
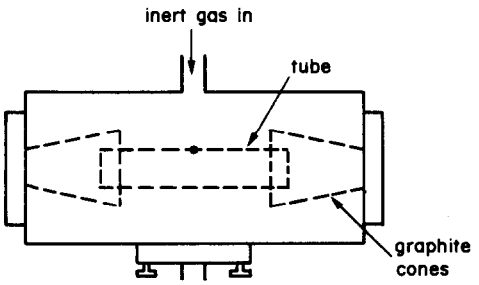

Fig. 1. HGA 72 carbon furnace (not to scale).

Reagents

All chemicals were of analytical-reagent grade. Stock standard solutions (1000 μg/ml) of arsenic(III) and arsenic(V) were prepared by dissolving As_2O_3 and As_2O_5, respectively, in 0.1*M* sodium hydroxide. Aliquots of these solutions were diluted, when required, with demineralized distilled water to give working solutions in the μg/l. range.

Procedure

The sample to be analysed was dissolved in 2*M* hydrochloric acid and sufficient potassium iodide and ascorbic acid were added to reduce all the inorganic arsenic present

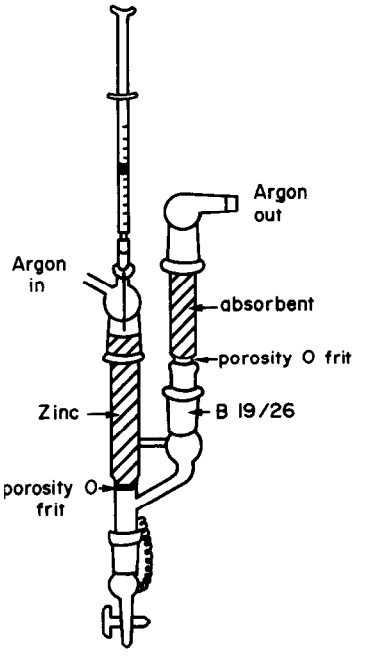

Fig. 2. Zinc-column arsine generator.

to the tervalent form (1 ml of 1*M* iodide/1*M* ascorbic acid solution per 20 μg of arsenic).

Before the injection of 1 ml of solution onto the zinc column the furnace (1700°) and recorder were turned on and a stable base-line was established (this took approximately 10 sec). The solution was injected as quickly as possible and the furnace was turned off when the recorder signal returned to the previously established base-line (approximately 20 sec).

RESULTS AND DISCUSSION

Zinc-column arsine generator

Two forms of zinc were tested in the column, namely zinc filings (<2 mm) from zinc sticks, and zinc shot (16–30 mesh) which was activated by removing the surface oxide coating by immersion in 0.5*M* hydrochloric acid for several minutes. Zinc shot gave delayed arsine generation, and the coefficient of variation for the signal for five successive injections of a 0.1-μg/ml As(III) standard was larger (4%) than that obtained with the zinc filings (2.7%). Zinc filings were therefore used in all further work.

Water vapour must be prevented from entering the carbon tube, as the molecular absorption of water and acid vapour interferes with the arsenic absorption signal. Moreover, the operational life of the carbon tube is drastically reduced. Anhydrous calcium chloride (8–16 mesh) and calcium sulphate (10–20 mesh) were found to be suitable absorbents for water vapour, but both remove small quantities of arsine and therefore before sample solutions are analysed an arsenic standard should be injected into the zinc column to saturate any arsine adsorption sites.

Optimization of operating conditions

All conditions were optimized with a 0.1-μg/ml As(III) standard. The effect of furnace temperature, flow-rate and acid concentration on the arsenic absorption signal (peak height) is shown in Figs. 3, 4 and 5, respectively. A linear relationship between absorbance and concentration was obtained up to a concentration of 70 ng/ml.

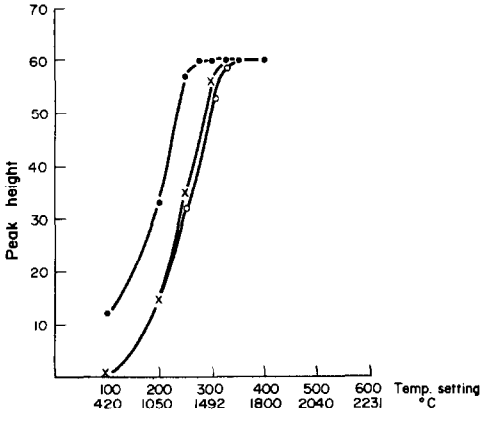

Fig. 3. Effect of furnace temperature on the absorption signal (arbitrary units). Flow-rate setting 5.0; [HCl] 2.0*M*; ● 5-mm tube; × 8-mm tube; ○ 10-mm tube.

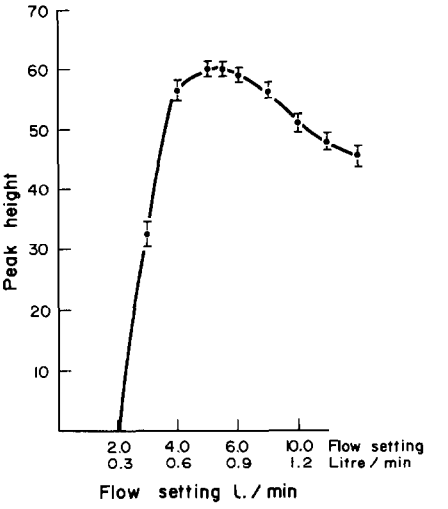

Fig. 4. Effect of flow-rate on the absorption signal (arbitrary units). Temperature setting 350; [HCl] 2.0*M*; 8-mm tube.

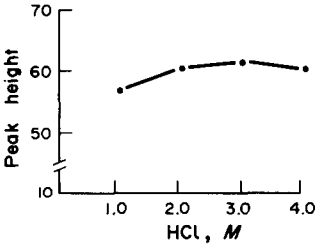

Fig. 5. Effect of hydrochloric acid concentration on the absorption signal (arbitrary units). Temperature setting 350; flow-rate setting 5.0.

Form of arsenic

Preliminary experiments showed that arsenic(V) was not quantitatively reduced to arsine by the zinc column (see Table 1).

The presence of 1 ml of 1*M* potassium iodide/1*M* ascorbic acid solution in a 50-ml sample containing hydrochloric acid and 5 μg of arsenic(V) was sufficient to give complete reduction to arsenic(III). The ascorbic acid was added to prevent oxidation of iodide to iodine; the removal of iodine also shifts the equilibrium of the As(V)/I^- reaction to the right:

$$As(V) + 2I^- \rightleftharpoons As(III) + I_2$$

The time required for the complete reduction of As(V) to As(III) was found to be dependent on the

Table 1. Generation of arsine from As(V)

[HCl], *M*	1.05	2.10	3.15	4.20
Conversion,* %	43 ± 1	49 ± 2	54 ± 1	57 ± 1

* As(V) standard 0.1 μg/ml, three determinations.

Table 2. Effect of acid concentration on time for reduction of As(V) to As(III) as shown by recovery of arsine

[HCl], *M*	2	3	6	12
Reduction time, *min**	45	20	5	5

* Reduction time for complete conversion of 5 μg of As(V) (in 50 ml of solution) into arsine.

hydrochloric acid concentration (Table 2). Up to 20 μg of arsenic(V) can be completely reduced with 1 ml of the reductant solution.

Interferences

The levels at which certain ions interfere are given in Table 3. A number of other ions (Al^{3+}, Ba^{2+}, Ca^{2+}, Cd^{2+}, Co^{2+}, Cr^{6+}, Fe^{3+}, K^+, Li^+, Mg^{2+}, Mn^{2+}, Na^+, Ni^{2+}, Pb^{2+}, SO_4^{2-}, Sn^{2+}, Zn^{2+}) were tested and showed no significant interference at concentrations up to 500 μg/ml (1.5 mg/ml for SO_4^{2-}).

Precision and detection limit

The precision was estimated from replicate analyses of a 0.01 μg/ml As(III) standard, made up in 2*M* hydrochloric acid that was 1*M* in potassium iodide and 1*M* in ascorbic acid. The relative standard deviation at this concentration was 1.4% (five determinations).

The standard deviation of the blank analyses, based on 5 determinations, corresponded to a concentration of 0.001 μg/ml. The source of the blank (<0.005 μg/ml) was mainly the hydrochloric acid.

Conclusion

The experimental system described in this paper allows the determination of arsenic down to 0.01 μg/ml with a relative standard deviation of less than 2%. The advantages of this system are the rapid throughput of prepared samples (one column injection per 30 sec) and the high concentration of foreign ions which can be present without causing interference. This makes the system particularly suitable for the determination of arsenic in environmental samples, which generally contain a wide range of other trace elements.

Table 3. Effect of inorganic ions on the generation of arsine from 0.1-μg/ml As(III)

Element	Form added	Interference level,* μg/ml
Cu	$CuCl_2$	50
Hg	$HgCl_2$	2.5
Mo	$NaMO_4 \cdot 2H_2O$	400
Sb	$SbCl_3$	25
Se	H_2SeO_3	0.1
Si	Na_2SiO_3	50
V	NH_4VO_3	250

* Interference was deemed to occur if the absorbance changed by 5% or more. Mo enhanced the signal, the other elements all suppressed it.

SPECTROPHOTOMETRIC DETERMINATION OF ATROPINE, PILOCARPINE AND STRYCHNINE WITH CHLORANILIC ACID

M. ABDEL-HADY ELSAYED and SURAJ P. AGARWAL*
Faculty of Pharmaceutical Sciences, University of Nigeria, Nsukka, Nigeria

(*Received* 4 *August* 1980. *Revised* 3 *August* 1981. *Accepted* 22 *October* 1981)

Summary—In dioxan–chloroform medium the acceptor chloranilic acid forms 1:1 molecular complexes with the alkaloids atropine, pilocarpine and strychnine, with maximum absorption at 535, 527.5 and 535 nm respectively. Conformity with Beer's law allows the use of the complexes for the assay of these drugs.

Molecular complexes are formed by interaction between electron donors and electron acceptors.[1] Donors fall into two major categories, lone-pair donors such as amines (including alkaloids), alcohols, sulphoxides *etc.*, and π-donors such as aromatics, particularly polycyclic systems. Some compounds such as azoaromatics and aromatic amines may behave as lone-pair donors towards some acceptors and π-donors towards others. Acceptors may be of σ- and of π-type. The former include iodine, recently employed in the assay of alkaloids[2–7] and antihistamines.[8] π-Acceptors are aromatic systems containing electron-withdrawing substituents such as nitro, cyano or halogen groups, *e.g.*, *p*-benzoquinone,[9] dichlorobenzoquinone,[10] fluoranil,[11] chloranil,[12] tetracyano-*p*-benzoquinone[13] and 7,7′,8,8′-tetracyanoquinodimethane.[14] *p*-Chloranilic acid has been largely used in the determination of metal ions,[15,16] but not hitherto in the assay of alkaloids.

The present work describes the spectrophotometric determination of atropine, pilocarpine and strychnine by complexation with chloranilic acid. These alkaloids are usually present in pharmaceutical dosage forms in very small amounts (1 mg or less per unit dose). Such small amounts preclude the use of many methods for assay of these alkaloids.

EXPERIMENTAL

Reagents

Alkaloids. Atropine base (BDH), atropine sulphate (Merck), pilocarpine hydrochloride (Merck), strychnine base (Merck), strychnine hydrochloride (Sigma).

Alkaloid dosage forms. Atropine sulphate eye-drops, 1% solution containing 0.002% phenylmercuric nitrate (Evans Medical). Atropine sulphate injections B.P., 0.1% (E.G.Y.T.) and atropine sulphate injections B.P., 0.06% (Evans Medical).

Chloranilic acid solution. p-Chloranilic acid dissolved in 1,4-dioxan to give 0.005*M* and 0.2% solutions, which were kept in the dark when not in use and under these conditions were stable for up to 6 weeks.

Other reagents and solvents were analytical grade and used as such.

Standard solutions

Atropine and strychnine bases. An accurately weighed amount of the base was dissolved in chloroform to give 0.2% and $5.0 \times 10^{-3}M$ solutions.

Pilocarpine hydrochloride. An accurately weighed amount (0.1173 g) was dissolved in about 15 ml of water in a 100-ml separatory funnel. The solution was alkalinized to litmus with a few drops of dilute ammonia solution and extracted with 15, 10, 10 and 10-ml portions of chloroform, each extract being washed with the same 15 ml of water in another separatory funnel. The washed extracts were filtered through anhydrous sodium sulphate in a filter paper in a small funnel, into a 50-ml standard flask. The funnel and paper were washed with 1–2 ml of chloroform and the volume was made up with the same solvent to 50 ml.

A $5.0 \times 10^{-3}M$ solution of pilocarpine base in chloroform was similarly prepared from 0.2447 g of pilocarpine hydrochloride, with final dilution to 200 ml.

Preparation of assay solutions

Atropine sulphate, pilocarpine hydrochloride and strychnine hydrochloride powders. About 0.12 g, accurately weighed, was dissolved in about 15 ml of water in a 100-ml separatory funnel and alkalinized. The bases were extracted with chloroform and collected in a 50-ml standard flask as described for pilocarpine hydrochloride.

Atropine sulphate eye-drops. A 5.0-ml portion was transferred into a 100-ml separatory funnel containing 10 ml of water and alkalinized. The base was extracted with chloroform and collected in a 50-ml standard flask as above.

Atropine sulphate ampoules. The contents of 12 ampoules were pooled in a dry 20-ml conical flask, and mixed; 10.0 ml were measured into a 50-ml separatory funnel, alkalinized to litmus with ammonia and extracted with 4, 2, 2 and 2 ml of chloroform, the extracts being collected in a 10-ml standard flask.

General procedure

An aliquot of assay solution was transferred into a 20-ml standard flask, 15 ml of 0.2% chloranilic acid solution were

added, and the solution was mixed and diluted to 20 ml with dioxan. The absorbance was measured at the corresponding λ_{max} against a blank solution prepared by diluting 15 ml of chloranilic acid solution with dioxan to 20.0 ml.

RESULTS AND DISCUSSION

Molecular complex formation

In dioxan–chloroform medium, atropine (**I**), pilocarpine (**II**) and strychnine (**III**) react instantaneously with chloranilic acid (CA) to give purple products having similar spectra (Fig. 1). Chloranilic acid in dioxan–chloroform mixture is golden yellow, with λ_{max} at 428 nm and a minimum near λ_{max} of the complexes. The similarity of λ_{max} for all three complexes is probably due to the reaction mechanisms being the same with the alkaloid as donor and chloranilic acid as acceptor.

Chloranilic acid exists in three forms,[18] the neutral yellow H_2A at very low pH, the dark violet HA^- which is most stable at pH 2, and the pale violet A^{2-}, stable at high pH. It gives a purple colour in water, acetonitrile, dimethylformamide and ammonia. As the reaction products in non-aqueous medium are purple, we conclude that HA^- is the form of chloranilic acid involved in the complexes. Previous reports on analogous systems[14,17,19–21] support this finding.

The colour of the complexes is stable for at least 24 hr if the solutions are kept in the dark. Doubts have been voiced about the utility of chloroform as the solvent[14,22,23] since it may give hydrogen-bonding with some alkaloids. Chloroform did not interfere in the present system and was preferred to dioxan because it gave lower experimental error.

Properties of the complexes

The continuous-variation[24] and molar-ratio[25] methods both showed that 1:1 complexes are formed as expected from the single donor centre in the alkaloids.

The mechanism is similar to that[17] for amino-acid complexes with chloranilic acid.

However, both methods of investigation indicate that a 2:1 donor:acceptor complex is also formed under certain conditions.

Hence for quantitative formation of the 1:1 complexes an excess of chloranilic acid is needed. Addition of 15 ml of 0.2% chloranilic acid solution in dioxan gives maximal complex formation with **I** in the concentration range 0.025–0.200 mg/ml, **II** at 0.01–0.08 mg/ml and **III** at 0.03–0.24 mg/ml (as free base in the final solution) and the solutions conform with Beer's law. Plots of absorbance (A) *vs.* concentration of free base (C) are linear but give small negative intercepts on the absorbance axis.

The accuracy of the method was tested by recovery experiments on known amounts of the salts of the alkaloids (Table 1). The error (95% confidence limits) was between 0.8 and 1.8% relative.

Various atropine dosage forms were also assayed. The phenylmercuric nitrate preservative in some of them (0.002%) did not interfere. The results are pre-

sented in Table 2. The recovery values are based on the amounts found and those calculated to be present from the nominal concentration of the preparations. The reproducibility was rather poorer than that for the pure salts.

Interferences

Substances having no basic centre are not expected to interfere, since extraction of the alkaloid base precedes the colour reaction. However, the method will not differentiate between the alkaloids investigated, and amines will interfere. Nevertheless, the method is useful for routine analysis and quality control, and the non-specificity could be overcome by using a preliminary chromatographic separation.

As the acceptor, chloranilic acid is superior to chloranil, reaction with which is slow[26–28] and gives complexes which are stable only for about 2 hr, whereas chloranilic acid gives immediate formation of a colour which is stable for at least 24 hr.

Acknowledgements—The authors are grateful to Professor P. Iwe Akubue, Dean of the Faculty, for providing facilities, to Mr. C. U. Ogbuehi, Chief Pharmacist, University Medical Centre, for providing dosage forms used in the analysis, and to Senate Research Grants Committee, University of Nigeria, Nsukka, for funds (Grant No. 00354/79).

ANALYTICAL DATA

MICROSCOPIC DISSOCIATION PROCESSES OF SOME TYROSINE DERIVATIVES

TAMÁS KISS and BÉLA TÓTH

Department of Inorganic and Analytical Chemistry, Lajos Kossuth University, H-4010 Debrecen, Hungary

(*Received* 14 *May* 1981. *Revised* 26 *October* 1981. *Accepted* 8 *November* 1981)

Summary—The macroscopic and microscopic thermodynamic quantities relating to the dissociation of *o*-, *m*- and *p*-tyrosine, tyrosinol and tyramine have been determined at 25° and $I = 0.2$ (KCl). The effects of the substituents are reflected unambiguously only in the ΔG values and are due to changes in the solute–solvent interaction.

The acid–base properties of polyprotic acids are usually characterized in terms of macroscopic thermodynamic quantities. If two or more groups are of comparable acidity, the dissociation steps overlap, and the thermodynamic macroquantities are composites of the micro-quantities which give an exact description of the acid-base properties. The microscopic acid dissociation constants can be determined if the degree of dissociation of at least one of the two groups can be measured as a function of pH. Several experimental procedures are known.[1–10] However, microscopic enthalpies and entropies have been reported only for cysteine and tyrosine. Coates *et al.*[3,4] calculated micro-enthalpies from the temperature-dependence of the micro-constants, but with rather large errors.

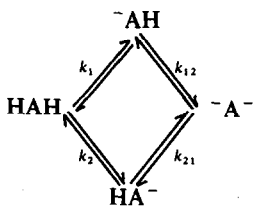
The aim of the present work is to clear up the relationships between the macro and micro-quantities.

The acid–base properties of various tyrosine derivatives are also elucidated.

THEORETICAL

Relationships between the thermodynamic macroscopic and microscopic quantities

The dissociation of a bifunctional acidic molecule can be described by the scheme:



$$H_2A \overset{K_1}{\rightleftharpoons} HA \overset{K_2}{\rightleftharpoons} A$$

where the micro-constants are related to the macro-constants by the expressions:

$$K_1 = \frac{[H]([HA^-] + [^-AH])}{[HAH]} = k_1 + k_2 \quad (1)$$

$$\frac{1}{K_2} = \frac{([HA^-] + [^-AH])}{[H][^-A^-]} = \frac{1}{k_{12}} + \frac{1}{k_{21}} \quad (2)$$

$$K_1K_2 = \frac{[H]^2[^-A^-]}{[HAH]} = k_1k_{12} = k_2k_{21}. \quad (3)$$

It is assumed that in the deprotonation of HAH (or protonation of $^-A^-$) an ideal mixture of ^-AH and HA^- with mole ratios α_1 and $\alpha_2 = 1 - \alpha_1$ is formed. We can define the microscopic free energy (Δg^0) similarly to the macroscopic quantity (ΔG^0):

$$\Delta g^0 = -RT \ln k \quad (4)$$

Accordingly, the following equations can be obtained:

$$\Delta G_1^0 = -RT \ln K_1 = \alpha_1 \Delta g_1^0 + \alpha_2 \Delta g_2^0 + RT \Sigma \alpha_i \ln \alpha_i \quad (5)$$

$$-\Delta G_2^0 = -RT \ln K_2^{-1} = -\alpha_1 \Delta g_{12}^0 - \alpha_2 \Delta g_{21}^0 + RT \Sigma \alpha_i \ln \alpha_i. \quad (6)$$

Substitution of $\alpha_1 = k_1/(k_1 + k_2)$ and equation (4) into equations (5) and (6) and solving for K_1 and K_2 gives equations (1) and (2). Similarly, by adding equations (5) and (6) and solving for K_1K_2, we obtain equation (3). On this basis we assume that the definition in equation (4) is valid.

Since an ideal mixture of ^-AH and HA^- is assumed to be formed, the macroscopic enthalpy changes are given by weighted averages of the microscopic enthalpies:

$$\Delta H_1^0 = \alpha_1 \Delta h_1^0 + \alpha_2 \Delta h_2^0 \quad (7)$$

$$\Delta H_2^0 = \alpha_1 \Delta h_{12}^0 + \alpha_2 \Delta h_{21}^0 \quad (8)$$

In the relationship between the macro- and micro-entropies, however, the entropy of mixing has also to be taken into account:

$$\Delta S_1^0 = \alpha_1 \Delta s_1^0 + \alpha_2 \Delta s_2^0 - R\Sigma\alpha_i \ln \alpha_i \quad (9)$$

$$-\Delta S_2^0 = -\alpha_1 \Delta s_{12}^0 - \alpha_2 \Delta s_{21}^0 - R\Sigma\alpha_i \ln \alpha_i. \quad (10)$$

Similar relations may be written for molecules containing more than two groups of comparable acidity.

Evaluation of micro-quantities

Microscopic dissociation constants. The basic principle of the methods used is that a certain (generally spectroscopic) parameter (molar absorptivity, chemical shift, *etc.*) of at least one of the acidic groups differs from that of its conjugate base, and hence the degree of dissociation of this group can be monitored specifically.

For a bifunctional acidic molecule, the measured values of the parameters for each acidic group at a given stage of titration may be expressed as:

$$p_1 = x^{HAH} p_1^{HAH} + x^{HA^-} p_1^{HA^-} + x^{^-AH} p_1^{^-AH} + x^{^-A^-} p_1^{^-A^-} \quad (11)$$

$$p_2 = x^{HAH} p_2^{HAH} + x^{HA^-} p_2^{HA^-} + x^{^-AH} p_2^{^-AH} + x^{^-A^-} p_2^{^-A^-} \quad (12)$$

The mole fractions are identified by one index, and the parameters by two indices, the upper referring to the protonation state of the two groups, the lower to the individual group. The values of these parameters for the species in which both groups are protonated (p_1^{HAH}, p_2^{HAH}) or fully deprotonated ($p_1^{^-A^-}$, $p_2^{^-A^-}$) can be measured experimentally, whereas their values for the intermediate species ($^-$AH and HA$^-$) cannot be determined directly. It may be assumed, however, that the molar values of these parameters for each individual group are independent of whether the other group is protonated (superscript p) or deprotonated (superscript d):

$$p_1^p = p_1^{HAH} = p_1^{HA^-}$$

and

$$p_1^d = p_1^{^-AH} = p_1^{^-A^-} \quad (13)$$

$$p_2^p = p_2^{HAH} = p_2^{HA^-}$$

and

$$p_2^d = p_2^{^-AH} = p_2^{^-A^-} \quad (14)$$

and

$$x_1^p = x^{HAH} + x^{HA^-},$$

$$x_1^d = x^{^-AH} + x^{^-A^-} \quad (15)$$

$$x_2^p = x^{HAH} + x^{^-AH},$$

$$x_2^d = x^{HA^-} + x^{^-A^-} \quad (16)$$

Substitution of equations (13)–(16) into (11) and (12) gives:

$$p_1^{exp} = x_1^p p_1^p + x_1^d p_1^d \quad (17)$$

$$p_2^{exp} = x_2^p p_2^p + x_2^d p_2^d \quad (18)$$

Substitution of $x_1^p = 1 - x_1^d$ and $x_2^p = 1 - x_2^d$ into (17) and (18) respectively leads to:

$$x_1^d = \frac{p_1^{exp} - p_1^p}{p_1^d - p_1^p} \quad \text{and} \quad x_2^d = \frac{p_2^{exp} - p_2^p}{p_2^d - p_2^p}. \quad (19)$$

The x_1^d and x_2^d values, which represent the fractional dissociation of each group, can be obtained from experimental data. For the scheme above, the fractional dissociation of each group is defined as:

$$x_1^d = \frac{[^-AH] + [^-A^-]}{[HAH] + [^-AH] + [HA^-] + [^-A^-]} = \frac{k_1[H] + k_1 k_{12}}{[H]^2 + (k_1 + k_2)[H] + k_1 k_{12}} \quad (20)$$

$$x_2^d = \frac{[HA^-] + [^-A^-]}{[HAH] + [^-AH] + [HA^-] + [^-A^-]} = \frac{k_2[H] + k_2 k_{21}}{[H]^2 + (k_1 + k_2)[H] + k_1 k_{12}}. \quad (21)$$

Microconstants can be calculated from the fractional dissociation as a function of pH [equations (20) and (21)] by graphical[1,2] or non-linear least-squares curve-fitting methods.[11,12] If the microconstants in equations (20) and (21) are replaced by the macroconstants K_1 and K_2, which are calculated from independent pH data, these equations yield simpler forms. On introduction of equation (1) into the denominator, equations (20) and (21) can be rearranged to linear forms and solved by a linear least-squares method.[13] Further substitution of (3) into (20) and (21) leads to even simpler forms which contain only one refinable parameter. In a given experimental arrangement, the accuracy and reproducibility of measurements of the pH and the characteristic parameter will decide which computational method is the most suitable for evaluation of the experimental data.

If the basic principle is not strictly valid, *i.e.*, the dissociation of at least one of the acidic groups cannot be followed specifically, equation (19) is not suitable for direct calculation. This is quite commonly the case with NMR methods when the two acidic groups are not sufficiently separated. In such cases, the effect of the other group on the parameter of the monitored group can be taken into account as follows:

$$x_1^d = \frac{p_1^{exp} - p_1^p - x_2^d \Delta p_2}{p_1^d - p_1^p - \Delta p_2}$$

and

$$x_2^d = \frac{p_2^{exp} - p_2^p - x_1^d \Delta p_1}{p_2^d - p_2^p - \Delta p_1}. \quad (22)$$

In (22), Δp_1 and Δp_2 are the total changes in the parameters of the monitored groups, caused by dissociation of the other group. The computational method suggested by Sayer and Rabenstein[7] is based on the iterative refining of all parameters (x_1^q, x_2^q, Δp_1 and Δp_2). The set of equations is poorly "conditioned", however, and thus reliable values for the microconstants cannot always be obtained. In another method, the effect of the other group is taken into account by means of suitable model compounds and in this way more reliable values are found[14] for x_1^q and x_2^q.

It often happens that the dissociation of only one of the two acidic groups can be followed (*e.g.*, in the case of molecules containing an –SH or –OH group, the dissociation of the group being monitored by ultraviolet spectroscopy). Then, a single fractional dissociation *vs.* pH curve serves for calculation of all the microconstants. In such cases, the utilization of macroconstant(s) determined by pH titration may be advantageous.

Microscopic dissociation enthalpy and entropy. Microscopic enthalpies cannot be determined calorimetrically. Since the thermodynamic microscopic quantities (Δg^0, Δh^0 and Δs^0) may be defined analogously to the macroscopic quantities (ΔG^0, ΔH^0 and ΔS^0), we have assumed that the same relationships are valid for the micro-quantities as for the macro-quantities. Hence the van't Hoff relation is also valid, *i.e.*, from the temperature-dependence of the microscopic dissociation constants the micro-enthalpies and micro-entropies can be obtained as follows:

$$\ln k_i = -\frac{\Delta h_i^0}{RT} + \frac{\Delta s_i^0}{R}. \qquad (23)$$

EXPERIMENTAL

Chemicals used and experimental conditions

DL-*p*-tyrosine, DL-phenylalanine and phenol (*p.a.*, Reanal), tyramine, 2-phenylethylamine, DL-*o*-tyrosine, DL-*m*-tyrosine and DL-tyrosinol·HCl (Fluka) were used for the experiments. Amino-acids were purified by recrystallization from ethanol–water mixture, and 2-phenylethylamine and phenol by distillation at reduced pressure.

The macro- and micro-constants were determined in a special experimental arrangement, where the dissociation was followed spectrophotometrically and by pH titration simultaneously. Ligand solutions (0.003 and 0.004*M*) were titrated with carbonate-free 0.2*M* potassium hydroxide in a closed system with circulation between the pH titration vessel and a flow-through quartz cell by means of a peristaltic pump. The ionic strength of the solution was adjusted to 0.2*M* with potassium chloride. At each titration point in the pH range 7.5–11.4 (7.5–12.4 in the case of *o*-tyrosine), the pH and the absorbance of the phenolate group (in the range 250–350 nm) were measured.

The measurements were carried out at 15, 20, 25, 30 and 35°. A Radiometer pHM-64 digital pH-meter with G 202 B glass and K401 calomel reference electrodes, and a Beckman ACTA MIV double-beam recording spectrophotometer were used. The dissociation macro-enthalpies were determined at 25° with an LKB 8700-1 solution and reaction calorimeter, by the method described previously.[15]

Calculation

The thermodynamic macroscopic quantities were calculated from the pH and calorimetric data as reported earlier.[15]

From the fractional dissociation curve [equation (21)] of the phenolic hydroxy group, the microscopic dissociation constants were calculated by four different methods:

(*i*) a graphical method;[1]

(*ii*) a linear least-squares method,[13] the K_1 value obtained from separate pH measurements also being used in the calculation;

(*iii*) a non-linear least-squares curve-fitting method,[12] in which all microconstants were iteratively refined;

(*iv*) the direct solution of equation (21), by using the values of K_1 and K_1K_2 determined from separate pH data.

RESULTS AND DISCUSSION

The dissociation macroconstants calculated from the pH titrations, and the macro-enthalpies calculated from the calorimetric measurements, together with the macro-entropies, are listed in Table 1.

It can be seen that the small but similar inductive effects of the *para* and *meta* hydroxy groups cause similar changes in the thermodynamic quantities of

Table 1. The thermodynamic macro-quantities for dissociation of ligands [25°C; I = 0.2 (KCl)]

		pK	ΔG, *kJ/mole*	ΔH, *kJ/mole*	$-\Delta S$, $J.mole^{-1}.K^{-1}$
	COOH	2.41	13.7	3.6	34
o-tyrosine	pK_1	8.67	49.3	39.0	35
	pK_2	11.01	62.6	28.2	115
	COOH	2.22	12.6	2.6	34
m-tyrosine	pK_1	8.94	50.8	38.5	41

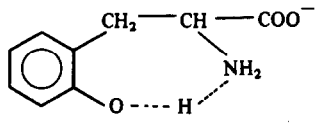
tyrosinol	pK_1	8.94	50.8	44.6	21
	pK_2	9.98	56.8	32.0	83
tyramine	pK_1	9.41	53.5	30.6	79
	pK_2	10.45	59.4	47.7	39

the carboxyl group relative to those of phenylalanine (see Table 5). With *o*-tyrosine, however, the sterically favoured interaction between the $-^{+}NH_3$ group and the hydroxy group decreases the electron-attracting effect of the $-^{+}NH_3$ group, so the intramolecular hydrogen-bond between the $-COO^{-}$ and $-^{+}NH_3$ groups is weakened, which results in slightly increased pK and ΔH values for the carboxyl group.

For *m*- and *p*-tyrosine, tyramine and tyrosinol, the macroquantities identified by subscripts 1 and 2 are combined quantities, since the acidities of the phenolic hydroxy and the protonated side-chain amino groups are comparable. For *o*-tyrosine, however, it may be assumed that in the dissociation of $H_2A^{\pm}$ the following molecule, which contains an intramolecular hydrogen-bond, is formed:



Hence, microscopic processes should not be reckoned with in this case.[10]

The microscopic dissociation constants for the phenolic hydroxy and $-^{+}NH_3$ groups were determined by selectively monitoring the dissociation of the phenolic hydroxy group spectrophotometrically. The micro-constants were then calculated from the fractional dissociation curves. The values obtained for *p*-tyrosine with the different computational methods are listed in Table 2.

It was found that the most reliable results could be obtained with method (*ii*) or (*iv*), when the macro-constant(s) determined in a separate pH study were used in the calculation process. The k_1/k_2 values calculated by these methods are in good agreement with most of the data reported earlier.[1,3,9,13] The slightly different results from the graphical method (*i*) are caused by the possible error in the extrapolation,[16] and from the non-linear least-squares method (*iii*) by the larger experimental error in the spectrophotometric titrations and because there are too many refinable parameters. It is noteworthy, however, that when the dissociation of both acidic groups can be independently monitored, the non-linear least-squares method provides excellent results.[14] The fractional dissociation curves were therefore evaluated by use of the separately determined macro-constant(s).

Table 3. Dissociation macro-constants and k_1/k_2 values at different temperatures [I = 0.2 (KCl)]

		15°	20°	25°	30°	35°
o-tyrosine	k_1/k_2	1.00	1.05	1.02	1.00	1.01

	pK_1	9.59	9.50	9.41	9.32	9.22
	pK_2	10.74	10.60	10.45	10.32	10.18

To determine the dissociation micro-enthalpies, the pH–spectrophotometric titrations were performed at five different temperatures. The calculated k_1/k_2 values, together with the macro-constants calculated from the pH titrations, are listed in Table 3. It can be seen that the k_1 and k_2 values for *o*-tyrosine are equal when calculated on the assumption that microscopic processes occur, and their ratio does not depend on temperature. Substitution of $k_1 = k_2$ and $k_{12} = k_{21}$ into equations (1) and (2) leads to $K_1 = 2k_1$ and $K_2 = k_{12}/2$. Spectrophotometric measurements showed that at 25° pk_1 = 8.98 and pk_{12} = 10.70, in accordance with these equalities (*cf.* Table 3). This confirms that HA for *o*-tyrosine has a single structure (obviously that shown above), and that accordingly the microscopic dissociation processes do not occur.

The k_1/k_2 values in Table 3 clearly show the order of acidity of the donor groups: the side-chain ammonium groups are more acidic than the corresponding phenolic hydroxy groups, exception in tyramine, where the absence of the carboxylate group reverses the order of the acidities. This is in agreement with the earlier data.[1–3,9,13]

Table 2. The dissociation micro- and macro-constants calculated for *p*-tyrosine by different computational methods [25°; I = 0.2 (KCl)]

	Graphical method	Linear regression	Non-linear regression	With fixed K_1 and K_1K_2 values

† Uncertainty ±0.5 kJ/mole.

The logarithms of the micro-constants are a linear function of the inverse of the absolute temperature, so the thermodynamic micro-quantities can be obtained by this method. The Δh_i and Δs_i values, together with the pk_i data, are listed in Table 4. Table 5 gives the thermodynamic macroquantities for some reference compounds.

The pk_1 values characteristic of the phenolic hydroxy groups can be compared with the dissociation constant of phenol, and the pk_2 values characteristic of the side-chain ammonium groups can be compared with p*k* for phenylalanine and 2-phenylethylamine. It can be seen that the weak electron-releasing effect of the phenolic hydroxy group is manifested in the pk_2 values, and the powerful electron-attracting effect of the $^+NH_3$ group in the pk_1 values. The substituent effect is also reflected in the Δh_1 and Δh_2 values, although not so definitely as in the p*k* data.

In accordance with this, the electron-releasing effect of the alkyl chain results in the pk_{21} values being larger than the pk_1 values and the p*K* of phenol. On the other hand, because the electron-releasing effect of the phenolate group is stronger than that of the phenolic hydroxy group, the pk_{12} values are larger than the pk_2 values and the p*K* of phenylalanine or 2-phenylethylamine, but the substituent effects are not exhibited in the Δh data. However, it frequently happens that there is no simple, easily interpreted relationship between the enthalpy change and electron shifts within the molecule, this being due to solute–solvent interactions, which also contribute to ΔH.

It can also be seen from Table 4 that the micro-enthalpies for a given acidic group depend slightly on the protonation state of the other group ($\Delta h_1 \sim \Delta h_{21}$ and $\Delta h_2 \sim \Delta h_{12}$); there is a bigger effect on the entropy changes. Thus, the protonation state of the other group affects the hydration conditions of the dissociation process.

Acknowledgements—We wish to thank Professor A. Gergely, who directed our attention to this work and provided much useful advice. We are also grateful to Mr. L. Zékány, for assistance in the solution of the computational questions.

SPECTROPHOTOMETRIC AND ANALOGUE DERIVATIVE SPECTROPHOTOMETRIC DETERMINATION OF ULTRAMICRO AMOUNTS OF CADMIUM WITH CATIONIC PORPHYRINS

HAJIME ISHII,* KATSUHIKO SATOH, YASUHIRO SATOH and HIDEMASA KOH†

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai-shi, 980 Japan

(*Received* 13 *November* 1981. *Accepted* 29 *January* 1982)

Summary—α,β,γ,δ-Tetrakis(1-methylpyridinium-3-yl)porphine [T(3-MPy)P] and α,β,γ,δ-tetrakis(1-methylpyridinium-4-yl)porphine [T(4-MPy)P] have been found to react rapidly with cadmium to give coloured complexes in weakly alkaline media at room temperature. Simple and practical methods for the determination of cadmium at ng/ml levels by conventional and analogue derivative spectrophotometry have been proposed. The analogue method gives higher sensitivity. T(3-MPy)P gives higher sensitivity than T(4-MPy)P. The interference of various foreign cations and anions has also been examined and in many cases eliminated or reduced. Adsorption of the porphyrins and their cadmium complexes onto the glassware, which is usually observed under the conditions of reaction and causes significant errors in the determination, can be suppressed almost completely by addition of fairly large amounts of a salt such as sodium chloride.

Water-soluble meso-substituted porphyrins are very useful as highly sensitive colour-producing reagents for metal ions because they possess Soret bands which have extremely large molar absorptivity (1×10^5–6×10^5 $l.mole^{-1}.cm^{-1}$) and are more easily handled than water-insoluble reagents. However, there are also a few disadvantages. One is that, in general, the complexation reaction of the porphyrin with the metal ion in aqueous medium is very slow at room temperature. Hence several attempts have been made to accelerate it, including (*a*) heating,[1–3] (*b*) addition of an auxiliary complexing agent such as pyridine or imidazole[4] or a reducing agent such as hydroxylamine or ascorbic acid,[5] and (*c*) utilization of the metal-substitution reaction with a cadmium, lead or mercury(II) porphyrin complex,[6] which is very rapid even at room temperature (although in the case of the cadmium complex, addition of pyridine or imidazole is usually necessary to accelerate the complexation[4]). These attempts were found to be quite effective for acceleration of the complexation of the porphyrin (*a*) with many metal ions, (*b*) with cadmium or copper(II), and (*c*) with copper(II), cobalt(II), manganese(II) and zinc. Another disadvantage is that the cationic porphyrin and its metal complexes are readily adsorbed on glass, especially in neutral and weakly alkaline media where the complexation reaction is more rapid than in acid. This causes significant errors in the determination of traces of metals. Therefore, acceleration of the complexation reaction and suppression of the adsorption are important in determinations with porphyrins.

On the other hand, during a series of studies concerning analytical application of porphyrins, it has been found that the cationic porphyrins α,β,γ,δ-tetrakis(1-methylpyridinium-3-yl)porphine [T(3-MPy)P] and α,β,γ,δ-tetrakis(1-methylpyridinium-4-yl)porphine [T(4-MPy)P], (Fig. 1) form complexes directly and rapidly with cadmium, copper(II), mercury(II), lead and zinc at room temperature in neutral and/or weakly alkaline media without addition of any auxiliary complexing agent or reducing agent. Adsorption of these porphyrins and their complexes on glass can be suppressed by addition of a salt such as sodium chloride, nitrate or sulphate.

On the basis of these findings, the spectrophotometric determination of cadmium with T(3-MPy)P and T(4-MPy)P has been studied. The analogue derivative technique[7,8] has been introduced to make the determination more sensitive. Thus simple and practical methods for the determination of cadmium at ng/ml levels have been developed, and these are described in this paper.

EXPERIMENTAL

Reagents

T(3-MPy)P was synthesized by the method described in an earlier paper[2] and T(4-MPy)P by the method of Pasternack, *et al.*[9] All other chemicals used were of analytical-reagent grade. All solutions were prepared with distilled, demineralized water unless otherwise described.

Apparatus

For measurements of the absorbance and the absorption spectrum, a Hitachi 139 spectrophotometer and a Hitachi 556 dual wavelength spectrophotometer respectively, were

* To whom correspondence should be addressed.

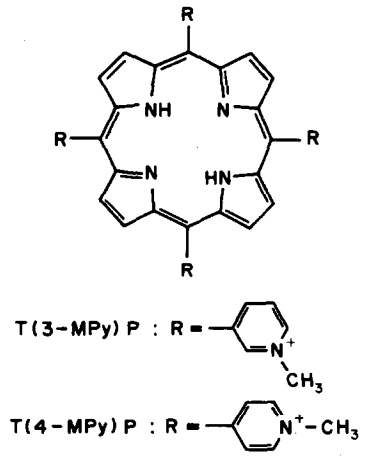

Fig. 1. T(3-MPy)P and T(4-MPy)P.

used, the latter being used as an ordinary double-beam spectrophotometer throughout all the measurements. To obtain the derivative spectra a modified Hitachi 200-0576 derivative unit (composed of two analogue differentiation circuits) was connected between the spectrophotometer output and a Hitachi 057 *X-Y* recorder input. The details of this apparatus and the principles and characteristics of the analogue derivative spectrophotometry are described in earlier papers.[7,8]

Procedures

Spectrophotometry with T(3-MPy)P. Place an aliquot of the sample solution containing less than 8 μg of cadmium in a 25-ml standard flask. Add 1 ml of 0.3*M* sodium tartrate, 1 ml of 0.3*M* sodium citrate, and 1 ml of 10^{-3}% triethylenetetramine solution or 0.5 ml of 1% dimethylglyoxime solution in ethanol as the masking agent, if necessary. After addition of 4 ml of $1 \times 10^{-4}M$ T(3-MPy)P, adjust the pH of the solution to 9.5–11 by adding a sufficient volume of sodium borate–sodium hydroxide buffer solution. Then add 2.5 ml of 4*M* sodium chloride and dilute to the mark with water. After allowing to stand for about 5 min, measure the absorbance at 441 nm against a reagent blank, using 1-cm glass cells.

Spectrophotometry with T(4-MPy)P. Place an aliquot of the sample solution containing less than 12 μg of cadmium in a 25-ml standard flask and treat as described above, but with T(4-MPy)P instead of T(3-MPy)P, and absorbance measurement at 450 nm (this wavelength is that of the absorption maximum when the complex is measured against a reagent blank, and differs slightly from that for measurement against water).

Second derivative spectrophotometry with T(3-MPy)P. Place an aliquot of the sample solution containing less than 380 ng of cadmium in a 25-ml standard flask. Add masking agent as in the spectrophotometric procedure, if necessary. Add 1 ml of $1 \times 10^{-6}M$ T(3-MPy)P solution, 1 ml of 0.1*M* sodium hydroxide and 2.5 ml of 4*M* sodium chloride, and dilute to the mark with water. After allowing the solution to stand for about 5 min, record the second derivative absorption spectrum of the resultant solution, in the Soret region, against a reagent blank, using 1-cm glass cells and the following conditions; circuit No. 6, scan-speed 150 nm/min, and recorder sensitivity $\times 1$. Measure the second derivative value (vertical distance from a peak to a trough or the base-line to a trough) on the chart.

RESULTS AND DISCUSSION

Effect of addition of salts

Suppression of adsorption. As the reason for adsorption of cationic porphyrins and their complexes on glassware is thought to be to the electrostatic interaction between positive charges on the substituents in meso-positions of the porphine ring and negative charges on the glass surface, it was thought that an increase of the cation concentration in the solution by addition of acids, bases or salts would be effective in suppressing the adsorption. In fact, adsorption is not observed in acidic or strongly alkaline medium. However, in acidic medium, the cadmium–porphyrin complex tends to decompose, and in strongly alkaline medium even such metal ions as silver and calcium interfere with the cadmium determination because their complexation reaction with the porphyrin is also accelerated. As salts such as sodium, potassium or ammonium chloride, nitrate or sulphate seemed to minimize the adsorption, in this study sodium chloride was added to give a concentration of about 0.4*M* in the final solution, which made the adsorption negligible. If perchlorate or thiocyanate is present, the cationic porphyrins and their complexes generally tend to precipitate because of formation of ion-pairs. Addition of fairly large amounts of these salts, therefore, should be avoided.

Chloride as an axial ligand. In general, the absorption spectrum of the metal–porphyrin complex is known to shift gradually and slightly with increasing pH or the concentration of a salt such as sodium chloride or thiocyanate. Figure 2 shows a set of the Soret bands for a series of solutions containing identical concentrations of cadmium–T(3-MPy)P complex and sodium sulphate but of varied pH, from which it is seen that the Soret band of the complex gradually shifts to longer wavelengths as the pH rises, and an

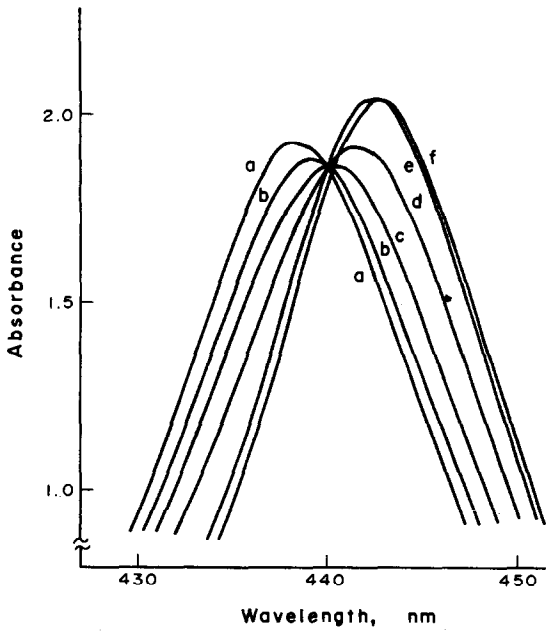

Fig. 2. Absorption spectra of Cd-T(3-MPy)P complex as a function of pH. [Cd-T(3-MPy)P] = $5.7 \times 10^{-6}M$; [$1Na_2SO_4$] = 0.5*M*; reference, water; pH—a 7.6, b 11.0, c 11.3, d 11.8, e 13.1, f 13.6.

isosbestic point exists at 440 nm over pH range 7.6–13.1. (In this case, sodium sulphate is added as an adsorption inhibitor which differs from chloride or thiocyanate and does not affect the spectrum of the complex.) A similar result was obtained for the T(4-MPy)P complex. These spectral variations are thought to correspond to dissociation of a proton from a water molecule co-ordinated axially to the central metal ion (*i.e.*, cadmium) of the complex, corresponding to the equations

$$Cd(H_2O)_2P^{4+} \rightleftharpoons Cd(H_2O)(OH)P^{3+} + H^+ \quad (1)$$

$$k_a = \frac{[Cd(H_2O)(OH)P^{3+}][H^+]}{[Cd(H_2O)_2P^{4+}]} \quad (2)$$

where P and k_a represent the non-dissociative part of T(3-MPy)P or T(4-MPy)P and the acid dissociation constant, respectively. Further shift of the Soret band at higher pH (Fig. 2) suggests the deprotonation of a further water molecule co-ordinated to the central metal ion, but this was not studied in detail. However, by analysis of the results shown in Fig. 2 and for the T(4-MPy)P complex, according to the method used by Pasternack *et al.*,[10] the dissociation of a proton from each complex was ascertained and the acid dissociation constants for both complexes were determined (Table 1).

A spectrophotometric titration in the Soret region of the cadmium(II)-T(3-MPy)P complex at pH 9 with sodium chloride was carried out and the result is shown in Fig. 3. The Soret band of the complex shifts gradually and slightly to longer wavelengths as the sodium chloride concentration is increased and an isosbestic point exists at 436.5 nm for the chloride concentration range 0–0.4*M*. This spectral variation is thought to be due to axial co-ordination of chloride (in general, the salt anion, X^-), in accordance with the equations

$$Cd(H_2O)_2P^{4+} + X^- \rightleftharpoons Cd(H_2O)XP^{3+} + H_2O \quad (3)$$

$$k_1 = \frac{[Cd(H_2O)XP^{3+}]}{[Cd(H_2O)_2P^{4+}][X^-]} \quad (4)$$

where k_1 represents the formation constant of the ternary complex. Further shift of the Soret band at a higher chloride concentration region (Fig. 3) suggests the axial co-ordination of another chloride ion. A similar result was obtained for the cadmium-T(4-MPy)P complex. The formation constants were determined in the manner used by Pasternack *et al.*[10] and are also given in Table 1.

Absorption spectra

Figure 4 shows the absorption spectra of T(3-MPy)P, T(4-MPy)P and their cadmium complexes under the conditions of the determination. The Soret, β and α bands of the T(3-MPy)P complex lie at 441, 573 and 613 nm, and those of the T(4-MPy)P complex at 448, 580 and 624 nm, respectively. The Soret bands (which are important for the determination because of their extremely large molar absorptivities) shift slightly to longer wavelengths than those found in the absence of sodium chloride. This suggests interaction between the complexes and chloride ions as described above.

Table 1. pk_a of Cd(II)–porphyrin complexes and log k_1 of Cd(II)–porphyrin–Cl^- complexes at 25°C, μ = 1.5 (Na_2SO_4)

Complex	pk_a	log k_1
Cd–T(3-MPy)P	11.6	1.5
Cd–T(4-MPy)P	11.6	1.7
$Cd(H_2O)_6^{2+}$	9.0*	1.4*

* Data from *Stability Constants*, The Chemical Society, London, 1964: pk_a: 25°C, μ = 3($HClO_4$ + $NaClO_4$); log k_1: 25°C, μ = 2 ($NaClO_4$).

Influence of sodium chloride concentration and selection of analysis wavelength

As already described, addition of sufficient sodium chloride is required to suppress the adsorption, and λ_{max} for the Soret band of the cadmium complex depends on the sodium chloride concentration. The selection of wavelength for the cadmium determination, therefore, needs to take both effects into consideration. Fortunately, the absorbance is practically unaffected over the chloride concentration range 0.2–1.0*M* for measurement at 441 nm in the determination with T(3-MPy)P and the range 0.1–0.5*M* for measurement at 450 nm in that with T(4-MPy)P.

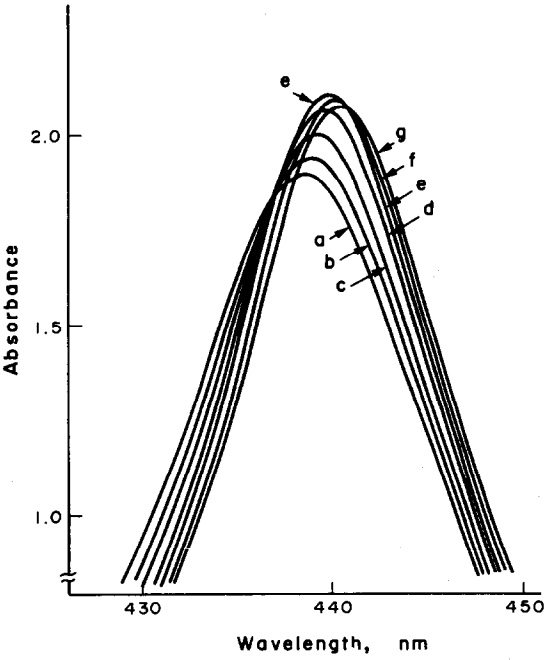

Fig. 3. Absorption spectra at pH 9 of Cd-T(3-MPy)P complex as a function of Cl^- concentration. [Cd-T(3-MPy)P] = 5.7 × 10^{-6}*M*; [Na_2SO_4] = 0.5*M*; reference, water; [Cl^-]—a 0, b 0.01, c 0.03, d 0.1, e 0.4, f 2.0, g 3.0*M*.

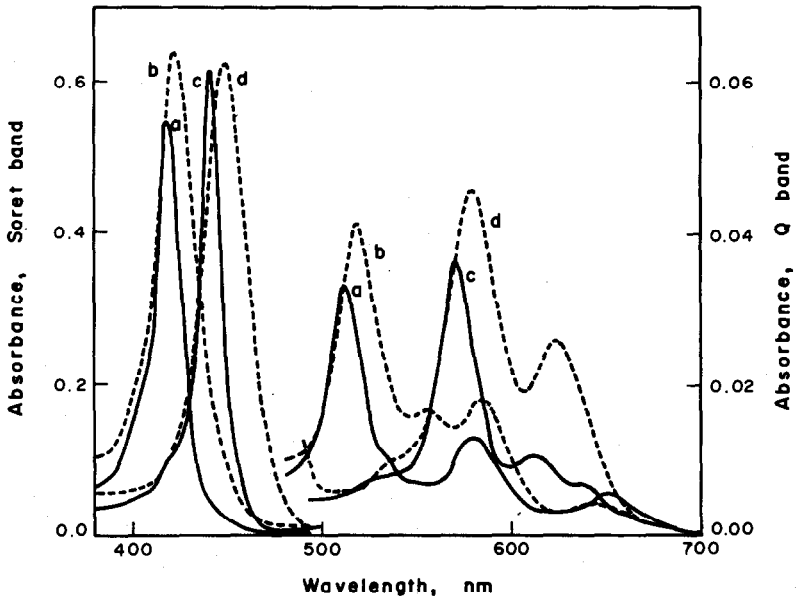

Fig. 4. Absorption spectra of T(3-MPy)P (a), T(4-MPy)P (b) and their cadmium complexes (c, d) in 0.4*M* sodium chloride medium: pH 10.5; reference, water; [T(3-MPy)P]—a, c $1.6 \times 10^{-6}M$, b, d nil; [T(4-MPy)P]—b, d $2.6 \times 10^{-6}M$, a, c nil; [Cd]—a, b nil; c, d $5.3 \times 10^{-6}M$.

