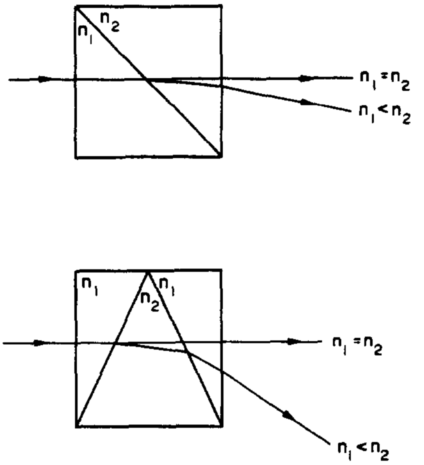

Fig. 1. Principle of the differential refractometer.

amount, then the ray of light suffers a correspondingly small deflection. For small changes in refractive index, the linear deflection of the ray of light will be proportional to the difference in refractive index and to the distance of the observer from the prism assembly. The sensitivity of the system is thus determined by the length of the optical lever and the accuracy with which the position of a spot of light can be determined. The only methods of increasing the sensitivity are to replace the double prism with a hollow right-angled prism within a rectangular tank, or to increase the number of times that the ray of light traverses the prism assembly, by the use of suitably placed mirrors.

The differential refractometer was first described many years ago, but the instrument was not used widely until the advent of chromatography, and then only when large numbers of samples had to be examined by a routine method. In this application it competes favourably with interferometry, but is often less sensitive or rapid than colorimetry when specific reagents are available.

The early differential refractometers were visual devices in which the displacement of the beam was measured optically. An excellent example of this type of instrument was designed by Brice[6] in 1951 and marketed by the Phoenix Precision Instrument Co. in America. The main problem with visual instruments is that they are tiring to use and this difficulty was overcome by Brice in a later design in 1957. Here the displacement of the light-beam was detected photoelectrically. A modern modification of the Brice–Phoenix design described by Pittz and Bablouzian[7] uses a monochromatic light-beam provided by a mercury vapour lamp and a 435.8 nm filter. The displacement of this beam is detected by the use of a pair of selenium half-cells (cut from a single cell) mounted 0.8 mm apart on a carriage. The outputs of the half-cells (about 100 mV) are connected, in opposition, to a microvoltmeter. The reading on the microvoltmeter is reduced to zero by moving the carriage in a direction at right angles to the light-beam, so that each half-cell is equally illuminated by the slit image. The extent of the deflection is read directly from a counter attached to the micrometer drive.

One disadvantage of the differential refractometer is that the glass interface between the sample and standard liquids is at an angle to the incident light-beam. This sets a limit to the refractive index of the solvent which may be used. Thus, in the original commercial cell of the Brice–Phoenix instrument, the glass interface had a refractive index of 1.52 and this restricted the choice of solvents to those having a refractive index of less than 1.62. This drawback was recognized by the manufacturers,[8] who recommended that the cell should be rotated through 90° when using highly refractive solvents (such as α-bromonaphthalene). Unfortunately, this results in a deterioration of performance, the sensitivity being only one-seventh of the initial value. Recently, Kratochvil and Babka[9] have reduced the problem of total internal reflection at the interface within the cell by constructing a modified design, in which the interface is made of highly refractive glass[10] ($n = 1.62$).

As a routine control instrument, the differential refractometer has been exploited most successfully by Jones,[11] who used it in the difficult problem of the determination of the isomers of benzene hexachloride.

Another elegant application is the study of adsorption from solution onto particulate matter. Ash, Brown and Everett[12] circulated a solution of cyclohexane in benzene through a bed of carbon black and through one side of the cell. A second stream of solution was circulated through the other side, the whole assembly being mounted in a thermostat. Adsorption on the carbon black was detected by the change in refractive index and a precision of 3 nmole/m^2 was achieved for adsorption on the carbon. When the differential refractometer is used to study the changes in the effluent from a chromatographic column or a bleed from a plant stream, then the problem of recording arises and this is a difficult problem to surmount because of the very small signals which the refractometer can provide. This difficulty has been the main obstacle to the widespread application of differential refractometry to plant control.

The first solution to the recording problem was made by Tiselius and Claesson[13] in their work on adsorption chromatography. In their design, the beam of light passing through the refractometer struck the apex of a hexagonal prism acting as a beam-splitter. The two beams then fell upon two photocells arranged in opposition so that when they were equally illuminated, no output signal was observed. When, as a result of change in refractive index in the contents of one of the refractometer cells, the incident beam was deflected, the intensity of illumination on the two photocells changed, and the galvanometer was deflected. The movement of a spot of light reflected from a mirror on the galvanometer suspension was recorded photographically, and by using a fairly long optical lever, a sensitivity of 3×10^{-5} refractive index units was achieved and this permitted the recording of changes in solute concentration of the order of 0.1%. As a further refinement, the instrument was made to record an elution curve directly, by collecting the eluate in a vessel on a spring balance and allowing the movement of this to be transmitted to the light-beam by means of a second mirror. The device of connecting the matched photocells to a galvanometer and studying the deflection of the secondary light-beam reflected from a suspended mirror has been used by a number of workers[14] to obtain the necessary sensitivity and modern spot-followers can be used to record the deflection of the secondary beam. The whole assembly, however, is very sensitive to mechanical vibration because of the number of mirrors involved and the length of the optical levers, so that its use is strictly limited.

The use of two matched photocells is expensive and most workers have preferred to use a single photocell with a split cathode, the two halves being arranged in opposition. Such a device was first used by Stamm[4] who also incorporated in his instrument an arrangement making it suitable for automatic operation. The deflection of the primary beam was neutralized by the rotation of a parallel-sided slab of glass placed before the split-cathode photocell. This was achieved with the aid of a micrometer screw and monitored by the deflection on a galvanometer attached to the photocell. Later models have used servo systems to couple the rotational movement of the compensating glass block to the photocell output. Alternatively, the output of the photocells may be recorded directly as in the instrument described by Zaukelies and Frost.[15] This design, which is extremely simple in construction, involves only a light-source and associated optical system, a refractometer cell and a twin-cathode photocell. The limiting factor in its sensitivity was noise in the photocell output, corresponding to 2×10^{-6} refractive index units. Recently an improved version of this instrument has been described in which great attention has been paid to the elimination of all sources of noise.

Much of the photocell noise was eliminated in a refractometer design due to Trenner,[16] by ensuring that the output signal from the sensing device was a.c. This is probably the most complex differential refractometer yet to be constructed and used the hexagonal prism beam-splitter in a novel fashion. Light from a slit source was focused on the apex of the hexagonal prism, which was mounted on a platform and could move in a direction at right angles to the path of the incident light. The two beams emerging from the other end of the prism were of equal intensity when the prism was precisely aligned. The beams were chopped alternately by a 60-Hz chopper and then entered an integrating sphere. Here the light was received by a photomultiplier. At balance, the light inside the sphere had no 60-Hz component. A change in refractive index in the refractometer cell caused a movement of the slit image from its position on the apex of the hexagonal prism and caused a change in the relative intensity of the two beams, so that the light in the integrating sphere then had a 60-Hz component. The corresponding a.c. output from the photomultiplier was fed to a recorder and also to the drive of a motor returning the hexagonal prism to the null position. Full-scale deflection of the recorder corresponded to approximately 1.5 mm movement of the prism and one division corresponded to a movement of 7 μm at the detector. The resulting sensitivity was 3.6×10^{-6} refractive index units. To attain this sensitivity very great care was exercised to eliminate thermal drift, the whole assembly being mounted in an air-conditioned room and all motors and sources of heat mounted outside an enclosed optical system.

The first successful recording differential refractometer for the analysis of plant streams was described by Miller.[17] This is a robust and stable but not highly sensitive design which has been produced commercially for use in the petroleum industry. Once again, a beam-splitter and a double photocell are used and the output from the sensing system is amplified and fed to a servo mechanism. This moves a reflecting prism in such a way that the light-beam is restored to its original position after a change of refractive index has occurred. Although the optical lever was quite long, the instrument was kept compact by the use of two reflecting prisms to return the light to a detector situated close to the light source. Full-scale deflection with this instrument was approximately 1×10^{-3} refractive index units, sufficient for the monitoring and control of hydrocarbon distillations. In the separation of cyclohexane and methylcyclopentane from n-pentane, the instrument maintained the refractive index of the sample within 3×10^{-4} units.

In a more sensitive design by Campbell,[18] the vacuum photocells were replaced by selenium cells and this made it possible to restore balance in the system by moving the compact photocell assembly. The refractometer cell consisted of a hollow prism within a cylindrical glass container, the whole serving as a cylindrical lens producing an image of the illuminated slit on the photocells. The output from the photocells was amplified and recorded and the signal used to drive a servo system moving the photocells to the position where they were equally illuminated. Full-scale deflection on this instrument corresponded to a change in refractive index of 3×10^{-4} units. The limit of detection was 3×10^{-6} units.

A new recording differential refractometer has been described by Vandenheuvel and Sipos.[19] It is an improved version of the original design due to Zaukelies and Frost. In their investigation every care was taken to reduce noise to a minimum. Mechanical noise was controlled by sturdy construction, electrical noise by shielding and choice of components, thermal noise by use of a thermostat and noise due to flowing liquid by accurate flow-control. Significantly, the authors did not stress the necessity to reduce convection currents in the optical path by enclosing it closely in a metal shield. The instrument was capable of a maximum sensitivity of 1 × 10^{-4} refractive index units for full-scale deflection, with a noise level of 5 × 10^{-7} and an error of 0.5%. A record of the separation by reverse-phase adsorption chromatography of a mixture of methyl laurate and methyl myristate showed two very well defined peaks, although the difference in refractive index at the tip of the largest peak was only 5 × 10^{-5}. While most of the instruments so far described have used vacuum photocells as the detectors, these require stable power supplies and electronic equipment and are often noisy at the levels of sensitivity at which they must be operated. There is an advantage in using detectors of the semiconductor type and an excellent example of this type of instrument was described by Jones,[20] who employed a pair of cadmium selenide photoconductive cells. The output from these was amplified by means of a high-gain solid-state amplifier and the sensitivity was further increased by placing graticules in the paths of the beams illuminating the detector, in such a way that when one graticule completely obscured one half of the detector, the other half experienced maximum illumination. At full sensitivity, this remarkable instrument, with an optical lever of only 20 cm, permits detection of changes in refractive index as small as 1 × 10^{-9}. An optical lever of this type is illustrated in Fig. 2.

The use of solid-state devices as differential refractometer detectors has now become standard. They have the great advantages of cheapness, stability, compact size and ease of replacement and do not require the use of expensive stable power supplies. The detectors may be of the photoconductive or photoemissive types. Suitable photoconductive cells have cadmium sulphide as the photosensitive element and a pair are used in opposition. They have the advantage over photoemissive types that they are sensitive to quite low light-levels, but do require a separate power supply.

Recently, very small light twin-photodiodes have become available. These may be of the silicon or germanium type and give a signal voltage when the two halves of the assembly are unequally illuminated. With such devices, it is a simple matter to measure deflections of the order of 10^{-7} rad so that they are highly suitable as detectors in differential refractometry. Furthermore, the output can be fed directly to a potentiometer recorder without further amplification. With the most primitive optical system it is possible to attain a sensitivity of 0.001 refractive index units for full-scale deflection. The full use of the ability of these detectors to measure deflection is limited by the necessity of providing adequate illumination. For full sensitivity an illumination of 0.03 lumens is required at the detector and this involves the use of large apertures or light-sources of high luminosity per unit area.

The development of stable robust differential refractometers has been stimulated over the past few years by the increasing interest in the newer forms

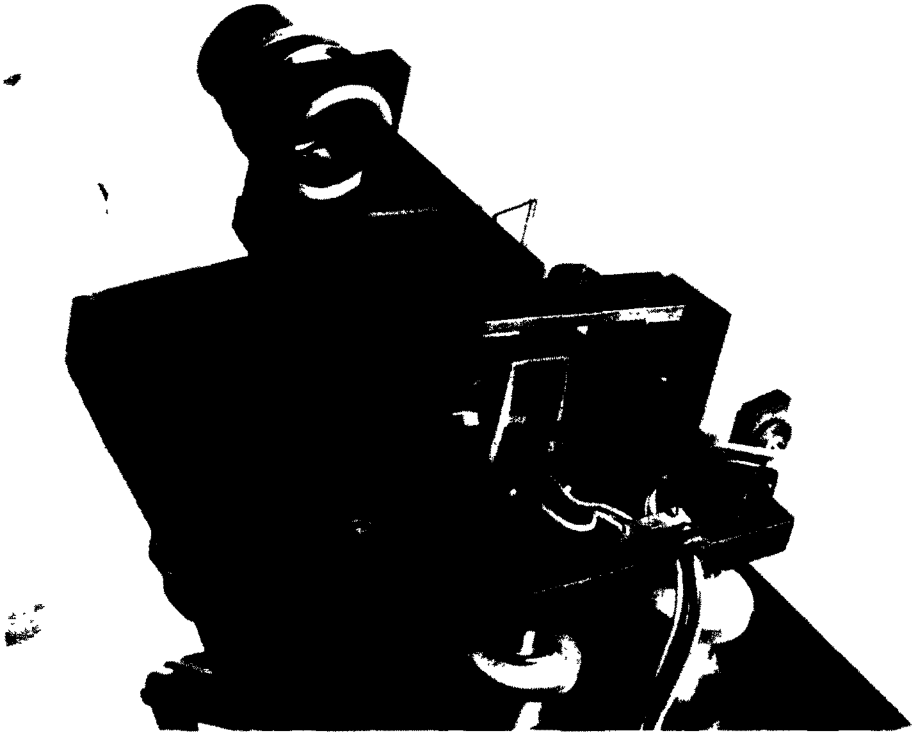

Fig. 2. A sensitive optical lever.

of column chromatography such as high-pressure liquid and gel-permeation chromatography. There are certain difficulties remaining in the use of these devices as detectors at the base of columns. It is necessary to avoid any degassing of the solvent as it passes through the refractometer cell. The appearance of small bubbles of air often accompanies a modest rise in temperature of the flowing liquid and this results in rapid oscillations of the light intensity reaching the detector, with a resulting noisy record. It is better, where possible, to ensure that the refractometer cell is maintained at a temperature slightly below ambient and to use a recording system with a long time-constant, which does not respond to rapid oscillations in detector output. The most serious problem is, however, the fluctuation in temperature between the reference liquid and the sample liquid. If one wishes to measure a refractive index to one part in a thousand then it is necessary to maintain the temperature to better than ± 1°. This requirement for temperature stability rises to ± 0.1° for measurements of refractive index reliable to the fifth decimal place. Fortunately, it is not necessary to maintain the temperature of the whole of the instrument constant, but merely to ensure that the temperatures of the two liquids do not vary differentially by more than this amount. The requirement is normally met by passing both liquids through two channels in an efficient heat-exchanger before they enter the refractometer cell and to ensure that the membranes separating the sample and reference liquids are thin and allow rapid heat transport. A simple refractometer cell which fulfils these requirements may be made by clamping microscope cover slips between drilled polished brass blocks to provide the dividing membranes. When a separate heat-exchanger is used it is important to design it so as to provide minimum hold-up and peak broadening.[21]

The Waters' Model R-4 differential refractometer is a good example of a modern instrument and illustrates many of the concepts discussed earlier. A collimated parallel beam of light passes through the cell, which is a hollow prism with an outer reference compartment, and is reflected back again through the cell to a detector close to the light-source. The detector assembly comprises a beam-splitter and a pair of cadmium sulphide photocells which are illuminated equally when the inner and outer refractometer cell compartments contain liquids of the same refractive index. Manipulation of the light-beam to achieve the null position is accomplished by the rotation of parallel-sided glass blocks in the path of the beam, giving the light-beam a transverse movement. Noise in the detector output other than electrical noise is minimized by reducing temperature fluctuations, keeping the flow-rate of the sample solution low to avoid turbulence and maintaining the temperature below ambient to avoid deaeration. The temperature of the sample and reference liquids is made identical by passing them through a heat-exchanger before they are admitted to the cell compartment. The maximum sensitivity is 1×10^{-5} refractive index units for full-scale deflection on the record.

Detectors for liquid chromatography must fulfil two requirements: they must be sensitive to very small differences in analytical properties of the solute and solvent so that total quantities of solute ranging between 10^{-3} and 10^{-8} g may be detected, and they must not reduce the efficiency of the column by peak broadening, *i.e.*, increasing the HETP. These two requirements are not independent and both are influenced by the size of the detector cell. If we assume that the slope of the elution curve is Gaussiam then the cell volume should be a fraction (1/3) of the total peak-width as calculated from the HETP and cross-section of the column. Commercially available refractometer cells having a volume in the range 5–10 μl may be used with high-efficiency liquid chromatography columns. Recently[22] the performance of two differential refractometers was compared. The first of these was a conventional beam-deflection type and the second was of the Fresnel type in which the intensity of the reflected beam, which depends upon the refractive index and the angle of incidence, is measured.[23] It can be seen from Table 1 that there is no great difference in the characteristics of the two detectors. A comparison of the differential refractometer with other types of detector shows that it is more sensitive than the ultraviolet spectrophotometer, but much less sensitive than transfer devices of the disc and wire type coupled to a flame-ionization detector.

Munk,[24] however, has shown that in comparisons of the differential refractometer with the ultraviolet absorption detector, if solutes giving maximum detector response are used, then this order may be reversed. Thus, the detection limit for a solution of sucrose in water was 3×10^{-9} g/sec for the differential refractometer,[25] while that for a solution of adenosine (molar absorptivity 1.40×10^{4} $\mathrm{l.mole^{-1}.cm^{-1}}$ at 254 nm) was 2×10^{-11} g/sec for the ultraviolet absorption detector.

The great advantage of the differential refractometer over the more sensitive interferometer in the measurement of small differences in refractive index has been its comparative simplicity and compact size. The use of lasers as light-sources makes it possible to design much smaller interferometers which can be used to monitor column effluents. An interferometric detector with a cell volume of only 4 μl has been reported by Hazebrook.[26] A helium–neon laser operating at a wavelength of 632.8 nm was used as a light-source. After polarization the beams were passed through the standard and reference cells and combined, the fringes being detected by silicon photodiodes. The large dynamic range (5000:1), rugged construction and small size make it suitable for such tasks as high-pressure capillary liquid chromatography or supercritical fluid phase separations. Although the limit of detection quoted was of the same order

Table 1. Comparison of detectors for column chromatography

Detector	Cell volume, *μl*	Sensitivity	Maximum detection, *mole/sec*	*mole/ml*
Refractometer (Laboratory Data Control)	5.0	2.87×10^{-7}	5.67×10^{-11}	2.67×10^{-8}
Refractometer (Waters Associates)	10.0	4.06×10^{-7}	9.86×10^{-10}	9.13×10^{-8}
UV detector ($l = 1$ mm)	27.2	8.68×10^{-3}	4.73×10^{-10}	5.69×10^{-8}
Wire detector	—	3.9×10^{-13}	3.93×10^{-8}	8.89×10^{-6}

as that for a sensitive differential refractometer, the ultimate sensitivity of an interferometer is theoretically much greater. It seems possible therefore that in the future these two devices will be in competition as detectors in liquid chromatography.

PRELIMINARY COMMUNICATION

THE RAPID SEPARATION AND DETERMINATION OF RARE EARTH ELEMENTS BY USE OF THE LIGAND VAPOUR GAS-CHROMATOGRAPHIC METHOD*

Taitiro Fujinaga, Tooru Kuwamoto and Takashi Kimoto

Department of Chemistry, Faculty of Science,
Kyoto University, Kyoto, 606 Japan

(Received 11 August 1976. Accepted 24 August 1976)

In our laboratory, a new gas-chromatographic technique called the "ligand vapour gas-chromatographic (LVGC) method" has been developed and successfully used for the determination of the trifluoroacetylacetone (HTFA) chelates of thorium and other metals.[1] Recently we have applied the LVGC method to the consecutive separation and determination of 4f rare earth elements. After thorough investigation of the experimental conditions, especially with respect to the composition of the stationary phase, it became possible to separate most of the neighbouring rare earth elements in one step, as demonstrated in the example shown in Fig. 1.

Sievers and others[2,3] have made extensive studies of the higher homologues of β-diketones which form thermally stable chelates when combined with the rare earth elements, but have not as yet reported a separation of the neighbouring elements.

A full report of the present work will be made later.

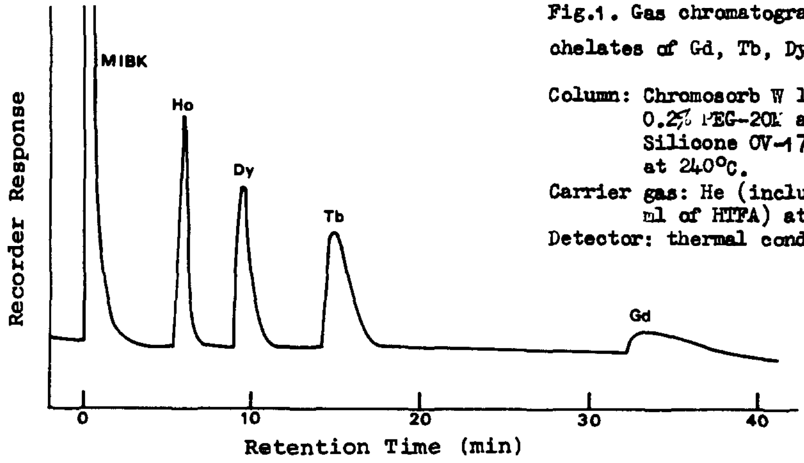

Fig.1. Gas chromatogram of TFA chelates of Gd, Tb, Dy and Ho.

Column: Chromosorb W loaded with 0.2% PEG-20M and 1.8% Silicone OV-17 and kept at 240°C.
Carrier gas: He (including 0.41 ml of HTFA) at 41 ml/min.
Detector: thermal conductivity.

TALANTA MINI-REVIEW*

THE DETERMINATION OF VANADIUM

G. Svehla† and G. Tölg
Max-Planck-Institut für Metallforschung, Laboratorium für Reinststoffe, Katharinenstrasse 17,
707 Schwäbisch Gmünd, West Germany

(*Received* 21 *November* 1975. *Accepted* 24 *May* 1976)

Summary—A review is given of the developments in the analytical chemistry of vanadium that have taken place in the last 15 years.

The importance of vanadium in modern science and technology is reflected in the growing number of publications dealing with the analytical characterization of vanadium: over 1000 have appeared in the past 15 years. The earlier literature has been covered by Grady.[1] Our intention in writing this paper is to give some guidelines to the analytical chemist who wishes to select a method for a particular problem. To this end, we quote only those papers that seem to us to have something new and important to say, but this must not be construed as meaning that the literature omitted is without value. The material is classified according to the techniques by which vanadium is determined. First classical, then electroanalytical, optical and finally other instrumental methods are described. This classification is, we hope, in accordance with the demands of the practising analytical chemist, who may have only a limited number of techniques at his disposal when choosing his method.

QUALITATIVE TESTS FOR VANADIUM

Of the many reagents mentioned in the literature kojic acid should be recommended first:[2] under the correct conditions 0.5 μg of vanadium in a 2-ppm solution may be detected in the presence of numerous cations and anions. Ferron has been investigated by the same authors,[3] while others[4] found the Schiff-base formed from anthranilic acid and salicylaldehyde to be an equally selective and sensitive reagent for vanadium.

QUANTITATIVE SEPARATION OF VANADIUM

Solvent extraction techniques

These may be based on direct extraction with a substance serving both as complexing agent and as the water-immiscible solvent. The efficiency of such separations depends on the pH of the aqueous phase. Among such reagents 4-methylpentan-2-ol[5] and mesityl oxide[6] can be mentioned. More suitable, however, are extractions based on binary or ternary systems. The binary systems consist of a reagent and a solvent; the ternary may have two reagents with one solvent or one reagent with a mixture of two solvents. Their use gives a wider choice of experimental conditions and the separations are generally sharper and more specific. 8-Hydroxyquinoline with chloroform[7] or isobutyl methyl ketone[8] gives a good separation; so does a ternary system based on 8-hydroxyquinoline, benzyldimethyltetradecylammonium chloride and chloroform.[9] Another long-chain alkylamine is the ion-exchanger Amberlite LA-2 which, when dissolved in chloroform, is a powerful extractant for vanadium.[10] Vanadium(III) can be extracted with ammonium thiocyanate and ethyl methyl ketone;[11] tin(II) chloride can be used for preliminary reduction of the vanadium. Thiocyanate combined with tributyl phosphate[12] is suitable for extracting vanadium(IV), and the tributyl phosphate also reduces any vanadium(V) present. Tributyl phosphate alone in hydrochloric acid solution is an effective reagent; both the theoretical and the practical aspects of this separation have been investigated.[13]

β-Diketones, such as acetylacetone (with butanol)[14] and 2-thenoyltrifluoroacetone with isopentyl or butyl acetate,[15] butanol,[16] chloroform[17] or a chloroform–benzene mixture[18] have also been recommended. Hydroxamic acids are well-known reagents for vanadium; they may be used as selective extractants with various solvents, 4-Methoxybenzothiohydroxamic acid,[19] *N*-phenylbenzohydroxamic acid[20,21] and *N*-phenyl-2-naphthohydroxamic acid[22] are the most suitable. Normally chloroform is the solvent, but the sensitivity may be increased by adding ethanol to it.[20] α-Benzoinoxime in chloroform,[23] quinaldinic acid in a mixture of pyridine and chloroform[24] and 1,2,3-phenyloxyamidine[25] in ether are also powerful combinations. A thorough study of some ternary systems containing di(2-ethylhexyl) hydrogen phosphate, kerosene and, as the third component, sodium fluoride or thiosalicylic acid,[26] led to a procedure for the quantitative extraction of vanadium(IV) and its separation from vanadium(III). The choice of the third partner depends on the composition of the matrix.

† On leave from Department of Chemistry, Queen's University, Belfast, Northern Ireland.

Another system for extraction of vanadium(IV) is 3-methylcatechol and lauryltrimethylammonium bromide in 1,2-dichloroethane.[27]

Chromatographic methods

As vanadium may be present in solution either as a cation or as an anion, depending on the oxidation state and the acidity, there are several possibilities on which separations may be based. The simplest way of removing small amounts of vanadium for a solution is co-precipitation, where aluminium hydroxide,[28,29] zirconium oxide[29] or iron(III) hydroxide[30] may serve as carriers. The theoretical aspects of the separation of vanadium and other metals by cation- or anion-exchangers have been elucidated in a series of papers.[31] Cation-exchangers retain vanadium(IV) or (V) from strongly acid solutions.

With Dowex 50 W-X8 (H^+-form) small amounts of vanadium can be separated quantitatively from 25 other metal ions.[32,33] In the presence of titanium the cation-exchanger KY-3 (H^+-form) has been used,[34] while in the analysis of ferrovanadium or iron ores[35] the cation-exchanger KU-2 can be used to advantage. Dowex-1 anion-exchanger, with an excess of fluoride,[36] chloride,[37,38] thiocyanate[39] or acetate[40] in the solution, is the most widely applicable.

The combined use of Dowex-1 anion-exchanger and Dowex-50 cation-exchanger facilitates the quantitative separation of six metals, including vanadium, from one another.[41] The anion-exchanger EDE 10 P with hydrochloric acid,[42] lithium chloride[43] or hydrogen fluoride[44] can also be used. The Chelex-100 chelating ion-exchanger is specially recommended for the removal of vanadium from sea-water.[45] The liquid anion-exchanger Aliquat 336, adsorbed on XAD-2 resin, can remove peroxovanadate(V) together with other peroxo anions.[46]

Redox ion-exchangers are also available for the retention of vanadium; tetrachloroquinol (on Celite A support)[47,48] and chloranil[49] (on polyurethane foam) are the most suitable.

Paper chromatographic separations with various solvents[50,51,52] and with impregnated papers[53,54,55] are also available, though thin-layer chromatographic methods[56,57,58] usually offer sharper separations.

Paper electrophoretic[59,60] and gas-chromatographic[61–64] methods are also available; the latter will be discussed again in more detail.

GRAVIMETRIC DETERMINATION

Some of the old methods have been improved. Vanadium sulphide can be precipitated from homogeneous solution[65] with thioacetamide. A critical re-examination of the well-known precipitation in the form of silver vanadate[66] has revealed that precipitation is only quantitative and stoichiometric between pH 6.2 and 6.8. Numerous new organic reagents have also been suggested for the gravimetric determination of vanadium. Some of these, such as *o*-hydroxyacetophenone oxime,[67] *N*-(2)-hydroxynaphthyl-1-methylene ethylamine and 2-hydroxynaphthaldoxime[68] and benzoylacetanilide[69] produce a high molecular weight compound which can be dried and weighed, allowing the accurate determination of 10–50 mg of vanadium.

TITRIMETRIC DETERMINATION

Vanadium can be titrated with redox, complexometric and precipitating agents. Some of the well-known methods have been examined further, and a few new reagents have been introduced. A large number of papers deal with the application of known methods for the determination of vanadium, to various matrices. These cannot be reviewed here for lack of space, and we decided to omit contributions which contained only minor variations on well-established methods. Some authors have made a critical comparison of known methods with the aim of finding the most reliable procedure.

One critical study[70] showed that the most reliable titrimetric method is to oxidize vanadium to vanadate, remove the excess of the oxidizing agent, reduce vanadate with a known excess of iron(II) ammonium sulphate (added as the weighed solid) and back-titrate with potassium dichromate.

Another[71] compared the precision of the titration of vanadium(V) with iron(II) sulphate and the titration of vanadium(IV) with potassium permanganate and found that the reductometric process is considerably the more accurate if *N*-phenylanthranilic acid is used as indicator.

Another group of researchers[72] examined and combined redox and complexometric titrations with spectrophotometric measurements to determine vanadium, molydenum, tungsten, phosphorus and silicon in the same sample.

The titration with permanganate becomes more sensitive if vanadium is reduced not to the quadrivalent, but to the tervalent state. A bismuth reductor is most suitable for the reduction.[73] With fluoride as complexing agent the permanganate titration gives good results even if chromium(III) ions are present.[74] If dichromate is used as the titrant, the titration reaction is normally slow. An analytical study has been made of the vanadium(IV)–chromium(VI) reaction.[75] In the presence of an excess of phosphoric acid the titration with dichromate can be carried out with normal speed,[76] and mixtures of vanadium(III) and vanadium(IV) can also be titrated.[77] Mixtures of iron(II) and vanadium(IV)[78] as well as of molybdenum(V) and vanadium(IV)[79] can also be titrated under similar circumstances. Cerimetric titration can be performed with photometric[80] and potentiometric[81] end-point detection, without the addition of external indicators. The limitations of the photometric method have been examined theoretically and experimentally.[80] With ferroin,[82] tris(bipyridyl)iron(II) and Rhodamine B[83] as indicators, visual titrations are also possible. Other oxidimetric titrants have also been suggested; potassium ferricyanide in alkaline medium,[84] potassium chlorate,[85] iodine cyanide and bromide cyanide[86] are all suitable reagents. Vanadate can oxidize vanadium(III) to vanadium(IV), and therefore ammonium vanadate can be used as titrant for the determination of vanadium(III),[87] and with some modifications for separate determination of vanadium(II) and vanadium(III).

Vanadium(V) can be reduced to vanadium(IV) with iron(II). With amperometric end-point detection this titration is very accurate,[88] but the change of potential at the end-point is not large enough to ensure an accurate potentiometric determination unless a complexing agent which keeps the free iron(III) concentration low is added. Such agents are EDTA with Methylene Blue or thionine (the latter two as photosensitizers),[89] glycerol in alkaline medium[90] and phosphoric acid.[91] In syrupy phosphoric acid medium vanadium(IV) can also be reduced with iron(II),[92] and in ammoniacal solutions containing catechol, the vanadium(IV)-vanadium(III) end-point becomes extremely sharp.[93] Among other reductometric titrants potassium ferrocyanide[94] has been suggested for potentiometric micro-titrations. Chromium(II) sulphate[95] with potentiometric or photometric end-point, copper(I) chloride with visual indicators,[96] molybdenum(III) with potentiometric end-point[97] and vanadium(II) with visual indicators[98] may also be used. The last-named reduces both vanadium(V) and vanadium(IV) to the tervalent state under the given experimental conditions. Sodium thiosulphate with copper as catalyst reduces vanadium(V) and the titration can be monitored by potentiometry.[99] Hydroxylamine can also be used to determine vanadium(II) and vanadium(III) in one sample, though not as a direct titrant,[100] the excess of the reagent and the vanadium(II) being back-titrated in two stages with permanganate or cerium(IV) with potentiometric end-point detection. Hydrazine sulphate alone[101] or combined with phosphoric acid[102] can be used as reductometric titrant with photometric, potentiometric and in some cases visual indication. Binary mixtures of vanadium(V) and chromium(VI) can also be analysed with these reagents; isonicotinic acid hydrazide can also be used, with photometric end-point detection, the two inflexions of the titration curve corresponding to the two equivalence points.[103]

Vanadate can be titrated with silver nitrate, forming a precipitate, the composition of which depends on the pH of the medium[104] but is always stoichiometric, facilitating the determination of vanadium with potentiometric, amperometric or conductometric end-point detection.[105]

Vanadium(IV) and (V) react with EDTA. These reactions have been re-examined[106] and improved procedures have been recommended.[107] In addition to the usual metallochromic indicators, ferron[108] and Variamine Blue[109] are also suitable. Some new complexation reactions have been found and made the basis of a titrimetric determination: the new titrants are 2'-hydroxy-5'-methylpropiophenone oxime,[110] sodium tungstate[111] and pyridine-2,6-dicarboxylic acid in the presence of hydrogen peroxide.[112] A redox titration with Methyl Orange can be used.[113,114] With 5,7-dibromo-8-hydroxyquinoline[115] or with the di-iodo derivative,[116] heterometric micro-titrations are possible. Non-aqueous reductometric titrations of vanadium with chromium(II) acetate in dioxan can be used for the determination of micro-amounts of vanadium(IV).[117]

Vanadate forms polyanions when the solution is acidified with a strong acid. The possibility of titrating vanadate with perchloric acid, using thermometric end-point detection, has been investigated and favourable results have been reported.[118]

Coulometry and chronopotentiometry

Coulometric determinations of vanadium are based either on the reduction of vanadium(V) or on the oxidation of vanadium(IV). The two forms can be determined in the presence of each other by *controlled-potential coulometry*,[119] and with an on-line computer end-points can be predicted accurately before the completion of the experiment.[120] Vanadium(V) can be reduced in the presence of manganese and iron, but chromium(VI) interferes.[121]

With *constant-current coulometry* we have the choice of a direct determination[122] or the coulometric generation of an auxiliary reagent. Of these, tin(II),[123,124,125] and iron(II),[126,127] iron(II)-EDTA,[128] titanium(III),[130] copper(I),[131] molybdenum(IV)[132] and vanadium(III)[133] are suitable for the determination of vanadium(V), and the lower oxidation states of vanadium can be oxidized with electrogenerated iron(III),[134] dichromate,[135] and *p*-benzoquinone[136] as coulometric titrants. The controlled-potential coulometric determination of vanadium can also be carried out in a *molten salt electrolyte*, the sample being fused with a lithium chloride-potassium chloride eutectic.[137] Vanadium(V) can also be determined in molten salts by *chronopotentiometry*.[138]

VOLTAMMETRY, POLAROGRAPHY AND RELATED TECHNIQUES

The *d.c. polarography* of vanadium is usually based on the cathodic reduction of vanadium(V), though reduction from other oxidation states is also possible. Some new developments in this field include the determination of vanadium in various industrially important matrices: the determination in the presence of titanium,[139] thallium,[140] molybdenum,[141] nickel, copper and manganese,[142] iron, nickel and cobalt[143] as well as tungsten, chromium, lead, copper and arsenic[144] is now possible. An unusual method[144] for the analysis of steel is based on the reduction of vanadium(II) to the amalgam. The polarographic behaviour of vanadium in concentrated phosphoric acid has also been studied.[145] An *inverse voltammetric* determination of small amounts (0.2 μg/ml) of vanadium is possible with the carbon-paste electrode.[146] With *d.c. or a.c. oscillopolarography*, capacitor currents can be eliminated from the measured signals, thus improving the sensitivity of the determination. The addition of complexing agents makes the method not only sensitive, but also selective; tartaric, citric and trihydroxyglutatic acids,[147] fluoride,[148] ferron,[149] and thiocyanate[150,151] are the most suitable. A detailed study of the oscillopolarographic behaviour of vanadium[147] revealed that both the reduction of vanadium(V) and the oxidation of vanadium(IV) are suitable for analytical purposes.

It has been established that, when subjected to *voltammetry at a pyrolitic graphite electrode*, vanadium(V) is reduced irreversibly, though the voltammetric peaks are fairly reproducible.[152]

For the determination of vanadium by *amperometric titration* the titrimetric determination reagents already listed can normally be used. There are, however, some unusual reagents which have only been suggested for use with amperometric end-point detection. As oxidimetric titrants, pyrogallolcarboxylic acid[153] and hexa-amminecobalt(III) tricarbonatocobaltate,[154] and as a reductometric titrant vanadium(II) sulphate,[155] have been suggested, the latter reducing vanadium(IV) to the tervalent state. For a precipitation titration lead nitrate,[158] 8-mercaptoquinoline[159] and, in a reverse titration procedure, selenious acid[160] can be used. In the last method a known amount of selenite is titrated with the sample solution. For a complexometric titration 2,4-dithiobiuret[161] and Tiron[162] may be used. A number of papers, not listed here, describe the biamperometric ("dead-stop") titration of vanadium(V) with iron(II); a useful method with ascorbic acid as titrant is available for the simultaneous determination of cerium(IV) and vanadium(V).[163]

SPECTROSCOPIC METHODS

Emission spectrography

A large number of papers have been published on the determination of vanadium in different raw materials and industrial products. Usually a spark spectrum is obtained. Most frequently the line at 3185.4 Å is used, but those at 2864.4, 3093.1, 4112.0 and 4379.0 Å are also useful, depending on the nature of the matrix and the internal standard used. Though a detailed review of this field cannot be included here, some important new developments should be mentioned. A direct-reading spectrochemical determination of vanadium and other elements in silicates, with automatic background and matrix corrections (carried out by an on-line computer) is now possible with a coefficient of variation better than 5%.[164] A simplified standardization method based on varying the exposure time can be applied for metal samples.[165] Solvent extraction coupled with emission spectroscopy enhances the sensitivity and permits the use of an emission line produced by the solvent (a C–Cl line from the chloroform) as the internal standard.[166] Co-precipitation of vanadium with compounds such as cadmium or zinc hydroxide[167] or molybdenum phosphate[168] as collector can also favourably enhance the sensitivity. Specially prepared samples (fused buttons) can be used in the analysis of cast iron samples.[169] Geological materials can be analysed for vanadium after being diluted with a mixture of carbon and barium carbonate powder.[170] Solution techniques, resembling flame photometry, allow a higher degree of reproducibility. Small amounts of vanadium can be determined by spraying a solution of the sample through a capillary graphite electrode into an a.c. arc.[171] Hollow-cathode excitation can also be used for the emission spectrographic determination of vanadium.[172] Improved reproducibility and sensitivity are attainable by using microwave-induced plasma excitation,[173] especially if the vanadium is reacted to form a volatile chelate before the measurement.[174] The excitation processes of vanadium have been studied by time-resolved spectroscopy.[175]

Emission flame photometry

A detailed study of the flame emission spectrum of vanadium in a fuel-rich oxyacetylene flame revealed that the best wavelength for the determination is 4379.2 Å, the limit of detection being 3 ppm of vanadium.[176] The inter-element effects in a nitrous oxide–acetylene flame have been thoroughly studied.[177] The introduction of separated flames has increased the sensitivity of the determination of vanadium; with the nitrous oxide–acetylene flame the detection limit is 0.2 ppm,[178] but if the same flame is sheathed with argon or nitrogen, the detection limit is as low as 0.05 ppm.[179]

Atomic-absorption and atomic-fluorescence spectrophotometry

The atomic-absorption spectrum of vanadium in a fuel-rich acetylene–oxygen flame has been recorded.[180] Atomic absorption has been applied by a number of researchers to the determination of vanadium in various samples and matrices, but these applications will not be reviewed here. However, useful studies of interferences by inorganic substances[181,182] and organic solvents[183] have been carried out, and the addition of an excess of iodide[184] or aluminium chloride[185] has been suggested for eliminating these interferences. A new technique, a variation of the standard-addition method, may be used to obtain more reliable results.[186]

Microwave discharge tubes can easily be prepared in the laboratory, and can be used instead of hollow-cathode lamps as radiation sources in the determination of vanadium.[189] The use of sheathed flames[189] increases the sensitivity.

Important increases in sensitivity are achieved by using flameless techniques. A graphite, tungsten or tantalum boat,[190] with electrical resistance-heating is suitable for determining as little as 0.6 ng of vanadium. With a carbon-filament atomizer a limit of detection of 0.3 ng may be achieved,[191] while with one particular carbon-rod furnace even 6.8 pg of vanadium can be detected,[192] though another author has reported the much worse figure of 1 ng for a similar carbon-rod atomizer.[193] Much depends on the matrix, and the order in which the elements in the sample are volatilized also plays an important role.[194] With commercial graphite furnaces (cuvettes) at 2700 K the limit of detection is about 20 ng.[195] Interesting further developments in flameless atomic-absorption techniques involve the use of a high-frequency flame-like discharge,[196] a d.c. arc[197] and a plasma jet[198] as the means of atomization.

Sensitivities may be improved by using indirect techniques, which were reviewed in this journal some years ago.[199] An interesting way of determining vanadium is to produce molybdovanadophosphoric acid, extract this with an organic solvent, re-extract into water and determine the molybdenum content of the solution by atomic absorption. With an acetylene–air flame 0.5 ppm of vanadium can be determined with a coefficient of variation of 3.4%;[200] a further increase in sensitivity can be obtained with a modified procedure, using the nitrous oxide–acetylene flame.[201]

In atomic-fluorescence spectrophotometry, using separated nitrous oxide–acetylene flames for atomization and a microwave-excited electrodeless discharge tube as a radiation source, the limit of detection was 88 ng/ml; of 23 ions investigated only aluminium, cobalt and tungsten interfere.[202]

Molecular-absorption spectrophotometry in the visible and ultraviolet region

This approach seems to be the most popular for the determination of small amounts of vanadium. In the last 15 years more than 320 papers have been published that recommend new reagents or new procedures with known reagents. It is again impossible to include all these works in this review; even stringent selection of the material still leaves 150 works worthy of mention. The most important inorganic and organic reagents will be discussed first, followed by an alphabetical list of some less common, but still useful, reagents.

Inorganic reagents. Several ionic species of vanadium in different oxidation states have characteristic colours: it is therefore possible to determine vanadium spectrophotometrically by its own colour. Tervalent,[203] quadrivalent[204] and quinquevalent[205] vanadium may all be determined in this way. Peroxovanadium(V) (known also as peroxyvanadic acid) is a well-known coloured product obtained by treating vanadium solutions with hydrogen peroxide. Its use for the determination of vanadium has been re-examined and the optimal experimental conditions have been established.[206] The determination in the form of heteropoly acids has the advantage that it can be combined with an extraction procedure, enabling vanadium to be separated at the same time. When determining vanadium as the yellow tungstovanadophosphoric acid the best wavelength for the measurement seems to be 364 nm,[207] but good results can also be obtained at 392,[208] 415,[209] or 436[210] nm. Use of molybdovanadophosphoric acid may have some advantages, especially if it is measured in the ultraviolet (228 nm),[454] though measurements at 360[211] and 323[212] nm are also used. Thiocyanate, depending on the experimental conditions, may be used as a reducing[213] or a complexing[214] agent; in both cases the resulting product can be measured by spectrophotometry. Recently, the use of ferrocyanide has been recommended.[215]

Important organic reagents. The most sensitive spectrophotometric reagents for vanadium are the various di-substituted aromatic hydroxylamines of *hydroxamic acids.* Over the years a large number of derivatives have been prepared and suggested as reagents. There are really no great differences in sensitivity and selectivity among the various reagents; the limits of detection lie between 10 and 100 ng/ml in most cases, and determinations are feasible up to concentrations of 10 μg/ml. It is not easy to select a "best" reagent because of the large choice; some authors, however, have made comparative studies which may be used as guides. Thus, one research group compared 52 saturated[216] and 23 unsaturated[217] *N*-arylhydroxamic acids, finding *N*-*m*-tolyl-*p*-methoxybenzohydroxamic acid and *N*-phenyl-3-styrylacrylohydroxamic acid as best choices out of the first and second groups respectively. In a previous study, which included 27 different hydroxamic acids, the same group singled out *N*-phenylcinnamohydroxamic acid[218] as the best choice. Other comparative studies[219,220] involved fewer reagents but may serve as a basis for choosing the best for a given task.

Simple benzohydroxamic acid[221] combined with solvent extraction can be used with advantage, but the best reagents seem to be the di-substituted acids. Out of these 4-methoxybenzothiohydroxamic acid,[222] benzoylphenylhydroxamic acid,[223] *m*-nitro-*N*-phenylbenzohydroxamic acid,[224] *m*-(*p*-chlorophenyl)-*N*-benzohydroxamic acid[225] and its *o*-chloro-derivative,[226] *N*-*o*-tolybenzohydroxamic acid,[227] *N*-phenyl-2-sulphobenzohydroxamic acid,[228] *N*-*p*-tolyl-2-furylacrylo- and *N*-phenyl-2-furylacrylo- hydroxamic acids[229] and thiophen-2-carboxyhydroxamic acid[230] are recommendable. Other simple hydroxamic acids which have been studied and recommended are the hexanohydroxamic,[231] nicotinohydroxamic,[232] 2-furohydroxamic,[233] cinnamohydroxamic,[233] quinaldohydroxamic[234] and 2-naphthohydroxamic.[235]

4-(2-Pyridylazo)resorcinol, better known as *PAR*, is a well-known chelating agent, used for the separation and spectrophotometric determination of a number of metals. Under certain conditions vanadium can be selectively complexed and the product extracted with an organic solvent. The organic phase, or, after stripping, the aqueous phase, can be subjected to spectrophotometry. At 560 nm, 0–2 μg of vanadium can be determined accurately. The choice of an auxiliary complexing agent is important; recent works recommend the use of tartrate,[236] fluoride,[237] phosphate,[238] EDTA,[239] chloroacetic acid,[240,241] 1,2-diaminocyclohexane-*N,N,N′,N′*-tetra-acetic acid[242] and citrate.[243] The composition of the vanadium–PAR complex has also been studied[244] and the optimal conditions for formation of the complex in the absence of auxiliary complexing agents have been established.[245] Another reagent, similar in structure, is 1-(2-pyridylazo)-2-naphthol (*PAN*). It has been recommended as a reagent for vanadium in ores[246] and steel.[247] A new reagent of similar nature, 5-ethylamino-2-(2-pyridylazo)-*p*-cresol, together with its two bromo-derivatives, is suitable for determining 0.1–0.5 μg/ml levels of vanadium.[248] A comparative study on the PAR and PAN complexes has been made.[249]

8-Hydroxyquinoline and its derivatives are also frequently used complexing agents. They react with a number of metals by forming precipitates in aqueous media, which can then be extracted and determined by spectrophotometry. The reagents on their own are not selective, but the use of an auxiliary complexing agent and the proper choice of pH can make these determinations highly selective. With 8-hydroxyquinoline itself, EDTA,[250] phosphate,[251] phenols,[252] sodium azide[253] and zephiramine[254] are suitable masking agents for a number of determinations on different matrices. Another way of improving the selectivity is to co-precipitate vanadium with 8-hydroxyquinoline and phenylphenol.[255] Some derivatives such as 7-arylazo-8-hydroxyquinoline,[256] 8-hydroxy-5,7-di-iodoquinoline[257] and 8-aminoquinoline[258] are also suitable reagents.

Methylthymol Blue is a well-known metallochromic indicator, used mainly in complexometric analysis. It forms coloured complexes with a number of metals,[259] but under certain conditions it can serve as a selective reagent for vanadium.[260] Usually the vanadium(V) complex is measured, but the vanadium(IV) complex is also suitable for qualitative determination.[261] The latter complex can also be extracted.[262]

1,10-Phenanthroline, often used as a reagent for bivalent iron, forms a coloured complex with vanadium(II) and can be recommended for its determination by spectrophotometry.[263] In the presence of sodium azide, vanadium(V) can be determined if the complex is extracted. Vanadium(IV) does not react under these conditions.[264] Alternatively, 6-hydroxy-1,7-phenanthroline may be used.[265]

Phenylfluorone reacts with quadrivalent metals; its use for the determination of tin(IV) is well known. In the absence of tin(IV) it can also be used for the determination of vanadium(IV);[266] with 9-(3-pyridyl)-fluorone[267] a vanadium concentration as low as 5 ng/ml can be determined.

With the use of complexing agents, maltol (3-hydroxy-2-methylpyran-4-one) is a selective reagent for vanadium(V);[268] the product can be extracted into chloroform. Interferences of a number of ions can be eliminated by proper choice of the acidity.[269,270]

Other organic reagents. The following reagents, listed in alphabetical order, can also be used for the spectrophotometric determination of vanadium under certain conditions: Acid Alizarin Black SN,[271] Acid Chrome Blue K,[272] Alizarin Red S,[273] 3-amino-5-hydroxy-naphthalene-2,7-disulphonic acid,[274] *p*-anisidine,[275] Arsenazo,[276] catechol alone[277] or with a tertiary amine[278] or as its 3,4-dinitro derivative,[279] Calcichrome,[280] *p*-chloroaniline,[281] Chrome Azurol S alone[282] or combined with zephiramine,[283] 1,2-di-(2-aminoethoxy)ethane-*N,N,N′,N′*-tetra-acetic acid and hydrogen peroxide,[284] 1,2-di-(2-aminoethyl)-ether-*N,N,N′,N′*-tetra-acetic acid,[285] *o*-dianisidine,[286] β-(diantipyrinylmethyl)styrene[287] and its derivatives,[287,288] 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol,[289] 5,7-dichloro-8-hydroxyquinaldine,[290] (diethylamino)pyridylazophenol derivatives,[291] 3,3-dimethylnaphthidine,[292] 2-dimethylaminoethanethiol,[293] diphenylamine,[294] Eriochrome Cyanine,[295] Eriochrome Red,[296] Erio Green,[297] ferron,[298] formaldoxime,[299] *o*-hydroxyacetophenone,[300] 3-hydroxyflavone,[301] bis(2-hydroxyethylimino)gossypol,[302] 2-(3-hydroxy-3-phenyltriazeno)benzoic acid[303] and its sulphonated derivative,[304] *N*-hydroxysuccinic acid,[305] 2,2′-iminodibenzoic acid (Vanadox),[306] β-isopropyltropolone,[307] the reagent called MAAF II,[308] Magneson (dimethylamino-2-[3-(1-methyl-2-piperidyl)-2-pyridylazo]phenol,[309] *N*-methylanabasine-α-azo-α-naphthol,[310] morin,[311,312] murexide,[313] naphthalene-2,3-diol,[314] nicotinic acid hydrazide,[315] organic dibasic acids,[316] oxalic acid,[317] phenothiazine derivatives,[318] *o*-phenylenediamine,[319] phenylthiosemicarbazide,[320] phthalocyaninetetrasulphonic acid,[321] picramic acid,[322] picraminazo N,[323] propane-1,2-diaminetetra-acetic acid (APDT),[324] propyl-2,3,4-trihydroxybenzoate,[325] protocatechuic acid,[326] pyridine thiocyanate,[327] pyridine-2,6-dicarboxylic acid,[328] pyridine-2,4,6-tricarboxylic acid,[329] 6-(2-pyridylazo)thymol,[330] 6-2(pyridylazo)-3,4-xylenol,[331] Pyrogallol Red,[332] quercetinsulphonic acid,[333] rutin,[334] salicyalaldehyde,[335] Schiff-base,[336] Solochrome Black RN,[337] Solochrome Violet RS,[338] sulphonated derivatives of diphenylcarbazone and dithizone,[339] Sulphonazo,[340] Sulphonitrazo,[341] sulphosalicylic acid,[342] tetraphenylphosphonium chloride,[343] various thiazolylazo-compounds,[344,345] thiosalicylamide,[346] tiron,[347] tribromopyrogallol,[348] tris(2-hydroxyalkyl)amine derivatives,[349] tropolone[350] and Xylenol Orange.[351]

Infrared spectroscopy

Infrared spectroscopy is a powerful technique for the qualitative characterization of substances. Though its main field of application is organic chemistry, it can be applied for inorganic systems. In one important paper[352] all previously published infrared data on vanadium have been collected. From the infrared spectra and correlation charts it is now possible to identify ortho-, pyro-, meta-, hexa and decavanadates. A quantitative determination of vanadium in infrared spectroscopy is possible by precipitating with 8-hydroxyquinoline, making a KBr disk and measuring the characteristic absorption band.[353]

Molecular-fluorescence spectrophotometry

The great advantage of molecular-fluorescence spectrophotometry is that by selecting the wavelengths of both the excitation and emission radiation separately, one has double the confidence in the qualitative characterization. The vanadium complexes of isophthalic acid[354] and benzoic acid[355] show characteristic fluorescence and can be used for the quantitative determination of vanadium. The structure of the complexes and the mechanisms of the reactions leading to the fluorescent compounds have also been discussed.

Electron paramagnetic resonance (EPR) and electron spin resonance (ESR) spectroscopy

These techniques are seldom used for quantitative analysis. Nevertheless, it is possible to determine 0.1–200 ppm of vanadium(IV) as vanadyl aetioporphyrin by EPR spectroscopy,[356] the method being especially suitable for the determination of vanadium in crude petroleum.[356,357] At low temperatures the Q-factor of the oscillator is considerably higher than at room temperature, facilitating the EPR spectroscopy determination.[358] Quantitative determination is also possible with ESR spectroscopy.[359,360] The reaction mechanism of the formation of the vanadium(IV)–Arsenazo complex has been investigated by EPR spectroscopy.[361]

X-Ray fluorescence

As the X-ray spectra of the elements are comparatively simple, consisting of only a few strong lines, the evaluation of the X-ray fluorescence spectrum of a sample containing several elements is relatively easy. This, together with the absence of chemical interferences and dependence on oxidation state, and its applicability to nearly all the elements, has helped to ensure the popularity of XRF in spite of the costs involved and the problems of sample preparation. Usually the unresolved $K\alpha_{1,2}$ lines are used for the analysis (with an LiF analyser crystal they appear at $2\theta = 76.91°$), without the use of a titanium filter, which absorbs these lines. For the same reason, titanium and also calcium interfere if present in the sample.

More than 40 papers have appeared in the past 15 years on the determination of vanadium by this technique, about half of them dealing with the analysis of steel, rock or petroleum samples. They describe various techniques for sample preparation, and there are differences in the choice of the line measured. These papers have not been included in this review. Some special methods of sample preparation have been developed, such as a device to handle small liquid samples,[362] a borax-disk technique for fusible substances,[363] a cellulose disk method,[364] adsorption of metal ions from solutions with cation-exchangers and use of the dried solid as the sample,[365] as well as dissolving the substance in sulphuric acid, evaporating to small volume and preparing a paste with magnesium oxide,[366] which is dried and then used as the sample in the X-ray spectrophotometer. When the amount of vanadium is too small for direct determination, preconcentration by precipitation with ammonium tetramethyldithiocarbamate[367] or diethyldithiocarbamate[368] as precipitants can be applied. The determination of vanadium in samples such as ultrapure chemicals,[369] air-borne dust[370,371] and organometallic compounds[372] is also possible by X-ray fluorescence. Electron-microprobe determinations of vanadium in silicates[373] and in samples containing titanium,[374] where spectral interferences have to be eliminated, have also been described. A simple mathematical method to evaluate matrix effects in X-ray fluoresence analysis can also be applied.[375]

ACTIVATION ANALYSIS

Neutron-activation analysis is one of the most powerful techniques, capable of determining as little as 10^{-12} g of some elements. By careful choice of neutron energy, neutron flux, length of irradiation and cooling time between irradiation and measurement, the method can be adapted for the determination of vanadium in almost any matrix. The number of papers which have appeared over the past 15 years demonstrates the popularity of the technique.

Usually, thermal neutrons are used to activate ^{51}V in an n,γ reaction to give ^{52}V which gives a γ-line at 1.433 MeV suitable for measurement. The isotopic abundance is almost 100%, the cross-section is reasonably high at 4.9 barns, but the half-life is rather short at 3.76 min. The limit of detection is usually better than 10^{-9} g, though it does depend on the composition of the matrix.

Methods are available for the determination of vanadium in iron alloys,[376] iron and iron ores,[377] high-purity iron,[378] aluminium,[379] petroleum,[380] fuel oil,[381] air-pollution particles,[382,383,384] rocks and meteorites,[385,386] cement,[386] nuclear graphite,[387] lunar samples,[388] human bone,[389] biological materials,[390] tissue[391] and plants.[392] Sometimes a chemical preconcentration or separation step is needed before activation analysis; this can be done with ion-exchangers,[393] extraction with 2-nonylpyridine N-oxide[394] or precipitation with 8-hydroxyquinoline.[395] Moderated fast neutrons[396] and charged particles[397,398] can also be used for the activation analysis of vanadium. A special technique called "re-activation analysis" can also be used[399] and a precipitation–exchange technique, based on the measurement of ^{110}Ag, has also been described.[400]

CATALYTIC ANALYSIS

There are two main advantages of catalytic methods of analysis. First, they allow the selective and sensitive determination of trace amounts (as low as 10–100 ng) with simple, cheap equipment. Secondly, they produce an analytical signal from a kinetic system which is moving towards equilibrium; this signal is different in principle from almost all other analytical signals, obtained from equilibrium systems. The rate of a reaction between two reactants, present in macro amounts, is measured; this depends on the analytical concentration of the catalyst present. Vanadium catalyses several redox processes in homogeneous solution; at least 50 papers have been published on its catalytic determination. The optimum concentration range is usually 0.1–1 ppm with a detection limit of 0.02 ppm (20 ng/ml). The methods reviewed here will be classified according to the oxidizing agents applied. Vanadium catalyses the bromate oxidation of iodide,[401,402] thiocyanate,[403] amidol,[404] 4-amino-5-hydroxynaphthalene-2,7-disulphonic acid,[504] Bordeaux Red[406] (this method being also adapted for the determination of vanadium in steel),[407] Bromopyrogallol Red,[408] Eriochrome Blue P,[409] Indigo Carmine,[410] 4-aminodiphenylamine-2-sulphonic acid,[411] *p*-phenetidine[412] and Solochrome Violet.[413] With chlorate as oxidizing agent, traces of vanadium can be determined by using *p*-aminodiethylaniline,[414] aniline,[415] benzidine,[416] 4-hydrazinobenzenesulphonic acid[417] or *p*-phenetidine[418] as the reducing agent. Hydrogen peroxide oxidizes iodide,[419,420] aniline[421] (this reaction can be adapted for the determination of vanadium in rocks),[422] benzidine[423] and diphenylcarbazide[424] in slow reactions which are catalysed by trace of vanadium. Oxidations with peroxodisulphate are also catalysed by vanadium; catechol[425] and gallic acid[426] can serve as reducing agents. With the latter, vanadium can also be determined in sea-water.[427] The oxidative coupling of 4-hydrazobenzenesulphonic acid with 1-naphthylamine is also suitable as a main reaction for the catalytic microdetermination of vanadium.[428] When Landolt reactions are used as the slow reaction, a simple visual procedure can be adapted, reaction times being measured with a stop-watch. Landolt systems involve one oxidizing and two reducing agents. With the bromate–iodide–ascorbic acid system 0.1 ppm of vanadium can be determined selectively in the presence of 22 foreign ions.[429] Good results are also obtainable with the bromate–bromide–ascorbic acid,[430,431] the chlorate–chloride–ascorbic acid[432,433,434] and the chlorate–bromide–ascorbic acid[435] systems. Chemiluminescence reactions are also catalysed[436,437] or quenched[438] by traces of vanadium, and these reactions can again be used for its determination.

MASS SPECTROMETRY

Although not a cheap technique, mass spectrometry produces an easily distinguishable analytical signal, and can be adapted for the qualitative and quantitative characterization of an element, such as vanadium, with a relatively low atomic weight. Spark-source mass spectrometry is normally used. ^{51}V is present in almost 100% abundance and the ^{51}V line is well separated (in an organic matrix no other line appears between mass numbers 50 and 52). The limit of detection is about 0.01 ppm, with 0.1–10 ppm the optimum concentration range.

The method can be adapted for various matrices, mass spectrometric determinations of vanadium in iron and steel,[439,440,441] other metals,[442,443] rocks,[444] coal ash,[445] marble[446] and titanium dioxide[447] having been described.

GAS CHROMATOGRAPHY

Some metal chelates with organic ligands are easily volatilized. This fact can be utilized for the gas chromatographic separation of vanadium from other metals and its determination. As chelating agents trifluoroacetylacetone,[61] thenoyltrifluoroacetylacetone,[62] bis(trimethylsilyl)trifluoroacetylamide[63] and salicylaldimine[64] have been suggested. Usually, the separated components are condensed and the vanadium is determined by spectrophotometric methods.

MISCELLANEOUS TECHNIQUES

Separations based on the ring oven technique coupled with spectrophotometry,[448] fluorescence measurements,[449] segment colorimetry[450] and the related technique of annular colorimetry[451] are also suitable for the qualitative and quantitative characterization of traces of vanadium. Thermogravimetric studies on vanadium precipitates[452] and alums containing vanadium(III)[453] have also been made.

As interest in the determination of vanadium seems to grow, the authors hope to prepare a further critical review when enough new material, worthy of appraisal, becomes available.

ACID–BASE TITRATIONS BY STEPWISE ADDITIONS OF EQUAL VOLUMES OF TITRANT WITH SPECIAL REFERENCE TO AUTOMATIC TITRATIONS—I

THEORY, DISCUSSION OF THE GRAN FUNCTIONS, THE HOFSTEE METHOD AND TWO PROPOSED METHODS FOR CALCULATING EQUIVALENCE VOLUMES

LENNART PEHRSSON, FOLKE INGMAN and AXEL JOHANSSON
Royal Institute of Technology, Stockholm, Sweden

(*Received* 5 *April* 1976. *Accepted* 13 *May* 1976)

Summary—The range of acid stability constants over which the Gran functions are applicable in evaluating acid–base titrations at normal concentrations is studied and found to be quite narrow. Alternatively, the titrations can be evaluated by using non-approximative methods based upon an equation that is derived without making the simplifying assumptions leading to the Gran functions. One such method, introduced by Hofstee, is discussed and the results of a study of the effects of a systematic error in the pH-determinations upon the determination of the equivalence volume are given. Two other non-approximative methods for evaluating acid–base titrations that are particularly suitable for use in automatic titrations of many similar samples are also described. These methods yield correct values of the equivalence volume regardless of a possible systematic error in the pH-values and are particularly useful for titrations of moderately strong and very weak acids (stability constants up to 10^{10}–10^{11} at $0.01M$ concentration) where the Gran functions cannot be used.

Over the years, the so-called Gran curves[1,2] have attracted the interest of analytical chemists. This interest has been intensified by the introduction of several new ion-selective electrodes. The Gran functions (founded upon an idea of Sørensen's[3]) represent one of the first attempts to linearize titration curves, thereby making it possible to calculate the equivalence volume by using several points on the titration curve instead of only the inflexion point. As shown by Johansson and Pehrsson[4] it is simple to design an apparatus for performing titrations automatically along the principles developed by Gran.

The Gran functions for titrations of acids with strong base are summarized in Table 1. Similar functions may be derived for titrations of bases and for compleximetric titrations, *e.g.*, of fluoride ions.[5]

The titrant is in each case assumed to be a strong base. V_0 is the volume of the sample solution before the titration is started, V the volume of titrant added, and k, k' are arbitrarily chosen constants. If the functions are plotted against V, straight lines are obtained that intersect the V-axis at V_e, the equivalence volume.

The great advantage of the Gran functions is that it is not necessary to determine absolute [H]-values (charges are omitted for simplicity). It suffices to determine values proportional to [H] which means that it is not necessary to calibrate the electrode system. However, the use of the traditional Gran curves is restricted to a limited range of acid strengths. The Gran function $(V_0 + V)10^{(k-\mathrm{pH})} = f(V)$ gives a straight line only when a strong acid is titrated. As shown below, $V\,10^{(k-\mathrm{pH})}$ will not give a completely straight line for any acid. However, for moderately weak acids, HA, having logarithmic stability constants

$$\log K_{\mathrm{HA}} = \log[\mathrm{HA}] - \log[\mathrm{H}] - \log[\mathrm{A}]$$

lying in the range 5.0–8.5, more than 50% of the function will lie on a straight line intersecting the V-axis at $V = V_e$ (assuming concentrations of the order of $0.01M$). There is a range of acids between strong and moderately weak within which neither of these simple functions will yield satisfactory results and this has not been generally recognized. When the acids are

Table 1. Gran's second method

Substance titrated	Gran functions	
	On the acid side of the equivalence point	On the alkaline side of the equivalence point
Strong acid	$(V_0 + V)10^{(k-\mathrm{pH})} = f(V)$	$(V_0 + V)10^{(\mathrm{pH}-k')} = f(V)$
Weak acid	$V10^{(k-\mathrm{pH})} = f(V)$	$(V_0 + V)10^{\mathrm{pH}-k'} = f(V)$

very weak, the Gran function $V\,10^{(k-\mathrm{pH})} = f(V)$ gives incorrect results.

Ingman and Still,[6] and Johansson,[7] have derived the following equation that is valid throughout the range of acidic strengths without approximations:

$$V_e = V + K_{HA}\left\{V[H] + \frac{V_0+V}{C}[H]^2 - \frac{V_0+V}{C}K_w\right\} + \frac{V_0+V}{C}\left\{[H] - \frac{K_w}{[H]}\right\} \qquad (1)$$

K_w is the ion-product of water and C the concentration of the titrant solution. This equation requires use of concentrations and concentration constants determined at the ionic strength in use. The different terms in equation (1) all have the dimension of volume and may be interpreted as being contributions in different pH-ranges to the equivalence volume of the acid. This makes it quite easy to judge whether a term is negligible or not. A similar equation can be derived for titrations of bases with strong acids.

It is easily seen that the Gran functions mentioned in the introduction may be obtained from equation (1) by making the appropriate simplifying assumptions. In strongly acidic solutions, in other words when a strong acid is being titrated, all other terms in equation (1) may be neglected in comparison with the term $(V_0 + V)[H]/C$ and so the Gran function for titrating strong acids is obtained. When a weak acid is titrated, the dominant term will be $K_{HA}V[H]$, thus yielding the Gran function for titrating weak acids. Finally, if the value of K_{HA} is not too high, equation (1), for strongly alkaline solutions, will be reduced to

$$(V_e - V) = -\frac{(V_0+V)}{C}\frac{K_w}{[H]}$$

which is the Gran function to be used after the equivalence point when base is being added in excess to the solution.

The aim of the first part of the present paper is to study the conditions under which titration data will give correct equivalence volumes when treated according to Gran. In the second part of the paper, a method given by Hofstee[8] is discussed. This method is based upon equation (1) and is thus non-approximative, but it requires knowledge of absolute [H] values and not simply values proportional to [H]. In this case it is consequently necessary to calibrate the electrode system. In the third part, two alternative non-approximative methods of calculating equivalence volumes from titration data are presented. The equivalence volumes are determined by using equation (1) and simple numerical methods. It is shown that even large systematic errors in the determination of the pH values can be tolerated without sacrifice in the accuracy of the results. A very rough calibration of the electrode system is therefore enough. An apparatus for automatic titration utilizing the principles put forward in this paper will be presented in a forthcoming communication.

MEASURING HYDROGEN-ION CONCENTRATIONS

The most common method of measuring hydrogen-ion concentrations is potentiometrically with the glass electrode. Though the electrode in principle responds to activity, it may be calibrated with known concentrations if precautions are taken in order to keep the activity factors constant. This can be done by using ionic media of constant ionic strength. Equation (2) relates the measured potential to the concentration of hydrogen ions in the solution:

$$E = E'_0 + Q\log[H] + E'_j \qquad (2)$$

Here, E'_0 stands for the standard potential, including the reference potential and the part of the activity coefficients and the junction potential that is independent of the acidity. $Q = RT\ln 10/nF = 59.2$ mV at 25°. In our experience, good glass electrodes do not deviate from this value in a thermostatically controlled system. $E'_j = j_H[H] + j_{OH}[OH]$ accounts for the acidity-dependent part of the activity coefficients and the junction potential. The constants j_H and j_{OH} are characteristic of the ionic medium.

In the following we denote $-\log$ [H] by ph to distinguish it from $-\log\{H\} = $ pH, where $\{H\}$ is the hydrogen-ion activity. Our experience shows that the main cause of errors in the determination of ph is the difficulty of obtaining a correct value of E'_0. The most accurate way to determine E'_0 seems to be by a so called E'_0-titration (see below). First, however, the values of j_H and j_{OH} must be determined.

The value of j_H may be determined once and for all by titrating a known amount of a rather concentrated solution of strong acid with strong base. The concentrations of the acid and base must be known. The base is added stepwise and E and V are measured after each addition of titrant. A plot of $E - Q\log[H]$ against [H] yields j_H as the slope and E'_0 as the intercept with the y-axis;[9] j_{OH} is similarly calculated from titration points taken after the equivalence point.

When j_H has been determined, E'_0 is preferably determined by titrating a more dilute solution of strong acid ($C_{HA} = 0.01$–$0.001M$) in order to minimize the effect of an error in j_H. For each titration, several values of E'_0 can be calculated by using equation (2) and the E'_0 value to be used is taken as the mean. Normally, an E'_0-titration is run in a separate vessel before the titration of the unknown in another vessel. A small change in E'_0 (of the order of a few tenths of a millivolt) may result when the electrode is transferred from one solution to another. This source of error can be eliminated by running the E'_0-titration before the determination of the unknown, which is then added to the same solution. This procedure is, however, time-consuming and is only used when a very high degree of accuracy in the determination of E'_0 is necessary.

The simplest, though less accurate, method of determining E_0' is to use a calibration solution of known hydrogen-ion concentration.

A change in E_0' also seems to take place in some glass electrodes on going from the acid to the alkaline pH-range. This change may amount to a few millivolts. An electrode system that is to be used on the alkaline side of this region should therefore be calibrated in alkaline solution and points that lie in the critical range should not be used in the evaluation of titrations.

THE GRAN FUNCTIONS

Since their appearance, the Gran functions have been discussed and further developed by several authors. In their monograph on computer calculations in analytical chemistry, Dyrssen and coworkers[10] discussed the approximations that need to be made in order to obtain the Gran functions for titration of bases with strong acids. They gave some rather crude rules for deciding when the Gran functions $V/[\mathrm{H}]$ and $(V_0 + V)[\mathrm{H}]$ may be expected to yield correct results. They also discussed the functions from the statistical point of view and devised methods for estimating the precision of the determination of the equivalence volume from the titration points and for deciding whether a point should be disregarded or not. Hansson and Jagner[11] modified the Gran plots for titration of the total alkalinity and carbonate content in ocean water by accounting for the interfering side-reactions of other species in sea-water.

Ebel and Krömmelbein[12,13] have discussed experimental sources of errors in the use of Gran functions. According to them, a 1% error in the slope of the electrode response will result in a titration error of 0.3% for a titration of strong acid with strong base. No such error has, however, been observed by the present authors if the temperature is properly controlled. Ebel and Krömmelbein have also shown[14] that the Gran function $V[\mathrm{H}]$ represents a poor approximation of the complete equation (1) for some ranges of K_{HA} values. Therefore, they applied orthogonal polynomials to approximate equation (1) but exchanged the (x,y)-values for (y,x)-values in the curve-fitting procedure. This was later commented upon by Wahbi[15] who considered it to be mathematically incorrect.

McCallum and Midgley[16] have discussed the effect of changes in activity coefficients upon the Gran functions during a titration. They took these changes into account by an iterative computer technique using the Debye–Hückel equation. They thus assumed that no attempts are made to keep the ionic strength of the solution constant during the course of the titration. In a second paper[17] the same authors have shown that the Gran function $V[\mathrm{H}]$ gives poor results for acids having $C_{\mathrm{HA}}K_{\mathrm{HA}} < 10^3$. They have also extended the equation given by Ingman and Still to make it valid for titrations of acids in the presence of a weak base. Furthermore, they have given an equation for evaluating titrations of biprotic acids. The main drawback of these methods is that it is necessary to know the stability constants of both the acids and the bases as well as the E_0' of the electrode system.

The principal advantage of the simple Gran function is that it is not necessary to compute [H] from the measured emf data by using equation (2). As soon as E_j' is negligible it will be possible to plot for example $(V_0 + V)10^{(E-k)/Q}$ (that is, $(V_0 + V) \times$ constant $\times$ [H]) instead of $(V_0 + V)[\mathrm{H}]$ against V, where k is a constant that may be chosen arbitrarily. This is a distinct advantage since it is rather easy to measure E with good precision but an accurate determination of E_0' (and thus of [H]) is considerably more difficult.

One case where E_j' is frequently negligible is when weak acids are titrated at ionic strengths equal to or exceeding 0.1. However, when strong acids are titrated, it is often not possible to neglect E_j'. To give an example: in 0.5M potassium chloride, $j_{\mathrm{H}} \approx -90$ mV and $j_{\mathrm{H}}[\mathrm{H}]$ will vary from 0.9 mV to negligible values for a titration of 0.01M hydrochloric acid; this will result in a curved Gran plot.

When a strong acid is titrated and E_j' cannot be neglected, iteration provides one way of calculating values that are proportional to [H] though E_0' may be unknown. An approximate value of the equivalence volume V_e is then first calculated by using $E_j' = 0$. Subsequently, E_j' is computed from j_{H} and approximate [H] values obtained from the approximate V_e value. Corrected relative values of [H] may then be calculated for each pair of $(E - E_j', V)$ data. It is only rarely necessary to repeat the iteration.

The limitations of the Gran functions

These have been studied for different values of K_{HA} by computing theoretical titration curves and using these data ([H], V) to test the Gran functions. The calculations were done for titration of 0.01M acid with 0.1M sodium hydroxide, and for titration of 0.001M acid with 0.01M sodium hydroxide. The results are shown in Table 2. The first column in the table gives the initial concentration C_{HA}^0 of the acid, the second column gives log K_{HA} and the other columns list the range of the titration parameter a (defined by $a = VC/V_0C_{\mathrm{HA}}^0$), within which the Gran functions yield straight lines that intersect the V-axis at $V_e \pm 0.1\%$. (An arbitrary criterion of linearity was chosen, *viz.* the ordinate value of the function should not deviate from the corresponding ordinate of the extrapolated linear portion of the function by more than 0.1% of the straight line ordinate at $V = 0$.)

As can be seen from Table 2, the Gran function $V[\mathrm{H}]$ (or $K_{\mathrm{HA}}V[\mathrm{H}]$) which is used to evaluate titrations of weak acids does not yield a straight line within the specified error limits in the entire range $a = 0$–1 for any value of the stability constant. In the following, three specific examples will be discussed in some detail.

Table 2. The range $a(=VC_B/V_0C^0_{HA})$ within which the Gran functions yield straight lines that intersect the V-axis at $V_e \pm 0.1\%$ for different values of K_{HA}. (see text for explanation.)

C^0_{HA}, M	log K_{HA}	$(V_0+V)[H]$ a	$V[H]$ a	$(V_0+V)/[H]$ a

	7.0		0.25–0.90	1.10–2.00

Example 1. An acid having log $K_{HA} = 3.0$. Figure 1 shows a plot of $V[H]$ against V compared with a plot of $(V_e - V) = f(V)$ calculated from the complete equation (1) for a titration of 100 ml of $0.01M$ solution of an acid having log $K_{HA} = 3.0$, with $0.1M$ sodium hydroxide. As said above, all the terms in equation (1) have the dimension of volume. During the course of the titration different terms will be predominant in different pH-regions. In Table 3 the values of the terms $K_{HA}V[H]$, $K_{HA}(V_0 + V)(H)^2/C$, $(V_0 + V)[H]/C$, $K_{HA}(V_0 + V)K_W/C$ and $(V_0 + V)K_W/C[H]$ in equation (1) are listed for different values of a. It is seen from the table that the second and third terms listed above are not negligible in comparison with the first term at the beginning of the titration. However, as the equivalence point is approached the predominance of the first term grows and for the titration shown in Fig. 1, a straight line will result for $a = 0.9$–1.0. After the equivalence point all other terms are negligible in comparison with $(V_0 + V)K_W/C[H]$ and a plot of this function *vs.* V will therefore yield a straight line that intersects the V-axis at the equivalence volume.

Example 2. An acid having log $K_{HA} = 10$. Figure 2 shows a titration of 100 ml of $0.01M$ acid having log $K_{HA} = 10.0$, with $0.1M$ sodium hydroxide. According to Table 4 it is not possible to neglect the terms $K_{HA}(V_0 + V)K_W/C$ and $(V_0 + V)K_W/C[H]$ in comparison with $K_{HA}V[H]$ before the equivalence point. It is also necessary to consider all three terms after the equivalence point.

Example 3. An acid having log $K_{HA} = 7.5$. As is clear from Table 2, the best results will be obtained with the Gran function $V[H]$ in the range $6.0 \leq \log K_{HA} \leq 8.0$ at normal concentrations ($\approx 0.01M$). A plot of this function against V is shown in Fig. 3, assuming that 100 ml of $0.01M$ acid having log $K_{HA} = 7.5$ is titrated with $0.1M$ sodium hydroxide. As is seen from Table 5, The term $K_{HA}V[H]$ predominates over all other terms in equation (1) in the interval $0.1 < a < 0.9$.

Systematic titration errors

As seen from the preceding discussion, in many cases the lines that result from plotting the Gran func-

tions will not be perfectly straight and this may lead to a systematic titration error. The magnitude of this error depends upon how large a part of the function is used for calculating the equivalence volume V_e. The theoretical systematic titration errors resulting when titrations of 0.01M solutions of acids of different strengths with 0.1M sodium hydroxide are evaluated by the diverse Gran functions have been collected in Table 6. It was assumed that the titrations were performed by stepwise additions of equal volumes of titrant in the range $a = 0$–1.0 so that $\Delta a = 0.1$. The equivalence volumes were calculated from not less than five titration points. If the only way to obtain an acceptable result is to use less than five points in the Gran evaluation, one of the methods presented below is definitely prefereable to the Gran method.

The applicability of the Gran functions

If it is desired that a Gran function should give a line that is straight over at least 50% of its course and such that the extrapolated straight-line portion intersects the V-axis at V_e with a maximum relative

Table 5. The table lists the contributions of the different terms in equation (1) to the equivalence volume at different values of a. It is valid for a titration of 100 ml of 0.01M solution of an acid having $\log K_{HA} = 7.5$, with 0.1M NaOH

10.0	0.10–0.90		+6.3

error of ±0.1%, then Table 2 can be used to formulate the following conditions for the applicability of the Gran functions.

Before the equivalence point:

$(V_0 + V)[H]$ $C_{HA} = 0.01M$ $\log K_{HA} \le 1.0$
$V[H]$ $C_{HA} = 0.001M$ $\log K_{HA} \le 2.0$
$C_{HA} = 0.01M$ $5.0 \le \log K_{HA} \le 8.5$
$C_{HA} = 0.001M$ $6.0 \le \log K_{HA} \le 7.0$

After the equivalence point:

$(V_0 + V)/[H]$ $C_{HA} = 0.01M$ $\log K_{HA} \le 8.5$
$C_{HA} = 0.001M$ $\log K_{HA} \le 7.0$

THE HOFSTEE METHOD

As is clear from the discussion above, the use of the simple Gran functions is severely restricted, which is particularly serious when using the method of stepwise additions of equal volumes of titrant. With data of good quality equation (1) should always yield good results and it is easily solved with the aid of a computer. A systematic deviation of the ph measurements was considered the most likely systematic error and a study of its effects upon the results yielded by equation (1) has been conducted.

Hofstee[8] in 1960 published a method for determining equivalence volumes which is, in principle, based upon equation (1). He used the equations for the total concentration of the acid and the electroneutrality condition in order to determine the concentration of acid and the stability constant of the acid in the following manner:

$$C_{HA} = [A] + \{H\}[A]K_{HA}$$

$$[A] = [Na] + [H] - [OH]$$

where K_{HA} in this case is a mixed constant, and $[Na] = VC/(V_0 + V)$. A plot of $[A] \approx [Na] = VC/(V_0 + V)$ against $\{H\}[A]$ yields C_{HA} as the intercept with the y-axis and K_{HA} from the slope. Hofstee used his method with the approximations shown here to evaluate titrations that could equally well have been evaluated by Gran's method ($\log K_{HA} = 7.02$ and 7.90). His method was used for titrations of moderately strong acids and very weak acids by Benet and Goyan,[18] who also pointed out that a systematic error in pH gives an incorrect value of the equivalence volume if the titration data are taken outside the pH interval 5–9. Their experiments were conducted in such a way that V was negligible in comparison with V_0.

Leeson and Brown[19] modified Hofstee's equation in order to account for dilution during the course of the titration. Briggs and Stuehr[20] used an iterative technique to allow for excess of strong acid or strong base in the solution.

Equation (1) is linear in V_e and K_{HA} and may be written in the form

$$-V_e + rK_{HA} + s = 0 \tag{3}$$

where

$$r = V[H] + \frac{V_0 + V}{C}[H]^2 - \frac{V_0 + V}{C}K_w$$

and

$$s = \frac{V_0 + V}{C}\left([\mathrm{H}] - \frac{K_w}{[\mathrm{H}]}\right) + V.$$

V and E are measured. [H] is calculated according to equation (2), by an iterative technique when E'_j cannot be neglected. (Those who have until the present time published work about the Hofstee method have determined the hydrogen-ion activity and not the concentration. In other words, they have calibrated the glass electrode for hydrogen-ion activity. For them, it has therefore been necessary to know or determine the activity coefficients.)

After calculation of r and s for each measured point on the titration curve, linear regression may thus be employed to fit a straight line to equation (3), yielding the unknowns V_e and K_{HA}. [One of the assumptions made when the method of least squares is used for regression of y on x is that there is no error in x and a normally distributed error in y. Care should therefore be exercised in order to ensure that the quantity having the greater errors is considered as y. In equation (3) both r and s are dependent upon the primary data V and [H] (or rather E). Errors in these quantities are propagated and give corresponding errors in r and s. A certain error in [H] gives a much greater relative error in r than in s. Therefore, r should be considered as y in the calculations.]

The main advantage of the Hofstee method in comparison with the Gran functions is that it is applicable to acids of any strength since it is based upon the complete equation (1), which was derived without approximations. The main disadvantage is that it is necessary to measure absolute values of [H] and not just values proportional to [H], *i.e.*, E'_0 in equation (2) must be determined. As has already been pointed out, E'_0 is difficult to determine with good *accuracy*, but it is much easier to determine E with good *precision*.

An incorrect value of E'_0 gives rise to a systematic error, Δph, in the ph value that is calculated from the measured emf data. The error at 25° is given by

$$\Delta\mathrm{ph} = \frac{\Delta E'_0}{59.155\,\mathrm{mV}}$$

A systematic error in the ph values gives rise in turn to a systematic titration error when Hofstee's method is used to calculate the equivalence volume. We have calculated this titration error for Δph = ± 0.01, corresponding to an error of E'_0 of ± 0.5 mV in the determination, and for different values of K_{HA}. The results are shown in Table 7. It has been assumed that the titrations are performed by stepwise addition of equal volumes of titrant. The calculations were made for titration of 0.01*M* (0.001*M*) solution of acid with 0.1*M* (0.01*M*) sodium hydroxide in the range $a = 0$–1.0 with $\Delta a = 0.1$.

The table shows that the titration error at constant Δph is dependent upon the stability constant K_{HA} and the concentration of the acid that is being titrated. It is seen from Table 7 and Fig. 4 that the systematic titration error obtained when the Hofstee method is used to evaluate titrations will be least for those values of the stability constant that are most suitable for evaluation with the Gran function V[H]. (The reader is referred to Table 2.) This is quite logical since, as shown above, this Gran function may be used without knowledge of the value of E'_0. In these cases, Hofstee's method will give a very nearly

Table 7. The systematic titration errors that result by Hofstee's method for different values of log K_{HA} and C^0_{HA} (0.01*M* and 0.001*M*, respectively) if a systematic error Δph = ± 0.01 is assumed in the ph values. (See text for explanation.)

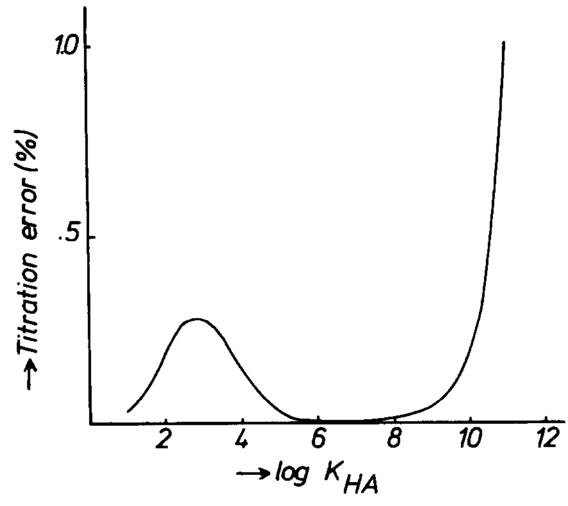

Fig. 4. The systematic titration error resulting by the Hofstee method from a systematic deviation $\Delta ph = \pm 0.01$ in the pH values as a function of log K_{HA}. The figure has been constructed for titrations of $0.01M$ acid with $0.1M$ NaOH. Ten additions of titrant were assumed so that $\Delta a = 0.1$. All points in the range of the titration parameter $a = 0.1$–1.0 were used in the evaluation.

correct value of the equivalence volume, but an erroneous value of the stability constant K_{HA} is obtained if there is an error in E_0'. In the K_{HA} range mentioned, the other terms in equation (1) are small in comparison with $K_{HA}V[H]$ and so the systematic titration error arising from an error in E_0' should also be small. It can be shown that *the titration error in most cases is approximately proportional to the error Δph in the ph values*, assuming moderate titration errors amounting at most to a few per cent. In the following, a few examples will be discussed. Titration of $0.01M$ solutions of the acids with $0.1M$ sodium hydroxide is assumed. Ten titrant additions ($\Delta a = 0.1$), all made before the equivalence point are also assumed.

Example 1. If log $K_{HA} = 7.5$ all terms in equation (1) except $K_{HA}V[H]$ are negligible in the range $0.1 \leq a \leq 0.9$ (refer to Table 5). A systematic error in the ph values will result in an incorrect value of K_{HA} but an almost correct value of the equivalence volume. $\Delta ph = +1.0$ thus yields log $K_{HA} = 8.5$ but an error in the equivalence volume V_e that is less than ±0.1%.

The largest systematic titration errors result when two or more terms in equation (1) are of the same magnitude. This is the case when values taken before the equivalence point are used to calculate the equivalence volume for titrations of moderately strong acids with K_{HA} values in the range $2.0 \leq \log K_{HA} \leq 3.5$ ($C_{HA} \approx 0.01M$). The terms $K_{HA}(V_0 + V)[H]^2/C$, $K_{HA}V[H]$ and $(V_0 + V)[H]/C$ will then all be of the same magnitude as shown by Table 3. Greater accuracy in the calculation of the equivalence volume may in such cases be achieved by omitting some of the first titration points (refer to Table 7). As shown by Table 3 the predominance of $K_{HA}V(H]$ grows as the equivalence point is approached.

At a constant value of Δph an increase in the titration error is also to be expected when very weak acids are titrated. The terms $K_{HA}(V_0 + V)K_w/C$ and $(V_0 + V)K_w/C[H]$ become increasingly important as compared to $K_{HA}V[H]$, with increasing values of K_{HA}.

The importance of the term $K_{HA}(V_0 + V)[H]^2/C$ is greatest when $a = 0$ and decreases rapidly with growing V. Because this term contains the square of the hydrogen-ion concentration, an error in [H] gives rise to a large error in the equivalence volume. This is the reason why *the point* a = 0 *should normally be disregarded* in the evaluation of the equivalence volume for weak acids.

Example 2. An acid having log $K_{HA} = 7.5$ is titrated. A Δph of ±0.01 is assumed. The titration error amounts to ±0.5% if $a = 0$ is included in the evaluation, whereas the error falls to less than ±0.01% if this point is left out.

In order to obtain good results when using the Hofstee method to compute equivalence volumes, only titration points *either* before *or* after the equivalence point should be used if there is a systematic error in the ph values. The reason for this is that for weak acids the predominant term in equation (1) before the equivalence point will be $K_{HA}V[H]$. After equivalence has been attained $(V_0 + V)K_w/C[H]$ will predominate.

Example 3. An acid having log $K_{HA} = 6.5$ is titrated. $\Delta ph = \pm 0.01$. If nine points before and nine points after the equivalence point ($\Delta a = 0.1$) are considered in the evaluation, the systematic error amounts to ±1%. With only the nine points taken before the equivalence point, the error is less than ±0.01%.

There is no reason to use the Hofstee method to evaluate titrations of acids having log $K_{HA} \leq 7.5$ and $C_{HA} = 0.01M$ (or log $K_{HA} \leq 6.5$ and $C_{HA} = 0.001M$) by using points taken after the equivalence point. The reason is that the Gran function $(V_0 + V)/[H]$ yields accurate equivalence volumes in these cases. In the same way it is best to use the Gran function $(V_0 + V)[H]$ for titrations of strong acids.

If the Hofstee method is to be used for calculation of the equivalence volume for *very weak acids*, E_0' for the electrode system should be determined in alkaline solutions. E_0' is then given by

$$\begin{aligned} E &= E_0' + Q \log [H] + E_j' \\ &= (E_0')_{OH} - Q \log [OH] + E_j' \\ &= (E_0')_{OH} - Q \log K_w + Q \log [H] + E_j' \\ E_0' &= (E_0')_{OH} + Q\,pK_w \end{aligned}$$

An error in K_w will result in an error in E_0' and thus in [H]. K_w is, however, also contained in equation (1). If the same value of K_w is used for calculation of E_0' and in equation (1), it can be shown that the errors will balance each other so that a correct value of the equivalence volume, V_e, is obtained. Consequently, in order to obtain a correct value of the equivalence volume it is not necessary to know K_w accurately *if the electrode is calibrated in alkaline solutions.* The value of K_{HA} will, however, be incorrect if the value of K_w is incorrect ($\log K_{HA}^{\text{obtained}} = \log K_{HA} + \Delta pK_w$, where ΔpK_w is the error in pK_w).

PROPOSED NON-APPROXIMATIVE METHODS NOT REQUIRING CALIBRATION OF THE ELECTRODE SYSTEM

The main disadvantage of the Hofstee method is that an accurate knowledge of E'_0 is required for certain ranges of acid strengths. It is true that E'_0 can be accurately determined by running an E'_0-titration before every analysis but this is a time-consuming and—especially in routine work—awkward procedure. Multiparametric refinement methods primarily designed for evaluating stability constants, such as Sillén's LETAGROP procedure,[21] can also be used for determining concentrations.[10] The value of E'_0 is refined by these methods during the calculations, and the problem of an E'_0 that varies from one titration to another may thus be solved. These methods are, however, rather complicated and generally require a considerable amount of computation time. Waldmeier and Rellstab[22] applied a similar technique to evaluate the concentration of a monoprotic acid. A disadvantage of their method is that it requires approximate values of all the parameters to be refined, *i.e.*, the concentration of the acid sample (in principle unknown), K_{HA} and E'_0.

The methods given below, however, do not require an approximate value of the concentration of the acid titrated, and one of the methods does not even require a value of K_{HA}. An approximate value of E'_0 must be known, but a very rough value is enough. This means that a crude calibration of the electrode couple is sufficient, and the value of E'_0 thus obtained can be used for months without recalibration. The methods include a non-linear regression procedure. In both cases a computer program can easily be written that performs the calculations according to the principles described below. The computation time required is short, generally only about 3–6 times that used for linear regression (for the same number of parameters).

The first method is intended for routine titrations of a particular acid, *e.g.*, in automatic analysis, and requires that K_{HA} is known, whereas this is not necessary in the second method. The methods are particularly useful for evaluating titrations of moderately strong acids ($1.5 \le \log K_{HA} \le 5$, $C_{HA} = 0.01M$) and very weak acids for which the results yielded by the Gran method are poor and the Hofstee method requires accurate determination of E'_0.

Method A, intended for use when the stability constant K_{HA} *is known*

If K_{HA} is known with sufficient accuracy it is possible to calculate V_e even without knowledge of E'_0, according to the following principle. An error (denoted by Δph) introduced into the ph values by an erroneous E'_0 will result in an incorrect [H], denoted by [H′]. Consequently,

$$\begin{aligned}[\mathrm{H}'] = 10^{-(\mathrm{ph}+\Delta\mathrm{ph})} &= [\mathrm{H}]\,10^{-\Delta\mathrm{ph}} \\ &= [\mathrm{H}]/f \text{ where } f = 10^{\Delta\mathrm{ph}} \qquad (4)\end{aligned}$$

Considering (4), equation (1) can be written in the form

$$y = -V_e + V + K_{HA}\left\{Vf[\mathrm{H}'] + \frac{V_0+V}{C}f^2[\mathrm{H}']^2 - \frac{V_0+V}{C}K_w\right\} + \frac{V_0+V}{C}\left\{f[\mathrm{H}'] - \frac{K_w}{f[\mathrm{H}']}\right\} \qquad (5)$$

The unknowns in the equation are V_e and f. In the first approximation f is put equal to 1. V_e is then obtained as the mean of the V_e values calculated from each titration point (V,[H′]) by using equation (5) (letting $y = 0$). If $f \neq 1$ (*i.e.*, the value of E'_0 is incorrect) and this mean value of V_e is inserted into equation (5), the equation will not give $y = 0$ for all V, [H′] pairs. Instead, y will have values denoted by Δy. Differentiation of equation (5) yields

$$\Delta y = -\Delta V_e + \Delta f\left\{K_{HA}V(\mathrm{H}') + \frac{V_0+V}{C}\left(K_{HA}\,2f[\mathrm{H}']^2 + [\mathrm{H}'] + \frac{K_w}{f^2[\mathrm{H}']}\right)\right\}$$

This equation is linear in ΔV_e and Δf. By use of calculated values of Δy from equation (5) and $f = 1$, these quantities may be calculated by linear regression. ΔV_e and Δf are used to correct V_e and f. The corrected values are in turn used to calculate new values of Δy by equation (5), and then new values of the differences ΔV_e and Δf are computed by equation (6) and so on. The iteration is repeated until two successive values of V_e differ by less than, for example, 0.01%.

The tolerable error in E'_0 which still gives convergence of the iteration to a correct result is at least ±60 mV (corresponding to an error in ph of ±1 unit). If desired, a corrected value of E'_0 may be obtained since $E'_0 = E'^{\text{guess}}_0 - 0.0592 \log f$ (at 25°C). In those cases where E'_j is not negligible when [H] is calculated, the following procedure is recommended: in the first approximation E'_j is neglected and a value of E'_0 is calculated according to the description above. This value of E'_0 is then used in calculating [H] values by using equation (2) and the calculations are repeated as described. Since E'_j in most cases is small, fast convergence may be expected.

When this method is used for titrations of many similar samples and the value of K_{HA} is unknown, an E'_0-titration is first performed. In the next titration, the first sample is titrated according to the Hofstee method, which gives the concentration of the sample and the value of K_{HA}. This value of K_{HA} is then used in the determination of the equivalence volumes of the other samples according to the proposed method.

Table 8. Titration error resulting from Method A, assuming an error of ±0.01 logarithmic units in log K_{HA} at different values of K_{HA} and C^0_{HA}. Ten titrant additions of equal volume are assumed

	7.0	0.10–1.00	<0.01
	8.0	0.10–1.00	0.04
	9.0	0.10–1.00	0.20
	10.0	0.10–1.00	1.7

The results of a study of the effect of an error in log K_{HA} on the determination of V_e according to the proposed method are summarized in Table 8. For moderate titration errors (up to a few per cent), the titration error is approximately proportional to the error in log K_{HA}.

In the discussion above it has been assumed that the value of K_w is known, since a very approximate value is usually enough. When the titrations are performed in the acidic range the terms in equation (5) which contain K_w are small and a rough value of K_w may be used. It can be shown that an approximate value of K_w is sufficient even when the titrations are run in the alkaline range, provided that the electrode is calibrated for hydroxide-ion concentration when K_{HA} is determined.

If an erroneous value of K_w is used when K_{HA} is determined by the Hofstee method and an E'_0-titration in the alkaline range, an erroneous value of K_{HA} is obtained, as said before (log K^{obtained}_{HA} = log $K_{HA} + \Delta pK_w$, where ΔpK_w is the error in pK_w). If these incorrect values of K_w and K_{HA} are used in the calculations according to the proposed method, the errors in K_{HA} and K_w cancel each other so that *a correct value of the equivalence volume is obtained.* The condition for this is that the terms $K_{HA}(V_0 + V)[H]^2/C$ and $(V_0 + V)[H]/C$ in equation (1) are negligible.

If a titration is carried out in both fairly acidic and alkaline solution, K_w must be accurately known for this method to be used. This is the case when titration points are taken both before and after the equivalence point when moderately strong acids are titrated. However, when such acids are titrated it is recommended that only points taken before the equivalence point be used in order to avoid interfering equilibria. (This will be discussed in a subsequent part of this series.)

Method B, intended for use when the stability constant is unknown

Putting $K'_{HA} = fK_{HA}$ and $K'_w = K_w/f$, equation (5) may be written

$$y = -V_e + V + K'_{HA}\left\{V[H'] + \frac{V_0 + V}{C}f[H']^2 - \frac{V_0 + V}{C}K'_w\right\} + \frac{V_0 + V}{C}\left\{f[H'] - \frac{K'_w}{[H']}\right\} \quad (7)$$

In this case the unknowns are V_e, K'_{HA}, f and K'_w. Approximate values of E'_0 and K_w are required. First values are calculated for V_e and K'_{HA} by linear regression, letting $f = 1$ and $y = 0$. If $f \neq 1$ and/or the value of K_w is incorrect, and these values and the calculated values of V_e and K'_{HA} are inserted into equation (7), it will not give $y = 0$ for all V, $[H']$ pairs, but values denoted by Δy. Differentiation of equation (7) yields

$$\Delta y = -\Delta V_e + \Delta K'_{HA}\left\{V[H'] + \frac{V_0 + V}{C}f[H']^2 - \frac{V_0 + V}{C}K'_w\right\} + \Delta f\frac{V_0 + V}{C}\left\{K'_{HA}[H']^2 + [H']\right\} - \Delta K'_w\frac{V_0 + V}{C}\left\{K'_{HA} + \frac{1}{[H']}\right\} \quad (8)$$

Linear regression yields ΔV_e, $\Delta K'_{HA}$, Δf and $\Delta K'_w$. The differences so obtained are used to correct V_e, K'_{HA}, f and K'_w. The same iteration procedure as described above is then repeated until the value of V_e remains constant during two cycles of iteration.

When titrations of moderately strong acids and very weak acids are evaluated, the number of parameters may be reduced to three. These cases will be treated in more detail since the results yielded by the Gran method are poor and the Hofstee method requires a very accurate calibration of the electrode system.

When a titration of a *moderately strong acid* is evaluated it is recommended to use only titration points taken before the equivalence point, as mentioned before. The terms containing K_w in equation (7) may then be neglected and the number of parameters reduced to three. The calculations yield values for V_e, K'_{HA} and f. It is possible to calculate subsequently K_{HA} and E'_0 according to $K_{HA} = K'_{HA}/f$ and $E'_0 = E'^{\text{guess}}_0 - 0.0592 \log f$ (at 25°).

In the cases where $E'_j = j_H[H]$ cannot be neglected, it is possible to use the same iteration procedure as described above (see method A).

A greater positive than negative error in the ph-values may be tolerated without impairing the convergence of the iteration. The tolerable positive error may, for all K_{HA} values in the range $1.5 \leq \log K_{HA} \leq 5$ ($C_{HA} = 0.01M$), amount to 2 units of ph. The maximum negative error that still gives convergence varies with K_{HA}. In the most unfavourable case, $\log K_{HA} = 1.5$ ($C_{HA} = 0.01M$), the negative error may not exceed 0.1 ph-units. (Our investigation was made assuming ten equidistant titration points in the range $a = 0.1$–1.0.)

When titrations of *very weak acids* are evaluated, $K'_{HA}(V_0 + V)f[H']^2/C$ and $(V_0 + V)f[H']/C$ in equation (7) can be neglected if points taken at the very beginning of the titration curve are omitted. The results give the values of V_e, K'_{HA} $(= fK_{HA})$ and K'_w $(= K_w/f)$.

For $\log K_{HA} \leq 10$ ($C_{HA} = 0.01M$), 2 or 3 iteration cycles are sufficient even when the error in E'_0 amounts to ± 60 mV (*i.e.*, an error in ph amounting to ± 1 unit) and in pK_w to ± 1 unit. At $\log K_{HA} = 11$, four cycles are needed (assuming ten equidistant points in the range $a = 0.1$–1.0 or 0.2–2.0).

CONCLUSION

The results of this study may be summarized as follows.

When strong acids ($K_{HA}C_{HA} < 10^{-1}$) are titrated, there is no reason for using the complete equation (1), as perfectly satisfactory results may be obtained by using the Gran function $(V_0 + V)[H] = f(V)$. Titrations of weak acids with K_{HA} values in the range $5 < \log K_{HA} < 8.5$ ($C_{HA} = 0.01\,M$) may satisfactorily be evaluated by using the Gran function $V[H] = f((V)$.

The Hofstee method is non-approximative and can be used to evaluate titrations of acids of most strengths. However, for those acidic strengths for which the Gran functions yield poor results, the Hofstee method requires accurate knowledge of E'_0.

In automatic titrations it is desirable to be able to use all the titration points in the evaluation. This is in most cases impossible with Gran's functions. Furthermore, it is not desirable to be forced to make time-consuming determinations of E'_0 before almost every sample titration, as required by Hofstee's method for some values of $K_{HA}C_{HA}$. This disadvantage can be overcome by using one of the two other non-approximate methods presented in this paper. These methods require only very approximate E'_0-values.

It will be shown in forthcoming communications how similar methods can be applied to titrations of mixtures of acids and acids and weak bases, and how the same principles can be used in photometric titrations.

Summary—A general method for evaluating titration data for mixtures of acids and for acids in mixture with weak bases is presented. Procedures are given that do not require absolute [H]-data, *i.e.*, relative [H]-data may be used. In most cases a very rough calibration of the electrode system is enough. Further, for simple systems, very approximate values of the stability constants are sufficient. As examples, the titration of the following are treated in some detail: a mixture of two acids, a diprotic acid, an acid in presence of its conjugate base, and an ampholyte.

In the first paper in this series,[1] the applicability of the Gran functions[2] and the Hofstee method[3] to titration of monoprotic acids was discussed and two non-approximate methods were introduced that can use relative values of the hydrogen-ion concentration [H]. By using these methods, it is thus not necessary to measure absolute [H]-values and a very rough calibration of the electrode system is enough. One of the methods does not even require knowledge of the stability constants of the acids. In this paper, the same approach will be extended to mixtures of acids and to acids mixed with weak bases. First, a general procedure for the treatment of these types of titrations will be given. Then, four common types of titrations will be treated in more detail, *viz.* those of a mixture of two acids, a diprotic acid, an acid in the presence of its conjugate base and an ampholyte.

The titration of mixtures of acids is a problem that has been treated by numerous analytical chemists in the past. Two acids in admixture with each other can quite simply be titrated if the stability constants K_{HA} of the acids differ enough. How great this difference should be when traditional methods are used is dependent on the ratio between the concentrations of the acids and on the method that is used to detect the equivalence points of the titration. As a rule of thumb, a difference of 4 logarithmic units is usually considered satisfactory for instrumental detection of the end-point. For smaller values of the difference, the acids will apparently be titrated simultaneously and the evaluation of the titration will become increasingly difficult, yielding less reliable results. Some specific reactions of the anions may be utilized in order to apparently strengthen one of the acids.[4] If a specific reaction is difficult to find, a mathematical approach to the problem can be used. During the years a wide variety of solutions to the problem have been suggested.

Auerbach and Smolczyk[5] derived mathematical expressions for the evaluation of a titration of two acids in a mixture (the acids could be mono-, di- or triprotic). They also gave an error function to make possible the estimation of which titration points will give the most accurate results. The concentrations of the acids are taken as mean values of the results calculated from these points.

Frisque and Meloche[6] gave a mèthod for calculating the concentrations of two monoprotic acids in a mixture from one titration point and the total acid concentration. The pH of the titration point giving the minimum error is calculated from the stability constants of the acids.

Purdie *et al.*[7] devised a method to compare data obtained by titration of a mixture of two acids with theoretical titration data calculated for several ratios of the concentrations of the two acids. By graphical interpolation they determined the relative amounts of the two acids and knowledge of the sum of the concentrations of the acids permitted them to calculate the amounts of the individual acids.

All the methods[5–7] referred to above require knowledge of the sum of the concentrations of the acids. This is a drawback since other weak electrolytes that might be present in the sample, as impurities in the titrant (*e.g.*, carbonate ions) or in the neutral salt used to keep the ionic strength constant, often make the determination uncertain. Determination of the total concentration is also difficult if the acids are weak (refer to Part I). The methods also require exact knowledge of the stability constants of the acids.

---

* Part I—*Talanta*, 1976, **23**, 769.

Methods for calculating the concentrations of two monoprotic acids in admixture with each other have been given by Komar,[8] Yui *et al.*[9,10] and Ivaska.[11,12] Ivaska[13] also gave a method for calculating the concentration of a diprotic acid. The methods require knowledge of the stability constants of the acids but not of the sum of the concentrations of the acids. Two titration points are enough for the calculations. If more points are used, better accuracy may be expected.

Kankare[14] devised a potentiostatic method for titrating mixtures of acids. This method has the advantage that the electrode system does not have to be calibrated. The sum of the concentrations of the acids must be known. Knowledge of the stability constants or of the "degree of deprotonation" of the acids is also required.

An error-minimization technique has been applied to the evaluation of mixtures of two acids by workers in this laboratory.[15] A similar technique has also been used by Meites *et al.*[16] for the titration of a weak acid contaminated by a small amount of a strong acid or base.

Midgley and McCallum gave a method for calculating the concentration of an acid in the presence of weak bases.[17] In the same paper they gave a method for the evaluation of a titration of a diprotic acid. The constants must be known. They also derived equations for the titration of a mixture of a weak acid (which may be polyprotic) and a strong acid.[18]

All the methods mentioned—Kankare's being the sole exception—require a very accurate calibration of the electrode system, *i.e.*, a very accurate determination of E'_0 (refer to Part I) should be made. This must be considered a drawback, especially in routine work, since it requires frequent and time-consuming E'_0-determinations. If the methods presented in this paper are used in calculating the equivalence volumes, approximate values of E'_0 and/or the stability constants are sufficient. The sum of the concentrations need not be known.

A GENERAL PROCEDURE FOR THE EVALUATION OF A TITRATION OF A MIXTURE OF ACIDS IN THE PRESENCE OF WEAK BASES

We assume that n acids having initial analytical concentrations $C^0_{HA_i}$ (*i.e.*, the total concentration irrespective of form) are titrated with V ml of a solution of strong base, *e.g.*, sodium hydroxide, of concentration C. There are also m weak bases present in the mixture, their initial analytical concentrations being $C^0_{B_j}$. The volume at the beginning of the titration is V_0 ml.

The stability constant (given in terms of concentrations of the different species and determined in a well-defined ionic medium) is given for the acid HA_i by

$$K_{HA_i} = \frac{[HA_i]}{[H][A_i]} \qquad (1)$$

if the charges are omitted for convenience. The stability constant of the conjugate acid HB_j of the base B_j is similarly given by

$$K_{HB_j} = \frac{[HB_j]}{[H][B_j]} \qquad (2)$$

and it is understood that $K_{HA_i} > K_{HB_j}$.

The total concentration of the acid HA_i when V ml of titrant have been added is

$$C_{HA_i} = [HA_i] + [A_i] = \frac{V_0 C^0_{HA_i}}{(V_0 + V)} \qquad (3)$$

Correspondingly, for the base B_j:

$$C_{B_j} = [HB_j] + [B_j] = \frac{V_0 C^0_{B_j}}{(V_0 + V)} \qquad (4)$$

The analytical concentration of added strong base, C_{OH}, in the solution is given by

$$C_{OH} = [OH] + \sum_i [A_i] - \sum_j [HB_j] - [H] \qquad (5)$$

Combination of equations (1) and (3) yields

$$[A_i] = \frac{V_0 C^0_{HA_i}}{(V_0 + V)(1 + [H]K_{HA_i})} \qquad (6)$$

and by combining equations (2) and (4) we obtain

$$[HB_j] = \frac{V_0 C^0_{B_j}}{(V_0 + V)}\left(1 - \frac{1}{1 + [H]K_{HB_j}}\right) \qquad (7)$$

The analytical concentration of added base is related to the concentration of the titrant by

$$C_{OH} = \frac{VC}{(V_0 + V)} \qquad (8)$$

By combining equations (5)–(8) we finally obtain

$$\sum_i \frac{V_0 C^0_{HA_i}}{1 + [H]K_{HA_i}} - \sum_j V_0 C^0_{B_j}\left(1 - \frac{1}{1 + [H]K_{HB_j}}\right) - (V_0 + V)\left([H] - \frac{K_w}{[H]}\right) - VC = 0 \qquad (9)$$

Equation (9) is valid for monoprotic acids and bases. Polyprotic acids and bases may under certain conditions be treated as mixtures of monoprotic species.[19,20] The constants for di- and polyprotic acids will then be titration constants and not true stability constants (*vide infra*).

In equation (9), V_0 and C are assumed to be known quantities. [H] is measured for different values of V. Furthermore, if K_{HA_i}, K_{HB_j} and K_w are known, then equation (9) is linear in $C^0_{HA_i}$ and $C^0_{B_j}$. In principle, $n + m$ corresponding values of V and [H] are sufficient to make possible the calculation of $C^0_{HA_i}$ and $C^0_{B_j}$. If there are more values of V and [H], equation (9) is solved for $C^0_{HA_i}$ and $C^0_{B_j}$ by linear regression analysis. Numerous manufacturers of computers have the necessary software ready for linear regression analysis. It should be noted that the accuracy of $C^0_{B_j}$ will be much less than the accuracy of $C^0_{HA_i}$.

Errors in the values of K_{HA_i}, K_{HB_j} and K_w (the constants may be known only approximately) give rise to errors in the resulting values of $C^0_{HA_i}$ and $C^0_{B_j}$. This is a problem that may often be solved by using a non-linear least squares method. Equation (9) may be written:

$$y = \sum_i \frac{V_0 C^0_{HA_i}}{1 + [H]K_{HA_i}} - \sum_j V_0 C^0_{B_j}\left(1 - \frac{1}{1 + [H]K_{HB_j}}\right) - (V_0 + V)\left([H] - \frac{K_w}{[H]}\right) - VC \qquad (10)$$

If incorrect values of K_{HA_i}, K_{HB_j} and K_w are used, equation (10) will not give $y = 0$ for all (V, [H])-pairs. Instead, y will have values denoted by Δy. Differentiation of equation (10) yields:

$$\Delta y = \sum_i r_{1i}\Delta C^0_{HA_i} + \sum_i r_{2i}\Delta K_{HA_i} + \sum_j r_{3j}\Delta C^0_{B_j} + \sum_j r_{4j}\Delta K_{HB_j} + r_5\Delta K_w \qquad (11)$$

where

$$r_{1i} = \frac{V_0}{1 + [H]K_{HA_i}}$$

$$r_{2i} = -\frac{V_0 C^0_{HA_i}[H]}{(1 + [H]K_{HA_i})^2}$$

$$r_{3j} = \frac{V_0}{1 + [H]K_{HB_j}} - V_0$$

$$r_{4j} = -\frac{V_0 C^0_{B_j}[H]}{(1 + [H]K_{HB_j})^2}$$

$$r_5 = (V_0 + V)/[H]$$

Equation (11) is linear in $\Delta C^0_{HA_i}$, $\Delta C^0_{B_j}$, ΔK_{HA_i}, ΔK_{HB_j} and ΔK_w. These quantities can be calculated by linear regression if the approximate values for K_{HA_i}, K_{HB_j} and K_w and the calculated values for $C^0_{HA_i}$ and $C^0_{B_j}$ are used. This requires at least $2(n + m) + 1$ corresponding values of V and [H]. The values of the difference so obtained are then used to correct the values of $C^0_{HA_i}$, $C^0_{B_j}$, K_{HA_i}, K_{HB_j} and K_w. New values of the differences are then obtained by using equations (10) and (11), and so on. The iteration is repeated until the value of $C^0_{HA_i}$ does not change by more than, for example, 0.01%.

Use of relative [H]*-values*

In the foregoing, absolute measurement of [H] has been presupposed. This implies that E'_0 (see Part I) for the electrode system in use is determined as accurately as possible. In the following, the possibility of calculating $C^0_{HA_i}$, though E'_0 is only approximately known, will be demonstrated. An error in the ph-values, denoted by Δph (ph = $-\log[H]$), introduced by an erroneous value of E'_0 will result in an incorrect [H] denoted by [H′]. Consequently,

$$[H'] = 10^{-(\mathrm{ph}+\Delta\mathrm{ph})} = [H]10^{-\Delta\mathrm{ph}} = [H]/f$$

where $f = 10^{\Delta\mathrm{ph}}$. Putting $K'_{HA_i} = fK_{HA_i}$, $K'_{HB_j} = fK_{HB_j}$ and $K'_w = K_w/f$, equation (10) may be written:

$$y = \sum_i \frac{V_0 C^0_{HA_i}}{1 + [H']K'_{HA_i}} - \sum_j V_0 C^0_{B_j}\left(1 - \frac{1}{1 + [H']K'_{HB_j}}\right) - (V_0 + V)\left(f[H'] - \frac{K'_w}{[H']}\right) - VC \qquad (12)$$

Differentiation of equation (12) yields:

$$\Delta y = \sum_i r'_{1i}\Delta C^0_{HA_i} + \sum_i r'_{2i}\Delta K'_{HA_i} + \sum_j r'_{3j}\Delta C^0_{B_j} + \sum_j r'_{4j}\Delta K'_{HB_j} + r'_5\Delta K'_w + r'_6\Delta f \qquad (13)$$

Here, $r'_{1i} - r'_5$ are defined as $r_{1i} - r_5$ above, except that K_{HA_i}, K_{HB_j}, K_w and [H] are replaced by K'_{HA_i}, K'_{HB_j}, K'_w and [H′], respectively; r'_6 is defined by

$$r'_6 = -(V_0 + V)[H'] \qquad (14)$$

Equation (12) is solved for $C^0_{HA_i}$ and $C^0_{B_j}$ by using approximate values of K'_{HA_i}, K'_{HB_j} and K'_w, and $f = 1$ (letting $y = 0$). Values of $\Delta C^0_{HA_i}$, $\Delta K'_{HA_i}$, $\Delta C^0_{B_j}$, $\Delta K'_{HB_j}$, $\Delta K'_w$ and Δf are then obtained from equation (13) by linear regression. The same iteration procedure as described is then repeated until the value of $C^0_{HA_i}$ remains constant during two cycles of iteration.

The number of parameters may in practice often be reduced by one. In *the acidic range* it is possible to neglect the term $(V_0 + V)K'_w/[H']$ in equation (12), and in *the alkaline range* $(V_0 + V)f[H']$ can be neglected. In the latter case K'_w $(=K_w/f)$ and not f appears as a parameter.

It is only for titration of rather simple systems that all parameters can be determined from a moderate number of titration points. This means calculation of the concentrations, and refinement of the constants and f. Examples are: most diprotic acids, an acid in the presence of its conjugate base and a mixture of two acids in about equal concentrations and having log K_{HA}-values that differ by 2 logarithmic units or more. For more complicated systems the iteration procedure will converge either not at all or only very slowly and with possibly poor accuracy of the results.

Further, the approximate values assigned to K_{HA_i}, K_{HB_j}, f and K_w must not differ too much from the correct values in order to give convergence. The more complicated the system is, the closer must the approximate values be to the correct ones.

The number of parameters can be reduced by measuring E'_0 as exactly as possible and/or determining some or all of the stability constants.

For routine work where many similar samples are to be titrated, a method that does not need an accurate value of E'_0 is desirable. Otherwise, too frequent E'_0-determinations with consequent low analysis rate would be required. A determination of the stability constants will often prove worthwhile even in cases when it is not essential in order to obtain convergence, as this will result in faster convergence and reduced computing times. The stability constants of monoprotic species are easily determined by the Hofstee method as described in Part I. (It should be noted that this method does not demand that the acid or base is completely pure; however, the impurities must not be interfering protolytes.) A method for determining the stability constants of a diprotic acid will be given below.

Convergence, precision and accuracy will be treated in more detail for a special case: titration of a mixture of two acids. Subsequently, some common titration problems will be treated that cannot be evaluated by the Gran method or by any of the methods presented in Part I that use points taken before the equivalence point (the drawbacks of using points taken after the equivalence point have already been discussed above). These problems include titration of (*i*) a diprotic acid, (*ii*) an acid in presence of its conjugate base (*e.g.*, acetic acid in presence of acetate ions) and (*iii*) an ampholyte (*e.g.*, potassium hydrogen phthalate).

TITRATION OF A MIXTURE OF TWO MONOPROTIC ACIDS

The stability constants of the acids are denoted by K_{HA_1} and K_{HA_2} and their initial total concentrations by $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$. The titration is assumed to be carried out in the acidic range so that the term $(V_0 + V)K_w/[\mathrm{H}]$ can be neglected. For calculation of $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ from the titration points (V, [H]), four different cases may be distinguished, depending on how many of the parameters K_{HA_1}, K_{HA_2} and f are to be refined.

1. *Refinement of* K_{HA_1}, K_{HA_2} *and* f. The calculation of $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ is based on equations (12) and (13). In this special case, equation (12) gives:

$$y = \frac{V_0C^0_{\mathrm{HA}_1}}{1 + [\mathrm{H}']K'_{\mathrm{HA}_1}} + \frac{V_0C^0_{\mathrm{HA}_2}}{1 + [\mathrm{H}']K'_{\mathrm{HA}_2}} - (V_0 + V)f[\mathrm{H}'] - VC$$

where $[\mathrm{H}'] = [\mathrm{H}]/f$, $K'_{\mathrm{HA}_1} = fK_{\mathrm{HA}_1}$ and $K'_{\mathrm{HA}_2} = fK_{\mathrm{HA}_2}$. Equation (13) gives:

$$\Delta y = r'_{11}\Delta C^0_{\mathrm{HA}_1} + r'_{12}\Delta C^0_{\mathrm{HA}_2} + r'_{21}\Delta K'_{\mathrm{HA}_1} + r'_{22}\Delta K'_{\mathrm{HA}_2} + r'_6\Delta f$$

where

$$r'_{11} = \frac{V_0}{1 + [\mathrm{H}']K'_{\mathrm{HA}_1}}$$

$$r'_{12} = \frac{V_0}{1 + [\mathrm{H}']K'_{\mathrm{HA}_2}}$$

$$r'_{21} = -\frac{V_0C^0_{\mathrm{HA}_1}[\mathrm{H}']}{(1 + [\mathrm{H}']K'_{\mathrm{HA}_1})^2}$$

$$r'_{22} = -\frac{V_0C^0_{\mathrm{HA}_2}[\mathrm{H}']}{(1 + [\mathrm{H}']K'_{\mathrm{HA}_2})^2}$$

$$r'_6 = -(V_0 + V)[\mathrm{H}']$$

$C^0_{\mathrm{HA}_1}$, $C^0_{\mathrm{HA}_2}$, K_{HA_1} $(=K'_{\mathrm{HA}_1}/f)$, K_{HA_2} $(=K'_{\mathrm{HA}_2}/f)$ and f are then calculated by the same procedure as described above.

2. *Refinement of* K_{HA_1} *and* K_{HA_2} *when* E'_0 *is known.* The calculation of $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ is based on equations (10) and (11). In this case, equation (10) gives:

$$y = \frac{V_0C^0_{\mathrm{HA}_1}}{1 + [\mathrm{H}]K_{\mathrm{HA}_1}} + \frac{V_0C^0_{\mathrm{HA}_2}}{1 + [\mathrm{H}]K_{\mathrm{HA}_2}} - (V_0 + V)[\mathrm{H}] - VC$$

Equation (11) gives:

$$\Delta y = r_{11}\Delta C^0_{\mathrm{HA}_1} + r_{12}\Delta C^0_{\mathrm{HA}_2} + r_{21}\Delta K_{\mathrm{HA}_1} + r_{22}\Delta K_{\mathrm{HA}_2}$$

where

$$r_{11} = \frac{V_0}{1 + [\mathrm{H}]K_{\mathrm{HA}_1}}$$

$$r_{12} = \frac{V_0}{1 + [\mathrm{H}]K_{\mathrm{HA}_2}}$$

$$r_{21} = -\frac{V_0C^0_{\mathrm{HA}_1}[\mathrm{H}]}{(1 + [\mathrm{H}]K_{\mathrm{HA}_1})^2}$$

$$r_{22} = -\frac{V_0C^0_{\mathrm{HA}_2}[\mathrm{H}]}{(1 + [\mathrm{H}]K_{\mathrm{HA}_2})^2}$$

3. *Refinement of* f *with known* K_{HA_1} *and* K_{HA_2}. With $[\mathrm{H}] = f[\mathrm{H}']$, equation (10) gives:

$$y = \frac{V_0C^0_{\mathrm{HA}_1}}{1 + f[\mathrm{H}']K_{\mathrm{HA}_1}} + \frac{V_0C^0_{\mathrm{HA}_2}}{1 + f[\mathrm{H}']K_{\mathrm{HA}_2}} - (V_0 + V)f[\mathrm{H}'] - VC \quad (15)$$

Differentiation of equation (15) gives:

$$\Delta y = r'_{11}\Delta C^0_{\mathrm{HA}_1} + r'_{12}\Delta C^0_{\mathrm{HA}_2} + r'_7\Delta f \quad (16)$$

where

$$r'_{11} = \frac{V_0}{1 + f[\mathrm{H}']K_{\mathrm{HA}_1}}$$

$$r'_{12} = \frac{V_0}{1 + f[\mathrm{H}']K_{\mathrm{HA}_2}}$$

$$r'_7 = -\frac{V_0C^0_{\mathrm{HA}_1}[\mathrm{H}']K_{\mathrm{HA}_1}}{(1 + f[\mathrm{H}']K_{\mathrm{HA}_1})^2} - \frac{V_0C^0_{\mathrm{HA}_2}[\mathrm{H}']K_{\mathrm{HA}_2}}{(1 + f[\mathrm{H}']K_{\mathrm{HA}_2})^2} - (V_0 + V)[\mathrm{H}']$$

Approximate values of $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ are calculated by equation (15), using linear regression and putting $f = 1$ and $y = 0$. Then corrections for $C^0_{\mathrm{HA}_1}$, $C^0_{\mathrm{HA}_2}$ and f are calculated by equation (16), and so on.

4. K_{HA_1}, K_{HA_2} *and* E'_0 *are known.* In this case the problem of calculating $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ is simply solved by linear regression with two parameters. It is also possible to solve it graphically, in which case one of the parameters is obtained from the intercept of a straight line with the *y*-axis and the other is calculated from the slope of the line.

Before deciding on a method, one should check whether the calculations give accurate results and how well the parameters that are to be refined must be known so that convergence of the iteration procedure is obtained. Table 1 shows the accuracy obtained by the four different methods described above for evaluating the results when mixtures of two acids are titrated with 0.1*M* sodium hydroxide. The stability constants and the concentrations of the acids are given in the table. Nine equal additions of titrant in the range $a = 0.1$–0.9 ($\Delta a = 0.1$) were assumed, a being the titration parameter defined by $a = VC/(V_0C^0_{\mathrm{HA}_1} + V_0C^0_{\mathrm{HA}_2})$. The results in the table were obtained by

Table 1. Random titration errors obtained with synthetic titration data of a mixture of two acids with properties shown in the first column when the parameters shown in the second column are refined. Exactly correct V-values and ph-values that were correct to the third decimal place were used in the calculation

using theoretically calculated values of ph, correct to three decimal places. The values of V were exact. This way of testing the evaluation methods gives an idea of their relative precisions. The data in the table give a representative selection from many calculations based on different values of the stability constants and the concentrations of the acids. The results may therefore be used to compare the different methods. As is seen from the table, it is possible to use approximate values of K_{HA_1}, K_{HA_2} and f but still calculate accurate values of $C^0_{\mathrm{HA}_1}$ and $C^0_{\mathrm{HA}_2}$ if there is a sufficient difference between the stability constants. When the difference between the stability constants decreases and/or the disproportion between the concentrations of the acids increases, the value of f—or better—the values of K_{HA_1} and K_{HA_2} must be known. Another way of improving the results in such a situation is by increasing the number of titration points. As seen from the table, determination of K_{HA_1} and K_{HA_2} in separate experiments and refinement of f gives accurate results even when the difference between the constants is small. This is also an attractive way of working for automatic titrations of many similar samples. As already mentioned, the Hofstee method can be used to determine the stability constant of a monoprotic acid. Experiments with formic acid

Table 2. Maximum errors in log K_{HA} and ph (E'_0) that give convergence of the calculations in evaluating titrations of a mixture of two acids. The first two subcolumns in the third column give the tolerable errors in K_{HA_i} for small errors in ph, and the tolerable errors in ph for small errors in K_{HA_i}. The third subcolumn illustrates the situation when both errors are of the same magnitude

* $\Delta \mathrm{p}K_w$ may in this case amount to ±1 [see equation (14)].

and propionic acid show that the values obtained by the Hofstee method are also valid for mixtures. Our method gives rather accurate values of f in addition to $C^0_{HA_1}$ and $C^0_{HA_2}$. Therefore, it is possible to calculate E'_0 by

$$E'_0 = E'^{\text{guess}}_0 - 0.0592 \log f \qquad (17)$$

and this E'_0-value can be used as a good starting value for E'_0 in the next titration, which is an advantage.

Table 2 gives the maximum errors that can be tolerated in the initial values of E'_0 (expressed as Δph) and K_{HA_1} and K_{HA_2} for some values of the stability constants and the concentrations. If the errors are greater, the iteration procedures either do not converge or converge to a completely wrong result. The values in Table 2 were calculated assuming titration with $0.1M$ sodium hydroxide and nine titration points with $\Delta a = 0.1$. The number of cycles required to give convergence to the correct result (the criterion here being less than 0.01% difference in $C^0_{HA_1}$ between two subsequent cycles) for the extreme values of $|\Delta \log K_{HA}|$ and $|\Delta ph|$ lies within the range 3–10. Greater errors can be tolerated if damping factors are employed. [The equations for Δy were derived assuming that the correction terms $\Delta C^0_{HA_1}$ *etc.* are very small. For greater values of the correction terms the equations do not hold exactly.] The use of damping factors implies computation of Σy^2 from the first calculated values of $C^0_{HA_1}$ and $C^0_{HA_2}$ and the approximately known values of K_{HA_1}, K_{HA_2} and f, then adjustment of these values by adding the correction terms $\Delta C^0_{HA_1}$, $\Delta C^0_{HA_2}$, ΔK_{HA_1}, ΔK_{HA_2} and Δf. The corrected values are then used to compute a new value of Σy^2. If this new value is less than the previous one the iteration procedure is continued. If the new value is greater than the first the correction terms are divided by a damping factor R which is first given the value 2. A new value of Σy^2 is computed and compared with the first. If it is still greater than this, the value of R is put equal to 4 (8, 16, 32 and so on) until the new value of Σy^2 is less than the first value. The iteration is then continued.

Examples. A mixture of two acids having $\log K_{HA_1} = 2$ and $\log K_{HA_2} = 4$ and $C^0_{HA_1} = C^0_{HA_2} = 0.005M$ is titrated. K_{HA_1}, K_{HA_2} and f are refined. Nine titration points with $\Delta a = 0.1$ are assumed. Without using damping factors the maximum tolerable errors are: $|\Delta \log K_{HA_i}| \leq 0.3$, $|\Delta ph| \leq 0.15$. With damping factors the tolerable errors are increased to $|\Delta \log K_{HA_i}| \leq 0.7$, $|\Delta ph| \leq 0.3$. In a similar case with $\log K_{HA_1} = 3$, $\log K_{HA_2} = 4$, $C^0_{HA_1} = 0.0075M$ and $C^0_{HA_2} = 0.0025M$, the maximum tolerable errors without the use of damping factors are $|\Delta \log K_{HA_i}| \leq 0.08$, $|\Delta ph| \leq 0.07$. With damping factors the corresponding values are $|\Delta \log K_{HA_i}| \leq 0.2$, $|\Delta ph| \leq 0.15$. It should be noted that the convergence will be slow in the cases when damping factors must be used.

Table 3 gives the errors in the calculated values of $C^0_{HA_1}$ and $C^0_{HA_2}$ that are introduced by an erroneous value of E'_0 if f is not refined. A value of $\Delta ph = \pm 0.002$ has been assumed. The table was calculated assuming titration with $0.1M$ sodium hydroxide, nine additions and $\Delta a = 0.1$. Moderate titration errors (up to a few per cent) are approximately proportional to the Δph-values.

Table 4, based on the same assumptions regarding titrant, number of titration points and distance between the points as Table 3, lists the errors in the calculated values of $C^0_{HA_1}$ and $C^0_{HA_2}$ that are introduced by using erroneous values of K_{HA_1} and K_{HA_2} if these are not refined. The error in the values of the logarithmic constants, $\Delta \log K_{HA_i}$, was assumed to be ± 0.002. The concentration errors were calculated for the most unfavourable case, *i.e.*, a positive error in K_{HA_1} and a negative error in K_{HA_2} (or the other way round). For positive (or negative) errors in both constants, the titration errors will be smaller, smallest when the titration points are obtained in the ph-range around ph = 7.

From the preceding tables it may be concluded that

when the difference between the stability constants of the acids is small, it will be advantageous to determine K_{HA_1} and K_{HA_2} in separate experiments. *When these quantities are known there is rarely much to be gained by an accurate determination of* E'_0. This is because the error in E'_0 is then added to the errors in the log K_{HA_i}-values and the resulting systematic error will often be greater than the random error introduced by the additional refinement of f (refer to Tables 1 and 3). When there is sufficient difference between the stability constants, all parameters can be refined, but faster convergence and less computational work can be expected if even in this case the constants are determined in separate experiments.

Titration of *a strong and a weak acid* is a special case of titration of two acids since, by definition, one of the acids is completely dissociated. Thus, the same value may always be assigned to the stability constant of the strong acid, *e.g.*, 10^{-10}. There is nothing to be gained by refining the value of this constant during the calculation and the number of parameters to be refined is therefore reduced by one.

TITRATION OF DIPROTIC ACIDS

If the difference between the successive stability constants of the diprotic acid is not less than about 0.6 logarithmic units,[19] the evaluation of the titration of a diprotic acid is the same as that of two monoprotic acids having $C^0_{HA_1} = C^0_{HA_2}$.

The number of parameters is consequently reduced by one, owing to the condition that $C^0_{HA} = C^0_{HA_1} = C^0_{HA_2}$. However, the "titration constants" that result by refining initially given approximate values of K_{HA_1} and K_{HA_2} are not identical with the true stability constants of the diprotic acid. The stability constants can be obtained from the titration constants or *vice versa*, according to Simms[20] or Klas.[21] If, for a certain titration problem, refinement of the constants is not desired, titration constants and not true stability constants should be used in the calculations. In the example below, the titration constants are denoted by K_1 and K_2 (generally K_n).

As an example, a titration of a 0.005M solution of an acid having $\log K_1 = 3$ and $\log K_2 = 4$, with 0.1M sodium hydroxide, will be considered. Nine titration points are used and $\Delta a = 0.1$. The parameters are C^0_{HA}, K'_1, K'_2 and f. The conditions for convergence are $|\Delta \log K_n| \leq 0.2$, $|\Delta \mathrm{ph}| \leq 0.5$, $|\Delta \log K_n| + |\Delta \mathrm{ph}| \leq 0.2$ (see text to Table 2). In addition to the concentration of the acid the results will thus comprise values of K_1, K_2 and f. It is thereby possible to calculate a good, approximate value of E'_0 by equation (17). As said before, this is an advantage in automatic titrations. The values of the titration constants can be obtained from $K_1 = K'_1/f$ and $K_2 = K'_2/f$. The values of the constants that are obtained when both f and K_1, K_2 are refined will not be highly accurate. If the intention is *to determine the constants*, E'_0 should be determined by an E'_0-titration before the sample is titrated and f should not be refined.

TITRATION OF AN ACID IN THE PRESENCE OF ITS CONJUGATE BASE

The parameters are C^0_{HA}, $C^0_A (= C^0_B)$, K_{HA} and f. This is a special case of a titration of a mixture of an acid and a weak base, having $K_{HA} = K_{HB}$. As an example, a titration of a 0.01M solution of an acid having $\log K_{HA} = 3.5$, with 0.1M sodium hydroxide, in the presence of 0.01M concentration of the conjugate base has been studied. Nine titration points with $\Delta a = 0.1$ were assumed. The conditions for convergence for calculation of C^0_{HA} and C^0_A with refinement of K_{HA} and f are

$$|\Delta \log K_{HA}| \leq 0.7, |\Delta \mathrm{ph}| \leq 1$$

$$|\Delta \log K_{HA}| + |\Delta \mathrm{ph}| \leq 0.7.$$

It should be noted, however, that when this method is used, an accurate value will be obtained for C_{HA}^0 only, whereas the values of C_A^0, K_{HA} and f will be approximate.

When determining the concentrations of many similar samples by automated analysis it may be worthwhile to determine the value of K_{HA} by the Hofstee method. This will reduce the computations appreciably. If this is done, values of C_{HA}^0 and C_A^0 are calculated and the value of f (initially put = 1) is refined. Use of this method will yield an accurate value of f which may be used to calculate an accurate value of E_0' by equation (17). This value of E_0' is subsequently used in the next titration, resulting in fast convergence and saving of computation time. For the example above, an error as large as ± 0.1 in $\log K_{HA}$ gives an error $<0.1\%$ in C_{HA}^0.

TITRATION OF AN AMPHOLYTE

This, too, is a special case of titration of a mixture of an acid and a weak base, but here $C_{HA}^0 = C_B^0$. The parameters are C_{HA}^0, f, K_{HA} and K_{HB}.

The example given is a titration of a $0.01M$ solution of an ampholyte having $\log K_{HA} = 5$ and $\log K_{HB} = 3$. Nine titration points having $\Delta a = 0.1$ are assumed. Refinement of all parameters gives slow convergence and not very accurate results. However, even if f is not refined, a large error in E_0' can be tolerated without impairing the result. A systematic error in ph corresponding to $|\Delta \text{ph}| = 0.3$ gives a titration error of less than 0.1%. Fast convergence and accurate results are obtained. The condition for convergence is $|\Delta \log K_{HA}| \leq 0.3$. The value of $\log K_{HB}$ may be set = 0.

Here, it would be appropriate to use "titration constants". However, for the sake of clearness, the notations K_{HA} and K_{HB} have been retained.

CONCLUSION

What distinguishes the proposed methods presented in this paper and in Part I from most other mathematical approaches to evaluation of titrations is that it is sufficient to use approximate E_0'-values, *i.e.*, often a very rough calibration of the electrode system is sufficient. Further, for titrations of monoprotic acids it is not necessary to know the stability constants of the acids. For other titrations, *e.g.*, mixtures of acids having stability constants that differ by more than 2 logarithmic units, and of most diprotic acids, it is mostly sufficient to know approximate values for the constants. When the values of the constants are unknown they may be guessed and, if necessary, the guessing is repeated until the calculations converge. For more complicated titrations, such as titrations of mixtures of acids with a small difference between their stability constants, knowledge of the constants is required for accurate results. For monoprotic and diprotic acids these constants are easy to determine, as described. An advantage of the proposed methods when mixtures of acids are titrated is that it is not necessary to determine separately the sum of the concentrations of the acids.

The method of stepwise addition of titrant, combined with the proposed evaluation methods, has the following advantages in comparison with conventional titration methods: it makes possible the titration of very weak acids (*e.g.*, $\log K_{HA} = 10$–11, $C_{HA} = 0.01M$) that cannot be determined by conventional methods in aqueous medium and also titration of a mixture of two acids with a small difference between the stability constants. Further, the results can be evaluated statistically and systematic errors traced.

Another advantage is that the method is very suitable for automation and experimental results supporting the theories presented in Parts I and II have been achieved by using an automatic apparatus. These results and the apparatus will be presented in Part III.

There are, of course, titration problems that can be solved equally well by conventional methods as by the methods presented in these papers. Part of the aim of these papers has, however, been to devise methods that make possible the solution of most titration problems by using similar or closely related techniques.

ACCURACY OF ANALYSIS OF STEELS BY USE OF A SPARK-SOURCE MASS SPECTROMETER WITH ELECTRICAL DETECTION

E. VAN HOYE, F. ADAMS and R. GIJBELS

(*Received* 12 *April* 1976. *Accepted* 23 *April* 1976)

Summary—The precision and accuracy of spark-source mass spectrometry with electrical detection has been studied, with five steel standard reference materials (NBS-SRM 661–665). Two different modes of analysis have been evaluated, magnetic scanning with electrical detection of the individual ions in sequence, using the total ion-current as reference, and magnetic switching between masses, with current integration. Measurements of isotope abundances have been used to evaluate the precision. The relative sensitivity coefficients of Ti, V, Cr, Mn, Co, Ni, Cu, As, Zr, Nb, Mo, Sb, La, Ta and W have been determined *vs.* iron as an internal standard. The accuracy of analyses based on these experimentally measured relative sensitivity coefficients was confirmed by comparing the results for a pure iron sample with those obtained by neutron-activation analysis.

In spark-source mass spectrometry two different modes of operation are possible with electrical detection, scanning of the mass spectrum with simultaneous detection of the total ion-current and switching to specifically chosen masses before a measurement until a preset total ion-current signal is reached. Several workers[1–4] have determined the precision of the peak-switching mode to be 2–5% relative standard deviation for several metals. This contrasts with a precision of 10–20% obtainable with photographic ion-detection.[5,6]

Standard reference materials are required for the experimental determination of the relative sensitivity coefficients (S_R). In this paper the coefficient for element x is defined as $S_R(x/y)_z$ and is equal to the ratio of the concentrations of elements x and y in the matrix material z as determined from the singly-charged ions, divided by the true concentration ratio:

$$S_R(x/y)_z = [(C_x/C_y)_{ms}/(C_x/C_y)_{true}]_z.$$

For steel standards, iron can conveniently be used as the reference element. Experimentally determined coefficients obtained by electrical detection with NBS steel standards have been published by Capellen, Conzemius and Svec,[7] Hull [8] and Blanchard.[9]

In this paper we report the precision and accuracy obtained for the analysis of steel by use of electrical detection in the magnetic scanning and peak-switching modes. In a previous paper[6] a similar study was described for the same samples and photographic ion-detection.

EXPERIMENTAL

Apparatus

The experiments were performed with a double-focusing mass spectrometer with Mattauch–Herzog geometry (JMS-01 BM-2, JEOL, Tokyo), incorporating an automatic spark-control system (MS-AS-01, JEOL) which allows continuous sparking between the electrodes by vibration of one electrode and control of the spark gap by shifting the other electrode by means of a servo-motor. The total ion-current is kept constant with an ion-beam control unit. When a preset value is reached, an electrostatic field is applied between two beam-suppressing plates to deflect the ions, preventing them from entering the analyser.

The electrical detection system (MS-ED-01, JEOL) has two modes of operation, as follows.

Magnetic scanning. While the sample is sparking, the magnetic field is increased linearly or decreased exponen-

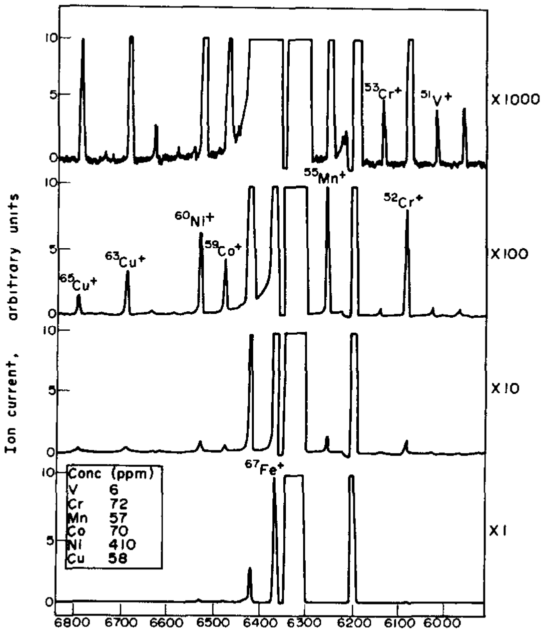

Fig. 1. Part of a mass spectrum with linear ratio scan output. Sample, NBS-SRM 665 steel standard.

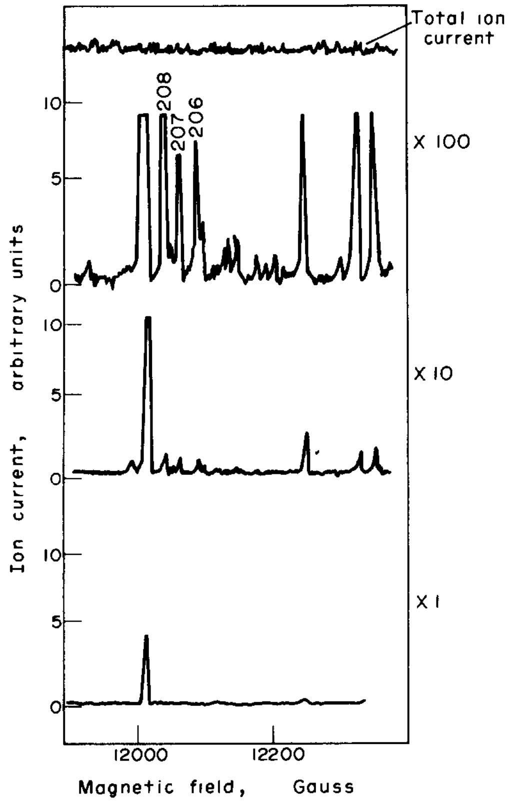

Fig. 2. Part of a mass spectrum with linear ratio scan output. Sample, NBS-SRM 661 steel standard (concentration Pb: 0.25 ppm).

tially, so that the ions of the individual isotopic species are swept sequentially across the first Cu–Be dynode of a 20-stage electron multiplier. The ratio of the instantaneous collector current to the total ion-current of the unresolved ion-beam is recorded with a 4-channel strip-chart recorder. The sensitivity of adjacent traces varies by a factor of 10, so that a dynamic concentration range of more than 10^5 is covered in a single scan. The magnetic field strength is also indicated at every 100 gauss. An example of part of a mass spectrum is shown in Fig. 1. The sensitivity of the technique is about 0.1 ppm. Figure 2 shows a mass spectrum of the isotopes of lead in the NBS-SRM 661 steel standard, the lead being present at a concentration of 0.25 ppm. One channel is used here to indicate the total ion-current, the others the mass spectrum.

Magnetic peak-switching. In this mode, 6 channels are available. The magnetic field can be switched to preset values at which the ion-beams of the isotopes of interest are detected by the electron multiplier. For each mass selected the collector current is integrated until a predetermined charge has been collected at the total ion-beam monitor. The ion-beam is then automatically switched off and the magnetic field is changed to a value corresponding to the next mass selected for measurement. The results are displayed on a digital voltmeter and are also printed. The sensitivity obtainable in this mode is more than 3 times better than that with the scanning mode.

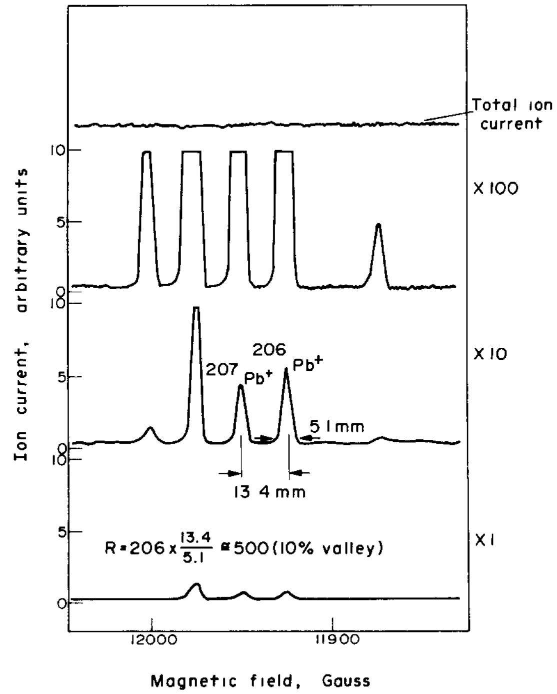

Fig. 4. Part of a mass spectrum showing the resolution for the magnetic scanning mode. Sample, NBS-SRM 664 steel standard.

Samples

The standard reference materials NBS-SRM 661–665 were used. They have been described elsewhere.[6] A high-purity iron sample, prepared for the "Verein Deutscher Eisenhüttenleute" was also analysed. It has already been studied by neutron-activation analysis.[10] The samples were prepared as described earlier,[6] but in order to improve the location of the spark, a portion of the top of both electrodes was cut away, leaving only a quarter of the original surface (Fig. 3).

Mass-spectrometry procedure

The width of the slits was adjusted as follows: object slit 100 μm, α-slit (in front of the electrostatic field) 2.0 mm,

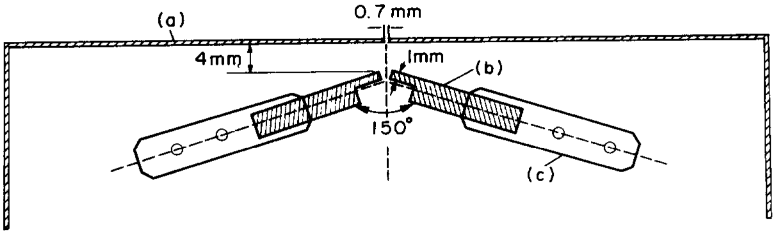

Fig. 3. Electrode geometry. (a) accelerating slit (tantalum), (b) sample electrode, (c) sample-holder (tantalum).

β-slit (energy-defining slit—behind the electrostatic field) 2.0 mm and collector slit 250 μm.

The following spark conditions, which ensured a stable continuous spark, were chosen: spark-source voltage 65 kV, pulse length 20 μsec, repetition frequency 3000 sec^{-1} and ion-accelerating voltage 29.5 kV.