Influence of pH

Figure 5 shows that both porphyrins form the cadmium complexes rapidly and give almost constant absorbances in the pH regions 9.3–11.7 and 8.7–11.1 for T(3-MPy)P and T(4-MPy)P respectively, in the presence of 0.4*M* sodium chloride. In these pH regions, cadmium exists as a monohydroxo, $Cd(H_2O)_5(OH)^+$, or a monochloro complex, $Cd(H_2O)_5Cl^+$, or both (depending on pH), before it reacts with the porphyrins, which is thought to be one of the reasons for the fast complexation. Further, the pH ranges where almost constant absorbances are obtained are remarkably broad, whereas in the absence of sodium chloride no such pH regions are found. The reason for this seems to be that the predominant complex formed in such pH regions in the presence of 0.4*M* sodium chloride is $Cd(H_2O)ClP^{3+}$, as may be deduced from the values of pk_a and k_1 in Table 1; further, the deprotonation of $Cd(H_2O)ClP^{3+}$ is negligible because it occurs only in more strongly alkaline media. Thus, the complex species scarcely change in the pH regions where almost constant absorbances are obtained, and the adsorption of the porphyrins and their complexes is considerably suppressed by the presence of the chloride as already described.

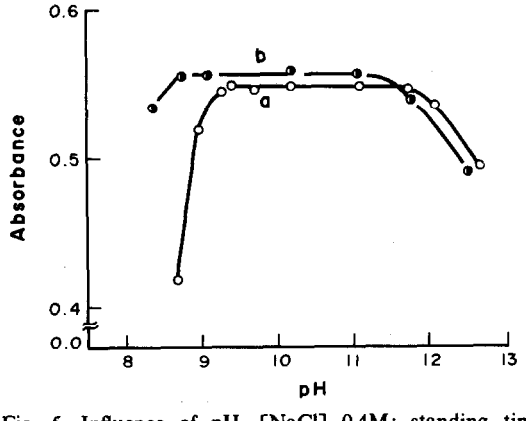

Fig. 5. Influence of pH. [NaCl] 0.4M; standing time 5 min; reference, reagent blank. (a) Cd-T(3-MPy)P system: [Cd] 178 ng/ml; [T(3-MPy)P] $1.6 \times 10^{-5}M$; wavelength 441 nm. (b) Cd-T(4-MPy)P system: [Cd] 284 ng/ml; [T(4-MPy)P] $1.6 \times 10^{-5}M$; wavelength 450 nm.

Influence of porphyrin concentration

The porphyrins were found (by the mole-ratio method) to form a 1:1 complex with cadmium, but about 100% excess of porphyrin is required to complete the complexation rapidly. To prevent decolouration of the porphyrin complex and allow for consumption of porphyrin by other metal ions, however, it is preferable to add fairly large amounts of the porphyrin.

Stability of the complexes to light

One of the present authors has already reported that solutions of the cadmium complex of the anionic porphyrin, α,β,γ,δ-tetrakis(4-sulphophenyl)porphine or α,β,γ,δ-tetrakis(4-carboxyphenyl)porphine, are appreciably decolourized by light.[4] Figure 6 shows that a solution of the cadmium–T(3-MPy)P complex is stable to light for at least 5 hr if excess of T(3-MPy)P is present, whether sodium chloride is also present or not. On the other hand, with excess of cadmium, the absorbance decreases by only about 3% in 5 hr in presence of 0.4*M* sodium chloride, but by about 12%

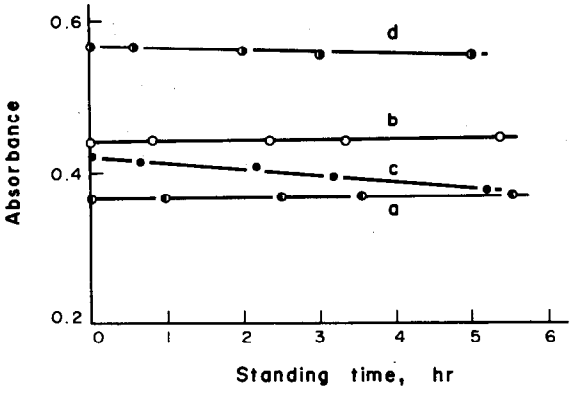

Fig. 6. Influence of light on stability of Cd-T(3-MPy)P complex at pH 10.5. [T(3-MPy)P]—a, b $1.6 \times 10^{-5}M$, c, d $1.6 \times 10^{-6}M$; [Cd(II)]—a, b $1.3 \times 10^{-6}M$, c, d $6.3 \times 10^{-6}M$; [NaCl]—a, c, nil, b, d $0.4M$; wavelength—a, c 443 nm*, b, d 441 nm; reference—a, b reagent blank, c, d, water. *The wavelength of the absorption maximum in sodium chloride medium.

in absence of the sodium chloride. Similar results were obtained for the T(4-MPy)P complex.

Thus the decolouration of the solutions of the complexes, which is attributed to a redox reaction, was found not to be as serious as expected, and it was suppressed almost completely by addition of excess of porphyrin and appreciably by addition of sodium chloride.

Calibration graphs

Linear calibration plots were obtained by the recommended procedures, the weight of cadmium in the sample taken being given by

$$\text{Cd} = 7.7_5A\ \mu\text{g} \quad (5)$$

$$\text{Cd} = 12.7_5A\ \mu\text{g} \quad (6)$$

where A is the absorbance, and equations (5) and (6) refer to T(3-MPy)P and T(4-MPy)P respectively. The optimum ranges for the cadmium determination and the molar absorptivities are summarized in Table 2.

The relative standard deviation for 3.55 μg of cadmium determined by the T(3-MPy)P procedure was 0.4% (16 variates).

Interferences

The possible interference in the determination of 3.55 μg of cadmium by the procedure with T(3-MPy)P, which gives rather high sensitivity, was examined. Cations were added in the form of chlorides, nitrates or sulphates; anions were added as sodium or potassium salts. The limiting value of the concentration of foreign ions was taken as that which caused an error of not more than 3%. The results are summarized in Table 3. Most anions do not interfere even when present in fairly large amounts, but most cations interfere because of their hydrolysis or their complexation with T(3-MPy)P when no masking agent is used. Interferences caused by cations except zinc, however, can be removed or reduced by addition

Table 2. Optimum ranges and molar absorptivities of the recommended procedures

Reagent	Optimum range, μg	Molar absorptivities, $l.mole^{-1}.cm^{-1}$
T(3-MPy)P	0.4–8	3.61×10^5
T(4-MPy)P	0.6–13	2.20×10^5

of sodium tartrate, sodium citrate, triethylenetetramine or dimethylglyoxime, and the tolerance limits thus obtained are those shown in Table 3. The interference of zinc can be reduced by modifying the procedure as follows.

The same volume of sample solution is placed in each of two 25-ml standard flasks. One sample flask is treated by the recommended procedure, and gives absorbance A_1. To the other sample flask 2 ml of $0.1M$ EDTA are added after the cadmium has reacted with T(3-MPy)P to give a full colour, and the mixture is let stand for about 10 min, for the cadmium complex has to decompose completely (the zinc complex remains stable). Then, 2.5 ml of $4M$ sodium chloride are added, the solution is diluted to the mark with water, and the absorbance (A_2) is measured. The cadmium content is obtained by subtracting A_2 from A_1. With this modified procedure, up to 10 μg of zinc will not interfere.

Sensitization by analogue derivative spectrophotometry

We have already reported that derivative spectrophotometry by use of an analogue differentiation circuit is extremely effective for increasing the sensitivity.[7,8] As an example, the second derivative spectrophotometric determination of cadmium with T(3-MPy)P is described here.

Selection of conditions for measurement of the second derivative spectrum. The second derivative spectrum of the analyte is recorded and the vertical distance from a peak to a trough or from the base-line to a trough of the spectrum is measured. Since this distance (D) depends on both the time constant of the analogue differentiation curcuit (our apparatus has 6 circuits, with different time constants) and the scanning speed used, these need to be selected to give a well-resolved large peak (to give good selectivity and higher sensitivity in the determination). This is done on the basis of the breadth of the bands in the ordinary absorption spectrum. In general, a large time constant and/or a fast scanning speed should be used for a broad band in the absorption spectrum. In Fig. 7 the second derivative spectra of the Soret band of a cadmium–T(3-MPy)P complex solution measured with varying circuit number or scanning speed are shown; circuit No. 6 and a scanning speed of 150 nm/min are seen to be preferable for the cadmium determination (the circuit numbers increase with increasing time constant).

Table 3. Influence of foreign ions

Ions added	Tolerance limit
Al(III)[a]*, Ca(II)*, Mg(II)*, V(IV)[a]*, V(V)[a]*	1000 μg
Cr(VI)[a], Fe(II)[a], Ni(II)[a]	500 μg
Fe(III)[a]	100 μg
Cu(II)[d]	50 μg
Ag(I), Co(II)[d], Cr(III)[b], Hg(II)[c]	10 μg
Mn(II)[d], Pb(II)[d]	4 μg
Zn(II)	<4 μg
Br^-*, Cl^-*, NO_3^-*, SO_4^{2-}*, tartrate*, citrate*	100 mg
ClO_4^-	50 mg
I^-, SCN^-	10 mg

Cd(II) taken 3.55 μg.
* Maximum tested.
(a) 1 ml of 0.3*M* sodium tartrate added.
(b) 1 ml of 0.3*M* sodium citrate added.
(c) 1 ml of 0.001% triethylenetetramine solution added.
(d) 0.5 ml of 1% dimethylglyoxime solution (in ethanol) added.

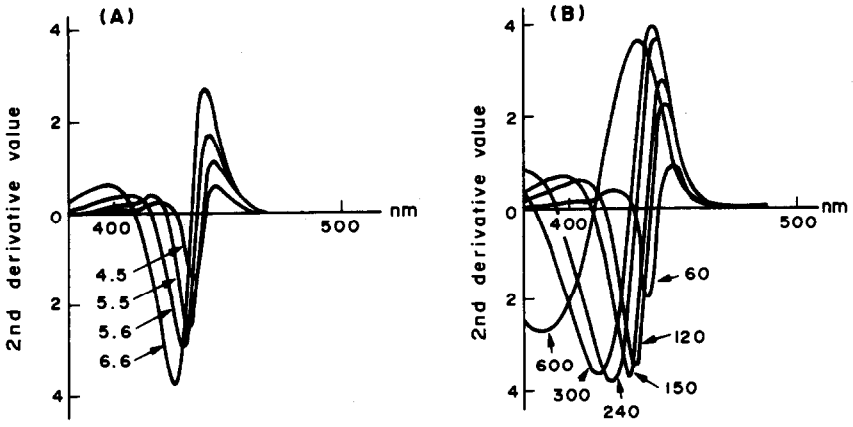

Fig. 7. Influence of (A) circuit number and (B) scan-speed on the second derivative spectrum of the Cd-T(3-MPy)P complex. [Cd(II)] 236 ng/ml; [T(3-MPy)P] $1.2 \times 10^{-6}M$, [NaCl] 0.4*M*, pH 10.5; cells 1 cm, reference water. Numerical values indicate 1st and 2nd differentiation circuit numbers in (A) and scan-speed (nm/min) in (B), respectively. The recorder sensitivity was set so that a derivative value of 1.0 corresponded to 1.0 cm on the chart. In (A) the scan-speed was 150 nm/min; in (B) both circuits were No. 6.

Calibration graphs. Linear plots of *D vs.* weight of cadmium were obtained up to 0.4 μg of cadmium, the equations being

$$\text{Cd} = 400D \text{ ng} \quad (7)$$

for the peak-to-trough measurements, and

$$\text{Cd} = 600D \text{ ng} \quad (8)$$

for the baseline-to-trough measurements, where *D* was the second derivative value obtained with the recorder sensitivity set so that a derivative value of 1.0 gave a signal of 20 cm (*i.e.*, full scale deflection) on the chart. Equation (8), although the sensitivity is lower, is preferable for the analysis of "real" samples because it is less affected by concomitant ions which give T-(3-MPy)P complexes with a Soret band near to that of the cadmium-T(3-MPy)P complex. As a second derivative value of 0.1 corresponds to a signal of 2 cm on the chart, cadmium at the ng/ml level can be readily determined by the proposed method.

SPECTROPHOTOMETRIC DETERMINATION OF TRACES OF IRON, COPPER, ZINC, ALUMINIUM AND BISMUTH IN LEAD- AND TIN-BASE SOLDERS AND WHITE-METAL BEARING ALLOYS

ZHENPU WANG* and K. L. CHENG

Department of Chemistry, University of Missouri-Kansas City, Kansas City, Missouri 64110, U.S.A.

(*Received* 14 *September* 1981. *Accepted* 29 *January* 1982)

Summary—Serious co-precipitation (>60%) of traces of tervalent metal ions has been found to occur in the precipitation of $PbSO_4$. A moderate amount (approximately 11%) of Zn^{2+} and an insignificant amount of Cu^{2+} are also co-precipitated. To deal with this problem, for the determination of Fe (with 1,10-phenanthroline), Al (with oxine–EDTA–KCN), Bi (with diethyldithiocarbamate–EDTA–KCN), and Cu (with 2,2′-biquinoline) in lead- and tin-base solders or white-metal bearing alloys, the $PbSO_4$ is dissolved in tartrate solution. Zinc is determined with dithizone after the $PbSO_4$ has been thoroughly washed with a dilute ammonia solution.

In general, in lead- and tin-base solders and white-metal bearing alloys, tin, antimony and lead are major constituents, with ranges 0.1–99% Pb, 0.5–95% Sn and <20% Sb. Arsenic is a minor constituent (0.01–2%). Iron, copper, zinc, aluminium and bismuth are trace constituents, and are often determined spectrophotometrically, but major interferences come from tin, antimony, lead and arsenic. Tin, antimony and arsenic are usually removed by volatilizing their bromides from perchloric acid or sulphuric acid medium.[1,2] Lead can be separated as lead sulphate[3–5] or chloride[6–8] or masked by complexation with tartrate, citrate or EDTA.[9] Luke,[3] Ota[4] and Karabash *et al.*[5] used sulphuric acid to separate lead, but did not consider co-precipitation of traces of other metals. We have found, however, that there is serious co-precipitation of traces of metals, especially tervalent elements.

In this paper, we report a study on the co-precipitation of iron, aluminium, bismuth and copper by lead sulphate, and suggest rapid and simple spectrophotometric procedures for determination of these elements in lead- and tin-base solders and white-metal bearing alloys, in a single sample solution without separation of lead. We have also studied the elimination of co-precipitation of zinc by lead sulphate, by use of ammonia as a complexing washing agent, thereby obtaining simple spectrophotometric procedures for determining zinc and copper in lead- and tin-base solders and white-metal bearing alloys, in a single sample solution. We have also examined the effect of pH and potassium cyanide on the spectrophotometric determination of aluminium with 8-hydroxyquinoline (oxine).

* On leave from the Nanking Institute of Chemical Technology, Nanking, China.

EXPERIMENTAL

All chemicals used were analytical reagent grade.

Preparation of sample solutions

(*A*) *For spectrophotometric determination of Fe, Al, Bi, Cu.* Depending on the content of iron, aluminium, bismuth and copper, weigh up to 2 g of sample into a 250-ml beaker. Add 20 ml of hydrobromic acid–bromine mixture (2 ml of bromine and 18 ml of concentrated hydrobromic acid). Cover with a watch-glass and heat gently, avoiding excessive loss of bromine, until dissolution of the sample is complete. When analysing high-tin alloys, it may be necessary to add a few extra drops of bromine to ensure complete dissolution of the sample and oxidation of the tin to the stannic state. When dissolution is complete, add 10 ml of concentrated sulphuric acid and heat under a well-ventilated fume-hood to expel stannic bromide, antimonous bromide and arsenious bromide. Heat until less than 2 ml of sulphuric acid remains. Let cool, then carefully rinse the watch-glass and the wall of the beaker with water. Add 6 g of tartaric acid and neutralize with concentrated ammonia solution until all the lead sulphate has dissolved (pH ~10). Transfer the clear solution to a 100-ml standard flask and dilute to volume. Run a blank through the entire procedure (the "procedure blank"), using the same amounts of all reagents.

(*B*) *For spectrophotometric determination of Zn and Cu.* After dissolving the sample with hydrobromic acid–bromine and volatilizing stannic bromide, antimonous bromide and arsenious bromide from sulphuric acid medium as described above, decant the supernatant liquid through a Whatman No. 40 paper into a 100-ml standard flask. Wash 5–6 times with 0.5*N* sulphuric acid, by decantation. Add 5 ml of ammonia solution (1 + 1) to the beaker, stir vigorously to dissolve co-precipitated zinc and copper(II) by formation of their ammine complexes and again decant the solution into the filter. Repeat the extraction with ammonia, then wash the precipitate with ammonia solution (1 + 20) several times, decanting into the filter each time. Adjust the pH of the filtrate to below 2 and dilute to the mark. Run a "procedure blank", using the same amounts of all reagents.

Determination of iron. Preparation of the calibration graph and the spectrophotometric determination of iron have already been described.[10]

Determination of copper.[11] For the calibration graph transfer 0, 0.50, 1.00, 2.00, 4.00 and 6.00 ml of standard copper solution (10.0 μg/ml) to 50-ml beakers and dilute to 20 ml. Add 1 g of hydroxylamine hydrochloride, 5 ml of 10% tartaric acid solution and 1 g of methenamine. Adjust the pH to approximately 5 with ammonia solution (1 + 1) (pH-meter). Transfer the solution to a separatory funnel. Add 10 ml of 0.02% 2,2'-biquinoline solution in isoamyl alcohol and shake vigorously for 1–2 min. Allow the phases to separate and transfer the alcohol layer to a 1-cm cell through a tuft of glass wool squeezed into the dry stem of the funnel. Measure the absorbance against a reagent blank at 545 nm.

For the determination, apply the same procedure (*A* or *B*) to a 10.00-ml or other suitable aliquot of sample solution and the same sized aliquot of the "procedure blank", prepared as described, and measure the absorbance against that of the "procedure blank".

Determination of zinc.[12,13] For the calibration graph, pipette 0, 2.00, 4.00, 6.00, 8.00 and 10.00 ml of standard zinc solution (1.00 μg/ml), into 60-ml separatory funnels and dilute to 20 ml. Add 10 ml of acetic acid–sodium acetate buffer solution (150 ml of glacial acetic acid and 300 g of anhydrous sodium acetate per litre, pH ~4.8, purified by extraction with dithizone solution in carbon tetrachloride) and 2 ml of 25% sodium thiosulphate solution, then shake vigorously for 2 min with 10.00 ml of 0.001% dithizone solution in carbon tetrachloride. Run the clear carbon tetrachloride extract into a 1-cm cell through a tuft of glass wool squeezed into the dry stem of the funnel. Measure the absorbance against a reagent blank at 535 nm.

For the determination of zinc, take a 10.00-ml or other suitable aliquot of sample solution (*B*) in a 60-ml separatory funnel, add 5 ml of 10% ammonium citrate solution (purified by extraction with dithizone solution in carbon tetrachloride), cool to room temperature, and adjust the pH to approximately 8.5. Add 5 ml of 0.01% dithizone solution in carbon tetrachloride (or 0.05% solution if more copper and other metals reacting with dithizone are present) and shake for 30 sec. If the dithizone solution is green, shake for another 30 sec. Allow the phases to separate and draw off the carbon tetrachloride layer into another separatory funnel. Unless the separated carbon tetrachloride phase is distinctly green, add another 5 ml of dithizone, shake for 30–60 sec, and draw off the organic phase; continue in this manner until the last portion is still green after the shaking. Combine the extracts, and shake for 1 min with 10 ml of 0.02*M* hydrochloric acid. Draw off the carbon tetrachloride into another separatory funnel and shake it vigorously for 1 min with a fresh 10-ml portion of the hydrochloric acid. Combine the two acid extracts, add 2 ml of carbon tetrachloride and draw off to remove any coloured droplets of carbon tetrachloride. Repeat once more with 2 ml of carbon tetrachloride. Transfer the acid solution to a 25-ml standard flask, and make up to the mark. This aqueous solution contains the zinc. The carbon tetrachloride layer contains the copper. Take a 10.00-ml or other suitable fraction of the aqueous extract, and determine the zinc in it by the procedure for the calibration graph, but measure the absorbance against a blank prepared by applying the *entire* procedure to an aliquot of "procedure blank" equal to the aliquot of test solution used.

Determination of aluminium.[14,15] For the calibration graph take 0, 2.00, 4.00, 6.00, 8.00 and 10.00 ml of standard aluminium solution in 0.02*M* hydrochloric acid (10.0 μg/ml) and dilute to 20 ml. Adjust the pH to approximately 10 and add 1 ml of 5% 8-hydroxyquinoline solution in ethanol. Extract with successive 10, 5 and 5-ml portions of chloroform, and dilute the combined extracts to 25.00 ml. Run each extract into a 1-cm cell through a tuft of glass wool squeezed into a dry funnel and measure the absorbance at 395 nm against the reagent blank.

For the determination, to a 10.00-ml or other suitable aliquot of sample solution (*A*) add 1 g of EDTA, and adjust to pH 9.5–10 with ammonia. Add 15 ml of pH 10 ammonia–ammonium chloride buffer solution.[9] Then add 1 g of potassium cyanide and stir to dissolve it. Heat slowly to boiling and boil for 3 min. Cool to room temperature, transfer to a 60-ml separatory funnel and add 1 ml of 5% 8-hydroxyquinoline solution in ethanol. Allow to stand at room temperature for 1 hr. Extract with chloroform and measure the absorbance against that of a blank prepared in the same way from the same size of aliquot of the "procedure blank".

Determination of bismuth.[9] For the calibration graph transfer 0, 1.00, 2.00, 3.00, 4.00, 5.00 and 6.00 ml of standard bismuth solution in 0.17*M* nitric acid (5.00 μg/ml) to 60-ml separatory funnels and dilute to 10 ml with 0.17*M* nitric acid. Add 0.5 g of EDTA and adjust the pH to 8. Then add 0.5 g of potassium cyanide and stir to dissolve it. Finally add 1 ml of 0.2% sodium diethyldithiocarbamate solution. Shake with 10.00 ml of carbon tetrachloride for 1 min. Run the extract into a 1-cm cell through a tuft of glass wool squeezed into the dry stem of the funnel. Measure the absorbance against a reagent blank at 400 nm within 30 min.

For the determination treat a 10.00-ml or other suitable aliquot of sample solution (*A*) as for the calibration graph but measure against a similarly treated "procedure blank" (if the sample contains more copper, add 1 g or more of potassium cyanide).

RESULTS AND DISCUSSION

Selection of high boiling-point acid

When lead- and tin-base solders and white-metal bearing alloys have been dissolved in hydrobromic acid–bromine mixture, the tin, antimony and arsenic are present as stannic bromide (b.p. 202°), antimonous bromide (b.p. 280°) and arsenious bromide (b.p. 221°), which can be volatilized. High boiling-point acids such as sulphuric (b.p. 338°) or perchloric (b.p. 200°) are usually used for this purpose. If perchloric acid is used, a special fume-hood is desirable, but may not be available, so sulphuric acid is commonly used.

Co-precipitation of traces of metals with lead sulphate

Luke[3] studied photometric determination of aluminium in lead, tin- and lead-base solders with aluminon; he suggested that lead should be removed as sulphate, but did not consider co-precipitation of aluminium with lead sulphate. His results showed that the amount of aluminium found was 8–20% lower than the amount taken. Ota[4] studied spectrophotometric determination of iron in tin and lead alloys with 1,10-phenanthroline, and also separated lead as lead sulphate with no consideration of co-precipitation of iron. Karabash *et al.*[5] reported a chemical–spectroscopic method for determining impurities in lead. Lead sulphate was precipitated in hot, dilute nitric acid medium, set aside for 3 hr at room temperature, then separated by decantation and heated with 6*M* nitric acid for 2 hr. They claimed that twenty metals, including iron, aluminium, bismuth, zinc and copper, at concentrations of 10^{-1}–10^{-6}% in the lead, were not co-precipitated with the lead sul-

phate, but this claim was in contradiction with the large errors in their results.

In contrast, our results display loss of trace constituents by co-precipitation with a large mass of lead sulphate (Table 1). The higher the charge on the cation, the more serious is the co-precipitation, in accordance with the general adsorption rule. Insignificant amounts of copper(II) and only about 11% of the zinc were co-precipitated, but more than 60% of the tervalent ions, aluminium, bismuth and iron (Table 1).

Determination of Fe, Al, Bi and Cu in sample solution (A)

To eliminate co-precipitation of iron, aluminium and bismuth, the lead sulphate precipitate was dissolved with tartaric acid as complexing agent at pH 10. Determination of iron, aluminium, bismuth and copper according to the procedures given above gave values (Tables 2–5) in good agreement with the certified values or the amounts added.

Elimination of co-precipitation of zinc

Sample solution (A) is unsuitable for determination of zinc by the dithizone method, because of the competitive reaction of lead, which is present as a major constituent. The lead must be separated first, and if this is done by precipitation as the sulphate, even though the amount of zinc co-precipitated is much smaller than that of iron(III), aluminium and bismuth (Table 1), it still cannot be tolerated. To recover co-precipitated zinc from the lead sulphate, after its separation and washing with 0.5*N* sulphuric acid by decantation the precipitate is again washed with ammonia solution to remove the zinc as the $Zn(NH_3)_4^{2+}$. The data in Table 6 confirm the effectiveness of this method. Hence sample solution (B) can be used for determination of zinc by the dithizone method. Because any co-precipitated copper will also be removed as the ammine complex, $Cu(NH_3)_4^{2+}$, sample solution (B) can be used for determination of both zinc and copper (with different aliquots).

Effect of pH on determination of aluminium with 8-hydroxyquinoline

Gentry and Sherrington[16] reported that extraction of aluminium with 1% 8-hydroxyquinoline solution in chloroform is complete in the pH range 8–11.5; however, our results (Table 7) for a synthetic sample containing trace aluminium, a minor amount of iron, and EDTA and potassium cyanide showed that extraction was incomplete at pH less than 9 and higher than 12, but almost complete in the pH range of about 9.5–11 (controlled with ammonia–ammonium chloride buffer solution) when 8-hydroxyquinoline was added to the aqueous solution after adjustment of the pH. This effect is presumably a consequence of complexation with EDTA (which is strongest at pH 5.0) at pH <9.5, and co-precipitation at pH >12.0 on the ferric hydroxide produced on decomposition of the

Fe–EDTA complex by boiling at high pH. Thus, as shown by Table 7, the optimum pH for determining aluminium by the 8-hydroxyquinoline method by the procedure given is about 10.

Elimination of interference of iron in determination of aluminium

Iron(III) reacts with 8-hydroxyquinoline to form the green-black ferric 8-hydroxyquinolate even in the presence of EDTA. To eliminate the resulting iron interference in the determination of aluminium, Pigott[15] and Claassen *et al.*[14] suggested masking small amounts of iron (<50 mg) by adding 1 g of EDTA and 3 g of potassium cyanide (*i.e.*, at least 8 times as much cyanide as needed to react with the amount of iron in the sample taken), and gently boiling the solution (pH >8) for 15–20 min; the ferricyanide formed was said to be reduced to non-interfering ferrocyanide. Our results show that besides pH, the amount of potassium cyanide is also important (Table 8). At the iron level examined, even 50 mg of potassium cyanide proved insufficient to mask 0.1 mg of iron(III), and positive errors were obtained for aluminium. An attempt was made to apply a correction for the iron by masking the aluminium with fluoride, but the correction was not reproducible, owing to either variation in the amount of iron(III) complexed or incomplete masking of the aluminium (or both). Addition of a large amount (3 g) of potassium cyanide caused the Fe–EDTA complex to decompose and yield ferric hydroxide during heating, resulting in adsorptive co-precipitation of aluminium by the ferric hydroxide. Addition of 1 g of potassium cyanide was optimum, at pH 10 (ammonia–ammonium chloride buffer), giving complete masking of the iron and avoiding its hydrolysis.

Pigott[15] assumed that on boiling, the hydroxide ions from hydrolysis of the cyanide reduced the ferricyanide to ferrocyanide:

$$2Fe(CN)_6^{3-} + 2OH^- \rightleftharpoons 2Fe(CN)_6^{4-} + H_2O_2$$

However this explanation seems untenable in view of the redox potentials, and also because ferricyanide is more stable than ferrocyanide and so should not interfere anyway. Moreover, we made direct tests for ferrocyanide and found that practically none was produced even with boiling for 20 min.

Effect of amount of hydroxylamine hydrochloride on development of the copper(I) 2,2′-biquinoline complex

Our results show that even 0.5 g of hydroxylamine hydrochloride was not enough for complete reduction of copper(II) and colour development in sample solutions, even though ample for traces of copper in pure solution. When 1 g of hydroxylamine hydrochloride was added, complete reduction and colour development were obtained. The most likely explanation is formation of an inert tartrate-bridged copper(II)–tartrate–aluminium(III) complex,[17] or an analogous complex with iron(III).

PERFORMANCE OF THE ORION 97-70 TOTAL RESIDUAL CHLORINE ELECTRODE AT LOW CONCENTRATIONS AND ITS APPLICATION TO THE ANALYSIS OF COOLING WATERS

N. A. DIMMOCK and D. MIDGLEY*
Central Electricity Research Laboratories, Kelvin Avenue, Leatherhead, Surrey, England

(*Received* 30 *October* 1981. *Accepted* 24 *January* 1982)

Summary—The performance characteristics of the Orion 97-70 total residual chlorine electrode have been determined and the electrode has been found to give a near-theoretical response down to chlorine concentrations in the range 1–5 μg/l. Within-batch relative standard deviations are about 6 8% at concentrations above 50 μg/l. and 10–15% at lower levels. The method is virtually free from interferences (only strong oxidizing agents such as permanganate interfere) but large variations in salinity affect the calibration by changing the conditional standard potential. The best performance at low concentrations (<50 μg/l.) is achieved only if the manufacturer's recommended procedure is changed, namely by using a more dilute iodide reagent, stirring constantly, adding the iodide reagent before the buffer solution and using chloramine-T as a standard.

Residual chlorine concentrations are measured by the Central Electricity Generating Board so that the chlorination of saline cooling water can be controlled, to prevent mussel settlement in the culverts leading to the condensers. Cooling waters at inland power stations are chlorinated intermittently to prevent the formation of bacterial slimes on the condensers themselves. A recent EEC directive[1] setting a limit of 5 μg/l. for chlorine in fresh waters "needing protection or improvement in order to support fish life" makes it prudent to be able to measure at this level in cooling tower discharges, although there is at present no obligation to make such measurements.

Methods for determining residual chlorine have been reviewed by Midgley.[2] The most commonly used method is colorimetry with *N*,*N*-diethyl-*p*-phenylenediamine (DPD) as reagent,[3] but this is insufficiently sensitive for low chlorine levels in discharges. Amperometric titration has adequate sensitivity, but is time-consuming, requires expensive apparatus and is not capable of continuous operation.

A potentiometric method using the Orion 97-70 residual chlorine electrode has shown considerable sensitivity in synthetic fresh-water solutions,[4] but the apparatus would be unsuitable for analysis *in situ*. Since chlorinated waters are chemically reactive, samples sent to the laboratory for analysis will often give low results because of decay of the residual chlorine. Jenkins and Baird[5] determined residual chlorine at high levels in waste-water, and Scarano and Saroglia[6] have measured chlorine in sea-water down to about 10 μg/l. This paper describes a study of the use of the Orion 97-70 electrode for measurements at low levels of total residual chlorine in both fresh and saline natural waters used for industrial cooling. The factors limiting the performance of the electrode are investigated and the dependence of the e.m.f. on the iodide concentration is demonstrated both theoretically and experimentally.

THEORY

Electrode potential

The total residual chlorine electrode consists of a platinum electrode and a silver iodide membrane electrode mounted on a common stem. Iodide is added to the sample solution to cause the reduction of all forms of residual chlorine, including chloramines, bromine, bromamines, *etc*., with the formation of iodine.

$$\text{oxidant} + 2I^- \rightarrow I_2 + \text{reduced oxidant}$$

The cell potential is given by

$$\begin{aligned} E &= E_{Pt} - E_{AgI} \\ &= E^0_{Pt} + \frac{2.3RT}{2F}\log\frac{[I_2]}{[I^-]^2} - E^0_{AgI} \\ &\quad + \frac{2.3RT}{F}\log[I^-] \\ &= E^0 + \frac{2.3RT}{2F}\log[I_2] \end{aligned} \qquad (1)$$

Since the iodide terms from the two electrode potentials cancel, leaving iodine as the only concentration variable, the neglect of activity coefficients in this treatment is justified. Equation (1) implies that the

* Author to whom correspondence should be addressed.

potential is independent of iodide concentration (provided that enough is added to reduce all the residual chlorine), but this is misleading because of the chemical equilibria discussed below.

Electrode calibration

The equation for the electrode calibration graph is of the form

$$E \simeq \text{constant} + k \log [\text{TRC}] \quad (2)$$

where [TRC] is the total residual chlorine concentration.

Equations (1) and (2) are related through

$$[I_2]/[\text{TRC}] = \alpha \quad (3)$$

$$k \simeq \frac{2.3RT}{2F} \quad (4)$$

$$E^0_{Pt} - E^0_{AgI} + k \log \alpha \simeq \text{constant} \quad (5)$$

Hence

$$E \simeq E^0 + k \log \alpha + k \log [\text{TRC}) \quad (6)$$

Although α depends on the total residual chlorine concentration and on the iodide concentration, the experimental conditions can usually be adjusted to make it virtually constant. In such circumstances, equations (5) and (6) are valid within the limits of experimental error.

Iodine complexes

Iodine forms complexes with halide ions in solution.[7]

$$I_2 + I^- \rightleftharpoons I_3^-; \quad \beta_1 = 724 \quad (7)$$

$$I_2 + Br^- \rightleftharpoons I_2Br^-; \quad \beta_2 = 15 \quad (8)$$

$$I_2 + Cl^- \rightleftharpoons I_2Cl^-; \quad \beta_3 = 1.7 \quad (9)$$

Thus the total residual chlorine concentration is

$$[\text{TRC}] = [I_2] + [I_3^-] + [I_2Br^-] + [I_2Cl^-] = [I_2](1 + \beta_1[I^-] + \beta_2[Br^-] + \beta_3[Cl^-]) \quad (10)$$

In fresh waters the concentrations of bromide and chloride are negligible compared with that of the iodide added during analysis and equation (10) can be simplified to

$$[\text{TRC}] \simeq [I_2](1 + \beta_1[I^-]) \quad (11)$$

From equations (3) and (11)

$$\alpha \simeq 1/(1 + \beta_1[I^-]) \approx 1/\{1 + \beta_1(T_A - 3[\text{TRC}])\} \quad (12)$$

where T_A is the total concentration of iodide added. Substituting for α in equation (6) gives

$$E \simeq E^0 - k \log\{1 + \beta_1(T_A - 3[\text{TRC}])\} + k \log [\text{TRC}] \quad (13)$$

Equation (12) shows the dependence of α on the total residual chlorine concentration. If, however, $\beta_1 T_A \ll 1$ or $T_A \gg 3[\text{TRC}]$, α is effectively constant, enabling a near-theoretical response to be obtained from the electrode.

In estuarine and marine waters, where the bromide and chloride concentrations cannot be neglected as above, we have from equations (3) and (10)

$$\alpha = 1/(1 + \beta_1[I^-] + \beta_2[Br^-] + \beta_3[Cl^-]) \quad (14)$$

At the normal level of chlorination of sea-waters, $[\text{TRC}] \ll [Br^-] \ll [Cl^-]$ and therefore, $[Br^-] \simeq T_B$ and $[Cl^-] \simeq T_C$ where T_B and T_C are the total concentrations of bromide and chloride respectively. Moreover, the ratio $\gamma = T_B/T_C$ is virtually constant. Hence we can write

$$\beta_2[Br^-] + \beta_3[Cl^-] = [Cl^-](\beta_3 + \gamma\beta_2) \simeq \beta'_3 T_C$$

where $\beta'_3 = \beta_3(1 + \gamma\beta_2/\beta_3)$. Substituting in equation (14) gives

$$\alpha \simeq 1/(1 + \beta_1[I^-] + \beta'_3 T_C)$$

In practice, however, $\beta_1[I^-] \ll \beta'_3 T_C$ and $\alpha \simeq 1/(1 + \beta'_3 T_C)$. Substituting for α in equation (6) gives

$$E \simeq E_0 - k \log(1 + \beta'_3 T_C) + k \log[\text{TRC}] \quad (15)$$

Equation (15) shows that increasing salinity (or T_C) causes a reduction in e.m.f. and the electrode apparently indicates a lower total residual chlorine concentration than expected from a calibration in demineralized water. The calibration slope at different salinities will, however, be unchanged.

In brackish water the condition $\beta_1[I^-] \ll \beta'_3 T_C$ may not be met and equation (15) may not be a good approximation. The trend in e.m.f. produced by increasing salinity will, however, be the same.

EXPERIMENTAL

Apparatus

Orion 97-70 total residual chlorine electrodes (MSE Scientific Instruments, Manor Royal, Crawley, England) were used for all experiments. Measurements in the laboratory were made with a Corning 110 digital pH-meter reading to 0.1 mV. Measurements in the field were made with a Corning 610 portable analogue pH-meter (smallest division 1 mV on expanded scale). Colorimetric measurements were made with a Lovibond 1000 Comparator (The Tintometer Ltd., Salisbury) and spectrophotometric measurements with a Pye–Unicam SP6-500 spectrophotometer. Solutions were stirred with a magnetic stirrer in the laboratory and a battery-powered LPL Vibro-agitator in the field.

Reagents

Distilled water was continuously circulated through a nuclear-grade mixed-bed ion-exchange column (Elga Spectrum). The chlorine demand of this water was in the range 0.5–5 μg/l., and usually less than 2 μg/l.

Acetate buffer solution, pH 4, was prepared by dissolving 243 g of sodium acetate trihydrate and 480 g of acetic acid in water and diluting to 1 litre; 1 ml of this solution was added per 100 ml of sample.

The iodide reagent solutions were 0.5, 0.125, 0.025 or 0.005*M* potassium iodide, and usually contained sodium hydroxide (1 g/l.) but in the preliminary investigations this was sometimes omitted or replaced by sodium hydrogen carbonate (2.1 g/l.). Chlorine standards were prepared (*a*) by adding small volumes of potassium iodate solution (1.006 g/l. ≡ 1 g/l. of Cl_2) to a mixture of 1 ml each of buffer and iodide reagent solutions, stirring for 2 min and diluting to 102 ml, (*b*) from sodium hypochlorite solution (B.D.H. laboratory reagent) standardized iodometrically, and (*c*) from chloramine-T (sodium salt of *p*-toluenesulphochloramide trihydrate, "Baker Analyzed" reagent).

Unless otherwise specified, analytical-reagent grade materials were used.

Procedure

To 100 ml of standard or sample solution 1 ml of iodide reagent solution and 1 ml of acetate buffer solution were added in that order. The electrode was rinsed and then immersed in the solution. Use of the 0.025*M* potassium iodide reagent is referred to below as the "high-level" procedure for the chlorine range 50–1000 μg/l. and that of the 0.005*M* reagent as the "low-level" procedure for the chlorine range 1–100 μg/l. The solutions were stirred gently throughout.

In the known-addition experiments the initial chlorine concentration was approximately doubled in the addition step.

Any variations from the procedures described above are detailed, as they occurred, in the next section.

PRELIMINARY INVESTIGATIONS

Calibration

The calibration graph of e.m.f. against the logarithm of the chlorine concentration was linear only over the range 0.2–10 mg/l. when the reagents supplied with the electrode were used with iodate standards according to the manufacturer's instructions.[8]

With attention to the factors discussed below, a linear calibration graph could readily be obtained for concentrations down to 50 μg/l. and with care the range could be extended down to 1 μg/l. The age, pH and concentration of the iodide reagent and the use of chloramine-T standards were the most important factors in this improvement in performance, and the final procedure differed in several ways from the Orion method.

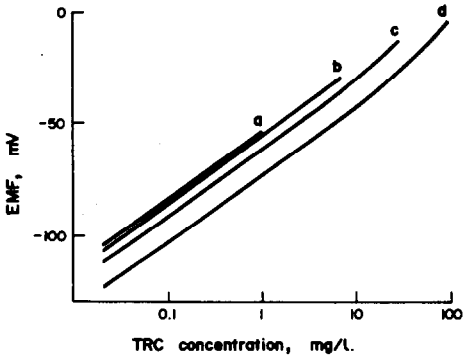

Fig. 1. Calculated effect of variation of the concentration of iodide reagent on calibration; 1 ml of reagent solution added per 100 ml of chlorine solution. Reagent concentration (*M*): (a) 0.005; (b) 0.025; (c) 0.125; (d) 0.50.

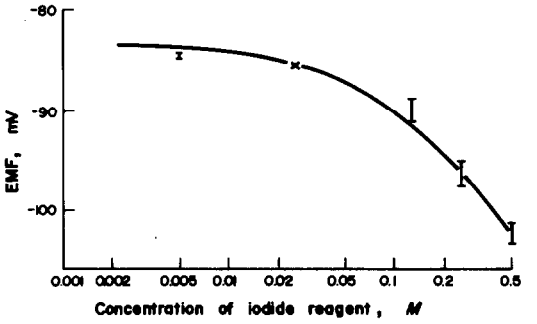

Fig. 2. Effect of variation of iodide concentration at constant total residual chlorine concentration (1 ml of reagent solution added per 100 ml of chlorine solution). Full line is response calculated relative to 0.025*M* KI as reference (×). Vertical error bars show observed ranges.

Iodide reagent concentration

In accordance with equation (13), increasing the iodide concentration produces a more negative e.m.f., corresponding to a lower concentration of free iodine, $[I_2]$. Calculated calibration curves for different reagent concentrations are shown in Fig. 1.

At TRC concentrations below about 1 mg/l. the e.m.f. is linearly related to log[TRC] and there is no theoretical reason why the calibrations should not be extrapolated downwards indefinitely. At higher concentrations deviations from linearity occur, because there is no longer a sufficient excess of iodide to keep the ratio $[I_2]/[I_3^-]$ virtually constant, so the proportion of molecular iodine increases. Eventually there is insufficient iodide to reduce all the residual chlorine; the upper extremities of the curves in Fig. 1 mark (approximately) these limiting TRC concentrations.

At a constant chlorine concentration, the rate of change of e.m.f. with iodide concentration increases as the iodide concentration increases, as shown in Fig. 2. In consequence, if the random errors in preparing and dispensing the iodide reagent are practically constant in absolute magnitude, there will be larger variations in e.m.f. and hence larger analytical errors, with the concentrated (0.5*M*) reagent recommended by Orion than with the more dilute reagents favoured in this work.

In practice, deviations from linearity were observed at low TRC concentrations (Fig. 3) where they would not be expected from the theory. These deviations increased with the concentration of iodide added, and for measurements in the range applicable to power station cooling waters (<1 mg/l.), the lower reagent strengths would be preferred. The deviations at low TRC concentrations were attributed to the presence of iodine in the reagent from oxidation of iodide by atmospheric oxygen. On standing, the reagent solutions developed the yellow colour typical of iodine; in the case of the solutions without added base, this occurred within a few hours, but for solutions containing sodium hydrogen carbonate several days were required. Solutions with sodium hydroxide remained colourless for even longer periods.

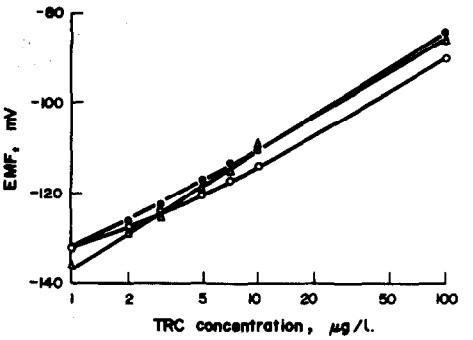

Fig. 3. Observed effect of variation of iodide reagent concentration on calibration; 1 ml of reagent solution added per 100 ml of chlorine solution. [KI]: ○ 0.125*M*; ● 0.025*M*; △ 0.005*M*.

The deviations from the extrapolated linear responses in Fig. 3 indicated that 0.0017% of the iodide in the freshly-prepared 0.5*M* solution (with added sodium hydroxide) had been oxidized to iodine. Further investigations into reagent oxidation are described below.

Age and pH of iodide solutions

Calibration with the 0.5*M* potassium iodide reagent prepared in different background media and stored in various ways was repeated over a period of time. Solutions were prepared in demineralized water, 0.025*M* sodium hydrogen carbonate, and 0.025*M* sodium hydroxide. Solutions were stored in both full and half-full bottles, and in the dark and in the light.

Potassium iodide solution was added (0.25 ml per 100 ml of standard solution of chlorine concentration 2000, 200, 50 and 20 µg/l.) and the e.m.f. values were recorded. The test was repeated at weekly intervals for four weeks. During this time, all the solutions except those containing sodium hydroxide developed the yellow iodine colour. The most negative e.m.f. values, *i.e.*, those indicating least iodine, were always obtained with solutions containing sodium hydroxide and the least negative always from solutions with no base added. The results were the same whether the solutions were stored in light or in the dark, and whether the bottles were full and unopened before use or half-full and opened several times over the period of the test. These results imply that high pH of the potassium iodide solution is the most important factor in minimizing oxidation to iodine, but although the trend in change in e.m.f. was always the same ($NaOH < NaHCO_3 <$ no base) over the four-week period, the differences were small and did not exceed $2\sqrt{2}\sigma_w$, where σ_w is the within-batch standard deviation. Over a period of four weeks from preparation, therefore, the method of preparation itself is not very critical for measurements at chlorine levels above about 20 µg/l., although a solution containing sodium hydroxide is to be preferred and such solutions were used for all further tests.

Twelve weeks after preparation of the solutions, the tests were repeated. Solutions containing sodium hydroxide showed no deterioration in performance but the other solutions (stored in the light) gave apparently lower sensitivities (21–23 mV per decade instead of 26–27 mV per decade) over the chlorine range 20–200 µg/l. The solutions containing sodium hydrogen carbonate and those with no added base that had been stored in the dark deteriorated less than those stored in the light (sensitivity ~25 mV per decade). For solutions containing sodium hydroxide, storage in the dark made no difference, and the sensitivity remained at about 27 mV per decade for the chlorine range 20–200 µg/l.

The reagent solutions supplied with the electrodes had a pH of 7.1 and were deep yellow. Their ages were unknown. With 1 ml of these solutions added per 100 ml of sample, the calibration started to deviate from linearity at about 200 µg/l., which is inconveniently high for the analysis of cooling water. Fresh solutions made 0.025*M* in sodium hydroxide were used for all further tests.

Standard chlorine solutions

Potassium iodate is a primary standard material and is recommended by Orion for calibration of the electrode. In this work, potassium iodate was found to be suitable for calibration at TRC levels down to 10 µg/l. when 0.025*M* potassium iodide reagent was used, but at lower concentrations of iodate or iodide, the contact time of 2 min recommended by Orion was insufficient to allow full conversion of iodate into iodine. Rigdon *et al.*[4] came to similar conclusions, although their concentration limits were different.

Sodium hypochlorite standards allowed calibrations to be made down to 1 µg/l. and reaction was complete even with the most dilute (0.005*M*) iodide reagent tested. The hypochlorite solution, however, is unstable and itself needs standardizing iodometrically by titration with thiosulphate.

Chloramine-T solutions allowed calibration down to 1 µg/l. with 0.005*M* iodide reagent. At higher levels the calibration coincided with that obtained with potassium iodate. Rigdon *et al.*[4] also found chloramine-T to be the most useful standard and chloramine-T solutions were used for almost all further work. The chloramine-T stock solution (chlorine equivalent 1000 mg/l.) was found to be stable for at least 4 months.

Stirring

The manufacturers recommend measurement without stirring of the test solution, but this was found to be unsuitable for measurements at levels below about 50 µg/l. At concentrations below 50 µg/l. the e.m.f. was too low (compared with the extrapolated Nernstian response) and drifted unsteadily to higher values without reaching equilibrium in 10 min. Without stirring there was no discrimination between concentrations of less than 10 µg/l. With stirring, however, steady e.m.f. values could be obtained at concentrations down to 1 µg/l., in accordance with the Nernstian

response at higher concentrations. Gentle stirring was used in all the other experiments reported in this work.

PERFORMANCE CHARACTERISTICS

Calibration

The e.m.f. was linearly related to the logarithm of the total residual chlorine concentration over the range tested (1 μg/l.–1 mg/l.), provided that the necessary precautions were taken in the preparation of the iodide solution. The slope was 95–98% of the theoretical (Nernstian) value of 29.58 mV per decade at 25°.

Precision

Direct potentiometry. The precision of measurements in fresh waters was estimated by analysing solutions of chloramine-T in demineralized water according to both the high- and low-level variants of the procedure. Duplicate measurements were made at each concentration in each batch, and six batches of measurements were made for each procedure, spread over three or four days. The results are given in Tables 1 and 2. The between-batch and total standard deviations were obtained after normalizing the results with respect to the mean e.m.f. for the most concentrated solution in each batch. The raw data for the most concentrated solutions were processed directly. A similar, but less extensive, series of tests was run with saline samples (0.6*M* sodium chloride in demineralized water). The results are shown in Tables 3 and 4.

The between-batch standard deviations of the normalized data were non-significant, with one possibly significant exception (1 μg/l. in saline water, Table 4). Such an absence of variation indicates that the slope factor is constant (within the range tested) over the period tested.

The between-batch standard deviations of the raw data were also non-significant with one possibly significant exception (1000 μg/l. in fresh water, Table 1), indicating that the standard potential did not vary significantly over the period of the test.

Known-addition potentiometry. Solutions of residual chlorine in demineralized water were analysed with five measurements made at each level. The standard deviations at concentrations of 150, 50 and 10 μg/l. were 9.5, 6.9 and 2.1 μg/l. respectively.

Effect of temperature

Calibrations were carried out according to the high- and low-level procedures at temperatures of 15, 25 and 35°, with the results shown in Fig. 4. With the

high-level procedure, the standard cell potential shifted by 0.6–0.7 mV/deg and the calibration slope changed in proportion to the absolute temperature (as would be expected for a Nernstian slope).

The low-level calibration shows a steeper slope than expected from theory, especially at the higher temperatures; this was thought to be caused by consumption of the residual chlorine by organic matter in the water used to prepare the solutions.

Response time

The response of the electrode was generally complete in less than 15 sec for increases in concentration and 30 sec for decreases in concentration. At concentrations below 10 μg/l., the response was apparently slower, but at such concentrations it is possible that the signal changed slowly because of concentration changes arising from the chlorine demand of the water. The response times quoted are for a rinsed electrode newly immersed in a fresh sample solution to which the reagents have already been added.

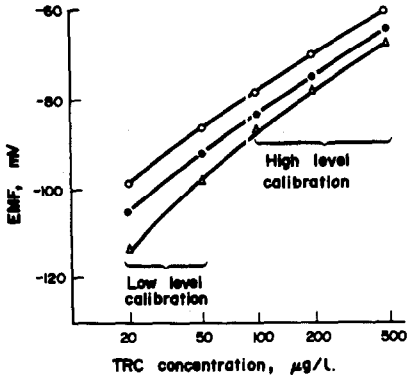

Fig. 4. Effect of temperature: ○ 15°; ● 25°; △ 35°.

Interferences

Interference tests were carried out at four levels of total residual chlorine, with permanganate, iron(III) and (the common contaminants occurring at highest concentration) calcium and magnesium. The effect of large concentrations of chloride is considered below under the heading of salinity changes and the effect of pH is also considered separately.

The results in Table 5 show that permanganate gave a positive interference. Although the metal ions caused consistently low readings, none of the differences exceeded two standard deviations and no significance can be attached to them. The following were also tested and shown to have no significant effect at the 1-mg/l. chlorine level: BrO_3^- (10 mg/l.); $Cr_2O_7^{2-}$ (1 mg/l.); Cu^{2+} (10 mg/l.); Pb^{2+} (1 mg/l.); Br^- (10 mg/l.); EDTA (10 mg/l.); NTA (10 mg/l.).

In a further test, the possibility of interference by iodate in sea-water was investigated. Solutions containing 0.6 mole of sodium chloride and 50 μg of chlorine per litre were analysed in the presence and absence of iodate (60 μg/l.). The readings with iodate present were about 6% high, but this was less than one relative standard deviation.

Salinity changes

The high- and low-level procedures were carried out in the presence of 0.0, 0.1, 0.3 and 0.6*M* sodium chloride, and the results are shown in Fig. 5. In both cases the e.m.f. values become more negative as the chloride concentration increases, but the calibration slopes stay the same. The shifts are caused by the formation of the I_2Cl^- complex, which diminishes the concentration of free iodine, I_2, and hence, from equation (1), the e.m.f. becomes more negative. Values of the stability constant, β_1, given in the literature[7] are grouped around two values, 3.6 and 1.7. Calculation of the shifts in e.m.f. with salinity gave the results in Table 6. The observed results are in good agreement with the calculated effect for the smaller stability constant of 1.7.