The scan-speed was 40 min/full range (m/e 1–250) and the recorder speed was 1 mm/sec. For peak-switching, an integrated monitor charge of 0.9 nC was chosen; the analysis time per element was about 15 sec.

The mass resolution in the magnetic scanning mode under the conditions described above was about 500 (10% valley) as appears from Fig. 4. All samples were presparked for at least 5 min.

RESULTS AND DISCUSSION

Evaluation of the precision by measurements of isotopic ratios

The abundances of the molybdenum isotopes in the steel standard NBS-SRM 661 were determined in order to evaluate the precision of the analysis. Molybdenum is present at a concentration of 0.19% by weight and the precision may be influenced by a heterogeneous distribution. The measurements were therefore repeated for the isotopes of iron. In addition, the precision was evaluated for impurities at lower concentration levels, namely tungsten (150 ppm) and silver (4 ppm).

Magnetic scanning. The mass intervals around the multi-isotopic elements iron, molybdenum, silver and tungsten were scanned, 20 scans being recorded in sequence. The precision of the measurements is shown in Tables 1 and 2. In order to calculate the isotopic abundances, the average intensity of the ion-current for an isotope was compared with the sum of the intensities for all isotopes of the element. The isotopes ^{58}Fe and ^{180}W were not considered because they are subject to interference from ^{58}Ni and ^{180}Hf respectively. The precision of the determination of the isotopic abundance appears to be considerably higher for iron than for the other elements, namely 11.6% relative standard deviation (r.s.d.) against 17.8% for molybdenum, 17.6% for silver and 13.4% for tungsten.

The average deviation between the calculated and true abundance for all isotopes is about 5%. The systematic positive deviation for ^{94}Mo is due to a small interference from ^{94}Zr which was also revealed by photographic detection. The systematic positive deviations for ^{54}Fe and ^{57}Fe are due to the large difference in the abundance of the iron isotopes, so their peaks have to be measured on 2 different recorder traces. Exact calibration of these 2 recorder channels showed a 13% deviation between them. After this correction the calculated abundance for the iron isotopes became 6.19% for ^{54}Fe, 91.29% for ^{56}Fe and 2.20% for ^{57}Fe.

Magnetic peak-switching. Similar experiments were performed by peak-switching. For iron, molybdenum, silver and tungsten, the isotopes were examined in sequence. For each measurement the magnetic field was manually optimized and the collector current was integrated until a preset exposure of 0.9 nC was recorded at the total ion-beam monitor. A total of 20 measurements was carried out for each isotope. The results are listed in Tables 3 and 4. Peak-switch-

ing appears to be capable of producing a more precise determination than does scanning, namely 3.3% r.s.d. for iron and about 5% for the impurities. The lower precision for the impurities suggests a contribution of the heterogeneous distribution of the impurities at the micro-level. It was found by weighing the electrodes before and after a controlled sparking that about 4 μg of material was consumed for each individual reading. For scanning, the amount of material consumed is about a tenth of this. This results in a larger contribution of the heterogeneous distribution of the impurities as is apparent from Table 5.

The average deviation between the calculated and true abundance of all the measured isotopes is about 3%. The systematic positive deviation which remains for ^{54}Fe and ^{57}Fe could be due to two causes: saturation of the electron multiplier for the intense ^{56}Fe ion-beam, or widening of this ion-beam by the space-charge effect, so that a different fraction of the isotopic ion-beam enters through the collector-slit for this isotope than for the others. Therefore the experiments were repeated for a lower multiplier voltage (0.5 kV instead of 1 kV) and for a wider collector slit-width (1 mm instead of 250 μm). The results summarized in Table 6 show that the systematic deviations remain at a lower electron multiplier voltage, but decrease considerably with a wider collector-slit.

With the electrical detection system used, it is possible to carry out repetitive measurements automatically, 1, 2, 4 or 8 integrations being made before the field is switched to the next mass. Within such a series of measurements, the reproducibility is expected to be better because in the previous experiments there is an uncertainty in the reproducibility of the magnetic field. Three series of eight integrations were performed for each isotope and the relative standard deviations within each series are listed in Table 7. For the iron isotopes the precision is 2% r.s.d. This represents the limit of the precision of the electrical detection system under the conditions used.

Instrumental parameters

To examine the influence of the spark conditions on the precision of the analysis, the mass range 51–60 a.m.u. was repeatedly measured in the scanning and in the peak-switching modes for the reference material SRM 661. All previous experiments were carried out with a pulse length of 20 μsec and a pulse repetition rate of 3000 sec^{-1}. When using a duty cycle higher than 6% (*e.g.*, 80 μsec × 3000 sec^{-1} or 40 μsec × 3000 sec^{-1}) it was difficult to obtain stable sparking conditions long enough to carry out the experiment. The sample electrodes burned up so quickly and irregularly that they soon made contact and fused together. The variation in precision with pulse length and repetition rate is summarized in Table 8. The r.s.d. for scanning is for 20 scans in sequence; for peak-switching it refers to 5 switching cycles in which 8 integrations are performed in sequence of increasing mass. It can be concluded that the pulse repetition rate and the pulse length have only a negligible influence on the precision. The standard deviations

shown in Table 8 correspond to the values found for the iron isotopes in Tables 2 and 7. Other experiments showed that the accelerating voltage has no detectable influence on the precision. The maximum accelerating voltage of 29.5 kV can thus be used to obtain the highest sensitivity.

Morrison and Colby[11] reported that the spark-gap voltage has an influence on the precision of the measurements. An accurate measurement of this parameter was not possible with our equipment since

it appeared impossible to control the spark gap precisely. A spark-source voltage of 65 kV was chosen as previous experiments showed this to be suitable for the steel samples.[6]

Reproducibility of experimental sensitivity coefficients

To perform quantitative analyses with an electrical detection system, the mass-analysed signal, which is in fact the ratio of the collector signal to the monitor signal, is compared with a signal corresponding to a known concentration. In this work, "matrix referencing"[12] is used: all signals are referred to ^{57}Fe.

A total of 20 scans ranging from 48 to 186 a.m.u. was recorded, each taking 15 min. The average concentrations and the standard deviations are listed in Table 9 for standard NBS-SRM 662. When more than one isotope was used, the weighted average concentration and the corresponding standard deviation were calculated from

where N is the number of isotopes. An average relative standard deviation of 18% was obtained. The results of similar experiments for the other steel standards are summarized in Table 10 and it may be concluded that the precision is about 18%.

For magnetic peak-switching, 8 successive measurements were carried out for each isotope before switching to the next. This sequence was repeated 10 times. The average of the 80 concentrations calculated for each isotope, the standard deviation and the S_R-values are shown in Table 11 for standard reference sample 662. An average standard deviation of 10% was obtained. Table 12 lists the average precision resulting

* Shown as coefficient ± relative standard deviation.

from similar experiments with the other standards. They confirm the 10% precision found for NBS 662. The experiments for scanning and peak-switching were carried out in 2 groups over a one-month period.

Sensitivity coefficients as a function of concentration—accuracy of analysis

The concentrations of the impurities in the steel standards NBS-SRM 661–665 cover one or more orders of magnitude. Hence, analysis of these standards shows whether the S_R-values vary with the concentration. The results are listed in Table 13 for the scanning mode and in Table 14 for the peak-switching mode.

The specified uncertainty of the certificate values differs widely for the different elements and was interpreted as being twice the standard deviation. The standard deviation of each S_R-value was obtained from

$$s = \frac{100}{S_R} \cdot \frac{a}{b} \sqrt{\left(\frac{s_a}{a}\right)^2 + \left(\frac{s_b}{b}\right)^2}\ \%$$

where a refers to value found by mass spectrometry and b to the certified concentration. The last columns of Tables 13 and 14 list the weighted averages of the relative sensitivity coefficients and the standard deviation

$$\bar{S}_R = \frac{\Sigma(S_{R,i}/s_i^2)}{\Sigma(1/s_i^2)}; \quad s = \frac{100}{\bar{S}_R} \frac{\sqrt{N}}{\Sigma(1/s_i^2)}\ \%.$$

The overall mean relative standard deviation obtained was 16% for scanning and 10% for peak-switching. Since there is no significant increase compared with the standard deviation for the individual standard samples, it can be concluded that S_R is not a function of the elemental concentration in steel at the level of precision allowed by spark-source mass spectrometry. By way of example, Fig. 5 shows the S_R-values measured by peak-switching for Ti, Cr, Co, Mo and W, plotted as a function of the concentration of these elements in the samples. The slope of the most probable straight line drawn through the data points does not significantly differ from zero in all cases. The results of regression analysis on the data are shown in Table 15 for all elements considered.

Tables 13 and 14 show that the precision of the experimental determination of S_R-values is of the order of 10% for magnetic peak switching and 16–18% for magnetic scanning. This gives an idea of the accuracy with which steels can be analysed by using the experimentally determined S_R-values. This was confirmed by comparing the results for the analysis of a high-purity iron sample with those obtained by neutron-activation[10] (Table 16); the results found by photoplate detection are shown for comparison.

CONCLUSIONS

Comparing Tables 13 and 14 it is apparent that there is fair agreement between the relative sensitivity coefficients for all the elements considered, obtained through magnetic scanning and magnetic peak-switching. Switching is the more precise method, with a 10% r.s.d., the corresponding precision of scanning being 16–18%. However, a quick survey by scanning provides quite acceptable results. A previous study showed that the precision with photographic detection was 15%. The accuracy was of the same order as the precision for the three modes of operation, as illustrated by the comparison of the results with those obtained by neutron-activation analysis.

Other workers have reported sensitivity coefficients for spark-source mass spectrometric analysis of steel standard samples by peak-switching. Their results are summarized in Table 17 and are in agreement with the values reported here. The S_R-value of iron was taken as unity by all authors with the exception of Hull, who used internal referencing to vanadium; these values have been converted for the comparison, setting the S_R-value of vanadium at 1.6.

Summary—Radiotracer studies with ^{45}Ca and ^{36}Cl demonstrate that PVC matrix membranes containing Orion 92-20-02 liquid calcium ion-exchanger are permselective to counter-cations. Diffusion coefficients are quoted for the migration of ^{45}Ca between pairs of calcium solutions and are discussed in terms of solution concentration, membrane thickness and concentration level of sensor in the membrane. Migration of calcium ions from calcium chloride solution to a Group (II) metal chloride solution through a PVC membrane containing calcium liquid ion-exchanger is discussed in terms of solvent extraction and electrode selectivity coefficient parameters. Thus, magnesium, strontium and barium ions appear to inhibit migration through the membrane by their low affinity for the membrane liquid ion-exchanger sites, while the inhibition by beryllium ions is attributed to site blockage by the strong affinity of dialkylphosphate sites for beryllium.

The high quality of ion-exchange membranes as selectively permeable devices is well established[1] but liquid ion-exchangers have greater selectivity for counter-ions than the resinous materials and it is for this reason that liquid ion-exchanger membranes have utility as selective ion-sensors in ion-selective electrodes.[2,3] The ideal in principle is a membrane of perfect selectivity for one counter-ion relative to all others, because the selectivity coefficient, $k^{\text{pot}}_{\text{AB}}$ would then approach zero and thus nullify the contribution of $k^{\text{pot}}_{\text{AB}}(a_{\text{B}})^{z_{\text{A}}/z_{\text{B}}}$ in equation (1) to give a simple linear relation between ion-selective electrode response, E, with respect to a suitable reference electrode, and the logarithm of the activity, a_{A}, of the principal counter-ion A:

$$E = \text{constant} \pm \frac{2.303RT}{z_{\text{A}}F}\log(a_{\text{A}} + k^{\text{pot}}_{\text{AB}}(a_{\text{B}})^{z_{\text{A}}/z_{\text{B}}}) \qquad (1)$$

In equation (1) the positive sign holds for cations and the negative for anions, a_B is the activity of the interfering counter-ion B, and the z terms refer to the number of charges on the counter-ions.

Perfect selectivity is unknown and the selectivity coefficient must always be borne in mind when using ion-selective electrodes. It is therefore desirable to have a better understanding of selectivity. As a step in this direction, the present paper reports a radiotracer study on the calcium ion permeability of PVC matrix membranes containing Orion 92-20-02 liquid-ion exchanger, and the membranes are also shown to be impermeable to chloride ions.

EXPERIMENTAL

Experiments using membranes prepared in the manner previously described[4–6] involved radioactive tracer exchange between two solutions separated by a membrane, studied either by continuous recording or by intermittent sampling and monitoring. The detailed procedures are described below.

Procedure I

A 7-mm diameter disc of PVC–liquid ion-exchanger ion-selective electrode membrane cut from a master membrane prepared from 0.17 g of PVC (Breon 111) + 0.40 g of Orion 92-20-02 calcium ion-exchanger, was sealed (with a cement made of PVC in tetrahydrofuran) to a PVC tube fitted to the end of a drawn-out B10 socket. A solution containing 0.1 ml of calcium chloride solution (*ca.* 1 mCi of ^{45}Ca per ml), diluted to 2 ml with water to give a 0.005*M* calcium solution, was placed inside the tube, which was then closed with a B10 stopper to prevent evaporation. This assembly was suspended inside a tube 14 cm long and 2.3 cm in internal diameter, sealed at one end with a mica window (5 mg/cm^2) by "Araldite". The outer tube contained 10 ml of $10^{-4}M$ calcium chloride or magnesium chloride, as appropriate. The entire assembly was positioned in a mica end-window Geiger-Müller counter system as depicted in Fig. 1. The increase in activity of the external solution was thus monitored continuously by the pen recorder as the β-emitting ^{45}Ca ions migrated through the membrane.

The design of this experiment is such that the results are only qualitative, but the preliminary results obtained led to the design of procedure II. Co-ion diffusion studies were made with calcium chloride labelled with chlorine-36.

Procedure II

Apparatus assemblies like that depicted in Fig. 2 were kept in an air thermostat at 35 ± 0.5°, a temperature higher than ambient being chosen in order to overcome problems of dissipating the heat generated by the magnetic stirrers. A 22-mm diameter disc of PVC–liquid ion-exchanger ion-selective electrode membrane cut from an appropriate master membrane prepared as in procedure I was cemented to a PVC tube of 16 mm internal diameter. The other end of the tube was connected to a glass tube (A) fitted with a side-arm and having a Teflon-covered magnetic-stirrer bar hanging from a fishing swivel by a nylon fishing line. The membrane end of (A) was immersed in a solution contained in a 25-ml beaker (B) provided

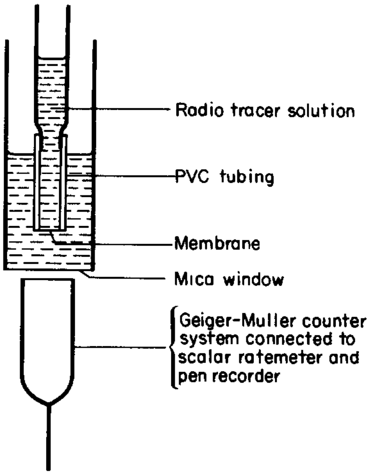

Fig. 1. Apparatus assembly for continuously monitoring the permeation of radiotracer ions through PVC matrix membranes.

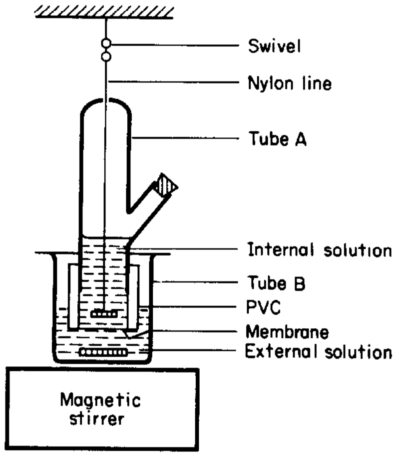

Fig. 2. Apparatus aassembly for studying the permeation of radiotracer ions through PVC matrix membranes by intermittent sampling.

with a Teflon-covered magnetic-stirrer bar. Both (A) and (B) were charged with appropriate solutions (10 ml) which were stirred with the magnetic stirrers during experimentation. The solutions were monitored for radioactivity by withdrawing 10-μl samples at appropriate times through the side-arm of (A). A Lang–Levy auto-zero micropipette was used to spot the samples onto 5.5-cm diameter discs of Whatman No. 1 filter paper and the ^{45}Ca activity was counted with a Geiger-Müller mica end-window tube.

Discs of PVC alone, and of PVC containing only dioctyl phenylphosphonate mediator were similarly examined. Additionally, permeation selectivity was examined with ^{36}Cl.

Calcium content of the liquid ion-exchanger

The calcium content of the liquid ion-exchanger was determined by Crump's EDTA procedure[7] and the results used for evaluating the calcium content of the various membranes.

Selectivity coefficient determinations

Selectivity coefficients, $k^{\text{pot}}_{\text{AB}}$, were determined by a mixed-solution method,[8,9] with a fixed level of interferent B.

RESULTS

Selectivity coefficients are summarized in Table 1 along with certain solvent extraction data.

The main results relate to the migration of calcium ions between solutions of calcium chloride or between solutions of calcium chloride and another Group (II) metal chloride separated by a PVC matrix membrane containing Orion 92-20-02 liquid calcium ion-exchanger based on a dialkylphosphate sensor plus phosphonate mediator. The selective permeability of the membrane to cations is shown by the non-diffu-

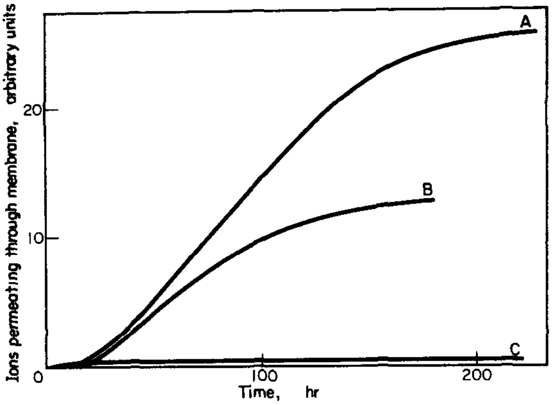

Fig. 3. Traces showing the permeation of $^{45}Ca^{2+}$ through a PVC matrix membrane with trapped Orion 92-20-02 liquid ion-exchanger, into calcium chloride (curve A) and magnesium chloride (curve B) solutions. Curve C confirms membrane permselectivity to counter-cations by the near-zero diffusion of $^{36}Cl^-$ under similar conditions to those prevailing for curve A.

sion of chloride ions through it (Fig. 3 and Table 2). Results obtained by both procedures I and II also confirm the impermeability of the PVC matrix to calcium ions, which gave no diffusion through a PVC membrane alone or containing dioctyl phenylphosphonate[11,12] mediator but no dialkylphosphate.

Both procedures approximate the way liquid ion-exchanger membranes are used in ion-selective electrodes, but procedure I serves only to demonstrate the migration or otherwise of radioactive species through the membrane (Fig. 3).

The quantitative migration data were obtained by procedure II. Thus, diffusion coefficients for calcium, $\bar{D}$, were calculated from steady-state ^{45}Ca diffusion across the membrane (with calcium solutions on each side) by means of the equation[13]

$$\bar{D} = \frac{d(C''/C')}{dt}\,\frac{V''Ch}{\bar{C}q} \qquad (2)$$

where h is the membrane thickness [0.050 cm except for membranes 9 and 10 (0.030 cm) and membrane 11 (0.025 cm)], measured with a micrometer gauge, q is the cross-sectional area of the membrane (2.01 cm^2), C' and C'' are the tracer concentrations (proportional to radioactivity) in the initially active and inactive solutions respectively, C is the total calcium ion concentration (that is, tracer + non-tracer) in the solutions on each side of the membrane (Table 2) and $\bar{C}$ that in the membrane ($4.34 \times 10^{-2}M$ except for membranes 9 and 10 where $\bar{C}$ is $3.35 \times 10^{-2}M$), and V'' is the volume (10 ml) of the initially inactive solution.

* These solutions are labelled with ^{45}Ca.

† Difficulty in guaranteeing time-independence of tracer flux at such high concentration.

Equation (2) was used under steady-state conditions when the tracer flux through the membrane was time-independent, that is, when the tracer concentration ratio between the initially inactive and active solutions increased linearly with time. The calcium diffusion coefficients between calcium solutions are summarized in Table 2.

Equation (2) is restricted to the measurement of self-diffusion coefficients, but the C''/C' *vs.* time profiles for the migration of ^{45}Ca from calcium solutions to other Group (II) metal solutions are similar to those for migration between calcium solutions. Hence, in order to compare the migration of labelled calcium between solutions of similar concentration and initially composed of calcium chloride and Group (II) metal salts respectively, $d(C''/C')/dt$ data for the time-independent regions are summarized in Tables 2 and 3.

Except for experiment 8 where there was extreme difficulty in locating the time-independent region of the tracer flux, the results in Tables 2 and 3 are means of replicate determinations with individual values within $\pm 8\%$ of the mean, except for experiment 4 where the mean is that of five determinations with a coefficient of variation of 4.7%. The results are discussed in the context of these error ranges.

DISCUSSION

The permeation of the counter-cations but not of the chloride co-ions (Fig. 3 and Tables 2 and 3) confirms that these membranes possess the permeation selectivity characteristic of ion-exchanger membranes. Thus, migration of counter-ions through the membrane placed between two solutions is not "one-way traffic", because in order to preserve electrical balance, counter-ion migration in one direction must be accompanied by an equivalent migration in the reverse direction. This is demonstrated by the results of experiments 4–7 (Table 2), 13–26 (Table 3), 28 and 29 (Table 3) based on migrations from internal to external solutions and *vice versa.*

* These solutions are labelled with ^{45}Ca.

Of course, diffusion behaviour may not be exclusively determined by the processes within the membrane, owing to the influence of such factors as concentration profiles within the bulk solutions. These are kept uniform by stirring in procedure II, but such agitation does not affect the Nernst diffusion layers or "films" which adhere to the membrane surfaces. However, film control of diffusion of counter-ions is less significant in the present systems for, compared with conventional ion-exchanger membranes with typical self-diffusion coefficients of $\sim 2 \times 10^{-6}$ cm^2/sec for counter-ions,[14] the coefficients here are smaller by 2–3 orders of magnitude (Table 2). This implies that the self-diffusion of counter-ions is more likely to be diffusion controlled.

In the present case, the diffusion coefficient is directly proportional to membrane thickness rather than being independent of it. This is a consequence of the observed permeation of calcium ions through the membrane (experiments 4 and 11) being independent of membrane thickness, a feature that may be attributed to the diffusing species experiencing the same resistances such as may occur from having a viscous interface at the membrane surface, arising from some loss of plasticizing mediator.

The observed values of *ca.* 10^{-8}–10^{-9} cm^2/sec for $\bar{D}$ (Table 2) are similar in magnitude to those found by Bailey and Dalziel[15,16] for the diffusion of calcium ions from solution to a small membrane disc; the low order of magnitude is considered as characteristic of diffusion through a very viscous medium.

The data in Table 2 indicate the effects of solution concentration and the amount of sensor in the membrane as well as the effect of membrane thickness. Experiments 4–10 (Table 2) show that increase in solution concentration leads to an increase in the diffusion coefficient. A similar dependence has been observed for ion-exchange resins[17–20] and attributed to an apparent increase of co-ion concentration in the pores to provide pathways of high mobility for the migration of counter-ions.[19,21] However, here it has been shown that there is no co-ion migration (Fig. 3 and Table 2) through the PVC membrane containing liquid ion-exchanger. Hence, the migrations suggest a lesser role for co-ion mobility pathways for counter-ions and a greater role for the solvent mediator and osmotic and other forces in the utilization of liquid ion-exchanger sites as pathways.

From the purely theoretical standpoint, the effect of a lower amount of exchanger in the membrane (Table 2, experiments 9 and 10) should, because of decreasing electrostatic retardation, increase the diffusion coefficient. The reverse is the case and $\bar{D}$ is even lower than expected from the reduced membrane thickness (from 0.05 to 0.03 cm). These low values arise from the low slope of the time-independent region of the C''/C' *vs.* time plot and are a direct consequence of a lower flux arising from having fewer liquid ion-exchanger site pathways in a more viscous PVC membrane (Table 2, experiments 9 and 10) than in the corresponding controls (Table 2, experiments 4–7).

Equation (2) cannot be applied to permeation between calcium chloride and Group (II) metal salt solutions, and suitable radiotracers in neutral solution are not conveniently available for a wider study of steady-state diffusion of alkaline earth metal cations. Nevertheless, interesting patterns emerge for the mobility of labelled calcium between calcium chloride and Group (II) metal salt solutions. These are based on the rate of attainment of tracer equilibrium, namely $\mathrm{d}(C''/C')/\mathrm{d}t$ data for the time-independent regions of C''/C' *vs.* time plots (Tables 2 and 3).

The low $\mathrm{d}(C''/C')/\mathrm{d}t$ values for calcium migration through the membrane into the chlorides (Table 3) of magnesium (experiments 15, 16, 21 and 22), strontium (experiments 17, 18, 23 and 24), and barium (experiments 19, 20, 25 and 26) relative to values for migration between calcium solutions at similar concentration levels (Table 2, experiments 4–7) match the low electrode selectivity coefficients ($k^{\mathrm{pot}}_{\mathrm{CaB}}$) for these ions (Table 1). This pattern may arise from the relative reluctance of the interferent ions even to enter the membrane, as illustrated by their tendency to have lower solvent extraction coefficients (Table 1). This reluctance decreases the migration of calcium ions in the reverse direction.

The low $\mathrm{d}(C''/C')/\mathrm{d}t$ values for the migration of calcium into beryllium solutions at $10^{-3}M$ level (Table 3, experiments 12 and 13) is rather surprising in view of this explanation for magnesium, strontium and barium. However, it is suggested that beryllium ions block the liquid ion-exchanger sites because of the high affinity of the exchanger for beryllium, as shown by the data for solvent extraction and electrode selectivity coefficients (Table 1). Kinetic forces may also be at work as in the exchange of solvent water with hydrated metal ions, which in the case of beryllium has a rate constant over six orders of magnitude less than that for calcium.[22]

Ion-selective electrodes having selectivity coefficients much greater than unity frequently need considerable recovery treatment after exposure to interferents. Also, ion-selective electrodes can suffer shocks on exposure to certain other ions, for example, the calcium ion-selective electrode with Orion 92-20-02 liquid ion-exchanger trapped in the PVC matrix membrane requires prolonged contact with calcium ions in order to recover from contact with zinc ions. That the sites may be blocked by zinc ions is suggested by $\mathrm{d}(C''/C')/\mathrm{d}t$ data for $10^{-3}M$ calcium and zinc solutions (Table 3, experiments 27–29) and those for the corresponding calcium and beryllium system.

The difference between beryllium chloride and beryllium sulphate (Table 3–experiments 12–14) appears to be due to the anion. A similar effect was observed for the selectivity coefficient, $k^{\mathrm{pot}}_{\mathrm{CaBe}}$, of the calcium ion-selective electrode in the presence of the two beryllium salts as interferents (Table 1). No such differences were observed for zinc.

CONCLUSION

The radiotracer studies have confirmed the selective permeability to counter-ions, of membranes made with calcium liquid ion-exchanger contained in PVC. The migration of calcium ions through such membranes under various conditions of concentration, interference and membrane thickness can be explained in terms of the availability of membrane pathways (which, of course, provide ways for ionic conduction as opposed to the electronic conduction of glass membranes).

The mobility of calcium ions between calcium chloride solutions and Group (II) metal salt solutions through the PVC matrix membranes is consistent with solvent extraction and ion-selective electrode parameters (possibly tempered by kinetic factors), but it has not been possible to distinguish between the separate roles of equilibrium ion-exchange and mobility in the membrane, which seem to be inter-related in electrode selectivity. Nevertheless, the consensus on ion-transport in untrapped liquid ion–ion exchange membranes is that the actual mobilities of the associated (ion *plus* site) pairs for the usual long-chain liquid ion-exchangers are approximately the same for all counter-ion species[23,24] so that electrode selectivities (and overall transfers of ions in the present study) are related simply to equilibrium ion-exchange.[23–26]

GAS CHROMATOGRAPHY OF TERNARY COMPLEXES OF MANGANESE(II), IRON(II), COBALT(II) AND NICKEL(II) WITH HEXAFLUOROACETYLACETONE AND DI-n-BUTYLSULPHOXIDE

THOMAS P. O'BRIEN and JEROME W. O'LAUGHLIN
Department of Chemistry, University of Missouri-Columbia, Columbia, Missouri 65201, U.S.A.

(*Received* 11 *February* 1976. *Accepted* 16 *June* 1976)

Summary—The gas chromatographic behaviour of the ternary complexes of selected bivalent first-row transition metal ions with 1,1,1,5,5,5-hexafluoro-2,4-pentanedione H(HFA), and di-n-butylsulphoxide, DBSO, was studied. Calibration plots of peak area *vs.* amount of metal injected were linear over a range of 60–900 ng for manganese(II), iron(II), cobalt(II) and nickel(II). The average relative standard deviation was less than 3·0% for all the metals studied. Detection limits of 60, 109, 112 and 115 ng for cobalt(II), nickel(II), iron(II) and manganese(II), respectively, were obtained with flame-ionization detection. Various liquid phases, including OV-1, SE-30, and Dexsil 300 were used. The best results were obtained on columns of 5% Dexsil 300. No appreciable thermal decomposition was observed on stainless-steel or glass columns, but the best formed peaks were obtained on all-glass columns. The elution of the metallic species was confirmed by venting the exit gases from the gas chromatograph directly into an atomic-absorption spectrophotometer.

The volatility of certain metal chelates, particularly those of chromium and beryllium with fluorinated β-diketones, has permitted their determination by gas chromatography.[1,2] With the use of the electron-capture detector, detection limits as low as 10^{-14} g have been reported for chromium.[3] A problem encountered with many cations is that the co-ordination number is more than twice the number of charges on the cation and the resulting chelates with bidentate β-diketones are hydrated or polymeric.[4–6] This problem can be surmounted by deliberate introduction of neutral donors such as tri-n-butyl phosphate, TBP, or di-n-butylsulphoxide, DBSO, to form anhydrous adducts of these chelates. The authors[7] have previously shown that the zinc adduct, $Zn(HFA)_2 \cdot 2DBSO$, was sufficiently volatile to be eluted from a gas chromatograph without apparent decomposition. The preparation of similar adducts and the gas chromatography of the DBSO adducts of the hexafluoroacetylacetonates of the lanthanides, thorium, and uranium have been reported.[8–13] Little work has been reported on this approach for the bivalent transition metal ions, although the gas chromatography of bivalent transition metal chelates has been reported by Sievers, Ross and co-workers,[14–17] where β-diketones with bulky terminal groups which gave anhydrous chelates were employed. Belcher, Uden and co-workers[4,18,19] also successfully chromatographed several bivalent metals as their monothio-β-diketonates and as chelates with bidentate and quadridentate β-ketoamines.

The synergic extraction and gas chromatography of iron(II) and iron(III) adducts with hexafluoroacetylacetone, H(HFA), and TBP was reported by Tomažič and O'Laughlin.[20] Burgett[21,22] reported that copper(II), iron(II), cobalt(II), nickel(II) and lead(II) were quantitatively extracted when 0.01*M* solutions of these metals were equilibrated with 0.03*M* H(FHD) (1,1,1,2,2,6,6,7,7,7-decafluoro-3,5-heptanedione) and 0.03*M* DBSO. Burgett reported that all the adducts, except for those of lead and copper, could be eluted from a gas chromatographic column. The lead adduct decomposed and copper was reported not to form an adduct. The synergic extraction and gas chromatographic behaviour of zinc(II), cadmium(II) and lead(II) with H(HFA) and DBSO have been previously reported.[7] Although all three were quantitatively extracted, only the zinc adduct could be eluted; the cadmium and lead adducts apparently decomposed on the column.

Several reviews on the determination of metals by gas chromatography have been published. These include books by Moshier and Sievers,[1] Guiochon and Pommier[23] and reviews by Belcher[24] and Kutal.[25]

The present paper reports on the gas chromatography of manganese(II), iron(II), cobalt(II) and nickel(II) as ternary complexes prepared by synergic extraction of the cations with H(HFA) and DBSO into cyclohexane. The gas chromatographic behaviour of these adducts was studied as a function of the metal concentration, neutral donor concentration and nature of the stationary phase in both glass and stainless-steel columns.

EXPERIMENTAL

Apparatus

The gas chromatographic studies were performed on a Bendix Model 2500-Life Sciences Gas Chromatograph equipped with on-column injection and a flame-ionization detector. A Loenco Model 15C-X Gas Chromatograph equipped with a thermal-conductivity detector was used in the atomic-absorption studies. The chromatograms were recorded on a Honeywell Model 194 Electronik strip-chart recorder.

Both the Perkin-Elmer Model 290B and Model 403 Atomic Absorption Spectrophotometers were used in the atomic-absorption studies. Each was used with an air–acetylene flame and a Perkin-Elmer Model 56 strip-chart recorder. A Perkin-Elmer Deuterium Arc Background Corrector was used on the Model 403.

A Cary Model 15 Spectrophotometer, a Perkin-Elmer Model 180 Infrared Spectrophotometer, and a Varian Model A-60 Nuclear Magnetic Resonance Spectrophotometer were employed to check the purity of the reagents, chelates, and adducts.

Reagents and materials

Reagent grade nitrate, chloride, or acetate salts were used to prepare stock metal solutions. H(HFA), 1,1,1,5,5,5-hexafluoro-2,4-pentanedione, was obtained from Pierce Chemical Company and its purity was checked by ultraviolet, NMR, and infrared spectroscopy as well as by gas chromatography. All solvents were reagent grade.

The H(HFA) complexes of Co(II), Fe(II), Mn(II), and Ni(II) were obtained from PCR, Inc. Tri-n-butyl phosphate, TBP, and di-n-butylsulphoxide, DBSO, were used without purification.

Chromosorb W-HP 100/120 mesh was obtained from Analabs, Inc., Dexsil 300 was obtained from Regis Chemical Company through the Bendix Corporation, and SE-30 and OV-1 were obtained from the Bendix Corporation.

Columns were constructed of borosilicate glass tubing or type 304 stainless-steel tubing.

Bendix "Col-Treet" and "Glass-Treet" were obtained from the Bendix Corporation. Dimethylchlorosilane and dimethyldichlorosilane were obtained from Pierce Chemical Company.

Column pretreatment

Before coating the Chromosorb W-HP was pretreated by a method described previously.[7,26]

The glass columns were rinsed with Bendix "Glass-Treet", and absolute methanol, then flushed with air and dried in an oven for several hr at 110°. The stainless-steel columns were treated as suggested by Analabs, Inc.[27] The columns were rinsed successively with absolute methanol, isopropyl alcohol, chloroform, isopropyl alcohol, dilute nitric acid (1.0*M*), and then thoroughly rinsed with demineralized water and finally with absolute methanol. The empty columns were then flushed with air and dried in an oven for several hr at 110°.

Preparation of column packing

The silated Chromosorb W-HP was coated with Dexsil 300, SE-30, or OV-1 by slurrying with a chloroform solution of the coating. Excess of solvent was removed in a rotary evaporator and the product dried at 110° with occasional stirring. The resulting product was dried for 24 hr in a vacuum desiccator, then placed in a large sintered-glass filtering funnel; a gentle stream of dry nitrogen was passed upwards through the funnel to remove any fines.

Packing and conditioning of the columns

Dry column packing was poured into the tube and compacted with gentle tapping. Use of a vibrator gives more fines and poorer performance. The ends of the columns were plugged with glass wool that had been soaked in a solution of 5% dimethyldichlorosilane and 5% dimethylchlorosilane in toluene, followed by an absolute methanol rinse and drying for several hr, at 110°. The columns were brought to conditioning temperature and 20 μl of Bendix "Col-Treet" were injected to silate any active sites. The Dexsil 300 columns were conditioned at 350° for 24 hr and the SE-30 and OV-1 columns at 300° for 24 hr with a low flow of nitrogen.

Preparation of organic solutions of mixed-ligand complexes

Solutions of the metal–H(HFA)–neutral donor complexes were prepared by solvent extraction utilizing the methods previously described[7] or by placing a weighed amount of the hydrated chelates in a volumetric flask and diluting to standard volume with a solution of DBSO or TBP in cyclohexane to yield a stoichoimetric adduct with a minimum excess of neutral donor present.

Solutions of mixtures of several metal complexes were prepared by solvent extraction or by mixing appropriate volumes of the solutions above to form mixtures. All solvent extraction mixtures were sampled directly from the organic layer in the extraction tubes or from the volumetric flasks by syringe.

RESULTS AND DISCUSSION

Metal–HFA–neutral donor adducts

Three different stationary phases were investigated for the best gas chromatographic response characteristics. Recent work[12,13,21,22,28] has shown the excellent gas chromatographic behaviour and thermal stability of the carborane-cage compound, Dexsil 300, which was the stationary phase used for the majority of the gas chromatographic studies. SE-30, a methylsilicone gum rubber phase which has also shown good utility for application to volatile metal chelates, and OV-1, also a methylsilicone gum rubber phase, were used for comparative purposes. McReynold's constants indicate that Dexsil 300 is more polar than SE-30 and OV-1 which have about the same polarity.

The metal–HFA–neutral donor complexes of Ni(II), Fe(II), Co(II), and Mn(II) were chromatographed. Several attempts were made to elute the TBP adducts but these proved unsuccessful, owing to the inability to separate the adduct peak from that of TBP. Only the DBSO adducts were studied further.

Initial studies were performed on glass columns packed with 5% OV-1 on 100/120 mesh Chromosorb W-HP. The peak representing the adduct was broad and not well resolved from that of DBSO. Somewhat sharper peaks were obtained by using SE-30; however, all the retention times on an 18 × 1/4 in. column packed with 5% SE-30 on Chromosorb W were less than 3 min and resolution was poor. The best formed peaks were obtained on short columns of 5% Dexsil 300 on Chromosorb W. The elution behaviour of the bivalent metal chelates was studied on both glass and stainless-steel columns of varying lengths from 18 in. to 6 ft, all of 1/4 in. o.d.

The chromatographic behaviour of $Co(HFA)_2 \cdot 2DBSO$ on both stainless-steel and glass columns packed with 5% Dexsil 300 and 5% SE-30 on 100/120 mesh Chromosorb W-HP was studied. The results were similar to those found for the zinc adduct $Zn(HFA)_2 \cdot 2DBSO$[7] with response decreasing in the order: 5% Dexsil 300-glass, 5% Dexsil 300-stainless steel, 5% SE-30-glass, 5% SE-30-stainless

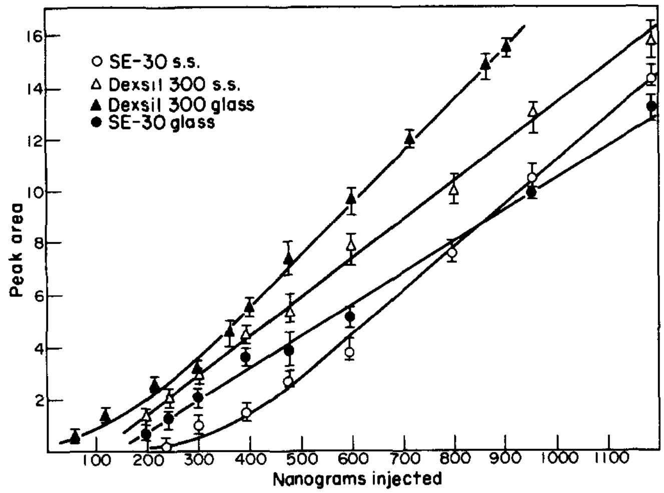

Fig. 1. Dependence of peak area on weight of $Co(HFA)_2 \cdot 2DBSO$ injected on glass and stainless steel columns packed with SE-30 and Dexsil 300 on Chromosorb W.

steel as shown in Fig. 1. Glass columns (10 × 1/4 in.) packed with 5% Dexsil 300 were used for all subsequent work. All calibration curves were obtained from 3–5 replicate injections for each concentration.

The areas of all peaks were determined by triangulation. The substantial difference in the response on stainless-steel and glass columns may be due in part to some decomposition on the hot steel column walls, but this could not be verified. The best formed peaks were consistently obtained on glass columns packed with Dexsil 300 on Chromosorb W.

The methods by which the columns were cleaned and packed obviously have some bearing on the different response curves obtained. The retention times were less for SE-30 than for Dexsil 300, making it more difficult to resolve the DBSO peak from that of the metal complex.

Determination of the H(HFA)–DBSO adducts

The DBSO adducts of Zn(II), Ni(II), Mn(II), Co(II), and Fe(II) were examined as shown in Fig. 2. A flame-ionization detector was used. The chelates were prepared by extracting various concentrations of the metals at the optimum conditions for extraction: pH 5.0–5.5, 0.01*M* K(HFA) and 0.05*M* DBSO in cyclohexane. Solutions of the various metals were also prepared by weighing appropriate amounts of the metal–HFA chelates (to give the same metal concentrations as when prepared by extraction) into a 100-ml volumetric flask and diluting to volume with 0.04*M* DBSO. The chromatographic peaks obtained from both types of solution were the same and subsequent studies were carried out with complexes prepared by the latter method.

The stoichiometry of the ternary complexes was inferred from the slopes of the log *D* *vs.* log [DBSO] plots. The formation of a di-adduct was indicated. Furthermore, solutions prepared by mixing the chelates of the metals with sufficient DBSO in cyclohexane to give a di-adduct gave chromatographic peaks identical with those for the metal complexes prepared by solvent extraction.

The detection limits for the 5 metal–HFA–DBSO complexes are shown in Table 1, the zinc chelate having the lowest detection limit. Electron-capture detectors cannot be used because they are swamped by the excess of H(HFA).

Retention time vs *metal concentration*

Studies of retention time as a function of metal concentration were performed (*a*) at constant DBSO concentration (0.04*M*) and (*b*) at constant ratio of DBSO to metal ion concentration. In both studies the retention times decreased with decreasing metal concentration.

The retention times in (*a*) decreased from 2.10 min for 952 ng to 1.43 min for 59.6 ng of cobalt, and from

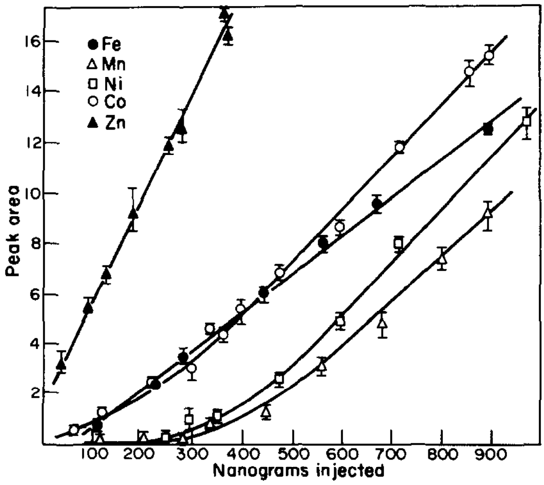

Fig. 2. Dependence of peak area on weight of the H(HFA)–DBSO complexes of Fe(II), Mn(II), Ni(II) and Co(II). Data on Zn(II) are included for comparison.[7]

Table 1. Gas chromatographic detection limits for some selected bivalent metal complexes

	Detection limit, *ng*
$Zn(HFA)_2 \cdot 2DBSO$	45.5
$Co(HFA)_2 \cdot 2DBSO$	59.6
$Ni(HFA)_2 \cdot 2DBSO$	109.0
$Fe(HFA)_2 \cdot 2DBSO$	112.0
$Mn(HFA)_2 \cdot 2DBSO$	115.0

2.53 min for 890 ng to 1.59 min for 115 ng of manganese. Nickel and iron gave similar results. In (*b*), retention times for 1112–222 ng of manganese varied from 2.39 to 1.54 min, and for 1172–234 ng of nickel from 3.15 to 1.93 min. Cobalt and iron gave similar results. Variations in retention times between the two studies at the same metal concentration are possibly due to changes in carrier-gas flow-rate and temperature during analysis.

Studies of the variation in peak area with DBSO concentration at a constant metal ion concentration of 0.008*M* are shown in Fig. 3. The initial DBSO concentration was 0.016*M* which is the minimum concentration required to form the di-adduct; 3–5 replicate 2-μl injections at each DBSO concentration were made. Some variations may be explained by the fact that as the excess of DBSO increases, the tail of the DBSO peak extends under the peak for the metal complex. Except possibly in the case of manganese, this study does not indicate the decomposition of the adduct at lower DBSO concentrations.

The response of the flame ionization detector is greater for zinc than for the other metals (Fig. 2). Because the areas under the peaks were determined by triangulation and some difficulty was caused by the tail due to excess of DBSO, the only real significance of the data in Fig. 3 may be that the excess of DBSO has no apparent effect on the stability of the complexes.

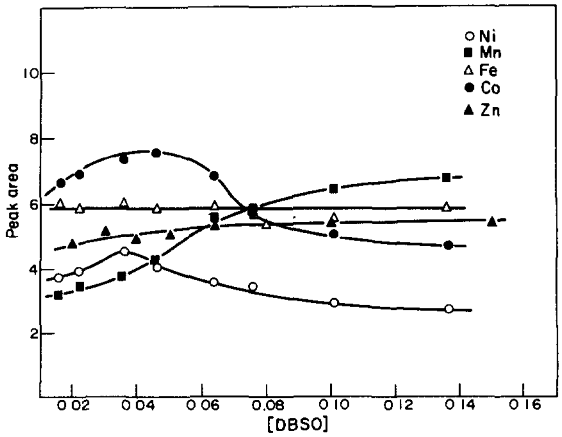

Fig. 3. Dependence of peak area on the concentration of DBSO for the H(HFA)-DBSO adducts of Fe(II), Mn(II), Ni(II) and Co(II). Data on Zn(II) are included for comparison.[7]

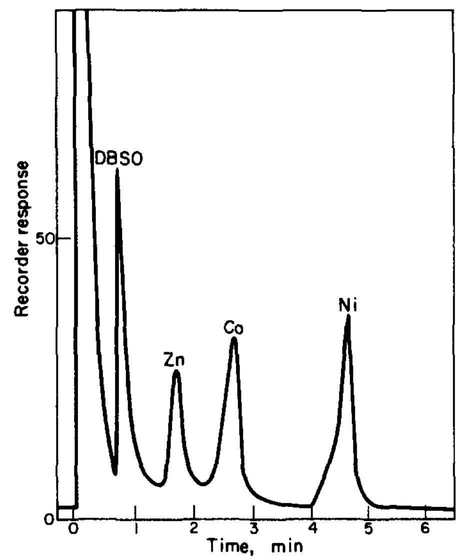

Fig. 4. Chromatogram of a mixture of the Zn(II), Co(II) and Ni(II) adducts of H(HFA) and DBSO at 170°.

Separation of mixtures of mixed-ligand complexes

Mixtures of the complexes were chromatographed and possible separations studied. The separation of a mixture of the zinc, nickel, and cobalt adducts isothermally or with temperature programming is shown in Figs. 4 and 5. Retention times for the individual complexes at uniform temperature indicated the elution order to be zinc, iron(II), cobalt, nickel, and manganese. As seen from the retention times in Table 2, possible separations include Zn–Co–Ni, Zn–Co–Mn, Zn–Fe–Ni, Zn–Fe–Mn mixtures. These

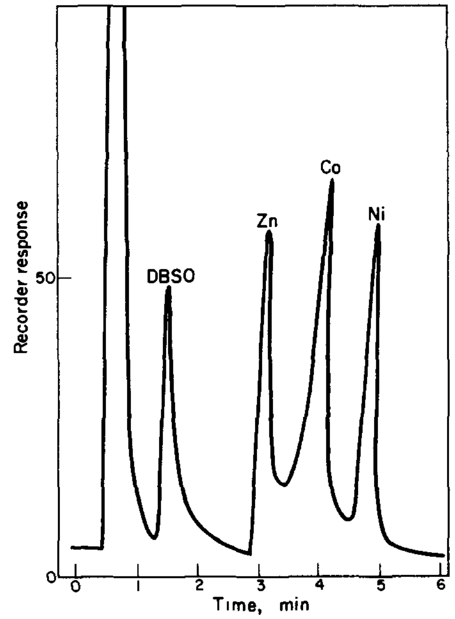

Fig. 5. Chromatogram of a mixture of the Zn(II), Co(II) and Ni(II) adducts of H(HFA) and DBSO temperature programmed from 150–185° at 8°/min.

Table 2. Retention times of metal–H(HFA)-DBSO adducts on an 18 × 1/4 in. glass column packed with 5% Dexsil 300 on Chromosorb W

Conditions	Metal	Retention time, *min* Leading edge	Centre of peak
170°,	Zn(II)	1.69	2.06
flow-rate	Fe(II)	1.85	2.18
38.26 ml/min	Co(II)	2.07	2.46
	Ni(II)	2.26	3.44
	Mn(II)	2.40	3.52
180°,	Zn(II)	1.38	1.58
flow-rate	Fe(II)	1.42	1.61
38.26 ml/min	Co(II)	1.58	1.74
	Ni(II)	1.65	1.84
	Mn(II)	2.01	2.60
150°–200°	Zn(II)	2.66	3.09
10°/min	Co(II)	3.00	3.16
flow-rate	Fe(II)	3.23	3.41
38.26 ml/min	Ni(II)	4.06	4.53
	Mn(II)	4.23	4.63

separations were performed isothermally at temperatures of 170°, 175°, 180° and 185° and by temperature programming from 150 to 200° at several programming rates from 2°/min to 15°/min, the results being essentially the same.

Loading effect in gas chromatographic analysis

The gas chromatographic work showed that multiple injections were necessary before reproducible peak areas could be obtained. This "loading effect" of the columns was found for all metals studied. It was observed that broad peaks or two separate peaks were obtained when one metal complex was chromatographed immediately after a different metal complex under isothermal conditions. This appeared to be caused by a peak with a retention time corresponding to the metal previously chromatographed, appearing along with that for the complex injected. After several injections this peak disappeared and the peak area for the complex injected became reproducible.

A possible explanation for this behaviour would be the retention of some of the first metal complex on the front end of the column and its displacement by the injection of the second metal complex. It is also possible that the first metal complex is partially decomposed in the injection area and reformed upon the injection of the second metal complex, by reaction with excess of H(HFA) and DBSO. The fact that this phenomenon was not observed when the column was left at temperature for several hours before the second metal complex was chromatographed favours the first explanation. Even then, it was still necessary to make several injections before the peak areas became reproducible. These phenomena would cause serious problems in the quantitative analysis of mixtures of metals.

Mass spectroscopy of the metal complexes

Mass spectra were obtained for the $Zn(HFA)_2 \cdot 2DBSO$ and the $Ni(HFA)_2 \cdot 2DBSO$ adducts, using GC-MS. The results obtained yielded little useful information. No molecular-ion peak and few fragments containing the metal ion could be unambiguously identified. The mass spectra for similar chelates reported in the literature also gave complex fragmentation patterns[21,29–32] which were only indicative of the nature of the species actually eluted.

Elemental analysis

Attempts to obtain the crystalline forms of the adducts for elemental analysis were unsuccessful. Evaporation at 100° of 5 ml of 0.01*M* solution of adduct in cyclohexane yielded a thick colourless oil for the zinc adduct and highly coloured oils for the others. These oils were dissolved in cyclohexane and injected into a gas chromatograph. The resulting chromatogram showed a peak for the adduct and a peak due to excess of DBSO. The oils could not be distilled without decomposition.

In order to verify the presence of the metal in the various adducts the exit gases from the thermal conductivity cell were vented directly into the nebulizer assembly of an atomic-absorption spectrophotometer *via* a short length of heated stainless-steel tubing. The

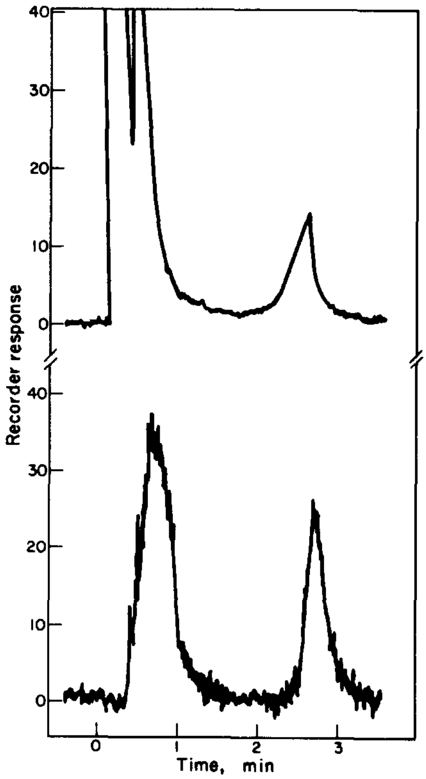

Fig. 6. Gas chromatographic (upper trace) and atomic absorption (lower trace) responses for $Co(HFA)_2 \cdot 2DBSO$. GLC parameters: 180°, 20 in × 1/4 in s.s. column, 5% Dexsil 300 on Chromosorb W. Atomic absorption parameters: Perkin-Elmer 403, 240.72 nm.

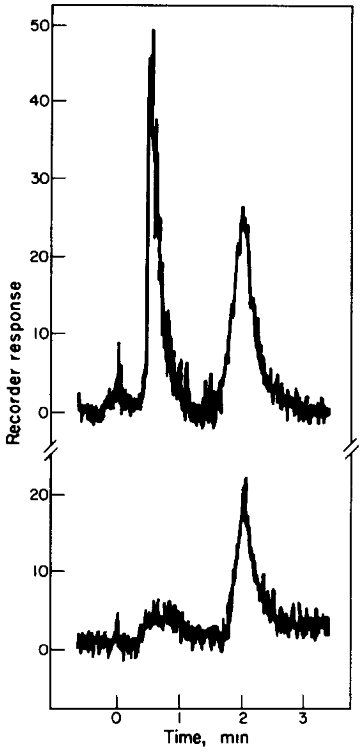

Fig. 7. Atomic-absorption responses for Fe(HFA)$_2$·2DBSO after gas chromatography at 180° with (lower trace) and without (upper trace) background correction on a Perkin-Elmer 403 at 248.32 nm.

spectrophotometer was set at the optimum wavelength for the metal concerned. The output of the spectrophotometer was recorded on a strip-chart recorder. Figure 6 shows the trace for the response from both the thermal conductivity detector and the Perkin-Elmer 403 unit for the elution of cobalt. The initial large peak was a non-specific absorption due to the elution of DBSO and could be largely eliminated by using the background corrector as shown in Fig. 7 for the iron complex. Similar results were seen for the other metals.

These results and similar studies on zinc, nickel, manganese, copper, and chromium complexes confirm that these metal complexes are eluted.

Acknowledgements—Mr. Roy Rice of the University of Missouri Agricultural Experiment Station, University of Missouri-Columbia, is thanked for help in obtaining the mass spectrographic data. This work was supported by National Science Foundation Grant No. SF-GP-33884.

A NEW ELECTROCHEMICAL ANALYSER FOR NITRIC OXIDE AND NITROGEN DIOXIDE

J. M. Sedlak and K. F. Blurton
Energetics Science, Inc., 85 Executive Boulevard, Elmsford, NY 10523, U.S.A.

(*Received* 20 *April* 1976. *Accepted* 4 *June* 1976)

Summary—Individual sensors employing Teflon-bonded diffusion electrodes have been developed to measure nitric oxide and nitrogen dioxide separately, simultaneously, and continuously at part-per-million levels. The NO sensor was biased at 1.5 V and that for NO_2 at 0.8 V, both relative to the hydrogen electrode. The crucial factor in the virtual elimination of response from carbon monoxide, a relatively abundant air-pollutant, was the use of gold electrodes for both detectors. At 0.8 V NO does not react on gold. Although NO_2 does oxidize at 1.5 V it was removed quantitatively from NO/NO_2 mixtures by triethanolamine on firebrick. The NO_2 reduction signal and the NO oxidation signal were stable and reproducible.

Knowledge of the nitric oxide and nitrogen dioxide concentrations in ambient air,[1] working environments[2] and stack gases[3] is frequently required. Many approaches have been suggested for their quantitative measurement, including spectroscopy, gas chromatography, chemiluminescence, ion-specific electrodes, coulometry and wet chemistry.[4,5] Most of these methods, however, measure only one of these oxides, and complete analysis requires conversion of one gas into the other or a third species, with the introduction of additional uncertainties.[5] Moreover, currently available techniques for NO and NO_2 measurement are not well adapted for use in portable instruments.[2]

We have previously reported techniques for measurement of carbon monoxide in ambient air,[6,7] of breath alcohol,[8] and of hydrogen sulphide,[9] based on the electrochemical oxidation of these gases at constant-potential Teflon-bonded diffusion electrodes. We now report the extension of this general technique to the separate and direct measurement of NO and NO_2, with particular reference to the characteristics of this technique which make it a useful addition to air-pollution monitoring instrumentation. An experimental monitoring system with separate sensing elements for both NO and NO_2 was constructed to demonstrate the feasibility of this electrochemical detection method. The selected operating conditions resulted in establishment of rapid response times, linearity of response, minimum interference by other common air constituents and pollutants, and signal stability.

EXPERIMENTAL

The instrument consisted of two independent gas-measuring systems, each comprising a pump, flowmeter, electrochemical sensor and electronic circuits. The sensor was similar to that reported previously[9] and contained a potentiostat, thermistors for signal-temperature compensation, and provision for battery recharge. The low power requirements of the pumping system (0.3 W) and of the electronic components (0.025 W) permitted continuous operation for at least 8 hr on batteries.

The physical dimensions of the NO and NO_2 sensors were identical to those of the sensors previously described.[6,7] In both sensors, the sensing and counter-electrodes were "Teflon"-bonded gold diffusion electrodes, while the reference electrode was a Pt-catalysed diffusion electrode. Although the latter is not a reversible electrode, its potential remained essentially constant (± 0.01 V) within the range 1.00 ± 0.03 V. The NO_2 and NO sensing electrodes were kept at a constant potential (0.8 V and 1.5 V, respectively, with respect to the hydrogen electrode). In a recent fundamental study of the reactivity of gold electrodes we found that both CO and NO gave negligible responses at 0.8 V but that NO_2 yielded a substantial reduction current.[10] Between 1.0 and 1.3 V, CO was oxidized at a small but significant rate, but at 1.5 V its reactivity virtually disappeared again. At 1.5 V NO and NO_2 were both oxidized (the signal for the former being 2–3 times that for the latter, for equal concentrations). However, a filter containing 4 g of triethanolamine-impregnated firebrick can be used to remove NO_2 quantitatively from NO/NO_2 mixtures.[11] To guard against SO_2 interference in NO_2 determination, any of several mercuric salts can be used in a small filter.

The electrolyte, 25% w/w sulphuric acid (3.4 molal) was chosen on the basis of experience, to maintain water balance in the sensor during operation in ambient air with variable humidity.

The NO_2 and NO instruments were zeroed with "Zero Grade 1.0 Air" from Airco Industrial Gases (<1.0 ppm CO, <0.1 ppm NO) which was first passed through activated carbon and alumina to remove traces of NO. All measurements were made at a constant gas flow-rate through the sensor, usually 700 ml/min. The signals (currents) were read on panel meters calibrated directly in ppm NO or ppm NO_2 and also displayed on a Hewlett-Packard Model 680 recorder. The actual currents were measured at the electrochemical sensor (*i.e.*, before amplification) by determining the potential drop across a precision resistor.

The relationship between sensor signal and concentration was checked in two ways. Reference gases of NO in nitrogen and NO_2 in air were obtained from Airco Industrial Gases. These gases and various dilutions with ultra high-purity nitrogen and "zero grade" air, respectively, were drawn into the instrument from 12-l. bags made of polyester-coated aluminium (3M Corporation). Nitrogen was used as the diluent for NO to preclude reaction with oxygen in the sample bag. Secondly, NO or NO_2 samples were drawn into the instrument after passage through an exponential-dilution flask[11] approximately 1.2-l. in volume, at constant flow-rate. In these experiments the NO_2 samples were generated in an air-stream by a permeation tube (at thermostatically controlled temperature) from Metronics Associates.

The response of the NO_2 instrument to NO and of the NO instrument to NO_2 was investigated, as were responses of both systems to SO_2, CO, *n*-propyl nitrate, nitromethane, aniline, nitrobenzene and ammonia. SO_2 and CO/air mixtures were obtained from Airco Industrial Gases and Matheson Gas Products Co., respectively. Samples of the organic compounds were conveniently prepared by collection of the vapour above several ml of pure liquid placed in a large flask, and the ammonia sample was collected from above an aqueous ammonia solution.

RESULTS AND DISCUSSION

Instrument signals

When nitric oxide was introduced into the instrument it was rapidly oxidized according to the equation

$$NO + 2H_2O \rightarrow NO_3^- + 4H^+ + 3e \qquad (1)$$

which was substantiated[10] by the observation that NO, NO_2^-, and NO_2 are all readily oxidized at 1.5 V. The current generated by the reaction reached a steady-state value, i_l, of approximately 11 μA/ppm NO.

When nitrogen dioxide was introduced into the appropriate intake port it was reduced:

$$NO_2 + 2H^+ + 2e \rightarrow NO + H_2O \qquad (2)$$

as evidenced[10] by the rapid reduction of NO_2^- and the unreactivity of NO. The current due to the electro-reduction process reached a steady-state value which was approximately equal to $-12\,\mu$A/ppm NO_2.

Instrument signals for both gases were reproducible to within $\pm 1\%$ in successive trials.

Signal/time behaviour

A sensing system with a first-order response can be described by the following equation

$$\frac{di}{dt} = k(i_l - i) \qquad (3)$$

where i is the instantaneous instrument signal at time t, k is the first-order response coefficient, and i_l corresponds to the signal which would obtain at steady state for the instantaneous concentration, n, of reactive gas in the sensor. For the systems described in this paper,

$$i_l = \alpha n \qquad (4)$$

where α is a constant of proportionality and is usually given in μA/ppm.

In the simplest case the sensor is suddenly subjected to a constant concentration of reactive gas, n_0, for which $i = 0$ at $t = 0$. In this instance

$$\ln\left(1 - \frac{i}{\alpha n_0}\right) = \ln\left(1 - \frac{i}{i_l}\right) = -kt \qquad (5)$$

Similarly, if at $t = 0$ the sensor is at steady state with concentration n_0 passing and then the active gas source is removed (*i.e.*, $t = 0$, $i = i_l = \alpha n_0$)

$$\ln\left(\frac{i}{i_l}\right) = \ln\left(\frac{i}{\alpha n_0}\right) = -kt \qquad (6)$$

The response/time curves for 5.8 ppm NO on signal rise and fall followed equations (5) and (6), respectively. The plots had nearly identical slopes from which the first-order response coefficient $k = 0.51\ \text{sec}^{-1}$ was derived. Approximately 6.6 sec was required for attainment of $0.95i_l$ (rise) and for relaxation to $0.05i_l$ (fall). Neither line extrapolated precisely back to the origin because there was a small lag time (< 1 sec) required at 700 ml/min flow-rate to flush the 5–10-ml volume of the tubing in the system before the sensor.

On the corresponding first-order plots for 4.2 ppm NO_2, both the rise to $0.95i_l$ and the decay back to $0.05i_l$ on admission and removal of the sample gas occurred in 48 sec, which amounts to $k = 0.062\ \text{sec}^{-1}$.

First-order rise and decay had been observed for electro-oxidation of CO,[7] whereas H_2S oxidation signals rose and decayed according to second-order kinetics.[9]

Instrument signal as a function of concentration

Eight concentrations of NO_2 in air in the range 0–4.2 ppm were passed into the NO_2 detector. Seven samples were prepared by dilution of a 4.2-ppm reference gas with "zero" air. The other sample, 3.1-ppm, was obtained from the permeation tube. Least-squares analysis of reduction current *vs.* ppm NO_2 yielded a straight line with a slope of -12.5 μA/ppm NO_2. The standard deviation of the data points from the line was 0.072 ppm NO_2, a portion of which reflects the uncertainty of gas mixing.

The signal/concentration relationship was also linear as determined from eleven gas mixtures from 0 to 39 ppm NO. The slope of the least-squares line was 11.5 μA/ppm and the standard deviation of the points from the line was 0.51 ppm NO. It is important to note that the value of the standard deviation is dependent on the highest concentration tested. In addition, the instrument panel meter was set at 70% full scale for 1410 ppm NO. Two gas samples containing 466 and 39 ppm of NO then gave readings of 22.5 and ~2% of full scale respectively.

Another method available for characterization of the signal/concentration relationship involves the use of an exponential-dilution flask.[12] After establishment of a constant concentration, n_0, of the reactive gas in the flask of volume V, dilution is begun at time zero with air or nitrogen at flow-rate G. With perfect differential mixing the concentration of NO or NO_2 leaving the flask and entering the instrument is given by

$$n = n_0 \exp(-\beta t) \qquad (7)$$

where $\beta = G/V$.

The exponential flask, in conjunction with a gas analyser, is useful for measurement of response to a continuously varying gas concentration. However, certain precautions need to be taken regarding interpretation of the results. The shape of the detector-response/time curve when sampling the dilution-flask effluent is influenced both by the rate of dilution (β) and by the instrument response constant (k). To demonstrate this point consider a system which (*a*) at $t = 0$ is sampling a constant NO or NO_2 concentration, (*b*) has a first-order instrument-response, and (*c*) has i_t and n related by equation (4). Substitution of equations (4) and (7) into (3) gives

$$\frac{di}{dt} + ki = k\alpha n_0 e^{-\beta t} \qquad (8)$$

With initial conditions $t = 0$, $i = \alpha n_0$, the solution of equation (8) is

$$i = \frac{\alpha n_0}{(k - \beta)} [k \exp(-\beta t) - \beta \exp(-kt)] \qquad (9)$$

The two limiting cases for equation (9) are:

$$(1)\ k \gg \beta : i = \alpha n_0 e^{-\beta t} \qquad (10)$$

$$(2)\ k \ll \beta : i = \alpha n_0 e^{-kt} \qquad (11)$$

In case (1), the instrument response is so rapid that the slope of the ln i *vs.* t plot equals β. In case (2), gas dilution is rapid compared with the instrument response, and therefore, the experimental slope corresponds to an assessment of the instrument response constant, k.

For cases in which $k \sim 10\beta$, for example, at times not too near zero, equation (9) can be approximated to

$$i = \frac{\alpha n_0 k \exp(-\beta t)}{(k - \beta)} \qquad (12)$$

Comparison of equations (10) and (12) reveals that the measured signal for the dilution-flask effluent will read higher by a factor of $k/(k - \beta)$ than is predicted by exponential-dilution theory *per se*. Nonetheless, the slope of the ln i *vs.* t plot will eventually equal β at some $t \gg 0$, provided that $k > \beta$.

Dilution tests were carried out for initial NO_2 concentrations of 3.08 and 0.77 ppm. The gas concentrations at the end of the runs were 45 and 11 ppM (parts per milliard), respectively. Background signal fluctuations with no NO_2 passing were equivalent to only ±2–3 ppM (peak to peak). The flask volume V was ~1200 ml and the gas flow-rate G was 650 ml/min which gave a theoretical β of 0.0090 sec^{-1}. Uncertainties were about ±25 ml/min for flow-rate and about ±50 ml for the effective flask volume. As predicted by equation (9), there was curvature of the plots for $t < 30$ sec ($k \sim 7\beta$). At longer times the plots became linear with slopes of 0.0087 sec^{-1} and 0.0083 sec^{-1}, respectively.

Dilution-flask measurements for two starting concentrations (466 and 5.8 ppm NO) were made at $G = 700$ ml/min. Background current fluctuations contributed an uncertainty of ±3 ppM NO. In this instance the slopes of the plots (0.010 and 0.0098 sec^{-1}) were in better agreement with $\beta = 0.0097$ sec^{-1}, probably because $k \sim 53\beta$ for NO.

The present results demonstrate, within experimental uncertainty, a linear relationship between signal and concentration for NO_2 and NO.

Specificity of instrument response

The extent of interference from common air pollutants with typical NO and NO_2 detection systems is indicated in Table 1. It was shown recently that commercial chemiluminescence NO_2-analysers respond nearly quantitatively to certain other nitrogen compounds.[13] By way of comparison, ammonia, n-propyl nitrate, nitromethane, nitrobenzene and aniline were essentially inert in the present electrochemical NO and NO_2 instruments, even at levels many orders of magnitude greater than ever exist in ambient air (Table 1). Moreover, carbon dioxide and water vapour, which cause significant negative interferences in chemiluminescence detection of NO,[14] do not alter the NO or NO_2 signals obtained with the electrochemical analyser.

Table 1. Response of NO and NO_2 measuring systems to various substances

	NO system		NO_2 system	
Interferent gas	Concentration tested, *ppm*	Concentration required to give signal equivalent to 1.0 *ppm* NO, *ppm*	Concentration tested, *ppm*	Concentration required to give signal equivalent to 1.0 *ppm* NO_2, *ppm*
SO_2	2150	No signal	20	No signal
NO	—	—	466	No signal
NO_2	25	No signal	—	—
CO	900	3000	900	1000
n-propylnitrate	2.6×10^4	$>2 \times 10^5$	2.6×10^4	$>2 \times 10^5$
nitromethane	4.0×10^4	$>2 \times 10^5$	4.0×10^4	$>2 \times 10^5$
aniline	520	30,000	520	No signal
ammonia	7300	No signal	7300	No signal
nitrobenzene	290	No signal	290	No signal

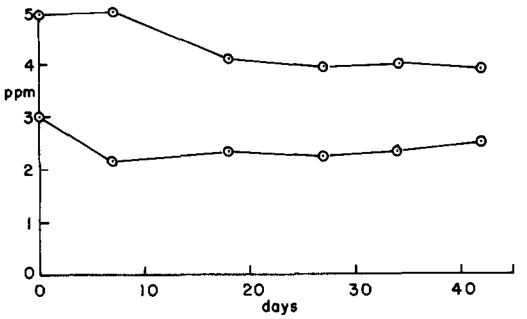

Fig 1. Long-term signal stability. Upper: ppm NO indicated on meter *vs.* time (days) since last calibration. Lower: ppm NO_2 indicated on meter *vs.* time (days) since last calibration.

Twelve-hour zero drift

This parameter has been defined[15] as the difference, expressed in ppm, between the maximum and minimum instrument signal during twelve consecutive hours, with "zero" air passing through the analyser. It is a mandatory test in the certification of automated analysers for certain pollutant gases.[15] Recorder traces showed twelve-hour zero drifts of 0.008 ppm for NO_2 and 0.06 ppm for NO.

Long-term signal stability

An NO/NO_2 instrument was calibrated and then permitted to run continuously on laboratory air for six weeks without recalibration. At weekly intervals meter readings were taken with 5-ppm NO and 3-ppm NO_2 samples. The variation of meter reading with time is shown in Fig. 1. These results, together with the zero drift data, demonstrate that the instrument gives reliable quantitative responses to NO and NO_2 after lengthy periods of non-exposure to these gases, without the need for frequent calibration.

ANALYSIS OF TUNGSTEN CARBIDES BY X-RAY FLUORESCENCE SPECTROMETRY

K. KINSON, A. C. KNOTT and C. B. BELCHER
The Broken Hill Proprietary Company Limited, Central Research Laboratories,
Shortland, N.S.W. 2307, Australia

(*Received* 20 *April* 1976. *Accepted* 29 *June* 1976)

Summary—Five sample presentation techniques were examined for the X-ray fluorescence spectrometric analysis of tungsten carbide alloys in powder and cemented forms. Powder samples may be oxidized by air at 600° before fusion (I), or preferably by lithium nitrate during fusion (II); the fusion is effected with lithium–lanthanum tetraborate followed by briquetting with graphite. Powder samples may also be blended with wax and briquetted (III). Cemented carbides are surface-prepared with silicon carbide before analysis (V). Briquettes prepared by blending carbide powder, lithium–lanthanum tetraborate and graphite (IV), give poor reproducibility, however, owing to micro-absorption effects the technique is not recommended. The determination of eight common elements in tungsten carbide is discussed and the relative standard deviations are 0.002–0.004 for major and 0.008–0.01 for minor elements.

The analysis of tungsten carbides (WC) by optical emission spectrometry (OES), the manufacturing process, the cost benefits of composition control, the preparation of standard samples and a literature survey have been discussed previously.[1]

X-Ray fluorescence spectrometry (XRF) of cemented hard metals or briquetted pre-sintered products affords a convenient method for the precise determination of tungsten, tantalum and niobium and is also suitable for titanium and cobalt, the other major alloying elements. Accordingly, tungsten carbides have been analysed by XRF, using the following sample preparation techniques: solutions,[2] prior oxidation and fusion with borates, incorporation of barium as a heavy element absorber,[3,4] pressure-compacted powders[5] and cemented hard metals.[6,7]

The objectives of the present work were: to develop flexible multi-element XRF methods which could be applied to unknown samples; to achieve the standardization of a suite of powdered and cemented reference standard samples for the direct analyses of intermediate and final products; to evaluate sample preparation and presentation methods compatible with point-to-plane OES techniques.[1] Five sample preparation/surface treatment techniques were examined: prior (I) or *in situ* (II) fusion conversion, of carbides into oxides, fusion with lithium–lanthanum tetraborate, blending with graphite and compaction to a briquette; blending of powdered carbides with wax (III) or powdered lithium–lanthanum tetraborate and graphite (IV) and compaction to a briquette; and sintered solids (V) with diamond or silicon carbide grit polishing.

EXPERIMENTAL

Apparatus

Spectrometer, Siemens automatic vacuum path SRS-1; generator, 4 kW Kristallflex IV; X-ray tubes, Cr 2.6 kW or Mo 3 kW; sample holders, sintered carbon, rotated during irradiation; crystals, LiF_{220} and Ge_{111}; collimator, 0.15°; detectors, gas flow proportional 90% Ar–10% CH_4 (Dz) or scintillation, Tl–NaI (Sz).

Table 1. X-ray fluorescence spectrometric measurement conditions

Element	Method	Line	Crystal	X-Ray tube	Detector
Nb	all (I–V)	K_α	LiF_{220}	Mo	Sz
Ta	all (I–V)	L_{α_1}	LiF_{220}	Mo	Sz
Ni	all (I–V)	K_α	LiF_{220}	Mo	Dz
Co	all (I–V)	K_α	LiF_{220}	Mo	Dz
Fe	all (I–V)	K_α	LiF_{220}	Mo	Dz
V	all (I–V)	K_α	LiF_{220}	Mo	Dz
W	fusion (I & II)	L_{α_1}	LiF_{220}	Mo	Sz
Ti	fusion (I & II)	K_α	Ge_{111}	Cr	Dz
W	unfused (III & IV) &	L_{β_2}	LiF_{220}	Mo	Sz
Ti	cemented (V)	K_{β_1}	LiF_{220}	Mo	Dz

Measurement conditions

Measurements terminated at a time (40–200 sec) adequate to accumulate counts sufficient for the required precision, using the conditions set out in Table 1.

Reagents

Graphite powder, briquetting grade; lithium nitrate, anhydrous; fusion mixture ($<500\ \mu$m) (64% lithium tetraborate–36% lanthanum tetraborate); cold-bonding paraffin wax powder; Johnson Matthey spectrographically pure oxides heated at 600–900° immediately before use.

Recommended procedures

Fusion briquettes. Hand-crush solid or chip carbides to 500 μm in a tungsten carbide mortar and further crush to $<125\ \mu$m in a 10-cm^3 tungsten carbide grinding barrel on a "Siebetechnik" vibratory disc mill.

Grind tungstic oxides to $<63\ \mu$m in a tungsten carbide grinding barrel and dry at 110°; prior oxidation of carbides can be achieved if desired by heating in air at 600° for 30 min. Weigh 100 mg (I) ($<63\ \mu$m oxide) or 85 mg (II) ($<125\ \mu$m carbide) into a 95/5% Pt/Au crucible containing 2 g of fusion mixture and 500 mg of lithium nitrate and mix with a platinum wire; also prepare calibration standards from appropriate pure oxides. Oxidize carbide samples *in situ* by heating from 400° to 800° (7°/min). Fuse all samples at 980° for 10 min. Cool, recover the fused bead, weigh and add graphite powder (1.5 × recovered bead weight). Mill the fusion bead and graphite powder for 3 min in a 100-cm^3 tungsten carbide grinding barrel. Press the milled powder to a 25 mm diam. briquette at 900 kg/cm^2 for 20 sec. Prepare a fresh surface for irradiation by rubbing on P600 grit SiC abrasive paper by hand.

Wax-bonded carbides (III). Weigh 5 g of carbide powder samples ($<10\ \mu$m) or analysed calibration standards into a phial containing 50 mg of cold-bonding paraffin powder and place on a high-speed mixer for 1 min. Add 5 g of boric acid to a press (25 mm ram) to form a backing, add the carbide–wax mixture and press at 5000 kg/cm^2 for 20 sec.

Cemented hard metals (V). Machine-brush on 60 grit silicon carbide abrasive discs. Use a fresh disc for each re-preparation.

Assays are referred to appropriate fused, wax-bonded or cemented solid calibration standards, using synthetic oxide, or powdered and cemented carbide primary standards as described previously.[1]

RESULTS AND DISCUSSION

The preparation, testing and standardization of a suite of powdered and cemented carbides has been discussed by the authors.[1] Other matters discussed were the possibility of elemental inhomogeneity, surface preparation techniques for cemented solid carbides and oxidation and fusion techniques for powdered oxides and carbides.

Klyachko and Yakovleva[8] state that tungsten losses are significant when tungstic oxide is heated at 900°, whereas 3-hr ignition tests at 750° (Gabler and Peterson[9]) showed that losses are confined to volatile elements, notably molybdenum, lead and tin. Blaas *et al.*[3] have advocated oxidation of carbide samples at 450° and this low temperature has particular application to the analysis of samples containing molybdenum. A study has been made of potential losses due to high-temperature oxidation; the oxidation of WC powders was necessary so that standardization analyses could be done against synthetic oxide standards.

Isothermal weight-change studies as a function of time were carried out by heating in air a 1-g ($<125\ \mu$m) sample (60% W, 11% Ti, 8% Ta, 1% Nb as carbides + 13% Co). Maximum weight increase was achieved in 15 min at temperatures in the range 600°–900° (100° intervals) and was in accordance with stoichiometric oxide formation and elimination of carbon; the stoichiometry of the conversion was not of great significance in view of the known uncertainty in the state of oxidation of ignited cobalt oxide. At 450° oxidation was only 50% complete in 45 min, and after 3.5 hr the sample still contained 0.8% residual carbon. Accordingly a 30-min oxidation at 600° was incorporated in the recommended procedure.

The fused oxide/briquette techniques described in the recommended procedure derive from the work of Hasler[10] and subsequent developments.[1,11–13] The present work required an assessment of the potentialities of the fusion/briquette techniques and the standardization of the prepared samples. Accordingly, 6 calibration mixtures were prepared from pure materials and fused and briquetted to cover the ranges: WO_3, 20–95%; TiO_2, 0–20%; Co_3O_4, Ta_2O_5, 0–15%; MoO_3, Fe_2O_3, SiO_2, Al_2O_3, 0–5%; Nb_2O_5, Mn_3O_4, 0–2%, and 20 other oxides, including V_2O_5, $<1\%$. For major elements, the incremental additions were randomized between the various mixtures and bore no relationship to the carbide compositions being analysed. The concentration ranges of Fe_2O_3, SiO_2, Al_2O_3, Mn_3O_4 are not relevant to the analysis of hard metals but were added because a variety of oxide products and residues are analysed by the same technique and it was desired to use a flexible, wide-ranging system to reveal interelement effects. A further 6 calibration standard briquettes were prepared to approximate to the composition of the 6 standard carbide samples after oxidation.

With flux/sample ratio of 21/1 and lanthanum oxide/sample ratio of 3.15/1, matrix effects were found to be negligible. The fusion briquette composition represents both increased dilution and lanthanum concentration as compared with the concentrations recommended by Norrish and Hutton.[11] However the freedom from interference effects is considered to justify the lower X-ray intensities, because results are obtained without the use of extensive computations. The further availability of the briquettes for optical emission measurements is of great benefit.[1]

Calibration graphs were linear for the elements measured and correlation coefficients and lower limits of detection are given in Table 2. The lower limits of detection, calculated as the equivalent of three standard deviations of the background, are adequate for present purposes. With this system a notable spectral interference is TiK_α with VK_α; however, measurement of the apparent VK_α/TiK_α ratio in vanadium-free standards provided a correction factor which was applied successfully to the VK_α count-rate for calib-

* Calculated as 3 standard deviations of background

ration standards and assays. With the measurement conditions used, 1% TiO_2 produced an interference equivalent to 0.024% V_2O_5 and a standard deviation of 0.008% was obtained at the 0.2% V_2O_5 level.

The 6 standard carbide powders were analysed by the proposed fusion techniques (I, II), supported by atomic-absorption spectrophotometry for trace elements, gravimetric techniques for carbon, absorbed water and oxygen, and by optical emission spectrometry for a range of trace elements. Summation of the results obtained (complete analyses) on the 6 powdered samples had a mean value of 99.8%, which is considered satisfactory.

Previous OES studies had been made of *in situ* oxidation–fusion of tungsten carbide powders as compared to air-oxidation followed by fusion.[1] However, the greater precision of measurement available with XRF necessitated an extensive study. The *in situ* oxidation–fusion technique involves a preheating and fusion cycle as compared to a simple fusion; however, a double weighing procedure and potential loss of volatile elements is avoided and calculations are reduced. A comparative set of results is presented in Table 3 and an oxidation temperature of 800° was used to accentuate possible losses.

Inspection of the data and application of statistical tests indicate that losses of tungsten oxide must be insignificant at temperatures below 800° and that the techniques give equivalent results. The temperature recommended for air-oxidation however is a conservative 600° and the *in situ* oxidation is in general the preferred technique and allows better precision for tungsten assays.

The standardized analytical data on the powdered carbide materials together with the subsidiary determinations indicated previously, allow the ready calculation of the compositions of the derived cemented products. Both the pre-sintered powders (III) and the cemented products (V) were examined directly by XRF, and calibration graphs were obtained for all major and trace elements.

Predictable interelement absorption effects were noted for pre-sintered and cemented carbides; however for practical analysis the usual matrix matching of calibration standard samples to assays, or correction techniques, would be appropriate. Absorption in-

* Not recommended for use.

terferences particularly noted were Co with Ta/W, and Ti with Co; spectral interferences were much less extensive than those observed in OES with the same system.[1] Calibration curves were of the same form for sets of wax-bonded pre-sintered carbides, and SiC- or diamond-polished cemented carbides; no advantage is derived from diamond-polishing.

An attempt was made to reduce absorption effects with the direct analysis of pre-sintered carbide powders; the powdered carbides were diluted with lanthanum–lithium tetraborate and graphite (IV) which is analogous to the dilution-buffer process in the oxidation–fusion work. However, matrix effects were not eliminated, as evidenced by deviations from calibration graphs. The associated poorer precision experienced can be attributed to the non-intimate mixing of the lanthanum and carbide particles and accordingly the simple wax-bonded procedure is to be preferred.

Reproducibility data for these different techniques are presented in Table 4.

The work presented demonstrates that accurate results for major element determinations in tungsten carbides can be obtained by XRF with briquettes which have been prepared by fusion. The direct XRF analysis of pre-sintered carbide powders or cemented products was demonstrated by at least one satisfactory technique; however, interelement absorption effects of the type common in XRF militate against simple calibration procedures and in situations where the precision of measurement is acceptable, OES may be a preferred technique.[1] The proposed methods are suitable for the complete composition control of a tungsten carbide manufacturing plant and similar standard deviations are observed for all the recommended techniques.

(*Received* 24 *September* 1975. *Revised* 28 *January* 1976. *Accepted* 31 *May* 1976)

Summary—Molybdenum(V) is quantitatively precipitated as sulphide ($\geq 99.7\%$) from $0.1M$ hydrochloric acid without formation of molybdenum blue and without need for a long digestion. Precipitation is more complete and co-precipitation less than with Mo(VI) sulphide. The precipitate can also be used directly for gravimetric estimation. In the presence of EDTA, molybdenum(V) sulphide is not precipitated from $0.1M$ hydrochloric acid and can be separated from copper, bismuth, antimony and tin sulphides and determined cerimetrically in presence of the EDTA.

Molybdenum is often precipitated as sulphide to separate it from elements[1a] forming acid-soluble sulphides. Complete precipitation is difficult from hydrochloric acid medium,[1a] and there is partial reduction to molybdenum blue,[2a] a milligram of molybdenum or more escaping the first precipitation. The precipitate, filterable only after long digestion, is contaminated by elemental sulphur[3a] and appreciable amounts of other elements, especially tungsten, vanadium and iron, present in the solution.[1a,2b,4a] Separation from other elements forming acid-insoluble sulphides is not possible. Other sulphide reagents have not found wide acceptance because of similar disadvantages or cost. Molybdenum in lower oxidation states is reported to give incomplete precipitation.[2a]

The precipitate cannot be used directly for gravimetric determination.[2c] Conversion into the oxide is unattractive because of sublimation losses, slowness of conversion and the unfavourable factor.[2c] The sulphide or oxide is often converted into molybdate and determined by the lead molybdate method, which is accurate only under rigorous conditions, is tedious and suffers interference from sulphate[5a] and many elements, especially iron, chromium, tungsten and vanadium. The oxine method is more suitable for semimicro amounts but titanium, vanadium, tungsten and uranium interfere even when complexed with EDTA.[5a]

Obviously, precipitation of molybdenum sulphide would be much more useful if the precipitate had constant composition and were suitable for direct determination. We have found that Mo(V) sulphide can be precipitated quantitatively from dilute acid solutions and not at all on complexation with EDTA,[2d] with possible uses for separation and determination of molybdenum, as described below.

EXPERIMENTAL

Reagents

Molybdenum solution. Sodium molybdate dihydrate was dissolved in water to give a stock solution containing 10 mg of Mo/ml. This was standardized by the cerimetric[6a] or the oxine method,[5a] and diluted to give concentrations of 500, 100 and 10 μg/ml.

Solutions of other elements. Prepared by dissolving suitable salts in water or dilute hydrochloric acid to give concentrations of 10 or 20 mg/ml.

Procedures

Precipitation of molybdenum(V) sulphide. A solution containing 5–100 mg of molybdenum was made $2M$ in hydrochloric acid and 10–15 ml in volume, boiled with 200 mg of hydrazine sulphate for 3–4 min in a covered beaker with frequent stirring, and diluted to $0.1N$ acidity. The solution was heated to about 90° and a rapid stream of hydrogen sulphide passed from a Kipp's apparatus for 15 min. The solution was reheated to about 90° and the precipitate immediately filtered off on a porosity-4 sintered-glass crucible and washed with four 5-ml portions of hot $0.1M$ hydrochloric acid saturated with hydrogen sulphide.

The filtrate was boiled free from hydrogen sulphide, then made just alkaline with sodium hydroxide and boiled with 5 ml of 6% hydrogen peroxide, then evaporated to 10–15 ml and subjected to the procedure above to recover the residual molybdenum ($< 0.3\%$). The precipitate was dried at $100 \pm 2°$ *in vacuo* for 1 hr, then cooled in a dry oxygen-free carbon dioxide atmosphere for 15 min (the vacuum being released slowly to avoid "blowing off" of the precipitate) and weighed quickly.

Separation from other elements by precipitation of molybdenum(V) sulphide. Solutions of molybdenum(VI) and either tungsten(VI), uranium(VI), vanadium(V), iron(III), nickel(II) or cobalt(II) were treated by the procedure above. Tartaric acid (3–4 g) was added to mask tungsten. Studies were made on co-precipitation of these elements, present in various ratios to molybdenum (Table 1). Each precipitate was washed 8 times with a total of 25 ml of hot $0.1M$ hydrochloric acid saturated with hydrogen sulphide.

Separation of other elements, by their precipitation as sulphides, from molybdenum(V) masked with EDTA. Solutions containing 20 mg of molybdenum and 10 mg of copper(II), bismuth(III), arsenic(III), antimony(III), tin(II), platinum(IV) or palladium(II), were adjusted to be $2M$ in hydrochloric acid and 10 ml in volume, boiled with 15 mg of hydrazine sulphate for 3–4 min in a covered beaker with frequent stirring, diluted 20-fold and heated to boiling again after addition of 150 mg of EDTA. The precipitation was then done as before. The amounts of hydrazine sulphate and EDTA were proportionately adjusted for other quantities of molybdenum.

Traces of bismuth, tin and arsenic were separated by adding 10 mg of a collector [copper(II) for bismuth; antimony(III) for tin or arsenic] and precipitating as just described.

Ferromolybdenum analysis. Finely powdered sample (0.1 g) was dissolved by gentle warming with 3 ml of concentrated hydrochloric acid and 1 ml of concentrated nitric acid. Nitrate was destroyed by careful addition of solid hydrazine. Any molybdenum blue was oxidized by bromine, the excess of which was boiled off. The solution was neutralized with sodium hydroxide and adjusted to be 2*M* in hydrochloric acid in 10–15 ml volume. The molybdenum was then precipitated.

Determination of elements. Milligram amounts of molybdenum were determined by the oxinate method[5a] or, in presence of EDTA, by cerimetric titration;[6a] microgram quantities were determined by the thiocyanate method.[7]

For determination of elements adsorbed on molybdenum(V) sulphide, the precipitate was dissolved in some water plus 8 ml of concentrated nitric acid, the solution was heated almost to dryness, and nitrate was destroyed by repeated heating to dryness with concentrated hydrochloric acid (3 ml each time). Any molybdenum blue formed was oxidized with bromine. The solution was neutralized with sodium hydroxide. Molybdenum was quantitatively extracted as molybdenum(V) xanthate[8] when tungsten was present, and as the molybdenum thiosulphato-complex[9] when vanadium, uranium, nickel, cobalt or iron was present. After oxidation of the xanthate or thiosulphate in the aqueous phase, the elements were determined by sensitive standard methods.

The molybdenum adsorbed on antimony, copper, bismuth and tin sulphide was determined by the thiocyanate method,[10] after dissolution of the precipitates as above.

RESULTS AND DISCUSSION

Molybdenum(VI) sulphide is precipitated more completely ($\sim 98.5\%$)[4a] from sulphuric acid than from other media. Molybdenum(V) also forms an insoluble sulphide[11] but this has not been investigated for analytical use. Molybdenum(V) obtained by reduction with hydrazine sulphate[6b] in 2*M* hydrochloric acid is quantitatively precipitated by passage of a rapid stream of hydrogen sulphide for 15 min into the solution (acidity 0.1*N*) at 90°. Less complete precipitation is obtained at lower temperature and with a shorter time of passage of the gas. Sulphuric acid medium is equally suitable. The precipitation decreases slightly as the acidity is increased (Fig. 1, curve A). More than 99.7% of the molybdenum is precipitated from 0.05–0.1*M* hydrochloric acid. The precipitate formed in $>0.05M$ hydrochloric acid is easily collected on a G-4 sintered-glass crucible, without need for aging. The precipitation is quantitative for molybdenum concentrations of 0.005–0.5 mg/ml under optimum conditions, though slightly lower at <0.01 mg/ml (Fig. 1, curve B). The formation of molybdenum blue is completely avoided as all the molybdenum is already in the quinquevalent state.

The traces of molybdenum in the filtrate can be recovered completely, if desired, by reprecipitation under the same conditions after expelling the hydrogen sulphide, oxidizing with peroxide, evaporating to about 20 ml and reducing with hydrazine to molybdenum(V). Without the reoxidation and reduction, no recovery is possible. Therefore, it seems that the molybdenum is present in the filtrate in the form of thiomolybdates. A collector is not necessary, unlike the case with molybdenum(VI).[12]

The precipitation of molybdenum(VI) sulphide is little affected by the presence of simple or complexing anions.[2a,b,e,4b] With 20 mg of molybdenum in 200 ml of solution, the precipitation of molybdenum(V) sulphide is not affected by 3–4 g of tartaric acid, 2 g of sodium or ammonium chloride and 1 g of sodium acetate or sulphate, but 1 g of sodium fluoride makes the precipitate slimy and the filtration very slow. Sodium citrate or oxalic acid (0.5 g) suppresses the precipitation almost completely and EDTA (0.15 g) does so completely. Oxidants interfere.

Separation from other elements by precipitating molybdenum(V) sulphide

Although quantitative information is not available, molybdenum(VI) sulphide is very much contaminated by iron,[2b] tungsten, vanadium,[1a] tin,[2b] copper,[4a] and perhaps cobalt, nickel, chromium, uranium. Therefore, reprecipitation is the rule. Precipitation from ammoniacal tartrate solution is preferred, but does not avoid contamination from vanadium and tungsten,[1a] without reprecipitation.

Molybdenum(V) belongs to the same qualitative analytical group as molybdenum(VI),[3b] so the same separations from other elements are possible with both. The adsorption of other elements on molybdenum(V) sulphide is shown in Table 1. It varies somewhat with the ratio of molybdenum to the element. Adsorption of tungsten, vanadium, iron and possibly other elements is much less than on molybdenum(VI) sulphide. Hence molybdenum can be separated from vanadium and tungsten even in acidic media, tungsten being kept in solution with tartaric acid. Acceptable accuracy for molybdenum can generally be obtained without reprecipitation (see Table 4).

Separation from elements of the acid sulphide group by precipitation of the sulphides, masking molybdenum(V) with EDTA

Molybdenum(VI) cannot be separated from copper, bismuth, antimony, arsenic and tin by sulphide precipitation, as they are all precipitated, even in presence of the usual complexing anions.[1b] For separation other methods must be used,[1c,2b,5b] after precipitation of the sulphides, but these methods are tedious and give unsatisfactory results.

If complexed with EDTA, however, molybdenum(V) is not precipitated as sulphide from 0.2*M* hydrochloric acid or at pH 9, whereas antimony, bismuth, copper and tin, in their usual oxidation states after the hydrazine reduction, are precipitated quantitatively or nearly so (Table 2). However, at least 10 mg of these elements should be present in 200 ml, if necessary by addition; otherwise, precipitation is less quantitative. Traces of bismuth and tin in the filtrate can be collected by using 10 mg of copper(II) and antimony(III) respectively. Excess of hydrazine has little effect except on tin. More than 150 mg of EDTA in excess leads to incomplete precipitation of these elements. Arsenic is > 95% precipitated, but about 2% still remains unrecovered even after use of Sb(III) as collector for the traces left in the filtrate. Cadmium and lead are precipitated only in traces. When molybdenum is present with these elements, the sulphide precipitates adsorb traces of molybdenum (Table 3), but a single reprecipitation, if thought necessary, gives acceptable separation of molybdenum from these elements, though in the case of copper a reprecipitation is not so useful. When the ratio of molybdenum to tin is 4:1, the tin precipitate should be allowed to stand for 1 hr at 90° before filtration. At higher ratios, quantitative precipitation of tin is not possible.

Gravimetric determination of molybdenum(V) as sulphide

Molybdenum(VI) sulphide tends to be heavily contaminated by sulphur and other elements such as iron, tungsten and vanadium, which are usually present in molybdenum materials. Ignition to the oxide deals only with the sulphur problem, but is still not attractive because of the long time needed,[1a] losses due to volatilization and the poorer conversion factor. These drawbacks do not apply to molybdenum sulphide, which can be weighed as such. Further, the precipitation is 99.7–99.8% complete. The conversion factor is 0.475, corresponding to $Mo_2S_5 \cdot 3H_2O$. Alcohol, acetone, and ether cannot be used for washing the precipitate, because of its slight solubility in these solvents. For drying, the temperature should not be more than 120°, and the time less than 1 hr. Several samples, including ferromolybdenum, were analysed for molybdenum by this method, with satisfactory results (Tables 4 and 5). As the adsorption of iron, vanadium and tungsten is only about 0.2% even at high concentrations of molybdenum, the method can be used with acceptable error for samples containing

SPECTROPHOTOMETRIC DETERMINATION OF TELLURIUM IN CONCENTRATES AND BRASSES BY CHLOROFORM EXTRACTION OF THE TELLURIUM (IV) HEXABROMIDE–DIANTIPYRYLMETHANE COMPLEX AFTER SEPARATIONS BY IRON COLLECTION AND XANTHATE EXTRACTION

ELSIE M. DONALDSON
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 13 *May* 1976. *Accepted* 6 *June* 1976)

Summary—A method for determining 0.0001–0.10% of tellurium in copper, nickel, molybdenum, lead and zinc concentrates is described. After sample decomposition, tellurium is separated from most of the matrix elements by co-precipitation with hydrous ferric oxide from an ammoniacal medium. After reprecipitation of tellurium and iron, the precipitate is dissolved in 12*M* hydrochloric acid, tellurium(VI) is reduced to the quadrivalent state by heating, and separated from iron, lead and other co-precipitated elements by chloroform extraction of its xanthate. The yellow ion-association complex formed between tellurium(IV) hexabromide and diantipyrylmethane is extracted into chloroform from a 2*M* sulphuric acid–0.6*M* potassium bromide medium. The molar absorptivity of the complex is 1.82×10^3 $1.\text{mole}^{-1}.\text{mm}^{-1}$ at 336 nm, the wavelength of maximum absorption. Small amounts of iron, copper and molybdenum are co-extracted as xanthates under the proposed conditions but do not cause error in the result. Interference from antimony, which is co-extracted as the chloro-complex, is eliminated by washing the extract with water. The proposed method is also applicable to brasses.

A current facet of the Canadian Certified Reference Materials Project sponsored by the Canada Centre for Mineral and Energy Technology involves the certification of various sulphide concentrates for both major and trace elements. As part of this project, the author is concerned with the development of methods for determining trace elements in concentrations as low as 1 ppm (10^{-4}%). Information obtained in previous work[1] involving the chloroform extraction of metal ethyl xanthates from hydrochloric acid media suggested the possibility that a single method for determining tellurium, selenium and arsenic might be developed, based on their co-precipitation with hydrous ferric oxide from an ammoniacal medium,[2] followed by their separation from iron by simultaneous extraction as the xanthates into chloroform and subsequent determination by flameless (carbon rod) atomic-absorption spectroscopy. However, this combined approach was ultimately abandoned because of the extremely poor reproducibility obtained for all three of the elements by the flameless technique. Consequently, an investigation was undertaken to develop a suitable spectrophotometric procedure for determining moderate and trace amounts of tellurium alone, based on the separations above, that would be applicable to diverse concentrates.

The most widely used methods for determining tellurium spectrophotometrically are based on the extraction of the diethyldithiocarbamate complex,[3] measurement of the absorbance of the hydrosol formed by reduction of tellurium with stannous chloride,[4] and formation of the thiourea complex.[5,6] The first two of these methods were not considered in the present work because of their low sensitivity and the instability of the complex and the colloidal sol. Tests with thiourea, which was used previously[1] and found to form a stable sensitive complex, showed that this method is subject to interference from selenium(IV) and from small amounts of iron(III) that are co-extracted with tellurium as the xanthate complex. Recently, methods based on the extraction of the ion-association complexes formed between tellurium(IV) hexahalides and pyrazolone or antipyrene derivatives have been reviewed,[7] and a method has been reported in which the tellurium(IV) hexabromide–diantipyrylmethane complex is extracted into dichloroethane.[8] In this method, the absorbance of the extract is measured at 450 nm (molar absorptivity = 4.2×10^2 $1.\text{mole}^{-1}.\text{mm}^{-1}$) although the absorption spectrum of the complex indicates that the molar absorptivity is at least 3–4 times greater at the wavelength of maximum absorption in the near ultraviolet. Preliminary tests using this method, in which absorbance measurements were made at the wavelength of maximum absorption, 336 nm, showed that moderate amounts of iron(III) and selenium(IV) do not interfere in the complex formation. Consequently, diantipyrylmethane was utilized in the present work, which de-

---

scribes the successful determination of tellurium in copper, nickel, molybdenum, lead and zinc concentrates and brasses. Interference from copper during the separation of tellurium from iron by chloroform extraction of its xanthate is avoided by prior separation of the tellurium from copper by a double coprecipitation of tellurium with hydrous ferric oxide.

EXPERIMENTAL

Reagents

Standard tellurium solution, 10 *μg/ml.* Dissolve 0.1251 g of tellurium dioxide by heating gently with 25 ml of concentrated nitric acid, cool, and dilute to 500 ml with water. Dilute 10 ml of this stock solution to 200 ml with water. Prepare fresh as needed. (The tellurium dioxide used was found to be pure, by titration with potassium permanganate.)

Diantipyrylmethane, 4*% w/v solution in ethyl alcohol.* Prepare a fresh solution every 7 days (Note 1).

Iron(III) sulphate solution (1 *ml* ≅ 20 *mg of iron*). Dissolve 25 g of ferric sulphate monohydrate in hot water, add 10 ml of 50% v/v sulphuric acid, cool and dilute to 250 ml with water.

Potassium ethyl xanthate, 20*% w/v solution.* Prepare fresh as required.

Potassium bromide, 3*M solution.*

Potassium sulphate, 2.5*% w/v solution.*

Sulphuric acid, 10*M and* 50*% v/v.*

Nitric acid, 50*% v/v.*

Hydrochloric acid, 20*% v/v.*

Ammonia, 5*% v/v.*

Chloroform. Analytical-reagent grade and high-purity (alcohol- and peroxide-free).

Procedures

Calibration curve. Add 2 ml of 2.5% potassium sulphate solution and 2 or 3 drops of 50% sulphuric acid to each of eight 50-ml beakers; then, by burette, add to the last seven beakers 0.5, 1, 2, 3, 4, 5 and 6 ml, respectively, of standard 10 μg/ml tellurium solution. The first beaker contains the blank. Evaporate each solution to dryness or near dryness, cool, wash down the sides of the beaker with a small amount of water and evaporate to dryness again to ensure the removal of nitric acid. Add 5 ml of 10*M* sulphuric acid and 2 or 3 ml of water, heat gently for 2 or 3 min and cool to room temperature in a water-bath.

Transfer each solution to a 60-ml separatory funnel, marked at approximately 25 ml and containing 5 ml of 3*M* potassium bromide. Add 2 ml of 4% diantipyrylmethane solution, dilute the resulting solution to the mark with water, stopper, mix thoroughly and allow the solution to stand for 15 min to complete the complex formation. By pipette, add 10 ml of high-purity chloroform to each funnel, stopper and shake for 2 min. Allow several min for the layers to separate, then drain the chloroform layers into dry 15-ml centrifuge tubes and centrifuge for 1 min (Note 2). Determine the absorbance of the blank and each extract, at 336 nm, against chloroform as the reference solution, using 10-mm cells. Correct the absorbance value obtained for each tellurium bromide–diantipyrylmethane extract by subtracting that obtained for the blank. Plot μg of tellurium *vs.* absorbance.

Concentrates and brasses. Depending on the expected tellurium content and/or the iron content (Note 3), transfer 0.2–1 g of powdered sample, containing not more than ~150 mg of iron, to a 250-ml beaker. Add ~1.5 g of potassium chlorate (Note 4), moisten with a few ml of water, cover and carefully add 15 ml of concentrated nitric acid in small portions. Heat gently until the sample is decomposed, then remove the cover, add 25 ml of 50% sulphuric acid, wash down the sides of the beaker with a small amount of water, and carefully evaporate the solution until copious fumes of sulphur trioxide are evolved. Cool, add ~100 ml of water, 5 ml of concentrated hydrochloric acid, and sufficient iron(III) sulphate solution, if necessary, for at least 80 mg of iron to be present. Cover and heat to dissolve the soluble salts.

Add sufficient concentrated ammonia solution to the resulting solution to precipitate iron as the hydrous oxide, then add 5 ml in excess and boil the solution to coagulate the precipitate. Allow it to settle, then filter the hot solution (Whatman No. 40 paper) and transfer the bulk of any insoluble material and any remaining globules of sulphur to the filter paper with a jet of 5% ammonia solution. Wash the paper and precipitate twice with 5% ammonia solution and discard the filtrate. Place the original beaker under the funnel and dissolve the precipitate with hot 20% hydrochloric acid contained in a wash-bottle. Wash the paper three times with the acid solution and discard the paper. Wash down the sides of the beaker with the hot acid solution, then reprecipitate the iron and filter as described above. Wash the beaker twice and the paper and precipitate three times with 5% ammonia solution. Place a 125-ml Erlenmeyer flask under the funnel, wash the precipitation beaker three times with concentrated hydrochloric acid from a plastic "squeeze" wash-bottle, and add the washings to the paper containing the precipitate. When the precipitate has dissolved, wash the paper three times with concentrated hydrochloric acid (Note 5), and discard it. Run a blank, with ~80 mg of iron(III) added, through the whole procedure.

Heat the blank and sample solutions in a hot water-bath at 90–95° for 30 min to ensure the complete reduction of tellurium(VI) to the quadrivalent state, then cool the solution to room temperature in a water- or ice-bath. Transfer each solution to a 125-ml separatory funnel, using concentrated hydrochloric acid to wash the flask, and dilute, if necessary, to ~50 ml with the concentrated acid. Add 10 ml of analytical-reagent grade chloroform, followed by 1 ml of freshly prepared 20% potassium ethyl xanthate solution, stopper and extract immediately (Note 6) by shaking for 1 min. Allow several min for the layers to separate, then drain the chloroform phase into a 125-ml separatory funnel. Extract the aqueous phase twice more, in a similar manner, with 10- and 5-ml portions of chloroform and 1 and 0.5 ml of xanthate solution, respectively, then wash the aqueous phase by shaking it for ~30 sec with 5 ml of chloroform. Add 15 ml water and 0.2 ml xanthate solution to the combined extracts, stopper, and shake for 1 min. Allow several min for the layers to separate, then drain the chloroform phase into a 150-ml beaker. Wash the aqueous phase three times, by shaking for ~30 sec each time, with 3 ml chloroform, and add the washings to the beaker containing the initial extract. Add 10 ml of 50% nitric acid to the combined extracts and heat in a hot water-bath to remove the chloroform. Add 0.5 ml of 50% sulphuric acid and 2 ml of 2.5% potassium sulphate solution, cover and heat until the volume of the solution has been reduced to ~3 ml. Remove the cover, wash down the sides of the beaker with water, and evaporate the solution to dryness or near dryness.

If the sample contains 60 μg or less of tellurium, evaporate both the sample and blank solutions to dryness or near dryness, after washing down the sides of the beakers with a small amount of water, to ensure the complete removal of nitric acid. Cool, add 5 ml of 10*M* sulphuric acid and 2 or 3 ml of water, heat gently for 2 or 3 min, cool to room temperature, and proceed with the determination of tellurium as described above (Note 7).

If the sample contains more than 60 μg of tellurium, add 10 ml of 50% nitric acid to both the sample and blank solutions and heat gently to dissolve the salts. Cool, transfer the solutions to volumetric flasks of appropriate size (50–200 ml) and dilute to volume with water. Transfer suitable aliquots (10–50 ml) of both solutions to 150-ml beakers, add 2 or 3 drops of 50% sulphuric acid and 2 ml of 2.5% potassium sulphate solution and proceed with the removal of nitric acid by evaporation and the subsequent determination of tellurium as described above.

Notes

1. Pure white diantipyrylmethane is recommended. The yellow compound sold by some manufacturers yields a high blank.
2. Filtration of the extracts through cotton-wool or filter paper to remove water droplets is not recommended, because of possible contamination from residual organic and other materials that absorb in the near ultraviolet.
3. Samples containing more than ~150 mg of iron should not be taken, because of the resultant slowness of the subsequent hydrous oxide filtration procedure, and particularly if a large amount of copper is present. In the presence of larger amounts of iron, sufficient copper is retained in the hydrous oxide precipitate, after a double precipitation, to cause low or negative results for tellurium.
4. The addition of potassium chlorate can be omitted for brass samples.
5. It is not necessary to remove all of the yellow iron colour from the filter paper. The total volume of the sample solution should be 40–50 ml at this stage.
6. Because of the known instability of many metal xanthate complexes, extraction immediately after the addition of chloroform and xanthate solution is recommended.
7. The presence of a small amount of co-extracted copper is indicated by the reddish colour obtained on addition of the sample solution to the potassium bromide solution in the separatory funnel. This colour disappears on dilution of the solution with water.

RESULTS

Extraction of the tellurium(IV) hexabromide–diantipyrylmethane complex

Busev and Babenko[8] found that the yellow 1:6:2 tellurium(IV) hexabromide–diantipyrylmethane ion-association complex can be extracted into chloroform and benzene but that it is most efficiently extracted with dichloroethane. Tests carried out with benzene, because dichloroethane was not immediately available, yielded extremely erratic results which were found to be caused by the presence of organic peroxides in the solvent. Subsequent tests with high-purity, peroxide-free (chromatographic quality) chloroform showed that up to at least 60 μg of tellurium contained in ~25 ml of solution can be extracted quantitatively in a single stage with 10 ml of chloroform. The extraction of larger amounts was not attempted because of the high absorbance of the resulting extract.

Busev and Babenko recommend measurement of the absorbance of the complex at 450 nm, but 336 nm, the wavelength of maximum absorption, was used in the present work because of the ~4-fold increase in sensitivity. The molar absorptivity at 336 nm is 1.82×10^3 $l.mole^{-1}.mm^{-1}$. Beer's law is obeyed over the range investigated, and the absorbance of the complex remains constant for at least 2 hr.

Factors influencing the formation and extraction of the tellurium complex

Effects of sulphuric acid and potassium bromide concentrations. Busev and Babenko[8] recommend the extraction of tellurium from a 1.8*M* hydrobromic acid–1*M* potassium bromide medium. However, initial tests in which the complex was extracted from hydrobromic acid media alone yielded high blank values, presumably caused by the co-extraction of residual bromine from the acid. Although this blank can be reduced by employing redistilled hydrobromic acid, subsequent tests showed that extraction from a sulphuric acid–potassium bromide medium is more satisfactory. The extraction of the complex is complete from solutions 1.5–3*M* in sulphuric acid and at least 0.5*M* in potassium bromide. Larger concentrations of potassium bromide do not affect the extraction. Extraction from 2*M* sulphuric acid–0.6*M* potassium bromide media was chosen for subsequent work.

Effects of diantipyrylmethane concentration and time. Tests performed with varying volumes of diantipyrylmethane solution showed that 1.5–2 ml of a 4% solution and approximately 15 min are required for complete complex formation under the conditions of the present investigation.

Separation of tellurium by extraction of its ethyl xanthate complex

Information obtained by the author in previous work[1] involving a study of the chloroform extraction of numerous metal ethyl xanthates from hydrochloric acid media showed that tellurium(IV) [or probably tellurium(II) after reduction by xanthate] can be quantitatively, or almost quantitatively extracted over a wide range of acidity. Consequently, it was considered that extraction from 12*M* hydrochloric acid, to minimize co-extraction of iron, copper, molybdenum and other elements, might be an effective means of separating small amounts of tellurium from large amounts of iron and from other co-precipitated elements after collection of tellurium by co-precipitation with hydrous ferric oxide from an ammoniacal medium; therefore the xanthate extraction procedure was investigated in the present work.

Preliminary experiments carried out with 12*M* hydrochloric acid containing up to 1 g of iron(III) showed that up to at least 1 mg of tellurium(IV) can be quantitatively extracted into chloroform as the xanthate in three successive extractions. Subsequent tests showed that if tellurium is present in the sexivalent state, prior reduction in a 12*M* hydrochloric acid medium, by heating at 90–95° for ~30 min,[9] is required in the presence of moderate amounts of iron(III). However, low or completely negative results were obtained for tellurium when the xanthate extraction procedure, after reduction of tellurium(VI) as described above, was applied to synthetic copper concentrate samples following a single separation of tellurium by co-precipitation with hydrous ferric oxides. Further work showed that the copper retained in the hydrous oxide precipitate, after a single precipitation, inhibits or completely prevents the extraction of tellurium as the xanthate. It is not known how the copper interferes, but tests showed that the inhibiting effect is much more pronounced in the presence of iron. Up to 50 mg of copper(II) alone will not interfere with the extraction of 50 μg of tellurium, but the same amount in the presence of 100 mg of iron(III) almost completely prevents extraction. Subsequent work showed that this interference effect can be avoided by removing the bulk of the copper retained in the initial hydrous ferric oxide precipitate, by performing a second precipitation.

Effect of diverse ions

It was found previously[1] that platinum(IV), palladium(II), gold(III), rhenium(VII) and selenium(IV) are partially or completely extracted into chloroform as xanthate complexes from 10M hydrochloric acid media, that germanium is extracted as the chloro-complex, and that arsenic(III) and arsenic(V) (after reduction by chloride[10]) are extracted as either xanthate- or chloro-complexes. In addition, it was found in the present work that small amounts of iron(III) are co-extracted from 12M hydrochloric acid media. Consequently, an investigation was made of the effects of moderate amounts of these ions on the determination of small amounts (50 μg) of tellurium. The results of these tests showed that up to at least 500 μg each of rhenium(VII), selenium(IV) and germanium, and up to at least 5 mg of iron(III), arsenic (III) and arsenic(V) do not interfere in the determination of tellurium by the proposed method. Although Busev and Babenko[8, 11] found that gold(III) interferes in their method because of its co-extraction into dichloroethane as the bromoaurate–diantipyrylmethane complex, up to at least 500 μg of gold(III) will not interfere in the present method. Small amounts of platinum(IV) (>50 μg) and palladium(II) (>25 μg) interfere during complex formation, but these elements are almost completely separated from tellurium during its co-precipitation from an ammoniacal medium with hydrous ferric oxide. Up to at least 200 μg of each will not interfere after a single ammonia separation of iron and tellurium. Residual copper and molybdenum, which are retained in the precipitate even after a double separation of iron and tellurium, are co-extracted to a slight extent from 12M hydrochloric acid media, but do not cause error in the tellurium result. Antimony(V), tin(IV) and bismuth are completely copreciptitated with tellurium and iron from ammoniacal media. Tin and bismuth do not interfere in the proposed method, but antimony(V) (more than approximately 1 mg) causes high results for tellurium because it is co-extracted, to a slight extent, as the chloro-complex, during the extraction of tellurium as the xanthate, and forms a similar extractable bromide-diantipyrylmethane complex. Interference from antimony (up to at least 50 mg) is eliminated in the present work by washing the tellurium xanthate extract with water. Large amounts of sulphate salts that are retained in the precipitate after a single precipitation and separation of tellurium may interfere in the subsequent reduction of tellurium(VI) in 12M hydrochloric acid medium. Consequently, a double precipitation is recommended. Nitrate salts interfere in a similar manner.

Applications

The proposed method was applied to the analysis of a series of five synthetic concentrates (*i.e.*, commercial mineralogical sulphide concentrates ground to finer than 200 mesh) in which the added tellurium was varied from 0.0005 to 0.10%. The standard tellurium solution was added directly to the powdered samples. Because of its high iron content, 0.5-g samples were taken of the copper concentrate; 1-g samples were taken of the remaining concentrates. The method was also applied to three standard reference cartridge-brass samples. The results of these analyses are given in Tables 1 and 2.

Table 1. Recovery of tellurium from synthetic concentrate samples

Matrix	Total Te present, %	Te found, %

Duplicate determinations of tellurium in the Cu, Ni, Mo, Pb and Zn concentrates by the proposed method gave 0.0020_5 and 0.0019_0, 0.0017_1 and 0.0016_0, 0.0004_4 and 0.0002_5, 0.0003_5 and 0.0003_3, 0.0000_6 and 0.0001_0%, respectively. The iron contents of the respective concentrates were 31.94, 1.58, 1.15, 8.40 and 11.10%.

Table 2. Determination of tellurium in N.B.S. cartridge brasses

Sample	Certified value, % Te	Te found, %
NBS-1100	0.0035	0.0034_8, 0.0034_3
NBS-1101	0.0015	0.0013_5, 0.0013_4
NBS-1102	0.0003	0.0000_8, 0.0000_8

DISCUSSION

Table 1 shows that the results obtained for the synthetic concentrate samples agree favourably with the total calculated amount of tellurium present. The results obtained (Table 2) for the first two of the National Bureau of Standards brass samples are in good agreement with the certified values, but that obtained for the third suggests that the certified value may be too high.

The proposed method is suitable for samples containing 0.0001% or more of tellurium. Probably samples containing approximately 0.01% or more can be analysed by flame atomic-absorption spectroscopy after removal of the chloroform from the tellurium xanthate extract by evaporation as described, followed by evaporation of the solution to dryness, dissolution of the residue in dilute nitric or hydrochloric acid, and dilution of the resulting solution to an appropriate volume (25 ml) with water.

Acknowledgements—The author thanks D. J. Charette for his critical review of this manuscript, and R. R. Craig for determining the iron contents of the concentrates.

BEHAVIOUR OF TRACE IMPURITIES DURING CHEMICAL DISSOLUTION OF A METAL: PLATINUM ELEMENTS IN ALUMINIUM AND NICKEL

A. A. SAMADI, R. GRYNSZPAN and M. FEDOROFF
Centre d'Etudes de Chimie Métallurgique 15, rue Georges Urbain, 94400 Vitry-sur-Seine, France

(*Received* 16 *March* 1976. *Accepted* 28 *May* 1976)

Summary—In order to study the behaviour of trace impurities during aqueous dissolution of a sample, aluminium and nickel-based alloys containing 10^{-4}–1% Ir, Os or Ru were used. Yields of chemical separations such as distillation and ion-exchange were chosen as dissolution criteria. Dissolution of aluminium samples leads to precipitation of the three impurities. The Os and Ru precipitates can afterwards be dissolved by an oxidation procedure, in contrast to commercial powders of these elements. This behaviour may be explained in terms of the small grain-size of the precipitates. The iridium precipitates cannot be dissolved, which prevents quantitative separation of this element from an aluminium matrix. In the case of nickel alloys, these three impurities are dissolved and can be quantitatively separated.

In many analytical methods samples must be dissolved in aqueous media. In activation analysis, use of solutions of samples and standards is actually the easiest way to achieve identical and reproducible counting geometry. Dissolution is also needed when a chemical separation is included in the analytical procedure.

A proper dissolution method should result in a particular component being dissolved either completely (in which case it should also be brought to a definite oxidation state), or not at all. Depending on the chemical properties of the elements, this is not always easy to achieve. It may be a difficulty in the determination of Ru, Os and Ir when present as the metals in more electropositive matrices such as aluminium and nickel. These impurities should be deposited in the metallic state during the dissolution of the sample in either acidic or basic medium, and because of the difficulty of dissolving them it is not easy to see how to bring them to the oxidation state necessary for determination.

We wanted to study this problem with experimental conditions as close as possible to those encountered with an actual sample. For the purpose, we made alloys containing a very small but known quantity of each of these elements in aluminium or nickel[1] and irradiated them in a thermal neutron flux. Thus, we had aluminium or nickel samples doped with radioactive tracer of Ru, Os or Ir. In order to state whether the tracer dissolves or not, we thought that the best way was to submit the dissolved sample to a chemical separation. We assumed that the extent of dissolution of the tracer would be defined by the yield of the chemical separation, calculated from radioactivity measurements.

From the possible chemical separations we chose distillation for Ru and Os, which have volatile oxides, and ion-exchange for all three elements. Anion-exchange was performed in hydrochloric,[2,3] hydrobromic[4] or nitrite media,[5] and cation-exchange in hydrochloric acid–ethanol medium.[6]

EXPERIMENTAL

Experiments were performed on Al or Ni containing from 0.5 to 20,000 μg of Os, Ru or Ir per g of matrix and on commercial Os and Ru powders. Samples (2–100 mg) were irradiated for periods ranging from 30 min to 2 days, according to the concentrations, in a thermal-neutron flux of $3 \times 10^{12}\,n \cdot cm^{-2} \cdot sec^{-1}$ in the EL_3 reactor at Saclay. After application of the experimental procedures, the yield of the chemical separation was calculated from radioactivity measurements of the various chemical fractions, on a Ge(Li) detector coupled to a pulse-height analyser.

Distillation procedures

These were studied only with aluminium samples. We used a distillation apparatus consisting of a 250-ml flask wherein the samples were dissolved, a 10-cm distillation column, a condenser, and two receivers containing 20 ml of 9*M* sodium hydroxide.[7] The apparatus was flushed with air at a flow-rate of 200 ml/min. Various techniques were tried, as follows. The samples were dissolved in 10–15 ml of the acids and bases mentioned.

Procedure D_1 (*Os, Ru*). The sample was dissolved in 10 ml of sodium hydroxide 6*M*. The solution was then adjusted to be 6–8*M* in hydrochloric acid and the distillation performed according to Payne.[8] After addition of 10 ml of 20% perchloric acid, and then 15 ml of 20% sodium bromate solution, the distillation was continued for 30 min longer, and then for a further 40 min after dropwise addition of 15 ml of 20% sodium bromate solution. The radioactivities of the receiver solutions and of the residue were compared.

Procedure D_2 (*Os, Ru*). The sample was dissolved in 6*M* hydrochloric acid. The acidity was adjusted to be 8*M* and the solution treated as in procedure D_1.

Procedure D_3 (*Os*). The sample was dissolved in 6*M* sodium hydroxide. The solution was adjusted to be 12*M* in sulphuric acid and the distillation performed according to Chung and Beamish[9] after addition of 30 ml of 30% hydrogen peroxide.

Procedure D_4 (Os). The sample was dissolved in 6*M* hydrochloric acid and the distillation performed as in procedure D_3.

Procedure D_5 (Os). The sample was dissolved in 6*M* hydrochloric acid and the distillation performed from *aqua regia.*

Procedure D_6 (Os, Ru). The sample was dissolved in 6*M* hydrobromic acid. After evaporation the residue was treated with a solution of 6*M* hydrobromic acid containing 2% of bromine. The solution was evaporated (during the evaporations only 0.01% Ru and 0.67% Os were lost) and submitted to distillation procedure D_3 for Os and D_1 for Ru.

Procedure D_7 (Os). The sample was dissolved in 8*M* sulphuric acid and then treated as in procedure D_3.

Procedures using ion-exchange for aluminium samples

Procedure E_1 (Os, Ru). The sample was dissolved in a 6*M* hydrobromic acid–2% bromine solution. The resulting solution was adjusted to be 0.5*M* in hydrobromic acid and 0.0035*M* in bromine and passed through a column (height 12 cm, diameter 1 cm) of Dowex 1 × 4 resin, Br^- form, at a flow-rate of 1.5 ml/min. The column was washed with 20 ml of a solution having the same concentrations of the acid and bromine as the test solution. The radioactivities of the primary solution, of the resin and of the eluate were measured.

Procedure E_2 (Os, Ru). The sample was dissolved as in procedure E_2 and the solution was evaporated almost to dryness. The residue was dissolved in 1*M* sodium nitrite and adjusted to be 0.1*M* in nitrite at pH 6 in a volume of 30 ml. This solution was passed through a column (height 10 cm, diameter 1 cm) of Dowex 1 × 8 resin, NO_2^- form, at a flow-rate of 1 ml/min. The column was washed with 30 ml of 0.1*M* sodium nitrite at pH 6. The radioactivities were measured as in procedure E_1.

Procedure E_3 (Ir). The sample was dissolved in 6*M* hydrochloric acid. The solution was evaporated almost to dryness, treated with 0.5 ml of 0.5% ceric sulphate solution in 4*M* sulphuric acid and adjusted to be 1*M* in hydrochloric acid in a volume of 30 ml. The solution was passed through a column (height 15 cm, diameter 1 cm) of Dowex 1 × 8 resin, Cl^- form, at a flow-rate of 2 ml/min. The column was washed with 30 ml of 1*M* hydrochloric acid containing 0.05% ceric sulphate. The radioactivity measurements were performed as in procedure E_1.

Procedure E_4 (Ir). The sample was dissolved in 6*M* hydrochloric acid. Concentrated nitric acid was added in order to produce *aqua regia*, which was then evaporated almost to dryness. The residue was dissolved in 2*M* hydrochloric acid and oxidized with a cerium (IV) solution. The solution obtained (20 ml) was passed through a column (height 10 cm, diameter 0.6 cm) of Dowex 1 × 8 resin, Cl^- form, at a flow-rate of 2 ml/min. The column was washed with 20 ml of 2*M* hydrochloric acid containing 0.05% ceric sulphate. The measurements were performed as in procedure E_1.

Procedure E_5 (Ir). The sample (5-μg/g alloy only), and 30 mg of non-irradiated 0.4% alloy used as carrier, were dissolved in 5*M* sodium hydroxide. The solution was then treated with sulphuric acid and cerium (IV) and boiled for 30 min. This solution (20 ml), 1*M* in sulphuric acid, was passed through a column (height 10 cm, diameter 6 cm) of Dowex 1 × 8 resin, initially in the Cl^- form and previously treated with 0.05% ceric sulphate solution. The column was washed with 20 ml of 1*M* sulphuric acid containing 0.05% ceric sulphate. The radioactivity measurements were performed as in procedure E_1.

Procedure E_6 (Ir). The sample was dissolved in 6*M* hydrobromic acid–2% bromine solution. After evaporation almost to dryness, the residue was dissolved in more of the solvent mixture, again evaporated almost to dryness, and redissolved in 20 ml of 0.5*M* hydrobromic acid. This solution was filtered through a porosity 4 sintered-glass filter covered with an Ederol No. 4/M filter paper. The filtrate was adjusted to be 0.05*M* in hydrobromic acid–0.0035*M* bromine in 20 ml. The radioactivities of the filtrate and of the filter were measured. The filtrate was passed through a column (height 15 cm, diameter 1.2 cm) of Dowex 1 × 4 resin, Br^- form, at a flow-rate of 1 ml/min. The column was washed with 20 ml of 0.05*M* hydrobromic acid–0.0035*M* bromine. The radioactivities of the resin and of the eluate were measured.

Procedure E_7 (Ir). The sample was dissolved in 6*M* hydrochloric acid. Concentrated nitric acid was added in order to produce *aqua regia*, which was then evaporated almost to dryness. The residue was dissolved in 4*M* hydrochloric acid and oxidized with hydrogen peroxide. The solution was evaporated and adjusted to be 0.1*M* in hydrochloric acid and to contain 90% ethanol. This solution (40 ml) was passed through a column (height 10 cm, diameter 1 cm) of Dowex 50 × 8 resin, H^+ form, at a flow-rate of 2 ml/min. The column was washed with 40 ml of 0.1*M* hydrochloric acid–90% ethanol.

The eluate was adjusted to be 0.2*M* in sodium nitrite and passed through a Dowex 1 × 8 column as in procedure E_2. The yields of sorption on both columns were determined by radioactivity measurements.

Procedure E_8 (Ir). The sample was dissolved in 5 ml of the bath used for chemical polishing of aluminium[11] (70% phosphoric acid, 25% sulphuric acid, 5% nitric acid) at 90°. The solution was diluted to 60 ml and passed through Dowex 50 × 8 resin as in procedure E_7.

Procedure E_9 (Ir). The sample was dissolved in a 1:1 v/v nitric acid–hydrofluoric acid mixture.[12] The solution was evaporated in order to eliminate the acids and then made 0.1*M* in hydrochloric acid and to contain 90% ethanol. It was then treated as in procedure E_7.

Procedure using ion-exchange for nickel samples

Procedure E_{10} (Ir). The nickel sample was dissolved in 6*M* nitric acid. The solution was evaporated twice in presence of concentrated hydrochloric acid, in order to eliminate the nitric acid. The solution was then adjusted to be 0.1*M* in hydrochloric acid and to contain 90% ethanol, and passed through Dowex 50 × 8 and Dowex 1 × 8 resins as in procedure E_7.

RESULTS AND DISCUSSION

Separation yield with a nickel matrix

We did not observe a precipitate during the dissolution of a nickel sample. The separation yields of platinum elements were always very good. It seems that the electropositivity of the matrix has no effect

Table 1. Chemical separation yield of Ru in Al by various procedures (%)

Sample	Procedure				
	D_1	D_2	D_6	E_1	E_2
Al–Ru 0.34%	96.2	—	—	—	—
Al–Ru 0.30%	—	95.1	98.2	84.5	99.8
Al–Ru 50 μg/g	95.3	97.1	97.8	—	—
Ru commercial powder	≤0.5	≤0.7	≤0.7	—	—

Table 2. Chemical separation yield of Os in Al by various procedures (%)

Sample	Procedure D_1	D_2	D_3	D_4	D_5	D_6	D_7	E_1	E_2
Al–Os 2%	70	—	99.8	99.2	—	—	99.2	68.3	—

Os commercial powder	⩽0.2	—	⩽0.8	⩽0.7	1	⩽0.5	⩽0.1	—	—

when nitric acid is used for the dissolution. Platinum elements are probably dissolved as soon as they appear at the sample surface.

Separation yield with an aluminium matrix

In the case of aluminium we observed black precipitates during the dissolution of the less dilute alloys. The behaviour of these precipitates depends on the element concerned and on the further treatment.

In Tables 1 and 2 are presented the separation yields for Ru and Os. We did not apply procedures D_3, D_4, D_5 and D_7 to Ru, as these methods do not give quantitative distillation of this element, even if a soluble salt is used.[9] Such methods could not be used to test the dissolution of ruthenium.

Tables 1 and 2 show that the alloys and commercial powders exhibit completely opposite behaviour. The commercial powders could never be dissolved, whereas Os and Ru resulting from alloy dissolution were separated in 95–100% yield by methods D_3, D_4, D_5, D_6, D_7, E_2 and D_1, D_2, D_6, E_2 respectively.

Distillation of osmium after oxidation by bromate (methods D_1 and D_2) and sorption of Os and Ru on an anion-exchange resin in hydrobromic acid medium did not give quantitative separations. Low yields were obtained even when soluble salts (ammonium hexachloro-osmate and hexachlororuthenate) were used. The results showed that methods D_1, D_2 and E_1 could not be used to test the dissolution.

Table 3. Fixation of Ir from Al samples, on anion-exchange resin by various procedures (%)

Ir in alloy, w/w	Procedure E_3	E_4	E_5
10^{-2}	—	92.6	—
4×10^{-3}	—	97.1	—

5×10^{-5}	—	88.7	88.5
5×10^{-6}	—	93.6	—

In the case of iridium neither of the ion-exchange methods leads generally to a quantitative separation (Table 3). The separation yield could not be correlated to the alloy concentration. Experiments performed with a soluble salt of iridium (tetrachloride obtained by electrolytic dissolution of Ir[10]) showed the same result, which could mean that the precipitate is dissolved during the oxidation process. However the presence of a black precipitate even after oxidation in the case of the 1% alloy, suggested that the ion-exchange resin might act as a filter. In order to check this hypothesis, we applied procedure E_6 in which the solution was filtered before passage through the resin. The results presented in Table 4 show that an appreciable fraction of the iridium was retained on the filter. This fraction was not very

Table 4. Separation of Ir from Al samples by procedure E_6. Ratio of fixation on filter to total quantity (F/T) and of fixation on resin to quantity introduced onto the resin after filtration [$R/(R + E)$]

Ir in alloy, w/w	Experiment 1 F/T, %	$R/(R + E)$, %	Experiment 2 F/T, %	$R/(R + E)$, %

Table 5. Fixation of iridium on Dowex 50 X8 and Dowex 1 X8 resins from Al and Ni samples after various dissolution procedures

Alloy Matrix	Ir μg/g	Procedure	Retained on Dowex 50, %	Retained on Dowex 1, %
Al	5	E_7	94.1	100
Al	50	E_7	96.6	100
Al	2900	E_7	97.8	100
Al	2900	E_8	84.1	100
Al	2900	E_9	94.4	100
Ni	744	E_{10}	4.8 3.0 2.2	100

reproducible, however, and could not be correlated to the alloy concentration. When the filtrate was passed through the ion-exchange column, the sorption yield was more reproducible and varied as the alloy concentration.

In order to check the possibility of fixing iridium on a resin by a filtration mechanism we applied procedure E_7, which is analogous to procedure E_{10} applied to nickel (Table 5). In the case of the aluminium alloys, iridium is fixed on the cation-exchange resin, even at very low concentration, but this is not the case with the nickel matrix nor, more generally, with soluble iridium salts. It can be explained by the filtration effect, which probably occurs for all fixations of iridium on Dowex 1 resin without previous passage through a Dowex 50 column.

The direct dissolution of iridium from a nickel sample can be attributed to the oxidizing character of the nitric acid used for dissolution. We tried to use oxidizing dissolution baths with aluminium also (procedures E_8 and E_9), but they did not lead to a better dissolution of iridium.

Structure of the precipitates

The oxidation treatments did not lead to complete and reproducible dissolution of iridium precipitates resulting from aluminium alloys. These results are more in agreement with those expected from the metallic properties of Ir, than those for Os and Ru.

The difference between the behaviour of Os and Ru precipitates from the aluminium alloy and that of the commercial powders may be explained either by a difference in chemical composition, for instance the presence of oxides, or by a difference in the crystallite sizes. In order to choose between these postulates we took X-ray diffraction patterns of the available commercial powders (Os and Ru) and of the precipitates. In all cases we observed the characteristic peaks of metallic Ru, Os and Ir; we did not detect any other peak. We concluded that the precipitates were mainly composed of pure metal crystallites. A more detailed analysis allowed an estimate of the crystallite size from the formula[13,14]

$$D = \frac{0.9\,\lambda}{2\cos\theta\sqrt{\Delta^2 - \Delta_0^2}}$$

where D is the particle diameter, λ the wavelength of the incident X-ray (the K_α X-ray of cobalt in our case, $\lambda = 1.78$ Å), θ the Bragg angle, Δ the half-height width of the observed peak and Δ_0 the half-height width of a standard peak close to the one observed and given by a product with large well-crystallized grains (sodium chloride in this case).

The grain size of the precipitates was within the range 35–100 Å. For the commercial powders of Ru and Os the peak widths were close to those which result from the spectral width of the incident X-rays. We could only calculate a lower limit of 1000 Å for the grain size of the commercial powders.[15]

In order to confirm these results we made light- and electron-microscopy observations. The light-microscopy measurements gave a mean size of 0.01 mm for the commercial powders.

The precipitates obtained during alloy dissolution were deposited, after washing and centrifuging, on collodion-covered grids and observed with a Philips EM 300 electron microscope. At high magnification (about 200,000 ×) we saw individual grains and formations which seemed to be grain clusters. We could not establish a correlation between the grain or cluster size and the nature or concentration of the alloys. The diameter of individual grains varied from 20 to 50 Å, that of the clusters from 150 to 400 Å.

All these results seem to show that the precipitates are in the metallic state. Both methods lead to the same range of grain size for the precipitates: 20–100 Å. The grain size of the commercial powders was found to be at least 1000 times larger. This value could explain the difference in the dissolution behaviour of the powders and precipitates.

CONCLUSION

Using dilute alloys of Os, Ru and Ir we have shown the decisive influence of the method of sample dissolution on the chemical separations and consequently on the analytical results. As might be foreseen from the chemical properties, Os, Ru and Ir are not dissolved during the dissolution of the aluminium-based alloy either in acid or in basic aqueous solutions. Further treatment could not completely dissolve iridium and allow a quantitative separation of this element.

The Os and Ru precipitates obtained can be dissolved by using a suitable oxidation treatment and quantitatively separated for instance by distillation. On the contrary, commercial powders of the same two elements cannot be dissolved. This difference of behaviour seems to arise from grain size differences, and probably explains why alloying platinum elements with an acid-soluble metal facilitates their dissolution.[16] When the alloy is attacked with acids, the platinum elements form finely divided precipitates which are more easily dissolved than the initial samples. Osmium and ruthenium impurities can thus be brought into aqueous solution. Although iridium as impurity gives precipitates of the same grain size as Os and Ru, it cannot be directly brought into aqueous solution and other means of dissolution have to be used, for instance alkaline fusion. Sodium peroxide attack was successfully used by some authors for the determination of iridium in rocks and meteorites.[3,17,18] Unfortunately this procedure is not suitable for aluminium. For the determination of iridium in this metal we recommend dissolving the sample in hydrochloric acid, evaporating to dryness and attacking the residue with sodium peroxide.

We observed that Os, Ru and Ir are dissolved from a nickel-based alloy during the dissolution of the sample in nitric acid. The difference in behaviour of aluminium and nickel alloys may be explained by a difference either in the alloy structure or in the dissolution mechanism. It is difficult to discuss the influence of alloy structure as the phase diagrams and solubilities of platinum elements in aluminium and nickel are not well known. For the dissolution mechanisms there is a real difference: nickel is dissolved by oxidation with nitric acid, whereas aluminium is dissolved by oxidation with protons, yielding hydrogen.

SELECTIVE DETERMINATION OF ARSENIC(III) AND ARSENIC(V) WITH AMMONIUM PYRROLIDINEDITHIOCARBAMATE, SODIUM DIETHYLDITHIOCARBAMATE AND DITHIZONE BY MEANS OF FLAMELESS ATOMIC-ABSORPTION SPECTROPHOTOMETRY WITH A CARBON-TUBE ATOMIZER

TOSHIHIKO KAMADA

(*Received* 3 *February* 1976. *Accepted* 1 *May* 1976)

Summary—The extraction behaviour of arsenic(III) and arsenic(V) with ammonium pyrrolidinedithiocarbamate, sodium diethyldithiocarbamate and dithizone in organic solvents has been investigated by means of flameless atomic-absorption spectrophotometry with a carbon-tube atomizer. The selective extraction of arsenic(III) and differential determination of arsenic(III) and arsenic(V) have been developed. With ammonium pyrrolidinedithiocarbamate and methyl isobutyl ketone or nitrobenzene, when the aqueous phase/solvent volume ratio is 5 and the injection volume in the carbon tube is 20 μl, the sensitivities for 1% absorption are 0.4 and 0.5 part per milliard of arsenic, respectively. The relative standard deviations are *ca.* 3%. Interference by many metal ions can be prevented by masking with EDTA. The proposed methods are applied satisfactorily for determination of As(III) and As(V) in various types of water.

Determination of arsenic in trace amounts has received increasing attention in connection with environmental pollution. Recently, a method involving the conversion of arsenic into arsine, and its subsequent introduction into the argon–hydrogen flame has been developed,[1–5] enhancing the sensitivity to the parts per milliard (ppM) level. Moreover, during the last few years there has been an increased interest in flameless methods for atomic-absorption analysis because of the increased sensitivity. In a previous paper[6] we reported an atomic-absorption spectrometric method with a carbon-tube atomizer for determinations of arsenic, antimony and selenium in aqueous solution. Neither the arsine method nor the carbon tube method will differentiate between arsenic(III) and arsenic(V), however.

The potential toxicity of arsenic is considered to depend on its oxidation state, but there are few techniques for determining the oxidation state of a trace amount of arsenic, though being able to do so would be extremely useful for understanding the biological function and availability of arsenic. From these aspects it appears very important to determine selectively arsenic(III) and arsenic(V). Solvent extraction followed by flameless atomic-absorption spectrophotometry seems profitable for this purpose. Extraction with ammonium pyrrolidinedithiocarbamate (APDC), sodium diethyldithiocarbamate (DDTC) and diphenylthiocarbazone (dithizone) has been widely used in atomic-absorption determination of various elements. Though these reagents, especially DDTC,[7–13] have been used for the extraction of arsenic, their combination with atomic absorption has scarcely been used for determination of the element, on account of the low sensitivity, only one report having been found by us in the literature.[14]

In this paper, we have studied the extraction behaviour of arsenic(III) and arsenic(V) with APDC, DDTC and dithizone in various organic solvents [carbon tetrachloride, methyl isobutyl ketone (MIBK) and nitrobenzene (NB)]. The paper further describes the selective extraction of arsenic(III) with these systems and the differential determination of arsenic(III) and arsenic(V) by the atomic-absorption method with a carbon-tube atomizer.

EXPERIMENTAL

Reagents

All solutions were prepared from analytical-reagent grade chemicals and demineralized water, and stored in polyethylene bottles.

Standard arsenic(III) solution, 1000 *ppm.* Prepared by dissolving 1.320 g of diarsenic trioxide in 10 ml of 10*M* sodium hydroxide, and diluting to 1000 ml with water. An aliquot of this solution was diluted with water to give a concentration of 0.4 ppm before use.

Standard arsenic(V), 1000 *ppm.* Prepared by dissolving 2.403 g of potassium dihydrogen arsenate in water and diluting to 1000 ml with water. An aliquot of this solution was diluted with water to give a concentration of 0.4 ppm before use.

Arsenic-76m solution. Prepared by diluting 1 mCi of the radioisotope arsenic-76m (arsenious acid in 1*M* hydrochloric acid) to a suitable concentration.

APDC solution, 1% *w/v aqueous.*

DDTC solution, 1% *w/v aqueous.*

Dithizone solution, 0.03% *w/v.* Prepared by dissolving 75 mg of refined dithizone in 250 ml of organic solvent.

Potassium iodide solution, 20% *w/v.*

Sodium thiosulphate solution, 1% *w/v.*

EDTA (disodium salt) solution, 5% *w/v.*

Buffer solution, *pH* 5.2. Prepared by mixing 1*M* acetic acid and 1*M* sodium acetate in suitable ratio.

Apparatus

Atomic-absorption measurements were made with a Nippon Jarrell-Ash Model AA-1 EW atomic-absorption spectrophotometer equipped with a Model FLA-10 flameless atomizer and a Model HU-10 furnace. Peak heights were recorded with a Yanaco Model YR-110 chart recorder. A Westinghouse arsenic hollow-cathode lamp was used as a light-source. Samples were placed in the carbon-tube with a Gilson Model P-20 digital micropipette. An Iwaki Model KM shaking apparatus was used for solvent extraction. Radioactivity measurements were made with an Aloka Model PSM-801 γ-ray spectrometer equipped with a 1.5 × 1 in. NaI(Tl) crystal.

Recommended general procedure

Arsenic(III) determination. Take an aliquot of a sample solution containing not more than 2 μg of arsenic(III), in a separatory funnel. Add 5 ml of the EDTA solution, 2 ml of the APDC solution and 5 ml of the acetate buffer solution. Dilute the mixture to 25 ml with water, the pH of the resulting solution being 5–5.6. Shake the funnel for 2–5 min with 10 ml of an organic solvent (MIBK or NB). Stand the funnel for 20–30 min and separate the organic phase.

Transfer 20 μl of the organic phase with the micropipette to the carbon-tube. Pass argon gas through the furnace at a flow-rate of 3 l./min, and then atomize the sample by the following heating sequence: drying for 30 sec at 30 A (*ca.* 350°), ashing for 120 sec at 70 A (*ca.* 1050°), atomization for 7 sec at 230 A (*ca.* 2400°). Record the absorption signal at 1937 Å. Run a reagent blank at the same instrumental settings and subtract it from the analytical value.

Total arsenic determination. Two methods are available as follows.

(*a*) *Extraction at* 1*N acidity.* Take an aliquot of a sample solution containing not more than 2 μg of arsenic, in a separatory funnel. Add 2 ml of 12*N* hydrochloric acid or sulphuric acid. Then add 5 ml of the EDTA solution and 2 ml of the APDC solution. Dilute the mixture to 25 ml with water, the acidity of the resulting solution being *ca.* 1*N*. Do the extraction and measure the atomic absorption as for arsenic(III).

(*b*) *Reduction of arsenic(V) to arsenic(III) and extraction at pH* 5.0–5.6. Take an aliquot of a sample solution containing not more than 2 μg of arsenic, in a separatory funnel. Add hydrochloric acid to adjust the acidity of the solution to *ca.* 0.5*N*. Then add 2 ml of the potassium iodide solution to reduce arsenic(V) to arsenic(III). After 5 min or more add 1 ml of the sodium thiosulphate solution. Add 5 ml of the EDTA solution and neutralize the solution with ammonia. Add 2 ml of the APDC solution, and adjust the pH to 5–5.6 with the buffer. Extract and measure as before.

The amount of arsenic(V) is estimated from the difference between total arsenic and arsenic(III).

Water analysis. Apply the general procedure to a 50-ml sample.

RESULTS AND DISCUSSION

Optimization of the atomization system

Heating conditions. The heating current and length of time for the dry, ash, and atomize steps of the atomization cycle were optimized as follows. At the drying stage, application of 30–40 A for 30 sec (*ca.* 350–500°) is suitable for removing the solvent. The temperature for the ashing stage considerably affects the arsenic atomization. Use of a current of less than 65 A for 120 sec (*ca.* 950°) gives a lower arsenic signal. This may be ascribed to insufficient decomposition of the organic extract. When the current is above 80 A (*ca.* 1200°), the signal is again lowered. This means that a considerable amount of arsenic is volatilized before the atomization stage. Accordingly the ashing current should be kept in the range 65–80 A for 120-sec heating. At the atomization stage, the arsenic peak height is maximal and constant over the tested current range of 220–260 A (*ca.* 2300–2700°) for 7-sec heating. From these results, a heating programme for the atomization of arsenic was chosen, as described in the general procedure.

Shielding-gas flow-rates. The peak signal of arsenic tends to decrease with increasing shielding-gas flow-rate in the tested range 0.5–5 l./min. This may be caused by the fact that the rate of diffusion of arsenic atoms in the carbon-tube is increased by increasing the flow-rate. On the other hand, the reagent blank signal increases considerably with a decrease in the flow-rate, which is possibly due to the molecular absorption of the products from atmospheric oxidation of the carbon tube. Accordingly, the flow-rate of argon gas was kept at 3 l./min.

Extraction

Extraction behaviour of As(III) and As(V). The extraction behaviour of arsenic(III) and arsenic(V) with ADPC, DDTC and dithizone in MIBK, nitrobenzene and carbon tetrachloride was investigated. The rather complicated effect of acidity on the extraction is shown in Figs. 1–3.

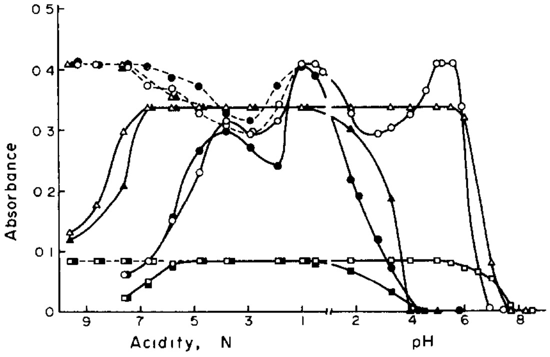

Fig. 1. Effect of pH and acidity on the extraction of As(III) and As(V) with APDC. ○, As(III)—MIBK; ●, As(V)—MIBK; △, As(III)—NB; ▲, As(V)—NB; □, As(III)—CCl$_4$; ■, As(V)—CCl$_4$; (——), hydrochloric acid medium; (- - -), sulphuric acid medium; aqueous phase, 25 ml; organic phase, 10 ml; As(III) or As(V), 2 μg.

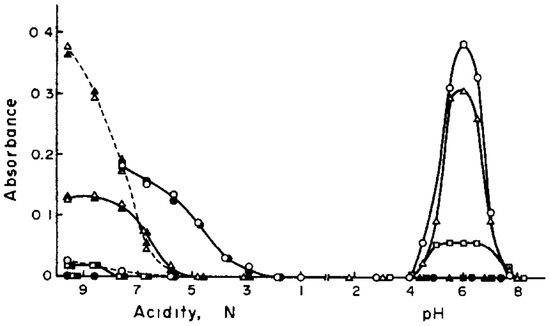

Fig. 2. Effect of pH and acidity on the extraction of As(III) and As(V) with DDTC. Symbols and conditions as for Fig. 1.