The known-addition method is not significantly affected by changes in salinity.

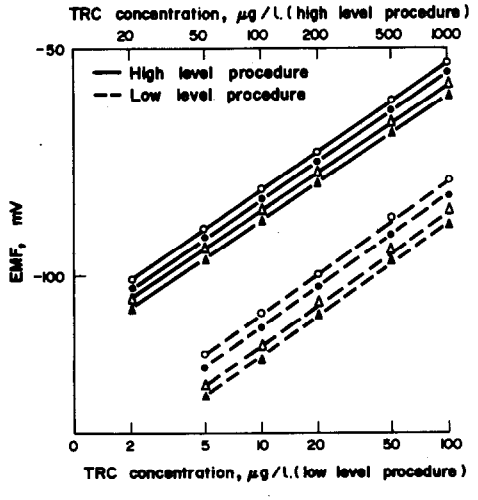

Fig. 5. Effect of salinity. [NaCl]: ○ nil; ● 0.1*M*; △ 0.3*M*; ▲ 0.6*M*.

Effect of pH

If the acetate buffer added to the samples fails to reduce the pH to about 4, the reaction between iodide and residual chlorine will proceed slowly and may not reach completion, *i.e.*, less than the stoichiometric amount of iodine will be formed and the electrode will indicate a residual chlorine lower than the true value. Figure 6 shows how much the calibration deviates from the Nernstian value even at pH 5. The pH affects the reaction and not the electrode itself: varying the pH of a solution after it has been allowed to react at pH 4 changes the e.m.f. by about 1 mV over the pH range 3–6.

For most natural waters, the addition of 1 ml of the acetate buffer solution should be adequate for adjustment of the pH to about 4. Before the technique is applied to highly alkaline waters, however, the effectiveness of the pH adjustment should be tested and more buffer used if necessary.

Effect of light

The effect of light on the e.m.f. was tested at 20 and 50 μg/l. by the low-level procedure and at 50 and 200 μg/l. by the high-level procedure. The maximum difference observed for any solution was 1.5 mV between dark and daylight conditions. The e.m.f. values in tungsten-lamp and fluorescent light were intermediate between the two extremes. The e.m.f. changes were reversible and independent of concentration.

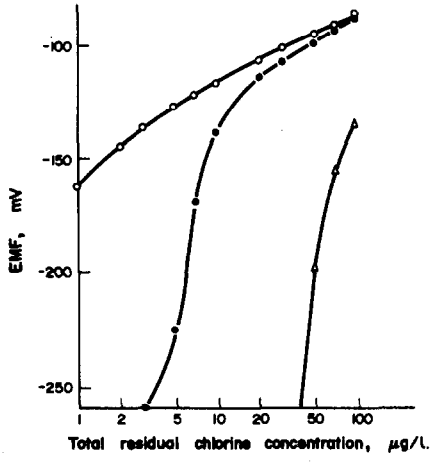

Fig. 6. Effect of pH: ○ pH 4; ● pH 5; △ pH 6.

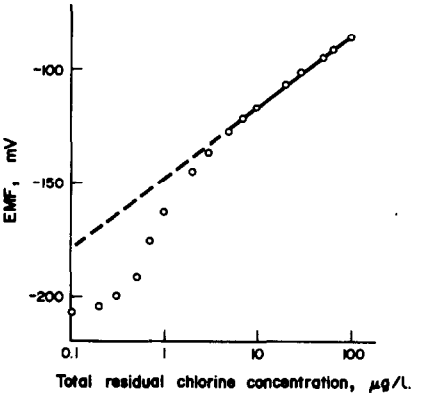

Fig. 7. Electrode calibration at low chlorine levels: 1 ml of 0.005*M* KI added per 100 ml of chlorine solution.

Order of reagent addition

Sodium hypochlorite was added to synthetic sea-water (0.6*M* NaCl + 65 mg/l. Br^-) and to a dechlorinated sample from Southampton Water. Measurements were made after adding reagents in the order:

(*a*) buffer first, then potassium iodide within 15 sec;
(*b*) potassium iodide first, then buffer within 15 sec;
(*c*) buffer first, then potassium iodide after 5 min;
(*d*) potassium iodide first, then buffer after 5 min.

The results in Table 7 show that, contrary to the recommendations of Orion, the potassium iodide reagent should be added *first* if loss of TRC from the sample is to be avoided, and this is particularly important in waters which have a chlorine demand. With a 5-min delay between additions, the losses are significant even in synthetic sea-water; the likely cause of this further loss of TRC is volatility of bromine and hypobromous acid, especially as the ratio of the concentrations of these species to hypobromite increases as the pH falls. Analysis of chlorinated samples from Southampton Water when buffer was added first gave results about half those indicated by the DPD colorimetric method.

Limit of detection

The limit of detection was not determined in a formal manner[9] because once the problem of molecular iodine in the iodide reagent had been minimized, the lower end of the calibration range was dominated by negative deviations, *i.e.*, the electrode indicated less residual chlorine than had been added. Figure 7 shows the typical shape of a calibration curve extending to low concentrations. The concentration at which the curve deviated from linearity varied between batches of water from the same source but was the same for two different electrodes. Figure 4 previously showed that the response deviated more from the theoretically expected values as the temperature increased.

Possible reasons for the presence of less iodine than expected from the quantity of chlorine added are (*a*) loss of iodine by volatilization, (*b*) incomplete reaction of the residual chlorine with the iodide reagent, (*c*) reaction of the residual chlorine or iodine with organic matter in the water or trace impurities in the buffer solution.

The volatilization of iodine should increase with temperature, which would agree with the results in Fig. 4, but should be independent of pH in the range tested and of the source of water. Moreover, in a system at equilibrium the relative loss of iodine, and, therefore, the effect on the e.m.f., should be independent of concentration. Although the apparatus used in these tests was open to the atmosphere, conditions were such that the relative loss by volatilization was not expected to depend significantly on concentration.

Table 7. Order of reagent addition

First reagents	Delay between reagents	E.m.f. readings for 100 µg/l. Cl_2*	
		Synthetic sea-water	Sea-water
Buffer	<15 sec	−88.4 (−3)	−98.2 (−58)
KI	<15 sec	−88.0 (0†)	−88.5 (−4)
Buffer	5 min	−94.3 (−4.2)	−115.2 (−90)
KI	5 min	−89.1 (−9)	−91.3 (−24)

* Figures in parentheses give percentage loss of TRC in sample compared with highest reading.
† Reference for percentage loss of sample.

Incomplete reaction of iodide with the residual chlorine should be less likely at high temperatures, which does not accord with the results in Fig. 4, nor should it depend on the water used to prepare the solutions. Increasing the pH should slow the reaction down, but at pH ≥ 5 the calibration curve had large negative deviations (Fig. 6). In very dilute solutions ($Cl_2 < 1$ μg/l.) at pH 4, it is possible that the reaction does not reach completion, but this does not account for the spasmodic occurrence of deviations at chlorine concentrations above 1 μg/l.

Reaction of the residual chlorine or iodine with organic matter in the water should increase with temperature, in accordance with Fig. 4, and would depend on the source of water. The effect of pH on these reactions is uncertain and would depend on the organic species present.[10] The water used in our laboratory had a chlorine demand of 0.5–5 μg/l. (usually 1–2 μg/l.), as calculated from the deviations of the electrode response from the Nernstian value.

It is unlikely that the response limit of the electrode itself has been approached in this work, and the problems encountered are probably not those of preparing and preserving pure standard solutions. Such problems are common to all methods of residual chlorine determination and it was concluded that for manual analyses the electrode could be calibrated directly with standard solutions down to 50 μg/l. TRC and in most cases down to 5 μg/l., depending on the quality of the water available for preparing the solutions. Since a Nernstian response can be obtained at a level of 1 μg/l. it is reasonable to calibrate at higher levels and extrapolate to 1 μg/l.

Analysis of chlorinated waters

The simplest method for a succession of samples with the same temperature (within 1°) and salinity (within 0.05*M* chloride) is direct potentiometry. If, however, samples vary in temperature or salinity, or if standard solutions matching the samples in temperature and salinity cannot be readily prepared, known-addition potentiometry is usually more convenient and accurate, since within fairly wide limits it allows for changes in equilibria caused by variations in conditions.

Results. Samples were analysed *in situ* at power stations on Southampton Water and the River Trent by using known-addition potentiometry with a portable pH-meter and checking the concentration by means of the DPD colorimetric method with a Lovibond Comparator having a 40-mm cell.

Samples from these locations were returned to our laboratory, chlorinated, and analysed in the laboratory, with use of a digital pH-meter for the potentiometric readings and a spectrophotometer for the colour method. Analyses were also done in the laboratory on the tap-water and drinking water, and on water from the Skegness sea-well which had been stored in tanks at the Central Electricity Research Laboratories. The results of the various analyses are shown in Table 8.

Some of the measurements referred to levels too low to be determined by colorimetry (<20 μg/l.), but at which the electrode was still capable of discrimination. The water from the Trent had such a high content of suspended solids (in addition to a natural yellow colour) that unfiltered samples could not be analysed spectrophotometrically. It was also evident from potentiometric measurements at CERL that the water from the Trent had a chlorine demand that prevented accurate measurements from being made. When the e.m.f. values were displayed on a chart-recorder, no stable reading could be obtained, since any chlorine added (up to at least 500 μg/l.) was

consumed in minutes. The method adopted with these samples was to insert the electrode in the sample, note the highest e.m.f. obtained and read the concentration from a calibration graph. For measurements *in situ*, the less sensitive portable pH-meter had to be used and the consumption of chlorine was not detected at concentrations above about 5 μg/l. At very low concentrations, however, such as in the discharge to the river, the chlorine added in the known-addition method was consumed before the electrode could indicate a change in e.m.f., and direct potentiometry had to be used in this case also. Jenkins and Baird[5] had similar problems and observed continuous drift for waste-water samples dosed with chlorine up to 3 mg/l., when the B.O.D. exceeded 50 mg/l.

In the analysis of Trent water, the electrode tended to become fouled by silt, particularly on the silver iodide membrane. With fouled electrodes, the results had a negative bias because of the chlorine demand of the silt. Wiping with a paper tissue adequately removed the fouling.

DISCUSSION

Analytical performance

When suitable precautions are taken, the slope of the electrode calibration agrees with the theoretical Nernstian value down to chlorine concentrations of about 1 μg/l. As this is equivalent to a concentration of less than $10^{-7}M$, this Nernstian limit is probably lower than has been demonstrated for any other ion-selective electrode in dilute solutions of determinand.[11] In this work the Nernstian response of the TRC electrode has been observed at lower concentrations than before,[4,6] probably because the more dilute iodide solution used introduced less trace iodine to bias the calibration. The precision of the measurements (7–10% relative standard deviation) is typical of electrodes used in manual analysis without special control of temperature.[12]

These characteristics, together with the electrode's rapid response and freedom from interferences, make this one of the best ion-selective electrodes. For measurements at low levels, however, considerable care must be taken over the method as a whole and it should be noted that the procedure recommended by the manufacturers differs in several respects from that found necessary in this work. In particular, the Orion iodide reagent is too concentrated in iodide and insufficiently alkaline; the order of addition of the reagents should be iodide first, then buffer; stirring is essential at low concentrations; potassium iodate is not a suitable standard at low concentrations.

Operational control of chlorination

The electrode has adequate sensitivity for measurement of residual chlorine at the 0.2-mg/l. level recommended for power station operations. The precision of such measurements should be at least as good as that obtainable by the method currently in use (colorimetry with DPD). In analysis by direct potentiometry, the dependence of the response on salinity is a possible source of error at estuarine power stations, but the known-addition method eliminates this problem.

Since this work started, the Orion 1770 continuous on-line monitor that uses this type of electrode has become available.

Analysis of environmental samples

The electrode has proved capable of making measurements at concentrations as low as those proposed for environmental protection,[1] *e.g.*, 5 μg/l. When used with a portable pH-meter and stirrer, the electrode can be used for measurements in the field. The known-addition method is recommended for such measurements unless the salinity and temperature of the samples are known to be constant, but for waters with an unsatisfied chlorine demand, measurement by the known-addition method is liable to error and direct potentiometry is preferred. Even so, the accuracy of measurements in such waters will be unpredictable and comparatively poor, but this would probably be true of any method.

Comparison with other methods

Methods for determining residual chlorine have recently been reviewed.[2,13] Earlier reviews[3,14,15] dealt mainly with colorimetric methods.

The concentrations measurable by the Orion electrode are considerably below those measurable by direct amperometry or colorimetry. Residual chlorine levels below 20 μg/l. have been determined by a time-consuming amperometric titration and by an indirect method using differential-pulse polarography, but neither method is suitable for field work and both involve considerably more expensive apparatus.

The DPD colorimetric method is suitable for field work when used with a colour comparator, but can measure only down to about 20 μg/l., and the precision is limited by the number of steps on the comparator disc. Even with a spectrophotometer, DPD is incapable of much better sensitivity and is prone to error from turbidity and natural colour in the sample.

The characteristics determined for the use of the Orion electrode in discrete analyses in this work indicate that the potentiometric method would probably be at least as suitable as direct amperometry for continuous on-line monitoring of residual chlorine. Comparative tests of the potentiometric and amperometric methods have not been carried out, except by Helz *et al.*,[13] whose results are of limited value since the model of Orion monitor used (SLeD) was suitable only for pure waters such as drinking water. No results for the later model 1770 monitor have been found in the literature.

CONCLUSIONS

The Orion 97–70 electrode is suitable for the determination of total residual chlorine down to levels of

1–5 μg/l., but accurate and precise measurement at μg/l.-levels depends on use of a procedure different in several ways from that recommended by the manufacturer.

At high total residual chlorine concentrations, the variation of e.m.f. with iodide concentration is shown to agree with that calculated from the effect of dissociation of the I_3^- ion, but at concentrations below 20–50 μg/l., the e.m.f. values also indicate production of iodine by atmospheric oxidation of the iodide reagent. The use of dilute, alkaline, iodide reagent solutions minimizes the bias from this source.

Salinity changes affect the response of the electrode but use of the known-addition method avoids analytical errors from this source. The only species found to cause significant interference was permanganate. Other oxidizing agents such as bromate, iodate, dichromate and copper(II) had no significant effect under the conditions tested. The electrode may be used for the analysis of fresh-water and sea-water samples in the laboratory or, with a portable pH-meter, in the field. A continuous on-line monitor that uses the same electrode is now commercially available. The potentiometric method is at least as sensitive as any other currently available and is cheaper and more convenient than other methods of comparable sensitivity and precision. In particular, the potentiometric method is more sensitive than the widely used DPD colorimetric method and is capable of better precision than the version of the DPD method in which a colour comparator is used.

EFFECT OF CATIONIC SURFACTANT ON THE FORMATION OF FERRON COMPLEXES

KATSUMI GOTO, SHIGERU TAGUCHI, KANJI MIYABE, and KEN-ICHI HARUYAMA

Department of Chemistry, Faculty of Science, Toyama University, Toyama, 930, Japan

(*Received* 21 *October* 1981. *Accepted* 16 *January* 1982)

Summary—In the spectrophotometric determination of aluminium and iron with ferron (7-iodo-8-quinolinol-5-sulphonic acid, H_2L), the addition of cationic surfactants greatly improves the linearity of the calibration curve and widens the useful pH range. The effect of cetyltrimethylammonium chloride (CTMAC) on the stepwise stability constants (K_1, K_2 and K_3) of the ferron complexes of aluminium and iron (ML^+, ML_2^- and ML_3^{3-}) and on the acid-dissociation constants (K_{a1} and K_{a2}) of ferron has been studied in connection with the role of the surfactant. CTMAC greatly increases the value of K_3 while exerting little effect on K_1 and K_2, thus rendering ML_3^{3-} the predominant species even at very low concentration of free L^{2-}. It also has some effect on the acid-dissociation constants of ferron, but sometimes it acts to decrease the free L^{2-} concentration. It is therefore concluded that the improvements due to addition of surfactant should be attributed to the increased K_3 value. The presence of surfactant micelles is not essential, because the surfactant has a favourable effect when present at well below its critical micelle concentration, and because the continuous variations plots show a peak at a point corresponding to the composition M:L:Q (Q = cationic surfactant) = 1:3:3.

Malát[1,2] found that the colour reaction between tin(IV) and Pyrocatechol Violet is greatly sensitized by addition of gelatin. Since then a number of spectrophotometric methods have been proposed in which cationic surfactants are used in conjunction with metallochromic reagents.[3–23]

Aluminium can be determined spectrophotometrically with ferron, but the method has several disadvantages. Ferron shows considerable absorbance at the wavelength of maximum absorption of the aluminium–ferron complex and the absorbance of the reagent varies considerably with pH. In addition, the calibration curve is non-linear unless very high reagent concentrations are used. These disadvantages can be drastically reduced by addition of a cationic surfactant, cetyltrimethylammonium chloride (CTMAC).[18]

Although iron(III) can be determined successfully with ferron in the absence of cationic surfactants, the addition of the latter is recommended because it extends the useful pH range down to 1.5.

Cationic surfactants frequently shift the absorption peak of metal–dye complexes to longer wavelengths. The shift is usually accompanied by increased molar absorptivity. The most widely accepted explanation for these effects is that the positive charge on the surfactant micelles enhances the acid dissociation of organic dyes so that the formation of higher ligand: metal ratio complexes is made easier.[14,24]

The acid dissociation of ferron, however, is not always enhanced by cationic surfactants. CTMAC suppresses it in neutral to alkaline medium when the ionic strength is high. Shijo and Takeuchi[11] also report that although the acid dissociation of Chrome Azurol S (CAS) is enhanced by addition of CTMAC at low pH, it is suppressed at pH > 12. Apparently other factors may be responsible for the improvements obtained by addition of cationic surfactants.

The present investigation was undertaken to obtain clearer insight into the role of cationic surfactants. The stepwise stability constants of the ferron complexes of aluminium and iron(III) were determined in the absence and presence of CTMAC. The results indicated that, of the three stepwise stability constants of the ferron complexes, the third is greatly increased by addition of CTMAC.

A study was also made of the composition of the ferron complexes formed in the presence of CTMAC. The results indicated the stoichiometry metal:ferron: surfactant = 1:3:3. It was also found that the presence of surfactant micelles is not of primary importance in the complex formation.

EXPERIMENTAL

Reagents

Standard aluminium solution, 2.5×10^{-3}M. Dissolve 0.2965 g of aluminium potassium sulphate 12-hydrate in a small volume of water containing 1 ml of concentrated sulphuric acid and dilute to 250 ml with water.

Standard iron(III) solution, 2.5×10^{-3}M. Dissolve 0.3014 g of ferric ammonium sulphate 12-hydrate in a small volume of water containing 1 ml of concentrated sulphuric acid and dilute to 250 ml with water.

Ferron solution, 2.5×10^{-3}M. Dissolve 0.2195 g of ferron in 250 ml of water.

CTMAC solution, 5.0×10^{-2}M. Dissolve 3.994 g of cetyltrimethylammonium chloride (CTMAC) in 250 ml of water.

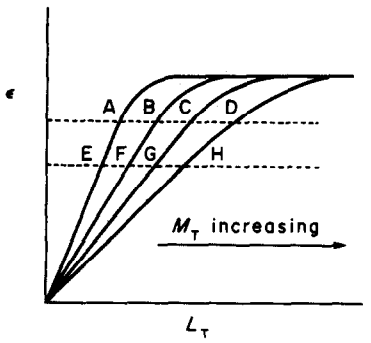

Fig. 1. Method of corresponding solutions for determination of $[L]_T$ and $\bar{n}$. ϵ as a function of L_T for different M_T's at constant pH.

Buffer solution (pH 4.5). Dissolve 6.804 g of sodium acetate trihydrate in 200 ml of water, adjust the pH to 4.5 with concentrated hydrochloric acid and dilute to 250 ml with water.

All reagents used were the purest grade commercial products.

Apparatus

A Hitachi 340 spectrophotometer with matched 10-mm cells was used. The Toa HM-20B digital pH-meter used was frequently calibrated with standard potassium hydrogen phthalate and phosphate buffer solutions. Conductivities were determined with a Toa CM-15A digital conductivity meter.

Determination of stability constants

Stability constants of metal ion–dye complexes are usually calculated from the absorbance *vs.* pH data for constant total concentration of metal ion in the presence of a large excess of the dye. For this method to be applied to complexes of hydrolysable metal ions, however, the hydrolysis constants of the metal ions must be known. The method of corresponding solutions[25] was therefore used because it permits stability constants to be calculated from the data obtained at constant pH, where the degree of hydrolysis is constant if the metal concentration is below the level at which the metal ion can polymerize. Thus, even when no reliable data are available about the hydrolysis equilibrium, conditional stability constants can be calculated.

Because the method of corresponding solutions is rarely used, a brief description of this method might be necessary.

Consider complex formation between a hydrolysable metal ion, M^{3+}, and ferron (H_2L), assuming that no polynuclear species exist in solution and that the pH is constant throughout.

We first define a measurable quantity ϵ as

$$\epsilon = \frac{A/l - \epsilon_L L_T}{M_T} \tag{1}$$

where A is the absorbance at the wavelength chosen (λ), l the optical path-length, ϵ_L the apparent molar absorptivity of ferron at the specified pH and λ, and L_T and M_T are the total concentrations of L and M, respectively.

Theoretically ϵ is given by

$$\epsilon = \frac{\epsilon_0 + (\epsilon_1 - \epsilon_L)K_1'[L]_T + (\epsilon_2 - 2\epsilon_L)K_1'K_2'[L]_T^2 + (\epsilon_3 - 3\epsilon_L)K_1'K_2'K_3'[L]_T^3}{1 + K_1'[L]_T + K_1'K_2'[L]_T^2 + K_1'K_2'K_3'[L]_T^3} \tag{2}$$

where ϵ_0 is the apparent molar absorptivity of the metal ion at the specified pH and λ, $[L]_T$ the total concentration of L not bound to M, ϵ_n the molar absorptivity of $ML_n^{(3-2n)+}$ at λ, and K_n' is the conditional stepwise stability constant, defined as

$$K_1' = [ML]/[M]_T[L]_T$$
$$K_2' = [ML_2]/[ML][L]_T$$
$$K_3' = [ML_3]/[ML_2][L]_T$$

where $[M]_T$ is the total concentration of metal ion not bound to ferron and charges are omitted for simplicity.

The average number, $\bar{n}$, of L bound to M is related to the stability constants and $[L]_T$ by the equation

$$\bar{n} = \frac{K_1'[L]_T + 2K_1'K_2'[L]_T^2 + 3K_1'K_2'K_3'[L]_T^3}{1 + K_1'[L]_T + K_1'K_2'[L]_T^2 + K_1'K_2'K_3'[L]_T^3} \tag{3}$$

The term "corresponding" means "having the same value of ϵ". Since ϵ is a function of only $[L]_T$, as will be seen from equation (2), corresponding solutions have the same value of $[L]_T$ and hence the same value of $\bar{n}$, because $\bar{n}$ is also a function of only $[L]_T$.

The technique is as follows: prepare a series of solutions having the same M_T and pH but different L_T values and measure the absorbance of each solution. Calculate the values of ϵ and plot them against L_T. Make similar plots for different values of M_T, obtaining a graph like that shown in Fig. 1. Then cut the curves with horizontal lines drawn at several points. The intersections of the straight lines and the ϵ *vs.* L_T curves, *e.g.*, A, B, C, D in Fig. 1, represent a series of corresponding solutions because they have the same value of ϵ. The points E, F, G, H represent another series of corresponding solutions.

Plot L_T against M_T for a series of corresponding solutions, obtaining a straight line (Fig. 2), the slope of which is $\bar{n}$ for the series. Obtain $[L]_T$ by extrapolating to $M_T = 0$. Establish the relationship between $\bar{n}$ and $[L]_T$ by repeating the procedure for different sets of corresponding solutions. Then find the conditional stability-constant values which minimize the sum of the squares of the differences between calculated and observed values of $\bar{n}$.

Under the conditions of the present investigation, where hydrolysis equilibria other than

$$M^{3+} + H_2O = MOH^{2+} + H^+$$
$$K_h = \frac{[MOH^{2+}][H^+]}{[M^{3+}]}$$

($pK_h = 2$ and 5 for Fe^{3+} and Al^{3+}, respectively) are not important, the stepwise stability constants defined by

$$K_n = [ML_n]/[ML_{n-1}][L]$$

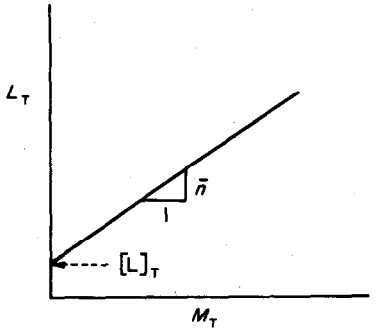

Fig. 2. Method of corresponding solutions for determination of $[L]_T$ and $\bar{n}$. L_T as a function of M_T for constant ϵ.

are related to the conditional stability constants by the equations

$$K_1 = K'_1\alpha_{L(H)}([H^+] + K_h)/[H^+]$$

$$K_2 = K'_2\alpha_{L(H)}$$

$$K_3 = K'_3\alpha_{L(H)}$$

where $\alpha_{L(H)} = 1 + [H^+]/K_{a2} + [H^+]^2/K_{a1}K_{a2}$, the quantities K_{a1} and K_{a2} being the first and second acid dissociation constants of H_2L.

Procedure

An appropriate volume of standard aluminium solution was placed in a 50-ml beaker. An appropriate volume of potassium chloride solution was added to adjust the ionic strength to 0.1, and then 0.25–5.0 ml of ferron solution and 5.0 ml of acetate buffer solution were added. For the study of the effect of CTMAC, 5 ml of CTMAC solution were added. The contribution of CTMAC to the ionic strength was neglected. The pH was adjusted to 4.30 ± 0.02 with hydrochloric acid or sodium acetate solution. The mixture was transferred into a 25-ml standard flask and diluted to the mark and equilibrated at 25°. The absorbance of the solution was measured and the stability constants were calculated as described above. Equilibrium was reached within 1 hr in the absence of CTMAC. In the presence of CTMAC, equilibrium was attained rather slowly, so the absorbance was measured after about 40 hr. The pH was checked again at the end of each run. Formation of aluminium–acetate complexes was neglected.

The stability constants of iron–ferron complexes were determined in much the same way, except that pH 2.00 was used, adjusted with hydrochloric acid and sodium hydroxide without a buffer. Equilibrium was attained within 1 hr both in the presence and absence of CTMAC.

The wavelengths used for absorbance measurements were 370 nm (Al–ferron system), 385 nm (Al–ferron–CTMAC system), 610 nm (Fe–ferron system), and 600 nm (Fe–ferron–CTMAC system).

RESULTS AND DISCUSSION

Calibration curve

The calibration graph for aluminium in the presence of CTMAC is linear up to $1 \times 10^{-4}M$, but nonlinear in its absence. The difficulties associated with the use of ferron are greatly reduced by addition of CTMAC. When the concentration of ferron is $5.0 \times 10^{-4}M$, the reagent blank absorbance is reduced from 0.2 to 0.05 by addition of CTMAC. The reduced reagent blank is of special advantage because the reagent blank changes remarkably with pH. In addition, the sensitivity is slightly increased.

The calibration graph for iron is linear at higher pH, but not at pH lower than 3.0 in the absence of CTMAC. In the presence of CTMAC, a linear calibration graph is obtained up to $2 \times 10^{-4}M$ iron even at a pH as low as 1.5.

Effect of CTMAC on the acid dissociation of ferron

Ferron dissociates in two steps, the zwitterion proton first and then a proton from the phenolic group. The first and second acid-dissociation constants, K_{a1} and K_{a2}, determined spectrophotometrically, are shown in Table 1 and Fig. 3.

The K_a values were determined at an ionic strength of 0.1 (KCl), except the value of K_{a1} in presence of CTMAC, which is so large that measurements had to be made at low pH, and this could not be attained without increasing the ionic strength to above 0.1. Thus it was calculated from the value obtained at $\mu = 0.5$, by means of the Debye-Hückel equation. The ion-size parameter for HL^- was assumed to be 8×10^{-8}.[26] As seen from Table 1, the value of K_{a1} is increased about tenfold by addition of CTMAC.

The effect of some strong electrolytes on the value of pK_{a2} in the presence and absence of CTMAC is shown in Fig. 3, which clearly shows that pK_{a2} is decreased by CTMAC at low ionic strengths, but increased at higher ones. This increase is lower for potassium nitrate than for potassium chloride as inert electrolyte.

Extrapolation to zero electrolyte concentration yields $10^{-7.15}$ and $10^{-6.85}$ for the thermodynamic K_{a2} values in the absence and presence of 0.01*M* CTMAC, respectively.

When potassium nitrate was added to a solution of CTMAC, a slight increase in viscosity was noticed at a nitrate concentration of about 0.2*M*. At nitrate concentrations higher than 0.6*M*, the solution became highly viscous. If potassium iodide was added instead of potassium nitrate, the solution became turbid at an iodide concentration as low as 0.025*M*. The turbidity was observed even when the concentration of CTMAC was below its critical micelle concentration (cmc). On the other hand, no apparent change was noticed on addition of potassium chloride. Appar-

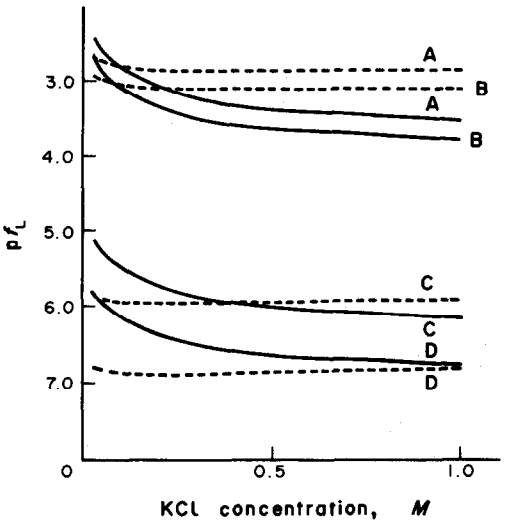

Fig. 4. Effect of KCl on f_L. CTMAC: ----- 0, —— $1.0 \times 10^{-2}M$; pH: A, 4.55; B, 4.30; C, 2.00; D, 1.50.

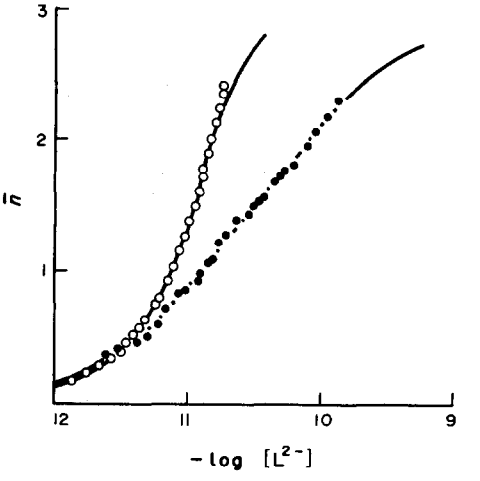

Fig. 6. Formation curve for Fe(III)–ferron complexes. Calculated from data obtained at pH 2.0 and $\mu = 0.1$ (KCl). CTMAC: —●— 0, —○— $1.0 \times 10^{-2}M$; ●○: observed, —— calculated.

ently there are specific interactions between the surfactant cation and added anions.

It is the fully deprotonated ferron which combines with M^{3+} to form the complexes ML^{+}, ML_2^{-} and ML_3^{3-}. The combined effect of CTMAC and inert electrolyte on K_{a2} will therefore alter the conditional stability constants of the complexes by changing the fraction of ferron present as L^{2-} (f_L). This effect was calculated for different pH values and is shown in Fig. 4. At pH 2.0, used for the iron–ferron investigation, CTMAC increases f_L at chloride concentrations $<0.4M$, but decreases it at higher chloride concentrations. The value of f_L is increased by a factor of nearly 5 by addition of CTMAC at pH 1.5 and ionic strength 0.1 (KCl), the conditions used for the calibration graph for iron. The aluminium–ferron system was investigated at pH 4.3, where the second acid dissociation of ferron is suppressed by addition of CTMAC if the chloride concentration is $>0.1M$. At pH 4.55 and ionic strength 0.8 (KCl), the value of f_L is decreased by a factor of about 4 by addition of CTMAC, but the linearity of the calibration graph for aluminium is greatly improved by addition of CTMAC. Apparently factors other than the enhanced dissociation of ferron should be taken into consideration to explain the role of CTMAC.

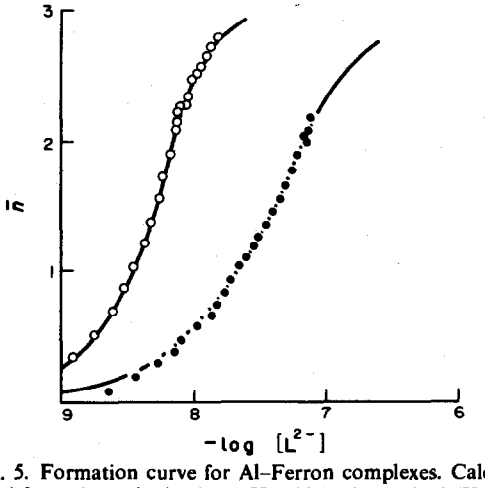

Fig. 5. Formation curve for Al–Ferron complexes. Calculated from data obtained at pH 4.30 and $\mu = 0.14$ (KCl). CTMAC: —●— 0, —○— $1.0 \times 10^{-2}M$; ●○: observed, —— calculated.

Effect of CTMAC on the stability constants of ferron complexes

Figure 5 shows the relationship between $\bar{n}$ and $[L^{2-}]$ for aluminium–ferron complexes at pH 4.3 in the absence and presence of CTMAC and Fig. 6 shows that for iron–ferron complexes at pH 2.00. Available data for the hydrolysis constants indicate that there is no polymerization of aluminium and iron(III) at these pH values. Best fits to the observed $\bar{n}$ and $[L^{2-}]$ data were obtained with the values of stability constants listed in Table 2. In the presence of CTMAC, the value of K_2 is very small in comparison with K_1 and K_3 and any value smaller than a certain limit will fit the experimental data if a proper value is assigned to the product K_2K_3. The curves in Figs. 5 and 6 for the presence of CTMAC were drawn with maximum possible values of K_2 ($10^{5.8}$ for aluminium–ferron and $10^{9.7}$ for iron–ferron).

In 1961, Langmyhr and Storm[27] reported values of the stability constants for the aluminium–ferron complexes. Their values, however, do not agree with ours. Close examination of Langmyhr and Storm's paper shows that their constants were based on tacit but incorrect assumptions. First they did not take hydrolysis into account, and then they calculated the stability constants by a method applicable only to a system for which $K_1 \gg K_2 \gg K_3$.

Table 2. Stepwise stability constants of ferron complexes (25°C)

Ion	μ	CTMAC	log K_1	log K_2	log K_3	log K_2K_3

		0.01*M*	11.5	<9.7	>12.2	21.9

μ = Ionic strength.

It is interesting that CTMAC increases the apparent value of K_3 while decreasing that of K_2. This may indicate that ML_3^{3-} combines more strongly than ML_2^- with surfactant cations.

To visualize more clearly the effect of CTMAC on the formation of ferron complexes, the distribution of metal ion between various complexes as a function of $[L^{2-}]$ was calculated with a maximum value assigned to K_2. The results (Figs. 7 and 8) show that in presence of CTMAC ML_2^- is not formed in appreciable quantities, but the domain where ML_3^{3-} is the predominating species is extended to lower $[L^{2-}]$. If enhanced acid-dissociation of ferron were the only cause for formation of the higher complexes, the distribution curves would have simply been moved to the left by addition of CTMAC to the system.

Both HL^- and L^{2-} have high absorptivities at the wavelength where the absorption spectrum of AlL_3^{3-} has a peak. Therefore it is not advisable to make the L^{2-} level sufficiently high for formation of only AlL_3^{3-} (*e.g.*, by adding large quantities of ferron or raising the pH). On the other hand, addition of cationic surfactants makes the AlL_3^{3-} species predominant even at low concentrations of L^{2-}. It also greatly reduces the absorptivity of the reagent itself at the absorption maximum of AlL_3^{3-}, so higher concentrations of ferron can be used.

For the determination of iron, addition of surfactants is not absolutely necessary, because FeL_3^{3-} is more stable than AlL_3^{3-} (so FeL_3^{3-} is the predominant iron species over a wide range of $[L^{2-}]$) and ferron has negligible absorptivity at the absorption peak of FeL_3^{3-} (so high concentrations of ferron can be used anyway). However, the addition of CTMAC may have merit on some occasions because it extends the useful pH range down to 1.5 (see Figs. 9 and 10).

Composition of the complex formed in the presence of CTMAC

In the discussion, CTMAC was regarded as one of the components of the medium and not treated as a complex-forming species, simply to avoid the difficult computation of so many equilibrium constants.

However, because it seemed very likely that CTMAC takes part in the complexation, a study was made of the composition of the iron(III)–ferron complex formed in the presence of CTMAC. The method of continuous variations was used. The absorbances of a series of solutions having the same total concentration but different individual concentrations of iron(III), ferron and CTMAC were

measured and plotted on a triangular diagram (Fig. 11), which shows that the absorbance is maximum at a point corresponding to the composition FeL_3Q_3 (Q = CTMAC). The same composition was found for the corresponding aluminium complex.

Nature of the complex formation

The favourable effects of cationic surfactants on complexation reactions are usually attributed to the unusual environment on the surface of surfactant micelles,[9,14,24] but the simple stoichiometry of the complex described above casts doubt on this explanation.

It was therefore interesting to study whether the favourable effects are observed at surfactant concentrations below the critical micelle concentration (cmc).

The cmc values obtained for CTMAC and cetyltrimethylammonium bromide (CTMAB) by various investigators[8,12,28,29] are shown in Table 3 together with ours. Agreement between the results is good except for the one reported by Bailey *et al.*,[8] who used a spectrophotometric method with Rose Bengal Extra. As pointed out by Mukerjee and Mysels,[30] the spectrophotometric method tends to give lower results than other methods; these authors postulate that the spectral change occurs when just a few surfactant cations have combined with the dye.

Hiskey and Downey[31] have shown that the colour change of Methyl Orange with increasing concentration of octadecyltrimethylammonium chloride can be accounted for by assuming a combining ratio of dye to quaternary ammonium cation of 1:1. Our preliminary investigation indicated that the spectral change of the ferron–CTMAC system at about pH 4.5

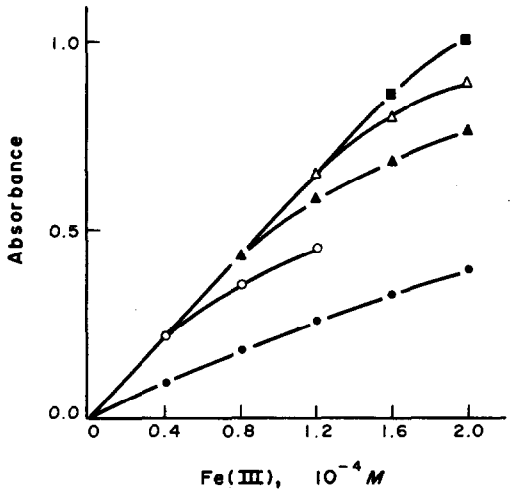

Fig. 12. Calibration curve for Fe(III) in the presence of different concentrations of CTMAC. pH: 1.5; ferron: $1.0 \times 10^{-3}M$; ionic strength: 0.1 (KCl); CTMAC: —●— 0, —○— $2.0 \times 10^{-4}M$, —▲— $4.0 \times 10^{-4}M$, —△— $6.0 \times 10^{-4}M$, —■— $8.0 \times 10^{-4}M$.

can be interpreted in terms of the equilibrium

$$Q^+ + HL^- = QHL \quad (\log K \text{ approx. } 3.7).$$

Thus there are good reasons for considering that the value reported by Bailey *et al.* is incorrect, and adopting a value of around $10^{-3}M$ as the cmc of CTMAC.

Figure 12 shows the effect of various concentrations of CTMAC on the shape of the calibration curve for iron at pH 1.5. Although the concentration of CTMAC did not exceed $10^{-3}M$, its presence increased the slope of the calibration curve.

At low iron concentrations, all the calibration curves obtained with CTMAC present were identical and linear. The length of the linear portion increased linearly with increasing concentration of CTMAC, and the deviation from linearity began when the CTMAC:iron(III) ratio fell below 5. This indicates that a very small amount of CTMAC is sufficient to obtain good results if iron is present at low concentration, and that surfactant micelles are not important.

Takeda *et al.*,[32] who studied the absorption spectrum of pinacyanol chloride–sodium dodecylsulphate mixture by a stopped-flow technique, showed that the first step in solubilization of the pinacyanol chloride was the formation of a dodecyl sulphate salt of the pinacyanol cation, which was then solubilized in the micelle phase.

In a practical application of the ferron–CTMAC procedure for the determination of iron and aluminium, it is recommended to add ferron and CTMAC in concentrations much higher than those used in the present study, to avoid slight changes in the absorption spectrum of the reagent blank with minor changes in the amount of CTMAC added and to make the method applicable to higher concentrations of the metal ions. Under these circumstances, CTMAC apparently does form micelles, but it is very likely that their role is merely to solubilize the electrically-neutral slightly soluble species QHL and ML_3Q_3.

Acknowledgements—The authors wish to express their thanks to Miss K. Hashizume and Miss S. Kyoden for their help in carrying out the experiments.

Zusammenfassung—Es wird ein Verfahren zur Profil- und Spurenanalyse in InSb-Materialien beschrieben. Zur Schichtabtrennung im nm-Bereich wird die Methode der anodischen Oxidation (galvanostatische Arbeitsweise) verwendet. Die Parameter der Schichtabtrennung wurden optimiert, die Messung der Schichtdicke der abgetrennten Schichten erfolgte ellipsometrisch. Die analytische Bestimmung der Spurenelemente erfolgte durch AES- und AAS-Messungen. Die erreichbaren Nachweisgrenzen liegen bei einer Oberfläche von 1 cm^2 und einer Schichtdicke von 60 nm in Bereich von 10^{17} Atome/cm^3. Verteilungsprofile für Mg und Te in InSb werden gezeigt.

Für die Profilanalyse von halbleitenden Materialien ist es erforderlich, über reproduzierbar arbeitende, gut auflösende Schichtabtrennungsverfahren und nachweisstarke, für Mikroproben einsetzbare Bestimmungsverfahren zu verfügen. Unsere ersten Untersuchungen zu dieser Problematik führten wir am GaAs durch.[1] Hinsichtlich der Tiefenauflösung sind die Verfahren des Ätzens nach anodischer Oxidation oftmals am günstigsten.[1–9] Für die Bestimmung der Spuren sind neben atomspektroskopischen auch elektrochemische Methoden und die Massenspektroskopie geeignet.

Ziel dieser Arbeit ist es, die am GaAs durchgeführten Untersuchungen auf den $A^{III}B^{V}$-Halbleiter InSb zu erweitern. Das betrifft sowohl die Verfahren zur hochauflösenden Schichtabtrennung als auch die Charakterisierung analytischer Bestimmungsmöglichkeiten.

Untersuchungen zur anodischen Oxidation mit dem Ziel der Herstellung von Dielektrika wurden bereits durchgeführt. Dewald[10] oxidierte InSb galvanostatisch (I = 0,2 mA/cm^2 in 0,1M Kalium hydroxid) Es wurde festgestellt, daß unmittelbar an der Oberfläche nur Indium vorliegt, weil SbO_x im gewählten Elektrolyten aufgelöst wird. Bereits in einer Tiefe von 20 nm ist das In:Sb Verhältnis gleich 1. Daraus kann man schlußfolgern, daß in dieser Tiefe kein Sb–KOH-Kontakt erfolgt. Diese Methode wurde auch von anderen Autoren zur Herstellung dicker Oxidschichten verwendet.[11–16]

Zur Verminderung der Auflösung der Schicht wurde als Elektrolyt 0,1M Borax-Lösung eingesetzt.[17,18] Einige Autoren stellen einen Zusammenhang zwischen der Oxidationszeit und der sich einstellenden Spannung fest.[11,12,17,18] Tschaikin und Mitarbeiter[19,20] fanden, daß die Schichtdicke anfangs proportional mit der Zeit (bis zu 0,1–0,2 μm) danach langsamer wächst. Ein anderes Resultat wird von Sakurai *et al.* angegeben.[12] Hier wurde Proportionalität zwischen Schichtdicke und Oxidationszeit bis zu 2,4 μm festgestellt (I = 3 mA/cm^2). Die Endspannung betrug nur 40 V. Bei Anwendung eines Impulsbetriebes[20] wurde ebenfalls ein linearer Zusammenhang für die Schichtdicken von 2 μm gefunden.

Festgestellt wurde, daß die Orientierung (111, 211, $\overline{2}11$) Einfluß auf die anodische Oxidation hat.[9,11,12,19–21] Neben wäßrigen, wurden auch

* Teil V—*Talanta*, 1979, **26**, 737.
† Korrespondenzanschrift.

nichtwäßrige Elektrolytlösungen als Medium verwendet: 2%iges Kaliumnitrit in Tetrahydrofurfurylalkohol (THF);[14] 5% Borax, 5% Wasser, 90% Ethylenglykol und Kaliumhydroxid in Tetrahydrofurfurylalkohol;[21] $KMnO_4$ in Aceton.[22]

Bei Einsatz der Dewald-Methode[9] wurden Oxidschichten bis zu 120 nm (KOH/THF, I = 1 mA/cm^2) bzw. bis zu 500 nm (Ethylenglykol, 1,5 mA/cm^2) erreicht.[21]

Die in einer früheren Veröffentlichung[1] formulierten Forderungen für die Anwendung der anodischen Oxidation zur Profilanalyse—gleichmäßige Oxidation der Komponenten und Oberfläche, keine Lösung des oxidierten Materials durch den Elektrolyten und reproduzierbare Beziehungen zwischen elektrischen Parametern und Schichtdicke—behalten volle Gültigkeit. Die galvanostatische Arbeitsweise ist aus diesen Gründen besser als die potentiostatische. Elektrolyt und elektrische Parameter sind experimentell zu prüfen.

EXPERIMENTELLER TEIL

Substanzen

(*a*) InSb—Einkristall-Blättchen, Orientierung 211 und $\overline{211}$.

(*b*) InSb—Na-dotiert (1–6 × 10^{17} At/cm^3), Orientierung 111 und $\overline{111}$.

(*c*) InSb vom *n*-Typ mit Trägerkonzentration 10^{14} (T = 180°C), Orientierung 111 und $\overline{111}$.

Elektrolyt. Ammoniumpentaborat—2 g/l. in H_2O, und 8 g/l. in Ethylenglykol–H_2O (1:1)[26] für InSb.

Apparatur

Amperostat, Eigenbau, UdSSR (0–100 mA, Stabilität ± 3%); Kathode 10 cm^2 Pt; Anodenhalter Ta (anodisch oxydiert); Stromdichte *ca.* 1 mA/cm^2 für InSb.

Jarrell-Ash Atomabsorptionsspektrometer 811, Beckman Graphitrohrküvette 1268, Untergrundkompensation nach der Zweilinienmethode. Perkin–Elmer Atomabsorptionsspektrometer 303 mit Graphitrohrküvette HGA 74, Untergrundkompensation mit Hilfe der Deuteriumlampe.

Schichtdickenmessung. Ellipsometrisch und chemisch. Letztere erfolgt durch Flammen-AAS am AA-Spektrometer 303 (Perkin–Elmer) mit C_2H_2–Luft-Flamme. Die Umrechnung erfolgt nach

$$d = \frac{M}{\varrho A}$$

A = Oberfläche-Areal; M = Masse InSb; ϱ = Dichte; InSb = 5,78 g/cm^3.

Verfahren der anodischen Oxidation

Die Oberflächen der Materialien wurden mechanisch bis zur Klasse 14 poliert. Ätzen mit einer Mischung von Milchsäure und Salpetersäure (10:1) hatte auf die Experimente keinen Einfluß. Die nicht zu oxidierende Seite wurde mit Paraffin bedeckt. Dann wurde das Material in die Ta-Halterung geklemmt und anodisch oxidiert. Die oxidierte Schicht wurde mit Flußsäure (1:10) aufgelöst. Die Lösung wurde aufgesaugt und analysiert. Beliebig viele Wiederholungen waren möglich.

Arbeitsweise der Spurenbestimmung

Die Flußsäure-haltigen Analysenlösungen werden eingedampft und in 50 µl 1*M* Salpetersäure aufgenommen. Die mechanisch abgetrennten Mengen können in 50–100 µl 1*M* Salpetersäure nach Einwaage gelöst werden. Bezogen auf 1 cm^2 werden bei einer Schichtdicke von 60 nm 35 µg InSb gelöst. Bei höheren Dotierungen erfolgt eine entsprechende Verdünnung. Probevolumina von 10 bis 20 µl werden in die Graphitrohrküvette gegeben und programmiert, getrocknet, verascht und atomisiert.

ERGEBNISSE

Optimierung des Abtrennungverfahrens

Es wurden Stromdichten zwischen 0,5 und 5 mA/cm^2 überprüft. Bei Anwendung des wäßrigen Elektrolyten war das In:Sb—Verhältnis in der oxidierten Schicht gleich 1, (s.a. Abb. 2), bei Verwendung des gemischten Elektrolyten war es <1, d.h. hier wurde Indium teilweise gelöst. In Wasser, Aceton, Ethanol und wäßrigem Elektrolyt trat während 24 Stunden keine Veränderung der Oberflächeninterferenz ein, d.h. es wurde nichts abgelöst. Hinsichtlich dieses Kriteriums konnten die obigen Stromdichten als gleichwertig angesehen werden.

In der Tabelle 1 wurden die relativen Standardabweichungen der Schichtdicken auf einer und von mehreren Oberflächen zusammengefaßt. Aus dieser Tabelle geht hervor, daß die relative Standardabweichung mit zunehmender Schichtdicke besser wird. Ein Vergleich mehrerer Proben weist bei 32 nm Dicke eine Toleranz von 0,08 aus.

In der Abb. 1 wurde die Abhängigkeit der sich mit der Oxidation einstellenden Spannungsdifferenz ΔU von der Oxidationszeit bei unterschiedlichen Stromdichten dargestellt. In der Anfangsphase ergibt sich in jedem Fall direkte Proportionalität. Ab einer bestimmten Spannungsdifferenz ($\Delta U_{\ddot{U}}$) ergibt sich eine Verlangsamung des Anstieges der Spannungsdifferenz. Dieser $\Delta U_{\ddot{U}}$-Wert ist von der Stromdichte abhängig. Bei ΔU_{max} wächst die Spannungsdifferenz mit zunehmender Oxidationszeit nicht mehr. Im Unterschied zu unseren früheren Untersuchungen[1] am GaAs hängt beim InSb die sich ausbildende Spannungsdifferenz von der Stromdichte und der Orientierung ab. Dies wurde auch von anderen Autoren gefunden.[11,12,17,19] Dieses Ergebnis ist jedoch schwer zu erklären. Man kann annehmen, daß die Erscheinung verbunden ist mit der Abhängigkeit der Raumladung von der Stromdichte. Trotz dieser Schwierigkeiten gelingt es

Tabelle 1. Reproduzierbarkeit der Schichtdicke bei anodischer Oxidation des InSb

Bedingung	Schichtdicke h, *nm*	Relative Standardabweichungen, s_r, %
jeweils eine	18	5
Schicht	28	3
(n_1 = 10–15)	92	2
mehrere	32	8
Schichten	75	5
(n_2 = 15)		

n_1 = Zahl der Messungen auf einer Schicht.
n_2 = Zahl der Schichten, die jeweils einmal vermessen werden.

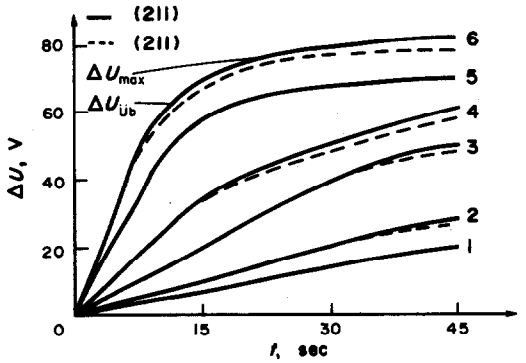

Abb. 1. Kinetische Kurve der anodischen Oxidation des InSb in Abhängigkeit von der Stromdichte: *1*—0,5 mA/cm²; *2*—2 mA/cm²; *3*—4 mA/cm²; *4*—10 mA/cm²; *5*—15 mA/cm²; *6*—20 mA/cm².

auch beim InSb im Gebiet bis zu $\Delta U_{Ü}$ oxidierte Schichten zu erhalten deren ΔU-Wert eine Funktion der Schichtdicke ist (vgl. Abb. 2). Es zeigte sich, daß bei diesen Bedingungen die Dicke der Oxidationsschicht, die bei gegebenem ΔU abgelöst wird, nicht von der Geschwindigkeit der Oxidation abhängt. Jedoch vermindert sich mit abnehmender Stromdichte die Streuung der Werte der Schichtdicke. Deshalb ist es günstig, bei niedrigen Stromdichten zu arbeiten. Infolge der Unlöslichkeit des Oxides im Elektrolyt ist das möglich. In der Abb. 3 wurde die maximal mögliche Schichtdicke, h_{max}, bis zu der eine lineare Abhängigkeit zwischen h und dem ΔU-Wert besteht, in Abhängigkeit von der Stromdichte aufgetragen.