In the APDC system, in the pH ranges 4.0–5.6 (MIBK), 4.0–6.0 (NB), 4.0–6.0 (CCl_4), arsenic(III) is extracted whereas arsenic(V) is not. The extraction efficiency of the solvents increases in the order $CCl_4 < NB < MIBK$. On the other hand, in strongly acidic medium both arsenic(III) and arsenic(V) are well extracted from sulphuric acid into all three solvents (distribution ratio: MIBK 19, NB 19, CCl_4 0.25), but from hydrochloric acid medium the extraction is much decreased as the acidity increases. The extracted species in neutral medium should be $As(APDC)_3$, which is confirmed by continuous variation plots as described later, and the structure is assumed to be analogous to that[15] determined by X-ray analysis for $As(DDTC)_3$. The reason for the complicated behaviour of the APDC–MIBK system which shows three maxima on the absorbance–pH curve is not at present clear.

In the DDTC system, there is a very narrow pH range (at *ca.* pH 6.0) for selective extraction of arsenic(III) and the order of extraction efficiency of the solvents is similar to that for APDC.

Dithizone does not extract either arsenic(III) or arsenic(V) in the pH range 1–10. At high acidity only arsenic(III) is extracted, and even then but poorly.

Selective determination of As(III) and As(V). From these results it may be concluded that with APDC extraction into MIBK or NB from neutral medium is best for the selective separation of arsenic(III) and arsenic(V). Total arsenic is separately determined either by extraction from 1*N* acid medium or from neutral medium after reduction of arsenic(V) to arsenic(III).

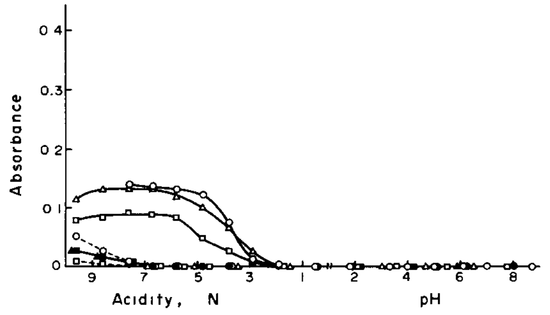

Fig. 3. Effect of pH and acidity on the extraction of As(III) and As(V) with dithizone. Symbols and conditions as for Fig. 1.

Table 1. Recovery tests

Extraction system	Arsenic added, *ng/ml* As(III)	As(V)	Arsenic found, *ng/ml* As(III)	As(total) *a**	*b**
APDC–MIBK	20	60	21	78	81
	40	40	41	77	80
	60	20	60	78	80
APDC–NB	20	60	20	80	81
	40	40	38	79	81
	60	20	59	80	82

* Procedure.

Recovery tests with known amounts of standard arsenic(III) and arsenic(V) showed (Table 1) that total arsenic can be determined with good recovery by both methods.

In the 1*N* acid method, the sensitivity is slightly higher with the APDC–MIBK system than with the APDC–NB system, but acidity has to be more carefully controlled.

In the reduction method, potassium iodide in 2–6*N* hydrochloric acid medium has been recommended for the reduction.[16] After completion of the reduction (half an hour in a heating bath), a reducing agent such as sodium thiosulphate or potassium metabisulphite is added to remove the iodine liberated. The tolerance ranges for these reagents were therefore determined, by tests with 2 μg of arsenic(V) and a final acidity of 0.6*N*. Thiosulphate will reduce arsenic(V) as well as remove iodine, but not completely, and Fig. 4 shows that the treatment with potassium iodide is essential, a concentration of at least 0.3% being necessary for complete reduction. The sodium thiosulphate concentration needed is 0.02–0.3%, and a large excess decreases the extraction of arsenic(III) by APDC. The optimum acidity is 0.3 *M* hydrochloric acid or above. It was also confirmed that the quantitative reduction to arsenic(III) requires not less than 5 min at room temperature.

Results of recovery tests for total arsenic are shown in Table 1.

Stability of the extracts. Extraction is quantitative in 15 sec shaking and continued shaking up to 20 min

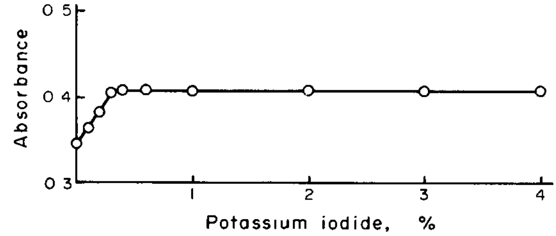

Fig. 4. Effect of potassium iodide concentration on reduction of As(V). As(V), 2 μg; sodium thiosulphate, 0.1%; aqueous phase 25 ml, organic phase 10 ml.

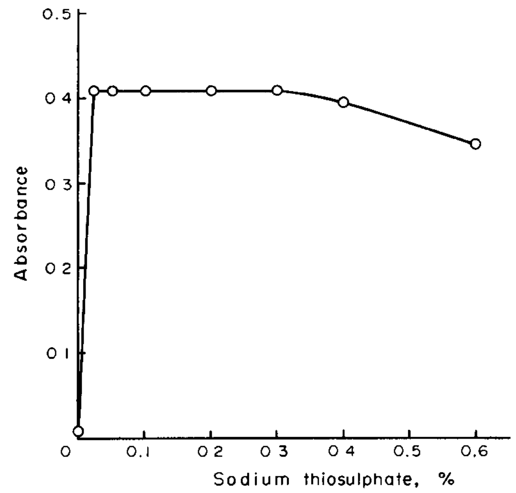

Fig. 5. Effect of sodium thiosulphate concentration on reduction of As(V) and removal of iodine. As(V), 2 μg; potassium iodide, 2%; aqueous phase 25 ml, organic phase 10 ml.

produces no further change in absorption. The absorption signal of the extract remains almost constant for at least 6 hr after the extraction.

Degree of extraction. This was investigated by the radio-tracer technique with ^{76m}As and a 1:1 volume-ratio of aqueous to organic phase. The results show that arsenic(III) is 95% extracted under these conditions (distribution ratio 19), while arsenic(V) is not appreciably extracted over the pH range used.

Composition of the extracted species. Continuous variation plots for the extraction process were made. The maximum absorption occurs at a mole-fraction of *ca.* 0.25 which suggests that the extracted species should have a composition of 1:3 (As:APDC).

Effect of phase-volume ratio on sensitivity. Although the degree of extraction appreciably decreases as the aqueous–organic phase-volume ratio (V_w/V_0) increases, arsenic(III) is extracted nearly quantitatively into the organic phase in a single extraction. To examine the effect of the volume ratio on the sensitivity of atomic absorption, 10 ml of MIBK or NB were used for the extraction from various volumes of aqueous phase, each containing 2 μg of arsenic(III). The result is shown in Fig. 6. With increasing V_w/V_0, the relative sensitivity in the case of NB appreciably decreases, while in the case of MIBK it remains almost unchanged owing to the solubility of MIBK in water (*ca.* 2%). If an appropriate V_w/V_0 ratio is chosen according to the arsenic content in sample, arsenic may be determined over a wide concentration range from ng/ml to μg/ml levels.

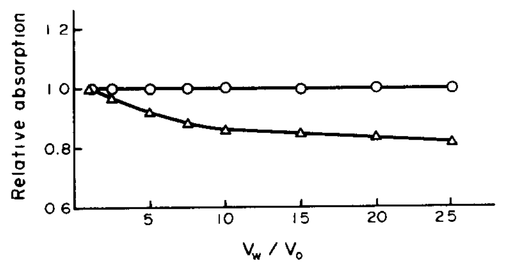

Fig. 6. Effect of initial volume ratio on atomic absorption of As. ○, MIBK; △, NB; As(III), 2 μg; initial volume of organic phase, 10 ml.

Calibration curve and precision

Under the established optimum conditions, the calibration curve was made, with the arsenic(III) solution as standard. Similar results are obtained with the arsenic(V) solution if the reduction procedure is used. The linearity is good over the range 2–40 ng/ml with an aqueous/organic solvent ratio of 5. The sensitivity for 1% absorption was found to be 0.4 ng/ml. The relative standard deviation was *ca.* 3% for 80 ng/ml of arsenic(III) (ten determinations, three injections of each).

Interference study

In the previous paper on arsenic determination by direct injection of aqueous samples,[6] large amounts of alkali and alkaline earth metals were found to interfere considerably with the determination. In the present investigation it was confirmed that these interferences could be avoided by the solvent extraction of arsenic before the atomic absorption analysis. However, large amounts of metal ions which react with APDC appreciably lower the degree of extraction of arsenic(III). In many cases, such interferences can be reduced by the use of EDTA as masking agent. Table 2 shows the effects of various ions; the data in parentheses were obtained with 1% of EDTA in the aqueous phase.

Table 2. Permissible amount of foreign ions in determination of 2 μg of As/25 ml (to give <10% error)

Application to water analysis

The results of the selective determination of arsenic(III) and arsenic(V) in various types of water are presented in Table 3 together with those of the recovery test run on the samples. All the samples used were acidified with hydrochloric acid to *ca.* pH 1 immediately after sampling. According to the method proposed here, ng/ml levels of arsenic(III) and arsenic(V) in waste water or sea-water can be selectively determined.

SHORT COMMUNICATIONS

SPECTROPHOTOMETRIC DETERMINATION OF PYRROLE DERIVATIVES

J. P. SHARMA*, V. K. S. SHUKLA† and A. K. DUBEY
Chemical Laboratories, University of Allahabad, Allahabad-2, India

(*Received* 28 *January* 1976, *Accepted* 1 *July* 1976)

Omosi[1] determined carbazole by a method based on nitrosation. Matraka and Navratil[2] determined carbazole polarographically. Furusawa *et al.*[3] determined carbazole with xanthydrol in glacial acetic acid. Byrom and Turnbull[4] used *p*-dimethylaminobenzaldehyde in aqueous trifluoroacetic acid for determination of indole and its derivatives. Furusawa *et al.*[5] determined carbazole with maleic anhydride in anthracene. Sawicki *et al.*[6] used *p*-nitrosophenol in benzene for the spectrophotometric determination of carbazole. In the present work a simple rapid ultraviolet procedure is described for the microgram determination of indole, carbazole, indole-3-propionic acid and indole-3-butyric acid. It was observed that reaction of a few drops of concentrated sulphuric acid in presence of acetic anhydride with these pyrrole derivatives leads to the rapid formation of products ranging from yellow to violet in colour.

EXPERIMENTAL

Reagents

Stock solutions of the pyrrole derivatives were prepared by dissolving 10–15 mg of the compound (analytical grade) in acetic anhydride and making up to the mark in 50-ml standard flasks.

Procedure

A 2-ml aliquot of stock solution was transferred to a 25-ml standard flask, 1 or 2 drops of concentrated sulphuric acid were added and the mixture was allowed to stand for about 5 min, then gently shaken and made up to the mark with chloroform for indole or carbon tetrachloride (except for indole). The absorbance was measured against a reagent blank at the appropriate wavelength.

Calibration curves were prepared by treating various aliquots of standard solutions as described.

Table 1. Absorption maxima of the reaction products

Compound	Colour	λ_{max}, *nm*
Indole	Violet	350
Carbazole	Blue	315
Indole-3-propionic acid	Violet	290
Indole-3-butyric acid	Light yellow	308

RESULTS AND DISCUSSION

Between 5 and 35 mg of indole, indole-3-propionic acid, indole-3-butyric acid and carbazole were determined with a general maximum deviation of 0.2 μg. Beer's law is obeyed up to 40 μg of each compound (in 25 ml of solution). If acetic acid is used in place of acetic anhydride or water instead of chloroform or carbon tetrachloride for dilution the colours formed are less intense. Ethanol cannot be used as solvent because the sulphuric acid reacts with it.

The absorbance of the blank is almost zero and the absorbance of the products is constant for at least 48 hr. The amount of sulphuric acid is not critical, but if dilute sulphuric acid is used, the colours obtained are less intense. The amount of acetic anhydride is also not critical.

The principal virtues of this method are its reproducibility, simplicity and speed.

DETERMINATION OF AMINOCRESOL ISOMERS BY HIGH-SPEED LIQUID CHROMATOGRAPHY

H. SAKURAI and M. KITO

Faculty of Pharmaceutical Sciences, University of Tokushima, Tokushima 770, and
Kyoto College of Pharmacy, Higashiyama-ku, Kyoto 607, Japan

(*Received* 3 *June* 1976. *Accepted* 1 *July* 1976)

The intramolecular migration of aromatic ring substituents (NIH shift), which occurs during hydroxylation by cytochrome P-450 mono-oxygenases had been observed usually from the NIH shift of deuterium, tritium or chloride.[1] The NIH shift of an alkyl group has also been found to occur in liver microsomes.[2] It may be considered that *p*-toluidine is a simple compound for a model substrate to observe the occurrence of methyl migration during hydroxylation.

It is well known that aminophenols can be determined by colorimetric, spectrometric, isotopic or liquid-chromatography methods.[3–7]

The present paper describes simultaneous determination of aminocresol isomers by use of a commercially available high-speed liquid chromatograph. This method was applied to the aminocresols and *p*-aminophenol formed by the model system of cytochrome P-450, for evaluating the capability of the chemical model system to detect the NIH shift occurring during hydroxylation.[8]

EXPERIMENTAL

High-speed liquid chromatography

A Du Pont Model 840 liquid chromatograph equipped with an ultraviolet detector (254 nm) was employed. The column was a Du Pont analytical column packed with Zipax SCX (1 m × 2.1 mm i.d.). The separation of aminocresol isomers was achieved with H_3PO_4–KH_2PO_4 buffer solution of various pH values as mobile phase, at 25° and a flow-rate of 0.64 ml/min. Samples of 10 μl were injected directly into the column through the septum.

Chemicals

4-Hydroxy-*m*-toluidine [I], 3-hydroxy-*p*-toluidine [II], 2-hydroxy-*p*-toluidine [III] and *p*-aminophenol, used as standards, were purified by sublimation before use. Haemin chloride and all other reagents were of analytical-reagent grade. The acetone used for reaction and the ether and chloroform for extraction were redistilled.

Reaction mixture

The reaction mixture used as a model system contained the following reagents; cysteine $10^{-1}M$, haemin chloride $10^{-3}M$, *p*-toluidine $10^{-1}M$, and sodium hydroxide. The reaction mixture was adjusted to 10 ml with acetone (80%), and the pH to 4. The mixture was vigorously shaken in an air atmosphere, at 40°, and stopped after 2 hr by addition of 0.5 ml of $2M$ hydrochloric acid.

Separation of aminocresols from reaction mixture

Aminocresols formed by the model system were extracted from the reaction mixture according to the separation method developed by Brodie.[9]

After evaporation of the acetone in the reaction mixture, at reduced pressure and a temperature below 40°, the remaining aqueous solution was saturated with sodium chloride, the pH adjusted to 7.5 and the solution shaken with 25 ml of ether. The ether layer (20 ml) was shaken with 3 ml of $0.1M$ hydrochloric acid, and the acid phase (2 ml), after separation, was extracted with an equal volume of chloroform to remove the excess of *p*-toluidine and the remaining ether, and then analysed.

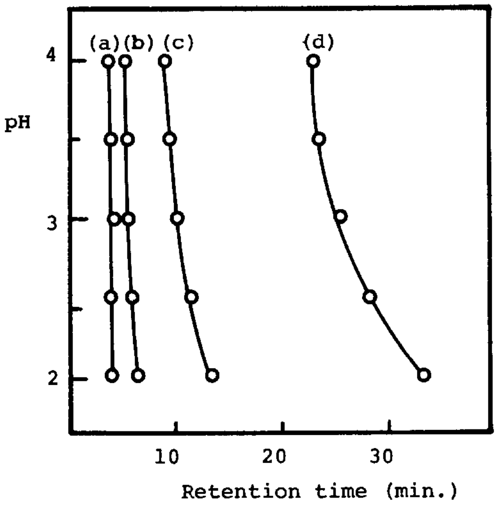

Fig. 1. Effect of pH of mobile phase on retention time of aminocresol isomers and *p*-aminophenol. Eluent $0.1M$ H_3PO_4–$0.1M$ KH_2PO_4; flow-rate 0.64 ml/min; column temperature 25° (a) *p*-Aminophenol, (b) 4-hydroxy-*m*-toluidine [I], (c) 3-hydroxy-*p*-toluidine [II], (d) 2-hydroxy-*p*-toluidine [III].

RESULTS AND DISCUSSION

Selection of mobile phase

Aminocresol isomers and *p*-aminophenol were separated with mobile phases consisting of $0.1M$ H_3PO_4–$0.1M$ KH_2PO_4 buffer solutions at pH 2.0, 2.5, 3.0, 3.5 and 4.0. In Fig. 1, it is seen that with a mobile phase of high pH, the time needed for separation of the four compounds was reduced but the resolution was inadequate, whereas, with a low-pH buffer solution the resolution was satisfactory but the time for separation longer. Hence pH 3 was chosen as a suitable compromise. With various concentrations of phosphate buffer (0.02, 0.05, 0.1, 0.3 and $0.5M$) as mobile phase, the four compounds were separated at pH 3. Figure 2 shows that high concentrations give fast but poor separation whereas low concentrations give good but slow separation. Hence a $0.1M$ buffer was chosen as eluent.

In Fig. 3, a chromatographic separation of three aminocresols and *p*-aminophenol is shown. The resolution values (R_s) of the adjacent peaks, *i.e.*, between the *p*-aminophenol peak and [I], between [I] and [II], and between [II] and [III], were 1.5, 4, and 5.4, respectively. As resolution in

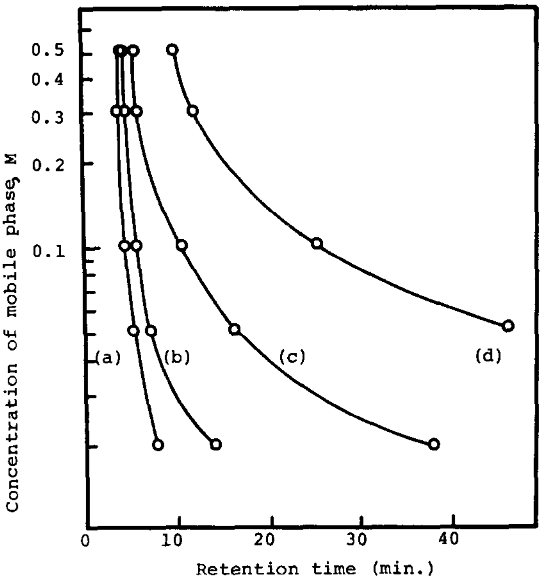

Fig. 2. Retention time of aminocresol isomers and *p*-aminophenol at various concentrations of mobile phase. Conditions are the same as those given for Fig. 1. (a) *p*-Aminophenol, (b) [I], (c) [II], (d) [III].

high-speed separation is adequate when R_s is greater than unity,[10] the separation conditions for Fig. 3 were used for the determination of the four compounds.

Determination of reaction products

Figure 4 shows a typical chromatogram obtained from the reaction mixture. It was confirmed that *p*-toluidine was hydroxylated by the model system, the products being mainly [I], [II] and [III]; only a trace amount of *p*-aminophenol was detected. The result agreed with that obtained by thin-layer chromatography (cellulose:silica gel G = 5:2; eluent butyl ether–ethyl acetate–acetic acid 50:50:5; detection by iodine vapour; R_f values [I] 0.11, [II] 0.33, [III] 0.41, *p*-toluidine 0.61).

For determination of [I], [II] and [III], a known amount of standard sample dissolved in 0.1*M* phosphate buffer (pH 7.5) was subjected to the procedure. In this case a known amount of cysteine (65 mg) was added to the buffer solution in order to give the same conditions as for the reaction mixture. The amounts and peak-heights of [I], [II], [III] and *p*-aminophenol gave a straight line relationship over the range studied (0–600 μg). The recovery was >95%. The method gave accurate and reproducible results.

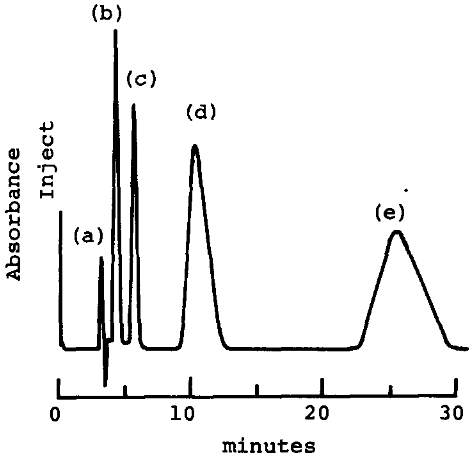

Fig. 3. Chromatogram for the separation of aminocresol isomers and *p*-aminophenol. Eluent 0.1*M* H_3PO_4–KH_2PO_4 (pH 3); flow-rate 0.64 ml/min; column temperature 25°. (a) Solvent front, (b) *p*-aminophenol, (c) [I], (d) [II], (e) [III]

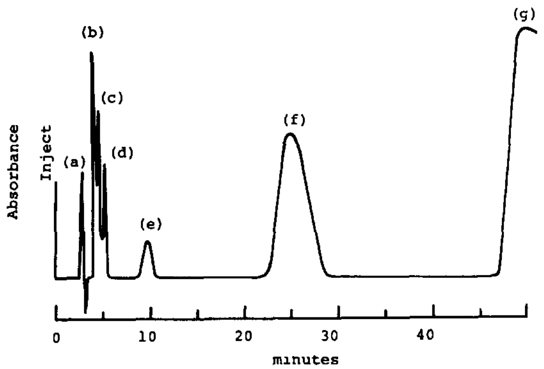

Fig. 4. Typical chromatogram of extracted reaction mixture. The reaction vessel contained, in a total volume of 10 ml (80% acetone), *p*-toluidine $10^{-1}M$, haemin chloride $10^{-3}M$ and cysteine $10^{-1}M$, and was incubated for 2 hr at pH 4 and 40° in air. Conditions are the same as those given for Fig. 3. (a) Solvent front, (b) *p*-aminophenol, (c) unknown peak, (d) [I], (e) [II], (f) [III], (g) *p*-toluidine.

Table 1 shows typical results of the hydroxylation of *p*-toluidine by the haemin–cysteine model system, providing positive evidence of methyl migration during hydroxylation of *p*-toluidine.

The method described is suitable for the simultaneous determination of aminocresol isomers in a sample. Further, it may be applied for the detection of aminocresols in biological materials such as liver microsomal fractions, since aqueous samples can be analysed.

Summary—Aminocresol isomers (4-hydroxy-*m*-toluidine [I], 3-hydroxy-*p*-toluidine [II], 2-hydroxy-*p*-toluidine [III]) and *p*-aminophenol have been separated and determined by a high-speed liquid chromatographic method. Since this method is applicable in aqueous media, it was used to investigate the suitability of a haemin–cysteine system as a model for the cytochrome P-450 mono-oxygenase system, by determination of the [I], [II], [III] and *p*-aminophenol formed.

EXTRACTION CHROMATOGRAPHY OF CHLORIDE COMPLEXES OF OSMIUM (III, IV AND VI) ON PAPER TREATED WITH TRIBUTYL PHOSPHATE AND AMBERLITE LA-1 HYDROCHLORIDE

S. PRZESZLAKOWSKI and A. FLIEGER
Department of Inorganic Chemistry, Medical School, Lublin, Poland

(*Received* 20 *April* 1976. *Accepted* 30 *June* 1976)

Osmium and ruthenium are usually separated from other platinum metals by oxidation to the volatile oxides OsO_4 and RuO_4 and distillation. The absorption of osmium tetroxide in hydrochloric acid leads to the formation of various chloride complexes of osmium, depending on the concentration of the acid and on the temperature.[1,2] The literature on the chromatographic separation of osmium complexes is somewhat scanty. Apart from the papers describing the separation of platinum metals, including osmium(IV)[3–5] or osmium(VIII),[6] there are only a few works concerned with the separation of some osmium(IV) or osmium(VI) halide complexes. Using paper chromatography, Rallo[7] separated the complex anion OsI_6^{2-} from mixed chloride–iodide complexes of osmium(IV) formed during reduction of OsO_4 by alkali metal iodides in hydrochloric acid media. Meier *et al.* investigated the chromatographic behaviour of the complex anions $OsCl_6^{2-}$, $OsBr_6^{2-}$ and $OsO_2Cl_4^{2-}$, developing the chromatograms with mixtures of oxo-solvents with hydrochloric or hydrobromic acid[8] or with aqueous solutions of hydrochloric acid and ammonium or alkali metal chloride.[9]

Extraction chromatography on paper treated with Amberlite LA-1 hydrochloride has been found to be useful in the separation of some platinum metals;[10] therefore the possibility of use of this chromatographic technique in separation of the chloride complexes of osmium(III, IV and VI) and in separation of osmium from ruthenium was investigated in the present work.

EXPERIMENTAL

Materials

Amberlite LA-1 and tributyl phosphate (TBP) were used as the extractants without further purification. The samples were spotted as 1% solutions of $(NH_4)_2OsCl_6$ in 6*M* hydrochloric acid and aqueous solutions of OsO_4. Solutions of the chloride complexes of osmium(VI) and osmium(III) were prepared by methods described in the literature.[1,2,11] The remaining reagents were of analytical grade.

Procedure

Benzene solutions (0.2*M*) of TBP or Amberlite LA-1 hydrochloride were used as impregnating solutions. Amberlite LA-1 was converted into the hydrochloride by shaking a 0.2*M* solution of it in benzene with an equal volume of 1*M* hydrochloric acid, separating the phases and filtering the organic phase through cellulose. The paper chromatography was performed in the manner described previously.[10] Descending development over a distance of 16 cm required from 2 hr 10 min to 3 hr, depending on the hydrochloric acid concentrations in the mobile phase. The complex anion $OsCl_6^{2-}$ forms a well-defined yellow spot on the chromatograms, which reacts very slowly with thiourea, changing to rose. The spots of other chloride complexes of osmium and also those of ruthenium were identified by spraying the chromatograms with a saturated solution of thiourea in 1*M* hydrochloric acid.

RESULTS AND DISCUSSION

The most promising extractants for the platinum metals appeared to be high molecular-weight amines or quaternary ammonium compounds and neutral organophosphorus compounds; some of them have been used in extraction of the chloride complexes of osmium. The complex anion $OsCl_6^{2-}$ is strongly extracted by tertiary and secondary amines from hydrochloric acid[12,13] as well as in a lesser degree by solutions of TBP in organic solvents.[14] The extraction of the complex anion $OsO_2Cl_4^{2-}$ from hydrochloric acid by primary, secondary and tertiary amines was investigated by Bolshakov *et al.*[15]

Liquid–liquid extraction and extraction chromatography are closely correlated practically as well as theoretically.[16] The R_F *vs.* eluent hydrochloric acid concentration relationships for extraction chromatography are available only for the anion $OsCl_6^{2-}$ on paper treated with tri-n-octylamine and Amberlite LA-2[17] and for the oxy-anion OsO_5^{2-} on thin layers of cellulose treated with TBP.[6] In view of the very high affinity of $OsCl_6^{2-}$ for tri-n-octylamine hydrochloride ($R_F = 0$ even at high concentrations of hydrochloric acid in the mobile phase), the chromatographic systems Amberlite LA-1–HCl and TBP–HCl were chosen in our investigations. The results obtained for chloride complexes of osmium are summarized in Table 1 (and presented graphically in the form of R_F *vs.* [HCl] relationships in Fig. 1). Table 1 also gives the chromatographic data

Summary—Aminocresol isomers (4-hydroxy-*m*-toluidine [I], 3-hydroxy-*p*-toluidine [II], 2-hydroxy-*p*-toluidine [III]) and *p*-aminophenol have been separated and determined by a high-speed liquid chromatographic method. Since this method is applicable in aqueous media, it was used to investigate the suitability of a haemin–cysteine system as a model for the cytochrome P-450 mono-oxygenase system, by determination of the [I], [II], [III] and *p*-aminophenol formed.

EXTRACTION CHROMATOGRAPHY OF CHLORIDE COMPLEXES OF OSMIUM (III, IV AND VI) ON PAPER TREATED WITH TRIBUTYL PHOSPHATE AND AMBERLITE LA-1 HYDROCHLORIDE

S. PRZESZLAKOWSKI and A. FLIEGER
Department of Inorganic Chemistry, Medical School, Lublin, Poland

(*Received* 20 *April* 1976. *Accepted* 30 *June* 1976)

Osmium and ruthenium are usually separated from other platinum metals by oxidation to the volatile oxides OsO_4 and RuO_4 and distillation. The absorption of osmium tetroxide in hydrochloric acid leads to the formation of various chloride complexes of osmium, depending on the concentration of the acid and on the temperature.[1,2] The literature on the chromatographic separation of osmium complexes is somewhat scanty. Apart from the papers describing the separation of platinum metals, including osmium(IV)[3–5] or osmium(VIII),[6] there are only a few works concerned with the separation of some osmium(IV) or osmium(VI) halide complexes. Using paper chromatography, Rallo[7] separated the complex anion OsI_6^{2-} from mixed chloride–iodide complexes of osmium(IV) formed during reduction of OsO_4 by alkali metal iodides in hydrochloric acid media. Meier *et al.* investigated the chromatographic behaviour of the complex anions $OsCl_6^{2-}$, $OsBr_6^{2-}$ and $OsO_2Cl_4^{2-}$, developing the chromatograms with mixtures of oxo-solvents with hydrochloric or hydrobromic acid[8] or with aqueous solutions of hydrochloric acid and ammonium or alkali metal chloride.[9]

Extraction chromatography on paper treated with Amberlite LA-1 hydrochloride has been found to be useful in the separation of some platinum metals;[10] therefore the possibility of use of this chromatographic technique in separation of the chloride complexes of osmium(III, IV and VI) and in separation of osmium from ruthenium was investigated in the present work.

EXPERIMENTAL

Materials

Amberlite LA-1 and tributyl phosphate (TBP) were used as the extractants without further purification. The samples were spotted as 1% solutions of $(NH_4)_2OsCl_6$ in $6M$ hydrochloric acid and aqueous solutions of OsO_4. Solutions of the chloride complexes of osmium(VI) and osmium(III) were prepared by methods described in the literature.[1,2,11] The remaining reagents were of analytical grade.

Procedure

Benzene solutions ($0.2M$) of TBP or Amberlite LA-1 hydrochloride were used as impregnating solutions. Amberlite LA-1 was converted into the hydrochloride by shaking a $0.2M$ solution of it in benzene with an equal volume of $1M$ hydrochloric acid, separating the phases and filtering the organic phase through cellulose. The paper chromatography was performed in the manner described previously.[10] Descending development over a distance of 16 cm required from 2 hr 10 min to 3 hr, depending on the hydrochloric acid concentrations in the mobile phase. The complex anion $OsCl_6^{2-}$ forms a well-defined yellow spot on the chromatograms, which reacts very slowly with thiourea, changing to rose. The spots of other chloride complexes of osmium and also those of ruthenium were identified by spraying the chromatograms with a saturated solution of thiourea in $1M$ hydrochloric acid.

RESULTS AND DISCUSSION

The most promising extractants for the platinum metals appeared to be high molecular-weight amines or quaternary ammonium compounds and neutral organophosphorus compounds; some of them have been used in extraction of the chloride complexes of osmium. The complex anion $OsCl_6^{2-}$ is strongly extracted by tertiary and secondary amines from hydrochloric acid[12,13] as well as in a lesser degree by solutions of TBP in organic solvents.[14] The extraction of the complex anion $OsO_2Cl_4^{2-}$ from hydrochloric acid by primary, secondary and tertiary amines was investigated by Bolshakov *et al.*[15]

Liquid–liquid extraction and extraction chromatography are closely correlated practically as well as theoretically.[16] The R_F *vs.* eluent hydrochloric acid concentration relationships for extraction chromatography are available only for the anion $OsCl_6^{2-}$ on paper treated with tri-n-octylamine and Amberlite LA-2[17] and for the oxy-anion OsO_5^{2-} on thin layers of cellulose treated with TBP.[6] In view of the very high affinity of $OsCl_6^{2-}$ for tri-n-octylamine hydrochloride ($R_F = 0$ even at high concentrations of hydrochloric acid in the mobile phase), the chromatographic systems Amberlite LA-1–HCl and TBP–HCl were chosen in our investigations. The results obtained for chloride complexes of osmium are summarized in Table 1 (and presented graphically in the form of R_F *vs.* [HCl] relationships in Fig. 1). Table 1 also gives the chromatographic data

Table 1. $R_F \times 100$ for chloride complexes of osmium and ruthenium as a function of the molarity of HCl in the eluent (paper impregnated with 0.2*M* solutions of Amberlite LA-1 hydrochloride or tributyl phosphate in benzene)

Complex anion	Amberlite LA-1 [HCl], *M*						TBP [HCl], *M*					
	1	2	4	6	8	10	1	2	4	6	8	10
$OsCl_6^{2-}$	0	0	0	2	8	10	58	34	24	26	30	36

* Double spots in the Amberlite LA-1 system.

for the chloride complexes of ruthenium(III and IV) which are formed during absorption of RuO_4 by hydrochloric acid.

All chloride complexes of osmium are strongly retained on paper treated with Amberlite LA-1 hydrochloride; nevertheless, $OsCl_6^{2-}$ was found to have a higher affinity than $OsCl_6^{3-}$ for the amine salt. The R_F values of all the complexes of osmium investigated increase (decreasing extraction) with increasing concentration of hydrochloric acid in the eluent, in agreement with liquid–liquid extraction data.[11,12,14] The differences between the R_F values of the complex anions $OsCl_6^{2-}$ and $OsO_2Cl_4^{2-}$ are too low to permit their separation; nevertheless it is possible to separate osmium(III) from osmium(IV) or osmium(VI) complexes by development of the chromatograms with 8 or 10*M* hydrochloric acid. Chloride complexes of ruthenium(III) and in a lesser degree those of ruthenium(IV) form elongated spots in this chromatographic system at [HCl] < 6*M*. It is possible to achieve a good separation of osmium from ruthenium by development of the chromatograms with more concentrated hydrochloric acid. It is worthwhile mentioning the chromatographic behaviour of osmium tetroxide on paper treated with Amberlite LA-1 hydrochloride—two rose spots were visible after development with 6—10*M* hydrochloric acid and spraying with thiourea in hydrochloric acid, their R_F values corresponding to $OsCl_6^{3-}$ and $OsO_2Cl_4^{2-}$. It seems that OsO_4 is strongly bound by the amine salt and reduced during elution with hydrochloric acid, in contrast to the TBP–HCl chromatographic system where osmium could not be identified after development with dilute hydrochloric acid (< 6*M*) owing to the high volatility of OsO_4.

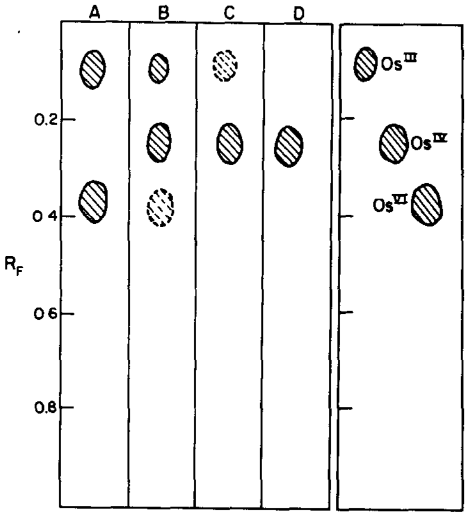

Fig. 1. Chromatographic separations of products of reduction of OsO_4 in concentrated HCl, obtained on paper impregnated with 0.2*M* TBP in benzene and eluted with 6*M* HCl: A—solution spotted immediately after dissolution of OsO_4 in cold concentrated HCl; B—the same, after 5 min heating on the water-bath; C—the same, after 30 min heating; D—solution obtained after evaporation of the solution of OsO_4 in concentrated HCl almost to dryness on the water-bath and dissolution of the residue in 6*M* HCl.

The chloride complexes of osmium(III, IV and VI) have distinctly different R_F values in extraction chromatography on paper treated with TBP, increasing in the order $OsCl_6^{3-} < OsCl_6^{2-} < OsO_2Cl_4^{2-}$. The curves of R_F *vs.* [HCl] show minima (maximal extraction) at 4*M* hydrochloric acid for $OsCl_6^{2-}$ and $OsO_2Cl_4^{2-}$ and at 6*M* hydrochloric acid for $OsCl_6^{3-}$. The maximal extraction of osmium(IV) in the system TBP–HCl was also reported by Meier *et al.*,[14] so our experiments confirm the analogies between extraction chromatography and liquid–liquid extraction. The chloride complexes of neither ruthenium(III) nor ruthenium(IV) are retained on paper treated with TBP and they can be easily separated from the chloride complexes of osmium.

The different R_F values of the various chloride complexes of osmium obtainable in the TBP–HCl system, combined with the colours of the zones (only $OsCl_6^{2-}$ forms a yellow zone, the others are colourless) and the rapidity of the reaction with thiorea, can be useful in identification of the oxidation states of osmium and in investigations of the reduction mechanism of osmium tetroxide in solution. The behaviour on evaporation of osmium tetroxide dissolved in concentrated hydrochloric acid is also interesting from the viewpoint of the conditions of preparation of platinum metal samples for chromatographic analysis; therefore some chromatographic experiments were carried out on solutions of OsO_4 in concentrated hydrochloric acid, heated for various periods of time on the water-bath (Fig. 1).

The results obtained indicate that OsO_4 absorbed by the cold concentrated acid is reduced to $OsO_2Cl_4^{2-}$ and $OsCl_6^{3-}$. After heating of the solution a yellow spot of $OsCl_6^{2-}$ appears, the colour intensity of which increases with time of heating, whereas the intensities of colour of the spots corresponding to $OsCl_6^{3-}$ and $OsO_2Cl_4^{2-}$ (visible after spraying with thiourea in hydrochloric acid) decrease. After evaporation of the acidic solution to dryness and dissolution of the residue in 6*M* hydrochloric acid, only the yellow spot of $OsCl_6^{2-}$ is visible. It seems that $OsO_2Cl_4^{2-}$, one of the products of reduction of OsO_4 by hydrochloric acid, oxidized the complex anion $OsCl_6^{3-}$, forming the most stable inert complex anion $OsCl_6^{2-}$.

THE DETERMINATION OF SELENIUM AND OTHER IMPURITIES IN HIGH-PURITY COPPER BY FLAMELESS ATOMIC-ABSORPTION SPECTROPHOTOMETRY

J. D. Mullen
British Copper Refiners Limited. Prescot, Merseyside, U.K.

(*Received* 5 *April* 1976. *Accepted* 1 *May* 1976)

The determination of traces of selenium in high-purity copper is of importance because of the effect of this element on the annealing properties. The methods of analysis in common use in the copper industry involve separation of the selenium from the dissolved copper by ion-exchange,[1] co-precipitation with ferric hydroxide[2] or lanthanum hydroxide,[3] or reduction by hypophosphorous acid and co-precipitation with arsenic.[4] The separated selenium is determined either colorimetrically using 3,3′-diaminobenzidine[5] or by atomic absorption. These procedures are slow and require skill and practice. Other techniques, such as gas chromatography[6] or hydride generation[7] appear impracticable with copper as the parent material.

A method has been devised involving co-precipitation of selenium, together with bismuth, antimony and tellurium, with ferric hydroxide and collection of the precipitate on a filter paper disc. Punched out portions of the dried disc are analysed by flameless atomic-absorption spectrophotometry (F.A.A.S.) Proficiency in the technique is soon acquired and results can be obtained within little more than an hour of sample receipt.

EXPERIMENTAL

Apparatus

A Varian Model AA-4 spectrophotometer with Model 63 carbon rod atomizer and an Oxford Instruments 3000-series chart-recorder were used.

Reagents

Ferric nitrate solution, 2%.

Standard Bi, Sb and Te solutions for atomic absorption. B.D.H. solutions were used.

Stock solution of selenium, 1000 *ppm*. Made by dissolving 1 g of pure Se in 10 ml of nitric acid and diluting to 1000 ml with distilled water.

*Whatman CF*11 *cellulose powder.*

Whatman 542 *filter paper discs*, 21 *mm diameter.*

Purified copper solution. Five 20-g samples of cathode copper drillings are each dissolved in 80 ml of nitric acid in 600-ml beakers, 20 ml of ferric nitrate solution are added to each, the solutions are diluted with water to *ca.* 300 ml and the temperature is raised to 75–85°. Concentrated ammonia is added, with stirring, until the solutions become dark green, a level spatula-spoonful of Whatman's CF11 is added as filter aid and the solutions are brought to the boil. After half a minute of boiling the covered beakers are set aside overnight to allow the coagulated ferric hydroxide and occluded impurities to settle, after which the blue supernatant liquor is decanted through a 541 filter paper. The precipitation and filtration procedure are repeated twice with further additions of ferric nitrate, the five liquors combined, acidified with 10 ml of concentrated nitric acid and made up to 2 litres with distilled water.

Analytical-grade reagents were used whenever possible.

THE DETERMINATION OF SELENIUM AND OTHER IMPURITIES IN HIGH-PURITY COPPER BY FLAMELESS ATOMIC-ABSORPTION SPECTROPHOTOMETRY

J. D. MULLEN
British Copper Refiners Limited. Prescot, Merseyside, U.K.

(*Received* 5 *April* 1976. *Accepted* 1 *May* 1976)

The determination of traces of selenium in high-purity copper is of importance because of the effect of this element on the annealing properties. The methods of analysis in common use in the copper industry involve separation of the selenium from the dissolved copper by ion-exchange,[1] co-precipitation with ferric hydroxide[2] or lanthanum hydroxide,[3] or reduction by hypophosphorous acid and co-precipitation with arsenic.[4] The separated selenium is determined either colorimetrically using 3,3′-diaminobenzidine[5] or by atomic absorption. These procedures are slow and require skill and practice. Other techniques, such as gas chromatography[6] or hydride generation[7] appear impracticable with copper as the parent material.

A method has been devised involving co-precipitation of selenium, together with bismuth, antimony and tellurium, with ferric hydroxide and collection of the precipitate on a filter paper disc. Punched out portions of the dried disc are analysed by flameless atomic-absorption spectrophotometry (F.A.A.S.) Proficiency in the technique is soon acquired and results can be obtained within little more than an hour of sample receipt.

EXPERIMENTAL

Apparatus

A Varian Model AA-4 spectrophotometer with Model 63 carbon rod atomizer and an Oxford Instruments 3000-series chart-recorder were used.

Reagents

Ferric nitrate solution, 2%.

Standard Bi, Sb and Te solutions for atomic absorption. B.D.H. solutions were used.

Stock solution of selenium, 1000 ppm. Made by dissolving 1 g of pure Se in 10 ml of nitric acid and diluting to 1000 ml with distilled water.

*Whatman CF*11 *cellulose powder.*

Whatman 542 *filter paper discs*, 21 *mm diameter.*

Purified copper solution. Five 20-g samples of cathode copper drillings are each dissolved in 80 ml of nitric acid in 600-ml beakers, 20 ml of ferric nitrate solution are added to each, the solutions are diluted with water to *ca.* 300 ml and the temperature is raised to 75–85°. Concentrated ammonia is added, with stirring, until the solutions become dark green, a level spatula-spoonful of Whatman's CF11 is added as filter aid and the solutions are brought to the boil. After half a minute of boiling the covered beakers are set aside overnight to allow the coagulated ferric hydroxide and occluded impurities to settle, after which the blue supernatant liquor is decanted through a 541 filter paper. The precipitation and filtration procedure are repeated twice with further additions of ferric nitrate, the five liquors combined, acidified with 10 ml of concentrated nitric acid and made up to 2 litres with distilled water.

Analytical-grade reagents were used whenever possible.

Table 1. Operating conditions for spectrophotometer

Element	Wavelength, *nm*	Spectral band width, *Å*	Ashing		Atomization	
			Voltage setting	*sec*	Voltage setting	*sec*
Se	196.1	9.9	7	12	7	3
Te	214.3	3.3	7	12	7	3
Bi	223.1	1.7	7	12	5.5	3
Sb	217.6	3.3	7	12	8	3

Procedures

Standards. To 20-ml portions of the purified copper solution in 150-ml beakers are added 0, 1, 2, 4 or 6 ml of a freshly prepared solution containing 0.5 ppm Se and Sb and 0.25 ppm, Bi and Te, followed by 1 ml of ferric nitrate solution and water to make up to 80 ml. The solutions are brought almost to boiling point, concentrated ammonia solution is added carefully until they turn green, 0.01 g of Whatman CF11 is added and the ferric hydroxide is coagulated by boiling for half a minute. After settling for 15 min the sediments are collected on 542 discs in Gooch crucibles by filtration under suction. To ensure an even deposit on the disc most of the supernatant liquor is decanted through the filter, the suction is removed, and the residue is swirled and poured quickly into the crucible. Gentle vibration is applied throughout, by such means as holding the rotating shaft of a stirrer motor against the crucible. After the precipitate has settled in the crucible the suction is re-applied and the disc finally washed carefully with 1 ml of water from a pipette. The discs are dried at 100° before their analysis.

Samples. One-gram samples are dissolved in 5 ml of concentrated nitric acid, 1 ml of ferric nitrate solution is added to each and the same procedure followed as for the standards.

Instrument operation. The appropriate monochromator wavelengths, spectral band-widths and instrument settings are shown in Table 1.

A graphite cup is used as furnace in the atomizer work head and oxygen-free nitrogen as the inert gas. After decontamination of the cup by preliminary atomization cycles 5/64-in. (2-mm) samples punched from the filter disc are dropped into it and subjected to the appropriate ashing and atomization cycles. The absorbances are recorded at a chart-speed of 2 cm/min and recorder sensitivity of 2 mV full-scale deflection. For highest accuracy, duplicate precipitate discs should be prepared and a number of replicate samples atomized, interspersed among standards.

RESULTS AND DISCUSSION

Results

Past experience had shown that although ferric hydroxide reproducibly collected selenium and many other impurities from copper solutions at a pH of 2.5–3.0, only about 90% was collected in one precipitation. The treatment of the standards in the same way as the samples obviated the need for more than one precipitation. For example, when three 0.5-μg amounts of selenium were precipitated and six samples from across the diameter of each disc were analysed, the relative standard deviations ranged from about 7 to 10%.

Figure 1 represents a typical series of recorder traces for 0, 0.25, 0.5 1.0 and 1.5 μg selenium standards. A large smoke signal occurs during ashing as the cellulose pyrolyses. A dull red heat (ashing voltage setting 7) is required for complete ashing but no loss of any of the four elements occurs. The blank atomization peak is higher for selenium than for the other elements. Use of the hydrogen continuum lamp showed that this was caused by background absorption.

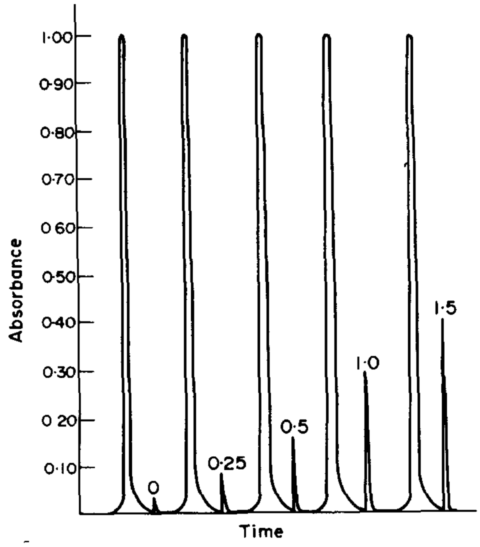

Fig. 1. Recorder traces for selenium (number of μg is shown above each peak).

Comparison of results obtained for selenium in high-purity copper by this method, by the conventional colorimetric method and by mass spectrometry show good agreement (Table 2).

A sample of electrolytic copper from the European Bureau of Standards was also analysed, and gave a mean of 0.12 ppm Se, standard deviation 0.04 ppm (duplicate precipitations, 4 analyses on each), compared with a range of quoted figures of 0.14–0.46 ppm Se, mean 0.22 ppm (9 laboratories, 4 techniques).

Typical absorbance curves for the Bi, Sb and Te standards are shown in Fig. 2.

No samples with well-established tellurium content were available and there was only one, namely the European

Table 2. Comparison of Se results (ppm) obtained by proposed method with those obtained by colorimetry and mass spectrometry

Sample	Proposed method	Colorimetry	Mass spectrometry
Rod 1	0.40	0.35	
Rod 2	0.95	0.8	
Rod 3	0.75	0.8	
Rod 4	2.2	2.0	
Cathode 1	0.50		0.6
Cathode 2	0.40		0.3

Table 3. Comparison of Bi results (ppm) obtained by proposed method by other methods

Sample	Proposed method	Other methods
BICC standard 1	0.45	0.42 (powder arc spectrography)
BICC standard 2	0.90	0.8 (powder arc spectrography)
European bureau of standards copper	0.12	Mean 0.2 ppm (range 0.046–0.53 ppm, 9 laboratories, 4 techniques)

Bureau of Standards sample, with quoted antimony figures [mean content 0.6 ppm with a range of 0.2–1.42 ppm (11) laboratories, 6 techniques)]. The result obtained by the proposed procedure was 0.56 ppm (s.d. 0.04 ppm, 2 precipitations, 4 atomizations on each). Three samples were available for comparison of bismuth content and the results are given in Table 3.

The sensitivity of the method and non-linearity of the curves (illustrated by Fig. 2) show the method to be most suitable for impurity levels below about 1 ppm. The upper limit can be extended by using a 0.5-g sample, no significant difference having been observed in the results obtained for impurities precipitated from 1-g and 0.5-g copper samples. With less than 0.5 g of copper in solution the ferric hydroxide precipitate tends to be too flocculent to spread evenly over the filter disc. A method of extending the upper limit which is often preferable is to use a less sensitive spectral line such as the 203.9 nm line for selenium.

The satisfactory agreement with the colorimetric method for selenium when the 203.9-nm line is used is exemplified by the results for two samples, 4.6 and 12 ppm by the present method, 4.8 and 12.2 ppm by colorimetry.

Interferences

The most likely impurities to interfere with any of the four elements are those co-precipitated with ferric hydroxide, namely, the other three elements and As, Sn, Pb. These are unlikely to be present at a level of more than 20 ppm in high-purity copper and no interference was observed at this level. During the precipitation stage small amounts of copper hydroxide may also precipitate, indicated by a cloudiness of the supernatant liquor. The presence of this amount of copper on the filter disc does not interfere with the determination.

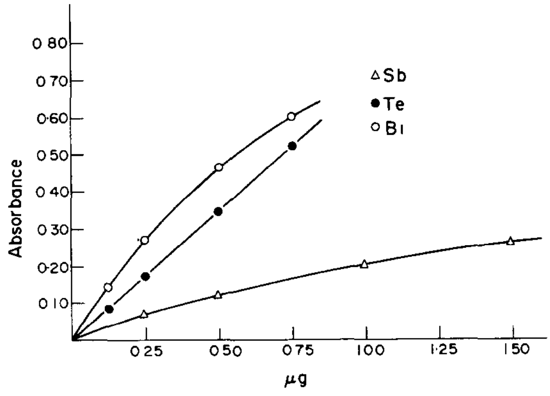

Fig. 2. Calibration curves for Sb, Te and Bi at 217.6, 214.3 and 223.1 nm respectively.

Discussion

The use of F.A.A.S. for direct determination of selenium in solutions of high-purity copper is impracticable because of both the high detection limits and the masking of the selenium absorption peak by large non-atomic absorption peaks. The same problem occurs to a lesser extent with the other three elements. Reduction of the selenium in solution to the metal and co-precipitation with arsenic is slow and the F.A.A.S. part of the procedure erratic. Although concentration by co-precipitation with lanthanum hydroxide has been used successfully for the determination of larger amounts of impurities the technique was found to be unsuccessful with F.A.A.S. owing to the occurrence of a large lanthanum peak during atomization.

Co-precipitation with ferric hydroxide is difficult on the large scale but quite simple from solutions of 1 g of copper. Precipitation at a pH of approx. 3 rather than from ammoniacal solution gives a residue which spreads more uniformly over the filter disc. The amounts of ferric nitrate solution and Whatman CF11 specified are the optimum for the production of a readily filterable solution and an even, coherent deposit on the filter.

The method has been in routine use for a year and has resulted in considerable savings of time and effort. Attempts to determine arsenic by this procedure have proved unsuccessful owing to high extraneous peaks during atomization and erratic response for the arsenic. A modified technique is being developed, with promising results.

Summary—Se, Te, Bi and Sb are co-precipitated with ferric hydroxide from a solution of 1 g of the copper. The precipitate is collected on a filter disc and punched samples are taken for flameless atomic-absorption analysis. Less than 0.5 ppm of the four elements can be rapidly determined.

APPLICATION OF THE ZEEMAN EFFECT TO ANALYTICAL ATOMIC SPECTROSCOPY—III

EXTENSION OF CALIBRATION CURVES

D. E. Veinot and R. Stephens
Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, N.S., Canada

(*Received* 31 *March* 1976. *Accepted* 26 *April* 1976)

The useful range of analytical calibration curves in flame atomic-absorption spectroscopy (AAS), assuming normal instrumental alignment, is limited to an upper analyte solution concentration of 10–100 ppm. Some extension may be obtained by use of less strongly absorbing atomic lines, such as the 2614 Å line for lead. In some instances, useful extensions may be achieved by use of non-resonance lines. Thus Thompson[1] has described the determination of calcium at concentrations up to 1500 ppm by use of the germanium 4226.57 Å line. Similarly Dagnall *et al.*[2] have examined the fluorescence of bismuth at 2061.2 Å excited by the 2061.63 Å line from an iodine electrodeless discharge lamp. Norris and West[3] have tabulated a number of potential spectral interferences in AAS which in principle could be used in an analogous manner.

In these techniques, the spectrometer requires some adjustment specific to the individual element considered, before the high concentration section of the calibration curve can be obtained. In addition, suitable low-sensitivity lines are available for only a limited number of elements, and even in these cases the range extension available is governed by the spectroscopic parameters of the system, rather than being subject to operator control.

The present work describes a generally applicable technique by which an extended range calibration curve may be obtained by using the Zeeman affect. Single beam AAS measurements are made on the σ-components of the Zeeman multiplet. The σ-components are displaced into the wings of an analyte absorption profile to an extent governed by the magnitude of the applied magnetic field, as in the measurement of line profiles by Zeeman scanning.[4–6] Thus the upper limit of the calibration curve may be extended simply by increasing the magnetic field strength, without moving the spectrometer off the optimum resonance line for the particular element considered. Since the σ-components may be selected electronically, the extension of range thus obtained may be controlled readily with either manual or automated instrumentation.

EXPERIMENTAL

The elements chosen for examination were Ca, Cd and Cu, the 4227, 2288 and 3248 Å lines being used. At the magnetic field strengths available, these lines show respectively a normal Zeeman triplet, a normal triplet with hyperfine structure, and an anomalous multiplet. The spectrometer used was that described in a previous communication.[7] The instrument was set up and operated as previously described, except that the amplifier was balanced to pass only signals generated by the σ optical channel. All instrumental parameters (lamp-current, monochromator slit-width, photomultiplier voltage, *etc.*) were optimized for each element to give the best zero-field sensitivity, and were left unaltered as the field strength was increased. The spectral sources used were modifications of an earlier design.[8] All anode electrodes were cut from 0.01-in. zirconium sheet (Alpha Products); copper and cadmium electrodes were prepared from copper foil and cadmium-coated copper foil as described previously.[8] The calcium electrode was prepared by immersing 1-mm^2 mesh stainless-steel gauze in fused calcium chloride and filing the cooled salt coating flush with the original mesh surface. During operation, sufficient metal was thus exposed to permit formation of a stable plasma, while volatilization of the deposited calcium chloride provided the required source of calcium atoms in the vapour phase. This technique is convenient for preparing cathodes for chemically reactive elements, and gives an operational lifetime comparable to that of the metallic cathodes used previously (the calcium lamp used here is still operable after some 0.5 ampere-hours). However the intensity was found to be only about 1% of that of a commercial source for a given power dissipation.

To assemble each lamp, platinum wire was attached to the base of each electrode. Electrodes were separated by 1-mm thick horseshoe-shaped insulators (Fig. 1) which were cut from 1/2" diameter silica discs. The whole assembly was mounted in a preformed Pyrex glass case (Fig. 1), with copper shims inserted behind the anode to hold the assembly in place. Silica capillary insulators were pushed over the platinum wires and the wires sealed into the case. A silica window was attached to the front of the lamp with epoxy resin cement. The lamps were conditioned and sodium deposited as described previously.[8]

This procedure extends lamp shelf-life almost indefinitely. In addition it improves lamp intensity because of reduced quenching within the plasma through the use of silica insulators.

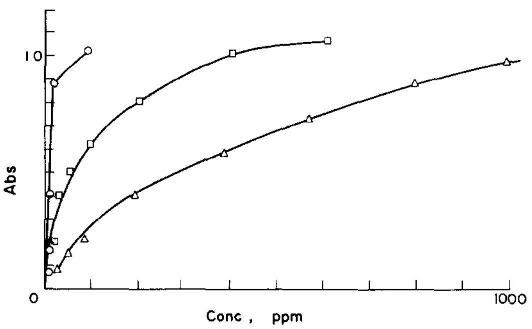

Fig. 4. Calibration curves for copper: ○ zero field, □ 6.6 kG, △ 16 kG.

RESULTS AND DISCUSSION

Figures 2–4 show the calibration curves obtained for calcium, cadmium and copper at field strengths from 0 to 16 kG. The extension obtained for cadmium is less than that for calcium or copper. This arises from the larger line-width observed for cadmium, this being due to isotopic hyperfine structure.[9] An analogous effect has been observed during Zeeman background-correction measurements on mercury.[10]

All the calibration curves obtained here show some departures from linearity and this arises from the following causes. De Galan and Samaey have shown that non-linear calibration curves are inherent whenever the monochromator bandpass covers more than one source-line.[11] This is true in the present case, since all the σ-components of the Zeeman multiplet, including hyperfine structure, are transmitted when the present techniques are used. It should, however, be pointed out that this defect is not inherent in the method, since σ_+ and σ_- components are separable, given parallel optical and magnetic axes[4] rather than the mutually perpendicular orientation used for the present study.

With the present orientation, minimum curvature can be expected for singlet transitions without hyperfine structure (*i.e.*, a single atomic line at ν_0 giving a normal Zeeman triplet with two σ-components spaced symmetrically about ν_0). Even in this situation, however, linear plots will not be attained with atmospheric absorption cells, because of the asymmetry in the analyte absorption profile, caused by pressure broadening.

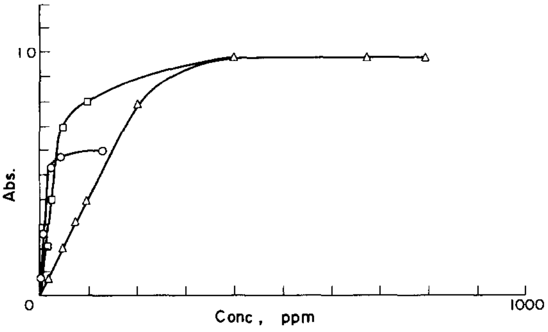

Fig. 3. Calibration curves for cadmium: ○ zero field, □ 6.6 kG, △ 16 kG.

CONCLUSIONS

The technique is of potential value in extending the working range of atomic-absorption spectroscopy. The method is of value for instruments employing the Zeeman effect for background correction, since such instruments can generate ambiguous data owing to the maxima observed in their calibration curves.[7] The present technique thus offers a means whereby such ambiguity may be removed by utilizing signals which are automatically available to any spectrometer of this type.

Summary—An application of the Zeeman effect is described by which calibration curves applicable to high analyte concentrations may be obtained. The procedure uses single-beam measurements on the displaced σ-components of the Zeeman multiplet, and thus permits controlled desensitization of an atomic-absorption signal to be obtained, simply by increasing the magnetic field strength, while leaving the monochromator permanently set on the optimum analytical line for the element considered Calibration curves for Ca, Cd and Cu are given for applied field strengths from 0 to 16 kG.

(*Received* 30 *March* 1976. *Accepted* 7 *April* 1976)

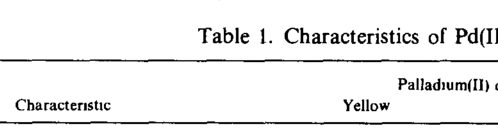
As a continuation of our studies on 1-substituted-4,4,6-trimethyl-1*H*,4*H*-2-pyrimidinethiols as analytical reagents,[1] the applications of the 1-amino- (**I**), 1-anilino- (**II**) and 1-(2′,4′-dinitroanilino)- (**III**) derivatives have been investigated. Of the metals belonging to the iron and platinum groups, only Pd(II) and Os(VIII) react instantly with the present compounds to form coloured complexes, at room temperature. The complexes are extractable into non-polar solvents and may be used for the spectrophotometric determination of the two metals.

EXPERIMENTAL

Reagents

Standard solutions of Pd(II) and Os(VIII) were prepared by dissolving appropriate amounts of anhydrous $PdCl_2$ in 1.0*M* hydrochloric acid and OsO_4 in 1.0*M* sodium hydroxide.

The thiols (**I**) and (**II**) were prepared by the method of Mathes[2] and melted at 209–210° and 170–171° respectively. To synthesize (**III**), 2,4-dinitrophenylhydrazine (3.96 g; 0.02 mole) and 2-methyl-2-isothiocyanato-4-pentanone (3.14 g; 0.02 mole) were taken in 50 ml of ethanol, 3 or 4 drops of conc. sulphuric acid were added and the mixture was refluxed for 5 hr on a steam-bath. The solvent was removed under reduced pressure and the residue washed with water. After 2 or 3 crystallizations from acetic acid, the m.p. was 223–224°. Calculated: C, 46.29%; H, 4.45%; N, 20.77%; found C, 45.9%; H, 5.0%; N, 20.5%.



Standard solutions (0.01*M*) of the ligands were prepared by dissolving appropriate amounts of (**I**) in dimethylsulphoxide (DMSO) and (**II**) and (**III**) in chloroform.

The pH of the solutions were adjusted with acetate buffers and dilute sodium hydroxide solution and hydrochloric acid. All other reagents used were of analytical grade. Demineralized water was used throughout.

RESULTS

The solutions of (**I**) and (**II**) are colourless and do not absorb significantly in the visible region. However, (**III**), being light yellow in colour, absorbs in this region and consequently a reagent blank was used in the complexation study. When a few drops of any of these reagents were added to either Pd(II) or Os(VIII) solution, two distinct coloured complexes appeared, depending upon the pH of the solution. It was established by the method of continuous variations that the metal to ligand ratio was 1:2. Except for the complexes of (**I**), the complexes were completely extractable into chloroform, carbon tetrachloride, benzene or n-butanol, and suitable for extractive determinations. Thiol (**I**) is insoluble in common organic solvents, so it was studied in 60% DMSO medium. The other complexes were investigated in chloroform in which their absorbance was maximum and constant. The characteristics of Pd and Os complexes of (**I**), Pd complexes of (**II**) and (**III**) and Os complexes of (**II**) and (**III**) are summarized in Tables 1, 2 and 3 respectively. The Os-complex, formed in acidic medium, showed a slight shift in λ_{max} towards shorter wavelength with time. The maximum shift was attained after 1 hr at room temperature or heating for 5 min on a steam-bath. Because of the poor solubility of (**I**) and its complexes in common organic solvents (except DMSO), comparative lack of selectivity and low sensitivity (*cf.* Tables 1–3), (**II**) and (**III**) are far better reagents for spectrophotometric determination of Pd(II) and Os(VIII).

Procedure

Adjust the acidity or pH of a Pd(II) or Os(VIII) solution (Table 2 or 3), add 10 ml of 0.02*M* (**II**) or (**III**) (in chloroform) and shake for 20 min. Allow to settle and remove the organic layer. For the determination of Os, keep the extract for 1 hr or heat it for 5 min on a steam-bath, if

extracted from acidic solution. Make up to volume, measure its absorbance at λ_{max} of the complex against a solvent blank [or reagent blank in case of the (III)] and calculate the amount of the metal from a calibration graph.

Diverse ions

The effect of a large number of diverse ions on the determination of 10.7 ppm of Pd and 11.6 ppm of Os with (II) and (III) was investigated. Up to 10^4 ppm of Cl^-, Br^-, NO_3^-, ClO_4^-, CH_3COO^-, SO_4^{2-}, Ca^{2+}, Ba^{2+}, Sr^{2+}, Zn^{2+}, Cd^{2+}, Al^{3+} gave no interference, nor did 5×10^3 ppm of Pb^{2+}, in any of the complexation reactions. Silver interfered when present at the 10 ppm level, and cyanide and thiourea must be absent. The other tolerance limits are incorporated in Table 4. It is evident that the determinations can be accomplished in the presence of large amounts of many species, including all the other metals of the iron and platinum groups.

DETERMINATION OF AMERICIUM AND CURIUM BY USING ION-EXCHANGE IN NITRIC ACID–METHANOL MEDIUM FOR ENVIRONMENTAL ANALYSIS

E. Holm and R. Fukai
International Laboratory of Marine Radioactivity, Musée Océanographique,
Principality of Monaco

(*Received* 16 *March* 1976. *Accepted* 29 *April* 1976)

Transplutonic elements are only slightly sorbed on anion-exchangers from hydrochloric or nitric acid media, but the presence of alcohol in the media enhances the anion-exchange of these elements, especially in nitric and sulphuric acid media. Von Haidvogel *et al.*[1] showed this enhancement in thin-layer chromatography; the sorption of transplutonic elements increased with increasing alcohol content and the binding with the ion-exchanger was stronger in nitric acid medium than in sulphuric acid medium. Guseva *et al.*[2,3] separated americium from curium, both at relatively high level, in a nitric acid–methanol medium, observing that the greater the atomic number, the stronger the sorption.

In the present work a method has been developed for determining americium and curium in environmental samples, on the basis of the difference between the sorption characteristics of these elements on anion-exchangers in an acid–methanol system and those of plutonium, polonium, thorium, *etc.* The method also permits us to perform sequential determination of plutonium, when necessary. The radiochemical separation of americium from curium is not generally required, since modern α-spectrometry resolves the major α-peak of ^{241}Am (5.49 MeV) from those of ^{242}Cm (6.10 MeV) and ^{244}Cm (5.80 MeV), which possibly co-exist with ^{241}Am in environmental samples.

EXPERIMENTAL

Reagents

Nitric acid–methanol mixtures: 1*M* HNO_3–90% CH_3OH solution (10*M* nitric acid–methanol) (1:9 v/v) and 0.5*M* HNO_3–70% CH_3OH solution (5*M* nitric acid–water–methanol, 1:2:7 v/v).

First anion-exchange resin column: Dowex 1 (X8, 100–200 mesh), bore 1 cm, volume 10 ml.

Second anion-exchange resin column: Dowex 1 (X2, 50–100 mesh), bore 1 cm, volume 20 ml.

Cation-exchange resin column: Dowex 50 (X8, 200–400 mesh), bore 1 cm, volume 5 ml.

Americium-243 solution in 1*M* nitric acid (5 dpm/ml): chemical yield monitor for ^{241}Am.

Plutonium-236 or plutonium-242 solution in 1*M* nitric acid (5 dpm/ml): chemical yield monitor for ^{238}Pu and ^{239,240}Pu.

Sample pretreatment

Biological or sediment samples are dried at 105–110°, weighed and placed in a porcelain crucible to which the chemical yield monitors, a few dpm each of ^{243}Am and ^{236}Pu or ^{242}Pu, are normally added. After drying again, the samples are ashed at 500° overnight. The ash obtained is leached with a mixture of concentrated nitric and hydrochloric acids and a few ml of 30% hydrogen peroxide.

Water samples are acidified, and iron carrier (50 mg of Fe^{3+}) is added.

The actinides are co-precipitated with ferric hydroxide by adding ammonia. The precipitate is centrifuged and dissolved in 9–12*M* hydrochloric acid. After the addition of a few drops of 30% hydrogen peroxide, the solution is heated and kept at 80° for 20 min. The acidity of the solution is finally adjusted to 9*M* in hydrochloric acid.

Ion-exchange

After cooling, the solution is passed through the first column of Dowex 1 and then through the Dowex 50 column, which is directly connected to the first column, at a flow-rate of 2 ml/min. Iron(III) is sorbed on the Dowex 1 column with plutonium(IV) as well as any uranium and polonium. Thorium is sorbed on the Dowex 50 column. Tervalent actinides, americium and curium, on the other hand, pass through both columns. The columns are washed with 50 ml of 9*M* hydrochloric acid, then the effluent and washings are combined and evaporated to dryness. The residue is dissolved in 1*M* HNO_3–90% CH_3OH solution (50–100 ml).

In order to obtain further purification of americium and curium, the solution is passed through the second Dowex 1 column at a flow-rate of 2 ml/min. Americium and curium are sorbed on the column with other impurities, such as remaining plutonium, polonium, thorium *etc.* The column is washed with 60 ml of 1*M* HNO_3–90% CH_3OH mixture. The tervalent actinides are then eluted with 0.5*M* HNO_3–70% CH_3OH mixture (70 ml).

When the plutonium determination is required, plutonium can be eluted from the first Dowex 1 column with

Summary—1-Amino-, 1-anilino- and 1-(2′,4′-dinitroanilino)- 4,4,6-trimethyl-1*H*,4*H*-2-pyrimidinethiols react with Pd(II) and Os(VIII), forming coloured complexes extractable into non-polar organic solvents. The optimum conditions for the complexation have been established. Beer's law is obeyed and by an extractive spectrophotometric procedure, microgram quantities of the two metals are determined in the presence of large amounts of diverse ions, including all the other metals of the iron and platinum groups.

DETERMINATION OF AMERICIUM AND CURIUM BY USING ION-EXCHANGE IN NITRIC ACID–METHANOL MEDIUM FOR ENVIRONMENTAL ANALYSIS

E. Holm and R. Fukai
International Laboratory of Marine Radioactivity, Musée Océanographique,
Principality of Monaco

(*Received* 16 *March* 1976. *Accepted* 29 *April* 1976)

Transplutonic elements are only slightly sorbed on anion-exchangers from hydrochloric or nitric acid media, but the presence of alcohol in the media enhances the anion-exchange of these elements, especially in nitric and sulphuric acid media. Von Haidvogel *et al.*[1] showed this enhancement in thin-layer chromatography; the sorption of transplutonic elements increased with increasing alcohol content and the binding with the ion-exchanger was stronger in nitric acid medium than in sulphuric acid medium. Guseva *et al.*[2,3] separated americium from curium, both at relatively high level, in a nitric acid–methanol medium, observing that the greater the atomic number, the stronger the sorption.

In the present work a method has been developed for determining americium and curium in environmental samples, on the basis of the difference between the sorption characteristics of these elements on anion-exchangers in an acid–methanol system and those of plutonium, polonium, thorium, *etc.* The method also permits us to perform sequential determination of plutonium, when necessary. The radiochemical separation of americium from curium is not generally required, since modern α-spectrometry resolves the major α-peak of ^{241}Am (5.49 MeV) from those of ^{242}Cm (6.10 MeV) and ^{244}Cm (5.80 MeV), which possibly co-exist with ^{241}Am in environmental samples.

EXPERIMENTAL

Reagents

Nitric acid–methanol mixtures: 1*M* HNO_3–90% CH_3OH solution (10*M* nitric acid–methanol) (1:9 v/v) and 0.5*M* HNO_3–70% CH_3OH solution (5*M* nitric acid–water–methanol, 1:2:7 v/v).

First anion-exchange resin column: Dowex 1 (X8, 100–200 mesh), bore 1 cm, volume 10 ml.

Second anion-exchange resin column: Dowex 1 (X2, 50–100 mesh), bore 1 cm, volume 20 ml.

Cation-exchange resin column: Dowex 50 (X8, 200–400 mesh), bore 1 cm, volume 5 ml.

Americium-243 solution in 1*M* nitric acid (5 dpm/ml): chemical yield monitor for ^{241}Am.

Plutonium-236 or plutonium-242 solution in 1*M* nitric acid (5 dpm/ml): chemical yield monitor for ^{238}Pu and ^{239,240}Pu.

Sample pretreatment

Biological or sediment samples are dried at 105–110°, weighed and placed in a porcelain crucible to which the chemical yield monitors, a few dpm each of ^{243}Am and ^{236}Pu or ^{242}Pu, are normally added. After drying again, the samples are ashed at 500° overnight. The ash obtained is leached with a mixture of concentrated nitric and hydrochloric acids and a few ml of 30% hydrogen peroxide.

Water samples are acidified, and iron carrier (50 mg of Fe^{3+}) is added.

The actinides are co-precipitated with ferric hydroxide by adding ammonia. The precipitate is centrifuged and dissolved in 9–12*M* hydrochloric acid. After the addition of a few drops of 30% hydrogen peroxide, the solution is heated and kept at 80° for 20 min. The acidity of the solution is finally adjusted to 9*M* in hydrochloric acid.