Unter diesen Bedingungen verhalten sich die Flächen 211 und 111 gleich. Zur laufenden Kontrolle des Prozesses der anodischen Oxidation wurden als Vergleichsmaterial Schichten in Abstufung von 0,01 bis 0,005 hergestellt. Die Interferenzfarben, die auch von anderen Autoren beobachtet wurden,[11,12,17,19]

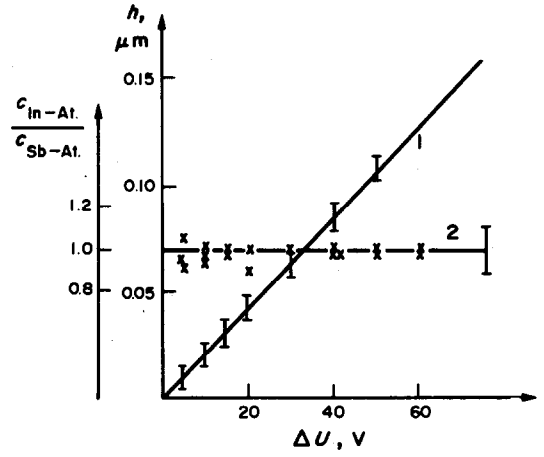

Abb. 2. Abhängigkeit der Schichtdicke der oxidierten Schicht (Kurve 1) und des In/Sb-Atomverhältnisses (Kurve 2) von der sich ausbildenden Spannungsdifferenz (ΔU). *1*—Mittelwert mit statistischer Sicherheit $P = 95\%$, *2*—Einzelwerte.

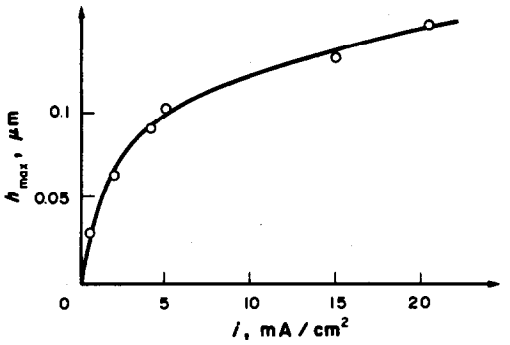

Abb. 3. Abhängigkeit der maximal möglichen Schichtdicke des oxidierten InSb von der Stromdichte.

sind sehr hell, so daß diese farbigen Interferenzen als Meßgröße (Eichskala) für die Dicke der Oxidationsschicht dienen können. Die Oxidationsschichten können mit Flußsäure (1:10 bis 1:20) schnell gelöst werden.

Mechanische Abtrennung von Schichten

Für die Abtrennung größerer Schichtdicken (> 1 μm) ist die anodische Oxidation zu zeitaufwendig. In diesem Fall ist es möglich, auf mechanischem Wege mit Hilfe eines Hartschnittmikrotoms in 1 μm-Schritten Schichtabtrennungen vorzunehmen. Die Methode wurde früher beschrieben.[1] Für ionenimplantierte Materialien hat das Verfahren wegen des zu geringen Auflösungsvermögens keine Bedeutung. Notwendig ist jedoch dieses Verfahren, wenn Elemente bestimmt werden sollen, die leicht flüchtige Fluoride bilden (z.B. Ge) oder deren analytische Bestimmung sehr durch Fluorid gestört werden kann (z.B. Ga).

Die Spuren- und Dotierungselemente wurden durch Emissionsspektrographie (AES) und Atomabsorptionsspektrometrie (AAS) bestimmt.

AES. Die Bestimmung der Spuren in den mit Flußsäure abgelösten Oxidationsschichten mit der AES wurde mehrfach beschrieben.[1,2,7,28] Die optimalen Arbeitsgrenzen, die in den In-haltigen Matrices erhalten wurden, entsprechen denen, die in GaAs erhalten wurden.[1,28] Bei der Bestimmung ist die Flußsäure-Lösung auf 20 mg C-Pulver (0,4% Natriumfluorid) zu geben und zu trocknen. Das homogenisierte Material wird im Gleichstrombogen angeregt. Da Indium—ähnlich wie Natrium—auch ein leichtionisierbares Element ist, treten systematische Fehler auf, wenn die Indiumkonzentration in C-Pulver >0,1% ist. Bei einer Oberfläche von 1 cm² können 60–70 nm dicke Schichten oxidiert, gelöst und auf 20 mg-C-Pulver gegeben werden. Dickere bzw. größere Schichten müssen auf eine entsprechend größere Menge C-Pulver gegeben werden.

AAS. Die Ergebnisse des Verfahrens sind in der Tabelle 2 dargestellt. Aus der Tabelle 2 geht hervor, daß Bestimmungen bei den gewählten Bedingungen bis zu Atomkonzentrationen von 10^{17} At/cm³ möglich sind. Dies entspricht dem normalen Dotierungsbereich.

Tabelle 2. Nachweisgrenzen von Spurenelementen in In-Materialien bei Bestimmung durch AAS mit elektrothermischer Atomisierung

Spurenelement	Wellenlänge, *nm*	Nachweisgrenzen absolut, *pg*	Nachweisgrenzen relativ,* At/cm^3
Be	234,9	10	5×10^{17}
Cd	228,8	3	1×10^{16}
Ga	294,4	60	4×10^{17}
Ge	265,2	100	7×10^{17}
Mg	202,2	50	1×10^{18}
Mg	285,2	2	4×10^{16}†
Pb	263,3	80	2×10^{17}
Sn	224,6	80	3×10^{17}
Te	214,3	100	4×10^{17}
Zn	307,6	10,000	$7{,}5 \times 10^{19}$
Zn	213,9	10	$7{,}5 \times 10^{16}$†

* Relative Nachweisgrenzen bezogen auf: 60 nm Schichtdicke, 1 cm^2 Oberfläche; aufgenommen in 0,1 ml; Analysenprobe 0,02 ml.
† Wert wurde extrapoliert. Infolge der Allgegenwartskonzentration sind Bestimmungen nur bis etwa 10^{17} At/cm^3 möglich.

Ergebnisse zur Profilanalytik

In der Abb. 4 ist die Verteilung von Magnesium im InSb (211) dargestellt. Die Dicke der abgetrennten Schichten betrug 60 nm. Die Messung erfolgte bei der empfindlichen Mg-Linie (285,2 nm). Die Herstellung des Materials erfolgte durch Ionenimplantation.

In Abb. 5 ist die Verteilung von Tellur im InSb, welches durch Epitaxie gewonnen worden war, dargestellt. Die Dicke der abgetragenen Schichten betrug 200 nm. Damit verbessert sich die relative Nachweisgrenze auf etwa 10^{17} At/cm^3. In dem gewählten Material lagen die Tellurgehalte (vgl. Tab. 3) im Bereich 10^{18} bis unterhalb 10^{17} At/cm^3. Wegen des Grenzbereiches des Nachweises erfolgte die Bestimmung auch auf inversvoltammetrischem Wege: Elektrolyse in 0,3*M* Salzsäure bei 0,8 V: danach wird Antimon bei −0,2 V gelöst (10 min): danach erfolgt die Bestimmung.

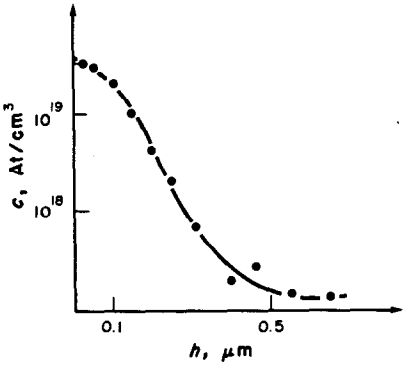

Abb. 4. Profil der Verteilung von Mg in InSb (211).

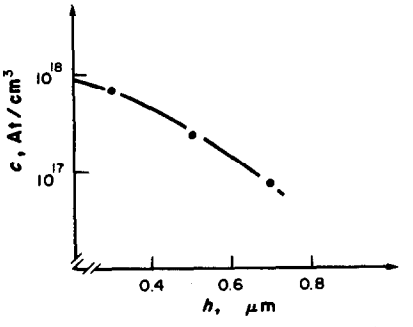

Abb. 5. Profil der Verteilung von Te in einer Epitaxieschicht des InSb.

Summary—A method for the determination of distribution profiles and traces in InSb-materials is described. Stripping of the layers of several nm thickness was achieved by anodic oxidation (galvanostatic conditions). The stripping method was optimized, and the thickness of the layers stripped was determined by ellipsometric measurements. Traces of elements were determined by atomic emission and flameless atomic-absorption spectrometry. Detection limits in the range of 10^{17} atoms/cm^3 for a 1-cm^2 surface layer 60 nm thick were observed. Distribution profiles for Mg and Te in InSb are shown.

(*Received* 14 *December* 1981, *Accepted* 13 *January* 1982)

Summary—A simple method is presented for the separation of lead-203 from copper-backed thallium cyclotron targets. The procedure involves cation-exchange chromatography in hydrochloric acid and hydrochloric acid–acetone mixtures. Further purification involves anion-exchange chromatography in nitric acid–hydrobromic acid mixtures. A cation-exchange column containing 3.0 g of resin can handle as much as 15 g of thallium and 160 mg of copper. An anion-exchange column containing 3.0 g of resin can separate lead from up to 200 mg of thallium and 10 mg of copper. Separations are extremely sharp and less than 0.1 μg of thallium and less than 0.1 μg of copper remain in the lead-203 fraction.

Lead-203 is the only isotope of lead suitable for use as a tracer in the field of nuclear medicine, because of its reasonable half-life (52.1 hr), gamma-ray emission (0.28 MeV) in the region most useful for *in vivo* counting and scanning, and absence of radioactive decay products. It has been used for imaging bleomycin in tumours,[1] for skeletal imaging,[2] and as a label for red blood-cells.[3] It has also been used as its ethylenediaminetetra-acetate chelate for cisternography.[4,5] Other applications of ^{203}Pb are in investigations on the effects of lead pollution, entailing biochemical, biological and ecological studies.[6]

Lead-203 is usually produced in a cyclotron by proton or deuteron bombardment of a thallium target, the nuclear reactions being ^{203}Tl(p,n)^{203}Pb, ^{205}Tl(p,3n)^{203}Pb, ^{203}Tl(d,2n)^{203}Pb, ^{205}Tl(d,4n)^{203}Pb. In an effort to obtain higher yields of ^{203}Pb, and also to eliminate some difficulties encountered in the radiochemistry, Chackett *et al.*[7] investigated the reaction ^{203}Tl(^{3}He,3n)^{203}Pb with a 29-MeV external ^{3}He beam. The ^{203}Bi produced (half-life 11.8 hr) decays to the desired ^{203}Pb. Their method of separation consisted of adding sodium hydrogen phosphate to precipitate the ^{203}Bi with 1–2 mg of bismuth (added as nitrate solution) as bismuth phosphate, thus separating the bismuth from the thallium. The bismuth solution was sorbed on an anion-exchange resin, and 24 hr later the ^{203}Pb produced *in situ* was eluted from the column with 0.3*M* hydrochloric acid, while the bismuth was retained on the column. Qaim *et al.*[8] suggested a separation scheme consisting of precipitation of ^{203}Pb with ferric hydroxide and removal of the carrier iron from the ^{203}Pb by anion-exchange chromatography. Neirinckx[9] also precipitated ^{203}Pb with ferric hydroxide but separated the carrier iron by solvent extraction. Ramamoorthy and Watson[10] separated the ^{203}Pb from the thallium by ion-exchange chromatography on hydrous zirconium oxide. The recovery of ^{203}Pb was about 75% and the thallium impurity level was below 10 ppm. Bonardi[11] separated ^{203}Pb and thallium by a combination of precipitation and anion-exchange. Levin *et al.*[12] separated ^{203}Pb from the thallium by dissolving the latter in sulphuric acid and isolating ^{203}Pb from the solution by co-precipitation. Bajo and Wyttenbach[13] separated the ^{201}Pb by solvent extraction with diethyldithiocarbamic acid in chloroform. Thallium-201 was separated from the mother activity (^{201}Pb) by solvent extraction with the same reagent. Toribara and Koval[14] removed the thallium from a dilute acid chloride solution by continuous extraction with ethyl ether. Essentially all of the thallium and almost none of the lead is removed in a 3-hr extraction. In most of the published methods only a few hundred mg of thallium target material had to be separated from the ^{203}Pb.[7,8,11,13]

A method of separating gram amounts of thallium from micro amounts of many other elements, such as lead, indium and copper by cation-exchange chromatography has been developed by Strelow and van der Walt.[15] The other elements are retained on Bio-Rad AG50W-X4 cation-exchange resin from 0.1*M* hydrochloric acid containing 0.05% chlorine, while the thallium passes through the column and can be eluted quantitatively with 0.1*M* hydrochloric acid containing 40% acetone. The other elements are then eluted with 3*M* hydrochloric acid or 3*M* nitric acid. Less than 10 μg of thallium remain in the elements separated from

10 g of thallium. This method has been adapted for the separation of ^{203}Pb from thallium cyclotron-target material. The general eluting agent (3*M* hydrochloric acid) is replaced by 0.1*M* hydrochloric acid containing 82% acetone, which elutes lead very selectively. Copper, which is used as a backing for the thallium target and may be present in milligram amounts, and most other elements are retained on the resin column. The chlorine (0.05%) is replaced by bromine (0.05%) reagent as oxidant for the thallium, since bromine is easier to use, serves as self-indicator for completion of the oxidation, and is more efficient in equilibrating the column.

This paper describes the modified cation-exchange separation. A second separation step on a column of Bio-Rad AG1-X4 anion-exchange resin is also described; it can be used to remove remaining traces of copper and thallium from the ^{203}Pb when an extremely pure product is required.

EXPERIMENTAL

Reagents and apparatus

The chemicals used were of analytical-reagent grade. Thallium metal (99.999%) was obtained from Fluka A. G., Buchs, Switzerland. Water was distilled and passed through an Elgastat demineralizer. Bio-Rad AG50W-X4 sulphonated polystyrene resin (100–200 mesh) and AG1-X4 quaternary amine resin (200–400 mesh) were used. The columns were made in borosilicate glass tubes (20.0 mm bore, 110 mm long) with a B19 female joint at the top, and at the other end a tube (14.4 mm bore, 200 mm long), fitted with a fused-in No. 1 porosity glass sinter and a burette tap at the bottom.

A Varian–Techtron AA-5 atomic-absorption spectrometer was used. A slotted quartz tube[15] was used in the beam-path over the burner head, as described by Watling,[16] to obtain better sensitivity for lead and thallium.

A 4096-channel gamma-spectrophotometer coupled to a Ge(Li) detector was used to measure the ^{203}Pb activity.

Elution curves

Thallium, copper and lead on the AG50W-X4 resin. The column was filled with a slurry of AG50W-X4 resin (100–200 mesh) to a mark at 13.0 ml. The resulting resin bed was about 80 mm in length and was equilibrated by passage of 50 ml of 0.1*M* hydrochloric acid containing 0.05% bromine (v/v) (solution A). A solution of about 10 g of thallium(III), 130 mg of copper(II) and 5 mg of lead(II) in 200 ml of 0.1*M* hydrochloric acid containing 0.05% (v/v) bromine was passed through the resin bed. The elements were washed onto the resin with small portions of solution A (about 40 ml altogether). The following sequence of reagents was used for elution: four 10-ml portions of 0.1*M* hydrochloric acid containing 60% acetone for thallium(III); 120 ml of 0.1*M* hydrochloric acid containing 82% acetone for lead(II); 100 ml of 3.0*M* hydrochloric acid for copper(II). A flow-rate of 3.5 ± 0.3 ml/min was used throughout. Fractions (10 ml in volume) were collected with an automatic fraction collector from the beginning of the sorption step. The amounts of thallium, copper and lead were determined in each fraction. Small amounts of the elements were determined by atomic-absorption spectrophotometry, with an air–acetylene flame and the 217.0, 278.6 and 324.8 nm lines for lead, thallium and copper, respectively. Larger amounts of the elements were determined by titration with EDTA. Copper was titrated at pH 5.6 ± 0.2 with Xylenol Orange as indicator in the presence of 1,10-phenanthroline, and thallium(III) in the presence of ammonium tartrate at pH 8.8 ± 0.2, with Methylthymol Blue as indicator. The results are shown in Fig. 1.

Thallium, copper and lead on AG1-X4 resin. The column was filled with a slurry of Ag1-X4 (200–400 mesh, chloride form) to a mark at 8.7 ml. The resulting bed was about 52 mm in length and was equilibrated by passage of 100 ml of 0.2*M* hydrobromic acid–0.1*M* nitric acid (solution B). A solution of about 100 mg of thallium(III), 10 mg of copper(II) and 2 mg of lead(II) in 25 ml of 0.2*M* hydrobromic acid–0.1*M* nitric acid was passed through the resin bed. The elements were washed onto the resin with small portions of solution B (30 ml altogether). The resin was eluted with the following sequence of reagents: 75 ml of solution B; 170 ml of 2.0*M* nitric acid–0.03*M* hydrobromic acid. Fractions (10 ml in volume) were collected from the beginning of the sorption step. The flow-rate was 2.4 ± 0.3 ml/min throughout. The amounts of thallium, copper and

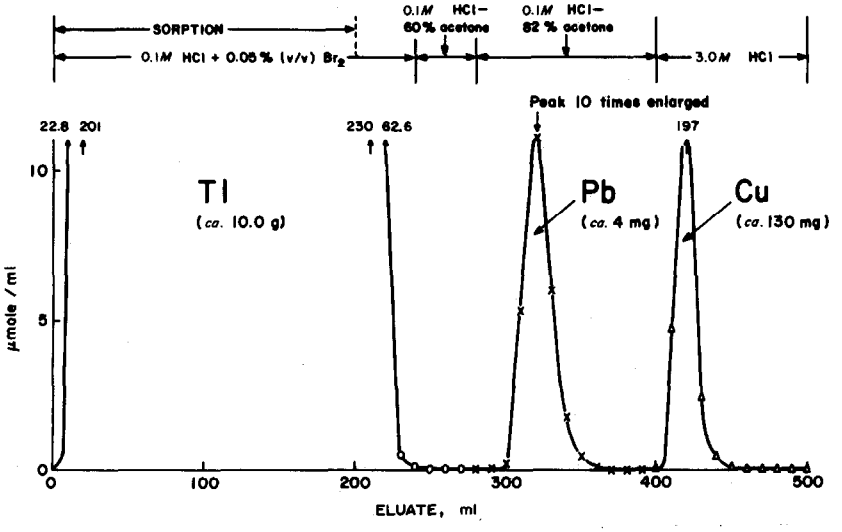

Fig. 1. Elution curve for Tl(III) (*ca.* 10.0 g), Cu(II) (*ca.* 130 mg) and Pb(II) (*ca.* 4 mg) with 0.1*M* HCl + 0.05% Br_2 and HCl–acetone mixtures. Column 13.0 ml (3.0 g) of AG50W-X4 (100–200 mesh), length 80 mm, diameter 14.4 mm. Flow-rate 3.5 ± 0.3 ml/min.

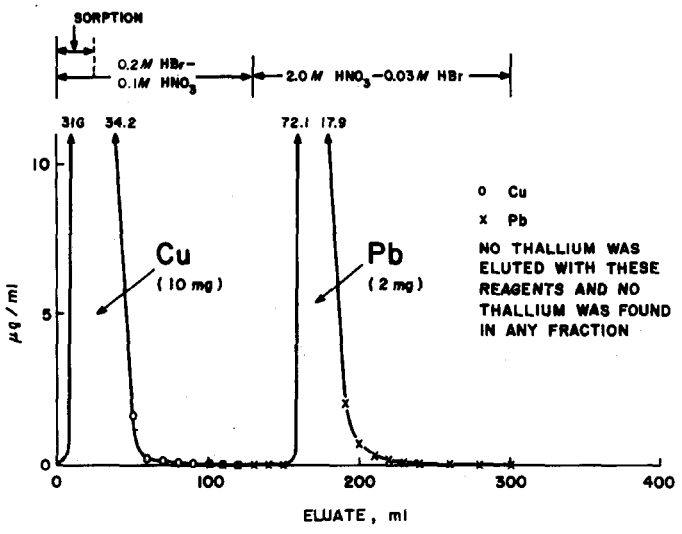

Fig. 2. Elution curve for Tl(III) (*ca.* 100 mg), Cu(II) (*ca.* 10 mg) and Pb(II) (*ca.* 2 mg) with nitric acid–hydrobromic acid mixtures. Column 8.7 ml (3.0 g) of AG1-X8 (200–400 mesh), length 52 mm, diameter 14.4 mm. Flow-rate 2.4 ± 0.3 ml/min.

lead were determined in each fraction by atomic-absorption spectrophotometry as above. The results are presented in Fig. 2.

Separation of lead-203 from thallium target material

Thallium metal (99.999%) was melted onto a water-cooled copper plate to give a cyclotron target with length 230 mm, width 10 mm and thickness 0.35–0.38 mm. The target was bombarded with 16-MeV deuterons for 42 min at a beam-current of 37 µA, and "cooled" for a few hr to let the short-lived isotopes decay. The thallium was milled from the copper plate to a depth of 0.35 mm, giving about 9.7 g of thallium target material, which was dissolved in 30 ml of 2*M* nitric acid. The nitrates were converted into chlorides by repeated evaporation with 10*M* hydrochloric acid, with bromine added dropwise to oxidize the thallium(I) to thallium(III). After a final evaporation of the solution to incipient dryness, the residue was dissolved in 50 ml of 0.4*M* hydrochloric acid, with dropwise addition of bromine until a clear solution was obtained. The resulting solution was boiled until light yellow in colour, diluted to 200 ml with demineralized water and cooled to room temperature. Saturated bromine water (3 ml) was added with stirring (solution C).

Cation-exchange separation of ^{203}Pb from thallium and copper on AG50W-X4

Solution C was passed through the resin bed (prepared and equilibrated as described above). The elements were washed onto the resin with small portions of 0.1*M* hydrochloric acid containing 0.05% v/v bromine (40 ml altogether), each portion being drained to the top of the bed before the next was added. The eluate was collected from the beginning of the sorption and the elution was completed with 60 ml of 0.1*M* hydrochloric acid containing 60% acetone, this eluate being collected separately. The ^{203}Pb was then eluted with 80 ml of 0.1*M* hydrochloric acid containing 82% acetone, and a further 20 ml of the same eluting agent, the two eluates being collected separately. Finally, the copper was stripped from the resin column with 80 ml of 3.0*M* hydrochloric acid. All the eluates were evaporated, or diluted with demineralized water, to give a volume of 50 ml (a 100-ml beaker being used). The ^{203}Pb activity was measured for all fractions, the 400-ml beaker used for collecting the thallium eluate, and the resin column. All results were corrected for decay and are presented in Table 1.

Anion-exchange separation of ^{203}Pb from the remaining micro amounts of thallium and copper impurities

The first ^{203}Pb fraction from the cation-exchange separation was evaporated to dryness and the residue treated twice with 2 ml of concentrated nitric acid, with evaporation to dryness each time, to convert the chlorides into nitrates. The residue was treated with 2 ml of concentrated nitric acid and 1 ml of concentrated hydrobromic acid and evaporated to incipient dryness. The salts were dissolved in 2.0 ml of 1.0*M* nitric acid, cooled, and diluted with 13 ml of demineralized water, then 5 ml of 0.8*M* hydrobromic acid were added and the solution was mixed. The solution was passed through the resin bed (prepared and equilibrated as described above). The elements were washed onto the resin with small portions of 0.2*M* hydrobromic acid–0.1*M* nitric acid (30 ml altogether) and the copper was completely eluted with a further 50 ml of this acid mixture. The eluate was collected from the beginning of the sorption. The ^{203}Pb was eluted with 70 ml of 2.0*M* nitric acid–0.03*M* hydrobromic acid and a further 30 ml of the same eluting agent, the eluates being collected separately. All the eluates were evaporated to 20 ml (a 50-ml beaker being used). The ^{203}Pb activity was measured for all fractions, the two beakers used for collecting the copper eluate and the first lead eluate, and the resin column. All the results were corrected for decay and are presented in Table 2.

RESULTS AND DISCUSSION

Figures 1 and 2 show that a sharp separation of lead from thallium and copper is obtained. No thallium (*i.e.*, less than 0.01 ppm) was found in any of the fractions collected from the anion-exchange resin column. The thallium can be eluted with 75 ml of 1.0*M* ammonia solution followed by 200 ml of 0.5*M* nitric acid—0.1*M* thiourea.[18]

The method described provides an excellent means

Table 1. Separation of ^{203}Pb from thallium cyclotron-target material on the cation-exchange resin AG50W-X4

Fraction	^{203}Pb activity,* *counts/200 sec*	Recovery, %
Main thallium fraction (eluted with 0.1*M* HCl + 0.05% Br_2)	87	0.08
Second thallium fraction (eluted with 0.1*M* HCl–60% acetone)	16	0.02
400-ml beaker used for collecting the main thallium eluate	0	0
First ^{203}Pb fraction (eluted with 80 ml of 0.1*M* HCl–82% acetone)	106,541	99.89
Second ^{203}Pb fraction (eluted with additional 20 ml of 0.1*M* HCl–82% acetone)	0	0
Resin column	0	0

* All measurements were carried out on a volume of 50 ml in a 100-ml beaker, except those on the 400-ml beaker and the resin column.

for the separation of lead from up to 15 g of thallium and up to 160 mg of copper. When only the cation-exchange separation was used, less than 15 μg of thallium was found in the lead fractions when 15 g of thallium were present originally. Only 3–8 μg of copper were found in the lead fractions when 130 mg of copper were present originally. When both cation- and anion-exchange columns were used in the separation of 10 g of thallium and 160 mg of copper from μg amounts of lead, less than 0.1 μg of thallium or copper was found in the lead fractions.

The method is well suited for the separation of ^{203}Pb from cyclotron-irradiated thallium target material and a carrier-free product of high purity is obtained. Very little ^{203}Pb activity is lost in the separation as can be seen from Tables 1 and 2. The recovery of ^{203}Pb activity was better than 99%. When a small thallium cyclotron target (less than 200 mg of thallium, containing less than 10 mg of copper) is used, the separation can be carried out either on the cation-exchange or the anion-exchange resin. The method can easily be adapted for hot-cell operation, with a lead shield, and can be carried out relatively rapidly, especially when only the cation-exchange separation is used.

According to the distribution coefficients published by Strelow *et al.*[17] the following elements should also be separated from lead by the cation-exchange procedure described above: uranium, gold, mercury, the platinum metals, arsenic, tungsten, molybdenum, iron, gallium, calcium, magnesium, manganese, cobalt and vanadium. Zinc and indium should accompany lead because of their similar distribution coefficients.[17] When the cation-exchange separation is followed by the anion-exchange procedure, zinc and indium should accompany copper because of their low distribution coefficients under these conditions.[18,19]

After the ion-exchange separations have been carried out, the eluates can be evaporated to dryness and the ^{203}Pb dissolved in a suitable solvent, providing a carrier-free product of high purity.

The method is also suitable for the separation of ^{201}Tl from the mother isotope ^{201}Pb by either the cation-exchange or the anion-exchange separation.

Table 2. Separation of ^{203}Pb from thallium and copper impurities on the anion-exchange resin AG1-X4

Fraction	^{203}Pb activity,* *counts/200 sec*	Recovery, %
Copper fraction (eluted with 0.2*M* HBr–0.1*M* HNO_3)	29	0.04
First ^{203}Pb fraction (eluted with 70 ml of 2.0*M* HNO_3–0.03*M* HBr)	76,264	99.90
Second ^{203}Pb fraction (eluted with additional 30 ml of 2.0*M* HNO_3–0.03*M* HBr)	6	0.01
150-ml beaker used for collecting the copper eluate	0	0
100-ml beaker used for collecting the first ^{203}Pb eluate	36	0.05
Resin column	0	0

* All measurements were carried out on a volume of 20 ml in a 50-ml beaker, except those on the 150-ml beaker and the resin column.

SELECTIVE SEPARATION AND DIFFERENTIAL DETERMINATION OF ANTIMONY(III) AND ANTIMONY(V) BY SOLVENT EXTRACTION WITH *N*-BENZOYL-*N*-PHENYLHYDROXYLAMINE AND GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY USING A MATRIX-MODIFICATION TECHNIQUE

(*Received* 12 *October* 1981. *Accepted* 13 *January* 1982)

Summary—If copper is used as a matrix modifier for the determination of antimony, the ashing temperature for antimony in aqueous solution and a BPHA–$CHCl_3$ extract can be raised to 1300° and 1100°, respectively. A selective procedure for separating antimony(III) from antimony(V) by extraction with BPHA in chloroform is described, along with the conditions for preserving trace antimony in water samples. The recommended method has been applied satisfactorily to the determination of antimony(III) and antimony(V) in various types of water at sub-ng/ml levels.

It is well recognized that the toxicity and physiological behaviour of antimony depend on its oxidation state. According to European Community Standards,[1] the maximum admissible level of antimony in surface and drinking water is 10 ng/ml. As Sb occurs in the environment at very low concentrations (<1 ng/ml), the development of methods for determination of antimony(III) and antimony(V) has received considerable attention. Although graphite-furnace atomic-absorption spectrometry (AAS) has been widely used for the determination of trace antimony in a variety of samples, it seems that there are only a few studies on the differential determination of antimony(III) and antimony(V) reported in the literature. With reference to industrial hygiene, Eller and Haartz[2] have presented a comprehensive review of sampling and analytical methods for antimony and its compounds. Kambara *et al.*[3] have described the extraction of antimony(III) with BPHA (*N*-benzoyl-*N*-phenylhydroxylamine), counting the activity of Sb(III) in the organic phase and of Sb(V) in the aqueous phase with a scintillation counter, but no detailed study of the extraction behaviour of antimony with BPHA was given. A procedure consisting of extraction of antimony(III) from atmospheric dusts into benzene and determination by hydride generation has also been suggested.[4] Recently, Nakashima[5] used zirconium(IV) to suppress the conversion of antimony(V) into stibine in hydrochloric acid medium (<2*M*) for selective determination of antimony(III) in the presence of antimony(V). No interference from antimony(V) was reported for Sb(V)/Sb(III) ratios up to 4:1, at an antimony(III) level of 50 ng/ml. Total antimony was determined after reduction of antimony(V) to antimony(III) with potassium iodide. The difference between the two determinations gives the concentration of antimony(V). Subramanian and Meranger[6] studied the solution conditions affecting the ammonium pyrrolidinedithiocarbamate–methyl isobutyl ketone (APDC–MIBK) extraction system for graphite-furnace atomic-absorption determinations of As(III), As(V), Sb(III), Sb(V), Se(IV) and Se(VI) in detail, and applied the method for the determination of antimony in polluted water. After comparing the extraction behaviour of antimony(III) and antimony(V) with APDC, diethyldithiocarbamate and dithizone, Kamada and Yamamoto[7] developed a method for selective extraction of antimony(III) and differential determination of antimony(III) and antimony(V) with the APDC–MIBK extraction system in conjunction with the use of EDTA to mask interferences from many metal ions. The detection limit for both the Subramanian and Meranger and the Kamada and Yamamoto methods is 1 ng/ml, and the methods are suitable for toxicity studies.

Unfortunately, all these studies were carried out with larger concentrations of antimony than occur in nature.

The present investigation describes the determination of antimony in aqueous solution and in BPHA–$CHCl_3$ extracts by graphite-furnace AAS, with copper as matrix modifier. Antimony(III) can be readily separated from antimony(V) by BPHA–$CHCl_3$ extraction over a wide range of acidity, and antimony(V) can be reduced to antimony(III) with potassium iodide. By this method, antimony can be

readily determined in its different oxidation states at sub-ng/ml levels.

EXPERIMENTAL

Apparatus

A Perkin–Elmer model 503 atomic-absorption spectrophotometer, equipped with an HGA-72 graphite furnace and a Hitachi model 56 chart-recorder, was employed for all absorption measurements of antimony at 217.6 nm under "argon stop" conditions. The Perkin–Elmer antimony electrodeless discharge lamp was operated under the conditions recommended by the manufacturer. A deuterium background corrector was used throughout.

For measurement of the appearance temperature of atomization, the absorbance–time profile for antimony and the temperature–time profile for the HGA-500 graphite surface were obtained simultaneously by using a laboratory-made photoconductive device and a double-pen recorder (Hitachi QD-25). The temperature scale was established by using the temperature programme on the HGA-500 power supply, and a linear response was obtained over the temperature region 1000–2500 K. The heating-rate setting of the atomizer was 0.10 K/msec. The appearance temperature T_{app} was determined by a method similar to that suggested by Sturgeon *et al.*[8]

Reagents

Standard antimony(III) solution, 1000 μg/ml. Prepared by dissolving 0.2742 g of potassium antimonyl tartrate (analytical-reagent grade) in demineralized water, adding 10 ml of 10% tartaric acid solution and diluting to 100 ml with demineralized water.

Standard antimony(V) solution, 10 μg/ml. Prepared by the procedure suggested by Kamada and Yamamoto.[7]

*N-Benzoyl-N-phenyhydroxylamine solution in chloroform, 0.10*M. Prepared by dissolving 2.13 g of BPHA (laboratory synthesized, m.p. 121°) in 100 ml of chloroform.

Saturated potassium iodide solution. Freshly prepared from the analytical-grade reagent and demineralized water just before use.

All other chemicals used were analytical-reagent grade.

Study on stabilizing effect of copper

A 20-μl portion of 0.050 μg/ml aqueous standard antimony solution was injected into a graphite tube with an Eppendorf microlitre pipette fitted with disposable polypropylene tip, along with the same volume of 1000-μg/ml aqueous copper solution. After drying the residue was ashed at various temperatures for 40 sec and atomized at 2600° for 5 sec, the absorption signals of antimony in the presence and absence of copper being measured and plotted against ashing temperature to assess the loss of antimony during the preatomization stages and the stabilizing effect of copper. The same procedure was used for the determination of antimony in the BPHA–$CHCl_3$ extract except that the organic extract was injected *after* 50 μl of 400-μg/ml copper solution had been injected and dried.

Extraction of antimony(III) and antimony(V) from water samples

All water samples were filtered through 0.45-μm Millipore filters after collection, if there was any suspended matter or sediment. A 50-ml water sample was then taken in a 100-ml separatory funnel, 4.5 ml of concentrated hydrochloric acid and 2 ml of 0.10*M* BPHA solution (in chloroform) were added, and antimony(III) was extracted by shaking for 1 min. The chloroform phase was transferred into a dry quartz centrifuge tube fitted with a quartz stopper. To the remainder of the aqueous phase 1 ml of saturated potassium iodide solution was added, the solution was thoroughly mixed and let stand for 10 min for reduction of antimony(V) to antimony(III), then 2 ml of 0.10*M* BPHA solution in chloroform were added and the extraction procedure was carried out as already described. Then 50 μl of 400-μl/ml copper solution were injected into the graphite furnace and dried, and 20 μl of the BPHA extract were injected and dried gently at 100°. The residue was ashed at 1000° for 40 sec and atomized at 2600° for 5 sec, and the antimony absorbance was measured.

RESULTS AND DISCUSSION

Stabilizing effect of copper

Antimony is one of the relatively volatile elements, so a certain loss of antimony may occur during the preatomization stages, and the ashing loss will increase with temperature and holding time. To prevent such losses, nickel has been applied as a matrix modifier.[9] From comparing the stabilizing effect of nickel, platinum and copper, it was found that copper is the most effective matrix modifier for antimony. In the presence of copper, the critical ashing temperature for antimony in aqueous solution and the chloroform extract can be raised to 1300° and 1100°, respectively. The sensitivity for antimony is improved by a factor of 1.8 for aqueous solution and 2.2 for the organic solution. The results are shown in Fig. 1.

The stabilizing effect of copper depends on the copper concentration. The absorbance for antimony increases over the range 0–12 μg of copper, and at higher amounts begins to level off. So addition of 20 μg of copper was employed for the remainder of experiments in this study.

The stabilizing effect of copper in the antimony determination has been attributed to the formation of more stable alloys or solid solutions.[10] The temperature–time profile for the graphite-tube surface at a heating rate of 0.10 K/msec and the absorbance–time profile for antimony in the absence and presence of matrix modifier are shown in Fig. 2. It can clearly be seen that the appearance temperature for antimony in the presence of copper is increased.

Effect of diverse ions

It has been reported that addition of a small amount of mercury(II) can reduce the interferences from some metals in the determination of antimony.[11] In the present method much higher concentrations of diverse ions can be permitted, since the ashing temperature that can be used is high enough for any complex matrix present in the water samples to be readily burnt off. Direct determination of antimony at a concentration of 40 ng/ml showed no interferences from Te(IV) (20 μg/ml), Se(IV) (25 μg/ml), As(III) and Sn(II) (30 μg/ml), Ni, Sr, Al, Au(III), Cd, Cr(VI), Co(III), Fe(III), Li, Mg, Mn(II), Pb, Ti(III), V(V), Ag, Hg(II), Ba, Bi, Ca, Mo(VI), Zn, K, Na, silicate, phosphate, bromate, chloride, EDTA, ascorbic acid, tartrate and oxalic acid (all at least 50 μg/ml). It must be noted that the permissible amount of selenium, arsenic and tin is relatively low. The reason for this is that copper can also stabilize these elements, presumably by a similar mechanism to that for antimony. Therefore, some competing reactions may occur if these elements are also present in the heated graphite tube, since a certain amount of copper is consumed in stabilizing them. Generally, however, the concentrations of these elements in water samples are lower than these tolerance limits. Furthermore a certain degree of separation of antimony(III) from diverse ions can be achieved by extraction, so no interferences are expected.

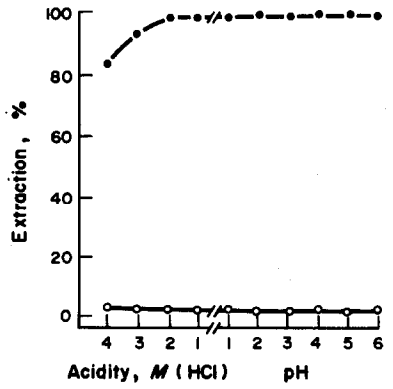

Fig. 3. Dependence of extraction of antimony(III) and antimony(V) on the acidity of the aqueous solution. Extraction conditions: aqueous phase and organic solvent both 10 ml, original concentration of Sb(III) or Sb(V) in aqueous solution 50 ng/ml. (●) Sb(III). (○) Sb(V).

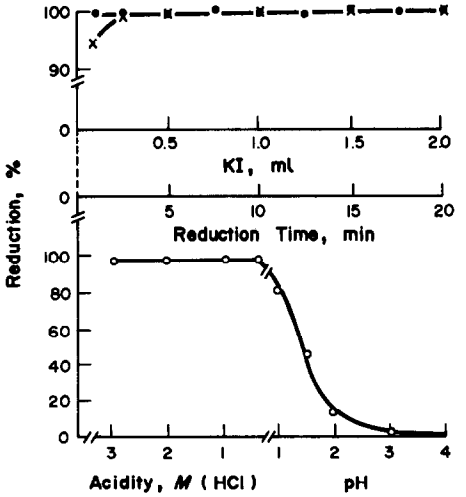

Fig. 4. Relationship between the reduction efficiency of antimony(V) and acidity of the aqueous solution, amount of KI added and reduction time. (●) Effect of amount of KI (1*M* HCl medium, 10 min reduction time). (×) Effect of reduction time (1*M* HCl, 1 ml of KI solution).

Selective extraction of antimony(III) and antimony(V)

The solution conditions affecting the selective extraction of antimony(III) and antimony(V) with the BPHA–$CHCl_3$ system were studied, including the acidity range, phase-volume ratio, conditions for reducing antimony(V) to antimony(III), and stability of the organic extract. All the results are shown in Figs. 3 and 4.

Figure 3 shows that antimony(III) can be extracted quantitatively over a wide range of acidity, from pH 6 to 2*M* hydrochloric acid, but there is virtually no extraction of antimony(V) over this acidity range, so reduction of antimony(V) to antimony(III) is a prerequisite for its successful determination. If the acidity of the aqueous solution is in the range 0.5–3*M* hydrochloric acid, addition of 0.1–2 ml of saturated potassium iodide solution and standing for 5–20 min will give quantitative reduction of antimony(V) to antimony(III). The optimum reduction conditions are: 1*M* hydrochloric acid, 1 ml of saturated potassium iodide solution, and a reducing time of 10 min.

To investigate the effect of phase-volume ratio, 5 ml of BPHA–$CHCl_3$ solution were used for the extraction of antimony from various volumes of aqueous phase containing 0.25 μg of antimony. The absorption signal obtained was constant up to an aqueous:organic phase-volume ratio of 25:1. Since

the solubility of the Sb(III)–BPHA complex in water is extremely low, the Sb(III) is quantitatively extracted into the organic layer. During and after the extraction fine droplets of chloroform containing the chelate may be dispersed in the water layer, but this does not affect the concentration of the chelate in the chloroform phase.

Varying the concentration ratio of antimony(III) to antimony(V) from 1:10 to 10:1 at a level of 11-ng/ml total antimony and determination of the antimony(III) or antimony(V) showed there was no mutual interference over this range of concentration ratios.

For the analysis of large numbers of samples, it is of prime importance that the chloroform extracts should remain stable for a sufficient period of time to permit precise determination. The absorption signals of the extract were found to remain almost unchanged for at least 48 hr (extracts kept at room temperature).

The main advantage of the proposed method using the BPHA–$CHCl_3$ extraction system in combination with matrix modification, over the APDC–MIBK method,[6,7] is that lower concentrations of antimony in water samples (down to 0.2 ng/ml) can be determined.

Stabilizing effect of tartaric acid on storage of antimony(III) and antimony(V) in water samples

Of great importance in the differential determination of antimony(III) and antimony(V) is the question of their interconversion during sampling, transport and analysis. Laboratory experiments were designed for studying this question. To a lake water or waste-water sample, in which no antimony could be detected by the present method, appropriate quantities of standard antimony(III) or antimony(V) solution were added to make the antimony concentration 2 ng/ml, and the concentration of antimony was determined at regular intervals to assess the stab-

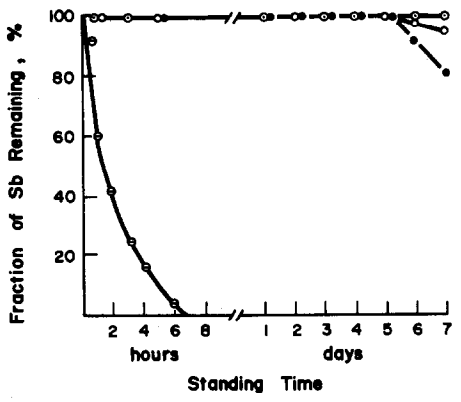

Fig. 5. Stabilizing effect of tartaric acid on antimony(III) and antimony(V). Antimony(III) or antimony(V) 2 ng/ml, concentration of tartaric acid 1%. (⊖) Water sample + Sb(III). (●) Water sample + Sb(III) + tartaric acid. (○) Water sample + Sb(V). (⊙) Water sample + Sb(V) + tartaric acid.

ND = not detected.

ility of the two oxidation states. Figure 5 shows the results. Antimony(III) in lake water or waste water appears to be unstable, since none could be detected after standing for 6 hr, presumably because of conversion into antimony(V) by some oxidants present in water samples. However, if tartaric acid was added to give a 1% concentration in the samples, the antimony(III) concentration remained unchanged for at least 5 days. Antimony(V) is relatively stable anyway, and no significant stabilizing effect of tartaric acid on antimony(V) during storage was observed.

The Kamada and Yamamoto method was also used, with the APDC–MIBK system applied for the extraction of antimony(III) at pH 6 and of total antimony at pH 1. The results confirmed that no antimony(III) was extracted at pH 6 in the absence of tartaric acid, but an equivalent amount of antimony(V) was found by extraction at pH 1 when only standard antimony(III) was originally added. This led us to the conclusion that a significant change in species distribution took place rapidly in the absence of tartaric acid. The decrease in absorbance of antimony(V) after a standing period of 6 days is probably due to adsorption of antimony(V) on the walls of the container.

The rate of conversion of antimony(III) into antimony(V) decreases with increasing acidity of the water samples. Addition of tartaric acid prevents the conversion and may be employed in the practical analysis of water samples.

Analysis of water samples

Although no pronounced interferences occur from diverse ions when the matrix modification technique is used in combination with the solvent extraction procedure, the standard-addition method was applied for the analysis of water samples to prevent unpredictable interferences due to the extreme complexity of industrial effluents. The results of some water samples are summarized in Table 1. The results refer only to the free extractable antimony(III) and reducible antimony(V). No attempt was made to recover other antimony species.

The relative standard deviation was found to be 3% for 9 replicate determinations at an average antimony level of 3.5 ng/ml. The characteristic concentration of the method for 1% absorption was found to be 0.04 ng/ml.

Tests for release of antimony from the Millipore filters,[1,12] failed to detect any.

SOME REMARKS ON THE QUANTITATIVE EXPRESSION OF THE SELECTIVITY OF AN ANALYTICAL PROCEDURE

J. INCZÉDY
Institute of Analytical Chemistry, University of Veszprém, Veszprém, Hungary

(*Received* 17 *September* 1981. *Revised* 1 *December* 1981. *Accepted* 31 *December* 1981)

Summary—The selectivity of an analytical method may be defined as expressing the degree to which a component can be determined in the presence of other but similarly behaving components without interference. The method itself will usually serve for determination of the other components, under slightly different conditions. The selectivity is closely related to the resolution of the method and also to the resolution of the instrument used for obtaining the signals. A simple formula is suggested for expressing the percentual degree of selectivity of an analytical procedure, on the basis of signal overlap caused by the interfering components, and can be used quite generally. A distinction is made between the terms analytical selectivity and selectivity of an analytical procedure, and between selectivity and specificity.

The term selectivity is widely used among analysts for characterization of a method or a reagent with respect to the species which is to be determined. The term is always concerned with the determination (or detection) of one component in the presence of other constituents. The more selective the method (or reagent), the less is the interference of the other components in the determination (or detection).

In a broader sense, the term is sometimes used by chemists to express the preferential reaction of a reagent with one component rather than another. For example the reaction between an optically active reagent and two enantiomers may be selective for one of them. If the free-energy changes of the two diastereomer formation reactions differ, *i.e.*, the equilibrium constants are not the same, the difference may be used as a quantitative expression of the selectivity.

Similarly we can say an ion-exchange resin is selective, if the free-energy changes for sorption of two similar ions with the fixed ionic groups of the resin are different from each other under the given conditions.

Since the characterization of an analytical method needs quantitative specification, many attempts have been made to give a quantitative formulation of selectivity. The first concept was by Belcher,[1] who proposed a "selectivity index", and was further developed by Belcher and Betteridge,[2–4] but only as a qualitative expression. Kaiser[5] gave a mathematical formula by which the selectivity of a method that is capable of determining several species may be expressed quantitatively. Both concepts have been criticised by Wilson.[6] The main objection to Kaiser's proposal was that it was not suitable for practical purposes. Pszonicki[7] proposed the use of what he called non-specifity coefficients, by which he could express quantitatively the interference of other components in the determination of one particular component. We think that Pszonicki was right in not calling these terms selectivity coefficients. Specificity is not the same as selectivity, since it is concerned with a reagent that reacts with only one component (or one group of components), and does not deal with the relative reactivity of more than one component.

In Gottschalk's concept[8] the selectivity is defined simply as the extent of non-interference, and the degree of selectivity is expressed by the threshold amount of an interferent that will produce a detectable effect on the main reaction. We think that this concept is too general, and includes too much in the term selectivity.

Recently Fujiwara *et al.*[9] successfully used an extended formula for quantitative expression of the selectivity of atomic-absorption and emission spectroscopic procedures in the determination of trace metal constituents in different matrices. They introduced into the original Kaiser equation the concentration of the analyte and the concentrations of the interferents, and also terms expressing the interaction effects of the interferents.

The intention of the present paper is no more than to support the concept just mentioned, and to suggest a slightly modified form for the general expression of the selectivity of an analytical procedure.

The following basic assumptions are made.

(1) We speak of the selectivity of a procedure only when more than one of the components present can give a response to the analytical system used.

(2) The selectivity of a procedure refers only to systems where components of similar behaviour and having similar physical and chemical properties are present. We would not speak of selective determination of manganese, if no other metal ions were

present in the system, even though interfering substances such as proteins might be present. This restriction of the term corresponds both to traditional analytical usage and the concept of Kaiser.[5] What is meant by similarity of the components depends, of course, on the actual analytical problem. Acetaldehyde can be determined selectively in a solution containing other types of aldehydes, but all primary amines can be selectively determined (as a group) in a solution in which secondary and tertiary amines are also present.

(3) Selectivity is concerned only with cases where the analytical method is suitable (or at least potentially suitable) for determination of more than one component of similar behaviour and giving similar signals. If the method serves for the determination (or detection) of only one component it is said to be specific, not selective. By extension, however, if the method gives identical response to a substituent group, irrespective of the matrix to which the group is attached, but to no other group, it can again be regarded as specific (for the group concerned).

(4) The quantitative expression of the selectivity will refer only to a given procedure with given concentration conditions.

(5) Analytical methods suitable for determination of different but similar components (elements, compounds, phases or groups of these) can be represented diagrammatically with two co-ordinates. One co-ordinate (let us call it z) identifies the components, the other (x) their amounts. Table 1 gives some examples. Selectivity is concerned with the resolution of the method along the z co-ordinate.

For example, a mixture of two acids can be analysed by titration with alkali in aqueous medium, with suitable acid–base indicators, if the logarithms of the dissociation constants differ by 4 or more. If a pH-meter is used instead of an indicator, the acids can be titrated selectively if their pK values differ by not less than 3, because the uncertainty of the end-point is lower. However, this rule only holds if the higher pK value does not exceed 9. If the pK values of the acids are too close to each other the selectivity can be increased by using a different solvent (*e.g.*, acetic acid if both acids are strong) or by adding a reagent which will make one of the acids appear stronger, *e.g.*, mannitol for boric acid, or copper for acetylacetone.[10]

Again, lead(II) and thallium(I) have half-wave potentials very close to each other, but thallium can be selectively determined polarographically if the half-wave potential of the lead is shifted to more negative values by use of complexing agents. If the half-wave potentials differ by at least 0.2 V, the determinations can be carried out selectively.

If two metal ions are to be determined spectrophotometrically in presence of each other and the absorption curves overlap extensively, we cannot selectively determine them directly, however good the resolution of the instrument. We have to use a selective reagent which will shift the absorption curves so that no overlap occurs.

Further, in a chromatographic separation compounds of similar behaviour can only be determined in presence of each other if there are no overlapping bands, or no components have the same retention volume. For completely successful determination of all the components the following requirements must be fulfilled. The ratios of the distribution coefficients of pairs of contiguous components (the separation factors, or selectivity factors) should be sufficiently different from unity; the column used should have adequate resolution (this determines the peak width); the absolute values of the distribution coefficients should be in a suitable range. If the distribution coefficients of two components are 10^{-1} and 10^{-2} (a separation factor of 10) they cannot be separated and determined individually, because they will both be eluted in the dead volume, without appreciable retention. If, however, we use another column with a different and more suitable stationary phase, we may be able to separate them. For chromatographic determination of all the components present a universal detector (with a cell size corresponding to the column resolution) must be used, but if only one component or group of components is to be determined a specific detector can be used. Thus chromatography may be selective or specific.

From these examples the following conclusions can be drawn.

(1) Analytical methods used for determination (or

Table 1. Two co-ordinate analytical methods

Method	z	x
Gravimetry	Solubility scale	Mass of precipitate
Acid–base titration	pH	Volume of titrant
Complexometric titration	pM	Volume of titrant
Redox titration	Redox potential	Volume of titrant
Spectrophotometry	Wavelength	Absorbance
NMR	Frequency	Peak area
Polarography (d.c.)	Voltage	Wave height
Chromatography	Volume, time	Peak area
Thermogravimetry	Temperature	Change in mass
Electrogravimetry	Electrode potential	Mass deposited

detection) of compounds similar to each other in behaviour can be characterized by the resolution along the z co-ordinate.

(2) This resolution depends on the following factors.

(*a*) The chemical and physical properties of the substances to be determined;

(*b*) The chemical and physical properties of the system used, *e.g.*, the solvent used for acidimetric titrations, the stationary phase for chromatographic separation.

(3) The resolution can be altered at will by means of physical and chemical factors, for all analytical methods.

(4) The selectivity is acceptable if the error caused by incomplete resolution in the z direction is less than that of the measurement itself (in the x direction).

(5) We may speak of selective determination of several compounds by use of the same method, but the number of such components which can be selectively determined when present together will depend on the informational power of the method used. Thus, theoretical considerations show that in aqueous medium only 3 or 4 acids at most can be titrated selectively in presence of each other, and even then only if their pK values are optimally spread. In methyl isobutyl ketone medium six or more acids can be titrated selectively. In chromatography, depending on the resolution of the column and on the components themselves, the number of selectively determinable components can be very large. Indeed, the information power of this technique is one of the highest of all analytical systems, if the components are distributed uniformly over the chromatogram.

(6) Selectivity, with respect to a pair of components, depends on the following factors.

(*a*) The thermodynamic (or kinetic) properties of the two components under the given conditions. In titrimetric determination of acids the corresponding quantities are the pK values, in spectrophotometry the electronic transition energies, in chromatographic separations the distribution coefficients; for separations based on differences in diffusion rates or mobilities, kinetic parameters are used instead of thermodynamic. For selective determinations both the ratios (or differences) of the parameters and their absolute values are important.