Ion-exchange

After cooling, the solution is passed through the first column of Dowex 1 and then through the Dowex 50 column, which is directly connected to the first column, at a flow-rate of 2 ml/min. Iron(III) is sorbed on the Dowex 1 column with plutonium(IV) as well as any uranium and polonium. Thorium is sorbed on the Dowex 50 column. Tervalent actinides, americium and curium, on the other hand, pass through both columns. The columns are washed with 50 ml of 9*M* hydrochloric acid, then the effluent and washings are combined and evaporated to dryness. The residue is dissolved in 1*M* HNO_3–90% CH_3OH solution (50–100 ml).

In order to obtain further purification of americium and curium, the solution is passed through the second Dowex 1 column at a flow-rate of 2 ml/min. Americium and curium are sorbed on the column with other impurities, such as remaining plutonium, polonium, thorium *etc.* The column is washed with 60 ml of 1*M* HNO_3–90% CH_3OH mixture. The tervalent actinides are then eluted with 0.5*M* HNO_3–70% CH_3OH mixture (70 ml).

When the plutonium determination is required, plutonium can be eluted from the first Dowex 1 column with

1.2M hydrochloric acid after washing with 7.2M nitric acid and determined by the procedure described by Talvitie.[4]

Electro-deposition

The eluate which contains americium and curium is evaporated to dryness and the residue is dissolved with 0.8 ml of conc. sulphuric acid. The solution is diluted with distilled water and adjusted to pH 2 with ammonia, the final volume being about 10 ml. The electro-deposition of americium and curium from this solution onto a stainless-steel disc is performed at a current of 1.2 A for 1 hr, with a disposable polyethylene vial as electrolysis cell. A similar procedure for the electrodeposition of plutonium has already been described.[5]

Alpha-spectrometry

In the present work, the α-spectrometry for americium and curium was carried out by using a silicon surface-barrier detector having a sensitive area of 300 mm^2. The resolution of α-spectra was 35–40 keV for the ^{241}Am peak (5.49 MeV) in terms of the full width at half maximum. The least detectable activity was 0.01 pCi for a 1000-min count under these conditions.

RESULTS AND DISCUSSION

The key to precise determinations of americium in environmental samples is to obtain good decontamination from naturally-occurring α-emitters, such as ^{210}Po (α-energy, 5.30 MeV) and ^{228}Th (5.42 MeV) as well as from the artificial fall-out radionuclides such as ^{238}Pu (5.49 MeV). Their α-energies would interfere with the α-spectrometry of ^{241}Am (5.49 MeV) or of the yield monitor ^{243}Am (5.28 MeV). For curium determinations separation from ^{236}Pu (5.76 MeV) is essential when ^{236}Pu has been used as the yield monitor for plutonium, as its α-peak overlaps that of ^{244}Cm (5.80 MeV).

* Not detected.
† Activity in Dec. 1974.
§ Activity in Oct. 1975.

The decontamination of polonium by the present procedure was verified by analysing samples which were known to contain relatively high levels of ^{210}Po, without adding any yield monitor. The decontamination factor for ^{210}Po is estimated to be of the order of 10^5.

However, since it was also observed that ^{210}Pb is strongly sorbed on the anion-exchange resin from the nitric acid–methanol medium, it is possible that a small fraction of the ^{210}Pb may be carried over to the americium fraction and interfere with the α-spectrometry of ^{243}Am, when the content of ^{210}Pb in the samples is exceptionally high. The interference comes from the build-up of ^{210}Po through β-decay of ^{210}Pb (half-life: 19.4 y) with an equilibrium time of approximately 6 months. This difficulty can be overcome by using clean ^{242}Cm or ^{244}Cm as the yield monitor for americium measurements, since it has been experimentally proved that there is practically no difference between the chemical yields of americium and curium in the present procedure.

The decontamination of ^{228}Th was tested either by spiking known amounts of ^{230}Th (α-energy, 4.69 MeV) or by verifying absence of the ^{224}Ra-peak (5.68 MeV) which should be built up during two weeks from the separation if the thorium decontamination has been incomplete. These tests indicated that the procedures decontaminate ^{228}Th by a factor of at least 10^4.

The absence of the $^{239,240}Pu$-peak (5.16 MeV) in the α-spectra obtained through the present procedure confirmed sufficient decontamination of $^{239,240}Pu$ as well as of ^{238}Pu. The activity of $^{239,240}Pu$ is 10–20 times that of ^{238}Pu in normal environmental samples.

To illustrate the decontamination from the interfering radionuclides mentioned above, an α-spectrogram obtained for the IAEA intercalibration sample, AG-I-1 (seaweed) by the present procedure is given in Fig. 1. The α-peaks of ^{243}Am, ^{241}Am and ^{244}Cm are seen to be clean.

If the plutonium and thorium were not preseparated through the first anion-exchange, about 10% of the plutonium and thorium would follow americium in the $0.5M$ HNO_3–70% CH_3OH eluate. Plutonium and thorium are also strongly sorbed on Dowex 1 from $1M$ HNO_3–90% CH_3OH, but partially eluted with $0.5M$ HNO_3–70% CH_3OH. Polonium is also sorbed, but not eluted under these conditions.

Since ^{243}Am often contains some ^{244}Cm as an impurity, a serious error may be introduced into curium determination when the curium concentrations are low and ^{243}Am is used as the yield monitor for ^{241}Am. This difficulty can be avoided by repeating the procedure without adding any yield monitor. In this case, the previously determined ^{241}Am concentration of the sample is used to measure the yield since, as has been mentioned, the chemical yield of ^{241}Am is practically identical to that of ^{242}Cm or ^{244}Cm.

The method described above was applied to several IAEA reference samples, such as AG-I-1 (seaweed), SD-B-1 (marine sediment) and SW-I-3 (seawater), for which the probable concentrations are already known for ^{238}Pu and $^{239,240}Pu$ as well as ^{241}Am.[6] The results of these analyses are given in Table 1. The recovery of americium in these analyses varied between 30 and 95%. Nevertheless, the results presented in Table 1 are in good agreement with the given probable concentrations, showing the usefulness of the present method for the determination of americium and curium in environmental samples.

A major part of ^{241}Am in the environment today results from the decay of ^{241}Pu (half-life 13.6 y, β-emitter) deposited as radioactive fall-out or from nuclear installations.[7] The method presented here is being used for studying the environmental behaviour of americium and curium isotopes originating from various sources.

DETERMINATION OF TRACES OF INDIUM, MANGANESE, ARSENIC AND ANTIMONY IN ZINC BY NEUTRON-ACTIVATION ANALYSIS*

M. Dermelj, V. Ravnik, L. Kosta, A. R. Byrne and A. Vakselj
Faculty of Natural Sciences and Technology and J. Stefan Institute, University of Ljubljana,
61000 Ljubljana, Yugoslavia

(*Received* 23 *December* 1975. *Accepted* 25 *March* 1976)

Zinc metal is available in different degrees of purity, from the so-called "five nines zinc" (99.999 + % Zn) to the grade with more than 1.6% of impurities. Among the main impurities in commercial zinc are iron, copper and lead, but many others (arsenic, antimony, tin, cadmium, germanium, indium, thallium, manganese and gallium) influence the mechanical, electrical and anticorrosion properties of zinc metal.[1–4] Some trace elements (10^{-4}–10^{-6}% of iron, manganese, copper, nickel and cobalt) may also change the luminescence properties of zinc sulphide.[5–8] The trace element composition also indicates the origin of the zinc ore.

Destructive and non-destructive activation analysis are both suitable for the determination of trace elements in high-purity materials but because the activity of ^{69m}Zn and of ^{64}Cu interferes in the determination of short-lived isotopes and the activity of ^{65}Zn interferes in the determination of long-lived isotopes, non-destructive analysis using high-resolution spectrometry is impracticable. Thus destructive methods for Cu, Ni, Co, Fe, Mn,[6,7,9] for Hg, U, Yb,[10] for Mo, Re,[11] for Te, Se, As, Sb[12] and for Co, Cd, Fe, In[13] in electrolytic zinc sulphate solutions, and for Co, Ag,[14] for 13 trace elements,[15] for Ge,[16] for Cu, Fe, Co, Ni[9] and for 27 trace elements [17] in zinc metal, have been reported. Experience in analysis of standard reference materials shows that chemical separations are essential for the majority of elements in the very low concentration range. The aim of the present work was to extend the applicability of methods for pure chemical reagents,[18,19] biological materials,[20–22] glasses [21–24] and calcium carbonate[24] to materials requiring a separation of gram quantities of the active matrix before the determination of microgram and submicrogram quantities of trace elements. Separations with very high decontamination factors are essential.

The present paper gives an account of the destructive determination of the trace elements indium, manganese, arsenic and antimony in different samples of pure zinc metal, by solvent extraction techniques. The various samples analysed included the NBS standard Zn 683, for which results for these four elements have not previously been published.[25]

EXPERIMENTAL

Irradiation

For the determination of indium and manganese, the samples (0.2–1.0 g) and standards, sealed in plastic tubes, were irradiated for 30–40 min in the Institute's reactor TRIGA MK.II at a neutron-flux of 4×10^{12} n.cm^{-2}.sec^{-1}, the pneumatic transfer system being used.

In the determination of arsenic and antimony, the samples, sealed in plastic tubes, were irradiated together with the standard for 18–20 hr at a neutron-flux of approximately 2×10^{12} n.cm^{-2}.sec^{-1}.

Nuclear data

The most important nuclear data for the elements determined are given in Table 1.[26]

Apparatus

Quantitative determinations of individual elements were based on activity measurements of the separated radionuclides at the γ-ray energies indicated in italics in Table 1. They were counted in a 3 × 3 in. well-type (NaI(Tl) detector connected to a 250-channel analyser.

Reagents and solutions

Apart from mineral acids and hydrogen peroxide used in the dissolution of samples, the following reagents were

* Presented in part at the IVth International Symposium: "Reinststoffe in Wissenschaft und Technik", Dresden, October 1975.

required. For the determination of indium and manganese: solutions of ammonium citrate (40%), potassium cyanide (5%), sodium diethyldithiocarbamate (1%), Cresol Red (0.1%), lanthanum nitrate in 0.1*M* nitric acid (La = 10 mg/ml), and ammonia, concentrated hydrobromic acid, carbon tetrachloride and alcohol. For the determination of arsenic and antimony: 5*M* and 0.5*M* potassium iodide, toluene and alcohol.

Standards were prepared from spectroscopically pure reagents (metallic indium, potassium permanganate, arsenic trioxide and antimony trioxide) and contained 0.1% w/w of the elements determined. The solutions were 0.1*M* with respect to nitric acid (hydrochloric acid for antimony) and after appropriate dilution, were used as carriers or standards.

Dissolution of samples

After irradiation, but before their dissolution, the surface contamination of the samples (except in the case of zinc dust) was removed by etching them in nitric acid (1 + 1) followed by washing in doubly distilled water and then 96% alcohol. After washing, the samples were dried, weighed and dropped into a Kjeldahl flask together with carriers (50 μg of indium, 250 μg of manganese, 500 μg of arsenic, 1 mg of antimony, 1 mg of copper and 10 mg of lanthanum) and heated in a mixture of nitric and sulphuric acids until SO_3 fumes appeared.

Determination of indium and manganese

After dissolution of the samples, a few ml of concentrated hydrobromic acid were added to the Kjeldahl flask and heating continued (to remove volatile bromides) until SO_3 fumes appeared. The solution was cooled and quantitatively transferred to a centrifuge tube. An excess of ammonia was added until the precipitate of zinc hydroxide was completely dissolved. To the ammoniacal solution a few ml of 32% hydrogen peroxide were added to precipitate manganese together with lanthanum and indium hydroxides. After 10 min heating on a water-bath, the solution was discarded, the remaining precipitate washed with a mixture of 1*M* ammonia and a few drops of hydrogen peroxide and centrifuged again.

The hydroxides were dissolved in 6*M* hydrochloric acid (5 ml) and quantitatively transferred to a separatory funnel. After addition of 5 ml of sodium diethyldithiocarbamate solution, indium and manganese were extracted as the diethyldithiocarbamates at pH 8–9 (Cresol Red) into 10 ml of carbon tetrachloride in the presence of ammonium citrate (5 ml) and potassium cyanide solutions (5 ml). Manganese was isolated from indium by the selective stripping of the organic phase with a 1:1 mixture of 4*M* hydrochloric acid and sodium diethyldithiocarbamate solution, which holds back indium in the organic phase.

After separation of manganese, the organic phase was mineralized with a mixture of sulphuric and nitric acid, cooled and transferred to a 5-ml counting vial. The activity of the 1.29-MeV ^{116m}In peak was measured and compared with the activity of the standard. The chemical yields, which were better than 98%, were determined by re-irradiation. The aqueous phase containing manganese was mineralized in the same way and transferred to a counting vial. The activity of the 0.85-MeV ^{56}Mn peak was measured and compared with that of the standard. The chemical yield was determined spectrophotometrically by the periodate method and was about 90%.

Determination of arsenic and antimony

After dissolution of the samples, the solution was transferred to a separatory funnel and diluted to a volume of 18 ml in which 13.4 ml of free 9*M* sulphuric acid were present. Then 2 ml of 0.5*M* of potassium iodide and exactly 15 ml of toluene were added and the mixture was shaken for 3 min. The aqueous phase was discarded and the organic phase washed with 10 ml of 6*M* sulphuric acid/0.05*M* potassium iodide. Antimony was stripped from the organic phase with two 5-ml portions of 6*M* hydrochloric acid/0.5*M* potassium iodide, being shaken for 2 min each time. The stripping solutions were collected in a 10-ml counting vial and the activity of the 0.56-MeV ^{122}Sb peak was measured and compared with that of the standard.

The activity of arsenic was measured in two ways, depending on the quantity in the sample. At high levels of arsenic, an aliquot of the organic phase (after separation of antimony) was transferred directly to the counting vial; at low levels the arsenic from the whole of the organic phase was stripped into dilute mineral acid. In both cases the activity of the isolated ^{76}As was measured in a counting vial at 0.56 MeV and compared with that of the standard. The yields for arsenic and antimony were shown by tracer experiments to be quantitative.

RESULTS AND DISCUSSION

Owing to the high activity of the matrix and the presence of copper isotopes arising from (n,p) parasite reactions, non-destructive activation analysis for determination of trace elements in different samples of zinc metal and its compounds is usually impracticable. For separation of gram quantities of zinc matrix from microgram and sub-microgram quantities of short-lived or long-lived isotopes, one-step separation methods usually fail. With a combination of two or more separation procedures or by repeated application of a single but very selective separation procedure, the decontamination factors required for such a separation can be obtained.

Since the larger quantities of zinc interfere with the extraction and determination of indium and manganese, even in the presence of larger quantities of potassium cyanide, both elements were (before extraction with sodium diethyldithiocarbamate) quantitatively co-precipitated with lanthanum hydroxide in the presence of excess of ammonia. Tracer experiments with ^{56}Mn and ^{116m}In confirmed that co-precipitation was quantitative. The quantities of indium and manganese carriers suitable for diethyldithiocarbamate extraction and yield determination are small enough to make their co-precipitation on lanthanum hydroxide desirable. This isolation of indium and manganese is convenient, since most of the matrix and those elements soluble in excess of ammonia are removed, *e.g.*, copper, which arises from the reactions ^{64}Zn(n,p)^{64}Cu and ^{67}Zn(n,p)^{67}Cu. The γ-spectra obtained by this method are clean and identical with the γ-spectra of the standards, for both elements.

In samples which had more than 100 ppm of cadmium, in addition to the peaks of ^{116m}In there was a peak due to the 0.34-MeV ^{115m}In activity ($t_{1/2}$ = 4.5 hr). This arises as a daughter of ^{115}Cd after the ^{114}Vd(n,γ) reaction. Since the γ-energy of ^{115m}In is lower than the energies of the ^{116m}In isotopes, the presence of ^{115m}In does not interfere with the evaluation of indium in the samples.

Determination of arsenic and antimony in different samples of zinc metals is based upon the extraction of the tri-iodides of both elements into toluene. From the extraction curves[27] it can be seen that both elements are quantitatively extracted into the organic phase from 6*M* sulphuric acid/0.05*M* potassium iodide. The high degree of extraction permits washing of the organic phase without appreciable loss of arsenic and antimony and so increases the degree of decontamination. The basis for the separation of the elements from the organic phase is the difference in the extraction coefficients of their iodides (for arsenic ~600, for antimony ~0.05) from 6*M* hydrochloric acid/0.5*M* potassium iodide solution into toluene.[22]

For samples with a high concentration of antimony compared with arsenic, traces of antimony in the organic

phase must be stripped a second time with 6*M* hydrochloric acid/0.5*M* potassium iodide. Similarly, for samples with a very high arsenic–antimony ratio, the antimony stripped from the organic phase should be washed with toluene to remove traces of arsenic.

The procedure is simple, fast and quantitative. The two elements are cleanly separated from zinc (the 0.44-MeV peak from ^{69m}Zn was not observed). In the analysis of zinc samples for arsenic and antimony it is essential to dissolve them in the presence of nitric acid, or low results may be obtained by the loss of the volatile hydrides.

The results for indium, manganese, arsenic and antimony are summarized in Table 2. We have been unable to check the accuracy of our results directly on zinc reference samples, since these are not available. From the high chemical yields, the clean γ-spectra and the good reproducibility of the results it is concluded that the values for indium, manganese, arsenic and antimony are close to the true values.

CONCLUSION

The solvent extraction method described is superior to earlier methods, involving precipitation, distillation or ion-exchange separations and has the advantages of simplicity and speed. The radiochemical purity of the separated fractions allows determinations to be made at the nanogram level.

Summary—Destructive activation determination of the trace elements indium, manganese, arsenic and antimony in different samples of pure zinc metal by solvent extraction techniques is described. Determination of indium and manganese is based on the quantitative co-precipitation of both elements with lanthanum hydroxide, followed by their extraction with sodium diethyldithiocarbamate in the presence of potassium cyanide and their subsequent separation by selective stripping. The quantitative determination of arsenic and antimony is based on the extraction of their iodides from sulphuric acid solution with toluene.

Some of the most useful methods employed in silicate analysis for major elements are flame photometry, colorimetry, and atomic-absorption spectrophotometry (AAS); all of them require prior dissolution of the sample. Much has been written about silicate rock decomposition, but in the authors' opinion most of the methods described present serious inconveniences for work in a routine laboratory where instrumental techniques are employed. The method applied has to fulfil certain requirements dictated by the nature of the work. Geochemistry laboratories are usually concerned with determination of SiO_2, TiO_2, Al_2O_3, total iron as Fe_2O_3, MgO, CaO, Na_2O, K_2O and P_2O_5. At present, all these except phosphorus and titanium oxides can be determined advantageously by AAS. Phosphorus cannot be determined directly by AAS, and the sensitivity for titanium is low. Colorimetric methods are preferred in both cases and so it is important not to introduce into the matrix components which interfere with the colorimetric and AAS determinations.

A very important aspect of AAS and the other techniques mentioned, and one that is directly connected with sample decomposition is the use of standards. For some elements many authors have successfully used standard solutions prepared from pure salts, but the results for elements such as silicon and aluminium are not very good. The use of artificial standards may produce poor results because of the differences in bulk composition and in physical properties between natural samples and artificial standard matrices. Thus it is highly desirable to use the various standard rocks with a well-established composition, but doing so demands that the solutions prepared from them have certain qualities, one being good stability so that they can be used for more than one set of samples, saving both time and material. Another requirement is that the level of dissolved solids in the matrix must be low in order to facilitate accurate determinations. It is also preferable to be able to use the same standard solution for all the determinations.

The present paper reports a rapid and versatile method for decomposition of silicate rocks, to give a solution which contains all the elements of the rock but only a low total amount of solids. The master solution can be treated in various ways to stabilize it with respect to various components and it is possible to determine all the major elements by atomic absorption and/or colorimetry. The most important methods described for silicate rock decomposition have been investigated and their useful aspects put together and in some cases improved to obtain the final procedure.

EXPERIMENTAL

Reagents

All chemicals used were analytical reagent grade.

Flux. A 1:1 mixture of boric acid and lithium carbonate.

EDTA solution. Prepared by dissolving 2 g of the acid in 250 ml of distilled water containing 10 ml of concentrated ammonia solution and diluting to 1 litre. Stored in a plastic bottle.

Fluoboric acid solution. This contains 30 g of boric acid and 30 ml of 45% hydrofluoric acid per litre.

Potassium and barium nitrate buffer solutions. These contain 10,000 ppm of potassium and barium respectively.

RESULTS AND DISCUSSION

Classical schemes

These usually involve separate attack on two samples, which we consider a serious inconvenience for economic and rapid work.

Methods designed for atomic-absorption analysis

There is a great variety of published methods but we will consider only those established on the basis of a single attack and further determination of all the major elements in the solution obtained. The methods are essentially variants of two themes.

Pressure vessel decomposition.[1–5] Hydrofluoric acid is used alone or together with other acids in a hermetically sealed bomb. The fluorides are then stabilized with alcohol, aluminium chloride, or more often boric acid. The last produces good results but has two main inconveniences: (*i*) some resistant minerals such as zircon, tourmaline, cassiterite, titanium oxides and in some cases polymorphous alumina are not completely decomposed; (*ii*) the fluoride anions produced cause the inconveniences discussed below.

Lithium metaborate fusion.[6–10] This flux has been shown to be one of the most effective in silicate rock decomposition, giving complete fusion of most silicate rock minerals. On the other hand we have found that a mixture of lithium carbonate and boric acid gives faster decomposition of minerals such as zircon concentrates. The product can be dissolved in hydrofluoric, nitric, hydrochloric acid and so on. The most important variants are the following.

(*a*) *Nitric acid.*[6–8] In this case the stability of silicon and aluminium species in the solution is somewhat questionable. We have found that polymerization begins after about 8 hr, as shown in Fig. 1, which refers to a solution prepared from a typical granodiorite. The apparent concentration of silicon in solution has been found to be the same after 20 hr, irrespective of the silica content of the original rock (from 50 to 96%). An equilibrium between the silica precipitated and the solution seems to be established after this time. In spite of these inconveniences the method has the advantages of simplicity and rapidity (it takes about 15 min to dissolve the fusion product), the matrix is very suitable for flame and colorimetric determinations because nitrate does not produce interferences, and the amount of solids in solution is low.

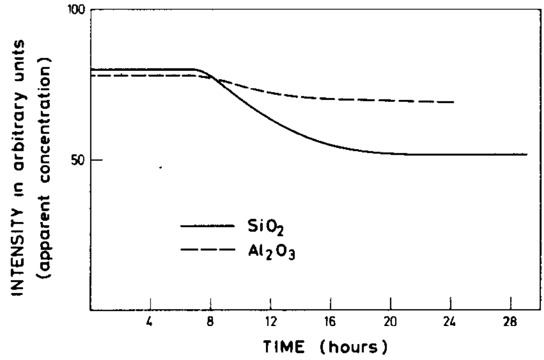

Fig. 1. Stability of signal for silicon and aluminium in a granodiorite rock. The same sample solution was measured at different times, and always compared with a fresh sample solution.

(*b*) *Hydrofluoric acid.* The fluorides can be stabilized with boric acid[9] or by direct dissolution with fluoboric acid.[10] The matrix is the same in both cases. The advantage of this method is that the solutions can be stored for a long time, but this is outweighed by several disadvantages. The high concentration of boron depresses the aluminium AAS signal by about 30% and increases the background by a factor of about ten, perhaps by formation of refractory compounds in the flame. The presence of fluoride interferes with the colorimetric determination of titanium, and in AAS if the amount of fluoride is high there is attack on any titanium parts of the instrument exposed to the sample. The amount of dissolved solids is also excessive, about 3.5% in Saavedra's method[10] and 2.2 or 1.3% respectively for the two solutions obtained by Abbey's method,[9] as we have found by evaporation of the solvent from different samples. In our experience, no atomizer can work satisfactory with solutions which contain more than 1% of solids. These problems also arise with the solution obtained by the pressure vessel method.

(*c*) *Complexing reagents.*[11] This method is very promising although it has not been employed to determine the total range of major elements. So far it has been mainly applied for determining alkali and alkaline earth metals. In our experience it is difficult to obtain clear solutions and the amount of solids in the matrix is also excessive.

Interferences

Some interference problems have been discussed above, and we will summarize some others here.

Chemical interferences. These can be classified into two groups.

(*a*) *Inter-element effects.* The most important are those produced by aluminium, silicate and sulphate in conjunction with calcium and magnesium. They can be overcome by using protecting agents, generally chelating agents such as EDTA[12] or releasing agents such as lanthanum, barium and strontium. In our experience barium is superior to strontium, Fig. 2, because of its lower ionization potential and its ability to form stronger Al-O-metal complexes.

(*b*) *Components introduced by chemical reagents.* The most important is that produced by fluoborate anions, described above.

Ionization interferences. These are important not only for alkali metals in an acetylene/air flame but also for alkaline earth metals, aluminium and silicon in an acetylene/nitrous oxide flame. The signals for aluminium and silicon decrease by about 20 and 5% respectively. We find potassium effective in suppressing these interferences.

The combined method

There is no doubt that the advantageous aspects of the different methods can be combined in a single procedure. We have taken Ingamell's method as a basis. In our opinion it is the most suitable, apart from the stability of the solutions.

We have found that if a small amount of EDTA is added before dilution to final volume, the apparent content of most ions except those derived from silica remains constant for several months. The apparent content of silica starts to change after 30 hr but less than in the absence of EDTA and the solution can be kept stable for months if some fluoborate is also added (Fig. 3), irrespective of the nature of the rock sample.

The nitrate–EDTA system produces no interelement interferences and the ionization interferences are suppressed by addition of barium for determination of alkali and alkaline earth metals, and of potassium for determination of silicon and aluminium.

Procedure

Weight 0.2000 g of the finely powdered sample into a gold or platinum crucible. Add 1.0 g of the 1:1 $LiCO_3$/H_3BO_3 mixture and heat in a furnace at 950° for 15 min. Remove the crucible from the furnace, rotate the melt over the wall in the usual way and return the crucible to the furnace for 5 min. Swirl the melt and cool the crucible quickly by putting it into a flat container with demineralized water in it, simultaneously adding a small amount of water to the crucible. Wash the outside of the crucible with demineralized water, place a small Teflon-covered magnetic bar in the crucible and put this into a 100-ml beaker. Add 5 ml of concentrated nitric acid to the crucible and set the beaker on a magnetic stirrer. Stir, with heating at 70–80°, until all the fusion cake has disintegrated. Transfer the solution to a 200-ml flask, add 20 ml of EDTA

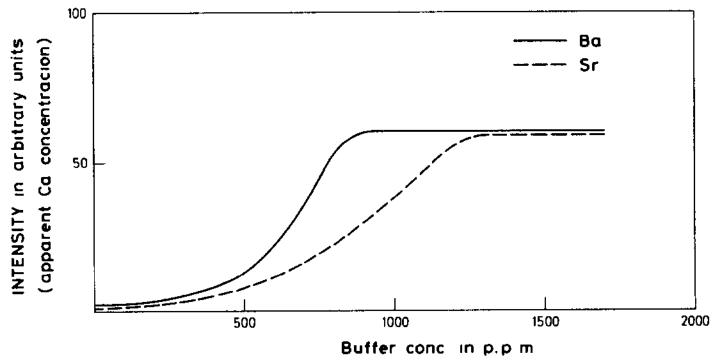

Fig. 2. Releasing effect of barium and strontium on the calcium signal. The effect on magnesium is similar.

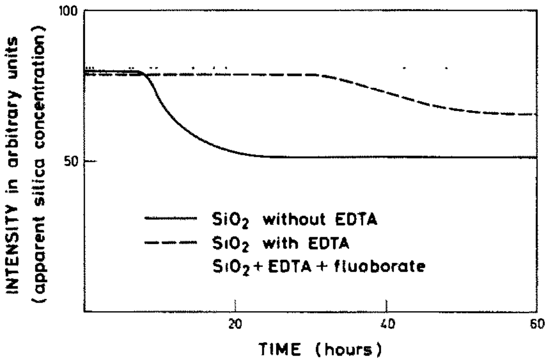

Fig. 3. Stability of signal for silicon in three different matrices, measured at different times and compared with that for a fresh solution.

solution and make up to volume with demineralized water. Prepare the solutions as follows.

Solution (*A*) *for Si and Mn.* Transfer a 25-ml aliquot immediately into a 50-ml flask, add 5 ml of fluoborate solution and 5 ml of the potassium buffer and dilute to volume with demineralized water.

Solution (*B*) *for Al and Mn.* To another 25-ml aliquot in a 50-ml flask add 5 ml of the potassium buffer and make up to volume with demineralized water. This solution is better than (A) for manganese determination.

Solution (*C*) *for Ca, Mg, Fe, Na, K, Ti,*[13] *P.*[14] Transfer a 5-ml aliquot to a 50-ml volumetric flask, add 5 ml of the barium buffer and make up to volume with demineralized water.

NON-DESTRUCTIVE RADIOCHEMICAL METHOD FOR DETERMINING CARBON CONCENTRATIONS IN THIN SHEET 3% Si–Fe ALLOY

W. M. Swift and K. W. Guardipee
Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235, U.S.A.

(*Received* 24 *February* 1976. *Accepted* 22 *April* 1976)

The carbon concentration in cold-rolled silicon–iron steel is typically above 200 ppm before decarburization. Carbon removal is necessary because of the undesirable magnetic losses imparted to fully processed (110)[001] 3% Si-Fe by impurities such as carbon. Hence accurate analytical methods are required to determine the effectiveness of decarburization annealing.

Classical methods for determining carbon involve sample combustion in dry air or oxygen and measurement of the liberated CO_2 gravimetrically or titrimetrically. For samples with low carbon levels (<60 ppm) these methods are subject to a variety of systematic errors which render them inaccurate. In principle, these sources of error can be overcome by combustion of large samples; however, such combustions are often incomplete. These methods are destructive analytical procedures.

Commercial carbon analysers are available which are designed to eliminate some of the sources of error inherent in classical procedures. In this laboratory, the Leco carbon analyser, which also uses a destructive method, is used for routine carbon determinations. The CO_2 generated from combustion of the sample in pure oxygen is measured

NON-DESTRUCTIVE RADIOCHEMICAL METHOD FOR DETERMINING CARBON CONCENTRATIONS IN THIN SHEET 3% Si–Fe ALLOY

W. M. SWIFT and K. W. GUARDIPEE
Westinghouse Research Laboratories, Pittsburgh, Pennsylvania 15235, U.S.A.

(*Received* 24 *February* 1976. *Accepted* 22 *April* 1976)

The carbon concentration in cold-rolled silicon–iron steel is typically above 200 ppm before decarburization. Carbon removal is necessary because of the undesirable magnetic losses imparted to fully processed (110)[001] 3% Si-Fe by impurities such as carbon. Hence accurate analytical methods are required to determine the effectiveness of decarburization annealing.

Classical methods for determining carbon involve sample combustion in dry air or oxygen and measurement of the liberated CO_2 gravimetrically or titrimetrically. For samples with low carbon levels (<60 ppm) these methods are subject to a variety of systematic errors which render them inaccurate. In principle, these sources of error can be overcome by combustion of large samples; however, such combustions are often incomplete. These methods are destructive analytical procedures.

Commercial carbon analysers are available which are designed to eliminate some of the sources of error inherent in classical procedures. In this laboratory, the Leco carbon analyser, which also uses a destructive method, is used for routine carbon determinations. The CO_2 generated from combustion of the sample in pure oxygen is measured by thermal conductivity after separation on a gas-solid chromatographic column. The method is more sensitive and faster than classical procedures, but is limited to carbon concentrations above the 60 ppm level.[1]

Radiochemical techniques are often applicable where conventional wet methods fail. In this laboratory, Goldman[2] developed a sensitive radiochemical procedure for measuring sulphur concentrations as low as 1 ppm by doping 3% silicon–iron with ^{35}S, a weak β-particle emitter. This material was used as a standard for measuring the accuracy of the Kriege–Wolfe method for accurate sulphur determination at the 1-ppm level.[3] Carbon-14 emits β-radiation comparable in energy to ^{35}S β-radiation,[4] but has a much longer half-life (5700 years for ^{14}C, 87 days for ^{35}S). Therefore, it seemed feasible to develop a radiochemical procedure for determining carbon in 3% silicon–iron by using ^{14}C as a tracer element. This paper describes a radiochemical procedure for measuring carbon concentrations by counting the β-radiation emanating from disks of ^{14}C-doped 3% silicon–iron. This technique is non-destructive and permits rapid analysis before and after annealing.

EXPERIMENTAL

Sample preparation

Ingots of 3% Si-Fe doped with ^{14}C were melted as follows. First, prepurified iron was vacuum-melted by induction heating. Second, additions of silicon, manganese and sulphur were made. The silicon reacts with oxygen, thus moderating any subsequent carbon–oxygen reactions which could produce a low recovery of ^{14}C. Third, helium was admitted to the vacuum system to a pressure of ~200 mmHg and the melt was cooled until a light crust appeared on its surface. The ^{14}C and the balance of the carbon (as Fe_3C) were added. To ensure that the ^{14}C dissolved after the Fe_3C, the ^{14}C powder (~6 mCi) was sealed in an iron capsule. Fourth, the melt temperature was increased to complete the mixing and dissolution of the carbon, and the melt was poured into a slab-like mould. The total mass of the alloy was about 2.5 kg. The composition was 3.20% Si, 0.08% Mn, 0.010% C, 0.025% S, <0.001% O, <0.001% N, balance Fe.

The ingot was processed to a final gauge of 0.30 mm in the following manner: (1) hot-rolled in argon at 1050° from an initial thickness of 25 mm to a thickness of 1.9 mm; (2) pickled to remove surface oxide; (3) cold-rolled to 0.63 mm; (4) annealed in helium at 800° for ~10 min; (5) cold-rolled to final gauge of 0.30 mm.

Carbon removal

Carbon was removed from samples of the 0.30-mm thick sheet by isothermal annealing in dry hydrogen (dew point −60°). Under these conditions carbon is removed as methane. Samples were in the form of circular disks 25.4 mm in diameter. Before annealing, samples were chemically polished with a 1:1 v/v mixture of phosphoric acid and 30% hydrogen peroxide solution. The polishing procedure removed a layer of material approximately 0.025 mm thick from each surface, and rendered these surfaces clean and free from surface oxides and imperfections. The isothermal annealing procedure involved the following steps: (1) the sample was mounted upright in a slot cut in a small stainless-steel annealing boat; (2) the boat was placed in the heating zone of an Inconel tube furnace and held at the required temperature for a predetermined time; (3) the boat was quickly withdrawn into a water-cooled chamber. Because of the small combined mass of the boat and sample (~10 g), rapid heating (at ~30°/sec) to isothermal soak temperatures between 800° and 1000° was achieved.

Radiochemical method

The radiochemical technique for carbon analysis is based on the supposition that the carbon is uniformly dispersed through the sheet thickness. Thus, low energy β-particles emitted from a thin surface layer can be correlated with the bulk carbon content. A 25.4-mm diameter disk of ^{14}C-doped 3% Si-Fe was placed in a circular groove in a brass block. The block was firmly seated in the sliding tray of the entrance port of a "castle" containing a Geiger-Müller (GM) end-window tube. Sliding the tray inward placed the sample in close proximity to the window of the GM tube. Thus, the counting geometry was constant. The GM tube was designed to operate at 1500 V and was equipped with a thin mica window 90% efficient in passing β-radiation. The dead-time was 200 μsec, and since the surface activity was always less than 20,000 cpm, no correction was necessary. The surface activity of the ^{14}C-doped disks was counted with a Tracer Lab Superscaler coupled to the output of the GM tube. The activity of both surfaces of a disk was measured, and the average value used to correlate ^{14}C activity with carbon concentration. Fixed-time counting was used. For samples with surface activities > 1000 cpm, a 3-min count was made for each surface of the disk. Longer counting times, *e.g.*, 10 min, were employed for surface activities < 1000 cpm. In all cases, the background activity (~20–30 cpm) was subtracted from the measured activity.

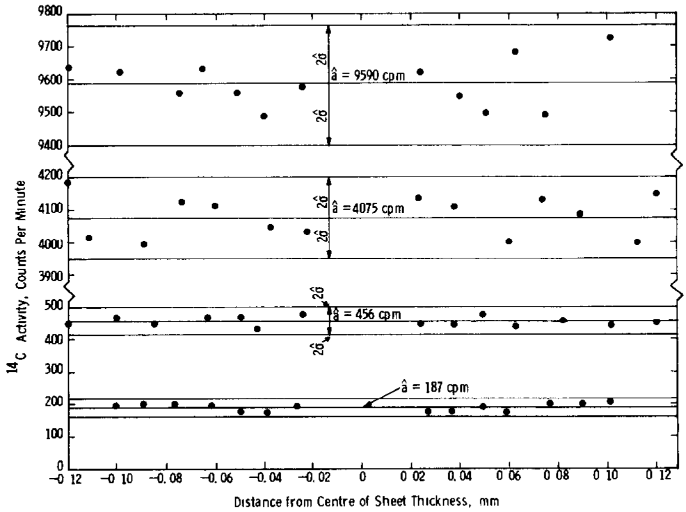

Fig. 1. Variation of ^{14}C activity as a function of sheet thickness.

RESULTS AND DISCUSSION

Disk samples of cold-rolled 0.30-mm thick sheet had ^{14}C surface activities of about 10,000 cpm which was equivalent to only about 1% of the total ^{14}C added during the melting operation. In other words, the measured radiation was associated with β-particles emanating from a surface layer only 1.5 μm thick. Consequently, it was necessary to establish that the ^{14}C surface activity was independent of sheet thickness and total carbon concentration, which is tantamount to testing for the existence of carbon gradients between the two surfaces. Testing for uniformity of ^{14}C concentration as a function of sheet thickness and total carbon concentration was done for four samples having ^{14}C surface activities ranging between ~ 180 (~ 1.5 ppm C) and 9600 cpm (~ 87 ppm C). How the carbon concentrations given in parentheses were obtained will become apparent shortly. The ^{14}C surface activity of each surface of these samples was measured at each thickness before thinning to the next thickness. The results are summarized in Fig. 1. These data show that the ^{14}C surface activity as a function of sheet thickness was within $\pm 2\hat{\sigma}$ of $\hat{a}$, where $\hat{a}$ is the estimate of the ^{14}C surface activity and $\hat{\sigma}$ is the estimate of the standard deviation from the mean. The value for $\hat{a}$ was obtained by averaging the ^{14}C surface activities based on measurements at various thicknesses, while $\hat{\sigma}$ was estimated to be $\sqrt{\hat{a}}$ which is a well-known relationship for radioactive decay processes.[4] The data in Fig. 1 are equivalent to accepting at a confidence level of 95% the hypothesis that ^{14}C is uniformly distributed through the sheet thickness.

Table 1 lists the carbon concentrations of twelve samples of ^{14}C-doped 3% Si-Fe having carbon concentrations > 60 ppm (according to the Leco method), and the corresponding ^{14}C surface activities. It was assumed that carbon measured by the Leco method was sufficiently precise for carbon concentrations > 60 ppm.[1] These data were used to calibrate the ^{14}C method. It is seen in Table 1 that 1 ppm of carbon corresponds to 110 cpm, compared to a background count of ~ 30 cpm. Thus, the limit of detection is about 1 ppm or slightly less, and in principle, could be lowered still further by using more ^{14}C in the melting procedure. Carbon concentrations determined by the Leco method and the ^{14}C method are shown in Fig. 2 for carbon concentrations ranging from 1.5 to 110 ppm. The agreement is excellent in the range 20–110 ppm. The linear correlation coefficient, ρ, in this range is $+0.96$ (23 variates). For carbon concentrations below 20 ppm (^{14}C method) the agreement is poorer, with a ρ of $+0.54$ (11 variates) in the range 1.5–20 ppm.

The ^{14}C radiochemical method described in this work was used to study carbon removal in 3% Si–Fe, as a function of annealing time, temperature and atmosphere.

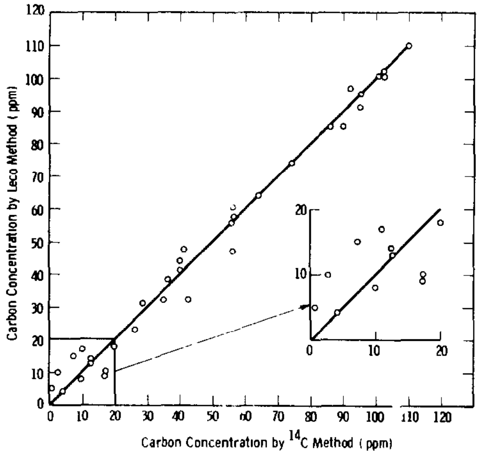

Fig. 2. Relationship between results of carbon measurement by the ^{14}C and Leco combustion methods.

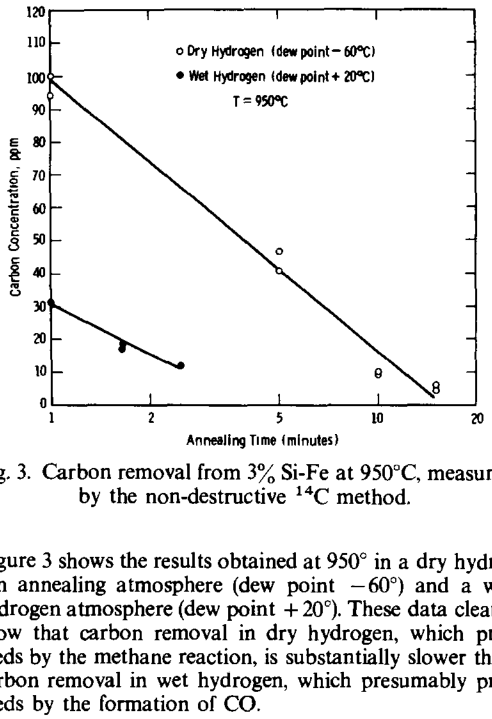

Fig. 3. Carbon removal from 3% Si-Fe at 950°C, measured by the non-destructive ^{14}C method.

Figure 3 shows the results obtained at 950° in a dry hydrogen annealing atmosphere (dew point −60°) and a wet hydrogen atmosphere (dew point +20°). These data clearly show that carbon removal in dry hydrogen, which proceeds by the methane reaction, is substantially slower than carbon removal in wet hydrogen, which presumably proceeds by the formation of CO.

Table 1. Calibration data for the ^{14}C carbon determination method

Carbon by Leco method, *ppm*	^{14}C surface radioactivity, *cpm*	Ratio $^{14}C/C^*$, *cpm/ppm*
60	6200	103
64	7000	109
74	8200	111
85	9500	112
85	9900	116

Summary—A non-destructive radiochemical method for determining carbon concentrations in thin sheet 3% Si-Fe has been developed. An ingot of 3% Si-Fe was doped with ^{14}C during the melting operation, and subsequently processed to give a 0.30-mm thick sheet. Decarburizing annealing conditions were controlled in order to obtain sheets having final carbon concentrations in the range 1.5–110 ppm. The β-radiation emanating from a thin surface layer of these sheets was found to be independent of sheet thickness, and linearly correlated to the bulk carbon content determined by the Leco carbon analyser, in the range 1.5–110 ppm. The radiochemical method is more sensitive for carbon concentrations below 20 ppm than techniques which rely on sample combustion.

A STUDY ON THE THEORY OF ACTION OF REVERSIBLE REDOX INDICATORS

K. SRIRAMAM

Department of Chemistry, Andhra University Postgraduate Centre, Guntur-5 (A.P.), India

(*Received* 21 *February* 1976. *Accepted* 7 *April* 1976)

In the traditional treatment for a two-colour indicator it was generally assumed that each of the two colours masks the other such that the first visible change in colour occurs only when 10% of the indicator has changed from one form to the other, and the last visible change occurs when 90% has changed. Thus, it could be said that 10% in one form is effectively invisible in the presence of 90% in the other form.

In more recent treatments such as Bishop's,[1] this idea has been amended to read instead "when colour 1 has ten times the intensity of colour 2 the indicator appears to be completely of colour 1. Thus, when $\epsilon_{ox}[\mathrm{Ind_{ox}}] = 10\epsilon_{red}[\mathrm{Ind_{red}}]$ the indicator appears to the eye to be completely oxidized, and when $10\epsilon_{ox}[\mathrm{Ind_{ox}}] = \epsilon_{red}[\mathrm{Ind_{red}}]$ the indicator appears to be completely reduced." Another recent treatment[2] questions the validity of this 10:1 ratio, and instead uses a variable ratio. These treatments, however, ignore the colour-sensitivity of the eye, and describe the situation in which the eye is replaced by a spectrophotometer. We shall use the term "theoretical" in connection with them, but will use the same approach.

Treatments of one-colour indicators have generally been quite different: the usual assumption is that the coloured form is not visible until a certain finite concentration is present, and that this critical concentration depends on the molar absorptivity of the species, on the depth of solution through which the colour is viewed, and on the minimum absorbance that the individual is able to detect at the particular wavelength. If this is true for the one colour of a one-colour indicator, then it must also hold for the two colours of a two-colour indicator, although if the colours are strong or if the concentration is high, it may not be observable. However, if the colours are weak or the concentration is low, it may be that one form is not observable in the presence of the other, irrespective of the fraction present, because the absorbance of that form is less than the minimum detectable. It may even happen that the colour of one form disappears before the colour of the other form becomes visible.

The present treatment develops this idea by postulating that a certain minimum concentration of an indicator species, in addition to the "theoretical" fraction in the "invisible" form, must be present before the species becomes discernible to the eye, and that this minimum concentration is the same as the minimum concentration which would be defined for a one-colour indicator.

Unsymmetrical stoichiometries occur only rarely, and their mathematical treatment is involved and time-consuming, so the treatment here has been confined to the symmetrical case with $n_{ind} = 1$. Also, the depth of the solution of which the colour is viewed has been assumed to be constant and equal to 1 cm. However, the theory is readily modified for higher values of n and for greater depth of solution.

SYMBOLS USED

E'_0	the conditional potential, or indicator constant, for the indicator.
E_{trans}	the transition potential—the potential at the point where the two colours have equal intensity.
E_{low}	the potential at the point where the second form of the indicator first becomes visible.
E_{high}	the potential at the point where the first form of the indicator finally becomes invisible.
A_c, A'_c	the critical absorbances—the minimum absorbances of the oxidized and reduced forms of the indicator that the individual is able to detect at the wavelength of maximum absorption.
m, m'	the concentrations of the oxidized and reduced forms of the indicator, in the absence of the other form, corresponding to the critical absorbance.
C_r	molar concentration of the indicator, added in reduced form.
x	fraction of indicator oxidized.
N	critical ratio of the absorbances of the two indicator forms (traditionally, $N = 10$).
ϵ_{ox}	molar absorptivity of the oxidized form of the indicator at its absorption maximum.
ϵ_{red}	molar absorptivity of the reduced form of the indicator at its absorption maximum.
k	$\epsilon_{red}/\epsilon_{ox}$.
k'	k/N.
k''	$1/Nk$.

A STUDY ON THE THEORY OF ACTION OF REVERSIBLE REDOX INDICATORS

K. SRIRAMAM

Department of Chemistry, Andhra University Postgraduate Centre, Guntur-5 (A.P.), India

(*Received* 21 *February* 1976. *Accepted* 7 *April* 1976)

In the traditional treatment for a two-colour indicator it was generally assumed that each of the two colours masks the other such that the first visible change in colour occurs only when 10% of the indicator has changed from one form to the other, and the last visible change occurs when 90% has changed. Thus, it could be said that 10% in one form is effectively invisible in the presence of 90% in the other form.

In more recent treatments such as Bishop's,[1] this idea has been amended to read instead "when colour 1 has ten times the intensity of colour 2 the indicator appears to be completely of colour 1. Thus, when $\epsilon_{ox}[Ind_{ox}] = 10\epsilon_{red}[Ind_{red}]$ the indicator appears to the eye to be completely oxidized, and when $10\epsilon_{ox}[Ind_{ox}] = \epsilon_{red}[Ind_{red}]$ the indicator appears to be completely reduced." Another recent treatment[2] questions the validity of this 10:1 ratio, and instead uses a variable ratio. These treatments, however, ignore the colour-sensitivity of the eye, and describe the situation in which the eye is replaced by a spectrophotometer. We shall use the term "theoretical" in connection with them, but will use the same approach.

Treatments of one-colour indicators have generally been quite different: the usual assumption is that the coloured form is not visible until a certain finite concentration is present, and that this critical concentration depends on the molar absorptivity of the species, on the depth of solution through which the colour is viewed, and on the minimum absorbance that the individual is able to detect at the particular wavelength. If this is true for the one colour of a one-colour indicator, then it must also hold for the two colours of a two-colour indicator, although if the colours are strong or if the concentration is high, it may not be observable. However, if the colours are weak or the concentration is low, it may be that one form is not observable in the presence of the other, irrespective of the fraction present, because the absorbance of that form is less than the minimum detectable. It may even happen that the colour of one form disappears before the colour of the other form becomes visible.

The present treatment develops this idea by postulating that a certain minimum concentration of an indicator species, in addition to the "theoretical" fraction in the "invisible" form, must be present before the species becomes discernible to the eye, and that this minimum concentration is the same as the minimum concentration which would be defined for a one-colour indicator.

Unsymmetrical stoichiometries occur only rarely, and their mathematical treatment is involved and time-consuming, so the treatment here has been confined to the symmetrical case with $n_{ind} = 1$. Also, the depth of the solution of which the colour is viewed has been assumed to be constant and equal to 1 cm. However, the theory is readily modified for higher values of n and for greater depth of solution.

SYMBOLS USED

E'_0	the conditional potential, or indicator constant, for the indicator.
E_{trans}	the transition potential—the potential at the point where the two colours have equal intensity.
E_{low}	the potential at the point where the second form of the indicator first becomes visible.
E_{high}	the potential at the point where the first form of the indicator finally becomes invisible.
A_c, A'_c	the critical absorbances—the minimum absorbances of the oxidized and reduced forms of the indicator that the individual is able to detect at the wavelength of maximum absorption.
m, m'	the concentrations of the oxidized and reduced forms of the indicator, in the absence of the other form, corresponding to the critical absorbance.
C_r	molar concentration of the indicator, added in reduced form.
x	fraction of indicator oxidized.
N	critical ratio of the absorbances of the two indicator forms (traditionally, $N = 10$).
ϵ_{ox}	molar absorptivity of the oxidized form of the indicator at its absorption maximum.
ϵ_{red}	molar absorptivity of the reduced form of the indicator at its absorption maximum.
k	$\epsilon_{red}/\epsilon_{ox}$.
k'	k/N.
k''	$1/Nk$.

THEORY

At the point where the colour of the oxidized form just becomes visible (the point corresponding to E_{low}), we can regard the absorbance of the oxidized form as composed of two parts, one imperceptible to the eye against the background of the reduced form, and the other the critical absorbance. Setting the imperceptible part equal to the background gives:

$$\epsilon_{\text{ox}} C_r x = (1/N)[\epsilon_{\text{red}} C_r(1 - x)] + A_c \qquad (1)$$

$$= (1/N)[\epsilon_{\text{red}} C_r(1 - x)] + \epsilon_{\text{ox}} m \qquad (2)$$

Substituting $k = \epsilon_{\text{red}}/\epsilon_{\text{ox}}$ and transposing gives

$$m = C_r x - (1/N)[kC_r(1 - x)] \qquad (3)$$

and further substitution of $k' = k/N$ gives

$$m = C_r[x(1 + k') - k'] \qquad (4)$$

The potential at this point is given by:

$$E_{\text{low}} = E_0' + 0.059 \log\left(\frac{x}{1 - x}\right) \qquad (5)$$

Substitution in this expression for x from equation (4) gives, on simplification:

$$E_{\text{low}} = E_0' + 0.059 \log\left[\frac{(m + k'C_r)}{(C_r - m)}\right] \qquad (6)$$

At the point where the colour of the reduced form just disappears (the point corresponding to E_{high}), similar reasoning gives:

$$\epsilon_{\text{red}} C_r(1 - x) = (1/N)\epsilon_{\text{ox}} C_r x + A_c' \qquad (7)$$

$$= (1/N)\epsilon_{\text{ox}} C_r x + \epsilon_{\text{red}} m' \qquad (8)$$

and substituting $k'' = 1/(Nk) = \epsilon_{\text{ox}}/N\epsilon_{\text{red}}$ gives:

$$m' = C_r[1 - x(1 + k'')] \qquad (9)$$

The potential at this point is given by:

$$E_{\text{high}} = E_0' + 0.059 \log\left(\frac{x}{1 - x}\right) \qquad (10)$$

and substitution for x from equation (9) gives

$$E_{\text{high}} = E_0' + 0.059 \log\left[\frac{(C_r - m')}{(m' + k''C_r)}\right] \qquad (11)$$

The transition interval, ΔE, is given by

$$\Delta E = E_{\text{high}} - E_{\text{low}}$$

$$= 0.059 \log\left[\frac{(C_r - m')(C_r - m)}{(m' + k''C_r)(m + k'C_r)}\right] \qquad (12)$$

and the transition potential is given by

$$E_{\text{trans}} = \frac{E_{\text{low}} + E_{\text{high}}}{2}$$

$$= E_0' + \frac{0.059}{2} \log\left[\frac{(C_r - m')(m + k'C_r)}{(m' + k''C_r)(C_r - m)}\right] \qquad (13)$$

Let us now see how these equations can be simplified when applied to specific situations.

(*a*) A one-colour indicator with colourless reduced form:

$$\epsilon_{\text{red}} = 0, \quad \text{so} \quad k = 0 = k',$$

and equation (6) reduces to

$$E_{\text{low}} = E_0' + 0.059 \log\left[\frac{m}{C_r - m}\right] \qquad (14)$$

E_{high} and E_{trans} are irrelevant because the eye is incapable of judging when the corresponding colour intensities have been reached.

(*b*) A one-colour indicator with a colourless oxidized form:

$$\epsilon_{\text{ox}} = 0,\ k = \infty \text{ and } k'' = 0,$$

so equation (11) reduces to

$$E_{\text{high}} = E_0' + 0.059 \log\left[\frac{C_r - m'}{m'}\right] \qquad (15)$$

E_{low} and E_{trans} are irrelevant in this case.

(*c*) A "normal" two-colour indicator (with both colours reasonably intense) m and $m' \ll C_r$ and equation (6) reduces to

$$E_{\text{low}} = E_0' + 0.059 \log\left[\frac{k'C_r}{C_r}\right]$$

$$= E_0' + 0.059 \log k'$$

$$= E_0' + 0.059 \log(\epsilon_{\text{red}}/N\epsilon_{\text{ox}}) \qquad (16)$$

and equation (11) reduces to

$$E_{\text{high}} = E_0' + 0.059 \log\left[\frac{C_r}{k''C_r}\right]$$

$$= E_0' + 0.059 \log(N\epsilon_{\text{red}}/\epsilon_{\text{ox}}) \qquad (17)$$

Equation (12) reduces to

$$\Delta E = 0.059 \log\left[\frac{C_r^2}{k'k''C_r^2}\right]$$

$$= 0.059 \log\left[\frac{N}{k} \cdot \frac{Nk}{1}\right]$$

$$= 0.118 \log N \qquad (18)$$

For $N = 10$, this becomes $\Delta E = 118$ mV.

$$E_{\text{trans}} = E_0' + \frac{0.059}{2} \log k^2$$

$$= E_0' + 0.059 \log(\epsilon_{\text{red}}/\epsilon_{\text{ox}}). \qquad (19)$$

(*d*) For a two-colour indicator with coloured forms of equal absorptivity, $\epsilon_{\text{red}} = \epsilon_{\text{ox}}$, and $k = 1$. Hence equation (6) becomes

$$E_{\text{low}} = E_0' + 0.059 \log\left[\frac{m + C_r/N}{C_r - m}\right] \qquad (20)$$

and equation (11) becomes

$$E_{\text{high}} = E_0' + 0.059 \log\left[\frac{C_r - m'}{m' + C_r/N}\right] \qquad (21)$$

and if the colours are reasonably intense, m and $m' \ll C_r$, they become

$$E_{\text{low}} = E_0' + 0.059 \log(1/N) \qquad (22)$$

$$E_{\text{high}} = E_0' + 0.059 \log N \qquad (23)$$

and again $\Delta E = 0.118 \log N$.

These simplified forms of the equations are in agreement with the equations derived for the same situations by other authors. However, the real test of this new treatment is its ability to deal with a situation which cannot be adequately treated by other theories. A suitable case is the indicator ferroin, which is sometimes considered as a one-colour indicator[3] and sometimes as a two-colour indicator. This arises because the two forms have strikingly different absorptivities ($\epsilon_{\text{red}}:\epsilon_{\text{ox}} = 20:1$). Its conditional potential in 1*M* sulphuric acid is 1.06 V,[4,5] and the point normally taken as the end-point corresponds to a potential of 1.12–1.14 V.[4,5]

In practical titrations with ferroin, the point normally taken as the end-point is the point where the pink colour of the reduced form just disappears, and this corresponds to E_{high} as defined above, and NOT to E_{trans}.

When the equation derived for two-colour indicators by Bishop[1] is applied to ferroin, the value found for E_{high} is 1.20 V, which obviously disagrees with the experimental evidence.

Applying the present treatment, and taking $m = 4.5 \times 10^{-5}M$ and $m' = 2.0 \times 10^{-6}M$, the following results are obtained:

(1) with 2 ml of 0.025*M* indicator per 100 ml of titration solution (*i.e.*, $C_r = 5 \times 10^{-4}M$)

$E_{high} = 1.18$ V

$E_{low} = 1.08$ V

(2) with 0.2 ml of 0.025*M* indicator per 100 ml of titration solution (*i.e.*, $C_r = 5 \times 10^{-5}M$)

$E_{high} = 1.14$ V

$E_{low} = 1.15$ V

(3) with 0.1 ml of 0.025*M* indicator per 100 ml of titration solution (*i.e.*, $C_r = 2.5 \times 10^{-5}M$)

$E_{high} = 1.12$ V

E_{low} = undefined

(note that *m* and *m'* are experimental parameters which must be determined by the individual analyst).

These figures show that, at the sort of ferroin concentrations normally used (*i.e.*, $5 \times 10^{-5}M$ and $2.5 \times 10^{-5}M$) the predictions for E_{high} are in good agreement with experiment. The E_{low} values are also of interest: at ferroin concentration $5 \times 10^{-5}M$, E_{high} is lower than E_{low}, and this agrees with the experimental evidence, since at this concentration, the pink colour of the reduced form disappears, leaving a colourless solution, and the blue colour does not become visible until more titrant has been added. At the lower concentration of $2.5 \times 10^{-5}M$, the blue colour never becomes visible, which is in accord with the undefined nature of E_{low}.

At the very much higher concentration of $5 \times 10^{-4}M$, ferroin does indeed behave very much as an "ordinary" two-colour indicator, because both the colours are now quite intense. For this solution, therefore, the values found from the present treatment are in reasonable agreement with values calculated from Bishop's equation.

ΔE for a two-colour indicator is a function of *N*, and it is easy to see that increasing *N* to 15 would increase ΔE by 0.021 V, and decreasing *N* to 5 would decrease ΔE by 0.035 V, relative to the value for $N = 10$. Values of *N* in the range 8–12 would give ΔE values within the range $\Delta E_{(N=10)} \pm 0.01$.

The treatment can be extended to acid–base indicators by writing equations analogous to (1) and (7), but such a critical treatment is less important, because of the availability of a large number of indicators, covering the entire pH range. However, it is obvious that one-colour indicators are superior for obtaining an end-point at a desired potential, or pH, because the value of E_{low} (or pH_{low}) is concentration-dependent and so adjustable over a narrow range.

Summary—A new approach is made to the evaluation of transition potentials and transition ranges for redox indicators, based on the idea that to see the first colour change in a two-colour indicator system, the eye needs a certain minimum amount of the developing colour in addition to the threshold amount. The approach is applied to ferroin and shown to explain the colour changes observed for this indicator.

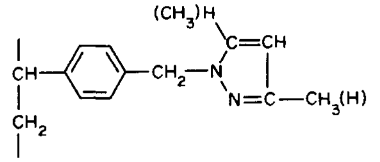
Pyrazole and its derivatives form complex compounds with many transition metals, including Ag, Au, Pd, Pt, Rh and Ir.[1] When a pyrazole ring is introduced into polymeric molecules, the latter also acquire the ability to interact with these elements.

We have synthesized chelate sorbents containing pyrazole groups as substituent by aminating chloromethylated styrene–divinylbenzene copolymers with 3(5)-methylpyrazole. The structure of the chelate group of the sorbents may be depicted as



Sorbents with such groups possess selectivity with respect to noble metals in the presence of Cu, Fe, Co, Ni, *etc.* This is caused by the fact that the introduction of the aromatic system (polystyrene) into 3(5)-methylpyrazole as an *N*-substituent leads to a decrease in the reactivity of the pyrazole ligand.[2] The sorption of Fe, Cu and other elements becomes slight, whereas noble metals, which exhibit typical *b*-group behaviour, interact with the pyrazole groups of the sorbent. This difference allows such sorbents to be used for selective concentration of noble metals during the analysis of various materials.

In the present paper the synthesis of the sorbents is described, and their sorption capacity and selectivity for noble metals.

EXPERIMENTAL

Synthesis of the sorbents

3(5)-Methylpyrazol (98%, b.p. 204–5°, 90 ml) is added to 30 g of a chloromethylated styrene–divinylbenzene macroporous copolymer and kept for 3 hr for swelling. Then the mixture is heated to 60–70° and kept at this temperature for 8 hr, with careful stirring. The polymer is filtered off, washed with water and dried in air.

(1) with 2 ml of 0.025M indicator per 100 ml of titration solution (*i.e.*, $C_r = 5 \times 10^{-4}M$)

$E_{\text{high}} = 1.18$ V

$E_{\text{low}} = 1.08$ V

(2) with 0.2 ml of 0.025M indicator per 100 ml of titration solution (*i.e.*, $C_r = 5 \times 10^{-5}M$)

$E_{\text{high}} = 1.14$ V

$E_{\text{low}} = 1.15$ V

(3) with 0.1 ml of 0.025M indicator per 100 ml of titration solution (*i.e.*, $C_r = 2.5 \times 10^{-5}M$)

$E_{\text{high}} = 1.12$ V

E_{low} = undefined

(note that m and m' are experimental parameters which must be determined by the individual analyst).

These figures show that, at the sort of ferroin concentrations normally used (*i.e.*, $5 \times 10^{-5}M$ and $2.5 \times 10^{-5}M$) the predictions for E_{high} are in good agreement with experiment. The E_{low} values are also of interest: at ferroin concentration $5 \times 10^{-5}M$, E_{high} is lower than E_{low}, and this agrees with the experimental evidence, since at this concentration, the pink colour of the reduced form disappears, leaving a colourless solution, and the blue colour does not become visible until more titrant has been added. At the lower concentration of $2.5 \times 10^{-5}M$, the blue colour never becomes visible, which is in accord with the undefined nature of E_{low}.

At the very much higher concentration of $5 \times 10^{-4}M$, ferroin does indeed behave very much as an "ordinary" two-colour indicator, because both the colours are now quite intense. For this solution, therefore, the values found from the present treatment are in reasonable agreement with values calculated from Bishop's equation.

ΔE for a two-colour indicator is a function of N, and it is easy to see that increasing N to 15 would increase ΔE by 0.021 V, and decreasing N to 5 would decrease ΔE by 0.035 V, relative to the value for $N = 10$. Values of N in the range 8–12 would give ΔE values within the range $\Delta E_{(N=10)} \pm 0.01$.

The treatment can be extended to acid–base indicators by writing equations analogous to (1) and (7), but such a critical treatment is less important, because of the availability of a large number of indicators, covering the entire pH range. However, it is obvious that one-colour indicators are superior for obtaining an end-point at a desired potential, or pH, because the value of E_{low} (or pH_{low}) is concentration-dependent and so adjustable over a narrow range.

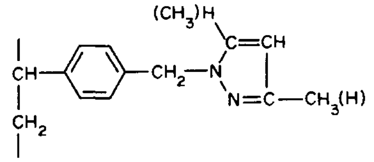
Pyrazole and its derivatives form complex compounds with many transition metals, including Ag, Au, Pd, Pt, Rh and Ir.[1] When a pyrazole ring is introduced into polymeric molecules, the latter also acquire the ability to interact with these elements.

We have synthesized chelate sorbents containing pyrazole groups as substituent by aminating chloromethylated styrene–divinylbenzene copolymers with 3(5)-methylpyrazole. The structure of the chelate group of the sorbents may be depicted as



Sorbents with such groups possess selectivity with respect to noble metals in the presence of Cu, Fe, Co, Ni, *etc.* This is caused by the fact that the introduction of the aromatic system (polystyrene) into 3(5)-methylpyrazole as an N-substituent leads to a decrease in the reactivity of the pyrazole ligand.[2] The sorption of Fe, Cu and other elements becomes slight, whereas noble metals, which exhibit typical b-group behaviour, interact with the pyrazole groups of the sorbent. This difference allows such sorbents to be used for selective concentration of noble metals during the analysis of various materials.

In the present paper the synthesis of the sorbents is described, and their sorption capacity and selectivity for noble metals.

EXPERIMENTAL

Synthesis of the sorbents

3(5)-Methylpyrazol (98%, b.p. 204–5°, 90 ml) is added to 30 g of a chloromethylated styrene–divinylbenzene macroporous copolymer and kept for 3 hr for swelling. Then the mixture is heated to 60–70° and kept at this temperature for 8 hr, with careful stirring. The polymer is filtered off, washed with water and dried in air.

Table 1. Characteristics of sorbents based on 3(5)-methylpyrazole

Initial copolymer*		Sorbent N, %	Degree of chlorine substitution,† %	Sorption, *mg/g*		
				Ag(I)		Au(III), 1*M* HCl
DVB, %	Cl, %			pH ~ 7	1*M* HNO_3	
8	23	11.6	65	177	164	170
12	17	8.2	63	116	142	182
20	16	6.5	51	92	102	160
40	11	4.1	47	45	53	116
60	9	3.9	55	—	50	95

* Size of granules for all sorbents is 0.25–0.5 mm, except for 60% DVB (< 0.25 mm).
† Calculated according to nitrogen content.

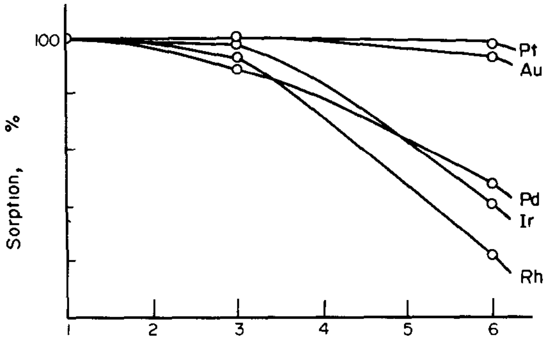


Fig. 1. Sorption of microgram amounts of noble metals from hydrochloric solutions. Solution volume 10 ml; 50 mg of sorbent (8% DVB); time of contact 2 hr; temperature ~100°.

Sorption

The sorption was studied under static conditions at room temperature and at 100°. The volume of solution was 10 ml, and the sorption time 2 hr. Standard solutions of the chloro-complexes were used: [Au(III)] = 1.02 mg/ml; [Pd(II)], [Pt(IV)] and [Rh(III)] = 10 μg/ml; [Ir(IV)] = 0.002–10 μg/ml. A 0.2*M* solution of silver nitrate was also used. The degree of sorption was estimated from the amount of metal found in the sorbent (after mineralization with acid). Silver was determined by titration, Au, Pd, Pt and Rh spectrophotometrically, and Ir radiometrically.

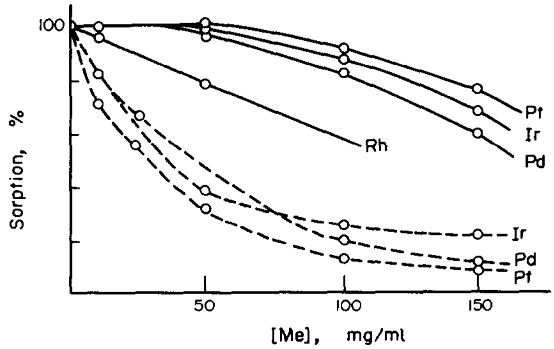

Fig. 2. Sorption of microgram amounts of noble metals in the presence of Cu (——) and Fe(III) (---) in 1 *M* HCl. Solution volume 10–20 ml; 50 mg of sorbent (8% DVB); time of contact 2 hr; temperature ~100°.

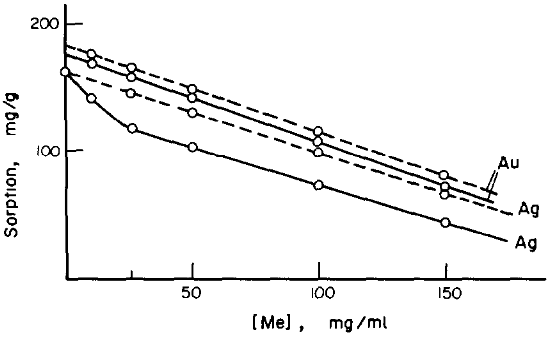

Fig. 3. Sorption of milligram amounts of Ag and Au in the presence of Cu (——) and Fe(III) (---) in 1*M* HCl. Solution volume 10–20 ml; 50 mg of sorbent (8% DVB); time of contact 2 hr; temperature 20°.

RESULTS AND DISCUSSION

The sorbents synthesized were based on styrene-divinylbenzene macroporous copolymers with different divinylbenzene(DVB) contents. The characteristics of the sorbents are given in Table 1.

As seen from the Table, the sorption properties are best for sorbents based on styrene copolymers with 8 and 12% DVB. The static capacity for the 8% DVB is 263 mg/g for Ag in 0.5*M* nitric acid and 660 mg/g for Au in 1*M* hydrochloric acid.

Sorption of the noble metals depends on the solution acidity and the concentration of other elements (Figs. 1–3). Microgram amounts of Pd, Rh and Ir are completely sorbed from solutions up to 3*M* in hydrochloric acid, and of Au and Pt from even more acid solutions. Sorption of Ag is maximal from 0.5*M* nitric acid.

The study of the noble metal sorption in the presence of Al, Ca, Co, Ni, Cu and Fe has shown that the extent of sorption depends on the concentration of the non-noble elements; they do not interfere in concentration below 50 mg/ml. Iron(III) has the largest effect (Fig. 3).

The selectivity for the noble metals is obviously due to the formation of Au, Pd, Pt, Rh and Ir co-ordination compounds with the functional analytical groups of sorbents. This may be confirmed by infrared spectroscopy. The appearance of absorption bands in the 200–400 cm^{-1} region in the spectra of the sorbents saturated with the metals indicates complexing of the metals with the nitrogen atom of the pyrazole group of the sorbent.[3] The low degree of sorption of Cu, Co and other elements is apparently because their complexes with the chelate groups of the sorbent have low stability.

This study has shown that these sorbents may be recommended for selective group concentration of noble metals in analysis of various materials. These sorbents may also be used for extraction of Au and Ag from solutions of salts of Cu, Fe and other elements (Fig. 3).

DETERMINATION OF SOME ORGANIC THIO-COMPOUNDS BY PRECIPITATION OF MERCURIC SULPHIDE FROM MERCURY(II) AMMINE COMPLEXES—I.

DETERMINATION OF THIOACETAMIDE AND THIOACETANILIDE

A. CYGAŃSKI
Institute of General Chemistry, Technical University, 90–924 Łódź, Poland

(*Received* 17 *February* 1976. *Accepted* 23 *June* 1976)

For the determination of thioacetamide (TAA), oxidimetric,[1,2] complexometric[3] and thiomercurimetric[4] methods have been developed. Among the instrumental methods, those based on the reaction of TAA with silver have been most widely used, including potentiometric,[5–8] amperometric[9] and coulometric[10] procedures. For the amperometric determination use has also been made of the reaction with copper(I).[11]

Mercury(II), in aqueous acid solution, forms with TAA a number of variously coloured precipitates. When boiled with potassium hydroxide solution these precipitates become converted into HgS.[12,13] Precipitation of HgS by TAA in an alkaline solution is made the basis for determination of mercury.[14–16]

The purpose of this paper is to describe an accurate and relatively rapid gravimetric method for determining thioacetamide and thioacetanilide at the concentrations conventionally employed in the quantitative precipitation of metallic sulphides. Thioacetanilide, a derivative of thioacetamide, can also be used for precipitating metallic sulphides from homogeneous solution.[17] The method for determining thioacetamide and thioacetanilide consists in precipitating HgS from solutions of ammino mercury complexes. When ammonia is added to a mercury(II) chloride or oxy-anion solution, mercury(II) ammine-chloride or a salt of Millon's base precipitates, respectively. If, however, the solution contains a high concentration of ammonium salts, the precipitates either dissolve or do not form. This is achieved by adding enough nitric acid (15 ml of conc. acid is usually enough) and ammonia (>30 ml of conc. solution) to prevent precipitation of mercury compounds other than the sulphide. Depending on the conditions, diammino or tetra-ammino mercury complexes are formed.[18–20]

These complexes have been utilized for separating iron from mercury[21,22] and bismuth from mercury.[22] Iron and bismuth are precipitated with ammonia, from a solution containing enough nitric acid to avoid formation of a transient precipitate of mercury compound.

EXPERIMENTAL

Reagents

Thioacetamide and thioacetanilide, repeatedly crystallized from ethanol, were used. The thioacetamide was analysed by Petri and Lipiec's gravimetric method.[5]

Procedure

Determination of thioacetamide. Concentrated nitric acid 15 ml, is added to V ml of $0.1M$ ($V = 0.2 \times$ number of mg of thioacetamide taken or 10 ml, whichever is the larger), then 100 ml of water and finally at least 30 ml of concentrated ammonia solution are added with stirring. The solution is heated to about 60° and the weighed sample of TAA dissolved in water is added to it. The solution is heated to boiling point, kept boiling for 3–5 min, and set aside. After the resulting precipitate has settled (a few minutes), it is collected on a porosity 4 or 5 sintered-glass crucible, washed with water and then several times with methanol, and dried for 15 min at 110°.