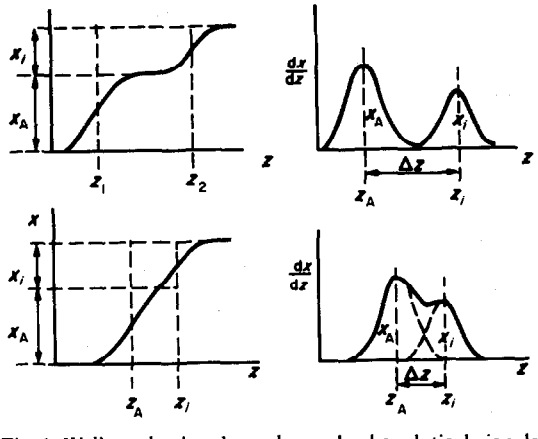

Fig. 1. Well resolved and poorly resolved analytical signals, and their derivatives.

(*b*) The resolution ability of the analytical system along the z co-ordinate. Figure 1 shows well resolved and poorly resolved signals for two similar components (A and B). If the signals are Gaussian the resolution R can be expressed in the usual way:

$$R = \frac{\Delta z}{2(\sigma_A + \sigma_B)}$$

where Δz is the difference in position of the two peaks, and σ_A^2 and σ_B^2 are the variances of the peaks. If $R > 1$, the determinations of both components are selective.

(*c*) The resolution power of the instrument used, along the z co-ordinate. This is usually expressed as $\delta z/z$. For selectivity to be obtained the following inequality must hold:

$$\delta z < \Delta z.$$

That is, the width of the "window" of the instrument must be smaller than the distance between the two adjacent signals. If this is not the case, the instrument cannot see separately the signals of the components.

This concept is in accordance with the selectivity term used for telecommunication systems, where the frequency width is the quantity responsible for the resolution.

On the basis of the discussion above the following definition is proposed for numerical representation of the selectivity of a procedure.

The *degree of non-selectivity* (Δ_A) will be defined as the ratio of the total signal from a given amount of interfering components to the signal for the component to be determined:

$$\Delta_A = 100 \frac{\Sigma \gamma_i c_i}{\gamma_A c_A} \%$$

where

$$\gamma_A = \partial x_A / \partial c_A \text{ and } \gamma_i = (\partial x_i / \partial c_i)_{c_A = 0}$$

are the sensitivities for the analyte A and the interfering (*i.e.*, similarly behaving) component i under given instrumental conditions (x_A and x_i are the signals, and c_A and c_i the concentrations). The selectivity (S_A) is then given by $S_A = (100 - \Delta_A)\%$.

In the simple case (Fig. 2) when the signals are Gaussian and the determination is based on the peak area T_A, if T_i is the area of overlap of x_A and x_i,

$$\Delta_A = 100 \frac{\Sigma T_i}{T_A} \%$$

Intercomponent effects may be taken into account by means of a term $\Sigma \mu_i c_i$ (see Fujiwara *et al.*[9]):

$$\Delta_A = 100 \frac{|\Sigma \gamma_i c_i + \Sigma \mu_i c_i|}{\gamma_A c_A} \%$$

where

$$\mu_i = \left(\frac{\partial x_A}{\partial c_i}\right)_{c_A}$$

A small problem arises with the sign of the numerator in this expression for Δ_A. To obtain a useful and practical expression for selectivity, the absolute value of the algebraic sum of the terms in the numerator should be taken used.

Example. In the paper by Fujiwara *et al.*,[9] in the determination of cadmium in sea-water by atomic-absorption and atomic-emission spectrometry, the sensitivity and concentration values summarized in Table 2 were found. From these data, the selectivities of the two procedures for determination of cadmium up to 0.5 mg/l. in the sea-water used are as follows.

For the atomic-absorption procedure

$$S_{Cd} = 100\left[1 - \frac{10500 \times 0.0009 + 1350 \times 0.0035 + 400 \times 0.0085}{0.5 \times 322}\right] = 89.1\%$$

For the atomic-emission procedure:

$$S_{Cd} = 100\left[1 - \frac{|-0.0011 \times 10500|}{0.5 \times 1480}\right] = 98.4\%$$

The corresponding values calculated by means of Kaiser's original formula are 2.5×10^4 and 1.35×10^6, and by means of the Fujiwara formula[9] 8.42 and 66.3 respectively.

Factors affecting selectivity

(1) We can choose conditions which will increase the resolution of the method by increasing Δz to decreasing the peak-width σ. The use of masking reactions for interfering (similarly behaving) components can either shift the positions of their signals (to increase Δz) or decrease their sensitivities. In both cases the overlap will be smaller and therefore the selectivity increased. If the sensitivity for the interfering components is sufficiently reduced, the method will become specific.

In chromatographic methods, both Δz and σ can be influenced by use of different stationary or mobile phases and column parameters.

(2) It was mentioned above that the resolution of the instrument must be higher than that of the method. Thus two components with adjacent light-absorption peaks cannot be selectively determined by colorimetry (*i.e.*, photometry with broad-spectrum polychromatic radiation). By means of a suitable band filter, however, selective determination can be realized unless the absorption bands overlap, in which case selectivity can only be achieved by using nearly monochromatic radiation. In the last case Δz will be lower but so will the quantity of light arriving at the detector.

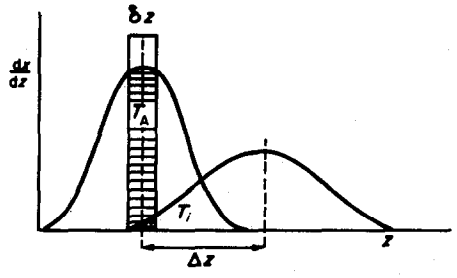

Fig. 2

Table 2. Concentration and sensitivity values for atomic-absorption and atomic-emission determination of cadmium in sea-water, with the 228.8 nm analytical line; data from the paper by Fujiwara *et al.*[9]

Metal	Concentration, *mg/l.*	Sensitivities (γ) AAS	AES
Cd	0.5	322	1480
Na	10500	0.0009	−0.0011
Mg	1350	0.0035	0
Ca	400	0.0085	0
Cu	0.5	0	0
Zn	0.5	0	0
Fe	0.5	0	0
Mn	0.5	0	0

Remarks

The proposed used of Δ_A values to define the degree of selectivity is very similar to that of the terms standard deviation and systematic error, which are accepted for the expression of precision and accuracy respectively.

The proposed percentual non-selectivity value ($\Delta_A\%$) should not be confused with the cross-contamination (overlap) factor used in chromatography, though in a few cases they are formally similar.

Since the selectivity of the method (or procedure) depends strongly on the conditions used, we may also speak of selective determination of a certain compound or element in the presence of specified amount (*e.g.*, 1000-fold ratio) of another (similarly behaving) component. In this case, the signals for calculation of the degree of selectivity are those corresponding to the specified ratio of the components, and this condition must be stated unambiguously.

It can happen that Δ_A exceeds 100%. In such cases, of course, there is no selectivity at all.

The parameters (selectivity coefficients, ΔpK values, *etc.*) affecting analytical selectivity play an important role in analytical chemistry, but are not in themselves sufficient to give quantitative information on the selectivity of an analytical method or procedure.

According to the basic assumptions—mentioned earlier—the term selectivity is restricted to systems of components that behave similarly. Therefore the interference of phosphate ions in the flame photometric determination of calcium is not a selectivity problem, but only a common interference problem (akin to turbidity in spectrophotometric methods), the

phosphate not being "similar" to calcium. Although phosphate can be determined indirectly by flame photometry, the principle of the method is not similar to that for the calcium determination.

Acknowledgements—Thanks are expressed to J. D. Winefordner and to Dr. R. A. Chalmers for their comments concerning the manuscript.

(*Received* 23 *November* 1981. *Accepted* 29 *December* 1981)

Summary—A simple fluorimeter assembled from commercial components and its use for the study and application of the Shpol'skii effect on polynuclear aromatic hydrocarbons (PAHs) in n-alkane matrices at 77 K are described. The correlation between the dimensions and geometries of PAHs and their corresponding Shpol'skii solvents is considered. Analytical figures of merit have been evaluated, and the power of the Shpol'skii technique with a conventional fluorimeter in the direct qualitative and quantitative determination of 11 PAHs in mixture is demonstrated. Comparisons with conventional room-temperature fluorescence and laser-excited Shpol'skii spectrometry are also commented upon.

The Shpol'skii effect was reported in 1952 by Shpol'skii *et al.*[1] Some aromatic compounds, when dissolved in selected n-alkane solvents and then frozen in liquid nitrogen (b.p. 77 K), exhibited extremely narrow-banded and line-rich "quasi-linear" fluorescence spectra. During the following two decades, several reports were published concerning the Shpol'skii effect, as well as many publications which described its application to both qualitative and quantitative determinations of real samples, as reviewed by Kirkbright and deLima.[2] In a series of three papers, Kirkbright and co-workers[2–4] reported an extensive study of the quasi-linear luminescence emission spectra of 23 PAHs in n-pentane, n-hexane, n-octane and n-decane, and the luminescence excitation spectra of 12 PAHs at 77 K in hexane, heptane and octane, and demonstrated the fingerprinting ability of quasi-linear emission and excitation spectra for qualitative and quantitative determination of a mixture of 8 PAHs without prior separation. Colmsjo and Stenberg illustrated the solvent effect and the improvement in spectral characteristics obtained by lowering the temperature from 77 to 63 K; the peaks become better resolved and better defined in position, which facilitates identification of PAHs in mixtures.[5,6] A library of 33 reference spectra of common PAHs was used to identify by comparison PAHs in fractions collected in the chromatography of a gasoline automobile exhaust sample; however, only 10 reference fluorescence spectra were shown.[7] The need to expand the library of reference spectra for the identification of the remaining peaks in well-resolved Shpol'skii fluorescence spectra from chromatographic fractions was again remarked on later.[8]

The application of laser excitation to low-temperature Shpol'skii luminescence spectra and determination of PAHs was pioneered by Vo-Dinh and Wild,[9] Abram *et al.*[10] and Winscom *et al.*,[11] who used commercially available lasers to enhance the selectivity and sensitivity of the method. In 1980, Fassel *et al.*[12] reported the use of a nitrogen-laser-pumped tunable dye-laser for the selective excitation of 4 PAHs in a solvent-refined coal liquid sample and a shale oil sample. Selected excitation wavelengths within the response curve of a single dye were employed. Recently, the same authors have presented the use of site-specific laser-excited Shpol'skii spectroscopy for the direct qualitative and quantitative characterization of complex mixtures of PAHs, including multialkylated isomers, at a temperature of 15 K obtained with a closed-cycle helium refrigerator.[13]

Laser-excited Shpol'skii spectroscopy seems to have great analytical potential, but the extremely high investment cost of tunable dye-lasers and pump-lasers and their complex and time-consuming operation hamper the use of this powerful technique. In this paper, a reliable double-monochromator spectrofluorimeter employing a xenon-arc continuum source is described. This system allows rapid and reproducible acquisition of quasi-linear luminescence emission spectra and rapid change of selected excitation wavelength for the analysis of multicomponent mixtures of PAHs. The correlation between the linear dimensions and molecular geometries of PAHs and their corresponding Shpol'skii alkane solvents is explicitly presented for 23 typical PAHs. Such a comprehensive survey should be a helpful guide in choosing the solvent that gives the best-defined, best-resolved and narrowest peaks for the unambiguous identification of other PAHs. Limits of detection obtained with the present system are evaluated; these values are the basis for comparison of the detection power for different PAHs. A table of excitation and emission maxima is also given which allows selection of optimal wavelengths for direct qualitative and quantitative determination of 23 PAHs in mixtures, as well as gener-

ation of a data base of reference spectra. In addition, the linear dynamic range and the upper limit of analytically useful concentration are discussed. Finally, results for the application of conventional fluorimetry with a Shpol'skii solvent (n-heptane) to the quantitative analysis of a synthetic mixture of 11 PAHs is presented.

EXPERIMENTAL

Apparatus

A simple spectrofluorimeter was assembled using an Eimac high-intensity xenon-arc lamp (300 W) (Varian/Eimac Division, San Carlos, CA) as the light-source, a Heath monochromator with wavelength-control unit as the dispersing element for excitation wavelengths, a commercial Dewar-flask cell compartment to hold liquid nitrogen and the quartz sample tube (3 mm i.d., 5 mm o.d.), a GCA/McPherson EU-700-77 scanning monochromator and an EU-701-30 photomultiplier tube as the dispersing element and detector for emission wavelengths (GCA/McPherson Co., Acton, MA), a low-noise nanoammeter[14] to process the photomultiplier current, and an Omniscribe B5217-51 recorder (Houston Instrument, TX).

Reagents

n-Pentane, n-hexane, n-heptane and n-nonane were distilled-in-glass grade solvents obtained from Burdick & Jackson Laboratories Inc. (Muskegon, MI). n-Octane was 99 + % gold-label grade obtained from Aldrich Chemical Co., Inc. (Milwaukee, WI). Standard PAHs were of different commercial brands,[22,23] and were recrystallized 3 times from ethanol, as necessary.

Procedure

High-resolution excitation and emission spectra were recorded for solutions in n-alkanes at 77 K. Each PAH solution (200 μl) was rapidly frozen in the quartz sample cell. To scan the luminescence emission spectrum, a 2-mm slit-width was used on the excitation monochromator (corresponding to a spectral band-pass of about 4 nm) and a 0.1-mm slit-width was used on the emission monochromator (corresponding to a spectral band-pass of 0.2 nm); and to scan the excitation spectrum, these monochromator slit-widths (and spectral band-passes) were interchanged. The emission monochromator was equipped with a programmable filter assembly (EU-700-56) which provided filters for broad-band isolation of given spectral regions to reduce stray light and scatter. The emission spectrum was scanned at a rate of 6.0 nm/min, and an RC-filter time-constant of 0.5 sec was used on the nanoammeter.

The internal reference method was used for calibration; the luminescence intensity of the internal standard was concurrently measured along with that of the analyte emission. The internal standard compensated for variation of experimental conditions such as the position of the sample cell in the optical path, the rate of cooling and hence the inhomogeneity of the sample surface, and the source intensity.[2,12,13] For quantitative work, a combined standard addition–internal standard procedure was used to compensate for any "inner filter" effect or the effect of energy transfer between the analyte and other molecules present.[2] The internal standard in this case could be another PAH in the sample instead of an externally added reference, since in analysis of "real" samples, it might be difficult to find a substance having a quasi-linear luminescence emission spectrum did not overlap that of the analyte(s) and whose excitation spectrum did overlap that of the analyte(s).

* Bond lengths used in the calculation of the lengths of the PAHs were: [25]C–C aromatic = 1.4 Å, C–C aromatic to aliphatic = 1.54 Å, C–C biphenyl = 1.48 Å.

[a] n-Pentane being the Shpol'skii solvent.

[b] n-Hexane being the Shpol'skii solvent.

[c] n-Heptane being the Shpol'skii solvent.

[d] n-Octane being the Shpol'skii solvent.

[e] n-Nonane being the Shpol'skii solvent.

[f] + some Shpol'skii effect, + + extensive Shpol'skii effect, 0 no Shpol'skii effect.

[g] Fwhm could not be determined because of overlap of peaks.

[h] Molecule has more than two layers of aromatic rings.

[i] No solvent had a clear-cut advantage as Shpol'skii solvent.

RESULTS AND DISCUSSION

Correlation between linear dimensions and molecular geometries of PAHs and their corresponding Shpol'skii alkane solvents

In Table 1, a qualitative picture is shown of the relationship between the size and shape of PAHs and the trend of the Shpol'skii effect with respect to n-alkane solvent type. PAHs having the same alkane as their "Shpol'skii solvent" are grouped together. The "Shpol'skii solvent" is taken as being that alkane which gives the best spectral resolution (*i.e.*, the luminescence emission and excitation spectral bands from the frozen crystalline matrix have the narrowest band-widths). It is often the case that use of the Shpol'skii solvent also results in the simplest luminescence spectra. The effective band-width depends on the number of "sites",[13] *i.e.* the number of different orientations of the molecules in the polycrystalline matrix, and the capability of the fluorimeter system to resolve them, yet, with a conventional fluorimeter, it is not possible to apply site selection, and hence the narrowest "band-width" has been used as the criterion for choosing the Shpol'skii solvent. It is evident that there is a general relationship between the dimensions and geometries of PAHs and the corresponding Shpol'skii solvents. Shpol'skii,[15] and more recently Brown *et al.*,[16,17] have mentioned that the degree of broadening of vibronic absorption linewidths caused by the specific orientation effect, depends on the degree of similarity between the molecular dimensions of the PAH and the n-alkane. The crystalline structures of n-pentane, hexane, heptane and octane have been well-characterized by X-ray methods.[18–21] The n-pentane structure is orthorhombic, with 4 molecules per unit cell and a volume of 543 Å^3. Both n-hexane and n-octane are triclinic with one molecule per unit cell and volumes of 165 and 208 Å^3, respectively; n-heptane is triclinic, with 2 molecules per unit cell and a volume of 382 Å.^{3} Santoni and Mandon have stated that the most favourable conditions for the appearance of quasi-linear spectra are equality of length of the alkane and PAH molecules and similarity of geometrical form.[24] Thus n-pentane would be the Shpol'skii solvent for naphthalene, n-heptane for anthracene, and n-nonane for naphthacene, as illustrated in Fig. 1. Such ideal matches do not exist for PAHs which are not straight chains of fused rings or which have alkyl groups at some position in the molecule. However, the effective lengths of these PAHs can be measured along an axis through the PAH molecule which, when placed parallel to the major axis of the n-paraffin, permits the PAH molecule to have maximum contact with the alkane. Their values are given in Table 1. Basically, it can be seen that the effective lengths serve as a reliable indication to the Shpol'skii solvents for the PAHs, failing only when the PAH molecule has more than two layers of aromatic rings in its structure, such as perylene, 1,2-benzopyrene and 1,12-benzoperylene, when the breadth of the molecule also comes into effect. In general the results in Table 1 agree with those of Kirkbright *et al.*[2,4] and Colmsjo *et al.*,[5,7] with a few contradictions which probably arise because of different opinions on the definition of "Shpol'skii solvents".

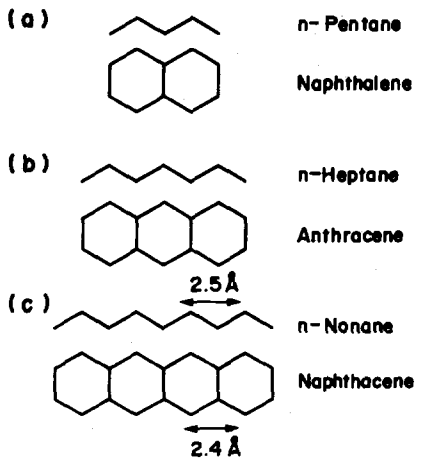

Fig. 1. Conditions favourable for the Shpol'skii effect: equality in dimensions and similarity of geometrical form between (a) n-pentane and naphthalene, (b) n-heptane and anthracene, and (c) n-nonane and naphthacene.[23]

Limits of detection and linear dynamic range of conventional Shpol'skii luminescence at 77 K

The detection power of the present system has been evaluated by calculating the limits of detection from the peak heights both in the excitation spectrum and the emission spectrum of individual PAHs at a concentration of about 1 ppm in their Shpol'skii solvents. Note that measurements were not always made at the most intense excitation and/or emission wavelengths; if the excitation and emission maxima turned out to be too close together, the next most intense excitation or emission peak was chosen in order to avoid extensive scatter; in such cases, the ratio of the height of the measured peak to that of the most intense peak in the same spectrum is given in parentheses after the wavelength of the measured peak. A second wavelength was also chosen if the overlapping region between the excitation and emission spectra was to be scanned and the most intense peak happened to fall inside that region. It can be seen from Table 2 that, in general, the system used results in limits of detection of about 10 ng/ml. The last column in Table 2 includes the limits of detection by conventional room-temperature fluorimetry.[22] The present method is about three orders of magnitude less sensitive than room-temperature fluorimetry. One reason is that much smaller spectral band-passes (4 and 0.2 nm) are used, compared to the 12 nm for the room-temperature work.[22] Another reason is that with a frozen crystalline alkane matrix, snow is formed, so only the front surface is irradiated instead of the entire volume.[23]

The standard calibration curve for 1-methylpyrene

[a] LODs were calculated as the concentration (ng/ml) of PAH that gave a signal 3 times the background noise, the latter being equal to $N_{p-p}/5$.

[b] Excitation LODs were determined at the excitation maximum, using the emission wavelength in parentheses; excitation slit-width = 0.2 nm, emission slit-width = 4 nm.

[c] Height of peak used for emission/excitation as percentage of height of the emission/excitation maximum; if no % is given, then percentage is 100%.

[d] Emission LODs were determined at the emission maximum, using the excitation wavelength in parentheses; emission slit-width = 0.2 nm, excitation slit-width = 4 nm.

[e] Reference 22 for RTF (conventional room-temperature fluorimetry).

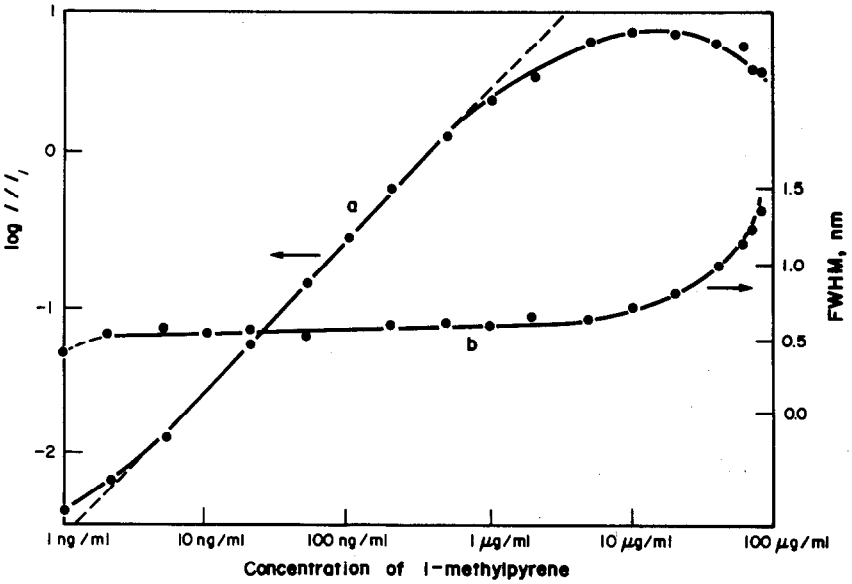

Fig. 2. (a) Analytical calibration curve for 1-methylpyrene (λ_{ex} = 346.2 nm, $\lambda_{em,measured}$ = 374.7 nm) using 3,4-benzopyrene (λ_{em} = 402.4 nm) as the internal standard, and (b) dependence of full-width at half-maximum of the 374.7-nm luminescence emission peak on concentration of 1-methylpyrene.

is shown in Fig. 2 as an example. The linear dynamic range of 3 orders of magnitude deviates from a slope of unity at about 1 μg/ml and reverses slope at concentrations above 10 μg/ml. This reversal of slope can probably be accounted for by the observation that the full-width at half-maximum increases dramatically at 10 μg/ml and higher concentrations, the PAH molecules in the host alkane matrix then being concentrated enough to allow site-to-site energy transfer.[17] Consequently Shpol'skii fluorescence is best utilized in the sub-μg/ml region.

UD = Fwhm could not be determined because of overlap of peaks.

PAHs in frozen Shpol'skii solvents facilitate selective excitation for the qualitative and quantitative analysis of mixtures.[13] Interference by weak emission from other components, because of partial overlap of absorption lines at the excitation wavelength, can be resolved by choosing a characteristic emission wavelength of the compound of interest for detection purposes. Selection of the excitation wavelengths that exhibit minimal spectral overlap is greatly facilitated by comparison of the excitation spectra of the individual compounds. For this reason, we strongly recommend potential users to collect a reference file of quasi-linear luminescence spectra obtained with their own instruments. In Table 3, a tentative scheme is presented in which the 24 PAHs are arranged in increasing order of excitation-maximum wavelengths. The third column shows that an emission wavelength can generally be found for selective detection even when the excitation maximum is overlapped by the excitation bands of neighbouring PAHs in the table. This table should be of help in analysing mixtures of PAHs, but should not be regarded as providing the only answer, as other emission wavelengths are sometimes used for resolving interfering components, especially when in analysis of "real" samples, or to reduce the analysis time and effort.

To test the power of the Shpol'skii technique with our fluorimeter system, a synthetic mixture of 11 PAHs was prepared in n-heptane, the concentrations ranging from 50 to 470 ng/ml. n-Heptane was chosen as a compromise among the five alkane solvents, as suggested by Fassel *et al.*[13] A combined standard addition–internal standard procedure was adopted, the internal standard being one of the components of the sample mixture.[12] This internal–standard approach was found to be quite feasible; 1,2-benzanthracene was chosen as the internal standard for the determination of 1,2-benzopyrene and 3,4-benzopyrene because it also emitted when the sample solution was excited at 292.2 nm for the determination of 1,2-benzopyrene, and 3,4-benzopyrene was used as the internal standard for the determination of the other PAHs because its strong emission at 402.8 nm lay in a region isolated from most emissions from other PAHs, and because almost any excitation wavelength would cause emission. With only 6 excitation wavelengths, all 11 PAHs could be identified and their concentrations determined. The results are shown in Table 4. Note that some excitation wavelengths were not those given in Table 2; 292.2 nm was the most selective excitation wavelength for 1,2-benzopyrene in the mixture, 361.6 nm was used for anthracene because the emission at 380.5 nm could then be used for its selective detection (its emission maximum at 402.1 nm was overwhelmed by the intense fluorescence from 3,4-benzopyrene), and 392.2 nm was used instead of 415.2 nm for perylene because only then could we observe the emission of 3,4-benzopyrene at 402.8 nm and use it as the internal standard for determination of perylene. As can be seen from Table 4, the average error was about 9%; the major sources of error could have been the inhomogeneity in orientation of the molecules in the matrix, the inherent uncertainty in fluorimetry, and penetration into the non-linear region on the high concentration side of the standard calibration curve if too large a standard addition were made.

Although quasi-linear peak widths became narrow with decrease in temperature,[6] 77 K was found to be low enough for satisfactory identification of 11 PAHs in the present study. A liquid–nitrogen bath is cheaper, simpler and easier to use than freezing nitro-

Table 4. Quantitative analysis of 11-component PAH mixture in n-heptane by conventional Shpol'skii luminescence at 77 K

λ_{ex}, nm	λ_{em}, nm	PAH	Taken, μg/ml	Found, μg/ml	Error, %
289.2	321.9	Naphthalene	0.05	0.05	5
	375.6	1,2;3,4-Dibenzanthracene	0.41	0.46	13
292.2	371.8	1,2-Benzopyrene*	0.38	0.40	5
	402.8	3,4-Benzopyrene	0.37	0.37	1
295.0	346.0	Phenanthrene	0.41	0.36	11
	360.6	Chrysene	0.45	0.49	8
306.6	319.3	Acenaphthene	0.08	0.08	5
	371.0	Pyrene	0.41	0.47	16
361.6	380.5	Anthracene	0.40	0.46	13
	383.9	1,2-Benzanthracene	0.48	0.44	8
392.2	443.9	Perylene	0.08	0.08	7

* Standard addition was done on two portions of the same sample solution. One portion was used for the determination of 1,2-benzopyrene and 3,4-benzopyrene, with 1,2-benzanthracene (λ_{em} = 383.9 nm) as the internal standard. Another portion was used for the determination of the other PAHs, with 3,4-benzopyrene (λ_{em} = 402.8 nm or 426.6 nm) as the internal standard.

gen or lower temperatures requiring liquid hydrogen or liquid helium. The limits of detection can be improved by using dye-laser excitation, but apparently by no more than 2 orders of magnitude, judging from the analytical curve for benzo[*a*]pyrene shown by Yang *et al.*[13] Moreover, the complications involved in changing dyes and tuning the frequency doubler when working at excitation wavelengths shorter than 360 nm can result in considerable consumption of time and effort; in addition, the initial cost and maintenance cost of lasers and the use of gated detection electronics must be considered. With the introduction of commercial spectrofluorimeters similar to the one described in this work, conventional Shpol'skii luminescence could develop into a routine analytical technique in any laboratory.

APPLIED POTENTIAL AND RADIOTRACER STUDIES ON POLY(VINYL CHLORIDE) MATRIX ION-SELECTIVE ELECTRODE MEMBRANES

B. DOYLE, G. J. MOODY and J. D. R. THOMAS
Applied Chemistry Department, Redwood Building, UWIST, Cardiff, Wales

(*Received* 11 *November* 1981. *Accepted* 29 *December* 1981)

Summary—This paper reports the effect of applied potentials on PVC matrix membranes containing (*i*) the barium ion-sensitive barium–Antarox C0880 complex and 2-nitrophenyl phenyl ether solvent mediator, and (*ii*) the calcium ion-sensitive Orion 92-20-02 phosphate-based calcium liquid ion-exchanger. Platinum electrodes were placed in solutions on each side of the membranes. The barium ion-sensitive membranes are unable to maintain stable current flows but the calcium ion-sensitive membranes are characterized by stable current flows over prolonged periods even after successive polarity reversals. Results are presented, from radiotracer experiments for permeation of ions through the membranes with and without an applied potential. No evidence was found for significant permeation of barium-133 ions through the barium ion-sensing membranes into an initially inactive solution, but it was found that barium-133 ions were incorporated into the membranes after removal of the applied potential. Permeation of sodium-22 ions through the calcium ion-sensing membranes occurred only to a limited extent in the presence of an applied potential and not at all in its absence, confirming electrode selectivity trends for calcium and sodium. Calcium-45 ions did not permeate the calcium ion-sensing membranes into an inactive counter-solution against the potential gradient, but on reversal of the polarity, permeation occurred to a far greater extent than in the absence of an applied potential. These differences in behaviour are compatible with the more complicated membrane pathways of the barium ion-sensing membranes, imposed by the complexing of barium ions by the ethyleneoxy units of Antarox C0880 in a tight helical conformation. The calcium ion-sensing membranes are much less constrained, thus permitting more facile replacement of the calcium ions in the membrane by ions from solution.

Radiotracer diffusion studies have been useful in establishing relationships between the availability of membrane pathways for ion transport and the potentiometric selectivity characteristics of PVC-matrix ion-selective electrodes containing calcium bis-dialkylphosphate ion-sensors.[1–3] Similar studies[4] have revealed that the availability of such membrane pathways is not important in determining the characteristics of electrodes containing the tetraphenylborate of the barium complex of a nonylphenoxypoly(ethyleneoxy)ethanol, $C_9H_{19}C_6H_4O(CH_2CH_2O)_{n-1}C_2H_4OH$ (Antarox C0880, in which $n = 30$). These studies implied that for these membranes an important role should be assigned to the ability of the membranes to incorporate and hold ions by complexation.

Studies of the effect of applied potentials and currents have been of use in other work[5–8] in leading to a better understanding of ion-transport phenomena within membranes. This paper reports a study of the effect of applied d.c. potentials on PVC-matrix membranes containing (*i*) the barium ion-sensitive barium–Antarox C0880 complex and 2-nitrophenyl phenyl ether solvent mediator, and (*ii*) the calcium ion-sensitive Orion 92-20-02 calcium liquid ion-exchanger, based on a calcium dialkylphosphate ion-sensor and dioctylphenyl phosphonate solvent mediator. Results are presented for potential-induced and zero-potential permeation of ions through these membranes, obtained by using appropriate radiotracers.

EXPERIMENTAL

Membranes

PVC-supported membranes were prepared as previously described[9,10] from PVC (0.17 g) and (*i*) a solution of the tetraphenylborate of the barium complex of Antarox C0880 (0.04 g) in 2-nitrophenyl phenyl ether (0.36 g) (barium ion-sensitive membranes) and (*ii*) Orion 92-20-02 calcium liquid ion-exchanger (0.40 g) (calcium ion-sensitive membranes).

Applied potential experiments

The cell (Fig. 1) enclosed in an air thermostat at 35° was charged with appropriate solutions (10 ml) on either side of the membrane. Fixed potentials were applied between platinum electrodes in the solutions on either side of the membrane, with a purpose-built potentiostat (up to 20 V). Currents flowing through the membranes were monitored by using a scaler (MS310) to count the charge passing between the two electrodes.

The barium ion-sensitive membranes and membranes containing only 2-nitrophenyl phenyl ether (NPPE) solvent mediator were used between barium chloride solutions ($10^{-3}M$), and the calcium ion-sensitive membranes between calcium chloride solutions ($10^{-3}M$); in some experiments the membranes were also used between volumes of doubly demineralized water.

Radiotracer studies

The radiotracer studies were performed by labelling one of the solutions in the cell with the relevant radioisotope. Permeation of sodium through calcium ion-sensitive membranes was followed by replacing one of the calcium chloride solutions by $10^{-3}M$ sodium chloride labelled with sodium-22.

Diffusion of radiotracers through a membrane was monitored[4] by periodically removing 20-μl (^{133}Ba) or 10-μl

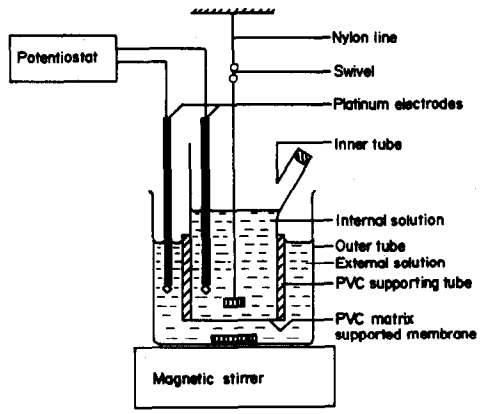

Fig. 1. Apparatus used.

(^{45}Ca, ^{22}Na) samples with a Lang-Levy auto-zero micropipette, placing them on filter paper (Whatman No. 1, 2.1 cm diameter), and counting with a Geiger-Müller mica end-window tube.

The activity of each membrane at the end of the experiment was monitored by (*i*) slicing the membrane from its supporting PVC tubing, counting each side of the membrane in turn with the Geiger-Müller tube, and using the data to calculate C_{act}/C_{inact} (C_{act} refers to the membrane surface in contact with the labelled solution, C_{inact} to the other surface), and (*ii*) dissolving the membrane in tetrahydrofuran (10 or 5 ml) and counting the activity of 10–60 μl samples of this solution, spotted onto filter papers, in order to determine the uptake (the activity contained by the membrane at the experiment conclusion as a percentage of the total initial activity in the radioactive solution).

All radiotracer counts were taken for 300 sec and corrected for background (*ca.* 170 counts). Count-rates of *ca.* 8, 133 and 50 cps were obtained from 10-μl samples for ^{133}Ba, ^{45}Ca and ^{22}Na respectively. The half-lives of the radioisotopes were long enough for the effect of decay during the experiments to be negligible.

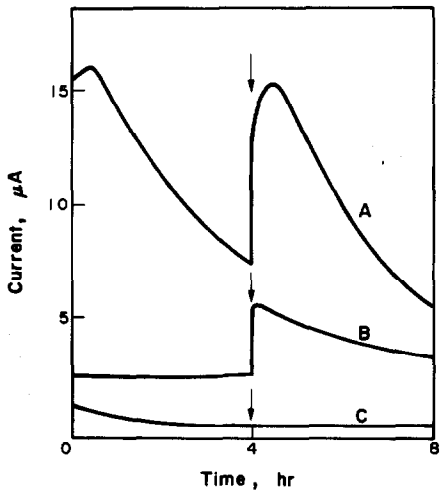

Fig. 2. Current-flow patterns for a potential of 2 V applied across membranes containing the barium–Antarox C0880 adduct, separating $10^{-3}M$ barium chloride solutions (A), or water (B), and across a membrane containing only 2-nitrophenyl phenyl ether (C) with reversal of the applied potential polarity after 4 hr (↓).

Materials

The Antarox C0880 was a gift by GAF (Great Britain) Ltd., Manchester. Metal chloride solutions were prepared from BDH Analar grade materials. Radioactive solutions were prepared by addition of (*i*) 1.4 ml of $6.39 \times 10^{-5}M$ barium chloride (*ca.* 0.08 mCi/ml barium-133 activity) to 100 ml of $10^{-3}M$ barium chloride, (*ii*) 0.2 ml of $1.1 \times 10^{-3}M$ calcium chloride (*ca.* 2.2 mCi/ml calcium-45 activity) to 100 ml of $10^{-3}M$ calcium chloride, and (*iii*) 0.3 ml of $1.9 \times 10^{-5}M$ sodium chloride (*ca.* 0.2 mCi/ml sodium-22 activity) to 100 ml of $10^{-3}M$ sodium chloride.

RESULTS

Membranes containing barium–Antarox C0880 complex

Current measurements. The patterns of current flow observed when a potential of 2 V was applied across membranes containing barium–Antarox C0880 complex are shown in traces A and B of Fig. 2, for barium chloride solutions and doubly demineralized water respectively. Trace C shows the pattern of current flow for a membrane containing only the solvent mediator, NPPE, separating barium chloride solutions. In all these experiments the polarity of the applied potential was reversed after 4 hr.

Trace A shows that the current flowing through these barium sensitive membranes decayed rapidly, to *ca.* 50% of the initial maximum value after ~3 hr, and that reversal of the polarity of the applied potential caused rapid recovery of the current flowing through the membrane to ~95% of the initial maximum value, followed by rapid decay of the current. There was no evidence for any significant recovery of the current upon further reversals of the polarity. Attempts to revive the limited current-bearing capacity of the membranes by immersion in $1M$ barium chloride for 18 or 72 hr before application of further cycles of potential also proved unfruitful. The current flow was found to be sensitive to temperature variations. Thus, the small initial increase in current shown in trace A corresponded to the time taken for the temperature within the air thermostat to reach 35°. Such initial current increases were eliminated by letting the temperature equalibrate before application of the potential. A similar pattern of current-flow decay and recovery was obtained with several membranes of this type for an applied potential of 2 V. When the potential was applied for 48 hr before reversal of the polarity, the current decayed to 1–2 μA after 24 hr and recovered to ~80% of its initial maximum value on reversal of the polarity. The initial maximum observed varied in the range 15–20 μA for different membranes, because of variations in membrane thickness and composition.

Similar patterns were also noted for applied potentials of 4 and 5 V, with intial maxima of 35 and 55 μA, respectively. For an applied potential of 10 V an initial maximum of 90 μA was observed, but the polarity could be reversed more than six times before the

current failed to recover; the maximum current decreased with each reversal of polarity.

Trace B shows that with a potential of 2 V across a barium-sensitive membrane separating two lots of demineralized water, the initial current was 2–3 μA (the same order as for demineralized water without the dividing membrane). It also shows that the current decayed more slowly, at $\sim$0.1 μA/hr and that reversal of the polarity caused an increase to 5–6 μA, followed by decay at 0.4–0.5 μA/hr.

Trace C shows that applying 2 V across a membrane containing only NPPE solvent mediator and separating barium chloride solutions gave an initial current of $\sim$1.0 μA, decaying to $\sim$0.1 μA, and that reversal of the polarity caused no significant recovery.

Barium-133 permeation studies. The activity measurements made at the conclusion of experiments are presented in Table 1. In experiments 1 and 2 the membranes were removed from contact with the solutions immediately after removal of the applied potential, but in experiments 3–5 they were not removed until at least 48 hr after removal of the applied potential. In all these experiments the polarity was reversed at least three times and the membranes were in contact with the solutions for at least 148 hr.

These studies showed no evidence that significant amounts of radioactive ions permeated through the membranes into the initially inactive solutions. The values of C''/C' in Table 1 refer to the end of the experiment, but, samples extracted at various times during a run never gave a ratio exceeding 0.02.

The values of C_{act}, C_{inact}, and the percentage uptake all show that barium-133 was incorporated into the membranes to a far greater extent after removal of the applied potential.

Control experiments already described[4] suggest that the value of C_{act}/C_{inact} would be $\sim$4 if all the incorporated barium-133 were concentrated at or near the active solution/membrane interface. Thus, the data in Table 1 show that while there was some permeation of radioactive ions into the membranes, there was not an equilibrium distribution of the radioactive ions within the membranes, (which would lead to a C_{act}/C_{inact} value of $\sim$1).

Membranes containing Orion 92-20-02 calcium ion-exchanger

Current measurements. The current-flow patterns observed are shown in Fig. 3. The traces shown were obtained with the same membrane. The polarity of the applied potential was reversed after 24 hr. The traces indicate that pseudo-stable current-flows were established within an hour of application of the potential, and that they decayed at $\sim$0.1 μA/hr. When the potentials were applied for longer than 24 hr there was no evidence for significant further decay in the current, *e.g.*, for an applied potential of 5 V the current was 4.4, 4.5, 4.7 and 4.9 μA at 25, 48, 96 and 120 hr, respectively, after the initial application of the potential.

† Direct comparison of ^{45}Ca, ^{22}Na and ^{133}Ba values is not possible because of the different natures and concentrations of the radiotracers used.

§ Membranes removed from contact with the solutions immediately after removal of the applied potential.

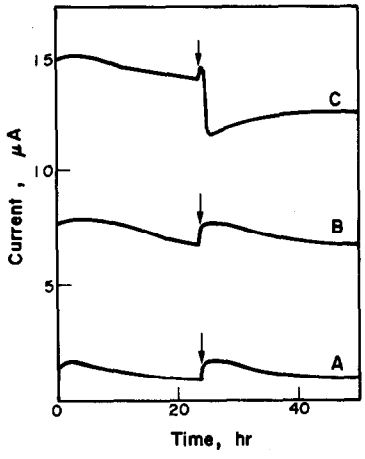

Fig. 3. Current-flow patterns for potentials applied across a membrane containing Orion 92-20-02 calcium liquid ion-exchanger separating $10^{-3}M$ calcium chloride solutions, with reversal of applied potential polarity after 24 hr (↓). Applied potential: 2 V (A), 10 V (B) and 20 V (C).

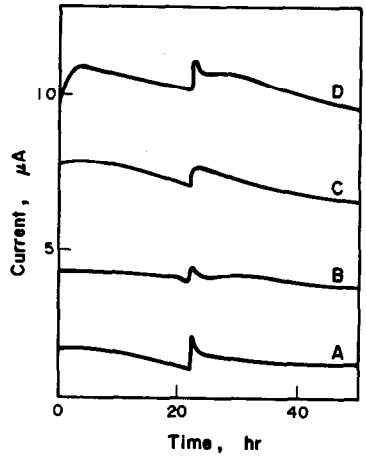

Fig. 4. Current-flow patterns for potentials applied across a membrane containing Orion 92-20-02 liquid ion-exchanger separating water, with reversal of applied potential polarity after 24 hr (↓). Applied potential: 2 V (A), 5 V (B), 10 V (C) and 15 V (D).

Though the current flowing under similar conditions of applied potential varied considerably from membrane to membrane of this type, *e.g.*, pseudo-stable currents of ~15 and 25 μA were obtained with two such membranes at a potential of 20 V, an individual membrane gave essentially the same current-flow pattern over several cycles of polarity reversal, changes in the applied potential, and replacement of the calcium chloride solutions by new solutions, although the current did eventually decrease if the changes were continued.

Replacement of the calcium chloride solutions by demineralized water caused no significant changes in the current-flow patterns (Fig. 4).

Ion permeation studies. In all the applied-potential experiments, current flows of ~5 μA were obtained.

The C''/C' data (Table 1) for the end of the experiment show that sodium-22 ions did not permeate these membranes in the absence of an applied potential, and only to a very limited extent in the presence of an applied potential. They show further that calcium-45 ions did not permeate the membrane into the inactive counter-solution against the potential gradient, that is, when the positive electrode was immersed in the inactive solution, but with the opposite polarity (experiment 7) the calcium-45 permeated into the inactive counter-solution to a far greater extent than in the absence of an applied potential (experiment 9).

Figure 5 shows plots of C''/C' *vs.* time. Traces A–D refer to experiments 7–10, respectively. These traces confirm the behaviour of sodium-22 permeation through the membranes. The traces for calcium-45 show an induction period which is shortened by application of a potential with the correct polarity. These traces also confirm the far greater extent of permeation of calcium-45 ions through the membranes under an applied potential of suitable polarity. The slopes of the linear regions on these plots provide a measure of the relative rates of permeation of the ions through the membranes. These slopes had values of 6×10^{-7} and 40×10^{-7} sec^{-1} for calcium-45 permeation in the absence and presence of an applied potential, and 0 and 1×10^{-7} sec^{-1} for sodium-22 permeation in the absence and presence of an applied potential.

The activity contained by the membranes at the end of the experiments shows that calcium-45 entered the membranes much more readily than sodium-22 did, and that the extent of incorporation of cal-

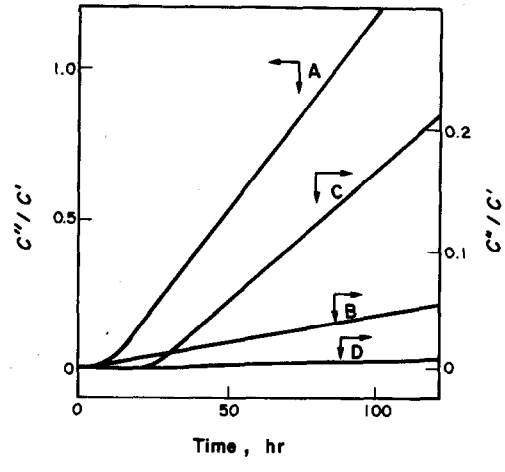

Fig. 5. Plots of C''/C' *vs.* time for the permeation of calcium-45 i (A) and sodium-22 (B) at an applied potential of 5 V, and for permeation of calcium-45 (C) and sodium-22 (D) at zero potential, through membranes containing Orion 92-20-02 calcium liquid ion-exchanger.

cium-45 ions by the membranes was about the same whether a potential was applied or not, whereby the extent of incorporation of sodium-22 was increased by an applied potential. The C_{act}/C_{inact} ratios show that considerable permeation of the incorporated radioactive ions occurred within the membranes. Control experiments already described[4] indicated that this ratio would be ~33 for calcium-45 and ~4 for sodium-22 if all the incorporated radioactive ions remained concentrated at or near the active solution/membrane interface, but the ratios obtained in experiments 7 and 8 suggest that these radioactive ions were concentrated near the inactive solution/membrane interface.

DISCUSSION

The results demonstrate that the application of d.c. potentials across these two different membrane systems causes markedly different current-flow behaviour. Radiotracer diffusion studies[1–4] have shown that primary ion transport through the membranes into the inactive counter-solutions occurs much more readily for the calcium ion-sensitive membranes based on calcium dialkylphosphate sensors than for the barium ion-sensitive membranes based on the barium–Antarox C0880 complex. The results of the present study favour the assignment of an important role to such differences in explaining the different behaviour of these membrane systems when potentials are applied across them.

The inability of the barium ion-sensitive membranes to maintain stable current-flows is due to the charge-carrying species being displaced faster from the membranes by application of a potential than they can be replaced by permeation of barium ions,[4] causing a rapid increase in the membrane resistance from the initial value of *ca.* 0.2 MΩ. Indeed, the very low values for percentage uptake of barium-133 in experiments 1 and 2, where the membranes were removed from the solutions immediately after removal of the applied potential, shows that even normal barium ion incorporation by the membranes is inhibited during the application of potentials. Thus, the overall effect of applying a potential across these membranes is to increase the membrane resistance, and if the potential is applied for lengthy periods the resistance approaches that of a membrane containing only the solvent mediator, NPPE, *i.e.*, ~10 MΩ with a consequent current of ~0.1 μA.

The fact that the current flow with these membranes recovers on potential-reversal only if there is still a significant current flow through the membrane, is probably due to total barium depletion of the barium-sensitive membranes causing changes in the membrane structure which make the uptake of barium ions from solution by the normal barium ion-exchanger sites within the membrane even more difficult. Thus, though barium ions are quite readily incorporated into the membranes after removal of the applied potential, (*cf.* uptake data for experiments 3–5), the fact that current-flow cannot be restored for these membranes, even by storage in concentrated barium chloride solutions between potential application cycles, suggests that this uptake of barium is not due to interaction with the normal ion-exchanger sites within the membranes. The stability of the barium–Antarox C0880 adduct is attributed[11] to 12 ethyleneoxy units assuming a tight helical conformation with a radius of ~1.3 Å in which a barium ion is held by a cage of 12 oxygen atoms (6 in each loop) through ion-dipole interaction, and the removal of barium ions from the membranes under an applied potential probably causes collapse of the helical loops, thus removing the pathways for permeation through the membrane, which are in any case more constrained that for the calcium ion-sensitive membranes.

The stable current-flows established through the calcium ion-sensitive membranes containing Orion 92-20-02 calcium liquid ion-exchanger suggest that calcium ions displaced from the membranes by application of a potantial are readily replaced by calcium ions from solution. This facile replacement is consistent with the ready permeation of calcium ions through these membrane systems under zero-potential conditions.[1–2] Indeed, application of an applied potential with the correct polarity increases both the rate and extent of radioactive calcium permeation through these membrane systems (*cf.* traces A and C in Fig. 5). The non-permeation of the calcium-45 into the inactive solution in experiment 6 is not really surprising, since it is the positive electrode that is immersed in this solution. However, the uptake data show that this unfavourable potential gradient does not prevent the uptake of the radioactive ions by the membrane itself, and indeed suggest that the total uptake is actually increased, because the polarity of the applied potential prevents the release of radioactive calcium ions into the inactive solution. Table 1 also shows that the application of a potential of suitable polarity only changes the distribution of the radioactive ions within the membrane and not the extent of incorporation of these ions.

The value of $d(C''/C')/dt$ obtained for the permeation of calcium ions through the membraness in the absence of an applied potential (6×10^{-7} sec^{-1}) is less than values previously reported[1,2] (18×10^{-7}, 11×10^{-7} and 22×10^{-7} sec^{-1}). The values vary widely between different batches of Orion 92-20-02 liquid ion-exchanger.[1,2] The use of a different batch of the ion-exchanger may also account for the extent of calcium-45 ion incorporation by the membranes in this study being much greater than that previously reported.[2] but the difference is much more likely due to the fact that in the previous study no account was taken of the self-absorption of activity by the membrane. Control counting experiments showing that the placing of a non-active membrane between a sample of calcium-45 and the counter reduced the count by a factor of ~33 suggest that ignoring the effect of mem-

brane thickness could cause considerable error. Thus, the present estimate of the uptake of calcium-45 is much more reliable than the previous one.

The current flows obtained through these membranes are consistent with membrane resistances of ~ 1 MΩ, similar to those reported for PVC membranes[7] and Millipore filters[8] containing Orion 92-20-02 calcium ion-exchanger. Variations in the currents flowing through these membranes on application of different potentials simply reflect Ohm's law and the varied resistances of the membranes.

Sodium-22 permeates through the membranes into the inactive counter-solution only to a very limited extent, even when a potential of suitable polarity is applied across the membrane. On the other hand, the extent of incorporation of sodium-22 into the membrane increases significantly on application of a potential, in agreement with the hypothesis[7,8] that the deterioration of the selectivity characteristics (relative to sodium) of Orion calcium liquid ion-exchanger membrane systems, upon application of potentials, is due to the greater extent of incorporation of sodium ions into the bulk of the membrane under these conditions.

(*Received* 2 *June* 1981. *Revised* 27 *November* 1981. *Accepted* 11 *February* 1982)

Summary—The activation of the vanadium(V)-catalysed aerial oxidation of sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate by iron(III) is discussed. The oxidation product is intensely fluorescent and allows fluorescence-monitoring of the slow reaction, which is preceded by an induction period. On the basis of this investigation, an accurate method for determination of vanadium(V) at the 1–10 ng/ml level has been developed.

Extremely low concentrations can be determined by means of catalytic analysis, but the selectivity of catalytic determinations is often rather lower than that of other methods for trace analysis. However, the specificity and selectivity of an analytical procedure depend on the specificity offered by both the chemical reaction and the monitoring technique and fluorescence-monitoring in catalytic methods of analysis has the additional advantage of improving the analytical characteristics of such methods.[1] Wilson and Ingle[2,3] have recently discussed the advantages of these methods.

The most sensitive catalytic methods are generally associated with the development of the theory and practice of activation and inhibition of catalytic reactions. Very interesting discussions of such effects has been given by Bontchev[4] and Hadjiioannou.[5]

A catalytic determination will be selective if either the individual catalyst shows very different catalytic activities under different reaction conditions, or a variety of catalysts react according to different reaction mechanisms. The selectivity of a catalytic method can often be improved by proper choice of pH, reagent concentration, temperature, complexing agents and monitoring technique, or by use of an activator to increase the rate of a given catalytic reaction in presence of a certain catalyst.[6]

This paper presents the catalytic fluorimetric determination of vanadium(V), based on activation by iron(III). The method allows the determination of V(V) at the 1–10 ng/ml level. This activation technique not only improves the sensitivity of the indicator reaction[7] used, but also makes the method more selective.

EXPERIMENTAL

Apparatus

A Perkin–Elmer fluorescence spectrophotometer, model MPF-43A, was used, equipped with an Osram XBO 150-W xenon lamp, excitation and emission grating monochromators, 1 × 1 cm quartz cells, an R-508 photomultiplier and a Perkin–Elmer 023 recorder. A standard "bar" of Rhodamine B (conc. $1 \times 10^{-7} M$) gave a scale reading of 60 units, with the following parameters: $\lambda_{ex} = 480$ nm, $\lambda_{em} = 570$ nm, excitation and emission wavebands 5 nm, sensitivity 10 coarse and 7 fine, temperature 25°. The variation of fluorescence intensity with time was recorded at a chart-speed of 2 cm/min with fixed excitation and emission wavelengths.