Determination of thioacetanilide. A weighed sample of thioacetanilide is dissolved in methanol and analysed as in the case of thioacetamide but with $V = 0.1 \times$ number of mg of thioacetanilide or 5 ml, whichever is the larger.

Table 1. Results

Compound	Taken, *mg*	Found, *mg*	Error, %
Thioacetamide	25.0	25.1	+0.4
	54.6	54.6	0.0
	104.0	104.4	+0.4
	150.2	150.0	−0.1
	203.8	203.8	0.0
Thioacetanilide	25.3	25.0	−1.2
	50.6	50.0	−1.2
	100.2	100.6	+0.4
	151.3	150.8	−0.3

CONSTANT-POTENTIAL ELECTROLYSIS: DETERMINATION OF DIFFUSION COEFFICIENTS OF THALLIUM BY USING A HANGING MERCURY DROP ELECTRODE

J. Hernandez Mendez and R. Carabias Martinez

Department of Analytical Chemistry, University of Valencia, Spain

(*Received* 11 *February* 1976. *Accepted* 14 *June* 1976)

For the determination of diffusion coefficients from measurements obtained in diffusion-controlled processes several methods have been used. Lingane and Loveridge[1] used conventional polarography, with the Ilkovič equation corrected for spherical electrodes. Other techniques used include alternating current techniques,[2] double galvanostatic pulse,[3] impedance measurements[4,5] and chronopotentiometry.[6]

Potentiostatic methods have been used for the determination of the rates and mechanisms of very fast electrode reactions that cannot be studied by polarographic methods.[7] The stationary mercury drop electrode has been used for this purpose, the electrode curvature being ignored; for this reason, electrolysis times of the order of μsec–msec were used and the equations for plane electrodes could be utilized.

Shain and co-workers[8–12] derived the theoretical equations for spherical diffusion conditions and used them for the determination of diffusion coefficients. There are no literature data on the diffusion coefficients of Tl(I) in sodium citrate–sodium hydroxide medium. For the diffusion coefficient of Tl in mercury, the value 0.99×10^{-5} cm^2/sec obtained by Cooper and Furman[13] by the polarographic method agrees with the value of 1.03×10^{-5} cm^{-2}/sec obtained by Wogau.[14] We have determined both coefficients by application of the potentiostatic method.

THEORY

The general equation of the I–t curves for processes controlled by spherical diffusion, deduced by Stevens and Shain[12] for systems where $D_o \neq D_r$, and valid for potentials more cathodic and more anodic than the standard potential of the system, is:

$$i = nFAD_0C_0^*\left[\frac{1}{(1+\gamma\sigma)(\pi D_0 t)^{1/2}} + \frac{1}{(1-\gamma^2\sigma)r_0} - \frac{\sigma(1+\gamma)^2 e^{\beta^2 t}\operatorname{erfc}\beta t^{1/2}}{r_0(1-\gamma^2\sigma)(\gamma\sigma+1)^2}\right] \quad (1)$$

where $\sigma = C_0/C_r = \exp[nF(E - E^0)/RT]$, C_0 and C_r are concentrations of the oxidized and reduced forms at the electrode surface, D_0 and D_r are the diffusion coefficients of the species, C_0^* is the bulk concentration of the oxidized form,

$$\gamma = \left(\frac{D_0}{D_r}\right)^{1/2}$$

and

$$\beta = \frac{1}{r_0}\left(\frac{\sigma D_0 - D_r}{\sigma D_0^{1/2} + D_r^{1/2}}\right).$$

Equation (1) can be reduced to simpler expressions for particular cases. Thus, for very cathodic potentials $\sigma \rightarrow 0$

RESULTS

Results of determinations of thioacetamide and thioacetanilide are presented in Table 1.

A comparison of the amounts taken and found proves that the present method shows good accuracy.

0.708			0.73	0.73		

and equation (1) reduces to

$$i = nFAD_0C_0^*\left[\frac{1}{(\pi D_0 t)^{1/2}} + \frac{1}{r_0}\right] \qquad (2)$$

For very short times or for very large radius the term $1/r_0$ is negligible and the equation is transformed into the corresponding expression for plane electrodes.

Expression (1) can also be simplified when the term $\sigma = C_0/C_r$ is very large (working at potentials more anodic than the standard potential, E_0):

$$i = nFAD_0C_0^*\left[\frac{1}{\gamma\sigma(\pi D_0 t)^{1/2}} - \frac{1}{\gamma^2\sigma r_0}\right] \qquad (3)$$

At potentials near to E_0 it is necessary to utilize the complete equation (1).

Calculation of D_0

By means of electrolysis at constant potential, working with a stationary mercury drop electrode, and using sufficiently cathodic potentials, the I–t curves are obtained. From these curves, the I *vs.* $1/t^{1/2}$ plots are obtained, and are linear; from the slope, intercept and equation (2) it is possible to obtain D_0.

Calculation of D_r *from cathodic curves (indirect method)*

To calculate D_r it is necessary to work at sufficiently anodic potentials. From the I *vs.* $1/t^{1/2}$ plots straight lines are obtained of which the slopes (m) and intercepts (i_∞) are functions of $\gamma\sigma$ and $\gamma^2\sigma$ respectively.

$$m = \frac{nFAD_0C_0^*}{\gamma\sigma(\pi D_0)^{\frac{1}{2}}} \qquad -i_\infty = \frac{nFAD_0C_0^*}{r_0\gamma^2\sigma}$$

$$\gamma\sigma = \frac{nFAD_0C_0^*}{m(\pi D_0)^{\frac{1}{2}}} \qquad \gamma^2\sigma = -\frac{nFAD_0C_0^*}{i_\infty r_0}$$

From these expressions it is possible to calculate γ and D_r, because D_0 is already known.

Calculation of D$_r$ *from anodic curves (direct method)*

D_r can be calculated in a similar way to D_0. It is necessary to obtain an amalgam of known concentration and record the I–t curves; from these curves the I *vs.* $1/t^{1/2}$ graphs are plotted, and the D_r value is calculated from the slope and the intercept.

EXPERIMENTAL

Reagents

Supporting electrolyte solutions of 1.0M sodium citrate and 0.1M sodium hydroxide. Tl(I) solutions obtained from hallium acetate and gravimetrically standardized by the Bashilova method.[15]

Apparatus

A Beckman Electroscan-30 with a three-electrode system was used; saturated calomel reference electrode; platinum auxiliary electrode separated from the solution by a sintered glass disc and agar-agar saturated KCl salt bridge; stationary hanging mercury drop working electrode. For more precise potential measurements a Metrohm E-510 potentiometer was used. To minimize convection the experiments were carried out on an antivibration table.

Procedure

The thermostatically controlled cell is put on the antivibration table and nitrogen is passed through the solution for 20 min to remove oxygen, then the solution is left for 3 min with no gas flow. The potential is applied and the cathodic or anodic I–t curve is scanned for 25 sec at 0.508 cm/sec. From these curves the I *vs.* $1/t^{1/2}$ diagrams are plotted. The slopes and intercepts are used to evaluate D_0. The Tl(0) amalgam is made by electrolysis of *ca.* $10^{-3}M$ Tl(I) solution at an applied potential of −0.80 V and then left long enough to become homogeneous. The amalgamated metal is dissolved electrolytically at −0.2 V to give the I–t curves. The electrode radius is evaluated by weighing 50 drops obtained under identical conditions.

RESULTS AND DISCUSSION

Determination of D$_0$ *from cathodic curves*

Influence of the applied potential. Table 1 shows that when potentials of −0.6, −0.8 and −1.0 V are used, the precision is poor and there is a great difference between the D_0 values obtained from the slope and the intercept of the I *vs.* $1/t^{1/2}$ graphs, except for values obtained with a large electrode radius, and the results obtained at the more negative potentials are superior. Though the poor precision was also caused, as can be seen later on, by the form and size of the electrode, −0.60 V is not sufficiently cathodic for the simplified equation to be valid.

Influence of convection. It was observed that convection had an effect when the time of electrolysis was very long or very short. With very long times, density gradients were produced in the cell, and vibrations causing current intensities higher than the theoretical. With very short times, higher current intensities than the theoretical were also obtained because the surface tension on the mercury drop changed, on application of the working potential; this effect caused the drop to fall if its radius was larger than 0.071 cm. An electrode of radius between 0.05 and 0.07

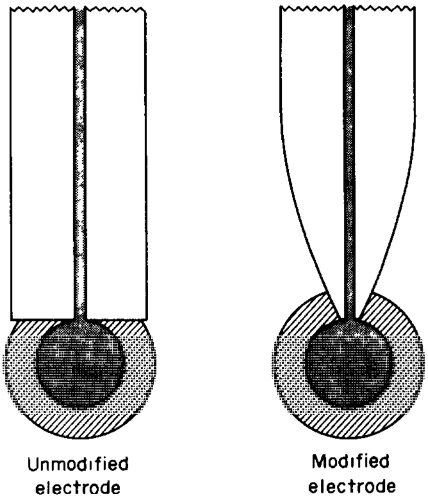

Fig. 1.

cm and electrolysis times between 5 and 25 sec were therefore used.

Influence of the electrode size. It was observed, for electrode radius smaller than 0.05 cm, that the D_0 values obtained from the intercept were smaller than those from the slope. This is probably due to the distortion of the limiting diffusion layer in the proximity of the capilary, causing smaller currents than the theoretical. The end of the capillary was therefore ground so that the orifice did not have a plane surface around it (Fig. 1). With this modified electrode agreeing values of D_0 were obtained by both methods over the radius range 0.05–0.07 cm (Table 2).

Determination of D_r *from cathodic curves*

The diffusion coefficient for the reduced form in the mercury can be calculated from the cathodic or the anodic curves. The advantage of the cathodic method is that a known concentration of amalgam is not necessary. On the other hand, the precision is poor, because the current values are low and the values of i_∞ are calculated by extrapolation.[10]

With the modified electrode, drop radius of 0.0599 and 0.0632 cm and several potentials between −0.420 and −0.478 V, two series of experiments were carried out. From the results a value of 0.91 × 10^{-5} cm²/sec was obtained (Table 3), not too close to the value found by other authors.[13,14]

Direct determination of D_r

In this method an amalgam of known concentration is used. Under these conditions, with an electrode radius of 0.05–0.07 cm, a value of (0.98 ± 0.01) × 10^{-5} cm²/sec is obtained, in agreement with the values found by other authors.[13,14] For electrode radii <0.05 cm (Table 4), the precision is poor and the values from the intercept are greater than those from the slope, because the distortion of the limiting diffusion layer is then not negligible; the errors are of different sign according to whether the process is controlled by divergent diffusion (the anodic process) or convergent diffusion (the cathodic process).

Summary—The technique of constant-potential electrolysis at a stationary spherical electrode (hanging mercury drop) was investigated for the determination of the diffusion coefficient of Tl(I) in sodium citrate–sodium hydroxide medium and of Tl in mercury. Current–time curves, at controlled potential, were obtained, covering periods from 1 to 25 sec after the start of the electrolysis. The influence of applied potential, time of electrolysis, convection and shielding of the electrode was studied.

THE pH-DEPENDENCE OF ENTROPY CHANGES OF METAL–EDTA COMPLEX FORMATION

Kotaro Ogura, Kiyosi Takatu and Takasi Yosino
Department of Applied Chemistry, Yamaguchi University, Ube, Yamaguchi-Ken 755, Japan

(*Received* 3 *February* 1976. *Accepted* 31 *May* 1976)

Various methods for the determination of metal chelate stability constants have been developed, and reviewed.[1] The structure of metal chelate complexes in solution has been discussed on the basis of thermodynamic and spectroscopic data.[2] The chelate effect on the stability constant of the complex is of special interest.

The temperature-dependence of the stability constant is here studied at various pH values, and the pH-dependence of the entropy change of metal–EDTA complex formation is estimated and interpreted.

EXPERIMENTAL

The stability constants were determined by means of potentiometric measurements with a mercury electrode.[3] The concentrations of the mercury chelate, the metal ion and the metal chelate were 10^{-4}, 10^{-3} and $10^{-2}M$, respectively, and the metal ions studied were Ca^{2+}, Mn^{2+}, Ni^{2+} and Pb^{2+}. All chemicals were purified by recrystallization. Sodium perchlorate solution (0.1*M*) was used as the supporting electrolyte, and the ionic strength was kept at 0.11. The solution pH was controlled in the range 3–8 by adding perchloric acid. The method could not be applied outside this pH range because of the formation of HgHY^- in the acid region and $\mathrm{Hg(OH)Y}^{3-}$ in the alkaline region. The solution was deaerated with purified nitrogen before measurement. The temperatures were kept constant within ± 0.05°.

RESULTS AND DISCUSSION

The reaction between a bivalent metal ion and EDTA in acidic solution is represented by

$$\mathrm{M}^{2+} + 2\,\mathrm{Y}^{4-} + i\,\mathrm{H}^+ \rightleftharpoons \mathrm{MY}^{2-} + \mathrm{H}_i\mathrm{Y}^{i-4} \qquad (1)$$

The conditional stability constant of this reaction is defined as

$$K_{\mathrm{M'Y'}} = K_{\mathrm{MY}}/\alpha_{\mathrm{Y}} \qquad (2)$$

where K_{MY} and α_{Y} are the thermodynamic stability constant for the metal–EDTA complex and the side-reaction coefficient, respectively. α_{Y} is given by

$$\alpha_{\mathrm{Y}} = 1 + \sum[\mathrm{H}]^i\Pi K_{\mathrm{H,Y}}. \qquad (3)$$

According to the Schmid and Reilley methods[3] a combination of the Nernst equation for a mercury electrode with the equations for the stability constants of mercury–EDTA and metal–EDTA complexes gives the equation

$$E = E'^{0}_{\mathrm{Hg}} + RT/2F \ln [\mathrm{M}][\mathrm{HgY}]\,K_{\mathrm{MY}}/[\mathrm{MY}]K_{\mathrm{HgY}} \qquad (4)$$

where $E'^{0}_{\mathrm{Hg}} = 612$ mV (*vs.* SCE), and [M], [HgY] and [MY] are the concentrations of metal ion, mercury–EDTA and metal–EDTA complexes, respectively.

By substitution of equations (3) and (4) into (2), the conditional stability constant is given by

$$K_{\mathrm{M'Y'}} = [\mathrm{MY}]K_{\mathrm{HgY}}/[\mathrm{M}][\mathrm{HgY}] \times \left(1 + \sum_i [\mathrm{H}]^i\Pi K_{\mathrm{H,Y}}\right)\exp[2F(E - E'^{0}_{\mathrm{Hg}})/RT] \qquad (5)$$

From (5), $K_{\mathrm{M'Y'}}$ is obtained as a simple function of the potential of the mercury electrode, provided that the concentrations of the mercury–EDTA and metal–EDTA complexes, metal ion and hydrogen ion are kept constant, and hence, can be estimated from the experimental data and the stability constant for the mercury–EDTA complex.

THE pH-DEPENDENCE OF ENTROPY CHANGES OF METAL–EDTA COMPLEX FORMATION

KOTARO OGURA, KIYOSI TAKATU and TAKASI YOSINO
Department of Applied Chemistry, Yamaguchi University, Ube, Yamaguchi-Ken 755, Japan

(*Received* 3 *February* 1976. *Accepted* 31 *May* 1976)

Various methods for the determination of metal chelate stability constants have been developed, and reviewed.[1] The structure of metal chelate complexes in solution has been discussed on the basis of thermodynamic and spectroscopic data.[2] The chelate effect on the stability constant of the complex is of special interest.

The temperature-dependence of the stability constant is here studied at various pH values, and the pH-dependence of the entropy change of metal–EDTA complex formation is estimated and interpreted.

EXPERIMENTAL

The stability constants were determined by means of potentiometric measurements with a mercury electrode.[3] The concentrations of the mercury chelate, the metal ion and the metal chelate were 10^{-4}, 10^{-3} and $10^{-2}M$, respectively, and the metal ions studied were Ca^{2+}, Mn^{2+}, Ni^{2+} and Pb^{2+}. All chemicals were purified by recrystallization. Sodium perchlorate solution (0.1*M*) was used as the supporting electrolyte, and the ionic strength was kept at 0.11. The solution pH was controlled in the range 3–8 by adding perchloric acid. The method could not be applied outside this pH range because of the formation of $HgHY^{-}$ in the acid region and $Hg(OH)Y^{3-}$ in the alkaline region. The solution was deaerated with purified nitrogen before measurement. The temperatures were kept constant within ± 0.05°.

RESULTS AND DISCUSSION

The reaction between a bivalent metal ion and EDTA in acidic solution is represented by

$$M^{2+} + 2\,Y^{4-} + i\,H^{+} \rightleftharpoons MY^{2-} + H_iY^{i-4} \qquad (1)$$

The conditional stability constant of this reaction is defined as

$$K_{M'Y'} = K_{MY}/\alpha_Y \qquad (2)$$

where K_{MY} and α_Y are the thermodynamic stability constant for the metal–EDTA complex and the side-reaction coefficient, respectively. α_Y is given by

$$\alpha_Y = 1 + \sum [H]^i \Pi K_{H_iY}. \qquad (3)$$

According to the Schmid and Reilley methods[3] a combination of the Nernst equation for a mercury electrode with the equations for the stability constants of mercury–EDTA and metal–EDTA complexes gives the equation

$$E = E'^{0}_{Hg} + RT/2F \ln [M][HgY]\,K_{MY}/[MY]K_{HgY} \qquad (4)$$

where $E'^{0}_{Hg} = 612$ mV (*vs.* SCE), and [M], [HgY] and [MY] are the concentrations of metal ion, mercury–EDTA and metal–EDTA complexes, respectively.

By substitution of equations (3) and (4) into (2), the conditional stability constant is given by

$$K_{M'Y'} = [MY]K_{HgY}/[M][HgY] \times \left(1 + \sum_i [H]^i \Pi K_{H_iY}\right) \exp[2F(E - E'^{0}_{Hg})/RT] \qquad (5)$$

From (5), $K_{M'Y'}$ is obtained as a simple function of the potential of the mercury electrode, provided that the concentrations of the mercury–EDTA and metal–EDTA complexes, metal ion and hydrogen ion are kept constant, and hence, can be estimated from the experimental data and the stability constant for the mercury–EDTA complex.

Table 1. Entropy changes of EDTA complex formation at various pH values

Cation	pH	ΔS°, $cal \cdot mole^{-1} \cdot deg^{-1}$
Ni^{2+}	3.71	21.0
	4.40	33.4
	4.90	41.1
	5.51	49.4
Pb^{2+}	3.00	16.3
	4.81	17.3
	5.10	18.1
	5.47	18.9
Mn^{2+}	3.00	29.9
	3.66	34.1
	5.86	34.6
	6.36	34.8
Ca^{2+}	4.10	13.0
	4.87	13.4
	6.31	13.5
	7.36	15.4

The standard free energy change for reaction (1) is related to the conditional stability constant by

$$K_{M'Y'} = \exp(-\Delta G^0/RT) \qquad (6)$$

From the temperature-dependence of $K_{M'Y'}$, the entropy change of reaction (1) can be calculated. The values found for the entropy change in formation of the complexes studied are shown in Table 1. The entropy changes for the Ca, Mn and Pb complex-formation reactions are practically independent of the pH, whereas for Ni there is a large change in ΔS with pH. The absorption spectra of the metal-EDTA complexes were measured at various pH-values, and the absorbances at the wavelength of maximum absorption are plotted against pH for each metal in Fig. 1. The absorbance of each metal complex decreases with pH. This decrease is ascribed to the side-reaction of EDTA with protons. However the drop in absorbance is much smaller for the Ni-EDTA complex, and this difference in behaviour must be related to the structure of this complex in solution. The Ni-EDTA complex should be octahedral, with two amino and four carboxylate groups co-ordinated to the central metal ion. This configuration may be sensitive to pH, since with decreasing pH the carboxylate group is prevented by protons from co-ordination with the metal ion, which would result in the formation of mixed-ligand (EDTA, water) complexes of nickel. Such a situation should lead to a decrease in the entropy change. Consideration of the log K and ΔH values for the complexes supplies an indication of the explanation. For the Ni, Ca and Mn complexes ΔH is comparatively small (-7.6, -6.5, -4.6 kcal/mole respectively) but the much bigger entropy change makes the nickel complex much the strongest of the three, and thus much less susceptible to the side-reactions of EDTA with protons. The lead complex has about the same stability as the nickel complex, but the ΔH is much more negative (-14.9 kcal/mole) and ΔS correspondingly less positive.

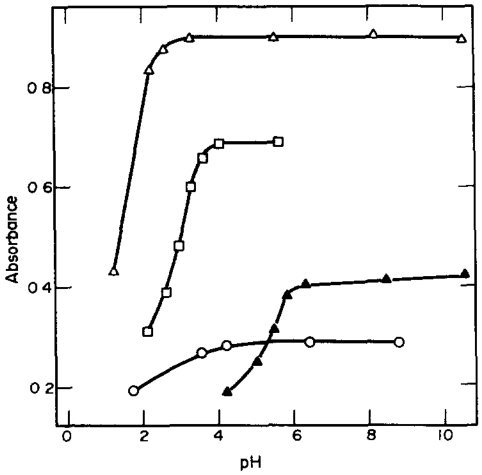

Fig. 1. The absorbance of the metal-EDTA complexes at λ_{max} *vs* pH. △: Pb–EDTA (0.1 m*M*), 242 nm; □, Mn–EDTA (0.5 m*M*), 210 nm; ▲, Ca–EDTA (0.5 m*M*), 210 nm; ○, Ni–EDTA (10 m*M*), 985 nm.

DETECTION OF SOME NITROGEN COMPOUNDS AND THE SEMIQUANTITATIVE DETERMINATION OF DIPHENYLAMINE WITH *p*-DIMETHYLAMINOBENZALDEHYDE BY CAPILLARY SOLID-STATE SPOT-TESTS

M. QURESHI, H. S. RATHORE and ALI MOHAMMED
Chemistry Section, Z.H. Engineering College, Aligarh Muslim University, Aligarh, U.P., India

(*Received* 3 *February* 1976. *Accepted* 31 *May* 1976)

Interest in solid-state chemistry is growing.[1–5] Solid-state reactions have much to offer to chemists concerned with synthesis, reaction mechanism or the chemistry of natural processes. Feigl[6] has shown some possibilities of using solid-state reactions in qualitative organic analysis. These include hydrolytic and ammonolytic cleavages, and displacement, condensation and redox reactions that occur when organic compounds are melted or sintered with suitable reagents. *p*-Dimethylaminobenzaldehyde[7] (*p*-DAB) is a useful reagent in organic analysis. It gives coloured products and also produces fluorescent[8] compounds in solution. We earlier proposed *p*-DAB in the presence of hydrochloric acid for the specific detection of diphenylamine.[9] The mechanism and kinetics of this reaction in the solid state were investigated later.[10] It was found to be a diffusion-controlled reaction; a coloured boundary is formed at the junction of the two reactants and the diffusing species is $Ph_2NH_2^+Cl^-$.

It was therefore considered worthwhile to use the formation of a coloured boundary for the detection of organic compounds in the solid state. For this purpose a new technique for solid-state spot-tests, called capillary spot-tests, was devised. This technique is very simple and can be used for semiquantitative determinations as well. This report summarizes the results obtained. Diphenylamine was also semiquantitatively determined by this technique.

EXPERIMENTAL

Procedures

Solid-state detection. A well powdered and thoroughly mixed mixture of *p*-dimethylaminobenzaldehyde (*p*-DAB) and potassium hydrogen sulphate (PHS) in equimolar ratio was used as the reagent (*A*). A little of the solid was mixed in a micro test-tube with several mg of *A*. The colour developed at room temperature (31°) as well as on heating was recorded. For heating, the tube was placed for a few sec in a water-bath preheated to 100°. The limits of identification were determined by starting with known volumes of standard solutions of the compound concerned, evaporating to dryness at 100°, and mixing the solid residue with A.

Detection in solution. A drop of ethanolic test solution was mixed with 1 or 2 drops of a 1% solution of *A* in 50% aqueous ethanol. The colour developed at room temperature as well as in the hot solution was recorded.

Solid-state detection in capillaries. A capillary (1-mm bore) was part-filled with *A* by continuous tapping and then the solid test material was added at the open end. The colour and fluorescence of the product at the junction were recorded. The limits of identification were determined by starting with various synthetic mixtures of the solid test materials with starch.

Semiquantitative determination. Capillaries containing *A* and solid test material (various concentrations of diphenylamine) were kept at 50° in an oven for 5 hr, and the length of the coloured boundary formed at the junction was recorded. A plot of diphenylamine concentration *vs.* boundary length was linear but did not pass through the origin. The sensitivity is rather poor, 10% of diphenylamine giving a length of 1.0 mm, and 100% giving 3.5 mm.

Visual colorimetry. Capillaries containing *A* and solid test material (0.1–10% diphenylamine) were kept at room temperature for 2 hr or at 50° in an oven for 15 min, and the colour intensities were compared visually. Both procedures are equally good but it is faster, of course, to use heating. The colour intensity is proportional to the concentration of diphenylamine.

DISCUSSION

The results in Table 1 indicate that the solid-state reactions are sufficiently sensitive, and can be used to distinguish similar compounds by means of the colours obtained in the cold and on heating.

It is known[11] that many reactions which take place in solution are also observed in the reactions between the solids, particularly on trituration, where there is a close contact between the reacting substances. It is also known that many reactions between solids take place on simple contact of the reacting substances. This means that many compounds can be distinguished by solid-state contact reactions in a capillary, *cf.* Table 2.

Further, of the substances tested, only acridine, *p*-toluidine and semicarbazide hydrochloride form products with reagent *A* which give fluorescence in the capillary, the colours being OY, Y and Y respectively and the limits of identification 5, 20 and 100 μg.

However, the method is not specific for detection of nitrogen compounds. For example, aliphatic amides do not react, nor do uracil, uric acid, adenine, glycine, phthalimide, sarcosine, EDTA, thebaine, papaverine, purines, α-amino-acids and pyridine derivatives. On the other hand, some compounds react although they do not contain nitrogen, *e.g.*, Feigl[12] and van Urk[13] found various such colour reactions of *p*-DAB, and we found that santonin, resorcinol, phloroglucinol and hydroquinone react.

APPLICATION OF TRIETHYLENETETRAMINE TO THE SEPARATION OF METAL IONS ON SELECTIVE EXCHANGE RESIN CHELEX 100

KRYSTYNA BRAJTER and JADWIGA GRABAREK
Institute of Fundamental Problems in Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 13 *January* 1976. *Accepted* 23 *April* 1976)

Separation of metal ions on the selective exchange resin Chelex 100 often requires the use of specially chosen complexing agents.[1–8] We have found triethylenetetramine (TETA) is a particularly useful complexing agent in this connection. The copper(II) complex is particularly stable,[9] which enables copper to be removed from the resin by elution with small quantities of TETA solution although the affinity of the resin for copper is high. In this paper the utility of TETA is illustrated by its application to the separation of Cu^{2+} from Ni^{2+} and of Pb^{2+} from Cu^{2+}. The problem of separation of these ions arises in the analysis of some natural raw materials. Mineral acids have been used to separate alkaline earth metals from others on the basis of the differences in stability of the metals complexes with the iminodiacetate functional groups of Chelex 100.[10–15]

EXPERIMENTAL

Reagents

Exchange resin. Chelex 100 (Bio-Rad Laboratories), 100–200 mesh, with maximum exchange capacity 3.0 mmole/g of the dry resin in Na^+-form and 3.48 mmole/g of the resin in H^+-form, and Dowex A-1, (Serva Entwicklungslabor, Heidelberg), capacity 2.4 mmole/g, were used. The capacity was determined from the sorption of $Cu(NH_3)_4^{2+}$,[16] and confirmed by elemental analysis

Standard solutions. These were prepared by dissolving enough of the appropriate nitrates for the concentrations of the metal ions to be: Ca^{2+} 24 mg/ml, Mg^{2+} 24 mg/ml, Cu^{2+} 1.2 mg/ml, Ni^{2+} 0.6 mg/ml, Pb^{2+} 1.0 mg/ml. The solutions were then standardized complexometrically.

The distribution coefficients

The batch method[16] was used. Weighed portions (0.2833 g) of Chelex 100 were placed in special vessels containing 0.085 mmole of Me^{2+} in 25 ml of solution in one series and 0.085 mmole of Me^{2+} and 0.85 mmole of TETA in 25 ml of solution in a second series. The pH was measured, then the solutions were shaken mechanically for 12 hr. After equilibrium was reached the aqueous phase was analysed for Me^{2+}. Ca^{2+} and Mg^{2+} were titrated with EDTA or determined by atomic absorption. Cu^{2+}, Ni^{2+} and Pb^{2+} were determined by atomic absorption.

APPLICATION OF TRIETHYLENETETRAMINE TO THE SEPARATION OF METAL IONS ON SELECTIVE EXCHANGE RESIN CHELEX 100

Krystyna Brajter and Jadwiga Grabarek
Institute of Fundamental Problems in Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 13 *January* 1976. *Accepted* 23 *April* 1976)

Separation of metal ions on the selective exchange resin Chelex 100 often requires the use of specially chosen complexing agents.[1–8] We have found triethylenetetramine (TETA) is a particularly useful complexing agent in this connection. The copper(II) complex is particularly stable,[9] which enables copper to be removed from the resin by elution with small quantities of TETA solution although the affinity of the resin for copper is high. In this paper the utility of TETA is illustrated by its application to the separation of Cu^{2+} from Ni^{2+} and of Pb^{2+} from Cu^{2+}. The problem of separation of these ions arises in the analysis of some natural raw materials. Mineral acids have been used to separate alkaline earth metals from others on the basis of the differences in stability of the metals complexes with the iminodiacetate functional groups of Chelex 100.[10–15]

EXPERIMENTAL

Reagents

Exchange resin. Chelex 100 (Bio-Rad Laboratories), 100–200 mesh, with maximum exchange capacity 3.0 mmole/g of the dry resin in Na^+-form and 3.48 mmole/g of the resin in H^+-form, and Dowex A-1, (Serva Entwicklungslabor, Heidelberg), capacity 2.4 mmole/g, were used. The capacity was determined from the sorption of $Cu(NH_3)_4^{2+}$,[16] and confirmed by elemental analysis

Standard solutions. These were prepared by dissolving enough of the appropriate nitrates for the concentrations of the metal ions to be: Ca^{2+} 24 mg/ml, Mg^{2+} 24 mg/ml, Cu^{2+} 1.2 mg/ml, Ni^{2+} 0.6 mg/ml, Pb^{2+} 1.0 mg/ml. The solutions were then standardized complexometrically.

The distribution coefficients

The batch method[16] was used. Weighed portions (0.2833 g) of Chelex 100 were placed in special vessels containing 0.085 mmole of Me^{2+} in 25 ml of solution in one series and 0.085 mmole of Me^{2+} and 0.85 mmole of TETA in 25 ml of solution in a second series. The pH was measured, then the solutions were shaken mechanically for 12 hr. After equilibrium was reached the aqueous phase was analysed for Me^{2+}. Ca^{2+} and Mg^{2+} were titrated with EDTA or determined by atomic absorption. Cu^{2+}, Ni^{2+} and Pb^{2+} were determined by atomic absorption.

Table 1. Distribution coefficients and degrees of adsorption of Ca^{2+}, Cu^{2+}, Ni^{2+}, Pb^{2+} on Chelex 100, as a function of pH

Ca^{2+}			Cu^{2+}			Ni^{2+}			Pb^{2+}		
pH	K_d	Bound to resin, %	pH	K_d	Bound to resin, %	pH	K_d	Bound to resin, %	pH	K_d	Bound to resin, %
1.6	0.16	0	1.85	4.0×10^2	82.1	1.6	14.6	6.3	2.0	2.43×10^2	49.3
1.9	0.41	0.3	1.99	6.75×10^2	86.8	2.6	8.8×10^2	77.7	4.5	$>6 \times 10^4$	100
2.8	33	21.3	2.35	7.45×10^3	98.8	4.3	2.9×10^4	99.1	7.0	$>6 \times 10^5$	100
4.5	6.84×10^3	98.3	3.0	3.0×10^4	99.6	6.5	$>10^5$	100	3.0	99.0×10^3	97.4
5.0	1.38×10^4	99.1	4.0	1.7×10^5	100	8.3	$>10^5$	100			

K_d was calculated from

$$K_d = \frac{\text{mmole of Me}^{2+}/\text{g of resin}}{\text{mmole of Me}^{2+}/\text{ml of solution}}$$

Separation procedures

Weighed portions (1.5 g) of Chelex 100, (Na^+-form) for separation I, or of Dowex A-1 (H^+-form, 2.0 g) for separation II, were placed in special flasks containing 25 ml of 0.1 *M* sodium hydroxide and shaken mechanically for 30 min until the pH of the solution in equilibrium with the resin was 5. The slurry thus prepared was poured into a column (12 mm bore), the bed being 13.5 cm high. A 10-ml sample, containing 120 mg of Ca^{2+}, 1.2 mg of Cu^{2+} and 1.2 mg of Ni^{2+}, or 120 mg of Mg^{2+}, 1.2 mg of Cu^{2+} and 1.0 mg of Pb^{2+}, was placed on the top of the column and allowed to percolate at a fixed flow-rate of about 2.5 ml/min.

Separation I. Ca^{2+} was washed out from the column with 200 ml of 0.5 *M* potassium nitrate, pH 2.5, Cu^{2+} with 100 ml of 0.17 *M* TETA at pH 5.0, and Ni^{2+} with 200 ml of 0.17 *M* TETA at pH 9.0.

Separation II. Mg^{2+} was eluted with 100 ml of 0.5 *M* potassium nitrate, pH 2.5, Cu^{2+} with 100 ml of 0.17 *M* TETA at pH 5.0 and Pb^{2+} with 100 ml of 0.5 *M* nitric acid.

The effluents from the column were collected in fractions either with an automatic fraction collector (at 2-min intervals), or in standard flasks, and analysed by titration or atomic absorption.

RESULTS AND DISCUSSION

Table 1 gives the distribution coefficients and degrees of adsorption of Chelex 100, as a function of pH.

The distribution coefficients increase regularly with increasing pH. The affinity of the cations for the resin is $Ca^{2+} < Ni^{2+} < Pb^{2+} < Cu^{2+}$.[10] Table 2 shows the corresponding data when TETA is also present.

The TETA greatly increases the selectivity of Chelex 100, and the variation in adsorption with pH indicates some possible separations. The remarkable increase in K_d at high pH may be due to formation of mixed complexes and is being further investigated. The best pH values for elution of Cu^{2+} and Ni^{2+} were found to be 5.0 and 9.0 respectively. In Table 3 the results of Ca^{2+}, Cu^{2+}, Ni^{2+} separation on Chelex 100 are given. The elution curves are presented in Fig. 1. The fractions were analysed by atomic absorption.

The elution of Cu^{2+} with TETA seems of practical interest because of difficulties recorded elsewhere.[10] This elu-

ION-EXCHANGE SEPARATION AND ATOMIC-ABSORPTION DETERMINATION OF FIFTEEN MAJOR, MINOR AND TRACE ELEMENTS IN SILICATES*

AMBROGIO MAZZUCOTELLI
Istituto di Petrografia, Università di Genova, Genoa, Italy

and

ROBERTO FRACHE, ARDUINO DADONE and FRANCA BAFFI
Istituto di Chimica Generale ed Inorganica, Università di Genova, Genoa, Italy

(*Received* 9 *January* 1976. *Accepted* 6 *May* 1976)

In geochemical analysis, it is often necessary to separate single elements (especially minor and trace elements) to avoid matrix interference in the subsequent quantitative determinations. Moreover, the development of analytical schemes to include as many major, minor and trace elements as possible, is important if it is desired to use only one or two portions of sample.

Generally speaking, especially in geochemistry, it is very important to develop standardized analytical methods which give selective separations and then quantitative determination of the elements in individual pure solutions.

Separation schemes have been extensively investigated, and the results have been examined in detail by Strelow in a recent review.[1] The same author and his collaborators[2] have described a scheme in which Fe(III), Al, Ti, Zr, V(V) and Mo(VI) are retained on an anion-exchanger in oxalic and hydrochloric acid media, and Na, K, Mn(II), Mg and Ca, which pass through the anion-exchange column, are retained on a cation-exchanger. The elements are then eluted selectively. Recently Strelow *et al.*[3] have presented an accurate determination of Al, Fe(III), Ti, Ca, Mg, Mn(II), Na, K, V(V) and Zr in silicate rocks, based on separation on a single cation-exchange resin, employing different acid mixtures. Govindaraju[4] has proposed a method of silicate analysis based mainly on ion-exchange dissolution and emission spectrometry; Al, Fe(III), Mg, Ca, Mn(II), Ti, Ba, Co(II), Cr(III), Cu, Ni, Sr and V(V) were accurately determined. Szlaurová *et al.*[5] have proposed an analytical scheme for fifteen radionuclides, Zr, Nb, Mo(VI), Sr, Ba, Y, Ce(III), Sc, Cs, Eu, Mn(II), Cu, Co(II), Fe(III), Zn, employing seven cation- and anion-exchangers.

In a previous work[6] we presented a method for separation of eighteen cations Li, Na, K, Mg, Ca, Sr, Ba, Al, Ti, Mn(II), Cu, Ni, Co(II), Fe(III), Zn, Hg(II), Sb(III) and Bi by means of cation- and anion-exchange resins. Mn(II), Cu, Fe(III), Zn, Hg(II), Sb(III) and Bi were absorbed after passage of the sample, dissolved in 7*M* hydrochloric acid in methanol, through a borosilicate glass tube filled with anion-exchange resin. The other ions were absorbed on a cation-exchanger before concentration of the sample. All the ions (0.1 meq of each) were then selectively eluted from the two columns with hydrochloric acid of concentration ranging from 0.05 to 12*M*.

In the present work we have examined the possibility of applying such a scheme to silicate materials, because of its simplicity and the large number of ions separated. We left Sb, Hg and Bi out of consideration because, although their separation is good, they are not easily determined owing to their extremely low concentration (< 1 ppm) in common silicate materials.

In the original work,[6] the eluted elements were determined by complexometric titration (Mg, Sr and Ba), flame photometry (Li, Na and K) and colorimetry the rest. In the present application atomic-absorption spectrophotometry (AAS) was used for all the elements except titanium (determined colorimetrically with Tiron[7,8]), in order to achieve maximum speed of analysis.

The necessity for separation of these elements, even though AAS is widely (but mistakenly) regarded as highly selective, is confirmed by the following reports: barium suffers interference from calcium, aluminium and alkali metals[9,10] and so does strontium;[11,12] Ca, Mg, Al, Na, Fe, Ti, Li and K are highly active as interfering agents;[13–16] Mn and Zn suffer from matrix interference.[14] Although no comparable data are available for Cu and Ni, we think it best to separate these elements from the silicate matrix for their concentration from trace levels.

EXPERIMENTAL

Ion-exchange

Dowex 50W X8 and Dowex 1 X8, both 200–400 mesh, were used. The cation-exchanger was converted into the H^+ form with 3*M* hydrochloric acid and washed with demineralized water. The anion-exchanger was treated first with 12*M* hydrochloric acid, then with 4% sodium hydroxide solution, and converted into the Cl^- form with 3*M* hydrochloric acid and washed with demineralized water. Borosilicate glass tubes (12-mm bore) were packed with 100- and 180-mm beds of the anion- and cation-exchanger respectively. Elutions were effected at 380 mmHg overpressure. An automatic fraction-collector was used.

Method

Weigh out 100 mg of finely powdered sample (120-mesh) in a PTFE dish. Moisten the powder with water to avoid spattering. Add 10 ml of 40% hydrofluoric acid and 10 ml of 70% perchloric acid, mixing with a platinum or PTFE rod. Allow to stand overnight in the fume-cupboard and then heat to dryness. Add 10 ml of hydrofluoric acid and 10 ml of perchloric acid and heat to dryness. Add 5 ml of perchloric acid and heat to dryness. Add 50 ml of a 7*M* solution of hydrochloric acid in methanol. Pass the sample solution through the anion-exchanger, pretreated with 20 ml of the 7*M* hydrochloric acid in methanol, at a flow-rate of 2.5 ± 0.3 ml/min. This column sorbs Mn(II), Co(II), Fe(III), Cu and Zn, which are later eluted as shown in Fig. 1. Wash the column with 30 ml of 7*M*

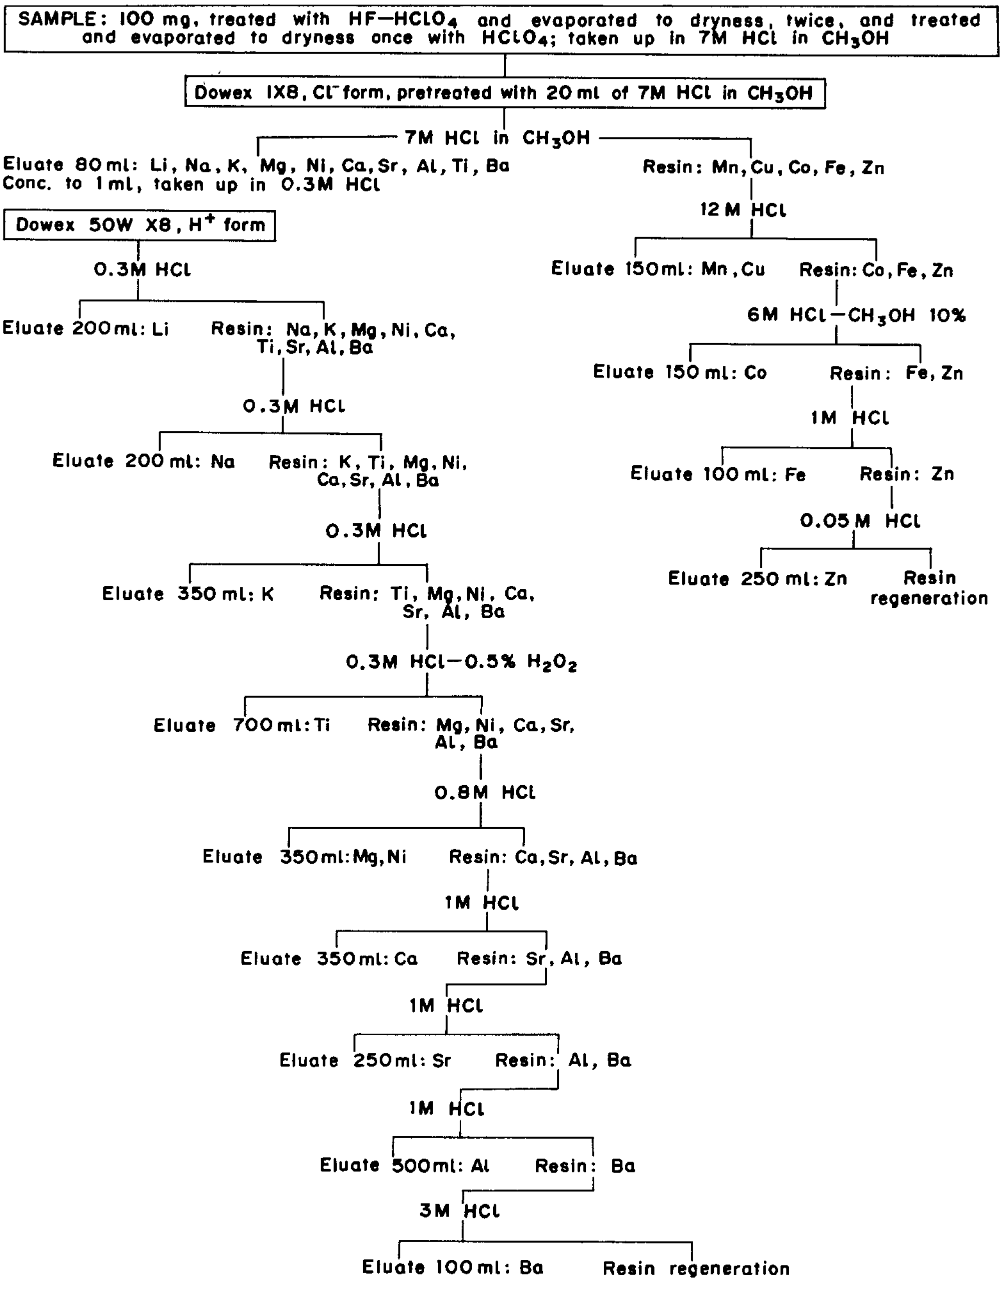

Fig. 1.

hydrochloric acid in methanol, evaporate the combined effluent to 1 ml, and add 50 ml of 0.3*M* hydrochloric acid. Pass this sample through the cation-exchanger, which sorbs Li, Na, K, Mg, Ca, Sr, Ba, Ni, Al and Ti, which are then eluted as described in Fig. 1. The columns are finally regenerated by the treatment described for preparation of the exchange-resins.

The ions are evaluated quantitatively by the methods given in Table 1. The calibration curves have been obtained by direct use of standard solutions of the element concerned.

RESULTS AND CONCLUSION

The scheme described earlier[6] referred to mixtures containing the same number of equivalents of each ion present. To evaluate the effectiveness of the scheme in silicate analysis, we prepared a synthetic sample containing these ions in the ratios found in common geological samples (Table 1).

Aliquots of this solution, containing the fifteen elements in the amounts corresponding to 100 mg of a common silicate sample, were treated according to Fig. 1 and the elements were collected in 10-ml fractions to determine the elution curves. Quantitative analyses were done, in order to test the reproducibility of the method. In the earlier scheme,[6] Mn and Cu were further separated on a third column filled with Amberlite CG 400, Cl⁻ form. These two elements show no interaction in AAS, so we prefer to determine them in the same solution instead of using the third column. The same applies to Mg and Ni.

Table 1. Analytical methods used in the separation scheme and composition of synthetic standard

Species	Content	Methods	Wavelength, *nm*	Flame
Al_2O_3	10.20 %	AAS K as ionization suppressor[8]	309.3	NA
Fe_2O_3	6.76 %	AAS[7]	248.3	AA
CaO	13.28 %	AAS La as releasing agent[7]	422.7	AA
MgO	13.80 %	AAS La as releasing agent[7]	285.2	AA
Na_2O	3.05 %	AAS Cs as ionization buffer[8]	589.0	AA
K_2O	1.40 %	AAS Cs as ionization buffer[8]	766.5	AA
TiO_2	2.60 %	COL Tiron as complexing agent[7]	580	—
MnO	0.20 %	AAS La as releasing agent[7]	279.5	AA
Ba	1050 ppm	AAS K as ionization suppressor[9]	553.6	NA
Co	50 ppm	AAS[14]	240.7	AA
Cu	70 ppm	AAS[14]	324.8	AA
Li	9 ppm	AAS Cs as ionization buffer[14]	670.8	AA
Ni	270 ppm	AAS[14]	232.0	AA
Sr	1350 ppm	AAS La as releasing agent[14]	460.7	NA
Zn	160 ppm	AAS La as releasing agent[14]	213.9	AA

Note. K and La were added because the ionization effect is independent of the separation. NA = nitrous oxide–acetylene flame; AA = air–acetylene flame.

Table 2. Synthetic solution analytical data

Species	Taken, *mg*	Found, *mg*	Final volume after sepn., *ml*	Concentration ratio	Dilution ratio	Relative concentration, *ppm*

Summary—A scheme of ion-exchange separation of fifteen elements (major, minor and trace) determined mainly by atomic-absorption spectrophotometry (Ti by colorimetry) is applied to rock, mineral and ceramic analysis. Mn, Cu, Co, Fe and Zn are separated on an anion-exchanger and Li, Na, K, Mg, Ca, Sr, Ti, Al, Ni and Ba on a cation-exchanger. The method has been tested by analysis of a synthetic mixture of the fifteen ions in the ratios in common rock samples, and of various international standards (100-mg samples).

LETTER TO THE EDITOR

SELECTIVITY INDEX

Sir,

Several years ago I pointed out that some system was needed to grade degrees of selectivity and I suggested that the term "Selectivity Index" might be used. I had discussed this matter at some length with Dr. Betteridge, who proposed a further scheme which provided considerably more detailed information. We arranged to publish our observations simultaneously.[1] The Selectivity Index was included in Dr. Betteridge's system.

Some interest was shown at the time[2] and later we submitted a further letter, covering the suggestions and criticisms which had been raised.[3] Since that time nothing further has been published.

Later, when I was Chairman of the Nomenclature Commission of the Analytical Chemistry Division of IUPAC, I included this subject in our general programme. A working party was formed, but more urgent matters had to take precedence and very little headway was made. The project was eventually abandoned. I believe that little progress is likely to be made until more opinions have been collected and the objectives have been clarified. The purpose of this letter is to attempt to stimulate further interest in this problem and to obtain some written or verbal contributions. Undoubtedly, this step is essential before the topic is suitable for Committee deliberation.

I believe that there are several reasons why little progress has been made.

1. When I first made this proposal, I deliberately avoided giving detailed conditions in the expectation that a discussion would be provoked which would cover all aspects. From the discussions I have since had with the Commission's working groups, it seems that it was this lack of precise definition which has provided a stumbling block to further progress.

2. My purpose was to provide a simple means of expressing by spoken word the reaction behaviour of a particular ion. I wanted a description that did not necessitate the use of a blackboard or pencil and paper to illustrate it. Dr. Betteridge's idea was intended for tabulation and thus would cover much more ground. Unfortunately, although Dr. Betteridge's scheme included my Selectivity Index, the whole issue has become confused. Before Dr. Betteridge's scheme could be implemented it would be necessary to agree on some form of my *original* proposal as to what is meant by Selectivity Index.

3. I used the term "index" in its general sense. Because of the system recommended by Dr. Betteridge, which uses indices in a different manner, it would perhaps be better to use the term Selectivity Number.

4. It seems that one of the main problems is whether the Selectivity Index should refer to the "natural" selectivity of a particular ion or the selectivity under the most favourable conditions, *i.e.*, the optimal pH; in the presence of masking agents; suitable oxidation state, *etc*.

This might be overcome by the use of two numbers, the one indicating the normal selectivity and the other the value under the most favourable conditions. For example, suppose that reagent X gives a reaction with six different ions under normal conditions. Under the most favourable conditions only two ions give the reaction. Then the selectivity numbers would be 6/2. Such an expression could provide all the information required completely verbally; it would also indicate the improvement in selectivity produced by the most favourable conditions. It is true that there are two selectivities, the "natural" (for want of a better term) and the most favourable selectivity. The latter could be called the "optimal" selectivity, but there may be better terms which could be used. Of course, a lot of complications can be introduced, as I have discovered from the many discussions. One popular question is "how to refer to the reaction of a trace of material in the presence of a large bulk of another". If it is kept in mind that one is only attempting to give a general description, then these special cases can be ignored. If an attempt is made to cover every special case, it would probably need a computer to analyse the systems. When one knows approximately the reaction behaviour in the presence of moderate amounts of other ions, it is sufficient for the purpose I have in mind. For special conditions one would need to look up the necessary reference books. As I have repeatedly emphasized, I am only seeking an expression which can be given verbally and which can convey an approximate idea of reaction behaviour. If a classification of this kind could be devised, the way would then be clear for preparing the more detailed information provided by Dr. Betteridge's system.

PRELIMINARY COMMUNICATIONS

THE ANALYTICAL POTENTIAL OF GAS-PHASE MOLECULAR ABSORPTION SPECTROMETRY FOR THE DETERMINATION OF ANIONS IN SOLUTION

Malcolm S. Cresser* and Peter J. Isaacson

Department of Soil Science, University of Aberdeen, Old Aberdeen, Scotland

(Received 10 September 1976. Accepted 15 September 1976)

We have recently demonstrated[1] that nitrogen may be determined by conversion into ammonia in solution and subsequent measurement of the absorption in the ultraviolet region by the ammonia gas displaced from the alkaline sample solutions by a current of air. The selectivity, sensitivity, and precision of the method were found to compare favourably with the corresponding parameters for possible alternative methods of analysis, and the method has been applied to the determination of nitrogen in soil and plant samples. Factors influencing the sensitivity of the method for the determination of ammonium-N have been investigated in detail,[2] using the standard absorption-tube cell from a Shandon-Southern A 3490 Arsenic/Selenium Detection Unit, and a hydrogen hollow-cathode lamp. Subsequent work has shown that the method may also be applied to the determination of nitrate, if the latter is first reduced to ammonia with titanous sulphate solution.[3]

Because of the simplicity of these methods, the speed with which analyses may be completed, and the relative ease with which the methods could be fully automated, it seemed worthwhile to investigate the feasibility of determining other species by similar procedures. Sulphur dioxide, hydrogen sulphide, and the nitrogen dioxide-dinitrogen tetroxide system all absorb strongly in the analytically-useful (non-vacuum) region of the ultraviolet spectrum. These gases may be readily prepared at room temperature by the addition of dilute acid to solutions of sulphite, sulphide, and nitrite respectively. The absorption spectra obtained by adding 5-ml aliquots of 6M hydrochloric acid to 100 mg portions of the sodium salts of these anions in 100-ml volumetric flasks fitted with rubber septa are shown in Figs. 1 (S^{2-} and SO_3^{2-}) and 2 (NO_2^-): 0.05 - 0.2-ml aliquots of the gas evolved were injected into the 10-mm silica sample cell, which was also fitted with a rubber septum. All reactions and cell-filling operations were performed in a nitrogen atmosphere in a dry-box, so that spectra could be plotted down to 185 nm against an appropriate blank, with a Cary-Varian model 118 double-beam solution spectro-

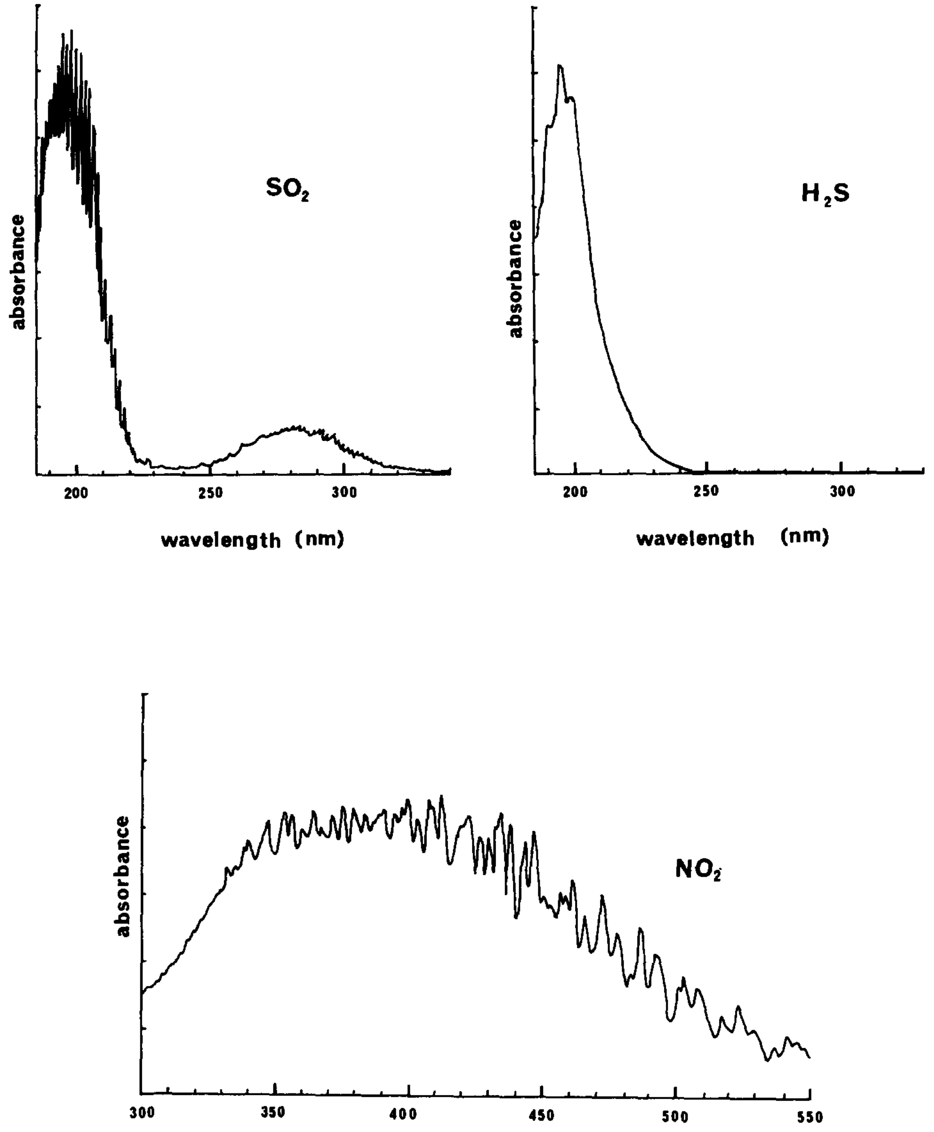

Fig. 1. Absorption spectra of sulphur dioxide, hydrogen sulphide, and nitrogen dioxide

photometer purged with dry nitrogen.

The results clearly indicate that gas-phase molecular absorption spectrometry (GPMAS) may be used for the sensitive determination of sulphide, sulphite and nitrite in solution, and that is is unnecessary to employ a nitrogen-purged monochromator. This has been confirmed for nitrite, using identical apparatus to that employed for the determination of ammonia,[2] but with 6M hydrochloric acid in place of the 40% sodium hydroxide solution used in the latter determination. The selectivity of the methods ultimately developed will depend upon the gas-generation system used. Thus, for example, the sensitivity of the nitrite determination deteriorates 100-fold if 6M sulphuric acid is employed in place of hydrochloric acid, and this could perhaps be used to improve the selectivity of the determination of sulphide or sulphite by GPMAS. Alternatively, suitable scrubbing solutions or solid absorbents or thermal decomposition techniques may be necessary to improve selectivity. No detectable absorbance was found for relatively large amounts of hydrogen selenide or hydrogen telluride, when these were prepared by reduction of selenite and tellurite salts with sodium borohydride in acid solution, so that selenide and telluride should cause no spectral interference in the determination of sulphide.

The absorption spectra of sulphur dioxide and hydrogen sulphide are relatively simple, and require no further comment here. The absorption spectrum obtained from the reaction between sodium nitrite and hydrochloric acid is more complex, however. The

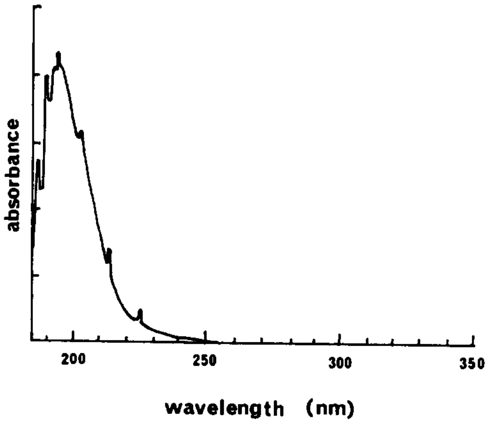

Fig. 2. Absorption spectrum of the undried products of the reaction between sodium nitrite and hydrochloric acid

structure which appears on the most sensitive band centred at 195 nm for this system is no longer observed if the gas mixture is dried with calcium chloride. The absorption spectrum might be expected to correspond to that of a relatively complex mixture of NO, NO_2, N_2O_4, N_2O_3 and HNO_2,[4-6] and possibly even NOCl.[7] The well-characterized part of the absorption spectrum of the NO_2-N_2O_4 system,[8] the lower spectrum in Fig. 1, is observable only at considerably higher gas mixture concentrations, and is of less interest from the analyst's viewpoint, because of the poorer sensitivity.

ÜBER CHEMOLUMINESZENZERSCHEINUNGEN BEI DER REAKTION ZWISCHEN SULFID UND HYPOHALOGENIT IN WÄSSRIGER LÖSUNG

Dieter Klockow und Jürgen Teckentrup

Chemisches Laboratorium der Universität Freiburg, Lehrstuhl für Analytische Chemie,
D-89 Freiburg, Albertstraße 21, Bundesrepublik Deutschland

(Eingegangen am 15. September 1976. Angenommen am 5. Oktober 1976)

Werden bei einer chemischen Reaktion Moleküle in elektronisch angeregten Zuständen gebildet, so ist die dabei oft auftretende Lumineszenz eine empfindlich meßbare physikalische Größe, mit deren Hilfe man den Verlauf einer Reaktion verfolgen bzw. einzelne Reaktionspartner quantitativ bestimmen kann.[1-4] Zum Zwecke der Sulfidbestimmung untersuchten wir deshalb die durch Sulfid katalysierte Reaktion zwischen Jod und Azid[5] auf eine eventuell durch Radikalreaktion auftretende Lumineszenz.

Wir fanden eine schwache Lumineszenz, deren Intensität von der Jod- und der Sulfidkonzentration abhängig war, ohne daß das Azid hierauf einen Einfluß ausgeübt hätte. Das bedeutet, daß die Lumineszenz die Oxidation des Sulfids durch Jod, eine Nebenreaktion der Jod-Azid - Reaktion, begleitet.

Die Lumineszenz trat nur im alkalischen Bereich auf ($pH > 8.0$), in welchem Jod bereits als Hypojodit vorliegt. Da das Jod als starker Quencher wirkte, durfte seine Konzentration nicht zu hoch sein. Mit Sulfidlösungen im $10^{-6}\underline{M}$ Bereich konnte ein Lumineszenzoptimum bei einer Jodkonzentration von $5 \cdot 10^{-6}\underline{M}$ beobachtet werden.

Wie weitere Untersuchungen zeigten, können außer Jod auch Brom bzw. Chlor[6] als Oxidationsmittel dienen. Die Lichtausbeute war sowohl bei Brom als auch bei Chlor um den Faktor 5 größer als bei Jod. Mit anderen Oxidationsmitteln [Hexacyanoferrat(III), Wasserstoffperoxid, Kaliumjodat] konnte keine Lumineszenz beobachtet werden. Sauerstoff[7] hat keinen meßbaren Einfluß auf die Reaktion zwischen Sulfid und Hypohalogenit, wie die Verwendung von Lösungen zeigte, welche vor und während der Messung gründlich mit Stickstoff gespült wurden.

Bei Anwendung höherer Konzentrationen an Brom wurde ebenfalls ein Quencheffekt beobachtet. Die besten Lichtausbeuten erhielten wir im Bereich $10^{-5} - 5 \cdot 10^{-5}\underline{M}$ Br_2. Die pH-Abhängigkeit der Reaktion (Abb. 1, Kurve a) weist auf Hypobromit als aktives Oxidationsmittel hin. Im weiteren Verlauf der Untersuchungen wurde wegen der höheren Lichtausbeute und des geringeren Quencheffektes nur Brom als Oxidationsmittel verwendet.

Zur Photonenzählung benutzten wir ein Flüssigkeitsszintillationsspektrometer (Intertechnique SL 30, Zählung bei ausgeschalteter Koinzidenzstufe und ganz geöffneten Fenstern). Die Lösungen wurden mittels einer Peristaltikpumpe durch ein Strömungssystem gefördert. In einer Mischzelle unmittelbar vor der Zählkammer wurde coulometrisch Brom aus einer $10^{-3}\underline{M}$ Kaliumbromidlösung produziert (Lösung I) und dort sofort mit einer Pufferlösung von geeignetem pH (Lösung II) vermischt. Dieser Reagenslösung wurde in der Durchflußzelle, die in die Zählkammer des Szintillationszählers eingesetzt war, das Sulfid in einer $10^{-4}\underline{M}$ Natriumhydroxidlösung (Lösung III) zudosiert.

Eine Erhöhung der Lichtausbeute um den Faktor 2 - 10 kann durch Zusatz von fluoreszierenden Substanzen erreicht werden, die zwischen 500 und 650 nm absorbieren. Es erwies sich dabei im pH-Bereich 9-11 Methylenblau als sehr günstig, da es mit keinem der untersuchten Oxidationsmittel allein zu einer nennenswerten Lumineszenz führte. Wie Abb. 1, Kurve b zeigt, erbrachte die Verwendung von Methylenblau als Sensibilisator eine beträchtliche Erhöhung der Lichtausbeute.

Eine Aussage über die angeregte Spezies, die bei dieser Reaktion entsteht, ist noch nicht möglich. Zwar beobachtet man im Szintillationszähler mit seiner sehr günstigen Zählgeometrie bei Zusatz von Methylenblau Zählraten von $5 \cdot 10^4 - 10^6$ cpm, doch ergibt die hieraus vorgenommene Abschätzung der Lumineszenzausbeute, bezogen auf die eingesetzte Sulfidmenge, Werte von nur $10^{-8} - 10^{-10}$. Deshalb gelang es bisher nicht, mit einer Anordnung aus Monochromator und Photonenzählgerät ein Spektrum der primär emittierten, d.h. aus der Reaktion zwischen Hypobromit und Sulfid herrührenden, Strahlung zu erhalten. Lediglich bei Verwendung von Methylenblau als Sensibilisator war ein Signal im Bereich der Fluoreszenzstrahlung dieses Farbstoffes zu beobachten.*

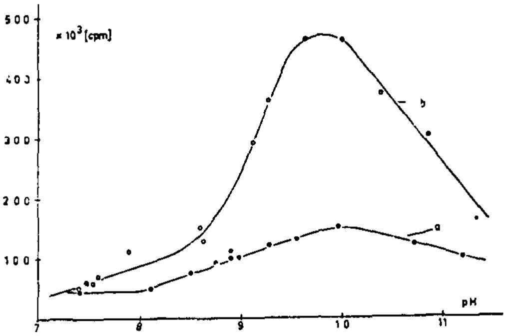

Abb. 1. pH-Abhängigkeit der Lumineszenz

Kurve a: ohne Sensibilisator
Lösung I: $5 \cdot 10^{-5}\underline{M}$ Br_2 in $10^{-3}\underline{M}$ KBr
Lösung II: HCl- bzw. NaOH-Lösung verschiedener Konzentration zur Einstellung der gewünschten pH-Wertes
Lösung III: $3 \cdot 10^{-5}\underline{M}$ Na_2S in $10^{-4}\underline{M}$ NaOH

Kurve b: mit Sensibilisator
Lösung I: $10^{-5}\underline{M}$ Br_2 in $10^{-3}\underline{M}$ KBr
Lösung II: wie bei a, jedoch mit jeweils $5 \cdot 10^{-5}\underline{M}$ Methylenblau
Lösung III: $10^{-6}\underline{M}$ Na_2S in $10^{-4}\underline{M}$ NaOH

Im Hinblick auf eine analytische Anwendung der Reaktion zur Sulfidbestimmung wurde die Abhängigkeit der Lumineszenz von der Sulfidkonzentration unter folgenden Bedingungen ermittelt:

Lösung I: $10^{-5}\underline{M}$ Br_2, coulometrische erzeugt in $10^{-3}\underline{M}$ Kaliumbromidlösung;
Lösung II: $5 \cdot 10^{-5}\underline{M}$ Methylenblau in $10^{-3}\underline{M}$ Boratpuffer vom pH 9;
Lösung III: Natriumsulfid in $10^{-4}\underline{M}$ Natriumhydroxidlösung;
Pumpgeschwindigkeit für jede Lösung: 2,2 ml/min.

Es ergab sich eine annähernd lineare Eichkurve im Bereich $10^{-7} - 5 \cdot 10^{-6}\underline{M}$ Sulfid.

Andere Reduktionsmittel (Thiosulfat, Sulfit, Äthylmercaptan) stören nicht durch eine Lumineszenz sondern durch Verbrauch an Oxidationsmittel.

Gegenwärtig wird versucht, das System zu einem empfindlichen Verfahren zur Sulfidbestimmung auszubauen. Hierbei steht das bislang nur unzureichend gelöste Problem der Erfassung von Schwefelwasserstoffspuren in der Atmosphäre unter Reinluft- und "background"-Bedingungen im Vordergrund.

EDITORIAL

For the last two years "card index summaries" of the papers in *Talanta* have been published in English, French and German as a separate part of each issue, the intention being to provide copies that could be cut out and pasted onto cards. This arrangement, however, is only of use to the first person having access to a copy and using it (always assuming that in the case of library copies the librarian has not mistaken the summaries for advertising matter and thrown them away). It therefore seems likely that demand for the service is low, and in view of its relatively high cost it is felt that readers would probably prefer to do without the card index summaries and have the savings used to stabilize the subscription rate, especially in these days of high inflation. This issue will therefore carry the last set of card index summaries. We shall, of course, continue to print summaries along with the papers themselves, and these will be in the same language as the paper, with an English translation for papers written in French or German.

PAPERS RECEIVED

Ferricyanide as an indicator in cerimetry: L. M. Bharadwaj, D. N. Sharma, P. D. Sharma and Y. K. Gupta. (8 *June* 1976)

Stability constants of rhodizonic acid complexes in solution: Srikumar Mukerjee and Narendra S. Rawat. (10 *June* 1976)

Determination of thiourea and its organic derivatives with iodine trichloride: Sameer Bose, M. P. Sahasrabuddhey and Krishna K. Verma. (11 *June* 1976)

Einflüsse dritter Partner bei der Losungspektralanalyse nach dem Zerstäuberverfahren—II: Einflüsse organischer Lösungsmittel: Gerhard Ackermann and Manfred Münx. (24 *May* 1976)

Determination of cadmium in soils by neutron-activation analysis: E. Steinnes. (15 *June* 1976)

Selektivitätssteigerung katalytischer Bestimmungsverfahren—extraktionskatalymetrische Molybdänbestimmung: Matthias Otto and Helmut Müller. (24 *May* 1976)

Separation of Cr(III) from numerous metal ions on stannic arsenate in DMSO–HCl systems: M. Qureshi, K. G. Varshney and N. Fatima. (17 *June* 1976)

2,2′-Diaminodiphenyldisulphide—a new sensitive spectrophotometric reagent for platinum: Saswati P. Bag and Susil K. Chakrabarti. (17 *June* 1976)

Selectivity index: R. Belcher. (21 *June* 1976)

Formation constants of metal complexes with Semi-Glycinecresol Red: Takashi Yoshino, Sadaaki Murakami and Osamu Ushimaru. (21 *June* 1976)

Properties of two-step redox titrations: Robert L. Epstein and James A. Goldman. (7 *June* 1976)

Analytical studies using iodine–luminol chemiluminescence: William M. Hardy, W. Rudolf Seitz and David M. Hercules. (1 *June* 1976)

Determination of mercury in manganese nodules and crusts: J. R. Toth and J. D. Ingle, Jr. (1 *June* 1976)

Simultaneous determination of oxygen and cadmium in cadmium and cadmium compounds: Kazuo Imaeda, Takeo Kuriki, Keiko Ohsawa and Yoshiaki Ishii. (22 *June* 1976)

Bromamine-T as a new oxidimetric titrant in aqueous medium—direct titrations employing potentiometry and visual indicators: C. G. R. Nair, R. Lalithakumari and P. Indrasenan. (29 *June* 1976)

All-*cis*-1,2,3,4-cyclopentanetetracarboxylic acid: a reagent for the estimation of zirconium: G. A. Rama Rao and K. Srinivasulu. (30 *June* 1976)

Chemical separation and spectrographic estimation of rare earths in PuO_2 and $(U,Pu)O_2$: A. G. I. Dalvi, C. S. Deodhar and B. D. Joshi. (30 *June* 1976)

Extractive spectrophotometric determination of codeine, narcotine, papaverine and thebaine with Solochrome Green V 150: N. V. Rama Rao and S. N. Tandon.

A simple expression for the buffer index of a polyprotic weak acid: Rolf Hesse and Åke Olin. (1 *July* 1976)

OBITUARY

PROFESSOR F. E. BEAMISH

Frederick E. Beamish, FCIC, Professor Emeritus, University of Toronto, died on 8 April 1976 at Guelph, Ontario. It is impossible to catalogue adequately the accomplishments of a man of his stature. He was simply the world's number one authority on the analytical chemistry of the noble metals, having to his credit over 150 publications in this field, including 3 books (one in press) and 20 critical review articles.

Those who knew him only as a renowned scientist knew only a fraction of the man. Dr. Beamish was a loving husband and father and leaves his wife Dorothy and sons Dr. Dick and Dr. Bill Beamish. Perhaps first of all he was a teacher of chemistry and the research process and by example the purveyor of the best values in life. A dedicated gardener and naturalist, he treated the often miniscule problems of his students and his friends in the same delicate and loving way he worked with his favourite begonias and ferns. Beamish was a very religious man with an infectious sense of humour, these attributes often becoming the strength, during troubled times, of those with whom he had close associations.

Dr. Fred Beamish was born in Hanover, Ontario in 1901. He completed his M.A. at McMaster in 1929. He was appointed lecturer at the University of Toronto in 1931, associate professor in 1935 and full professor in 1946. He was accorded the title of Professor Emeritus, University of Toronto, in 1969, but he never really retired, continuing his writings until in 1974 a serious illness terminated his work.

Dr. Beamish was a tireless researcher, often spending 12 hours a day, 6 days a week at his desk and in the laboratory. He expected the same dedication and honesty of approach from his students. To have been a Beamish student was to have lived among the chosen few. Dr. Beamish left an indelible mark on those whom he taught, as is evidenced by the success of his students in government, industry and universities.

Among his other accomplishments Dr. Beamish was the first chairman of the Analytical Chemistry Division of the CIC, Canadian representative on the Analytical Section of IUPAC and on the advisory or editorial boards of the journals *Talanta*, *Analytical Letters* and *Analytical Chemistry*. He received an honorary D.Sc. from McMaster University in 1962, won the Fisher Award for Analytical Chemistry in 1970 and was appointed Fellow of the Royal Society of Canada in 1958.

Fred Beamish's devotion to hard work, clean living and complete honesty is an example to all. In this respect, Fred lives on amongst that large group of people who knew him well.

PAPERS RECEIVED

A new selective reagent for the spectrophotometric determination of palladium: F. Corigliano, S. Di Pasquale and A. Ranieri. (22 *March* 1976)

Polarographic behaviour of some *o*-hydroxyketoximes: R. P. Singh, K. B. Pandeya and Asha Kapahi. (24 *March* 1976)

Coulometric determination of ascorbic acid with electrogenerated octacyanomolybdate(V): R. Cordova-Orellana and F. Lucena-Conde. (24 *March* 1976)

Determination of strontium in human tooth enamel by flameless atomic-absorption spectrometry: Christine A. Helsby. (26 *March* 1976)

Potentiometric determination of hydrogen peroxide and sodium perborate with potassium dichromate: N. Krishna Murty and K. Rama Rao. (29 *March* 1976)

Titrimetric estimation of phosphate, molybdate, tungstate and sulphate with lead(II) nitrate solution, using 1,2-naphthoquinone-2-semicarbazone-4-sulphonic acid (NQS-4S) and 1,2-naphthoquinone-2-thiosemicarbazone-4-sulphonic acid (NQTS-4S) as visual indicators: Shanthi Kesavan, B. S. Garg and R. P. Singh. (30 *March* 1976)

Selective complexation of palladium and osmium with substituted pyrimidinethiols: A. K. Singh, Mohan Katyal, R. P. Singh and N. K. Ralhan. (30 *March* 1976)

Development of the differential refractometer: J. R. Majer. (31 *March* 1976)

An application of the Zeeman effect to analytical atomic spectroscopy—III: The extension of calibration curves: D. E. Veinot and R. Stephens. (31 *March* 1976)

Induced reduction of thallium(III) by hydrogen peroxide: P. D. Sharma and Y. K. Gupta. (2 *April* 1976)

Limit of detection and selectivity coefficients of liquid membrane electrode: Naoki Kamo, Norio Hazemoto and Yonosuke Kobatake. (5 *April* 1976)

The determination of selenium and other impurities in high-purity copper by flameless atomic-absorption spectrophotometry: J. D. Mullen. (5 *April* 1976)

Acid-base titrations by stepwise additions of equal volumes of titrant, with special reference to automatic titrations—I: Theory, discussion of the Gran functions, the Hofstee method and two proposed methods for calculating equivalence volumes: Lennart Pehrsson, Folke Ingman and Azel Johansson. (5 *April* 1976)

Acid-base titrations by stepwise addition of equal volumes of titraut, with special reference to automatic titrations—II: Theory, titration of mixtures of acids, polyprotic acids, acids in mixture with weak bases, and ampholytes: Lennart Pehrsson, Folke Ingman and Sten Johansson. (5 *April* 1976)

An improved turbidimetric procedure for the determination of sulphate in plants and soils: Balbir C. Verma, K. Swaminathan and K. C. Sud. (6 *April* 1976)

Dalzin as an analytical reagent and its application in analysis: M. R. Navaratna and C. S. P. Iyer. (6 *April* 1976)

Polarographic studies on cadmium(II) and lead(II) complexes of 2-amino-3-hydroxypyridine: R. S. Sindhu, K. B. Pandeya and R. P. Singh. (6 *April* 1976)

A new chelate-forming resin with dithizone functional group prepared by the conversion of an anion-exchange resin: H. Tanaka, M. Chikuma, A. Harada, T. Ueda and S. Yube. (6 *April* 1976)

L'étude du métavanadate comme réactif pour le dosage colorimétrique des acides: Florica Dima and G. Ghimicescu. (9 *April* 1976)

A study on the theory of action of reversible redox indicators: K. Sriramam. (21 *February* 1976)

Colour and precipitation reactions of heavier rare earth chlorophosphonazo III chelates: Tomitsugu Taketatsu. (12 *April* 1976)

Accuracy of steel analysis by using spark-source mass-spectrometry with electrical detection: E. Van Hoye, F. Adams and R. Gijbels. (12 *April* 1976)

Talanta, Vol. 23, p. i. Pergamon Press, 1976. Printed in Great Britain

PAPERS RECEIVED

Ion-exchange separation and atomic-absorption determination of fifteen major, minor and trace elements in silicates: AMBROGIO MAZZUCOTELLI, ROBERTO FRACHE, ARDUINO DADONE and FRANCA BAFFI. (9 *January* 1976)

Extraction and spectrophotometric determination of nickel(II) with potassium butyl xanthate: PRAPHULLA K. PARIA and SANTOSH K. MAJUMDAR. (9 *January* 1976)

Peroxydisulphate oxidations—V. Identification of some aromatic alcohols by thin-layer chromatography: S. P. SRIVASTAVA and R. G. SHARMA. (9 *January* 1976)

Application of triethylenetetramine (TETA) to the separation of metal ions on selective exchange resin Chelex 100: KRYSTYNA BRAJTER and JADWIGA GRABAREK. (13 *January* 1976)

Determination of uranium and impurities in Portuguese uranium concentrates: MARIA DE JESUS TAVARES, JOÃO SEABRA E BARROS and FELISMINA MATOS. (13 *January* 1976)

Remarques sur le microdosage du selenium dans les composes organiques: E. DEBAL, G. MADELMONT and S. PEYNOT. (28 *November* 1975)

Electroreduction of molybdenum(VI) at a prehydrogenated platinum electrode: P. ZANELLO, G. RASPI and A. CINQUANTINI. (15 *January* 1976)

A study on the formation of Fe(II), Co(II), Ni(II), Cu(II), Zn(II), Ag(I) and Cd(II) hexacyanocobaltates: ALESSANDRO DE ROBERTIS, ATHOS BELLOMO and DOMENICO DE MARCO. (15 *January* 1976)

Analytical applications of complex formation in non-aqueous solutions—I. Complexes of bismuth(III) with potassium diphenyldiselenophosphate in organic solvents: N. T. YATISIMIRSKAYA, ARAIN RAFEE and A. I. BUSEV. (15 *January* 1976)

Application of zone melting technique to metal chelate systems—X. Zone refining of bis(acetylacetonato)beryllium(II), tris(acetylacetonato)aluminium(III) and bis(di-isovalerylmethanato)copper(II): ISAO YOSHIDA, HIROSHI KOBAYASHI and KEIHEI UENO. (27 *January* 1976)

Application of zone melting technique to metal chelate systems—XI. Refining of tetrakis(dipropionylmethanato)zirconium(IV) from hafnium and trace amounts of some other metals: ISAO YOSHIDA, HIROSHI KOBAYASHI and KEIHEI UENO. (27 *January* 1976)

Spectrophotometric determination of pyrrole derivatives: J. P. SHARMA, A. K. DUBEY and V. K. S. SHUKLA. (28 *January* 1976)

Dynamic surface tension measurements for the assessment of potable water quality: G. LOGLIO, U. TESEI, A. FICALBI and R. CINI. (28 *January* 1976)

The solubility products of some slightly soluble lead salts and the potentiometric titration of molbydate, tungstate, perrhenate, and fluoride with lead ion-selective electrode: E. E. CHAO and K. L. CHENG. (23 *January* 1976)

Detection of some nitrogen compounds and the semi-quantitative determination of diphenylamine with *p*-dimethylaminobenzaldehyde by capillary solid-state spot tests: M. QURESHI, H. S. RATHORE and ALI MOHAMMED. (3 *February* 1976)

Einfluss von verschiedenen Parametern und Messbedingungen auf die anfängliche Neigung von atomabsorptiometrischen Eichkurven: B. MAGYAR and G. WIDMER. (3 *February* 1976)

Extraction behaviour and selective determination of arsenic(III) and arsenic(V) with ammonium pyrrolidinedithiocarbamate, sodium diethyldithiocarbamate and dithizone by means of flameless atomic-absorption spectrophotometry with a carbon-tube atomizer: TOSHIHIKO KAMADA. (3 *February* 1976)

The pH-dependence of entropy changes in metal–EDTA complex formation: KOTARO OGURA, KIYOSI TAKATU and TAKASI YOSINO. (3 *February* 1976)

Electrolysis at constant potential. Determination of diffusion coefficients of thallium by using a hanging mercury drop electrode: J. HERNÁNDEZ MÉNDEZ and R. CARABIAS MARTÍNEZ. (11 *February* 1976)

Talanta, Vol. 23, p. I. Pergamon Press, 1976. Printed in Great Britain

EDITORIAL

In this issue we present the first article in our new feature in which critical reviews are given of the development of particular types of instrument and of the equipment currently available. This first paper is on the mass filter, used in mass spectrometry. For the feature to become a success it is vital that we have the co-operation of our readers both in identifying the areas in which such reviews would be topical and useful, and in contributing to the feature. Anyone interested should write in the first instance to Dr. J. R. Majer, Chemistry Department, The University, P.O. Box 363, Birmingham 15, U.K., who will be responsible for this section, and who has written the first contribution to it.

Talanta, Vol. 23, p. i. Pergamon Press, 1976, Printed in Great Britain

PAPERS RECEIVED

Iron(II)-induced oxidation of hypophosphite by peroxydiphosphate in acid medium: SURINDER KAPOOR and Y. K. GUPTA. (11 *December* 1975)

The use of long chain alkylamines for preconcentration and determination of traces of molybdenum, tungsten and rhenium by atomic absorption spectroscopy—III. Tungsten in geological samples: C. H. KIM, P. W. ALEXANDER and L. E. SMYTHE. (15 *December* 1975)

Gravimetric estimation of palladium with *m*-(mercaptoacetamido)phenol: GEETHA PARAMESWARAN. (15 *December* 1975)

The application of ternary complexes to spectrofluorometric analysis: P. R. HADDAD. (18 *December* 1975)

Studies on some metal hydrous oxide sols, using electrocapillary curves: WAHID U. MALIK, RAMESH BEMBI, AJAY K. JAIN and J. S. TYAGI. (22 *December* 1975)

Interpretation of selectivity coefficients of solid-state ion-selective electrodes by means of the diffusion layer model: ADAM HULANICKI and ANDRZEJ LEWENSTAM. (22 *December* 1975)

Catalytic ion-exchange method for detection of microgram amount of amino-acids: SAIDUL ZAFAR QURESHI and IZZATULLAH. (22 *December* 1975)

Controlled-potential iodometric determination of iron after extraction with di-isopropyl ether: RONALD KARLSSON and LO GORTON. (23 *December* 1975)

Dosage du cuivre, plomb, cadmium, zinc dans l'eau de mer par redissolution anodique en utilisant un standard interne: PHILIPPE GOUT. (23 *December* 1975)

Determination of some trace impurities, indium, manganese, arsenic and antimony in different samples of zinc metal by neutron-activation analysis: M. DERMELJ, V. RAVNIK, L. KOSTA, A. R. BYRNE and A. VAKSELJ. (23 *December* 1975)

A study of the simultaneous determination of lead and barium as chromates by amperometric titration: B. PIHLAR and L. KOSTA. (23 *December* 1975)

Precipitation of zinc ammonium phosphate from homogeneous solution: G. SIVA REDDY and Y. KRISHNA REDDY. (24 *December* 1975)

A coulometric method for the assay of some easily oxidized organic substances with iodine as an oxidizing agent: L. E. EDHOLM. (29 *December* 1975)

Determination of 14 trace elements in cobalt by instrumental proton activation analysis: V. KRIVAN. (31 *December* 1975)

TALANTA ADVISORY BOARD

The Editorial Board and Publishers of *Talanta* take pleasure in welcoming the following new members to the Advisory Board of the journal.

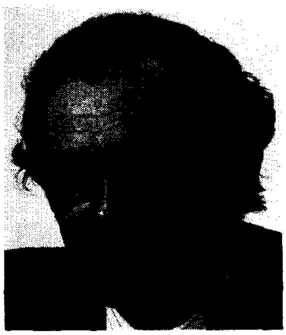
J. K. Foreman
H. V. Malmstadt
H. M. Ortner

They also wish to record their sincere thanks for the help given by

D. M. W. Anderson
F. E. Beamish
H. B. Mark Jr.

who retire from the Advisory Board.

Since graduating from London University Mr. Foreman's career has been largely divided between the Windscale Works of the United Kingdom Atomic Energy Authority and the Laboratory of the Government Chemist in London; he has been Deputy Government Chemist since 1970. His principle analytical interests have been in the field of radiochemistry, physical methods of analysis, separation techniques and automation of analytical techniques for both laboratory and chemical plant use. He is co-author of a recently published book entitled *Automatic Chemical Analysis*.



Professor Malmstadt was educated in chemistry at the University of Wisconsin and in electronics at Princeton and MIT during the war, when he was a Radar Officer in the U.S. Navy. He is now Professor at the University of Illinois and is kept busy by teaching, research, consultancy work, designing instruments, writing (8 books and over 120 research papers), lecturing throughout the world, and serving on numerous advisory boards. He has received several awards for his outstanding contributions to instrumentation and analytical chemistry.

Dr. Ortner was trained at the home of microanalysis, Graz, and since 1970 has worked at the chemical laboratory of Metallwerk Plansee, in Austria, and is now head of this laboratory. His work has ranged over a variety of topics, from clinical trace analysis to work on the refractory metals and their alloys. His current interests include X-ray fluorescence analysis, bulk and topochemical trace analysis of Mo, W, Nb, Ta and their alloys, and gel chromatography, especially the behaviour of isopoly and heteropoly acids. For several years he was Secretary of the Austrian Society for Microchemistry and Analytical Chemistry, and is now a member of several working groups dealing with standardization of methods.

Talanta, Vol. 23, p. i. Pergamon Press, 1976. Printed in Great Britain

PAPERS RECEIVED

Synthesis and evaluation of some pyridyl-substituted pyrimidines as copper-specific chromogenic reagents: A. A. Schilt, J. F. Wu and F. H. Case. (13 *November* 1975)

Concentration and separation of trace metals with an arsonic acid resin: J. S. Fritz and E. M. Moyers. (10 *November* 1975)

Zero-current bipotentiometric end-point indication with pretreated electrodes—IV. Use of pretreated silver electrodes: L. Kékedy and M. Serban. (26 *November* 1975)

A study on compounds of Cr(NCS)$_6^{3-}$ with Tl(I) and Ag(I): Alessandro de Robertis, Athos Bellomo and Domenico de Marco. (26 *November* 1975)

Use of Zeo-karb 226 and Dowex A-1 in the analysis of high purity zinc and zinc-base alloys for Tl and In: S. Ganapathy Iyer, P. K. Padmanabhan, L. D. Nair and Ch. Venkateswarlu. (26 *November* 1975)

Spectrophotometric determination of osmium with prochlorperazine maleate: H. Sanke Gowda and P. G. Ramappa. (27 *November* 1975)

Acid–base equilibria in ethylene glycol—III. Selection of titration conditions in ethylene glycol medium, and protolysis constants of alkaloids in ethylene glycol and its mixtures: P. Zikolov, T. Zikolova and O. Budevsky. (27 *November* 1975)

Some comments on the progress of analytical chemistry 1910–1970: T. Braun. (28 *November* 1975)

Synergic uranium extraction from phosphoric acid media with di(2-ethylhexyl)phosphoric acid and tri-n-octylphosphine oxide: Florin T. Bunus and Victoria C. Domocos. (1 *December* 1975)

Construction and analytical evaluation of a mercury(I)-sensitive extractive membrane electrode: G. E. Baiulescu and N. Ciocan. (2 *December* 1975)

Derivation of the sampling constant equation: C. O. Ingamells. (3 *December* 1975)

Physical studies on the compound of zirconium with tartrazine: A. Pogorevici Papandopol, D. Todor, S. Badilescu and G. E. Baiulescu. (8 *December* 1975)

Fitting equations to parabolic graphs: V. Rozenblum. (8 *December* 1975)

Interference by hypophosphite, pyrophosphate and phosphate in cerimetry and its removal: Surinder Kapoor and Y. K. Gupta. (9 *December* 1975)

Redox reactions in non-aqueous media. Determination of organotrithiocarbonates with iodine and iodine halides: Balbir Chand Verma and Swatantar Kumar. (9 *December* 1975)

Polarographic behaviour of chromium(VI) at various pH values: I. M. Issa, M. Tharwat, M. G. Allam and M. Ismail. (10 *December* 1975)

Thin-layer chromatographic separation of alkaline earth metals on microcrystalline cellulose: Koji Ishida, Fuyuki Oryu and Tomoshige Morita. (10 *December* 1975)

Talanta, Vol 23, pp i–ii Pergamon Press, 1976 Printed in Great Britain

PAPERS RECEIVED

Mixed-ligand complexes of lead(II) with dicarboxylic acids: S. C. BAGHEL, K. K. CHOUDHARY and J. N. GAUR. (14 *April* 1976)

Extraction chromatography of chloride complexes of osmium(III, IV and VI) on paper treated with tributyl phosphate and Amberlite LA-1 hydrochloride: S. PRZESZLAKOWSKI and A. FLIEGER. (20 *April* 1976)

The analysis of tungsten carbides by X-ray fluorescence spectrometry: K. KINSON, A. C. KNOTT and C. B. BELCHER (20 *April* 1976)

A new electrochemical analyser for nitric oxide and nitrogen dioxide: J. M. SEDLAK and K. F. BLURTON. (20 *April* 1976)

Structural effects in partition chromatography of amino derivatives of acridine in ion-association systems with HDEHP: EDWARD SOCZEWIŃSKI and DANUTA RATAJEWICZ. (21 *April* 1976)

A selective gravimetric method for simultaneous determinations of copper(II) and palladium(II) in presence of other ions with 3-(*o*-carboxyphenyl)-1-phenyltriazene *N*-oxide and application of the copper determination method to copper ore and alloys: S. C. SAHA, P. K. CHAKRABORTY and D. CHAKRABORTI. (21 *April* 1976)

Dissociation and homoconjugation equilibria of some acids and bases in *N,N*-dimethylformamide: EZIO ROLETTO and ADRIANO VANNI. (22 *April* 1976)

Determination of calcium in urine by titration with EDTA: BYRON KRATOCHVIL and PETER G. JEREMY. (22 *April* 1976)

Analytical application of *o*-hydroxymercuribenzoic acid, dithiofluorescein and mercurated fluorescein: MIECZYSLAW WROŃSKI. (22 *April* 1976)

Thermodynamic examination of galvanic cell measurements: BJØRN BERGTHORSSON. (26 *April* 1976)

Spectrophotometric determination of titanium in ores with cyclopentanone-2-carboxyanilide: SANAT KUMAR MANDAL and JYOTIRMOY DAS. (27 *April* 1976)

Equilibria of iron(III) complex formation with Methylthymol Blue and Xylenol Orange: TAKASHI YOSHINO. (28 *April* 1976)

Room temperature phosphorescence of several polyaromatic hydrocarbons: T. VO DINH, E. LUE YEN and J. D. WINEFORDNER. (3 *May* 1976)

Determination of aspirin and alkali metal salts of salicylic acid in complex mixtures: L. SZEKERES and J. A. JOSEPH (4 *May* 1976)

Titrimetric determination of ferrocyanide with zinc(II) sulphate solution, using heterocyclic azo-dyes as visual indicators: J. P. GUPTA, B. S. GARG and R. P. SINGH. (6 *May* 1976)

Determination of certain hydrocarbons by photometric titration with permanganate in non-aqueous medium: CZESLAW WYGANOWSKI. (7 *May* 1976)

Spectral and pH studies on some azo compounds: MAMDOUH S MASOUD, T. M. SALEM and M. ELHENAWI. (11 *May* 1976)

Investigation of phase growth kinetics during interaction of silicon single crystals and molybdenum thin films: B. I. FOMIN, A. E. GERSHINSKII and E. I. CHEREPOV. (12 *May* 1976)

Spectrophotometric determination of tellurium in concentrates and brasses by chloroform extraction of the tellurium(IV) hexabromide–diantipyrylmethane complex after separations by iron collection and xanthate extraction: ELSIE M. DONALDSON (13 *May* 1976)

Characteristic of the specificity of analytical methods—I: Non-specificity coefficients: LEON PSZONICKI (17 *May* 1976)

Use of hydroxylamine hydrochloride in the complexometric determination of manganese in pyrolusite: B. P. CHATTERJEE and S. K. MUKHOPADHYAY. (18 *May* 1976)

Equipment stability in IR spectrometry: A statistical approach by serial correlation: CANDIN LITEANU and IOANA ILEANA PANOVICI. (18 *May* 1976)

A compilation of nuclear data relevant to thermal-neutron activation analysis: T. D. MACMAHON. (21 *May* 1976)

Evolution des solutions aqueuses de niobates alcalins: existence de hauts polymères: ALINE GOIFFON and BERNARD SPINNER. (21 *May* 1976)

Photometrische Bestimmung von Quecksilber(II) im Nanogrammbereich mit Thio-Michlers-Keton: GERHARD ACKERMANN and HEINO RODER. (6 *May* 1976)

Study of mixed chelates by solvent extraction: Mixed chelates of indium with *β*-diketones in carbon tetrachloride and xylene media: M. SUDERSANAN and A K. SUNDARAM. (24 *May* 1976)

Matrix problems in the determination of lithium by flameless atomic-absorption spectrometry and their solution: AMITAL KATZ and NURIT TAITEL. (25 *May* 1976)

On the errors in acid-base determination by titration to preset pH values: ÅKE OLIN and BO WALLÉN. (26 *May* 1976)

L'acide phosphomolibdyque réactif pour la détermination spectrophotométrique de quelques dérivés de phénothiazine des produits pharmaceutiques: MARIA STAN, V. DORNEANU and GH. GHIMICESCU (27 *May* 1976)

2-Carboxy-2′-hydroxy-3′,5′-dimethylazobenzene-4-sulphonic acid (CHDMAS) as a spectrophotometric reagent for the simultaneous determination of nickel(II) and cobalt(II): B. K. Deshmukh, V. M. Parate and R. B. Kharat. (27 *May* 1976)

Microdetermination of thiourea and phenylurea with tervalent gold as oxidizing agent in alkaline medium: S. J. Rai, R P. Chamoli, G. C. Mishra and P. C. Gupta. (28 *May* 1976)

A new analytical procedure for quantitative determination of Al^{3+} in the presence of Fe^{3+}: Mansour Abedini. (28 *May* 1976)

Estimation of methionine and its metal complexes by oxidation with chloramine-T and dichloramine-T: N. M. M. Gowda and D. S. Mahadevappa. (3 *June* 1976)

Determination of aminocresol isomers by high-speed liquid chromatography: H. Sakurai and M. Kito. (3 *June* 1976)

Luminescence characteristics of several classes of drugs affecting the central nervous system: L. A. Gifford, J. N. Miller, J. W. Bridges and D. T. Burns. (4 *June* 1976)

Oxidations with ammonium hexanitratocerate(IV)—I: Milligram determination of polycyclic hydrocarbons: Q. S. Usmani, M. M. Beg and I. C. Shukla. (6 *June* 1976)

A modified oxidative microcoulometric method for determination of sulphur in hydrocarbons containing large amounts of chlorine: Anders Cedergren. (6 *June* 1976)

Talanta Vol 23, pp i-ii Pergamon Press 1976 Printed in Great Britain

PUBLICATIONS RECEIVED

Flame Emission and Atomic Absorption Spectrometry, Vol. 3—**Elements and Matrices**: JOHN A. DEAN and THEODORE C. RAINS (Eds.). Dekker, New York, 1975. Pp. xii + 674. $49.50.

At last the third and final part of this treatise has arrived, and it has been worth waiting for. Fourteen chapters by many well-known authorities selectively review the literature on the determination of some 80 elements, making comparisons between the emission, absorption and fluorescence modes when possible, and covering choice of wavelength, solvent, flame, and so on. Interferences and ways of dealing with them also receive due attention. A further eleven chapters cover specific applications where the methods have been found useful—analysis of biological fluids, food, petroleum products, glass, cement, metals (ferrous and non-ferrous) rocks, water, and air. Recent up-dating has ensured uniform coverage of the literature up to mid-1974. The volume is adequately indexed, and even without the first two volumes will prove a very useful reference work for most laboratories.

Chromatographic Analysis of the Environment: ROBERT L. GROB (Ed.). Dekker, 1975. Pp. x + 752. $49.50.

This book is too long—the organization into sections dealing with air pollution, soils, water pollution, and waste, each divided into chapters on gas-, liquid-, paper-, and thin-layer chromatography has resulted in too much overlap and in the subject matter being too widely dispersed (*e.g.*, pesticides are discussed in at least eight different places). It seems scarcely necessary to devote over 70 pages to the theory of chromatography when this is already covered in so many other texts. The law of propagation of errors is illustrated in an all too common way in the quotation "average error ranging from 0·6716 to 2·9190 g/ml"—apparently neither editor nor the original writer has stopped to consider whether such figures are meaningful or not. But to be fair, one must admit that the volume represents a detailed review of a large section of the literature of analytical chemistry, albeit very much a western view, and with few references later than 1971.

Power Sources, 5—Research and Development in Non-mechanical Electrical Power Sources: D. H. COLLINS (Ed.). Academic Press, London, 1975. Pp. xii + 740. £21.00; $54.00.

The texts of 47 papers presented at the 9th International Symposium in Brighton, 1974, are presented in this volume. Most papers deal with aspects of electrochemical cells or the individual electrodes. Edited discussions of the papers are also included. The contents will be of interest to those involved in development work on electrochemical cells.

Trace Element Analysis: VLADO VALKOVIĆ. Taylor & Francis, London, 1975. Pp. x + 229. £7.00.

This nicely produced little book gives a succinct account of a very wide field indeed, ranging from theories of the origin of the elements to the latest methods for finding and determining minute traces of the elements and their compounds. There is a lot of compression, of course, and sometimes one feels that other source books might have been mentioned in the text, since some of those given are a little out of date, but the book has pace, and can be dipped into almost anywhere with profit to the reader. At the price it is a good buy.

A Handbook of Organic Analysis, 5th Ed.: H. T. CLARKE, revised by B. HAYNES. Arnold, London, 1975. Pp. x + 291. £12.00, boards, or £4.95, paper.

There are already so many undergraduate texts on organic analysis that one wonders whether this book can possibly hope to corner a share of the market. However, it has been nicely produced on good quality paper, and the price of the paperback edition is not much greater than those of other comparable texts. The usual topics—preliminary tests, examination for functional groups, separation of mixtures, preparation of derivatives, and determination of physical properties—are covered thoroughly but succinctly, although the language does sometimes give away the fact that the first edition of this book appeared in 1911. A small section on spectroscopic methods is included, but this is not really adequate for a chemistry degree course nowadays. Like most similar texts, this book includes a number of classified tables of organic compounds, but these tables are more extensive than usual, since they include a large number of structural formulae, and much detailed information about the particular reactions of each individual compound. Another unusual feature of this book is the inclusion of two chapters on quantitative organic analysis—one on elemental analysis and the other on functional group analysis. The choice of methods is generally satisfactory, although some may prefer not to ask a student to carry out a digestion with sulphuric–perchloric acid mixture. The procedures are sometimes discussed in too much detail, particularly when such details refer only to a particular model of the apparatus concerned. Inclusion of some references to the original literature would also be an improvement. However, these chapters offer a sound and thorough introduction to quantitative organic analysis, and it is to be hoped that future organic chemists who have used this book will have a much greater understanding of the intricacies and problems of organic microanalysis.

Chemical Analysis of Organometallic Compounds, Vol. 4: T. R. CROMPTON, Academic Press, London, 1975. Pp. x + 302, £9.40.

Volume 4 of this series covers the elements phosphorus (244 pages), arsenic (23 pages), antimony (2 pages) and bismuth (2 pages), and also mentions that no references have been found to the analytical chemistry of organometallic compounds of vanadium, niobium, tantalum or palladium, although it is difficult to see why palladium is included as a Group VA element. As in previous volumes, methods are given for determination of elements, functional groups, and the compounds themselves. Procedures are given in detail, so the methods can be used without reference to the original literature. The literature is covered only to 1970.

Radioactivity and Atomic Theory: FREDERICK SODDY, edited with commentary by THADDEUS J. TRENN. Taylor & Francis, London, 1975. Pp. xvii + 518. £12.00.

This volume consists of facsimiles of Soddy's Annual Progress Reports on Radioactivity, over the period 1904–1920, together with an annotated review and a biographic sketch. It will be a handy acquisition for those libraries that do not possess the originals.

Scandium: Its Occurrence, Physics, Chemistry, Metallurgy, Biology and Technology: C. T. HOROVITZ (editor), K. A. GSCHNEIDNER JR., G. A. MELSON, D. H. YOUNGBLOOD and H. H. SCHOCK. Academic Press. New York, 1975. Pp. xvi + 598. £16.00, $42.25.

From eka-boron to 1974, all one might wish to know about scandium, nicely printed and reasonably priced for these days. The interdisciplinary approach gives several books for the price of one.

Talanta, Vol 23 pp i–iii Pergamon Press, 1976 Printed in Great Britain

PAPERS RECEIVED

Assay of *p*-aminobenzenesulfonamides with chloramine-T: Norman M. Trieff, V. M. Sadagopa Ramanujam and G. Cantelli Forti. (8 *June* 1976)

Juglone and lawsone as acid–base indicators: Krishna C. Joshi, P. Singh and Girraj Singh. (8 *July* 1976)

Colorimetric and volumetric determination of some penicillins with ammonium vanadate: E.-Sebai A. Ibrahim, Y. A. Beltagy and M. M. Abe El-Khalek. (8 *July* 1976)

Spectrophotometric studies on complex formation of niobium(V) with 7-phenylazo-8-hydroxyquinoline-5-sulphonic acid: A. Salaam A'Azmi and G. C. Shivahare. (13 *July* 1976)

Determination of 30 elements in coal and fly-ash by thermal and epithermal neutron activation analysis: J. J. Rowe and E. Steinnes. (13 *July* 1976)

Thermodynamic parameters and stability constants of Cu(II), Ni(II), Co(II), Zn(II), Pd(II), Rh(III) and Pt(IV) complexes with diaminoacetylurea: P. C. Srivastava, S. K. Adhya and B. K. Banerjee. (13 *July* 1976)

Ultraviolet-absorption spectra of colourless molybdate complexes of phosphorus compounds—I. Formation of pentamolybdodiphosphate complex and its absorption spectra: Toshitaka Hori. (13 *July* 1976)

Ultraviolet absorption spectra of colourless molybdate complexes of phosphorus compounds—II. Formation of pentamolybdodiphosphite complex and its absorption spectra: (13 *July* 1976)

Chromazurol S ion-selective electrode for chelatometric titration: M. Kataoka, M. Shin and T. Kambara. (13 *July* 1976)

Organic phase species in the extraction of molybdenum(VI) by Aliquat 336: A. S. Vieux, N. Rutagengwa, L. Basolila and C. Mulenga. (13 *July* 1976)

An abbreviated fire-assay/atomic-absorption method for the determination of gold and silver in ores and concentrates: P. E. Moloughney. (13 *July* 1976)

Homogenitätskriterien für festkörperanalytische Untersuchungen: Klaus Danzer and Ludwig Küchler. (13 *July* 1976)

Etude à l'aide d'une microsonde électronique de trouvailles archéologiques gauloises: C. Triché, G. Fouet and G. Saves. (4 *June* 1976)

Optimization of the synergic extraction of iron(II) from water into cyclohexane with hexafluoroacetylacetone and tri-n-butyl phosphate: Michael L H. Turoff and Stanley N. Deming. (16 *July* 1976)

Behaviour of lead(II) in stripping voltammetry from a stationary, flat, thin-layer mercury electrode: A. E. Charola and R. J. Manuele. (8 *July* 1976)

Letter to the editor: J. Versieck, F. Barbier, J. Hoste, R. Cornelis and J. de Rudder. (16 *July* 1976)

The rapid separation and determination of rare earth elements by the use of the ligand vapour gas-chromatographic method: Taitiro Fujinaga, Tooru Kuwamoto and Takashi Kimoto. (20 *July* 1976)

Direct potentiometric determination of nitrate nitrogen and pH in soil suspensions: V. Simeonov, I. Asenov and V. Diadov. (20 *July* 1976)

Formation constants of Pd^{2+}, Pt^{2+}, Rh^{3+}, Fe^{3+} and Pt^{4+} chelates of biuret: P. C. Srivastava and B. K. Banerjee. (23 *July* 1976)

Quantitative ion-exchange separation of submicrogram amounts of Fe^{3+} from phosphate medium: J. W. Mitchell and V. Gibbs. (23 *July* 1976)

Determination of calcium in cement by flame emission with strontium as an internal standard: I. Voinovitch, G. Legrand and J. Louvrier. (23 *July* 1976)

Liquid–liquid extraction of Fe(III), Zr(IV) and U(VI) with 1-phenyl-3-methyl-4-caproyl-pyrazolone-5: M. Y. Mirza and E. C. Okafor. (28 *July* 1976)

Tensammetric determination of microgram amounts of vanadium by catalytic oxidation of *o*-aminophenol: Tsuyoshi Nomura and Genkichi Nakagawa. (28 *July* 1976)

Iodometric determination of peroxydisulphate, with copper(II) as catalyst, at room temperature: Ratan Swaroop. (28 *July* 1976)

Vanadium as an oxidizing agent—I. Titrimetric determination of As(III), with iodide as catalyst: Ratan Swaroop. (28 *July* 1976)

A direct method of estimating cyanide ion in metal salts and complexes by means of chloramine-T, dichloramine-T and lead tetra-acetate: B. T. Gowda and D. S. Mahadevappa. (28 *July* 1976)

Polarographic determination of some metal diethyldithiocarbamates: R. Cordova, A. Oliva and R. Schrebler. (19 *August* 1976)

Acetylacetone as chelating reagent, extracting solvent, and electrolysis medium. Polarographic determination of uranium(VI) and iron(III): Taitiro Fujinaga and Heung Lark Lee. (19 *August* 1976)

Trace enrichment with activated carbon. Determination of trace metals in high-purity zinc and zinc(II) nitrate: M. Kimura. (19 *August* 1976)

The determination of lead and antimony in firearm discharge residues on hands by anodic stripping voltammetry: N. K. Konanur and G. W. van Loon. (19 *August* 1976)

Preparation and properties of *N*-arylhydroxamic acids containing a triple bond in the side-chain. Spectrophotometric determination of vanadium(V) with *N*-phenylphenylpropiolohydroxamic acid: B. S. Chandravanshi and V. K. Gupta. (20 *August* 1976)

Complexometric determination of copper, calcium and phosphate in Cu and Ca hydroxyapatite: Prema N. Patel and S. V. Chiranjeevi Rao. (20 *August* 1976)

Contributions to the basic problems of complexometry—XXVI. Determination of calcium in the presence of large amounts of magnesium: Rudolf Přibil and Jiří Adam. (23 *August* 1976)

Determination of the chemical forms of trace metals in natural waters: T. M. Florence and G. E. Batley. (23 *August* 1976)

The determination of orthophosphate after precipitation as Ag_3PO_4, using a silver-sensitive electrode: E. J. Duff and J. L. Stuart. (23 *August* 1976)

A new basis for the analysis of ion activity-coefficient data—I. The parabolic law: L. S. Levitt and H. Widing. (4 *August* 1976)

Use of a periodate-sensitive perchlorate ion-selective electrode in the kinetic ultramicrodetermination of manganese(II) based on a catalytic effect on the periodate–acetylacetone reaction: C. E. Efstathiou and T. P. Hadjiioannou. (23 *August* 1976)

Thermodynamics of the complexes of lead(II) with *m*-methoxybenzoate in aqueous medium and effect of non-aqueous solvents on the overall formation constants: S. C. Baghel, K. K. Choudhary and J. N. Gaur. (23 *August* 1976)

Studies on the polarographic reduction of the azomethine bond in coupled products of β-keto esters with aryldiazonium chlorides: Wahid U. Malik, R. N. Goyal and Rajeev Jain. (23 *August* 1976)

Acid–base titrations by stepwise addition of equal volumes of titrant with special reference to automatic titrations—III. Presentation of a fully automatic titration apparatus and of results supporting the theories given in the preceding parts: Lennart Pehrsson and Folke Ingman (24 *August* 1976)

Acid–base titrations by stepwise addition of equal volumes of titrant with special reference to automatic titrations—IV. Photometric titration of an acid: Lennart Pehrsson and Folke Ingman. (24 *August* 1976)

The "intrinsic" solubility of insoluble salts: L. S. Levitt. (2 *August* 1976)

Calibration of a photographic emulsion for spectrographic analysis, using a desk programmable computer: Bernard H. Strauss. (2 *August* 1976)

Extractive spectrophotometric determination of uranium (UO_2^{2+}) with Malachite Green: S. C. Dubey and M. N. Nadkarni. (24 *August* 1976)

Oxidation of sulphide minerals—I. Determination of ferrous and ferric iron in samples of pyrrhotite, pyrite and chalcopyrite: H. F. Steger. (24 *August* 1976)

Application of polyethylene glycol for "electrochemical masking" in DC-polarography: Z. Łukaszewski. (24 *August* 1976)

Atomic-absorption spectrophotometric determination of traces of manganese with thenoyltrifluoroacetone: Kaneharu Kato. (24 *August* 1976)

Spectrophotometric determination of arsenic in concentrates and copper-base alloys by the molybdenum blue method after separations by iron collection and xanthate extraction: Elsie M. Donaldson. (26 *August* 1976)

Microscopic acid dissociation constants of 3,4-dihydroxyphenylalanine (DOPA): T. Ishimitsu, S. Hirose and H. Sakurai. (26 *August* 1976)

Ultraviolet absorption spectra of colourless molybdate complexes of phosphorus compounds—III. Molybdate complexes of monosubstituted phosphorus compounds: Toshitaka Hori. (26 *August* 1976)

Spurenanalyse in Wolfram: Eisen. Ein kritischer Vergleich standardisierter Analysenverfahren: H. M. Ortner and V. Scherer. (26 *August* 1976)

Polarographic behaviour of cadmium(II) in the presence of mixed ligands: P. D Jadhav, R. G. Bidkar, D. G. Dhuley and R. A. Bhobe. (27 *August* 1976)

Polarographic behaviour of *trans*-decafluoroazobenzene: B. A. Akrawi and Z. Y. Al-Saigh. (27 *August* 1976)

A new boron-specific resin derived from guar gum: Rita Bhatnagar and N. K. Mathur. (30 *August* 1976)

Colour reactions of iron(III) with salicylhydroxamic acid and its substituted derivatives: Ratnakar G. Deshpande and D. V. Jahagirdar. (2 *September* 1976)

Selective determination of antimony(III) and antimony(V) with ammonium pyrrolidinedithiocarbamate, sodium diethyldithiocarbamate and dithizone by atomic-absorption spectrometry with a carbon-tube atomizer: Toshihiko Kamada and Yuroku Yamamoto. (2 *September* 1976)

High-precision gravimetric coulometry using the silver–perchloric acid coulometer: Titration of arsenious oxide with electrogenerated iodine: G. M. Newton. (30 *August* 1976)

Separation and determination of lead(II) by extraction with thiobenzoylacetone: M. V. R. Murti and S. M. Khopkar. (7 *September* 1976)

A method for following the kinetics of the reaction of aromatic amines with formaldehyde in acid medium: M. R. G. Nayar and D. J. Francis. (8 *September* 1976)

Determination of thiol groups with *o*-diacetoxyiodobenzoate: Ashutosh Srivastava and Sameer Bose. (8 *September* 1976)

Aqueous acetic acid as a medium for the facile titration of iron(II) in the presence of perchloric acid, with ferroin as redox indicator: G. Gopala Rao and S. G. Viswanath. (9 *September* 1976)

The analytical potential of gas-phase molecular absorption spectrometry for the determination of anions in solution: Malcolm S. Cresser and Peter J. Isaacson. (10 *September* 1976)

Detection and measurement of volatile hydrocarbons at ambient concentrations in the atmosphere—a review: P. Leinster, R. Perry and R. J. Young. (10 *September* 1976)

Literature interpolation—a possible source of error in flame atomic-absorption spectrometry: Malcolm S. Cresser. (10 *September* 1976)

Development and publication of new polarographic and related methods of analysis: Louis Meites, Bruce H. Campbell and Petr Zuman. (10 *September* 1976)

The effect of trace quantities of cyanide on the extraction of copper diethyldithiocarbamate: E. O. Umeh. (13 *September* 1976)

Ultraviolet absorption spectra of mercury–iodide complexes and the effect of low concentrations of cyanide: E. O. Umeh and O. O. Fadiya. (13 *September* 1976)

Characteristics of the specificity of analytical methods—II. Estimation and experimental verification of the non-specificity coefficients: Leon Pszonicki and Anna Bieńkowska. (13 *September* 1976)

Simple and high-precision determination of lead in whole blood by APDC–MIBK extraction and atomic absorption: Shozo Toda. (14 *September* 1976)

Synthesis of a new heterocyclic azo dye 1-(2-lepidylazo)-2-acenaphthylenol and spectrophotometric investigations of its metal chelates: Ishwar Singh, B. S. Garg and R. P. Singh. (15 *September* 1976)

Über Chemolumineszenzerscheinungen bei der Reaktion zwischen Sulfid und Hypohalogenid in wässriger Lösung: Dieter Klockow and Jürgen Teckentrup. (15 *September* 1976)

Aerosol deposition in furnace atomization: J. P. Matousek. (17 *September* 1976)

Annual Subscription Rates (1976)

Published monthly—1 volume per annum

$125—For libraries, government laboratories, research establishments, manufacturing houses and other multiple-reader institutions

$10—For *bona fide* students, who place their orders with the publisher together with a note from their professor or tutor certifying their status

Specially Reduced Rates to Individuals

In the interests of maximizing the dissemination of the research results published in this important international journal we have established a three-tier price structure. An individual whose institution takes out a library subscription, may purchase a second or additional subscriptions for personal use at a much reduced rate of U.S. $25.00 per annum.

All subscription enquiries should be addressed to the Subscription Fulfillment Manager, Pergamon Press, Headington Hill Hall, Oxford OX3 0BW.

Payments must be made in advance

Microform Subscriptions and Back Issues

Current subscriptions and back files on microfilm as well as back issues in the regular editions of all previously published volumes are available from Microforms International Marketing Company (MIMC) a Division of Pergamon Press Inc., at the most convenient address:

Fairview Park, Elmsford,
New York 10523, U.S.A.

Cowper House, Olney,
Bucks, England.

Publishing and Advertising Offices

American Continent: Pergamon Press Inc., Maxwell House, Fairview Park, Elmsford, New York 10523, U.S.A.
Rest of the World: Pergamon Press Ltd., Headington Hill Hall, Oxford OX3 0BW, England

PUBLICATIONS RECEIVED

Handbook of Enzyme Technology: A. WISEMAN, editor. Ellis Horwood, Chichester, 1975. pp. 275. $15.00.

There have been considerable developments in the biochemistry of enzymes, stemming largely from fundamental studies on their large scale application in the food and pharmaceutical industries. Professor Wiseman, especially in his annual "Summer Schools" on fermentation, has done much to establish a bridge between academic and industrial research. This book is a further contribution to this liaison. In a short volume but with a high information density, it offers a particularly complete overall view of the problems posed by preparation and use of enzymes in all their forms. After a brief theoretical survey of the nature, mode of action, kinetics and analysis of enzymes, the book deals with culture of micro-organisms, sources, methods of extraction, and purification of enzymes, methods of fixing them on insoluble supports, methods of conferring new properties on enzymes, and finally a panoramic view of the applications of enzymes in industry and research. A very stimulating aspect of this last chapter is its suggestions of new applications. The balance between theory and practice is excellent throughout. The contributors' personal experience is well illustrated by their justifiably severe criticism of manufacturers who supply insufficient information or use peculiar activity units. The chapter on transfer coefficients and scale-up problems in fermentation is admirably clear and concise. Other notable features are the fullness of the bibliography and the list of suppliers of equipment and enzymes. The only criticism is that though the book is nominally divided into two parts—theory and practice—both aspects occur in both halves, and the reader needs to go back and forth to find all the information on a particular point, but this is a minor drawback in an outstandingly useful book that fully justifies the name of handbook.

ICP Information Newsletter: RAMON M. BARNES, editor. University of Massachusetts. $30.00 per annum (12 issues). $3.00 for individual issues.

This new publication is intended to serve as a vehicle for information and opinions on use of inductively coupled plasma discharge sources in spectrochemical analysis. It includes contributed papers, abstracts, information about equipment commercially available, news of conferences, etc. Further information is obtainable from Dr. Barnes, Department of Chemistry, GRC Tower I, University of Massachusetts, Amherst, Massachusetts 01002.

Chemical Information Systems: J. E. ASH and E. HYDE, Ellis Horwood, Chichester, 1975. pp. x + 309. £12.00.

This book is an admirable introduction to a complex subject, and it should be read by anyone contemplating making use of modern information systems. The first chapters discuss in general terms the nature and development of chemical information systems, methods of organizing information for efficient retrieval by computer, and the cost-effectiveness and cost-benefits of these complex systems. Later chapters cover in some detail the methods which are used to represent chemical structures (mainly organic) in information systems, with particular reference to the Wiswesser Line-Formula Notation, the Dyson-IUPAC notation, and the use of connection tables. Two industrial systems (Hoechst's GREMAS and I.C.I.'s CROSSBOW) are discussed in some detail, to illustrate the wide range of techniques involved in a complete system. Methods of file-screening, and the problems of indexing chemical reactions are also discussed. The final chapter, Information Science in Relation to the Chemist's Needs, discusses the needs and problems of inorganic, physical, organic, engineering and macromolecular chemistry: readers of *Talanta* will be disappointed that analytical chemistry is not mentioned.

Talanta, Vol 23, p iii Pergamon Press, 1976 Printed in Great Britain

PUBLICATIONS RECEIVED

Spectrophotometric Determination of Elements: ZYGMUNT MARCZENKO, Horwood, Chichester, 1976. Pp. xi + 643. £19.50.

All of those associated with the translation and revision of this book from the Polish (1968) and Russian (1971) are to be congratulated. It is all that the analyst could desire for a one-volume manual and reference text on spectrophotometry. The first hundred pages discuss the principles of the method, the principal organic reagents and procedures for preconcentration and separation. The rest of the book describes for each element two or three tested methods of determination and reviews suitable separation procedures and alternative methods of determination. The presentation is extremely clear. The judgements of alternative methods are both comprehensive and fair, whilst the accounts of the selective procedures are full of the practical details necessary for their application. The layout is similar to Sandell's well known text, but this is a very individual work. Professor Marczenko has achieved the remarkable feat of extracting the essence of 7000 references and distilling from them an invaluable, judicious and readable book, which should be within easy reach of all who use spectrophotometric methods. The publisher has co-operated by providing a good typographical layout and binding which allows the book to be handled comfortably and to be laid open on the bench.

Handbook of Organic Reagents in Inorganic Analysis: Z. HOLZBECHER, L. DIVIŠ, M. KRÁL, L. ŠŮCHA and F. VLÁČIL, Horwood, Chichester, 1976. Pp. 734. £19.50.

Organic reagents play a very important part in inorganic analysis, as this monograph illustrates very comprehensively. The earlier chapters give a critical account of theoretical aspects of the structure and properties of organic reagents and their compounds with metals, covering such varied topics as the nature of the bonds in complexes, absorption spectra of reagents and their complexes, and methods of investigating structures of complexes. In the treatment of solution equilibria which follows, the topics discussed include thermodynamics and kinetics of complexation reactions, redox reactions, partition and precipitation equilibria, and masking. Also included is an account of the applications of organic reagents in separations, distillation, extraction, chromatography, ion-exchange, spot tests, gravimetry, titrimetry, photometry, kinetic methods and ion-selective electrodes. This section of the book could well serve as a general text for students of analytical chemistry. The later chapters of the book describe practical applications of organic reagents. In chapter 5, for each element (or group of closely related elements) the most useful reagents are tabulated, with, for each, the method of use, the relevant conditions, and the range of application. The final chapter is a selective compilation of currently-used organic reagents: in addition to the reagents for spectrophotometry, fluorimetry, gravimetry and spot tests which frequently appear in lists like this, it includes numerous examples of masking agents, buffers, indicators (acid-base, redox, metallochromic, adsorption), complexing titrants, extractants and ion-exchangers. The comprehensive index and extensive cross-referencing between chapters and sections add greatly to the practical utility of this part of the book.

NOTICES

XXth COLLOQUIUM SPECTROSCOPICUM INTERNATIONALE
7th INTERNATIONAL CONFERENCE ON ATOMIC SPECTROSCOPY

The XXth Colloquium Spectroscopicum Internationale and the 7th International Conference on Atomic Spectroscopy will be held jointly at Prague, Czechoslovakia, from August 30, to September 7, 1977.

The meeting will cover all branches of atomic and molecular spectroscopy. The official languages are English, French, German and Russian.

All correspondence should be directed to:

Secretariat XX.C.S.I. and 7. ICAS
Technical University Prague
16628 Prague, Suchbatarova 5
Czechoslovakia

INTERNATIONAL SYMPOSIUM ON MICROCHEMICAL TECHNIQUES 1977

22–27 May 1977, Davos, Switzerland

The topics covered by the Symposium will include new or optimized chemical and physical methods for qualitative and quantitative analysis of elements, organic and inorganic compounds, with reference either to very small samples (MICROANALYSIS) or to very low concentrations (TRACE ANALYSIS), concentration profiles, microprobe and surface analysis, and microchemical preparations, and also the application of these techniques to chemistry, pharmacy, biochemistry, environmental studies, clinical chemistry, forensic science, archaeology, geology, geochemistry, cosmochemistry, materials science, etc.

FOURTH SAC CONFERENCE 1977

The Fourth SAC Conference of the Analytical Division of the Chemical Society will be held in the University of Birmingham, England, 17–22 July 1977. Plenary lectures will be given by Professors R. Belcher, V. A. Fassel and Yu. A. Zolotov among others. The scientific programme will also contain invited lectures on topics of major current interest, contributed papers, and group discussion sessions. An extensive social programme is also planned.

Further information can be obtained from The Secretary, Analytical Division, Chemical Society, Burlington House, London W.1. Intending delegates who wish to offer papers should contact the Secretary as soon as possible. Abstracts (about 200 words) must be submitted before 31 December 1976.

ERRATUM

In Fig. 4 (on p. 236) in the paper by Takayoshi Yoshimori and Noriyuki Sakaguchi, *Talanta*, 1975, **22**, 233, the numbers on the ordinate should be 25, 50, 75 and 100 ppm of water, not 50, 100, 150, 200.

PUBLICATIONS RECEIVED

Operational Amplifiers in Chemical Instrumentation: Robert Kalvoda. Horwood, Chichester, 1975. Pp. 178. £7.50.

Too many chemists refuse to give even a moment's thought to what goes on inside their many "black boxes", while some who do are baffled rather than helped by textbooks on electronics. For such people this book is written—by the expert, himself a chemist, for other chemists. The treatment of circuit theory and the concept of the operational amplifier (OA) as a design element is thorough but also clear and readable, with numerical examples used frequently to illustrate the points being made. Some fifteen basic types of circuits built round OA's are discussed in detail (such as followers, differentiator, integrator, log-converter, active filter, regulator *etc.*). The measurement and significance of the most important parameters of an OA are outlined in another chapter. A substantial section of the book is devoted to applications of OA's in the basic circuits combined to form complete instruments, *e.g.*, for measurement of temperature, potential, current, light intensity or absorbance, and in equipment for polarography and coulometry. This book can be strongly recommended both as interesting reading and as a working manual.

Encyclopedia of Electrochemistry of the Elements, Vol. IV: Allen J. Bard (Ed.). Dekker, New York, 1975. Pp. 488, $79.50.

As successive volumes of this series appear it becomes increasingly evident that it is likely to constitute the leading work of reference in the field of electrochemistry for many years to come. A firm editorial hand has ensured that all contributors work to the same format so that one quickly gets to know where to look for any specific piece of information. The group of authors in this volume is quite international (USA, UK, Poland, USSR) and the standard of the English is consistently high with the result that the reviewer could enjoy reading several chapters and comparing the chemistry of the elements dealt with. The elements in this volume are Au, F, Po, S, Sb, Se, Sn, Te and Tl.

Thermodynamics of Fluids: K. C. Chao and R. A. Greenkorn. Dekker, New York, 1975. Pp. xi + 553. $29.75.

The subtitle of this book "An Introduction to Equilibrium Theory" defines the scope of the treatment. The fundamentals of classical thermodynamics are summarized in the first chapter. This is followed by a development of the concepts of partition functions and the role of intermolecular forces. Chapter 3 deals with the thermodynamic properties of gases and gas mixtures and introduces the ideas of fugacity and energy functions. The text continues with the definition of ideal solutions and theory is then applied to real solutions. The book ends with a study of phase equilibria including chemical and vapor–liquid equilibria and adsorption. The book is written from the point of view of the process engineer and it includes at the end of each chapter useful lists of data, problems and references.

Aldehydes—Photometric Analysis, Vols. 1 and 2: Eugene Sawicki and Carole R. Sawicki. Academic Press, London, 1975. Pp. xxviii + 283 and xiv + 344. £10.50 and £10.80.

These are the first two volumes of an exhaustive treatise on the analysis of aldehydes written by the acknowledged experts in the field. Each aldehyde is discussed in a separate chapter unless the treatment can be applied to a similar group of compounds. Each chapter gives the physical properties of the aldehyde or group of aldehydes and outlines the spectral characteristics. Details of suitable methods of assay are then provided together with a list of the relevant references. Each volume has a separate author and subject index.

PUBLICATIONS RECEIVED

Gas and Liquid Chromatography Abstracts Cumulative Indexes 1969–1973: Compiled and edited by C. E. H. KNAPMAN, Applied Science Publishers Ltd., Barking, 1976. Pp. 381. £16.00.

The dust-jacket of this book says that to obtain maximum benefit from the publication it is advisable to have the bound volumes of *Gas and Liquid Chromatography Abstracts*. The reader (unless an avid reader of telephone directories as a hobby) is more likely to think that the book is of very little use at all *unless* the abstracts themselves are readily available. Except for the umlaut and accents on French names, no notice is taken of diacritical marks in spelling authors' names, which seems somewhat impolite. The subject index is arranged in seven sections dealing with subjects such as apparatus and technique; sample type; applications and specialized separations. The sections are themselves subdivided into narrower categories, within which there is an alphabetical listing of the subjects of the abstracts. The index is therefore arranged in a way that involves a two-step process for finding a particular bit of information. It would have been helpful if the running headlines had given the section numbers and/or names instead of the uninformative "Author Index" or "Subject Index". One look at the page makes it obvious which is which!

Principles and Practice of Analytical Chemistry: F. W. FIFIELD and D. KEALEY, International Textbook Co., London, 1976. Pp. vi + 378. £4.50 limp, £8.50 cased.

According to the back cover, the purpose of this book is to provide the non-specialist with a broad understanding of the principles of modern analytical chemistry. To a large extent it succeeds in its aim, especially when it is dealing with instrumental methods, but there are some surprising omissions and oversimplified statements, which may prove misleading. For example, the statement "When the reduction potentials of two species differ by 0.1 V or more, the resulting redox reaction will proceed rapidly and stoichiometrically so that it may be used as the basis for a titrimetric procedure". Apart from the false logic caused by the English, there are at least two bits of wrong information in this statement, one of which is put right (by implication) on the following page. Older readers will deplore the use of the term "strong hydrochloric acid", and the slavish devotion to SI units when the use of "*M*" instead of "mol dm^{-3}" would have saved a great deal of type, paper and reading strain. On the whole, in spite of the numerous blemishes, the book is a useful survey of the subject, though much the stronger on the instrumental side. It must be stressed, however, that the class of reader for whom the book is intended will not usually be well enough informed to identify and correct the errors.

New Developments in Separation Methods: edited by ELI GRUSHKA, Dekker, New York, 1976. Pp. viii + 246. $23.50.

This is a selection of papers from Volumes 9 and 10 of *Separation Science*, covering some of the less widely known modern separation techniques and the newer applications of old ones. Topics covered include the logistics of separation, liquid membrane technique, clathrates, electrochemical methods, foam technique, and ultracentrifugation.

Chelates in Analytical Chemistry, Volume 5: edited by H. A. FLASCHKA and A. J. BARNARD, JR., Dekker, New York, 1976. Pp. xiii + 328. $36.50.

With its two articles, one on polyaminocarboxylic acids as colorimetric reagents, the other on *o*-dihydroxy compounds as reagents, this volume brings the series to a close. The present volume keeps up the standards set and will be useful to all who are interested in the applications of chelation in analysis.

Chemical Analysis, Second Edition: H. A. LAITINEN and W. E. HARRIS, McGraw-Hill, New York, 1975. Pp. xix + 611. £12.95.

This book, like its predecessor, should be prescribed reading for anyone aspiring to call himself an Analytical Chemist. Once again, the emphasis of the text is on the "processes occurring in sampling, separation and measurement, emphasizing the chemistry, rather than the physics, of analysis", because "knowledge of chemical reactions is important, first because it is needed for direct application to classical methods, and second because it is essential in instrumental methods where chemical reactions are involved in operations preceding the use of an instrument in the final measurement." The immediate overall impression of this new edition is that of greater maturity: the authors have been better able to stand back from the subject, enabling them to explain it better to the uninitiated. Despite new chapters on chemical standards, ion-selective electrodes, liquid–liquid extraction, separations, and two on chromatography, the total number of chapters, and (surely by coincidence!) the number of pages remain the same as in the first edition. To make room for the new material, the section on precipitations has been reduced from eight chapters to four, and the section on redox reactions has been shortened by omitting some of the less important applications. Some chapters, such as those on equilibrium and activity and sampling, remain essentially unchanged, but others, like those on complexation equilibria, reaction rates, and statistics, have been almost completely rewritten Usually, rewriting was necessary to allow incorporation of new ideas and material, but with the statistics chapter, the content is largely unchanged, but it is presented in a much more comprehensible style. As before, many important references to the original literature are included: in this edition, the literature is covered to the end of 1973. Undoubtedly, many previous devotees will find that their favourite topics have been omitted, and will wish to retain their copies of the first edition—but they should definitely give high priority to the acquisition of the second edition as a "companion volume". To those previously unacquainted with "Laitinen", this book is even more heartily recommended.

Inorganic Chemistry: R. B. HESLOP and K. JONES, Elsevier, Amsterdam, 1976. Pp. viii + 830. Dfl. 49.00, $17.95.

This is the successor to "Heslop and Robinson", so well known that it was hardly ever referred to by its title. Like its predecessor, this is a welcome blend of traditional "descriptive" inorganic chemistry with modern "theoretical" inorganic chemistry, clearly set out and easily understood. It also manages to instil a good deal of common sense appraisal into its treatment of current fashions and ideas, and utters appropriate warning notes where confusion may arise in the mind of the unwary. Thus at a time when the use of equivalents is decried on the grounds that the term equivalent is not unequivocal, it is pleasant to see a clear warning that the sacred animal the "mole" needs exactly the same kind of qualification as the equivalent does (specification of what the quantity refers to). However, most good things have a flaw somewhere, and here it takes a particularly unfortunate form, namely the use of "p" as an operator to mean $-\log X$ in one context, and $+\log X$ in another, especially as the latter use is accompanied by the statement that it is frequently used for the particular purpose. The use of SI units in the shape of "kmol m^{-3}" will stop most analysts dead in their tracks, and the amount of effort needed to translate SI units *into each other* (not to mention writing them out) is sufficient condemnation of the "prohibition" of well known, universally used, and readily understood units such as mole/litre (*M* for short). The use of pm for units in dealing with atomic radii also comes as rather a shock to the older reader. About a fifth of the problems are analytical in nature, although analysis itself seems to manage to escape mention. The index is comparatively poor.

Advances in Chromatography, Vol. 13: J. C. GIDDINGS, E. GRUSHKA, R. A. KELLER and J. CAZES (Eds.) Dekker, New York, 1975. Pp. 374. $28.50.

Two more editors have been added to give increased breadth to the subject matter of the series. Volume 13 is nevertheless, cast very much in the style of its predecessors. Some of the articles are very theoretical, but practicalities are discussed by Gouw and Jentoft (Supercritical fluid chromatography), Algelt and Gouw (Chromatography of heavy petroleum fractions) and Leathard (Qualitative analysis by GC). All of these are interesting and of sufficient generality to be read with pleasure and interest by the non-specialist.

Ultra-violet and Visible Spectroscopy, 3rd Edition: C. N. R. RAO, Butterworths, London, 1975. Pp. VII + 242. £4.90.

This new edition of a standard work is updated by the inclusion of photoelectron spectroscopy, circular dichroism and liquid crystals, and by a revision of all the chapters. A few references from 1972 are given but most are pre-1970. It remains a compact and useful companion and source book to those engaged with ultraviolet–visible spectroscopy.

Analisis por Activacion Neutronica: Teoria, practica y aplicaciores: A. TRAVESI, J. E. N., Madrid, 1975. Pp. XVIII + 717. Pesetas 1500.

It is a pleasure to handle again a book which is beautifully laid out, has clear illustrations and tables, has an attractive cover and may be placed open on the table or bench without either cracking or shutting. It comprehensively surveys activation analysis up to *ca.* 1970. The text starts with neutrons and nuclear reactions and concludes with a reveiw of industrial applications. In between lies all that is relevant to activation analysis and the basic tables of nuclear properties are included as appendices. It is certain to become a standard work.

NOTICES

SHORT SUMMER COURSE IN X-RAY SPECTROMETRY

A two-week short course in modern X-ray spectrometry will be offered at the State University of New York at Albany from 7 to 18 June, 1976. The course will be instructional and will develop the basic theory and techniques starting from elementary principles. No previous knowledge or experience are required. The first week will cover basic principles and techniques and the second week will continue with further fundamentals and practical applications. Both weeks will illustrate and employ the wavelength-dispersive and energy-dispersive methods. Emphasis in the second week will be placed on advanced principles and techniques, absorption-enhancement corrections by several procedures including mathematical methods and computer automation of modern X-ray spectrometers. Equal time will be devoted to lectures and laboratory-problem solving sessions. Registration may be made for either week at a registration fee of $375.00 or for the entire two-week session at a registration fee of $700.00, payable in advance. For further information and to register please communicate with:

Professor Henry Chessin,
State University of New York at Albany,
Department of Physics,
1400 Washington Avenue,
Albany, New York 12222,
U.S.A.

SHORT SUMMER COURSE IN X-RAY POWDER DIFFRACTION

A two-week short course in modern X-ray powder diffraction will be offered at the State University of New York at Albany from 21 June to 2 July, 1976. The course will be tutorial in nature and will develop the basic principles and practical applications starting from elementary considerations. No previous knowledge or experience are required. The first week will cover principles and practice of instrumentation, specimen preparation, identification of powder patterns including complex phase identification, practical considerations on the use of the several indices with emphasis on computer retrieval and computer-assisted identification. The second week will cover qualitative identification of powder patterns in greater depth, computer-assisted search for correct powder identification, quantitative analysis of polycrystalline mixtures of two or more phases, automated powder diffractometers and other topics in depth. Equal time will be devoted to lectures, laboratories and problem-solving sessions. A suitable amount of time will be set aside for discussion of individual problems. The registration fee is $375.00 for either week, or $700.00 for the entire two-week session, payable in advance. For further information and to register please communicate with:

Professor Henry Chessin,
State University of New York at Albany,
Department of Physics,
1400 Washington Avenue,
Albany, New York 12222,
U.S.A.

TRACE ANALYSIS OF ENVIRONMENTAL MATERIALS
TARC INTERNATIONAL SYMPOSIUM III

The third of a continuing series of international conferences on analytical chemistry will be held from 4 to 6 August, 1976 at Dalhousie University, Halifax, Nova Scotia. The conference is co-sponsored by the Chemical Institute of Canada and the Trace Analysis Research Centre at Dalhousie University. Papers on all aspects of trace analysis of environmental samples will be presented. Information on the conference may be obtained by writing to:

Professor D. E. Ryan,
Trace Analysis Research Centre,
Dalhousie University,
Halifax, Nova Scotia, B3H 4J1, Canada

FOURIER TRANSFORM NMR SPECTROSCOPY

University of East Anglia: 13–17 September 1976

A Residential School of the Chemical Society's Education and Training Board

During the past five years advances in NMR have been particularly characterized by the utilization of Fourier transform methods. These have resulted in the merging of techniques associated with pulsed NMR and continuous wave NMR. Most chemical spectroscopists have been more familiar with the latter than with the former and there is, therefore, a need for a Residential School dealing with the relevant aspects of pulsed NMR and spin relaxation processes, leading to a full discussion of Fourier transform NMR techniques and applications. The subject matter will be taught at a level suitable for spectroscopists with a working knowledge of continuous wave ^{1}H NMR but with little or no previous knowledge of Fourier transform techniques or relaxation concepts. The aim is to provide a working knowledge of Fourier Transform NMR and its applications (for instance, in organic and inorganic structure determination, in biochemistry and polymer chemistry).

For full details and application form please contact:

Miss M. Virginia Auguste,
The Chemical Society,
Burlington House,
Piccadilly,
London W1V 0BN.

Volume 23, 1976
January December

SUBJECT INDEX

Talanta, Vol. 23, p. iv. Pergamon Press, 1976. Printed in Great Britain

ERRATA

In the paper by P. R. Haddad, P. W. Alexander and L. E. Smythe, *Talanta*, 1975, **22**, 61, the following corrections should be made.

Page 62, 10 lines up from foot of page, for "10*M* sulphuric acid" read "10*N* sulphuric acid"

Page 66, line 12 of text, for "1.8*N* sulphuric acid" read "1.6*N* sulphuric acid"

Talanta, Vol 23, pp iv–v Pergamon Press, 1976 Printed in Great Britain

PUBLICATIONS RECEIVED

The Determination of Sulphur-containing Groups, Vol. 2: M. R. F. Ashworth, Academic Press, London, 1976. Pp. xi + 288. £9.80.

The subject of the second volume of this series is the analysis of compounds containing the —SH group. The large number of methods which have been described in the literature are collected together under general headings which identify the dominant feature of the method. Chapter 1 is concerned with the most important of the chemical methods, that is the oxidation of the thiol group and the chapter has some 54 subsections each dealing with a specific oxidant. Subsequent chapters describe other chemical methods such as the formation of mercaptides, addition to double bonds, reactions with acyl or alkyl halides and reduction. There are also chapters dealing with physical methods, such as polarography or chromatography. The style of the book is that of a critical review, experimental details being kept to a minimum in order to permit coverage of the very wide field. The readers are referred to the original literature for precise information and each separate chapter is provided with its own bibliography.

Detectors in Gas Chromatography: Jiři Ševčik, Elsevier, Amsterdam, 1976. Pp. 192. S23.25.

This book is the fourth volume in a series devoted to various aspects of chromatography, entitled the *Journal of Chromatography Library*. It is surprising that so much effort and ingenuity has been expended in the design and development of gas chromatography detector systems that it is now possible to devote a whole book to their description. Further, it is interesting to see that some detectors, which in their day had good performance and characteristics, have now become obsolete and do not merit even a mention in the text. The thrust and argument of this present work is that the behaviour of the detector is all-important in determining the ultimate efficiency of the gas chromatographic analyser. The detectors considered are those based on thermal conductivity, ionization, electron-capture and solution properties or reactions. The characteristics of each system are outlined and special attention is paid to the effects of detector geometry and experimental conditions on the ultimate performance. As a result this book will be of considerable value, not only to those involved directly in research, but also to those using gas chromatography as a routine analytical tool and to those analysts who may contemplate its use in the future.

Analytical application of Complex Equilibria: J. Inczédy, Ellis Horwood, Chichester, 1976. Pp. 415. £17.50.

Chemical systems used routinely by the analyst have always been complex, and with the spread of organic reagents, instrumental methods and trace analysis, they have become even more complicated. It is possible to find the optimum conditions for any reaction by purely empirical means, but intelligent use of equilibrium constants make the selection more rapid and certain. Ringbom showed how the concept of the conditional constant enables complex equilibria to be easily handled. His approach illuminates the workings of many analytical systems. This is illustrated by this book which first reviews methods for measuring equilibrium constants and then shows how Ringbom's methods can be applied to gravimetry, titrimetry, polarography, spectrophotometry, solvent extraction and ion-exchange separations. It is an eminently practical book with 82 worked examples, which show how calculations can be made for many important systems. There is also a useful collection of constants for common analytical reagents. It is not bedside reading, but it is strongly recommended as a laboratory manual and a teaching aid, on account of the breadth of examples selected and the clarity of the presentation.

Handbook of Analysis of Organic Solvents: V. Šedivec and J. Flek, Ellis Horwood, Chichester, 1976 Pp. 455. £18.00.

This is essentially a reference book of organic solvents containing an incredible amount of information. There are tables of the important physical constants, the boiling points of 1662 azeotropic mixtures, the densities and vapour pressures of many solvents, all in ascending order of magnitude. The common impurities for each solvent are noted and trade and trivial names given. Chemical tests for the solvents and some of the impurities are given. It is to be regretted that no account is taken of the common spectroscopic methods. The inclusion of spectra in discussion of the solvents and spectral data in the Tables would have improved the book. Nevertheless, it still remains a very valuable and convenient reference book for all users of organic solvents.

Aldehydes—Photometric Analysis, Vol. 3: Eugene Sawicki and Carole R. Sawicki, Academic Press, London, 1976. Pp. xiii + 341. £10.80.

This book is a further volume in the series which provides a comprehensive treatise on the analysis of aldehydes by optical methods. It is the first of five volumes which are to be devoted to the analysis of aldehyde precursors. These substances are first converted into the appropriate aldehyde before determination by methods which have been described in earlier volumes in the series. Each aldehyde is dealt with in a separate chapter and where it has more than one precursor these are described in order in the appropriate subsections. Very full experimental details are given and there is a very wide range of precursors covered, many of which are of biochemical or medical importance. Although the treatment is restricted to determinations by absorption or emission methods it is suggested that many of the isolations and conversions described could be followed by determinations using other physical techniques. There is a full list of references given at the end of each chapter and author and subject indexes are provided at the end of the book.

Nukleare Analysenverfahren: T. BRAUN and E. BUJDOSO (Eds.), Akadémiai Kiadó, Budapest, 1976. Pp. 269. £13.90.

This is a collection of 27 papers presented at a Conference in Dresden from 12 to 16 May, 1975 and concerned with analytical methods based on the properties of nuclei. The papers are written in French, German and English and are provided with summaries in English. They are collected together under three separate headings and form part of Volume 28 of the Journal of Radioanalytical Chemistry. The first section deals with methods based on heavy particle bombardment and has papers on Rutherford back-scattering, ion generators and X-ray emission. The second section contains eleven papers dealing with aspects of radiochemical assay including substoichiometry and automation. The final section comprises nine papers which deal with activation analysis, including both gamma-ray and charged-particle methods. It should be noted that the items in the contents list entitled "Bibliography Section" and "Index to Volume 28" do not appear in the book.

Biological Separations in Iodinated Density Gradient Media: D. RICKWOOD (Ed.), Information Retrieval Ltd., London, 1976. Pp. 205. £5.50.

This is a collection of research communications delivered at a colloquium recently held at the University of Glasgow (1975). It is therefore of direct interest to biologists currently using centrifugation technology. This collection of papers illustrates the wide range of biological problems which can be studied by employing ultracentrifugation techniques involving iodinated density gradient media, particularly the non-ionic compound given the trivial name "Metrizamide". For example, such gradients have been used to study nucleic acid–protein interactions, and to fractionate chromatin and other nucleoprotein complexes such as ribonucleoprotein particles and virus particles. Enzymes differing only in buoyant density, because some of them have been synthesised from deuterated amino-acid precursors, can be separated without loss of biological activity. The successful separation of cultured mammalian cells has been achieved, and the potential of such gradients for separating subcellular components is considered. This book also provides an ideal introduction for research workers who are interested in, but as yet unfamiliar with, the special qualities of iodinated density gradient media. For example the first article deals with the physicochemical properties of such media and discusses some of their advantages over the well-established media such as sucrose and caesium salt solutions.

Nitrogen Metabolism in Plants: LEONARD BEEVERS, Arnold, London, 1976. Pp. x + 333. £14.00 (Boards), £6.95 (Paper).

This book in the Contemporary Biology series, though not of direct concern to analytical chemists, does contain a great deal of chemistry and could give researchers who are stuck for a problem some new ideas on fruitful areas for investigation. The author has undoubtedly succeeded in bringing together a very wide range of material from scattered sources and welding it into readable and useful form.

Biochemical Fluorescence: Concepts, Vol. 2: RAYMOND F. CHEN and HAROLD EDELHOCH (Eds.), Dekker, New York, 1976. Pp. xv + 536. SFr. 133.00.

This is the second half of a book for biochemists on the principles and applications of fluorescence spectroscopy, with sixteen chapters on various applications, the first volume having contained seven chapters on the theoretical principles. The pages in this volume are numbered from 409 to 944, and the last 44 are the cumulative indexes for the two halves. This state of affairs is presumably due to the book's being reproduced from typescript, and one wonders whether the publishers would not have been better advised to have it printed in a single volume selling at the price of this half. The object of the book is to show that it is not enough merely to collect spectroscopic data, and that interpretation is necessary if the techniques are to be of real use. The contributors were asked to indicate future trends in application and seem to have been quite good at gazing into the future.