Reagents

Solutions were made of sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate ($1 \times 10^{-2} M$), vanadium(V) ($1 \times 10^{-3} M$, from ammonium vanadate and standardized gravimetrically) and iron(III) [$1.79 \times 10^{-2} M$ from $Fe(NO_3)_3 \cdot 9H_2O$ and standardized gravimetrically], and diluted as required.

Doubly distilled and demineralized water and analytical grade reagents were used.

Procedure

Place 5 ml of $10^{-4} M$ sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate and 5 ml of $2M$ hydrochloric acid in a dry 25-ml standard flask. Add enough demineralized water to give a final volume of 25 ml when all the reagents are present. Finally add the volumes of premixed vanadium(V) and iron(III) solution needed to give final concentrations of 1–10 ng/ml for vanadium and 5 μg/ml for iron. Measure fluorescence intensity as a function of time, starting 60 sec after addition of the vanadium–iron solution, with $\lambda_{ex} = 524$ nm, $\lambda_{em} = 582$ nm. All the solutions should be at 28°.

RESULTS AND DISCUSSION

In an attempt to increase the sensitivity of the proposed method for determination of V(V),[7] an examin-

ation was made of the activating action of certain substances that had previously been employed for this purpose in the indicator reactions of V(V)-catalysed oxidation of aromatic amines.[4] No activation of the reaction was observed when phthalate, phosphate, citric acid, phenol, hydroquinone, oxalate or ethanol was added. However, the presence of Fe(III) accelerated the V(V)-catalysed overall reaction.

The kinetic curves obtained in presence of Fe(III), of V(V) and a mixture of both, under identical conditions, are shown in Fig. 1. As observed, when both Fe(III) and V(V) are present in the medium, the slope of the curve increases and the length of the induction period decreases.

Iron(III) acts in a similar manner to V(V), by catalysing the aerial oxidation of the disulphonate reagent, giving rise to the same fluorescent product. However, under the optimum experimental conditions for the catalytic action of V(V), the effect of Fe(III) is slight. The kinetic data are summarized in Table 1.

The action of one-electron oxidizing agents on arylamines or phenols is based on an oxidation process which proceeds by a homolytic mechanism. This includes the subtraction of one electron from the organic substrate as the first step,[8] with formation of free radicals.

$$ArNH_2 - e^- - H^+ \rightarrow ArNH \quad (1)$$

$$ArOH - e^- - H^+ \rightarrow ArO \quad (2)$$

Iron(III) or V(V) can act in a similar manner on the disulphonate reagent, the free radicals formed reacting with atmospheric oxygen (electron acceptor) with formation of hydrogen peroxide in a subsequent step. The peroxide could cause regeneration of the catalyst according to equations (3) and (4):

$$2Fe^{2+} + H_2O_2 + 2H^+ \rightarrow 2Fe^{3+} + 2H_2O \quad (3)$$

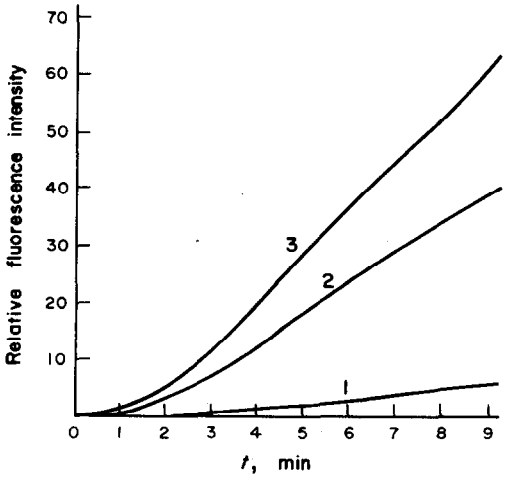

Fig. 1. Fluorescence *vs.* time curves for: 1, 5 ppm Fe(III); 2, 0.1 ppm V(V); 3, 5 ppm Fe(III) and 0.1 ppm V(V). [DADHADS] = $2 \times 10^{-5}M$. [HCl] = $0.4M$; λ_{ex} = 524 nm; λ_{em} = 582 nm.

Table 1. Reciprocal induction-periods and initial rates for iron(III)–DADHADS reaction ([DADHADS] = $2 \times 10^{-5}M$, [HCl] = $0.4M$)

Fe(III), *ppm*	$1/T$, cm^{-1}	log (100 tan α)
2	0.10	0.49
5	0.14	0.96
10	0.20	1.30
15	0.27	1.57

$$2VO^{2+} + H_2O_2 \rightarrow 2VO_2^+ + 2H^+ \quad (4)$$

On the other hand, studies on the nature of the reaction product reveal it is a diquinone type compound, which according to previous studies[7] results from the hydrolysis of the corresponding imine compound. Consequently, in going from the amino-hydroxy compound to the imino-quinone compound two electrons are involved. During the time necessary to complete the induction period, formation of the amino-quinone compound takes place, the accelerated step being characterized by formation of the imine-quinone and subsequent hydrolysis.

In order to understand the action of Fe(III) on the V(V)-catalysed oxidation, the kinetic curves in presence of 0.1 ppm V(V) and various concentrations of Fe(III) were recorded (Fig. 2). As shown, when both iron and vanadium are present in the reaction medium, the rate of oxidation increases, *i.e.*, the consumption of the reagent is speeded up. This could occur through a reaction sequence such as that represented by equations (5)–(8):

$$RH_2 + VO_2^+ + H^+ \rightarrow RH + VO^{2+} + H_2O \quad (5)$$

$$2VO^{2+} + H_2O_2 \rightarrow 2VO_2^+ + 2H^+ \quad (6)$$

$$RH_2 + Fe^{3+} \rightarrow RH + Fe^{2+} + H^+ \quad (7)$$

$$2Fe^{2+} + H_2O_2 + 2H^+ \rightarrow 2Fe^{3+} + H_2O \quad (8)$$

If the assumption is made that equation (7) is slower than equation (5), then the following reaction could occur

$$VO_2^+ + Fe^{2+} + 2H^+ \rightarrow VO^{2+} + Fe^{3+} + H_2O \quad (9)$$

with a decrease in the rate of the accelerated step

$$VO_2^+ + RH + H^+ \rightarrow R + VO^{2+} + H_2O \quad (10)$$

$$Fe^{3+} + RH \rightarrow R + Fe^{2+} + H^+ \quad (11)$$

This is manifested in Fig. 2 by the rate values being lower than those obtained by adding the velocities of the reactions catalysed by V(V) and Fe(III) considered individually, the difference increasing with the concentration of iron. However, the primary step would occur more extensively (activation) if both vanadium and iron were present in the medium, with the nett result of decreasing the length of the induction period.

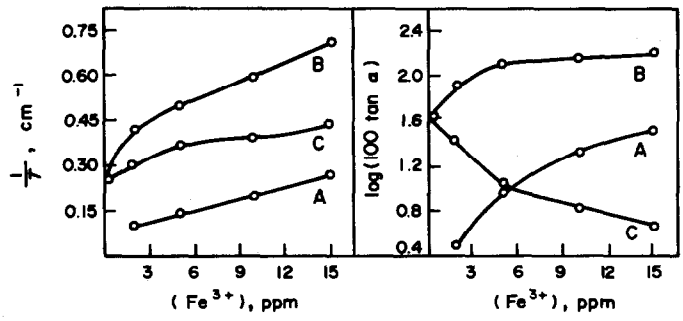

Fig. 2. Induction period and initial rate *vs.* iron concentration. A, [V(V)] = 0; B, [V(V)] = 0.1 ppm; C, difference (B-A): [DADHADS] = $2 \times 10^{-5}M$; [HCl] = $0.4M$: λ_{ex} = 524 nm: λ_{em} = 582 nm.

Studies on the variables affecting the fluorescence development

The characteristics of the fluorescence excitation and emission spectra and the procedure for optimization of the acidity ($0.4M$ HCl) and reagent concentration ($2 \times 10^{-5}M$) have been described in a previous paper.[7]

The Fe(III) concentration was optimized by recording the fluorescence–time curves at different Fe(III) concentrations, in the presence and absence of V(V). Plots of the the initial rate and reciprocal of the induction period *vs.* concentration of Fe(III) provide the optimum values of this variable.

Figure 2 shows the effect of Fe(III) concentration on the reaction rate. For a fixed concentration of V(V), a diminution in the Fe(III) concentration increases the induction period and the time necessary for full oxidation of the reagent. For Fe(III) concentrations above 5 ppm, the initial rate is virtually constant. For concentrations lower than this, the length of the induction period cannot be evaluated accurately, since the completion of the induction period and the accelerated reaction do not occur sharply, but only gradually, according to the amount of the imine compound formed.

Thus, an Fe(III) concentration of 5 ppm has been taken as optimum, since it ensures a small blank reaction, while still making it possible to determine V(V) with adequate sensitivity.

Table 2. Reciprocal induction periods and initial rates for activated V(V)–DADHADS reaction ([DADHADS] = $2 \times 10^{-5}M$, [HCl] = $0.4M$, [Fe(III)] = 5 ppm)

V(V), *ng/ml*	1/T, cm^{-1}	log (100 tan α)
1	0.26	1.34
2	0.29	1.38
3	0.32	1.40
5	0.38	1.43
8	0.48	1.45
10	0.53	1.47

Characteristics of the kinetic methods

The fluorescence–time curves for different amounts of V(V) and constant concentration of Fe(III) have been obtained. The results are summarized in Table 2.

The data obtained after analysis of such curves by the induction period and initial rate methods are summarized in Table 3. The effect of foreign ions on the determination of V(V) by the induction period method is summarized in Table 4. It is noteworthy that the selectivity of the method in absence of Fe(III)[7] is notably improved in presence of the activators. The tolerance ratios (foreign ion:vanadium) increased for the majority of the interferent ions, except for Ce(IV) and Hg(II), for which the ratio was lower, as a result of the oxidizing character of these ions.

Table 3. Characteristics of the kinetic methods

Method	Range of applicability, *ng/ml*	Taken, *ng/ml*	Found($\bar{x}$), *ng/ml*	*n*	*S*, *ng/ml*	*W*,%	*G*,%
Induction period	1–10	5	4.86	11	0.15	3.1	2.1
Initial rate	1–10	5	4.81	11	0.32	6.6	4.6

$\bar{x}$ = mean value; *n* = number of determinations: *S* = standard deviation: *W* = coefficient of variation; *G* = mean relative error ($= 100tS/\bar{x}\sqrt{n}$, where *t* is Student's *t* for 95% confidence).

Table 4. Effect of diverse ions on the determination of 5 ng/ml V(V)

Ion added	Tolerance ratio* [ion]/[V(V)]
Cd(II), Cr(III), W(VI), Br^- Li(I), Pd(II), Mn(II), Zn(II)	4000

Hg(II), Au(III)	1
Fe(II), I^-	0.8
Ce(IV)	0.2

*For <2% relative error.

Application

The method was applied to determination of non-volatile vanadium in two crude oils. The sample was evaporated to dryness on a hot-plate and then heated for 15 min at 600–700° in a muffle furnace. The cooled residue was dissolved in a minimum of nitric acid (1 + 1) and diluted with water to volume in a 50-ml standard flask. A 1-ml aliquot was analysed by the procedure given.

The values obtained were 8.3 ± 0.4 μg/ml for oil A (atomic absorption spectrometry gave 7.1 μg/ml) and 14.2 ± 0.3 μg/ml (AAS gave 12.5 μg/ml). The values are averages of 6 replicates for the fluorescence method and 5 for the AAS.

SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM WITH 1,5-DIPHENYLCARBAZIDE

S. JAYA and T. V. RAMAKRISHNA
Department of Chemistry, Indian Institute of Technology, Madras-600036, India

(*Received* 5 *May* 1981. *Revised* 2 *December* 1981. *Accepted* 28 *December* 1981)

Summary—The formation of the bluish violet osmium–diphenylcarbazide complex in weakly acidic solution is utilized for the determination of osmium by spectrophotometry. When measurements are made at 560 nm, after extraction of the complex into isobutyl methyl ketone, Beer's law is obeyed up to 150 μg of osmium. Relatively few ions interfere, and these can be masked with EDTA and fluoride.

Spectrophotometric methods using thiourea[1] and thiocyanate[2,3] are generally employed for the determination of osmium. These procedures lack adequate sensitivity and selectivity and necessitate the separation of osmium by extraction[3] or distillation[4] before the determination.

Although many reagents[5–7] have been proposed for osmium, their sensitivities do not approach that provided by 1,5-diphenylcarbazide, the osmium complex of which ($\epsilon = 1.5 \times 10^5$ $1.mole^{-1}.cm^{-1}$)[8] was formed by heating for 5 min at 65° in a medium made 1.4*M* and 1.2*M* with respect to acetic acid and perchloric acid respectively. This determination was completed after extraction of the blue-violet diphenylcarbazide complex into chloroform. Interference from many elements was overcome, to some extent, by prior extraction of osmium tetroxide into chloroform and reaction with the diphenylcarbazide (DPCI) in the organic phase,[9] but this caused considerable diminution of the sensitivity ($\epsilon = 3.1 \times 10^4$ $1.mole^{-1}.cm^{-1}$), and the reaction took 2 hr to go to completion in the organic phase. It seemed to us, however, that further investigation of this colour reaction could yield interesting results. Detailed examination disclosed that the extraction of the complex formed in weakly acidic solution into isobutyl methyl ketone (IBMK) can form the basis of a rapid, simple and reliable method for determination of osmium. The method, though slightly less sensitive ($\epsilon = 2.7 \times 10^4$ $1.mole^{-1}.cm^{-1}$) can be rendered sufficiently selective by use of EDTA and fluoride for application to samples containing various metal ions, including noble and base metals.

EXPERIMENTAL

Reagents

Osmium solution, 10 μg/ml. Weigh an ampoule containing ~1 g of osmium tetroxide, then break it under water in a glass-stoppered bottle. Make up the solution and washings to volume in a 250-ml standard flask, collecting, drying and weighing the glass fragments. Find the amount of OsO_4 dissolved from the difference in weight. Prepare a working solution (osmium 10 μg/ml) by suitably diluting the stock solution with water.

Diphenylcarbazide solution, 1%. Dissolve 1 g of reagent in 100 ml of high-purity acetone.

Buffer solution, 0.5M. An equimolar mixture (0.5*M*) of acetic acid and sodium acetate solution, adjusted to pH 5.0.

Procedure

Place a sample solution containing not more than 150 μg of osmium in a 60-ml separatory funnel, and add 5 ml of buffer solution and 1 ml of DPCI solution. Extract with two 10-ml portions of IBMK, shaking for 1 min. Collect the organic phases in a 25-ml standard flask and make up to the mark with IBMK. Measure the absorbance in 10-mm cells at 560 nm against a reagent blank carried through the procedure. Prepare a calibration graph with 0.5–15 ml of standard 10-μg/ml osmium solution.

RESULTS AND DISCUSSION

Preliminary studies showed that the reaction proceeds smoothly in solutions buffered to pH 4.0, to give a bluish violet precipitate which can be dissolved by the addition of acetone. However, it takes at least 30 min for the absorbance to reach its maximum even in the presence of excess of reagent. It was later found that the reaction can be made to go to completion rapidly by extracting the precipitate into an organic solvent such as IBMK, chloroform, amyl acetate, isoamyl alcohol, benzene, carbon tetrachloride, cyclohexane, cyclohexanol and cyclohexanone. Though IBMK and isoamyl alcohol were found to be the most suitable, the former was preferred for further studies.

Absorption spectrum

The absorption spectrum of the osmium complex extracted into IBMK (Fig. 1) showed that the complex absorbed maximally over the range 555–570 nm. The reagent blank under similar conditions showed no absorption over the wavelength range 450–700 nm. For further studies 560 nm was chosen as the optimum wavelength.

Optimal conditions and spectral properties

Variation of the pH of the reaction medium revealed that the complex formation remained maxi-

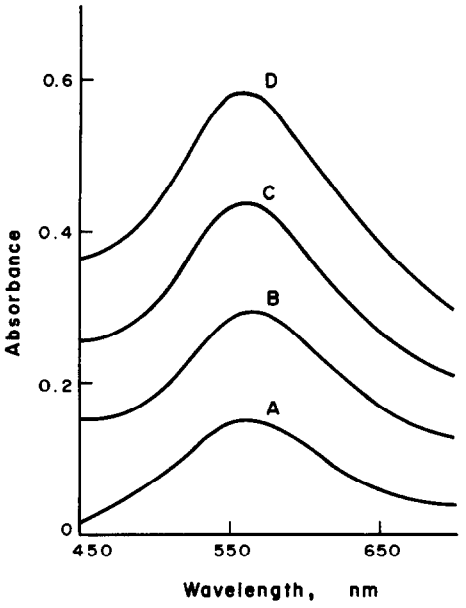

Fig. 1. Absorption spectra: (A) 25 μg of osmium (VIII) + 1 ml of 1% DPCI solution + 5 ml of pH-5 buffer, extracted with 2 × 10 ml of IBMK and extract made up to 25 ml; (B, C and D) as in (A) but with 50, 75 and 100 μg of osmium(VIII).

mal and constant over the pH range 4.0–6.0 (Fig. 2). Though the addition of 8 mg of DPCI to solutions containing 25 μg of osmium and buffered to pH 5.0 in a final volume of 25 ml was found to be sufficient, amounts up to 20 mg did not affect the absorbance. It was found that the use of an IBMK solution of DPCI was ineffective, and that equilibration for 1 min was sufficient for maximum extraction of osmium. An aqueous to organic phase volume-ratio of up to 3:1 did not affect the absorbance.

Under optimum conditions, Beer's law was obeyed over the range 5-150 μg of osmium and an apparent molar absorptivity of 2.7×10^4 l.mole^{-1}.cm^{-1} was obtained.

Ten replicate analyses of standard solutions each containing 25 μg of osmium gave an average recovery of 100.5% with a relative standard deviation of 1.2%.

The composition of the complex was established as 1:1 Os:DPCI by the continuous-variation, mole-ratio and equilibrium-shift methods.

Interference studies

The effect of mg amounts of several ions on the determination of 10 μg of osmium was studied. No interference was noticed in the presence of NO_3^-, NO_2^-, Br^-, SCN^-, SO_3^{2-}, AsO_3^{3-}, AsO_4^{3-}, Li^+, Mg^{2+}, Ca^{2+}, Ba^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+}, Al^{3+}, Tl^+, Pb^{2+}, Sb^{3+}, Bi^{3+}, Ce^{4+}, UO_2^{2+}, Se^{4+}, Cr^{3+}, Mn^{2+}, Fe^{2+}, Rh^{3+}, Ni^{2+}, Pt^{4+}, MoO_4^{2-} and WO_4^{2-}. The presence of Fe^{3+}, Ru^{3+}, VO_4^{3-}, CrO_4^{2-}, Pd^{2+}, Cu^{2+} and Co^{2+} gave high recoveries while Ir^{4+}, Zr^{4+}, Ti^{4+}, La^{3+} and Be^{2+} caused low recoveries.

The interference due to Fe^{3+}, Zr^{4+}, Ti^{4+}, Be^{2+} and Ir^{4+} (500 μg) was overcome by the addition of 1 ml of 2% sodium fluoride solution, and the addition of 1.5 ml of 0.1*M* EDTA eliminated the interference due to La^{3+}, Co^{2+}, Cu^{2+}, Pd^{2+}, VO_4^{3-} and Ru^{3+} (250 μg). Addition of 1 ml of saturated sodium chloride or sodium sulphate solution had no effect on the recovery of osmium.

Difficulties were encountered with acidic sample solutions which required adjustment of pH to the desired range, if this was done before the addition of DPCI, the results being low by 7, 20 and 37% for solutions which had stood for 5, 10 and 15 min respectively. No such effect occurred, however, when the pH adjustments were made in the presence of DPCI, even for samples that stood for 30 min before the extraction.

As the masking agents were found to be ineffective for destroying the interfering metal–DPCI complexes after the extraction with IBMK, care must be exercised to mix the solution thoroughly before the extraction.

Recovery studies

Table 1 furnishes the results for recovery of osmium from synthetic mixtures to which EDTA and fluoride were added before the DPCI. The data clearly show that the method works satisfactorily in the presence of noble and base metals. As no standard samples were available for testing the validity of the method for the analysis of real samples, the method was applied to synthetic mixtures corresponding to osmiridium (syserkite) and iridio-osmium (nevjanskite) samples. Appropriate metal solutions were mixed in the ratios given by Mellor[10] then treated with 1 ml of 5% hydrazine sulphate solution and heated gently almost to dryness. The residue was mixed with 3 g of an 8:1 mixture of potassium hydroxide and nitrate and heated at 800°C for 30 min.[11] The cooled melt was leached with water, acidified with about 10 ml of concentrated hydrochloric acid and made up to volume in a 100-ml standard flask. Aliquots of the solution

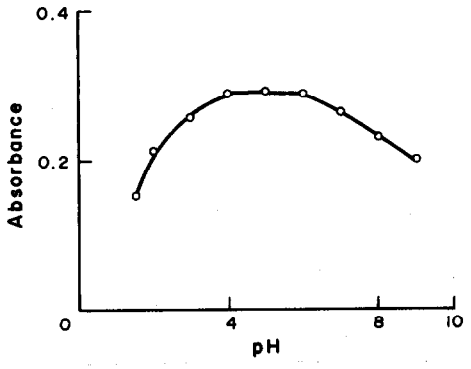

Fig. 2. Effect of pH: 50 μg of osmium(VIII) + 1 ml of 1% DPCI, adjusted to different pH values, extracted with 2 × 10 ml of IBMK and extract made up to 25 ml; measured at 560 nm against solvent in 10-mm cells.

were analysed by the described procedure, with fluoride and EDTA added to overcome interference. The results in Table 2 show that the recoveries are satisfactory. The method would therefore be of value in the rapid analysis of osmium-containing samples, as it does not require a prior separation of osmium by distillation.

DETERMINATION OF MOLYBDENUM BY EXTRACTION OF ITS THIOCYANATE INTO ETHYL METHYL KETONE

USHA MADAN and L. R. KAKKAR*
Chemistry Department, Kurukshetra University, Kurukshetra 132119, Haryana, India

(*Received* 1 *April* 1981. *Revised* 11 *August* 1981. *Accepted* 29 *January* 1982)

Summary—A simple, sensitive and selective spectrophotometric method for determination of molybdenum is described. A solution containing 100 μg of Mo in 2.5*M* hydrochloric acid is treated with ascorbic acid and ammonium thiocyanate and after standing for 8 min is shaken with an equal volume of ethyl methyl ketone for 30 sec. The absorbance of the complex is measured at 465 nm against a reagent blank. The complex is stable for 1 hour. There is no interference from Re(VII), SO_4^{2-}, Cl^-, CH_3COO^-, PO_4^{3-}, NO_3^-, $C_2O_4^{2-}$, citrate or tartrate, and at least 5 mg of U(VI), 10 mg of Cr(III, VI), Th, or Ni, and 20 mg of W(VI) can be tolerated. Vanadium(V) interferes at the 500 μg level, and fluoride slightly decreases the absorbance.

Stannous chloride[1–6] is often used to reduce molybdenum for formation of the Mo(V) thiocyanate complex, but the molybdenum may be further reduced, which lowers the sensitivity of the method. Other elements, *e.g.*, rhenium, vanadium, tungsten, uranium, chromium, which in their lower oxidation states form thiocyanate complexes are also reduced and interfere in the determination of molybdenum. Hence, a milder reductant which reduces molybdenum quantitatively to Mo(V) is desirable, and ascorbic acid has been recommended.[7,8] We have found that use of this reagent, coupled with extraction into ethyl methyl ketone, makes the method highly sensitive.

EXPERIMENTAL

Materials

A stock solution of molybdenum was prepared from sodium molybdate dihydrate, standardized gravimetrically by the oxine method,[9] and diluted to give a working solution with molybdenum concentration about 10 μg/ml. Solutions of other metal ions (mg/ml level) were made from commonly available salts.

Ethyl methyl ketone was distilled and the fraction distilling at 79–80° collected for use.

Procedure

Place the sample solution, containing about 100 μg of molybdenum, in a 100-ml separatory funnel, add 5 ml of concentrated hydrochloric acid, 2 ml of 10% ascorbic acid solution and 2 ml of 20% ammonium thiocyanate solution, dilute to 20 ml with distilled water, mix and let stand for 7–10 min. Then shake with 20 ml of ethyl methyl ketone for 30 sec. Transfer the organic phase to a 25-ml standard flask and make up to the mark with the pure solvent. Measure the absorbance at 465 nm against a similarly prepared reagent blank.

If the sample solution also contains iron(III) and/or copper(II), strip these from the extract by shaking it with 20 ml of 2% stannous chloride solution (in dilute hydrochloric acid). If ruthenium(III) is present, strip it similarly with 2% thiourea solution.

RESULTS AND DISCUSSION

In acid solution, molybdenum forms an orange complex with thiocyanate in presence of ascorbic acid; the complex is quantitatively extractable into ethyl methyl ketone, giving a golden yellow colour. The absorbance is a function of various parameters.

For 20 ml of solution containing 100 μg of Mo, 3 ml of 10% ascorbic acid solution and 2 ml of 20% ammonium thiocyanate solution, the absorbance varies with acidity, and is maximal and constant over the hydrochloric acid concentration range 2.25–3.5*M*.

The absorbance also depends on the ascorbic acid concentration, and for 2.5*M* hydrochloric acid medium (20 ml) containing 2 ml of 20% ammonium thiocyanate solution, the absorbance is maximal and constant if 1.5–5.0 ml of 10% ascorbic acid solution are present and a 7–10 min colour development time is allowed.

The absorbance is similarly dependent on the ammonium thiocyanate concentration and is constant and maximal if 1.8–4.0 ml of 20% thiocyanate solution are present per 20 ml of aqueous phase.

Isoamyl alcohol, isobutyl methyl ketone, isoamyl acetate, or 1% tribenzylamine solution in chloroform can also be used for the extraction but give an absorbance only about 90% of that obtained with ethyl methyl ketone. Chloroform itself does not extract the complex. The extraction is complete if the shaking time is at least 30 sec.

The conditions given in the procedure are based on these data and are selected as giving wide tolerances.

The absorbance at 465 nm remains constant for an hour, and the molar absorptivity is 8.03×10^3

Table 1. Comparison of the proposed method with the existing thiocyanate methods

Method		Sandell sensitivity, $\mu g/cm^2$	Ref.
Aqueous phase	Organic phase		
Mo(VI), 3*M* HCl, SCN^-, I^-, SO_3^{2-}	—	0.031	13
Mo(VI), 1*M* HCl, Fe^{2+}, SCN^-, Sn^{2+}	isoamyl alcohol	0.018	1
Mo(VI), 2*M* HCl, $N_2H_4.H_2SO_4$, SCN^-	tribenzylamine–chloroform	0.016	14
Mo(VI), HCl–H_2SO_4, tartaric acid, Fe^{3+}, Cu^{2+}, SCN^-, Sn^{2+}	isobutyl methyl ketone	0.015	2
Mo(VI), HCl, SCN^-, ascorbic acid, Cu^{2+}	tributyl phosphate–chloroform	0.015	15
Mo(VI), HCl, ascorbic acid, SCN^- (proposed method)	ethyl methyl ketone	0.012	

$l.mole^{-1}.cm^{-1}$. Beer's law is obeyed up to a molybdenum concentration of 6 μg/ml in the extract.

The continuous-variation[10,11] and mole-ratio[12] methods show that the ratio of Mo(V) to thiocyanate in the complex is 1:3.

Interferences

At the aqueous-phase concentrations (mg/ml) shown in brackets, sulphate (50), chloride (25), nitrate (25), acetate (25), tartrate (5), citrate (5), phosphate (10), oxalate (2.5), W(VI) (0.1), Cr(III, VI) (0.5), U(VI) (0.25), V(V) (0.025), Th (0.5), Ni (0.5) have no effect, but fluoride slightly decreases the absorbance. The interference due to Fe(III) (0.05) and Cu(II) (0.1) is eliminated by washing the organic extract with 2% stannous chloride solution, and Ru(III) is similarly removed with 2% thiourea solution. Re(VII) does not interfere.

Conclusion

The method compares favourably with existing thiocyanate methods for determination of molybdenum (Table 1). The complex formed is sufficiently stable and the results are reproducible. It is a sensitive and selective method. The validity of the method has been tested by the analysis of several synthetic samples, some having compositions representative of different molybdenum alloys (Table 2), and of some steels.

Table 2. Analysis of samples by the proposed method

Sample*	Composition of sample		Mo found, μg
	Other elements†	Mo, μg	
I	V(0.5)	40	41

A SERIAL ASCII KEYBOARD–PRINTER

D. F. MARINO and J. D. INGLE, JR.
Department of Chemistry, Oregon State University, Corvallis, OR 97331, U.S.A.

(*Received* 26 *October* 1981. *Accepted* 13 *January* 1982)

Summary—The construction of a simple keyboard–printer is described. It is intended for use with single-board microcomputers such as the KIM and SYM which have a 20-mA loop ASCII interface.

It is now common to interface microcomputers with many types of instruments. Many inexpensive 8-bit single-board microcomputers (SBC) can be purchased for less than $300. Most SBCs do not have a printer, video display, or full alphanumeric keyboard but usually provide ASCII serial interface hardware and software. The hexadecimal keyboard and display on many SBCs is adequate only for entry and display of machine language codes. To use assembler–editors or higher level languages such as BASIC, a full ASCII keyboard and display unit is required for initial programming and for interaction of the operator with the experiment. However, if many SBCs are used as stand-alone units with various instruments in a laboratory, as in ours, the cost of purchasing a separate commercial teletype or CRT terminal plus printer combination for each SBC becomes prohibitive. These commercial units are 2–10 times the cost of the SBC.

This paper is concerned with the construction of a keyboard–printer which costs about $300 in parts. It is constructed with commercially available sub-units and requires the construction of only one small interface board. A printer was chosen for the display unit instead of a video display, because it is less expensive and because hardcopy is desired in most experiments. The keyboard–printer was constructed specifically for the KIM (MOS Technology, Norristown, PA) and SYM (Synertek Systems Corp., Santa Clara, CA) SBCs used in our laboratory, but it can be used with any SBC with a standard ASCII serial interface. The keyboard–printer has no local copy capability, however, and the printer responds only to characters from the keyboard that are echoed by the serial interface of the SBC or to characters generated directly by the SBC.

The keyboard–printer was constructed with a commercially available keyboard and electrostatic printer [George Risk (George Risk Industries, Kimball, NE) model 753 ASCII encoded keyboard kit ($50), Panasonic (Panasonic Company, Secaucus, NJ) model EUY10E011L line printer ($85) and a Panasonic model EUYPUD7001L parallel ASCII decoder/printer driver board ($115)]. The printer uses 60-mm wide electrostatic paper, and either 16 or 32 characters per line may be selected (other models provide longer line length). The printing speed is two lines/sec and the decoder board has a one-line memory buffer.

Both the commercial keyboard and printer are designed to work with parallel TTL level ASCII data. The KIM TTY (teletype) line, however, delivers 20-mA current-loop serial ASCII. The UART (universal asynchronous receiver and transmitter) board shown in Fig. 1 was constructed to transform the parallel ASCII from the keyboard into serial ASCII, and the serial ASCII from the KIM into parallel ASCII for the printer.

The UART circuit (Fig. 1) operates as follows. When a key is struck on the keyboard, it triggers IC2 to deliver a 15-μsec logic 0 pulse to pin 23 of IC1, after which, on the positive edge the 7-bit parallel ASCII character is strobed into IC1. The 555 timer (IC3) then shifts these character data out of IC1 at pin 25, along with the two stop bits provided by the UART at 1.7 kHz (106 baud). IC8, T2, and T3 then transform these TTL level data with optical isolation into 20-mA current-loop data for the KIM TTY interface.

Serial ASCII from the KIM TTY interface enters IC9 and T4 in 20-mA current-loop form and is translated into TTL level serial ASCII. It then enters pin 20 of IC1 and is shifted into the second half of IC1 at 1.7 kHz. When the 7 bits of the ASCII character are received, IC1 (pin 19)—through T1—delivers a logic 0 level STROBE signal to the printer interface. The interface senses the STROBE level, latches the ASCII character data into a buffer, and sends out a logic 0 acknowledge (ACK) pulse which resets the STROBE level. The UART will continue to process further ASCII characters even if an ACK pulse is not received, in which case the STROBE line remains low. During the print cycle, ACK pulses are not generated and the ASCII character data from IC1 are not accepted by the printer interface.

In some cases, pins 6–12 of IC1 could be directly connected to the ASCII parallel port of a printer interface. However, the particular printer interface board chosen uses 8-bit negative true parallel ASCII logic and translates ASCII codes with the MSD (most significant digit or HEX representation of ASCII bits

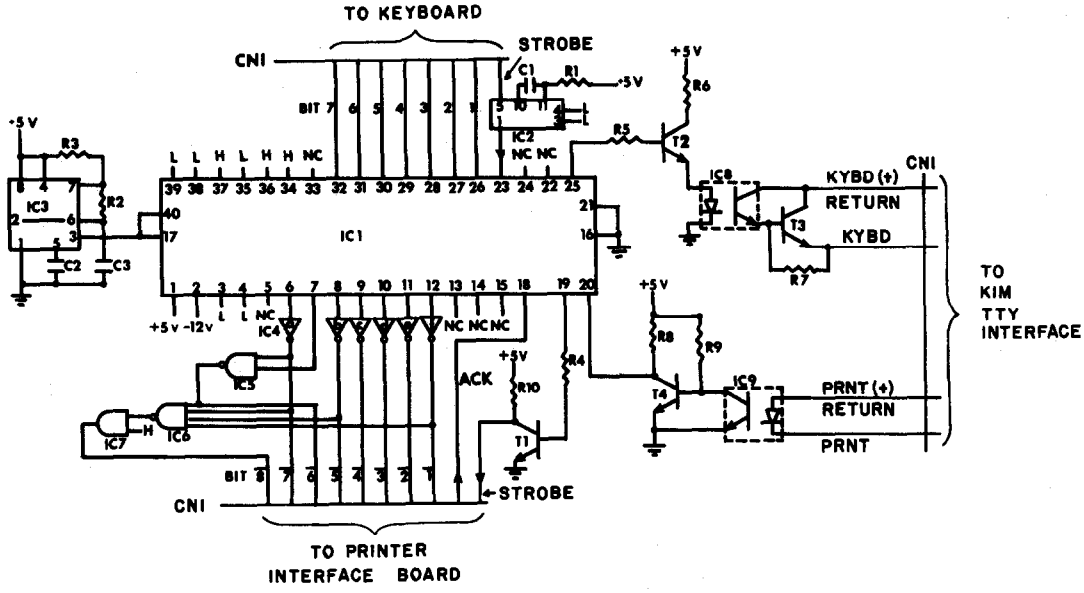

Fig. 1. UART keyboard/printer interface. IC1, AY5013A UART; IC2, 74121 one-shot; IC3, 555 timer; IC4, 7404 hex inverter; IC5, IC7, 7400 NAND gate (2 gates for IC7); IC6, 7420 NAND gate; IC8, IC9, TI111 opto isolator; T1–T4, 2N3904; R1, 2.2 kΩ; R2, 39 kΩ; R3, 27 kΩ; R4, R5, R8, 10 kΩ; R6, 220 Ω; R7, 100 Ω; R9, 270 kΩ; C1, 0.01 μF ceramic; C2, 0.02 μF ceramic; C3, 0.01 μF tantalum; CN1, 30-pin edge-connector on UART interface board.

5–8) equal to 0 as a CR–LF and with the MSF equal to 1, 6–9, E, and F, into a SPACE. Thus upper-case letters, numbers, and symbols are unaffected (the MSD equals 2–5). However, lower-case letters (bits 6 and 7 high or MSD = 6 or 7) and control characters (bits 6 and 7 low or MSD = 0 or 1) with bit 5 high are printed as a SPACE and with bit 5 low are translated as a CR–LF (PRINT).

Therefore IC4 inverts the ASCII data bits from the UART for logic compatibility, while IC5, IC6 and IC7 act as decoding circuitry to transform certain ASCII control codes into spaces (NULL and LF in particular), and all ASCII letters into upper case. This decoding logic works in the following manner (an ASCII code chart is helpful in understanding the following).

The lower case letter problem is solved by "NANDing" ASCII bits 6 and $\overline{7}$. If ASCII bit 7 is high, the character just received by the UART is a letter, and the output of IC4a is low, forcing the output of IC5 high regardless of the status of ASCII bit 6. Hence, ASCII bit $\overline{6}$ (output of IC5) which goes to the printer interface is high, and ASCII bit 6 is translated by the printer as being low even if it is high, so a lower-case letter (ASCII bits 7 and 6 high) will be printed as an upper-case letter (ASCII bits 7 and 6, high and low respectively).

The control characters are decoded by "NANDing" bits $\overline{7}$, $\overline{6}$, $\overline{5}$ and $\overline{1}$ so that a CR–LF or PRINT occurs only once at the end of a line rather than after certain control characters which the KIM transmits after a line. If a control code with bit 5 low is transmitted to the UART, bits 5, 6 and 7 will be low, forcing three inputs of IC6 high. If ASCII bit 1 is high, the fourth input of IC6 will be low, causing its output to be high, and bit $\overline{8}$ to the printer will remain high, resulting in a CR–LF. This is the case for all odd ASCII control codes (such as CR). Any control code with bit 5 low reaching the UART with bit 1 low, however, causes the output of IC6 to go low, causing bit $\overline{8}$ to the printer to go low, and resulting in a SPACE being printed. ASCII control codes with bit 1 low include NULL and LF. Control characters with bit 5 high will also cause a SPACE to be printed although none of these is transmitted by the KIM. Thus the decoding prevents certain control characters from causing a CR–LF when not desired.

The KIM transmits each line of data as DATA, CR, LF and then outputs six NULLs. A CR will cause the printer to print the data line in the buffer. The LF and six NULLs (translated into seven SPACES by the UART), which are also transmitted, will not be accepted by the printer while the printer is printing. Inclusion of seven spaces (translated LF and NULLs) in this KIM data transmission allows the printer enough time to finish printing before any real data from the next line arrive, privided that the transmission rate is $\leqslant 110$ baud, preventing the loss of some of these data.

The UART interface board, along with the keyboard, the Panasonic printer interface unit, and a line printer were encased in an aluminium box along with a dedicated power supply delivering +5 V at 800 mA, −12 V at 400 mA, and −24 V at 1.5 A (circuit diagram available from the authors). Both +5 V and −12 V are used by the keyboard, UART board, and printer interface board, and the printer interface board also requires −24 V.

Although this keyboard–printer was designed for use with a KIM, it can be used with other microcomputers, in some cases with modification. Other keyboard–printer units have been interfaced to SYMs by using the SYM 110-baud TTY lines. The KIM synchronizes to any baud rate while the SYM TTY interface is constructed to accept only exactly 110 baud. For keyboard–printer units interfaced to SYMs, R2 in Fig. 1 was replaced by a 10-turn 50 kΩ pot to allow fine tuning of the frequency or IC3 was replaced by a baud-rate generator (MC14411) and a 1.8432-MHz crystal. The circuitry connected to pins 25 and 20 of IC1 in Fig. 1 can be replaced by standard circuitry for TTL to RS232 interconversion for microcomputers that use RS232.

The UART board has been used with other printers and keyboards. Keyboard–printer units have been constructed with capacitive touch-switch keyboards, including ones made by Tasa (Santa Clara, CA) and RCA (model VP-601) (Lancaster, PA) which are similar in cost to the George Risk keyboard. More expensive printers such as the Axiom EX801 (Glendale, CA) have been used in place of the Panasonic printer and interface card. For this particular unit, IC4-IC7 and T1 in Fig. 1 are eliminated and direct connection is made to IC1.

SPECTROPHOTOMETRIC DETERMINATION OF URANIUM(VI) WITH 2-(3,5-DIBROMO-2-PYRIDYLAZO)-5-DIETHYLAMINOPHENOL IN THE PRESENCE OF ANIONIC SURFACTANT

SHUI-CHIEH HUNG, CHANG-LING QU and SHUI-SHENG WU
Institute of Environmental Chemistry, Academia Sinica, P.O. Box 934, Peking, China

(*Received* 16 *September* 1981. *Accepted* 26 *December* 1981)

Summary—A highly sensitive method for spectrophotometric determination of uranium has been devised. The method is based on formation of a red-violet 1:2 (metal:ligand) complex from the reaction of uranium(VI) with 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol (3,5-diBr-PADAP) in the presence of an anionic surfactant, sodium lauryl sulphate. Its molar absorptivity is found to be 9.1×10^4 l.mole^{-1}.cm^{-1}. The absorbance is constant in the range pH 8.4–9.9 Beer's law is obeyed for 0–1.4 μg/ml concentrations of uranium. In the presence of DCTA the method is selective for uranium, and can be used for the determination of trace amounts of uranium in water samples.

Florence and co-workers described the use of 2-(2-pyridylazo)-5-diethylaminophenol (PADAP)[1] and 2-(5-bromo-2-pyridylazo)-5-diethylaminophenol (Br-PADAP)[2] for the spectrophotometric determination of uranium(VI) and reported the practical molar absorptivities to be 6.59×10^4 and 7.4×10^4 l.mole^{-1}.cm^{-1} respectively. However, as these methods require the presence of 45% of ethanol or acetone in the final solution, routine analysis for uranium would require a lot of ethanol or acetone.

We have studied the spectrophotometric characteristics of the complexes formed by some metal ions with the dibromo derivative of PADAP, 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol (3,5-diBr-PADAP), in the presence of an anionic surfactant, sodium lauryl sulphate (SLS), and devised a method for spectrophotometric determination of trace silver[3] based on this reaction. We have now extended this approach and worked out a sensitive spectrophotometric method for uranium. The practical molar absorptivity is 9.1×10^4 l.mole^{-1}.cm^{-1} at pH 9.3 and 576 nm, making the reaction one of the most sensitive known for uranium(VI). Furthermore, the method needs no ethanol or acetone. If DCTA is used as masking agent the colour reaction is highly selective for uranium(VI). The method has been applied to the direct determination of uranium in several water samples.

EXPERIMENTAL

Reagents

Standard uranium solution, 1.00 × 10^{-3}M. Dilute the solution as required, before use.

3,5-DiBr-PADAP solution in ethanol, 5.00 × 10^{-4}M. Dissolve 0.020 g of 3,5-diBr-PADAP, synthesized by the procedure described previously,[3] in 100 ml of ethanol.

SLS solution, 4.0 × 10^{-2}M. Dissolve 5.76 g of sodium lauryl sulphate (C.P.) in 500 ml of warm water.

DCTA solution, 0.1M. Suspend 8.65 g of 1,2-diaminocyclohexane-*N*,*N*'-tetra-acetic acid in about 200 ml of water, neutralize to pH 8.5 with sodium hydroxide, then dilute to 250 ml with water.

Buffer solution, pH 9.0. Adjust 0.1*M* sodium borate to pH 9.0 with hydrochloric acid.

Unless otherwise stated, all reagents used were of analytical-reagent grade, and demineralized water was used throughout the investigation.

Recommended procedure

Place an accurately measured volume (not more than 18 ml) of nearly neutral sample solution, containing less than 35 μg of uranium, in a 25-ml standard flask. If a larger sample volume is desired, it should be evaporated to about 10 ml and then transferred to the flask. If the sample is strongly acidic, take an equal volume and determine the volume of 1*M* sodium hydroxide required for its neutralization. Add, in the following order and with mixing between additions, 1.25 ml of DCTA solution, 2.0 ml of pH-9.0 buffer, the volume of 1*M* sodium hydroxide required for neutralization, 2.0 ml of SLS solution and 1.25 ml of 3,5-diBr-PADAP solution. Dilute to volume with water and mix. Unstopper the flask and place it in a water-bath at 70–80° for 2 min. Cool the flask in running water for 1.5 min, let it stand at room temperature for about 5 min, then measure the absorbance at 576 nm against a reagent blank, in a cell of suitable path-length.

RESULTS AND DISCUSSION

Absorption spectra

In the presence of SLS, 3,5-diBr-PADAP dissolves in water quite well, and exhibits an absorption maximum at 462 nm. Its uranyl complex is red-violet in colour and exhibits two absorption peaks, at 570 and 600 nm. With excess of 3,5-diBr-PADAP present, the optimum wavelength for measurement is 576 nm. The absorption spectra for the reagent and its uranyl complex are shown in Fig. 1. Figure 2 shows that the absorbance is practically constant when the colour is developed over the pH range 8.4–9.9.

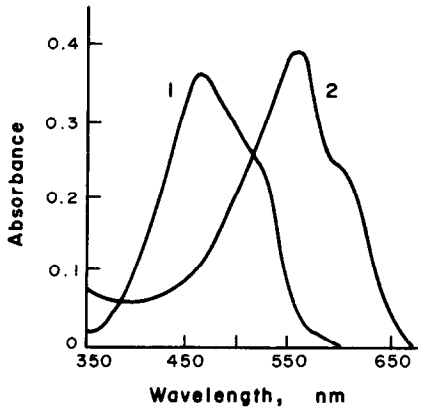

Fig. 1. Absorption spectra: (1) 3,5-diBr-PADAP ($1.00 \times 10^{-5}M$)–SLS ($4.0 \times 10^{-3}M$); (2) 3,5-diBr-PADAP ($1.00 \times 10^{-5}M$)–SLS ($4.0 \times 10^{-3}M$)–U(VI) ($5.00 \times 10^{-6}M$), pH 9.3; measured in 1-cm cells against water.

Effect of reagent concentration

For ~35 μg of uranium(VI) in 25 ml of solution, the optimum reagent concentrations of the final solution were found experimentally to be: $2.00–4.50 \times 10^{-5}M$ 3,5-diBr-PADAP, $3.5–5.0 \times 10^{-3}M$ SLS and $1.0–6.0 \times 10^{-3}M$ DCTA. Higher concentrations of DCTA decrease the absorbance of the uranyl complex.

The effect of ethanol on the absorbance was also tested. The absorbance gradually decreases with increasing amount of ethanol, and there should not be more than 10% v/v of ethanol in the final solution, a difference from the methods of using PADAP and Br-PADAP described by Florence *et al.*[1,2]

Effect of time and temperature for colour development

Uranium(VI) appears to react sluggishly at room temperature with 3,5-diBr-PADAP in the presence of SLS and DCTA, and the maximal absorbance is not reached even on standing for 45 min, but heating in a water bath at 70–80° for 1.5–2 min give complete colour development. The absorbance at 576 nm then remains constant for at least 48 hr.

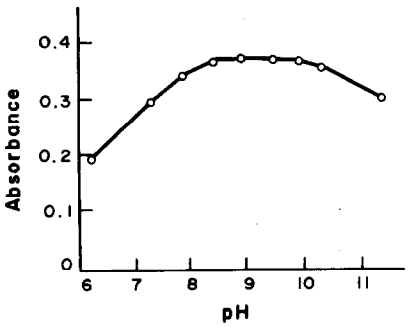

Fig. 2. Effect of pH. The composition of each solution was $4.20 \times 10^{-6}M$ U(VI), $5.0 \times 10^{-3}M$ DCTA, $4.0 \times 10^{-3}M$ SLS, $2.5 \times 10^{-5}M$ 3,5-diBr-PADAP. Measured at 576 nm, in 1-cm cells, against reagent blank.

Adherence to Beer's law

The calibration graph prepared according to the recommended procedure is linear and passes through the origin, the colour system obeying Beer's law for uranium concentrations up to 1.4 μg/ml. The practical molar absorptivity is 9.1×10^4 $l.mole^{-1}.cm^{-1}$ at 576 nm.

Composition of complex

The nature of the complex was investigated by the continuous variation and molar ratio methods, with a fixed concentration of SLS, and the molar ratio of uranium(VI) to 3,5-diBr-PADAP in the complex was found to be 1:2.

Comparison of solubilizing agents

The colour reaction of uranium(VI) with 3,5-diBr-PADAP in the presence of different solubilizing agents, namely ethanol, tetradecyldimethylbenzylammonium chloride (Zeph), cetylpyridinium bromide (CPB), polyoxyethylene sorbitan mono-oleate (Tween 80) and SLS, was examined (Table 1). It can be seen that SLS gives the highest sensitivity.

Effect of diverse ions

The selectivity of the method was investigated by the determination of 25 μg of uranium in the presence of various ions, examined individually. An ion was considered not to interfere if it caused a change of less than 2% in the absorbance obtained for uranium alone. The amounts found to be tolerable were as follows: 5 mg of zinc, 2.5 mg each of aluminium, barium, cadmium, calcium, chromium(VI), copper(II), iron(III), lead, magnesium, manganese(II), mercury(II), nickel, tungsten(VI) and yttrium, 0.75 mg each of bismuth, cobalt(II), niobium, thorium and zirconium, 0.5 mg each of arsenate, carbonate, chromium(III) and phosphate, 0.025 mg each of silver (pH adjusted with nitric acid instead of hydrochloric) and vanadium(V). The tolerance levels for many of the metal ions can be increased by adding more DCTA as masking agent, but the concentration of the excess of DCTA must not exceed 0.006*M* in the final solution, or it will cause low results for uranium.

This was tested with 25 mg of calcium chloride or magnesium sulphate, as follows. After addition of the

3,5-diBr-PADAP to the test solution according to the recommended procedure, 0.1*M* DCTA was added dropwise until the colour of the solution changed from red to orange yellow, then one or two drops in excess. This proved satisfactory, but for larger amounts of the two salts the sensitivity of the colour reaction for uranium was decreased.

The effect of high concentrations of sodium chloride and sulphate was also investigated, and the results showed that less than 30 mg of the chloride or 25 mg of the sulphate caused no interference, but larger amounts decreased the absorbance of the uranium complex (*e.g.*, by about 10% with 125 mg of the sulphate and about 25% with 1.25 g). However, the absorbance of the complex still obeyed Beer's law.

Bromide and iodide were also found to be well tolerated, but only the 2.5-mg level was tested.

Determination of uranium in water samples

The uranium contents in a reservoir water, a waste-water from a copper refinery and water from a well containing copper uranite ore were examined by the recommended method and with addition of standard uranium(VI) solution. The recovery of uranium was 95–100% (Table 2). Nine analyses of the well water gave an average uranium concentration of 0.238 mg/l., with a relative standard deviation of 3.8%.

ANALYTICAL DATA

EFFECT OF INTERACTION OF THENOYLTRIFLUOROACETONE WITH NEUTRAL OXO-DONORS IN THE SYNERGISTIC EXTRACTION OF TERVALENT ACTINIDES

J. N. MATHUR and P. K. KHOPKAR
Radiochemistry Division, Bhabha Atomic Research Centre, Bombay-400 085, India

(*Received* 6 *October* 1981. *Revised* 24 *November* 1981. *Accepted* 16 *January* 1982)

Summary—The interaction of HTTA with TBP, DOSO, DBBP and TOPO in xylene has been studied by a spectrophotometric method. The complex species formed is HTTA.S (where S is a neutral donor) and the equilibrium constants for the formation of the species follow the order TOPO > DBBP > DOSO > TBP. After application of a correction for the HTTA–S interaction, the free HTTA and S concentrations in the organic phase were calculated. Plots of log *D* *vs.* log [HTTA] for the tervalent actinides Am, Cm, Bk and Cf gave straight lines with a slope of 3 only after application of the interaction correction; otherwise curves with slopes varying from 3 to 2 were found. The equilibrium constants of the organic phase synergistic reactions of the tervalent actinides are found to be ~10% higher after application of the HTTA–S interaction correction.

The synergistic extraction of metal ions by mixtures of chelating agents (HA) and various neutral oxo-donors (S) has been much studied.[1–3] If the equilibrium constant for a synergistic extraction of a metal ion is to be determined, it must be shown that HA and S do not react with one another, unless the association constant for HA and S is already known, in which case the free concentrations of HA and S can be calculated. There are only a few reports[4–8] of the interaction of neutral donors with chelate extractant molecules. The interaction of thenoyltrifluoroacetone (HTTA) with tributyl phosphate (TBP) in benzene[4] and kerosene,[5] has been reported, but no data are available on the interaction of HTTA with dioctyl sulphoxide (DOSO), dibutylbutyl phosphonate (DBBP) or trioctylphosphine oxide (TOPO) in the organic phase. The present study concerns the interaction of HTTA with TBP, DOSO, DBBP and TOPO in xylene. The equilibrium constants for organic-phase reactions have been calculated. Irving and Edgington[9] considered that the variable slope they found for the plot of log *D* *vs.* log [HTTA] in the system Th(IV)–HTTA–TBP was caused by interaction of HTTA with TBP, but they did not attempt to apply numerical corrections for the interaction. The importance of this interaction correction in the study of the synergistic extraction of the tervalent actinides is illustrated here for the system M(III)–HTTA–TOPO (where M is Am, Cm, Bk or Cf).

EXPERIMENTAL

Reagents

The HTTA used was Merck *pro analysi*. TBP (BDH, laboratory grade) was distilled under reduced pressure after an initial treatment with dilute sodium hydroxide solution. DOSO was kindly supplied by Dr. M. S. Subramanian of this laboratory; its purity was checked by measurement of the melting point. DBBP (K & K) was purified by distillation under reduced pressure after treatment with sodium hydroxide. TOPO (Eastman Kodak) was used as received. Xylene (BDH "AnalaR") was the solvent. The tervalent actinides Am, Cm, Bk and Cf were purified and radioassayed as described previously.[10] All other reagents used were of analytical-reagent grade.

Equilibration of neutral oxo-donors with HTTA

Organic phases (2 ml) containing mixtures of HTTA (at a fixed concentration of 0.02*M*) and varying concentrations of neutral oxo-donors (TBP, DOSO, DBBP 0.0–0.3*M* and TOPO 0.0–0.4*M*) were equilibrated with the same volume of 0.13*M* hydrochloric acid for 5 hr. After centrifugation, 1-ml aliquots of the aqueous phase were taken and diluted to 10 ml and the absorbance measured at 292 nm (Cary-14 spectrophotometer) against 0.13*M* hydrochloric acid. From the known molar absorptivity (7.88×10^3 l.mole^{-1}.cm^{-1})[11,12] at 292 nm, the aqueous-phase HTTA concentrations were determined. Free neutral oxo-donor concentrations in the organic phase were calculated from values for the distribution coefficient (*D*) for HTTA with and without neutral oxo-donors present.

HTTA variation experiments

Aliquots (1 ml) of xylene solutions of varying HTTA concentration and a fixed initial concentration of TOPO

($3.0 \times 10^{-4}M$) were equilibrated for 1 hr with an equal volume of a chloroacetate buffer (pH 2.70, $I = 0.005$) spiked with the tracers of various tervalent actinides at $30 \pm 0.1^{\circ}$. After the solutions had been left to settle for 30 min, aliquots of both phases were taken for radioassay.

Calculation of the HTTA–S interaction equilibrium constant (K)

The distribution coefficient (D) for HTTA is given by

$$D_{HTTA} = [HTTA]_{org}/[HTTA]_{aq}. \quad (1)$$

The equilibrium between HTTA and the neutral oxo-donors (S) may be written as

$$[HTTA]_{org} + n[S]_{org} \rightleftharpoons [HTTA.nS]_{org} \quad (2)$$

for which the equilibrium constant, K, is given by

$$K = [HTTA.nS]_{org}/[HTTA]_{org}[S]^{n}_{org}. \quad (3)$$

The distribution coefficient for HTTA in the presence of neutral oxo-donors may be expressed by

$$D = \frac{[HTTA]_{org} + [HTTA.nS]_{org}}{[HTTA]_{aq}}. \quad (4)$$

Substituting for $[HTTA.nS]_{org}$ from equation (3) gives

$$D = \frac{[HTTA]_{org} + K[HTTA]_{org}[S]^{n}_{org}}{[HTTA]_{aq}} \quad (5)$$

or

$$D = D_{HTTA}(1 + K[S]^{n}_{org}). \quad (6)$$

Values for the free neutral donor concentrations $[S]_{org}$ can be calculated by assuming that $n = 1$ in equation (4), as it can be easily shown that,

$$[S]_{org} = \text{Initial}\,[S]_{org} - (D - D_{HTTA})\frac{0.02}{D + 1} \quad (7)$$

where 0.02 is the initial value of $[HTTA]_{org}$ in all cases.

A graph of D *vs.* $[S]_{org}$ (equilibrium concentration of the free neutral oxo-donors) should give a straight-line plot if $n = 1$ in the systems studied. In the above treatment, hydration of HTTA, S and HTTA.S has been ignored, and it is assumed that changes in the activity coefficients over the concentrations used are not significant. As seen from Fig. 1, straight lines are observed when D is plotted *vs.* [S], so n has a value of one in all the systems studied. The equilibrium constants for HTTA–S species are evaluated from the slopes and intercepts of these straight lines.

RESULTS AND DISCUSSION

Table 1 gives values of the distribution coefficient for HTTA with various neutral oxo-donors and Fig. 1 shows the least-square straight line plots of D *vs.* equilibrium concentrations of the free neutral oxo-donors. The values of K calculated from the slopes and intercepts of these lines, along with values for equilibrium constants for some similar systems, are given in Table 2. From Fig. 1 it can be seen that the D-values for TOPO at a concentration greater than a $0.2M$ fall much below the line for the lower TOPO concentrations. This lowering of D-values at higher TOPO concentrations could result from some form of non-ideal behaviour of concentrated TOPO solutions. Cox and Davis[5] in their studies of the interaction of HTTA and TBP in kerosene suggested that a complex formed by hydrogen bonding of TBP to the keto-

* log D values normalized for [TOPO] = $2.35 \times 10^{-4} M$

Cox and Davis[5] found $n = 1$, as found in the present work for all the systems studied.

From Table 2, it may be seen that K follows the order TBP < DOSO < DBBP < TOPO, which is also the order of basicity of these neutral oxo-donors. A similar order of the equilibrium constants (TBP < TOPO) was observed by LeRoux and Fouche[6] in studies of the interaction of *N*-benzoyl-*N*-phenylhydroxylamine (HBPHA) with TBP and TOPO. In the literature, K values for HTTA–TBP in benzene (2.9)[4] and in kerosene (3.5)[5] have been reported which agree well with our value (2.6) in xylene.

From the K values (Table 2) the free concentrations of S were calculated for the extraction of tervalent actinides (*i*) at fixed TOPO and varying HTTA concentrations and (*ii*) at fixed HTTA and varying TOPO concentrations. As an example Table 3 gives values of the distribution coefficient for the M(III)–HTTA–TOPO system (M = Am, Cm) at fixed TOPO and varying HTTA concentrations before and after applying the correction for the HTTA–TOPO interaction. It can be seen from Table 3, column 4, that the corrected log D^* values (details on obtaining this value are given in Refs 13 and 14) are much higher than the experimental log D values. Also it is observed that $\Delta \log D$ (log D^* − log D) value increases

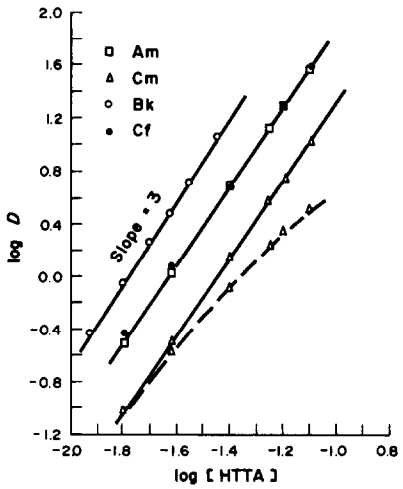

Fig. 2. Variation of the distribution coefficient of tervalent actinides as a function of HTTA concentration at a fixed TOPO concentration.

with increasing HTTA concentration at a fixed TOPO concentration. The graph (Fig. 2) of log D (for Cm) *vs.* log [HTTA] is a curve (broken lines) from which three straight lines with slopes 2.8, 2.4 and 2.0 could be drawn, but log D^* *vs.* log [HTTA] is a single straight line with a slope of 3 (continuous lines), as expected from the known composition of the species extracted, $M(TTA)_3.nTOPO$ (n = 1 and 2, M = Am, Cm, Bk and Cf). Similar straight lines with slopes equal to 3 are obtained for Am, Bk and Cf. This shows the importance of applying the correction. Most previous authors have not applied such corrections, which is obviously unsatisfactory. The equilibrium constants for the organic phase synergistic reactions for the tervalent actinides were found to increase by $\sim 10\%$ when the HTTA–S interaction correction was applied.

FORMATION CONSTANT AND STOICHIOMETRY OF THE ACETONITRILE:18-CROWN-6 COMPLEX BY NUCLEAR MAGNETIC RESONANCE, RAMAN AND INFRARED SPECTROSCOPY

HARVEY S. GOLD* and MICHAEL R. RICE
Department of Chemistry, University of Delaware, Newark, DE 19711, U.S.A.

(*Received* 10 *December* 1981. *Accepted* 10 *January* 1982)

Summary—Crown ethers are increasingly used in a variety of chemical applications. While crown ether complexes with alkali-metal cations have been extensively studied, relatively little is known about their complexes with neutral molecules to form so-called host: guest complexes. The use of NMR is reported for the determination of the formation constant (2.1 ± 0.1) for the acetonitrile:18-crown-6 complex. The suitability of Raman spectroscopy for studies of the solid-phase complex is demonstrated and limitations in the use of infrared spectroscopy are discussed.

Crown ethers are of considerable importance because of their ability to complex cations, especially alkali-metal cations, by ion–dipole interaction. This mechanism permits solvation of ionic salts in non-aqueous solvents, a phenomenon frequently utilized in phase-transfer catalytic systems. In addition, crown ethers provide good model systems for biochemical and biological membrane transport agents, such as the macrocyclic antibiotics, one of which, valinomycin, is the principal intracellular transport agent for potassium. Complete understanding of the interaction of crown ethers with traditional alkali-metal cation complexants requires that other effects be recognized and understood. We have recently reported the spectroscopically evidenced changes of dichromate, oxalate, and permanganate anions in the presence of their crown ether–cation complexes.[1] The current study probes specific effects by looking at a specific complex of 1,4,7,10,13,16-hexaoxacyclo-octadecane (18-crown-6) with acetonitrile (MeCN).

Considerable interest has been generated in recent years concerning neutral complexes comprised of crown ethers (termed the donor or host molecule) and small organic guest molecules. The driving force in these types of interaction is formation of hydrogen bonds between the *n*-donor oxygen atoms of the crown ether and the acidic hydrogen atoms of the CH or NH groups in the guest molecule.[2] This phenomenon has been termed "host–guest complexation"[3] and is germane to understanding the interactions that occur in biological systems, such as enzyme catalysis.

The complex that forms between 18-crown-6 and MeCN has been recognized since at least 1973,[4] but its formation constant has not hitherto been reported. In this paper, we report the stability constant determined by nuclear magnetic resonance techniques. Because of the inherent instability of the complex, spectroscopic investigations of its nature are difficult. Infrared, Raman, and nuclear magnetic resonance methods are considered below with respect to the 18-crown-6:acetonitrile complex.

EXPERIMENTAL

Instrumentation

The NMR studies were performed with a Bruker WM250 NMR spectrometer operating at 250 MHz for protons. Raman spectra were run on a Spex 1401 Raman spectrometer interfaced to a Nicolet 1180 data-acquisition system. A Perkin-Elmer 180 infrared spectrophotometer was used to obtain infrared spectra.

Reagents

All solvents were reagent grade and were dried over 8–12 mesh activated molecular sieves (Fisher Scientific). 18-Crown-6 (Parish) was purified as described below. 18-Crown-6/MeCN complex was obtained from Parish and was also prepared by the methods described below.

Purification of 18-crown-6

18-Crown-6 was purified by a modification of the method used by Cram *et al.*[5] It was dissolved with heating (but not boiling) in enough acetonitrile to effect solution.

The solution was allowed to cool slowly to room temperature, and was then further cooled in an acetone/ice slurry (at between -15 and $-20°$). The resulting crystals (18-crown-6/MeCN complex) were rapidly vacuum-filtered. It was essential to filter rapidly in order to prevent the crystals from sequestering atmospheric water. The crystals were then transferred to a round-bottomed flask and left under reduced pressure (about 15 mmHg) for about 6 hr. This treatment completely removed all MeCN present as solvent and in the complexed form. The purified crown ether was a fine, hygroscopic white powder, m.p. 38–40°.

Preparation of 18-crown-6/MeCN complex

The complex obtained from Parish appeared "wet". Therefore, during the course of this work two methods

* Author to whom correspondence should be addressed.

were used to synthesize the complex in order to make comparisons with the Parish product. In the first method, the Parish product was first subjected to vacuum to remove MeCN, leaving the 18-crown-6. Then the MeCN was replaced by passage of a stream of nitrogen saturated with MeCN over the 18-crown-6 for 6 hr. The product of this treatment exhibited a Raman spectrum that did not differ significantly from that of the original Parish complex, but the material did not have the "wet" appearance of the Parish complex. Formation of the complex was evidenced by the Raman spectrum and by marked increase in the melting point to 73–78°.

The second method consisted of the procedure used to purify the 18-crown-6, but stopping after collection of the complex. This procedure yielded a product which exhibited the "wet" appearance of the Parish complex. However, all three preparations of the complex gave rise to the same Raman spectral features and to identical melting point ranges.

RESULTS AND DISCUSSION

Purification of 18-crown-6

When 18-crown-6 was used as received, non-reproducible results were obtained in the stability constant studies (*vide infra*). The crown ether was therefore purified by the procedure described above, and the product was found to be highly satisfactory. The manufacturer apparently packs the crown ether in the liquid form into the glass bottle, and upon cooling a single mass is formed. When this clump is fractured, the crystals appear "wet" and exhibit a hydroxyl vibrational intensity in the 3500 cm^{-1} region of the infrared spectrum. In addition, a wide melting point range is observed: 34–38°. After purification, the crown ether is in the form of a fine white powder which exhibits negligible hydroxyl vibrational intensity and melts in the range 38–40°, in excellent agreement with the literature value of 39–40°.

Nuclear magnetic resonance spectroscopy

Owing to the nature of the hydrogen bonding between 18-crown-6 and MeCN in the complex, a rather weak overall interaction is expected. Indeed, even passing a stream of dry nitrogen over the crystalline complex is sufficient to remove the MeCN completely. This characteristic behaviour prompted a search for a method to determine the stability constant of weakly associated species.

The method selected was that of Foster and Fyfe.[7] A series of solutions was prepared, containing guest molecule (MeCN, concentration 5 m*M*) and varying concentrations of the host molecule (18-crown-6) chosen so that the host was present in great excess. Carbon tetrachloride was used as the solvent because it is considered not to form a complex with 18-crown-6. The experimental NMR parameter observed was the chemical shift (*vs.* tetramethylsilane, TMS, internal standard) of the MeCN methyl protons as a function of host concentration. MeCN is ideal for this type of study since it exhibits a single sharp resonance near 2.0 ppm, which is not obscured by the 18-crown-6 proton resonance at 3.55 ppm.

The relationship between the chemical shift of the MeCN methyl protons and the donor concentration is given in equation (1).

$$\Delta/[H] = -K\Delta + \Delta_0 K \qquad (1)$$

where $\Delta = \delta^G_{obs} - \delta^G_o$, $\Delta_o = \delta^G_{GH} - \delta^G_o$, [H] = host concentration, K = formation constant, δ^G_{obs} = observed chemical shift of guest (MeCN) protons in the presence of host (18-crown-6), δ^G_o = chemical shift of guest protons in the absence of host, and δ^G_{GH} = chemical shift of guest protons in "pure host-guest complex".

A plot of $\Delta/[H]$ *vs.* Δ is linear, with slope equal to $-K$. Typical data are shown in Table 1. Three determinations yielded an average value of 2.1 (standard deviation 0.1) at 298 K. These plots exhibited good linearity, with high correlation coefficients, suggesting the existence of a 1:1 complex [equation (1) was derived on the assumption of 1:1 stoichiometry; see reference 6]. The MeCN methyl protons shift downfield with increasing 18-crown-6 concentration, an observation consistent with a hydrogen-bonded system undergoing rapid exchange.[8,9]

An attempt was made to determine the stoichiometry of the solid complex. A 0.1*M* solution of the complex in carbon tetrachloride was examined by NMR and the integrated peak intensities were used to calculate the relative concentrations of 18-crown-6

Table 1. Effect of 18-crown-6 concentration on the chemical shift of acetonitrile present at 0.005*M* in CCl_4 at 298 K

18-Crown-6 concentration [H], *M*	MeCN methyl proton chemical shift *vs.* TMS, *Hz*	Δ	$\Delta/[H]$
0	488.70	0	—
0.202	493.68	4.98	24.7
0.257	494.73	6.03	23.4
0.307	495.34	6.64	21.7
0.399	496.59	7.89	19.8
0.602	497.62	8.92	14.8
0.700	498.66	9.96	14.3
0.800	499.49	10.79	13.5

For explanation of Δ and $\Delta/[H]$ see text. The data constitute a representative set for which the calculated *y*-intercept, slope, and correlation coefficient are 35.8, −2.14 and −0.98, respectively.

and MeCN present in solution. Repetitive analysis of the same sample failed to give consistent values for the stoichiometric factors. Values ranged from as high as 2.4:1 (MeCN:18-crown-6) to as low as 1.4:1 for replicate analyses. This is undoubtedly a manifestation of the instability of the complex (volatility of MeCN present in the complex). Furthermore, the method of preparation of the complex affects the apparent stoichiometry, the complex formed in solution having higher ratios of MeCN to 18-crown-6 than the complex formed by adsorption of MeCN from MeCN-saturated nitrogen gas (*vide supra*). This type of complication seems to have resulted in a good deal of confusion in the literature concerning the nature of the solid crystalline complex. For example, reported stoichiometric values include 1:1,[10] 2:1,[4] and 1.6:1[11] (MeCN:18-crown-6).

Infrared and Raman spectroscopy

A definitive Raman spectroscopic study of the complex was reported in 1974 by McLachlan.[4] This study demonstrated that the 18-crown-6 molecule exists in approximate D_{3d} symmetry when present in the solid crystalline complex. Little was said regarding the orientation of the MeCN with respect to the crown ether. The MeCN may reasonably be postulated to be oriented perpendicularly to the plane of the 18-crown-6 with the methyl protons directed toward three of the 18-crown-6 oxygen atoms. This type of orientation is analogous to that found in the complexes which form between some alkylammonium ions and 18-crown-6,[12] although the interaction is of course much weaker in the complex with MeCN.

The Raman data obtained were generally consistent with those reported by McLachlan, with the exception of one rather striking feature. The CN stretching frequency in the solid crystalline complex appears at 2243 cm^{-1}, a shift of 10 cm^{-1} from the CN stretching frequency in pure liquid MeCN. This shift was confirmed by repetitively running pure MeCN and the solid complex in succession and comparing their respective Raman spectra (Fig. 1). This shift has not previously been reported in the literature. It may be rationalized by postulating a weakening of the force constant of the CN band by the increased electron density acquired by inductive effects through the methyl protons. However, hypotheses of this type can never be certain; final confirmation would require a normal co-ordinate analysis, a task which poses a formidable computational problem and remains to be done.

Infrared data for comparison with the Raman data are of course desirable. However, difficulties were encountered during attempts to record infrared spectra of the complex. These problems are a direct result of the inherent instability of the complex and the nature of 18-crown-6. Alkali-metal halide cell materials are not recommended for use when analysing species containing 18-crown-6. The crown ether will attack these materials (especially potassium salts), rendering the infrared data obtained questionable or even invalid in regions where spectral changes occur on alkali-metal cation complexation. This limitation is especially important when analysing solutions, since the crown ether will cause solvation of the cell material, resulting in formation of potassium: 18-crown-6 complex; this complex is known to be very stable.

Infrared spectra of the solid complex could not be obtained, owing to the instability of the complex. Any perturbation applied to the complex is sufficient to destroy it. For example, a perturbation as gentle as passing a stream of dry nitrogen over the complex volatilizes the MeCN and is evidenced by marked changes in melting point before and after such treatment. Standard procedures used to obtain infrared spectra of solids generally employ much harsher treatments, such as pressure (to form an alkali-metal halide pellet) and heating (to form a film). Results obtained by utilizing these methods, a number of which are extant in the literature, should be treated with caution. Despite the growing use of crown ethers in research and catalysis, the problems associated with infrared analysis of crown ether complexes have not always been recognized.

While the lack of complementary infrared spectroscopic data for this system is unfortunate, Raman spectroscopy provides a nearly ideal alternative since it is non-intrusive and overcomes the need for halide salt plates.

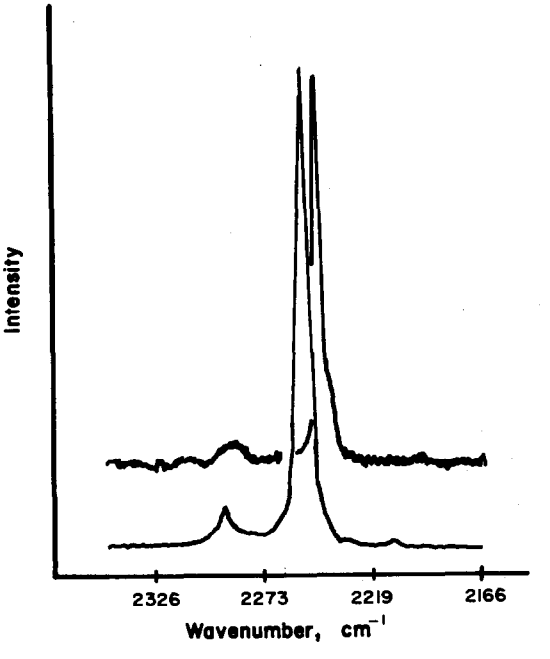

Fig. 1. C–N stretching region in Raman spectra of acetonitrile (MeCN); in the complexed (solid) state, upper and as pure liquid MeCN, lower curve. The relative intensities are arbitrary.

Conclusion

The widespread use of crown ethers requires that the details of crown ether complexation be investigated. While a good deal of effort has been directed towards complexes with alkali-metal cations, little attention has been directed towards complexes with neutral organic molecules. We have demonstrated the applicability of NMR methods to the determination of the formation constant of a representative very weak host–guest complex. This method is applicable to the entire class of complexes. The spectral shift evidenced in the Raman spectra has not been reported before, but is definitely indicative of formation of the crystalline MeCN:18-crown-6 complex. While the lack of infrared data is unfortunate, the considerable effort directed towards trying to obtain satisfactory infrared spectra has resulted in identification of problems inherent in the infrared analysis of crown ethers. These limitations have not always been clearly stressed in the literature. NMR is thus seen to be a valuable probe for determining weak formation constants of compounds in the liquid state, while Raman spectroscopy constitutes a near-ideal non-intrusive probe for solid-state complexes of crown ethers.

Acknowledgement—The assistance of Dr. Roger Crecely in the acquisition and analysis of the proton NMR spectra is appreciated.

ANNOTATIONS

THE EFFECT OF HEATING TIME IN THE DETERMINATION OF PHOSPHORUS BY WET DIGESTION

S. A. THOMAS and I. F. ANDENYANG
Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 4 *August* 1981. *Accepted* 7 *January* 1982)

Summary—It is shown that the length of heating during wet digestion is a critical factor in the determination of phosphorus in some seeds and nuts. For each sample a certain minimum heating time at a chosen temperature is necessary.

The interest in trace elements, whether as essential constituents in biological systems, or a potential source of danger to life, or on account of their physicochemical properties, has led to the publication of many analytical procedures for their determination.[1–4] An essential preliminary step in the determination of mineral elements in ecological materials is the decomposition of the organic matter, either by wet- or dry-ashing. Although the choice of procedure is still largely a matter of personal preference, for phosphorus wet digestion with mixed acids is preferred,[5] to minimize volatilization losses. In the last decade efforts have been directed towards reducing the deficiencies of the conventional digestion procedures. Thus, Adrian[6] proposed a wet digestion performed under pressure at low temperature. John[7] has reported an automated digestion method which is superior to dry-ashing for most elements.

The new digestion methods often show no advantage in precision or accuracy over the conventional methods, but are known to be easy, fast and safe, and require virtually no equipment.[6]

However, many of the published procedures are rather vague about the heating conditions during the wet digestion stage. For instance, we consider that instructions that digest mixtures be heated initially at moderate heat, with a later increase,[5] or until white fumes of sulphuric acid are evolved,[8] are inadequate. In the course of our study of the phosphorus content of the edible parts of certain seeds and nuts we have therefore examined systematically the effect of heating time on the amount of phosphorus found.

EXPERIMENTAL

Reagents

All reagents were of analytical reagent grade. Phosphorus standard stock solution was prepared by dissolving 0.4393 g of dry potassium dihydrogen phosphate in 1 litre of distilled water. Ammonium molybdate–sulphuric acid reagent was prepared by dissolving 25.0 g of ammonium paramolybdate tetrahydrate in 200 ml of warm distilled water, filtering the solution into 680 ml of 70% v/v sulphuric acid, and diluting to 1 litre; the solution was stored in the dark. Stannous chloride solution was prepared immediately before use by dissolving 0.5 g of stannous chloride dihydrate in 250 ml of 2% v/v hydrochloric acid.

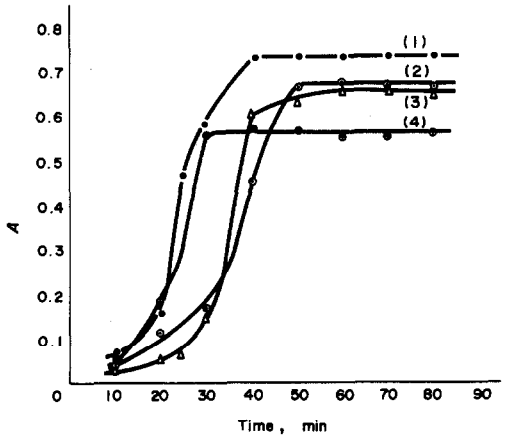
Procedure

A 0.25 g sample was placed in a 100-ml digestion flask, and 1 ml of 60% perchloric acid, 5 ml of 70% nitric acid and 0.5 ml of 98% sulphuric acid were added.[5] Two variations of the digestion procedures were then used. In one (P1), the flask was heated at 65° for 10 min, then the mixture was allowed to cool and total phosphorus was determined by the molybdenum blue method. The procedure was repeated for each sample, for periods of 20, 25, 30, 40, 50, 60, 70 and 80 min. In each case excessive charring of samples was avoided, and the mixture always contained free liquid.

In the second procedure (P2), the sample was heated initially at "moderate heat", starting at a temperature below 65°, with gentle swirling of the flask. The heat was gradually increased, and digestion was stopped 15 min after the appearance of white fumes.[5] About 25 min of heating were required. Blank determinations were also made.

RESULTS AND DISCUSSION

Figure 1 shows the variation of absorbance with heating time for eight seeds and nuts, studied by procedure P1. A characteristic curve is obtained for each sample. Although the chemistry of the reactions involved in wet digestion is still not well understood, it would appear that the reactions go to completion after a time interval which depends on the material being digested. It is of interest that different completion times are observed for the apparently similar samples used in this study. This would indicate that generalizations of methods should be done with due care. The initial slopes of the curves shown are prob-



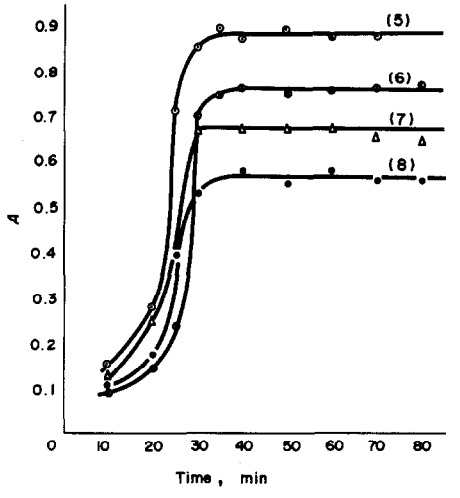


Fig. 1. Variation of absorbance with time for (1) Elaeis guineansis, (2) Arachis hypogaea, (3) Sorghum bicolor, (4) Voandzeia subterranea, (5) Cucumis melo, (6) Phaleolus vulgaris, (7) Tamarindus indica, (8) Irvingea gabonensis.

ably a reflection of the resistance of the organic matter in the samples to decomposition.

The maximum phosphorus contents estimated by procedure P1 are compared in Table 1 with the values obtained by the conventional heating procedure (P2). The P2 values are generally lower than the P1 values, suggesting that procedure P2 gave incomplete decomposition. It was also observed that increasing the heating temperature in procedure P1 did not significantly alter the maximum phosphorus value found, but did reduce the heating needed to reach it. However, heating too rapidly should be avoided.

Table 1. Results for the determination of phosphorus (%)* by procedures (P1) and (P2)

Sample	P1	P2
Elaeis guineansis	0.24	0.22
Arachis hypogaea	0.22	0.14
Sorghum bicolor	0.21	0.08
Voandzeia subterranea	0.17	0.04
Cucumis melo	0.29	0.14
Phaleolus vulgaris	0.25	0.21
Tamarindus indica	0.22	0.08
Irvingea gabonensis	0.18	0.10

*Average of at least three determinations.

CONCLUSION

It is evident that it is essential to ensure that digestion reactions proceed to completion to avoid underestimation of the desired element. The requirement that digestion be done at "moderate heat" until the evolution of white fumes of sulphuric acid appears liable to produce errors. For an accurate determination, preliminary runs should be carried out to determine the minimum heating time necessary for each sample. Furthermore, the lower the temperature that can be used, the less the risk of apparent loss through polymerization or volatilization of phosphorus compounds.

HOMOGENEITY OF SOLIDS: A PROPOSAL FOR QUANTITATIVE DEFINITION

J. INCZÉDY
Institute of Analytical Chemistry, University of Veszprém, Veszprém, Hungary

(*Received* 9 *October* 1981. *Accepted* 29 *January* 1982)

Summary—A simple formula has been deduced to predict the detectability of chemical homogeneity of solid substances by use of an analytical method with known spatial resolution. The formula includes the ratio of the spatial resolution of the method to the spatial distribution of the component to be determined, and the standard deviation of the method.

Investigations of the chemical uniformity of solid substances are becoming more and more important. Solid raw materials or products used in electronics or in metallurgy must be, in many cases, rigorously analysed, since their chemical homogeneity decisively influences their use and the physical properties of the product.

Danzer *et al.*[1] recently published a paper in which, using statistical criteria, they deduced a formula by which the homogeneity of a solid sample could be evaluated. The resolution and the standard deviation of the analytical procedure were included in the formula. Another approach is described here, in which the effect of the spatial resolution of the analytical method on the detectability of inhomogeneity is also included.

Principles of homogeneity

The concentration distribution of an element in the surface layer of a solid sample can be readily followed in the direction of the two co-ordinates by a scanning analytical method, assuming that the concentration change in the direction of the co-ordinates is relatively high and the distances between areas of different compositions are easily measurable. Thus, the local concentration of the components in a very small area on the surface can be determined precisely. If, however, the diameter of the spot analysed is comparable with the distance between the areas of high and low concentrations, or the standard deviation of the method is comparable with the difference between the high and low concentrations, reliable information on the homogeneity or the concentration distribution of an element cannot be obtained.

For surface-spot analysis many new high-efficiency scanning methods are now available, *e.g.*, laser-generated atomic-emission spectroscopy, electron-beam microanalysis, secondary ion mass spectrometry, *etc.* Their spatial resolution varies between 1 and 100 μm.

It is clear that the extent of information on homogeneity depends on the following factors.

(1) The amount or volume of the subsample which is directly analysed. The smaller this is, the higher will be the geometric resolution of the scanning process, and concentration changes over very short distances can be recognized.

(2) The statistical error of spot analysis. Concentration differences can be detected only if they are significantly greater than the statistical error of the analysis.

(3) The distance between the points of high and low concentrations of the components in the direction of the space co-ordinates.

(4) The mean value of the concentration differences of the elements to be determined, in the direction of the three co-ordinates.

It is easy to see that four factors are not independent. The higher the geometric resolution and precision of the analytical method, and the greater the distance and concentration difference between the points of low and high concentrations, the more reliable will be the results of the scanning process, or the information on the inhomogeneity of the solid sample. If, however, the geometric spatial resolution is poor, and the standard deviation is high, inhomogeneity of the sample cannot be detected.

Deduction of the formula proposed

For calculation of the approximate limits of detection, or determination of inhomogeneity, the following assumptions are made.

(1) For simplification the solid sample is considered to be analysed only in the direction of the z co-ordinate.

(2) The change in signal caused by a change in concentration of the component of interest, in the direction z, can be approximated by a sine curve, which can be characterized by an average amplitude and wavelength. The amplitude is denoted by $\Delta x/2$, and the wavelength by Δz.

(3) The "window" for spot analysis is characterized

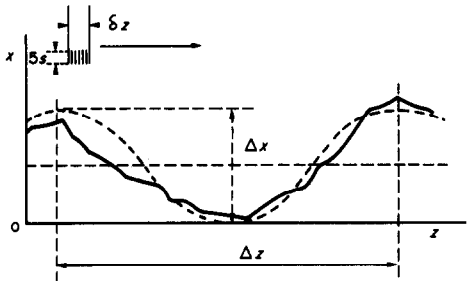

Fig. 1. Concentration distribution of an element in a solid. The resolution of the instrument is high compared to the concentration change. The error is also very low. ($\Delta z \gg \delta z$; $\Delta x \gg s$). The vertical lines indicate the uncertainty of the measurement; the standard deviation s can be taken as a fifth of the range of the signals for a given level.[2]

by a diameter, or, in the direction of z, a linear width which is denoted by δz.

(4) The standard deviation of the analytical measurement is denoted by s. This is used in connection with the determination of signal difference Δx.

The reader may wonder why a sine wave is chosen rather than, for example, square waves of random phase and amplitude. We believe that the wave function selected to describe the concentration profiles does not significantly influence the formula deduced, but the use of the sine wave makes the whole deduction much simpler.

In Fig. 1 the concentration change of a component in the direction of the z co-ordinate in a solid sample, and the sine wave used for approximation of the changing signal are shown. The frequency of the change is relatively low compared to the "window" or spatial resolution of the profiling methods, and the amplitude is quite high compared to the standard deviation of the analytical measurement ($\Delta z \gg \delta z$; $\Delta x \gg s$). This is the most favourable case, where the change of concentration can be determined quite rigorously. Figure 2 presents the case of a solid sample with an inhomogeneity occurring with higher frequency, analysed by a method of low spatial resolution (*i.e.*, with large window width), and higher standard deviation; it can immediately be seen that the presence of inhomogeneity cannot be verified ($\delta z > \frac{1}{2}\Delta z$; $s > \Delta x'$). This occurs because the large window acts as a filter (moving window average[3]) giving the average composition of the substance, integrated over the distance δz. The signal difference observed will be lower than in the case of high resolution, *i.e.*, the observed amplitude will be lower than the true value ($\Delta x' < \Delta x$).

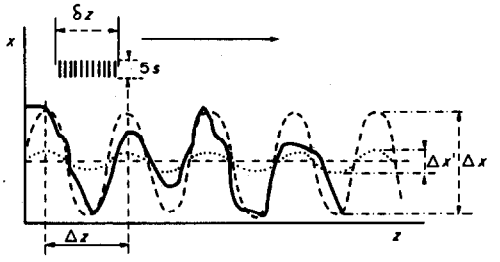

Fig. 2. Concentration distribution of an element in a solid. The spatial resolution of the instrument is low compared to the concentration changes. The error is also considerable. Because of the integrating effect, the signal difference observed will be $\Delta x'$ rather than Δx. See caption to Fig. 1 for note on range = 5s, and on uncertainty of measurement.

For a concentration change in the direction of the z co-ordinate to be detected with acceptable confidence, the following condition must be fulfilled:

$$\Delta x' > 3s, \tag{1}$$

i.e., the signal difference observed between the points of low and high concentration should be at least three times the statistical error (or noise) of the measurement. This signal difference is connected with the "window" of the single analytical measurement and with the distance between the points of low and high concentration. The relationship can be expressed easily, if we consider spot analysis as giving an integrated value of the composition of the substance over the distance δz.

Using the transfer function of a boxcar window with a width of δz, we obtain

$$\frac{a'}{a} = \frac{\sin \pi f \delta z}{\pi f \delta z} \tag{2}$$

where a is the original amplitude, a' is the amplitude of the smoothed sine wave, and f is its frequency. Since in this case $f = 1/\Delta z$ and $2a = \Delta x$, $2a' = \Delta x'$, we can write:

$$\frac{\Delta x'}{2} = \frac{\Delta x}{2} \frac{\sin(\pi \delta z/\Delta z)}{\pi \delta z/\Delta z} \tag{3}$$

from equations (1) and (3) we obtain the formula

$$\Delta x > \frac{3s\pi \delta z/\Delta z}{\sin(\pi \delta z/\Delta z)} \tag{4}$$

For the presence of inhomogeneity to be detectable equation (4) must be satisfied. Taking into consideration the concentration difference, Δc, corresponding to Δx, and the standard deviation in concentration units (s_c), the following condition must hold for the verification of homogeneity:

$$\Delta c(\Delta z, \delta z, s_c) < \frac{3s_c\pi \delta z/\Delta z}{\sin(\pi \delta z/\Delta z)} \tag{5}$$

The solid sample appears homogeneous if the concentration differences Δc at distances $\Delta z/2$ are lower than the quantity on the right-hand side, and the measurements are made with a window δz and standard deviation s_c.

A similar formula can be obtained if the Fisher significance test is used instead of the 3s criterion.

Thus the system appears homogeneous if

$$\frac{\sigma^2}{s^2} < F(95) \tag{6}$$

where $F(95)$ is the critical value for the F-test, σ^2 is the apparent variance of the changing concentration of the component, and s^2 is the square of the standard deviation of the measurements.

The variance of the sin or cos function is $a^2/2$, where a is the amplitude. From equation (3):

$$\sigma^2 = \tfrac{1}{2}\left[\frac{\Delta x \sin(\pi\delta z/\Delta z)}{2\pi\delta z/\Delta z}\right]^2 \tag{7}$$

From (6) and (7) we get the condition

$$\Delta x < \sqrt{8}\, s \sqrt{F(95)}\left[\frac{\pi\delta z/\Delta z}{\sin(\pi\delta z/\Delta z)}\right] \tag{8}$$

for homogeneity.

The critical value of $F(95)$ for $n_1 = n_2 = 20$ degrees of freedom (easily obtainable by means of the usual methods) is 2.12.

With $\sqrt{8}\sqrt{2.12} = 4.12$, Δc instead of Δx, and s_c instead of s, condition (8) becomes:

$$\Delta c(\Delta z, \delta z, s_c) < 4.12\, s_c\left[\frac{\pi\delta z/\Delta z}{\sin(\pi\delta z/\Delta z)}\right] \tag{9}$$

If we treat the spatial resolution problem more rigorously, *i.e.*, the real composition change along the z co-ordinate is decomposed into cosine-wave-components (by the Fourier method), we come to the conclusion that the concentration difference is detectable only when the amplitude ($\Delta x/2$) and frequency ($1/\Delta z$) of the components satisfy the conditions given in equation (5) or (9). All other components with higher frequency or lower amplitude contributing to the real spatial distribution will be filtered out and not be observable.

Remarks. For the sake of simplicity only one-dimensional changes were considered in the deduction of the formula. However, the pattern in the direction of the other co-ordinates can be treated in a similar manner.

Examples. (1) A perfectly mixed 1:1 (particle ratio) mixture of chromium oxide and manganese oxide is examined by laser-generated emission spectroscopy. The average size of the particles of both components is the same, 25 μm. A circular spot with a diameter of *ca.* 100 μm can be analysed by the laser-generation system. The relative standard deviation of the determination for chromium is 5%. Can heterogeneity of the mixture be detected by laser emission spectroscopy?

The chromium concentration difference between the particles (between chromium oxide and manganese oxide) is $\Delta c = 68 - 0 = 68\%$; $s_c = 68 \times 0.05 = 3.4\%$; $\Delta z = 50\,\mu$m; $\delta z = 100\,\mu$m; (Δz is the average distance between centres of chromium oxide particles).

Using formula (5) we obtain

$$68 \ll 3 \times 3.4 \times \frac{2\pi}{\sin 2\pi}$$

The mixture appears completely homogeneous.

(2) From the same chromium oxide and manganese oxide another perfectly mixed sample is prepared, but with a 1:40 composition. The mixed sample is carefully spread on a glass plate, and chromium is determined in the surface monolayer. Does the mixture appear homogeneous or not?

The dilution is to be taken into consideration when obtaining the Δc value:

$$Ac = \frac{68}{40} - 0 = 1.7\%$$

Since the concentration is much lower than before, the relative standard deviation of the determination will be taken as 10%:

$$s_c = 1.7 \times 0.10 = 0.17\%$$

$\delta z = 100\,\mu$m as before, but Δz is now $\approx 150\,\mu$m. Hence

$$1.7 > 3 \times 0.17 \times \frac{\pi\frac{100}{150}}{\sin \pi\frac{100}{150}} = 1.2$$

The mixture will behave as a heterogeneous one.

Conclusions

By taking into consideration the spatial resolution of the analytical method and the spatial distribution of the elements in the surface of solid materials, and using the formula for filtering by moving window average, it is possible to deduce a simple formula for the prediction of homogeneity.

THE USE OF OUTER-SPHERE COMPLEX FORMATION REACTIONS IN ION-EXCHANGE CHROMATOGRAPHY

SEPARATION OF MALEATE AND FUMARATE IONS

PÁL HALMOS and JÁNOS INCZÉDY
Institute for Analytical Chemistry, University of Chemical Engineering, Veszprém, Hungary

(*Received* 23 *November* 1981. *Accepted* 23 *March* 1982)

Summary—Outer-sphere complex formation reactions have been used to increase the selectivity of ion-exchange separation of maleate and fumarate ions. The stability constants of the maleate and fumarate complexes of tris(ethylenediamine)cobalt(III) and hexa-amminecobalt(III) have been determined at different ionic strengths from the elution volumes and the parameters of the ion-exchanger bed, and the values at $I = 0$ obtained by extrapolation. They are: $\log K\,[Co(en)_3^{3+} + Ma^{2-}] = 3.33$; $\log K\,[Co(NH_3)_6^{3+} + Ma^{2-}] = 3.77$; $\log K\,[Co(en)_3^{3+} + Fu^{2-}] = 1.19$; $\log K\,[Co(NH_3)_6^{3+} + Fu^{2-}] = 1.99$. The two anions can be separated quantitatively.

In a previous paper[1] we reported the use of outer-sphere complex formation reactions for enhancing the selectivity of separation of oxalate and sulphate ions.

We now report on the changes in the retention of maleate and fumarate ions on an anion-exchanger column when cationic cobalt(III) complexes [such as tris(ethylenediamine)cobalt(III) and hexa-amminecobalt(III)] are added to the eluent.

The stability of an outer-sphere complex strongly depends on the possibility of hydrogen-bond formation.[2–8] Therefore, because of their *cis–trans* isomerism, fumarate and maleate ions form outer-sphere complexes of different stability with cobalt(III) complexes,[9] and the selectivity of the maleate–fumarate separation is enhanced by the presence of these complexing agents. The stability constants of the outer-sphere complexes have been calculated from the elution volumes and the column parameters.

EXPERIMENTAL

Reagents

Analytical grade potassium chloride, maleic and fumaric acid were used. Tris(ethylenediamine)cobalt(III) chloride and hexa-amminecobalt(III) chloride were prepared from cobalt(II) chloride,[10] recrystallized from aqueous solution and dried, after washing with ethanol, at 105°. The column was packed with 100–200 mesh strong anion-exchanger (Dowex AG1X4 in chloride form). A weak cation-exchanger was used for the binding of the complex cations (Bio-Rex 70, 100–200 mesh).

Elution experiments

A 172 × 4.0 mm column was packed with the anion-exchanger (bed volume 2.16 cm^3). The column was equilibrated with potassium chloride, tris(ethylenediamine)-cobalt(III) chloride or hexa-amminecobalt(III) chloride solution, as required for the experiments. The chloride concentration of the eluents was determined by argentometric titration. The pH was adjusted to between 8.0 and 10.0. A 30–50 μl portion of 0.1*M* maleic or fumaric acid solution (previously adjusted to pH 8.0–9.0 with potassium hydroxide) was injected with a Hamilton microsyringe for the elution experiments. The absorbance of the eluate at 207 nm was monitored in a flow-cell. Since the absorbance of the cobalt(III) complexes in the eluent is high at this wavelength, a weak cation-exchanger column was connected between the anion-exchanger column and the flow-cell to remove the cobalt(III) complexes. Column dead volume was determined by injecting 100 μl of 4*M* potassium chloride. The eluents contained various concentrations of potassium chloride, tris(ethylenediamine)cobalt(III) chloride and hexa-amminecobalt(III) chloride. The chloride concentration was varied between 0.1 and 0.22*M*.

All the elution experiments were repeated with each eluent. The retention volumes were determined and the distribution coefficients were calculated.

Separation of anions

An anion-exchanger column was used for the separation of maleate and fumarate ions. A 290 × 6.5 mm cation-exchanger column was connected after the anion-exchanger column. The procedure was identical with that used for the elution experiments. Elution was carried out first with 0.13*M* potassium chloride at pH 8.88 [Fig. 2(*a*)], then with 0.13*M* tris(ethylenediamine)cobalt(III) chloride solution at pH 8.55. The separation was repeated with the hexa-amminecobalt(III) eluent [Fig. 3(*b*)]. An 80-μl sample was injected in both cases. The test sample was 0.05*M* in both maleic and fumaric acid.

DISCUSSION

The distribution coefficient of an ion can be determined from the data obtained from elution experiments:[11]

$$V_{max} = V_N + V_0 \tag{1}$$

$$D = \frac{V_N}{X} \tag{2}$$

where V_{max} is the elution volume, V_N the adjusted elution volume, V_0 the dead volume, D the volumetric

distribution coefficient, and X the volume of the ion-exchanger bed.

The distribution coefficient can also be calculated, with a good approximation, from other data collected during the ion-exchange separation:[11]

$$D = K_x Q^Z/[B]^Z \quad (3)$$

where K_x is the concentration equilibrium constant of the ion-exchange reaction, Q is the capacity of the resin, Z the charge of the anion, and $[B]$ the concentration of the counter-ion in the eluent.

If the anion examined participates in side-reactions with positively charged ions (*e.g.*, in complex formation, protonation reactions, *etc.*) then the conditional distribution coefficient is:

$$D' = K_x Q^Z/\alpha_L[B]^Z \quad (4)$$

where α_L is the side-reaction coefficient.

If outer-sphere complex formation is the only possible side-reaction and the complex formed is a 1:1 species, then the stability constant of the outer-sphere complex can be derived from equations (2)–(4):

$$\log D - \log D' = \log \alpha_L \quad (5)$$

$$\log \alpha_L = \log (1 + [M(X)_n]K_1 \quad (6)$$

where $[M(X)_n]$ is the concentration of the inner-sphere complex ion which participates in the side-reaction and K_1 is the stability constant of the 1:1 outer-sphere complex formed with it in the side-reaction.

The maleate and fumarate ions were eluted with potassium chloride, tris(ethylenediamine)cobalt(III) chloride and hexa-amminecobalt(III) chloride solutions, each at different chloride concentrations. The distribution coefficients were determined by means of equation (2) from the adjusted elution volumes (Tables 1 and 2). Their logarithms are plotted in

**D* = distribution coefficient with KCl as eluent.
†*D*' = distribution coefficients with cobalt(III) complexes as eluents.

Fig. 1 against the logarithms of the chloride concentration. The slopes of the lines are described by equations (3) and (4). It can be concluded from Fig. 1 that the distribution coefficients of maleate and fumarate differ more when the eluent contains tris(ethylenediamine)cobalt(III) chloride or hexa-amminecobalt(III) chloride, than when it contains potassium chloride. Thus, a higher selectivity can be achieved and the two anions separated from each other.

Quantitative separation can be achieved with either 0.13*M* tris(ethylenediamine)cobalt(III) chloride or 0.12*M* hexa-amminecobalt(III) chloride [Figs. 2(*b*) and 3(*b*)] but not with potassium chloride solutions at the same chloride concentrations [Figs. 2(*a*) and 3(*a*)].

It is apparent from Fig. 1 that the distribution coefficients of the two anions change significantly with change in eluent. The stability constants of the outer-sphere complexes formed at various ionic strengths can be calculated by means of equations (5) and (6) from the distribution coefficients calculated at identical chloride concentrations from the regression lines (Table 3).

The logarithms of the stability constants determined at various ionic strengths are plotted against the cube root of the ionic strength of the solutions in Fig. 4. The stability constants at $I = 0$ can be obtained from the intercepts. They are:

$$\log K\,[Co(en)_3^{3+} + Ma^{2-}] = 3.33$$

$$\log K\,[Co(NH_3)_6^{3+} + Ma^{2-}] = 3.77$$

$$\log K\,[Co(en)_3^{3+} + Fu^{2-}] = 1.19$$

$$\log K\,[Co(NH_3)_6^{3+} + Fu^{2-}] = 1.99$$

Figure 4 is in agreement with the cube-root law of ionic strength described in the literature.[12]

The log *K* values of the maleate complexes are remarkably higher than those of the fumarate complexes, in accordance with the *cis* and *trans* structures of these anions, *i.e.*, their complex-forming tendency.

The complexes formed with hexa-amminecobalt(III) are more stable than those formed with tris(ethylenediamine)cobalt(III). This agrees with the order found earlier[1] and also corresponds to the order of polarizability of these complex cations.

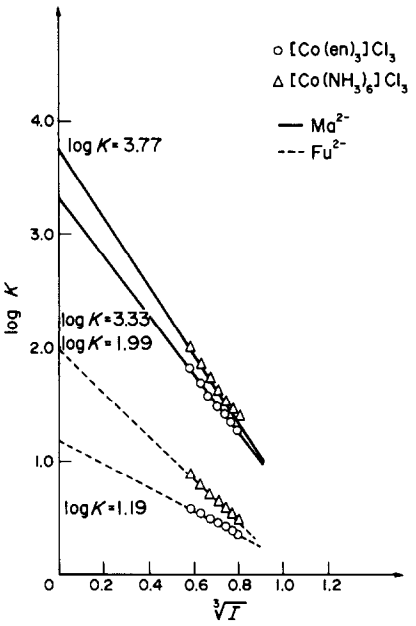

Fig. 4. Extrapolation of the stability constants to $I = 0$. The slopes, intercepts and regression coefficients are tabulated below.

Complex	Intercept	Slope	Regression coefficient
$[Co(NH_3)_6]Ma^+$	3.77 ± 0.04	−3.03 ± 0.06	−0.9990
$[Co(en)_3]Ma^+$	3.33 ± 0.04	−2.58 ± 0.05	−0.9989
$[Co(NH_3)_6]Fu^+$	1.99 ± 0.03	−1.89 ± 0.04	−0.9988
$[Co(en)_3]Fu^+$	1.19 ± 0.02	−1.04 ± 0.03	−0.9983

STUDIES OF PRETREATMENTS IN THE DETERMINATION OF Zn, Cd, Pb, Cu, Sb AND Bi IN SUSPENDED PARTICULATE MATTER AND PLANKTON BY DIFFERENTIAL-PULSE ANODIC-STRIPPING VOLTAMMETRY WITH A HANGING MERCURY DROP ELECTRODE

G. GILLAIN
Laboratoire d'Océanologie, Université de Liège au Sart Tilman,
B-4000 Liège, Belgique

(*Received* 19 *January* 1982. *Accepted* 16 *March* 1982)

Summary—The determination of Zn, Cd, Pb, Cu, Sb and Bi by differential-pulse anodic-stripping voltammetry has been applied to samples of plankton and suspended particulate matter after decomposition of organic matter by two methods: low-temperature ashing with microwave-activated oxygen and wet-ashing in pressurized Teflon crucibles. The loss of these elements, and contamination, were studied with a standard reference material. The relative merits of these oxidation techniques are discussed.

Determination of trace elements in environmental science raises two difficult problems concerning contamination during sampling and analysis. The first problem has been solved with the help of an appropriate sampling apparatus.[1]

A recent paper has described the direct and simultaneous determination of Zn, Cd, Pb, Cu, Sb and Bi in sea-water by differential-pulse anodic-stripping voltammetry (DPASV).[2] In this paper the application of this technique has been extended to the determination of the same elements in solid matrices such as suspended matter and plankton. We have adopted this technique for various reasons: the equipment is simple and inexpensive, and the method exhibits high sensitivity, which offers the possibility of analysing the small quantities of matter collected on the filters used.

Analysis for trace elements in solid samples (suspended particulate matter, plankton, sediment) includes decomposition of the organic matter followed by a dissolution step leading to a solution for subsequent analytical determinations. This ashing may be achieved by various "classical" or more recently developed procedures, each of which has particular advantages and disadvantages.[3,4] It appears that at the ultratrace level very promising results can be obtained with low-temperature ashing[5] or by pressurized acid decomposition.[6] The latter technique offers an excellent approach for elements such as Hg, As, Se, Sb.

EXPERIMENTAL

Apparatus

An E 310 Brucker polarograph was used with a controlled-temperature Metrohm polarographic cell (25 ± 1°) fitted with a saturated calomel electrode (SCE), a platinum counter-electrode and a hanging mercury drop electrode (Metrohm E 410).[2]

The dry ashing was performed with microwave-activated oxygen in an apparatus manufactured by Trapelo Division, Mass, U.S.A.

A home-made Teflon digestion bomb was employed for the wet-ashing.[7] It is shown in Fig. 1. It is hermetically sealed with a cover and an O-ring made of dense Teflon. The vessel (35 ml) fits into a duralumin container covered by a plate fastened to it by means of 4 screws. The cover is machined so that it presses on the Teflon lid, providing a simple and effective seal. The whole device can be brought to the required temperature for mineralization either by warming in an oven or on a hot-plate, with constant stirring. The life-time of the O-ring depends on the number of digestions. It generally has to be replaced after 8–10 digestions.

Reagents

Standard metal stock solutions (10^{-2}–$10^{-3}M$) were prepared by weighing out the pure metal, dissolving it in a few ml of nitric or hydrochloric acid, and making up to volume. They were further diluted daily as necessary.

The water was demineralized and purified with a Millipore "Milli-Q" water system.

Hydrochloric, perchloric and nitric acids were all Merck "Suprapur".

Sampling and storage of the sample

Suspended particulate matter. The samples were filtered through a preweighed 0.45-μm Millipore filter (47 mm diameter), dried at 60° and stored in individual plastic Petri dishes until further treatment ashore. After drying at 60°, the filters were weighed again with the same accuracy (0.05 mg). The mass of total suspended matter was determined by difference.

The complete sampling procedure is described elsewhere.[1]

Plankton. The plankton was collected with a 100-μm mesh nylon net and washed several times with ultrapure water in order to remove all the sea-water salts. The samples were then frozen at −20° in polyethylene bottles, for analysis.

In the laboratory, the samples were lyophilysed (Leybold-Heraeus GT 2 apparatus) for 24 hr. The dry residue was very heterogeneous, so it was ground in a mechanical corundum mortar to pass a 50-μm sieve. The samples were stored in hermetically stoppered vials. As shown by Duyckaerts and Gillain,[5] by application of the Fisher–Snedecor test, the samples prepared in this way can be considered as homogeneous if their weight exceeds 300 mg.

Decomposition of the sample

Low-temperature ashing (LTA). The filter with the suspended particulate matter or 300 mg of plankton is decomposed in a stream of oxygen excited by a radiofrequency discharge. Low temperatures (70–150°) can be maintained by using low excitation power.

We have shown[5] that the LTA method does not introduce any noticeable losses of Zn, Cd, Pb and Cu. The ashing was conducted under the following conditions:

power 200 W
oxygen pressure 1 mmHg
oxygen flow 40 ml/min
time 10–15 hr

Pressurized acid digestion. The material collected on the filter or approximately 300 mg of plankton (accurately weighed) was transferred to the Teflon vessel in the bomb, 4 ml of concentrated nitric acid and 4 ml of 30% hydrogen peroxide solution were added, then the bomb was closed and heated at 150° for 6 hr. After cooling to room temperature, the bomb was opened and the acid digest evaporated to dryness so that the most suitable supporting electrolyte could be used for the DPASV. Purified nitrogen was passed over the acid to accelerate the evaporation and to avoid contamination by dust. A blank solution containing 4 ml each of the nitric acid and the hydrogen peroxide was prepared in the same way.

Analysis of the residue

The residue from the LTA or from the Teflon bomb was dissolved in 1 ml of "Suprapur" concentrated hydrochloric acid. The solution was then diluted to volume with purified water in a 100-ml standard flask. After both digestion techniques, a Rhodamine test proved that antimony was at least partly oxidized to the quinquevalent state. To reduce Sb(V) to electroactive Sb(III) sulphur dioxide was bubbled through the solution for 1 hr. The excess of sulphur dioxide was removed by a flow of purified nitrogen.[8]

The metal concentrations in the particulate matter and plankton were determined by the method of standard additions. The following procedure is recommended: the sample solution (pH 1, 30 ml) is introduced into the electrolysis cell and adjusted to 2*M* sodium chloride concentration by addition of the high-purity solid (*e.g.* Merck "Suprapur"). The sample is stirred (magnetic stirrer, 450 rpm) and oxygen removed by passage of pure nitrogen for 30–40 min. Electrolysis is done at a potential of −1.200 V (*vs.* SCE) for 1–5 min, with a flow of nitrogen through the space above the surface of the solution. Stirring is stopped 1 min before the end of the electrolysis, and the current–potential curve is then recorded from −1.200 to −0.350 V. The potential is held at −0.350 V, with stirring, for 3–8 min. At the end of this plating time, the stirring is again stopped and the resulting current–potential curve is recorded down to a potential of 0 V, with an appropriate current sensitivity.

The sensitivities for Cu and Sb are different because of the number of electrons exchanged (1 for Cu and 3 for Sb), and because the pre-electrolysis potential lies on the plateau of the $i_p = f(E_p)$ curve for Sb but not for Cu.[2] From calibration curves obtained after a systematic parametric study of the analysis of Cu, Sb, Bi mixtures, we found that the Cu and Sb give the same peak current when the copper concentration is about 100 times that of antimony.

RESULTS AND DISCUSSION

The LTA method minimizes sample handling, is simpler to perform and gives very low blank values because it avoids the use of reagents (Table 1).

Nevertheless, the mineralization of a standard sample (NBS No. 1571) under the conditions described, has shown that losses of antimony can occur (Table 2), chiefly in the presence of chloride. Because of the dependence of temperature and oxidation rate on the applied power, different powers and ashing times were investigated (Fig. 2), with a standard solution of Sb(III). We found that quantitative recovery of antimony is obtained only with a low power used for a very short time.

The conclusion is that volatilization losses cannot be prevented under the conditions previously cited as necessary for complete mineralization of marine samples (power 200 W, time 10–15 hr). Consequently, low-temperature ashing appears to be acceptable only when non-volatile compounds are dealt with.

A definite advantage of the wet-ashing in a Teflon bomb is that no significant loss of antimony is observed after treatment for 6 hr at 150°. Recoveries were satisfactory as shown in Table 2.

For the pressurized acid digestion, we determined the volume of acid (nitric or a 1:1 nitric–sulphuric mixture) necessary to dissolve completely in 6 hr, a

300-mg sample[5] at a temperature that would give a pressure lower than 10 atm in the bomb. From these experiments it was concluded that samples with a high organic content were easily decomposed but not completely mineralized when these acids were used. Consequently, the use of the nitric acid–hydrogen peroxide mixture in the bomb was deemed necessary.

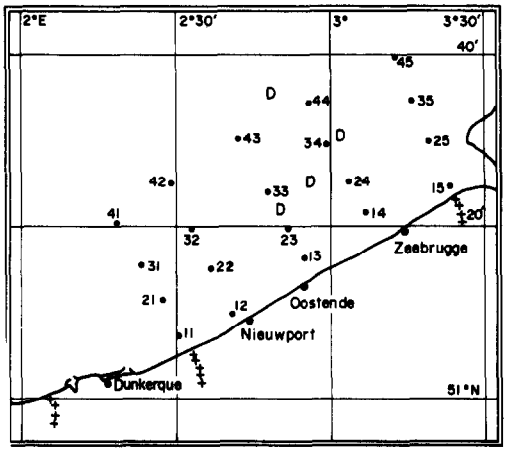

Fig. 3. Location of sampling in the North Sea (Belgian Coast). D = dumping.

The pressurized acid decomposition method has the additional advantage of reducing the digestion time from 15–20 hr to 5–6 hr. Nevertheless the blank values are somewhat higher than those obtained by LTA (Table 1).

The results obtained by both methods show good agreement and appear to be within the limits of precision achievable by DPASV. The general levels and distribution of Zn, Cd, Pb, Cu, Sb and Bi in Belgian coastal water are shown in Table 3 and Fig. 3. The dominant sources of material controlling trace-metal levels in this selected area are coastal discharges, dumping and rivers (mainly the Scheldt). The values increase towards the coast. High levels of these elements occur chiefly in the vicinity of the coasts and the river Scheldt. The highest levels are found at station 14, and are mainly due to the considerable

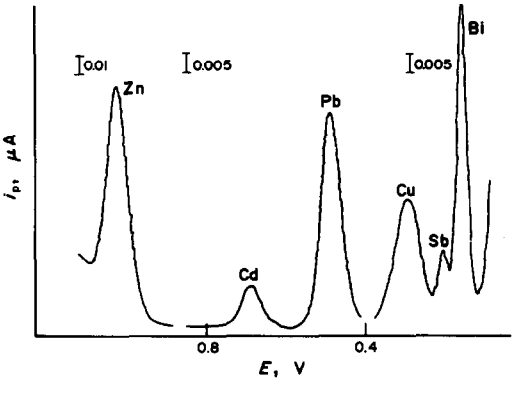

Fig. 4. Voltamperograms of Zn, Cd, Pb, Cu, Sb and Bi in particulate matter (sample from station 45, at pH 1 and 2*M* chloride concentration). Deposition times 2 min (Zn, Cd, Pb) and 5 min (Cu, Sb, Bi). Pulse amplitude 35 mV (Zn, Cd, Pb) and 10 mV (Cu, Sb, Bi); scan-rate 2 mV/sec (Zn, Cd, Pb) and 0.5 mV/sec (Cu, Sb, Bi). The concentrations of metals in the sample (station No. 45) used for Fig. 4 were (μg/l.): Zn, 1.21, Cd 0.019, Pb 0.41, Cu 0.22, Sb, 0.006, Bi 0.030.

and continuous suspension of material near the harbour of Zeebrugge.

The values found for the Cd, Pb and Cu concentrations are of the same order of magnitude as those reported by Mart[9] for the same area.

Results for plankton are given in Table 4. The biological concentration factors for a given element may be expected to vary over a range of five or ten times the mean value. Copper and especially zinc show remarkably high concentration factors in plankton.

Further investigations are being made to establish a more detailed geographical picture of the metal distribution, detect any seasonal cycles involving metals, determine a possible relationship between the particulate and dissolved phases, and study the interrelation between the metals and dissolved organic matter (speciation).

The DPASV/HMDE method is convenient for the simultaneous determination of Zn, Cd, Pb, Cu, Sb and Bi in suspended matter and plankton (Fig. 3). Zn has no effect on the copper stripping peak: the intermetallic Zn–Cu compounds were found only at relatively high concentration of both elements in the electroanalysis solution (Zn 500 μg/l., Cu 80 μg/l.). In this case, the problem of interaction can easily be overcome by the addition of gallium.[7]

CONCLUSION

In the course of this work, we have tried to demonstrate that both decomposition techniques perform equally well. The choice of the one rather than the other depends only on the general trends of the research work in hand. The Teflon bomb is most convenient for the determination of volatile metals such as Hg, Sb, As, Se, and LTA will yield very good results in the determination of less volatile heavy metals.

The blanks for both pretreatments are very low and the recovery levels obtained under routine conditions are generally good, considering the problems inherent in this type of trace analysis.

DIFFERENTIAL-PULSE POLAROGRAPHIC DETERMINATION OF *N*-NITROSOPROLINE IN UNCOOKED MEAT

KIYOSHI HASEBE* and JANET OSTERYOUNG†
Department of Chemistry, State University of New York at Buffalo, Buffalo, NY 14214, U.S.A.

(*Received* 1 *December* 1981. *Accepted* 9 *March* 1982)

Summary—Ham and bacon have been analysed for *N*-nitrosoproline by differential-pulse polarography. Quantitative polarograms without interfering peaks were obtained from ethanol extracts prepared after extensive clean-up which included freeze-drying and column chromatography. Differential-pulse polarography proved sufficiently sensitive to give peaks corresponding to *ca.* 100 μg of *N*-nitrosoproline per kg in several commercial samples of cured meat.

N-Nitroso compounds are well-known as carcinogens, mutagens, and teratogens.[1–4] Study of these compounds and their effects has been hampered by lack of suitable analytical methods. The analytical problems have been discussed recently.[5] In general, the identification and determination of *N*-nitrosamines are considered scientifically acceptable if satisfactory gas chromatography/mass spectroscopy results can be obtained. The GC–MS method is time-consuming and expensive and useful only for volatile compounds. Non-volatile compounds are mainly dealt with by preparation of volatile derivatives. Recently Fine *et al.* have applied high-pressure liquid chromatography to analysis for non-ionic non-volatile *N*-nitroso compounds in foodstuffs.[6] Walters *et al.* have determined *N*-nitrosarcosine on powdered cornflakes by a method involving denitrosation with hydrogen bromide.[7] Hasebe and Osteryoung have systematically studied the application of differential-pulse polarography (DPP) to the determination of various *N*-nitrosamines.[8,9] These results, together with those of other workers,[10] have demonstrated that for most *N*-nitrosamines DPP gives detection limits of about $10^{-7}M$ and therefore this technique is comparable to GC–MS when coupled with appropriate sample clean-up procedures. Because of the difficulty involved in analysis of complex materials for non-volatile (*i.e.*, non-steam-distillable) *N*-nitrosamines and because of the recognized importance of the problem of *N*-nitrosoproline (NOPro) and other non-volatile *N*-nitrosamines in cured meats, we elected to develop procedures for determination of NOPro in bacon and ham.

The focus of this work is not on qualitative identification of NOPro. It has been amply demonstrated that NOPro occurs in raw cured meats, and that it is there in substantially higher concentration than other *N*-nitrosamines. We have confirmed the identity of NOPro by the R_f value and by DPP peak potential. This combination of information is adequate for our purposes because of the substantial amount of information which has been accumulated on NOPro in cured meats.[5] We were more interested in demonstrating the applicability of the DPP method for NOPro, which was developed with standards,[8] to an analytical problem involving a difficult matrix. The objective was to devise sample clean-up procedures, using previous work as a guide, which would prove appropriate for use with the electrochemical analysis technique.

EXPERIMENTAL

Materials

Chloroform, n-hexane, n-heptane, and methylene chloride were redistilled in glass. Absolute ethanol (ACS grade) and methanol (analytical reagent grade) were used without further purification. *N*-Nitrosoproline crystals were prepared according to a modification of the method of Lijinsky *et al.*[8,11] Column separation was performed on Sephadex LH-20 in ethanol.

Apparatus

Polarographic data were obtained with a Model 174 Polarographic Analyzer (Princeton Applied Research Corporation, Princeton, N.J.) and Model 174/70 Drop Timer. Polarograms were recorded on an Omnigraphic Model 2000 X-Y recorder (Houston Instrument Company, Austin, Texas). The polarographic conditions employed were those described before.[8] A Sorvall superspeed automatic refrigerated centrifuge, Model RC-2-B, a macro homogenizer, Model 45 VirTis 16-200, and a freeze-drier, Freeze Mobile, VirTis, were used.

RESULTS AND DISCUSSION

The experimental work was done in the following sequence. First, a procedure was developed for the isolation and concentration of NOPro, and was tested with NOPro standards. Next, several clean-up methods reported for samples containing non-volatile

*Present address: Department of Chemistry, Faculty of Science, University of Hokkaido, Sapporo, 060, Japan.
†To whom correspondence should be addressed.

N-nitrosamines were examined for their utility in the DPP analysis. The significance of this step lies in the fact that clean-up requirements for DPP are not necessarily the same as those for GC. The examination of these procedures led to development of a suitable scheme for the DPP analysis. Finally, samples of bacon and ham were analysed for NOPro.

Isolation and concentration procedure

Following the suggestion of Kushnir *et al.*[12] the initial isolation and concentration procedure was carried out as follows.

A weighed 50-g sample of bacon or ham was ground and blended with 100 ml of water for 20 min in the homogenizer, then the material was centrifuged at 10,000 rpm for 20 min. The supernatant liquid was decanted and kept, and the blending step was repeated. The two supernatant liquids were combined and then decanted through glass wool to remove any remaining particles. The liquid (pH 5.2–5.5) was adjusted to pH 7.5 with 5*M* sodium hydroxide and stored in a refrigerator overnight to facilitate removal of fat and lipid. The cold aqueous solution was then separated from the solids by decanting and extracted twice with a total volume of 400 ml of methylene chloride. The resulting solution is referred to below as the clarified aqueous solution and is nominally free from fat and lipids.

Re-examination of modification of the activated carbon adsorption method

It has been reported that NOPro can be quantitatively adsorbed by activated carbon.[13] The clarified aqueous solution was stirred for 4 hr with granular activated carbon (*ca.* 2 g per 100 ml). After the residual liquid had been decanted, the carbon was washed with two 10-ml portions of distilled water, and then refluxed with ethanol for about 3 hr to desorb the *N*-nitrosamines. After removal of the solvent from the ethanolic extract by use of a rotary vacuum evaporator, the residue was dissolved in 0.1*M* hydrochloric acid. Examination of the resulting solution by DPP revealed a large background current caused by failure of the clean-up procedure to remove other compounds of the matrix. The interfering compounds are undoubtedly lipids, which give rise to a capacity current due to adsorption at the electrode surface. This problem seemed so serious that this procedure was not studied further.

Re-examination of a modification of the solvent extraction method

Solvent extraction methods for sample clean-up were based on the work of Kawabata.[14] Clarified aqueous solutions obtained as described above were made acidic with 6*M* hydrochloric acid. NOPro was extracted from the homogenate with two portions (each twice the aqueous phase volume) of methylene chloride or of ethanol–methylene chloride mixture (1 : 3 v/v). The combined extract was dried over small amounts of anhydrous sodium sulphate in a dried Erlenmeyer flask fitted with a screw cap. The solvent was evaporated from the extract with a rotary vacuum evaporator. Residual material was treated several times with a total volume of 10–20 ml of 0.1*M* hydrochloric acid. Differential-pulse polarograms gave a large background current at potentials near −0.8 V *vs.* SCE, which is the reduction potential of NOPro in 0.1*M* hydrochloric acid.[8] Therefore, attempts to clean up the supernatant by using solvent extraction also gave poor results.

Modification of the freeze-drying method using Sephadex

For the isolation of NOPro from raw bacon, Kushnir *et al.* have developed a procedure which uses freeze-drying.[12] The subsequent analysis involves derivative-formation and GC. We examined a variation of this procedure[15] to test its utility in the DPP determination.

The clarified aqueous solution obtained as described above was freeze-dried. The residual material obtained was extracted three times with a total volume of 45 ml of ethanol. Small solids were separated by passing the extract through glass wool. The clarified extract was concentrated to 0.20–0.25 ml by evaporation with prepurified nitrogen gas and its volume measured accurately. A known volume of the concentrated liquid was dissolved in 0.1*M* hydrochloric acid (as supporting electrolyte), and then analysed by DPP. This procedure gave a well-defined DPP peak for NOPro. However, compounds giving rise to currents at more positive potentials interfered. The freeze-drying approach appeared promising, so attempts were made to modify it by providing an additional stage of clean-up.

The original procedure used[12] included a silica-gel clean-up stage. In agreement with Wasserman[12] we found that that step gave poor recoveries, and (at least in our hands) was not reproducible. Use of silica gel was especially difficult under our ambient conditions, which exhibited large changes and large rates of change in relative humidity.

Sephadex column chromatography has been used for clean-up of fish extracts for analysis for pesticide residues and for the clean-up of cutting fluids for analysis for nitrosamines.[16,17] We tried that approach to purify further the freeze-dry residue. An LH-20 column was prepared by soaking 15 g of dry LH-20 overnight in ethanol. The gel was slurried into a 55 × 1.2 cm bore column and compressed to *ca.* 45 cm during assembly of the column. The solution resulting from elution at about 1 ml/min was collected in fractions and each fraction was evaporated in a tared vial with prepurified nitrogen. The vial was rinsed out with 0.1*M* hydrochloric acid, the resulting solution accurately made up to 5 ml, then analysed by DPP. If air was used instead of prepurified nitrogen, the NOPro decomposed during the evaporation, and

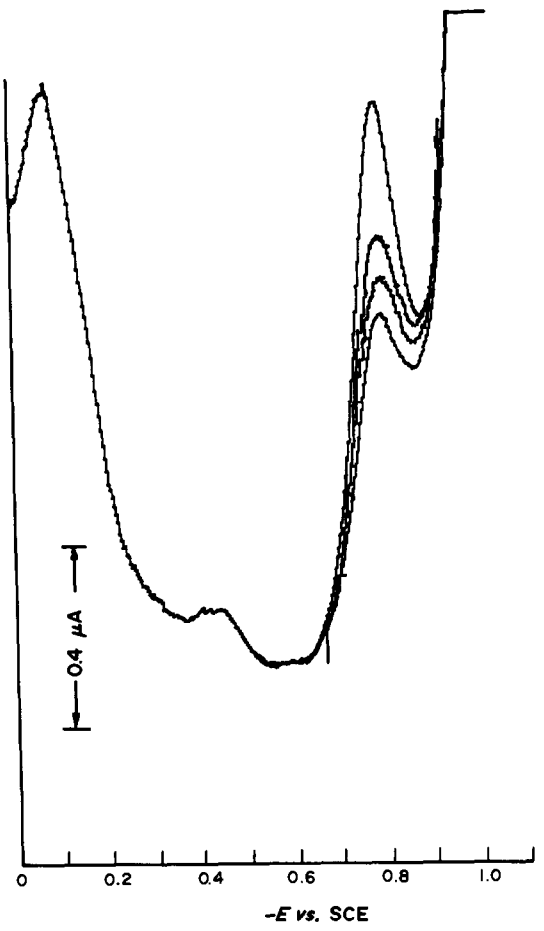

Fig. 1. DPP of raw bacon sample. Scan-rate 2 mV/sec; drop time 2 sec; pulse amplitude −50 mV. The lowest curve is for the sample in 5 ml of 0.1 *M* HCl and the successively higher curves correspond to the sample after addition of 10, 20 and 50 μl respectively of 21.5 μg/ml NOPro solution.

the DPP peak for NOPro disappeared. Polarograms obtained from these solutions are shown in Fig. 1.

Examination of 10-ml fractions showed that essentially all the NOPro is eluted with 40–60 ml of eluent under these conditions. Some interfering substances are eluted in the earlier fractions, and in some samples elution of higher molecular-weight interferents begins at about 60 ml. The optimum procedure appeared to be to use the 40–55 ml fraction for analysis.

Thin-layer chromatographic characterization of the concentrated liquid was carried out on silica gel 60 *F*-254 (Merck) plates developed with chloroform–methanol (9:1 v/v). NOPro was clearly separated from associated interfering materials, the maximum R_f of which was about 0.10. The R_f of NOPro was about 0.26.

Proposed procedure

The work described above resulted in the following procedure. Take 50 g of uncooked bacon or ham. Mince, grind and blend with 150 ml of water for 15 min. Centrifuge the resulting pap-like material at 10,000 rpm for 20 min. Decant the supernatant liquid and keep it. Repeat the blending with another 150 ml of water, centrifuge, and decant. Filter the combined liquid extract through glass wool. Adjust the pH of this liquid to about 7.5, and then refrigerate overnight. Remove the coagulated material from the supernatant. Extract the aqueous solution with two 200-ml portions of methylene chloride. Freeze-dry the clarified aqueous solution and extract the residual material three times with a total of 45 ml of ethanol. Filter the resulting solution through glass wool and then concentrate it to 0.25–0.20 ml by passing prepurified nitrogen through it, and measure the volume accurately (in a 1-ml graduated tube). Chromatograph a known volume of the concentrate on a Sephadex LH-20 column with ethanol. Evaporate the 40–55 ml fraction of eluate to dryness with prepurified nitrogen. Take up the residue in 0.1*M* hydrochloric acid and make up to 5 ml, with the same acid, and analyse by DPP. The total time required to analyse a sample is 2 days or less.

Recovery of NOPro from aqueous solution

Recoveries of NOPro by both the solvent extraction and freeze-drying methods were tested with aqueous solutions of standards. It has already been established[12] that good recoveries are obtained for NOPro added to raw bacon and taken through the freeze-drying step. This appears to be sufficient evidence that the steps leading to the defatted, lipid-free solution, which is the starting point for the clean-up methods investigated, yield satisfactory recoveries of NOPro. It should be noted that the problems with recoveries experienced by Kushnir *et al.*[12] arose in the silica-gel clean-up step, which we did not employ. We used aqueous solutions of standards to represent the defatted, lipid-free solution. Results were unaffected by addition of vegetable oils.

To study recoveries in the solvent extraction method, *ca.* 0.2*M* hydrochloric acid solutions containing various amounts of NOPro were extracted for 10 min each time with two portions of methylene chloride (each twice the aqueous phase volume). There was no significant difference in the DPP peak heights obtained with and without use of sodium chloride as a salting-out agent, although its use was recommended for improving the extractability.[14] After drying with a small amount of anhydrous sodium sulphate, the combined extract was evaporated with a rotary vacuum evaporator, and the residue extracted several times with a total of 10 ml of 0.1*M* hydrochloric acid. Recoveries determined by DPP are presented in Table 1.

To test recoveries in the freeze-drying method, similar solutions were freeze-dried. The resulting residue was extracted several times with a total of 10 ml of 0.1*M* hydrochloric acid. Recoveries as determined by

Table 1. Recovery of *N*-nitrosoproline from aqueous solution

Method	Added, μg	Recovery, %
Solvent-extraction	2.15	95
	4.30	97
	6.45	99
Freeze-drying	5.0	90
	10.0	92
	20.0	99

DPP are also shown in Table 1. Both the solvent extraction and freeze-drying methods give satisfactory recoveries of NOPro from pure water.

In the Sephadex clean-up step, conditions were adjusted so that recoveries were 100%, within the experimental error, determined from elution of standard samples of NOPro from the column and analysis by DPP with use of both standard curves and standard additions.

Determination of NOPro in commercially available cured meat

Ham and bacon samples obtained from a local major chain supermarket were analysed according to the procedure outlined above. The quantitative analysis for NOPro was done by the standard-addition method as illustrated in Fig. 1. From this figure it is apparent that addition of the analyte changes the background current (which is due to catalytic reduction of protons, probably with NOPro as catalyst), and therefore the faradaic current is estimated by drawing for each current–voltage curve an artificial base-line in the form of a straight line across the bottom of the peak, tangential to the upward curve before and after the peak. The standard-addition graph from the data in Fig. 1 has an intercept of 0.31 μA, slope (m) of 2.00 $\mu A.ml.\mu g^{-1}$, and standard deviation about the line (s_m) of 0.02 μA. Thus the unknown amount of NOPro in the cell is 0.78 μg, and the detection limit estimated from $ts_m/m = 0.04$ μg/ml at 95% confidence, where t is the Student-t statistic. This corresponds to a concentration of about 0.2 μM in the cell, which is reasonable considering the complexity of the sample. Expressed in terms of a sample size of 50 g, this corresponds to a detection limit of 4 μg/kg. If a single fixed base-line is used, the amount of NOPro estimated from Fig. 1 is 0.73 μg; the difference is not regarded as significant. Results for NOPro in three different ham samples were 0.17, 0.20 and 0.07 mg/kg, and for one bacon sample 0.27 mg/kg. These values are in reasonable agreement with those for NOPro in uncooked bacon, as found by Wasserman.[15] The elaborate efforts required to establish a laboratory standard sample were not undertaken. Because the degree of homogeneity of individual samples is not known, it is not possible to state a standard deviation for the procedure as a whole with confidence. However, on the basis of the estimate of the detection limit given above we infer that the precision of these results is about 5–10%.

This procedure has the advantages that it avoids the silica gel clean-up step and also avoids the esterification step essential for the GC determination. It therefore decreases both the analysis time and the amount of work required for the determination. Also, from this evidence and the experience gained with other sample types,[18] Sephadex column chromatography for sample clean-up appears to be a generally effective procedure for complex samples intended for *N*-nitrosamine determination by DPP.

Note—This work was supported by NIH grant 1 R01 CA15028-01 MCHB. It was reported on in part at the 169th ACS Meeting, September, 1976, San Francisco. Portions of the work were carried out at Colorado State University.

FLOW-INJECTION ANALYSIS OF SILICATE ROCKS FOR TOTAL IRON AND ALUMINIUM

TADASHI MOCHIZUKI, YASUHIKO TODA and ROKURO KURODA*

Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Yayoi-cho, Chiba, Japan

(*Received* 7 *January* 1982. *Accepted* 7 *March* 1982)

Summary—A flow-injection method is described for the spectrophotometric determination of total iron and aluminium in silicate rocks. Rock samples are opened up by fusion with a mixture of lithium carbonate and boric acid, the melt is taken up in 1*M* hydrochloric acid and the resulting solution is used for the determination of both iron and aluminium. The flow system for the determination of iron needs no particular reagents, involving simply measurement of the absorbance of the chloro-complex of iron(III) at 335 nm. The system for aluminium consists of the reduction of iron(III) to iron(II), colour development with Xylenol Orange (XO), destruction of XO-chelates other than that of aluminium by addition of EDTA and subsequent measurement of the absorbance of the aluminium–XO complex at 506 nm. The systems permit semi-automatic, rapid analysis of silicate rocks for iron and aluminium. Results obtained for standard rocks were in good agreement with the recommended values. The precision ranged from 0.1 to 0.9% for iron and from 0.3 to 0.7% for aluminium.

Geochemical research and the ceramic industries require vast number of chemical analyses of silicates, and the methods employed should yield a high productivity per analyst. In this respect, instrumental techniques, particularly emission spectroscopy, X-ray fluorescence spectroscopy, atomic-absorption spectrophotometry, fast-neutron activation analysis, *etc.*, have made considerable progress and are becoming capable of answering the need for accurate, rapid rock analyses on a routine basis.[1,2]

Chemical methods involving "complete analysis" and individual determinations have also been fully developed and established on a firm foundation.[1,3] Because of the capabilities of flow-injection analysis,[4–9] as developed by Růžička and Hansen and by Stewart, it is of interest to assess its value for silicate analysis. The automatic nature of FIA appears to ensure large throughputs and to serve to reduce the need for highly competent and well organized analysts in the chemical analysis of silicates. However, FIA needs liquid samples to work with, so for highest efficiency as many elements as possible should be determined by FIA of separate portions of a sample solution obtained from a single decomposition, since it is the decomposition step that is the most labour-intensive, and has the lowest throughput.

On the basis of these considerations we have developed methods for the continuous spectrophotometric determination of total iron and aluminium in silicate rocks by FIA.

EXPERIMENTAL

Reagents

Standard solutions. A stock solution of iron (1 mg/ml) was prepared by dissolving about 1 g of iron(III) chloride hexahydrate in 1*M* hydrochloric acid and diluting to 200 ml with the same acid and standardized complexometrically. Working standards were prepared by diluting the stock solution with 1*M* hydrochloric acid. A stock solution of aluminium (1 mg/ml) was prepared by dissolving about 0.9 g of aluminium chloride hexahydrate in 1*M* hydrochloric acid and making up to 100 ml with the same acid, and complexometrically standardized. Working standards were obtained by appropriate dilution with distilled water or 0.1*M* hydrochloric acid, so that they were 0.1*M* in hydrochloric acid.

Masking solutions. A 0.1% ascorbic acid solution and 0.02*M* EDTA.

Xylenol Orange–buffer solution. One g of Xylenol Orange was dissolved in 1 litre of 1*M* acetic acid–1*M* sodium acetate buffer solution (pH 4.3).

All chemicals used were of analytical-reagent grade.

Apparatus

The flow diagrams for the determination of iron and aluminium are shown in Fig. 1. The peristaltic pumps, sample-injection valve, spectrophotometer, flow-through cell (volume 31.4 μl, light-path 10 mm) and data-processor were the same as described previously.[10,11] The flexible silicone rubber tubes (bore 4.0 mm, length 20 cm) were connected immediately after the pumps to damp the pulsed stream generated by the pumps. The systems were assembled from 1.0-mm bore Teflon tubing [except for the back-pressure coils (bore 0.5 mm) and the dampers] and connectors. Cylindrical mantle heaters were used for heating the mixing coils to control the reaction of aluminium with Xylenol Orange and to enhance the rate of reduction of iron(III) with ascorbic acid and the EDTA destruction of the iron(II)–Xylenol Orange complex.

Dissolution of silicate rocks

About 50 mg of powdered rock sample (accurately weighed) is placed in a platinum crucible and mixed with 0.15 g of anhydrous lithium carbonate and 0.15 g of boric acid. The mixture is fused in a muffle furnace by heating gently for 3 min and then strongly for 12 min at ~950° to yield a clear melt.[12] The contents are swirled occasionally

*Author for correspondence.

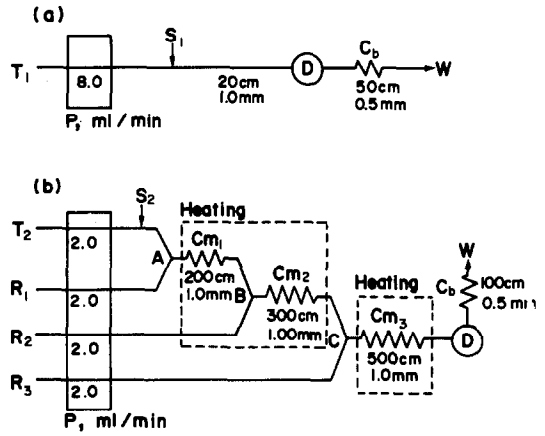

Fig. 1. Flow diagrams. Systems (*a*) and (*b*) are used for the determination of iron and aluminium respectively. T_1, carrier (1*M* HCl); S_1, sample (318 μl); T_2, carrier (0.1*M* HCl); S_2, sample (125 μl); R_1, reducing solution (0.1% ascorbic acid); R_2, Xylenol Orange–buffer solution; R_3, masking solution (0.02*M* EDTA); P, peristaltic pumps; D, spectrophotometer; W, waste; Cm_1, Cm_2, Cm_3, mixing coils; C_b, back-pressure coil; A, B, C, confluence points. The numerals under the coils and tubing refer to their lengths in cm and internal diameters in mm. The parts of the manifold enclosed by the dotted line are placed in the mantle heaters and kept at about 140°.

to ensure complete oxidization of ferrous iron. After cooling the melt is dissolved in 20 ml of 1*M* hydrochloric acid, with magnetic stirring. It should take less than 20 min to achieve the dissolution. The clear solution thus obtained is made up to volume in a 100-ml standard flask with 1*M* hydrochloric acid. The resulting solution is used as such to determine iron. For the determination of aluminium a ten-fold dilution is made with distilled water.

Flow-injection analysis

Determination of iron. Carrier solution T_1 (1*M* hydrochloric acid) is pumped into the analytical line at a flow-rate of 8.0 ml/min with a peristaltic pump, Fig. 1(*a*). The sample solution (318 μl) is introduced into the carrier stream by a six-way loop-valve injector and the absorbance is monitored in the flow-through cell at 335 nm against distilled water as reference.

Determination of aluminium. The flow system illustrated in Fig. 1(*b*) is used.[11] The sample solution (125 μl) injected into the carrier stream T_2 of 0.1*M* hydrochloric acid (flow-rate 2.0 ml/min) is merged into the ascorbic acid solution R_1 (flow-rate 2.0 ml/min) at the point A, and iron(III) is reduced to iron(II) in the mixing coil Cm_1 (bore 1.0 mm, length 200 cm). At the point B the sample zone is mixed with Xylenol Orange–buffer solution R_2 (flow-rate 2.0 ml/min). The colour-forming reactions of aluminium, iron(II) *etc.* with Xylenol Orange proceed in the mixing coil Cm_2 (bore 1.0 mm, length 300 cm), and are accelerated by placing the coils Cm_1 and Cm_2 in a mantle heater (inside temperature ~140°). After the sample slug meets the EDTA masking solution R_3 (flow-rate 2.0 ml/min) at the point C, Xylenol Orange complexes other than the aluminium chelate are completely destroyed by the EDTA, in the mixing coil Cm_3 (bore 1.0 mm, length 500 cm) heated to ~140° (inside the mantle heater). The temperature at the outlet of Cm_3 is ~50°. The absorbance of the aluminium–Xylenol Orange chelate is measured at 506 nm against a reagent blank. The pH of the waste is 4.05.

For calibration a series of working standard solutions is injected into the analytical line before and after the sample runs. All solutions are analysed in triplicate.

RESULTS AND DISCUSSION

Lithium metaborate fusion has been advocated by Ingamells and widely adapted for spectrometric, colorimetric[13] and atomic-absorption analysis,[14,15] where the sample must be brought into solution. Dissolution of the cooled melt obtained with the 1:1 mixture of lithium carbonate and boric acid used in this work is rather slow but can be accelerated by magnetic stirring (a Teflon-coated stirring bar should be used). It usually takes less than 20 min to complete the dissolution. Polymerization of silica appears to proceed slowly, as judged from successive spectrophotometric determinations of silica by molybdate method, but no deposition of silica was found. We found that letting the solution stand for up to a week or more does not affect the determination of aluminium with Xylenol Orange to any great extent.

Determination of iron

The absorption of ultraviolet radiation by solutions of iron(III) in hydrochloric acid has already been applied for the determination of iron[16,17] and the detection of iron in liquid chromatography.[18] Iron(III) in 0.1–4.2*M* hydrochloric acid exhibits an absorption maximum at 330–345 nm, and the sensitivity increases with increasing concentration of hydrochloric acid (Fig. 2). With 6*M* hydrochloric acid there are absorp-

tion maxima at 325–330 and 365 nm. If 1*M* hydrochloric acid medium is used, measurement at 335 nm (molar absorptivity 1.84×10^3 $l.mole^{-1}.cm^{-1}$) is satisfactory, although the sensitivity is low and the dependence on chloride concentration is rather severe. However, preparation and use of a large enough batch of 1*M* hydrochloric acid minimizes the effect of variation of acid concentration, giving better precision. Beer's law is obeyed from 0.9 to 60 μg/ml.

This simple system is based on the injection of sample solution (318 μl) into the carrier stream pumped at 8.0 ml/min and allows a very rapid continuous analysis by direct monitoring of the absorbance, throughput being as high as 280 measurements per hour.

The effect of foreign ions on the determination of iron(III) at the 10 μg/ml level (equivalent to 2.86% Fe_2O_3 in rocks) was investigated. Table 1 indicates that neither the major elements (amounts equivalent to 41% SiO_2, 3.3% TiO_2, 53% Al_2O_3, 35% MgO, 32% CaO, 2.8% P_2O_5) nor the borate flux used interfere.

Routine runs for determination of total iron in eight standard rock samples gave the results in Table 2, which agree well with the recommended values. The iron content ranged from 2.2 to 13.4% Fe_2O_3 in these rocks and could be determined with a relative standard deviation of 0.1–0.9% for three measurements.

Determination of aluminium

In previous work[11] we found that Xylenol Orange could be successfully used for the selective spectrophotometric determination of aluminium in brasses and aluminium bronze when suitable conditions were chosen. The absorption maximum of the aluminium–Xylenol Orange complex is at 506 nm at pH 3.8–5.5.

The flow system used for analysis of silicate rocks is essentially the same as that described previously[11] except for the back-pressure coil and heating of coil Cm_3 (Fig. 1). Both iron(III) and iron(II) react with Xylenol Orange to give coloured chelates,[21,22] with strong absorption at the wavelength used for measuring the aluminium absorbance, so an effective masking system must be incorporated in the flow system. The system chosen consists of reduction of iron(III) to iron(II) with ascorbic acid and destruction of the iron(II)–Xylenol Orange chelate by EDTA. In static tests, the colour of the iron(II) chelate (iron at the 0.4 μg/ml level) was found to fade slowly after the addition of EDTA, being masked completely within 12 min at room temperature, whereas the absorbance of the aluminium chelate (aluminium 0.4 μg/ml) remained almost unchanged with time. In the continuous flow system, the iron is rapidly and completely masked by heating the coil Cm_3 or using a stopped-flow technique to ensure long enough reaction time. The stopped-flow technique, however, gives lower sample throughput. The heating conditions were optimized by varying the temperature of coil Cm_3 over the range 35–140° (internal temperature of mantle heater), coils Cm_1 and Cm_2 being kept at 140°. The results are shown in Table 3. The effect of iron(III) can be eliminated completely by heating at a temperature of about 80° or above.

†4.55 and 3.33 μg/ml, respectively.

The effect of various ions, including those of some minor elements that give stable Xylenol Orange complexes, was then examined. The results obtained are summarized in Table 4. Major components of rocks, including SiO_2, MgO and CaO in much larger amounts than the sample weight in the aliquot used (1.25 mg), have no effect on the determination of aluminium (174 μg, equivalent to 26.3% Al_2O_3 in rocks), assuming a tolerance of ±3.5 μg (relative error ±2.0%). This is also the case for iron (up to 260 μg, equivalent to 30% Fe_2O_3). Titanium (2.3% as TiO_2), manganese (54% as MnO), and phosphate (47% as P_2O_5) do not interfere. Vanadium(V), lanthanum, cerium, zirconium and thorium (~3200 ppm levels), which all form Xylenol Orange complexes, give rise to no serious errors for the rock types usually encountered.

Table 4. Effect of various ions on the determination of aluminium [174 μg/25 ml]*

The recommended procedure was applied to the determination of aluminium in eight standard rocks and the results are summarized in Table 2. They are in good agreement with the recommended values. The precision for three measurements is satisfactory (0.3–0.7% relative standard deviation) and the throughput of 50 determinations per hour is sufficiently high. For both the iron and the aluminium systems, the precision of measurement, the base-line stability, and the linearity of the calibration graph are all satisfactory. Flow systems for determination of other elements in the same sample solution basis are being developed.

CHLOROFORM EXTRACTION OF ETHYL XANTHATE COMPLEXES FROM SULPHURIC ACID MEDIA

ELSIE M. DONALDSON and E. MARK

Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 13 *January* 1982. *Accepted* 24 *February* 1982)

Summary—The chloroform extraction of 30 elements (Fe, Co, Ni, Zn, Cd, Ge, Sn, V, As, Sb, Bi, Cu, Ag, Au, Mn, Re, Ga, In, Tl, Se, Te, Cr, Mo, U, Pt, Pd, Rh, Ir, Ru and Ce) from 0.1–8*M* sulphuric acid in the presence of potassium ethyl xanthate has been studied. Pd(II), Bi, As(III), Sb(III), Se(IV) and Te(IV) are completely extracted and Au(III) is largely extracted over the range of acid concentration investigated. Fe(II), Tl(I), Rh(III) and Cr(VI) are only slightly extracted and Se(VI), Te(VI), Ru(III), Cr(III), Mn(II), Zn, Ce(IV), Ir(IV) and Ge(IV) are not extracted at all. Depending on the acid concentration, the remaining elements are all partly extracted. Results are compared with those obtained in an earlier study of the extraction of xanthate complexes from hydrochloric acid media. The processes involved in the formation of some xanthate complexes and potential analytical separations are discussed.

Recently, one of the authors published a review[1] on the solvent extraction, characteristics and analytical uses of ethyl xanthate complexes and a study of the chloroform extraction of 32 elements from 0.1–10*M* hydrochloric acid in the presence of potassium ethyl xanthate.[2] The information obtained from this study led to the development of spectrophotometric and atomic-absorption spectrophotometric (AAS) methods—based on xanthate extraction separation schemes—for the determination of minor and trace amounts of tellurium,[3] arsenic,[4] selenium,[5] bismuth,[6] antimony[7] and molybdenum[8] in diverse ores, concentrates and other materials. This study also suggested that the extraction of some species, notably antimony(III), molybdenum(VI), bismuth and silver, from fairly concentrated hydrochloric acid media is probably inhibited by the formation of chloro-complexes, and that antimony(V) is extracted as a chloro-complex. The extraction of selenium(VI) and tellurium(VI) was considered to be due to their reduction by chloride ions, xanthate ions, or both. Most of the published information[1] on the solvent extraction of xanthates is based on extractions from hydrochloric acid media. Consequently, it was considered that a study of the extraction of xanthate complexes into chloroform from sulphuric acid media would be of use to analytical chemists and would yield additional useful information on the processes involved in the formation of some complexes.

EXPERIMENTAL

Reagents

Solutions of thallium(I), antimony(III), manganese(II), uranium(VI), rhenium(VII), chromium(VI) and silver were prepared by dissolving $(Tl)_2SO_4$, $KSbOC_4H_4O_6$, $MnSO_4.H_2O$, $UO_2SO_4.3H_2O$, NH_4ReO_4, $K_2Cr_2O_7$ and Ag_2SO_4, respectively, in water. A solution of antimony(V) was prepared by treating some of the antimony(III) solution with sulphuric acid and *aqua regia*.[7] After evaporation of the solution to ~1 ml, potassium hydroxide solution and sufficient tartaric acid to give a final concentration of ~0.1% were added. Subsequently, the pH of the solution was adjusted to ~7 with dilute sulphuric acid, then sufficient concentrated sulphuric acid was added for the final solution to be 1*M* in sulphuric acid. A solution of chromium(III) was prepared by treating some of the chromium(VI) solution with hydrogen peroxide plus sufficient concentrated sulphuric acid to give a final concentration of 1*M* and then boiling the solution to decompose the excess of hydrogen peroxide.

Solutions of cerium(IV), selenium(IV), gallium and iron(II) were prepared by dissolving $Ce(NH_4)_4(SO_4)_4.2H_2O$, H_2SeO_3, Ga_2O_3 and $(NH_4)_2Fe(SO_4)_2.6H_2O$, respectively, in water containing sufficient concentrated sulphuric acid for the final acid concentration to be 1*M*. Ascorbic acid was added to the iron(II) solution to prevent aerial oxidation. Solutions of molybdenum(VI), arsenic(III), vanadium(V) and germanium were prepared by dissolving the oxides in dilute sodium hydroxide solution and adjusting the pH to ~7 with dilute sulphuric acid. A solution of arsenic(V) was prepared by treating a part of the arsenic(III) solution with nitric acid, hydrogen peroxide and sufficient concentrated sulphuric acid for the final acid concentration to be 1*M* and then evaporating the solution to fumes of sulphur trioxide.

Nickel, zinc, cobalt and cadmium solutions were prepared by dissolving the metals in dilute sulphuric acid followed by evaporation of the solutions to dryness and dissolution of the salts in water. An iron(III) solution was prepared by dissolving the metal in water plus sufficient concentrated sulphuric acid for the final concentration to be 1*M*, then oxidizing the iron(II) with hydrogen peroxide and destroying the excess of peroxide by boiling. Indium, bismuth, copper and tellurium(IV) solutions were prepared by dissolving the respective metals and TeO_2 in nitric acid plus the volume of concentrated sulphuric acid required for a 1*M* solution and evaporating the solution to fumes of sulphur trioxide. Palladium(II) and platinum(IV) solutions were prepared in a similar manner after dissolution of the metals with *aqua regia*.

Iridium(IV) and ruthenium(III) solutions, 1*M* in sulphuric acid, were prepared by dissolving $(NH_4)_2IrCl_6$ and $(NH_4)_2RuCl_5$, respectively, in water containing the required volume of concentrated sulphuric acid and evaporating the solutions to fumes of sulphur trioxide. A gold(III) solution was prepared by dissolving the metal in *aqua regia* plus the required volume of concentrated sulphuric acid and ~1 ml of concentrated perchloric acid and evaporating the solution to fumes of perchloric acid. A rhodium(III) solution was prepared by dissolving $(NH_4)_3RhCl_6 . 1\frac{1}{2}H_2O$ in dilute sulphuric acid and evaporating the solution to dryness. The residue was dissolved in dilute potassium hydroxide solution, the pH adjusted to ~7 with dilute sulphuric acid, and sufficient concentrated sulphuric acid added for the final acid concentration to be 1*M*.

A stock solution of tin(IV) was prepared by dissolving the metal in the volume of concentrated sulphuric acid required for a 5*M* solution. Hydrogen peroxide was added to oxidize the tin and the solution was evaporated to fumes of sulphur trioxide to destroy the excess of peroxide. A working solution, 1*M* in sulphuric acid, was prepared by fivefold dilution of this solution.

In all these working solutions the concentration of the element concerned (assuming the starting materials were nominally 100% pure) was 100 μg/ml. Analytical-reagent grade chloroform was used without further purification.

General extraction procedure

Five-ml aliquots of working solution (*i.e.*, 500 μg of the element concerned) were added to a series of 125-ml separatory funnels containing sufficient 10*M* sulphuric acid to provide a final acidity in the range 0.1–8*M*, then each solution was diluted to 50 ml with water (Note 1). Ten ml of chloroform and 1 ml of freshly prepared 20% potassium ethyl xanthate solution were added to two solutions at a time and, after ~30 sec, the solutions were shaken for 1 min. Each chloroform phase was drained into a 150-ml beaker (Note 2). Each aqueous phase was extracted twice more, in a similar manner, with 5-ml portions of chloroform and 1 and 0.5 ml of xanthate solution, then washed by shaking for ~30 sec with 5 ml of chloroform. Except for certain tests (Note 3), the combined extracts were treated with 10 ml of nitric acid (1 + 1) and chloroform was removed by evaporation in a hot water-bath. Depending on the volatility and other properties of the element investigated and the method used for its determination, the resulting solutions were either evaporated to dryness (Note 4) or to fumes of perchloric acid or dryness after treatment with suitable acids (Note 5) or *aqua regia* (Note 6).

The amount of the element in the chloroform extract was determined by the methods listed in Table 1. The percentage of the element extracted was then calculated from the initial amount of the element and that extracted.

Notes

1. Tests with selenium, tellurium and thallium in their highest oxidation states were carried out after oxidation of these elements with 0.5% potassium permanganate solution in 1*M* sulphuric acid medium before adjustment of the acid concentration of the solution with 10*M* sulphuric acid. In tests with platinum and gold, 5-ml aliquots of the solutions in 1*M* sulphuric acid were treated in a similar manner to ensure that these elements were in their highest oxidation states before the extraction step.

2. In tests with arsenic(III) and arsenic(V), each chloroform phase was drained into a 125-ml separatory funnel and the arsenic(III) in the extract was oxidized to arsenic(V) with bromine–carbon tetrachloride solution. Arsenic was then stripped into water and determined by the molybdenum blue method.[4]

3. Extracts obtained during tests with ruthenium(III) were evaporated to dryness with hydrochloric acid to prevent loss of ruthenium as the volatile tetroxide. In tests with iridium(IV) the extracts were treated in a similar manner except that the salts were subsequently treated with *aqua regia*, followed by evaporation to dryness, to ensure that any iridium present would be in the oxidized condition required for complex formation with *o*-dianisidine.

4. Solutions obtained during tests with germanium, chromium, cerium, rhenium and tellurium were evaporated to dryness as described.

5. Solutions obtained during tests with molybdenum, manganese, iron, copper, bismuth, silver, cobalt, nickel, zinc, cadmium, gallium, indium and thallium were treated with perchloric acid and evaporated to dryness. Solutions obtained during tests with selenium and vanadium were treated similarly but evaporated to fumes of perchloric acid. Solutions obtained during tests with antimony were treated with perchloric and sulphuric acids, evaporated to fumes of perchloric acid and treated with *aqua regia* to convert any unreactive antimony species present into antimony(V) species. After the removal of *aqua regia* by evaporation of the solutions almost to dryness, the salts were dissolved in dilute potassium hydroxide solution and antimony was determined by the iodide method.[7] Solutions obtained during tests with tin or uranium were treated with sulphuric, hydrochloric and perchloric acids and evaporated to dryness before the determination of tin by AAS[9] or of uranium with azide. In tests with rhodium, the solutions were treated with hydrochloric acid and evaporated to dryness, the residues were dissolved in dilute potassium hydroxide solution and the resulting solutions were acidified with hydrochloric acid before the AAS determination of rhodium.

6. Solutions obtained during tests with platinum, gold and palladium were treated with *aqua regia* and evaporated to dryness. Gold and platinum were determined by AAS after dissolution of the residues with *aqua regia*.

RESULTS

The degree of extraction of a number of elements into chloroform, as ethyl xanthate complexes, from 0.1–8*M* sulphuric acid is given in Table 2 and Figs. 1–4. Extraction from >8*M* sulphuric acid was not investigated because the density of these solutions is greater than that of chloroform, which precludes the use of a simple triple extraction. The acid concentrations shown are the initial concentrations of the solutions before the addition, in three successive extraction steps, of a total volume of 2.5 ml of 20% potassium ethyl xanthate solution. The oxidation states of the elements shown are those in which they were initially added. Tests with arsenic, antimony, thallium, selenium and tellurium were also carried out on the highest oxidation states because of the known reducing action of xanthates.[1] Tests with platinum, palladium, rhodium, ruthenium and iridium were done on their most common oxidation states. The extraction of osmium and lead was not investigated because a suitable osmium compound was not immediately available and because lead sulphate is formed in sulphuric acid medium. Tests with some of the elements listed and with other metal ions (not shown) showed that manganese(II), zinc, selenium(VI), tellurium(VI), cerium (IV), chromium(III), ruthenium(III), iridium(IV) and germanium(IV) are not extracted from 0.1–8*M* sulphuric acid.

Table 1. Analytical methods used to determine the degree of extraction

Iron, cobalt, nickel and cadmium

Table 2 shows that iron(II), iron(III), cobalt(II), nickel and cadmium are partly extracted as ethyl xanthate complexes at low sulphuric acid concentrations, particularly in the range 0.1–1*M*. This is consistent with the extraction of these ions from hydrochloric acid media[2] except that more iron(III) is extracted from 0.1*M* sulphuric acid than from 0.1*M* hydrochloric acid, probably because it forms a weaker sulphato-complex than chloro-complex.

Gallium, indium and thallium

Gallium(III) xanthate is only slightly extracted from 0.1*M* sulphuric acid. More is extracted from 0.1*M* hydrochloric acid.[2] The extraction of indium(III) xanthate is better from sulphuric acid media. The colourless thallium(I) complex, which is of limited solubility in non-polar solvents,[10] is only slightly extracted from either 0.1*M* sulphuric or hydrochloric acid. The yellow thallium(III) complex is partly extracted from 0.1–2*M* sulphuric acid. Previous work[2] showed that it is more readily extracted from hydrochloric acid media.

Tin, copper and silver

Tin(IV), which is probably reduced to tin(II) by xanthate,[11] is appreciably extracted as a yellow complex from 0.1–2*M* sulphuric acid. This is consistent with its extraction from hydrochloric acid solutions except that the complex is more readily extracted from sulphuric acid medium, probably because of the more feeble complexing action of sulphate ions.

Copper(II) is largely extracted over the whole range of acid concentration investigated. However, as in previous work involving its extraction from hydrochloric acid media,[2] the results obtained were erratic. This is because of the low solubility in chloroform of the copper(I) ethyl xanthate complex, which is formed by the decomposition of the copper(II) complex.[12]

Silver is appreciably extracted over the whole range of sulphuric acid concentrations investigated. Earlier work[2] showed that it is not extracted from >3*M* hydrochloric acid, which suggests that it forms a stronger chloro-complex than xanthate complex. The degree of extraction is influenced by the limited solubility of the yellow complex in chloroform, since, as found previously, some of the precipitate remained at the interface after the extraction step.

Gold, platinum and palladium

Gold(III) and platinum(IV) are both appreciably extracted from 0.1–8*M* sulphuric acid. The erratic results obtained for these elements are consistent with those reported for their extraction from hydrochloric acid media.[2] In tests with gold, a yellow colour was produced in the aqueous phase on the initial addition of xanthate solution. This colour rapidly disappeared when the solution was mixed or after it was shaken with chloroform. As found previously,[2] this suggests that gold reacts to form a gold(III) complex that rapidly decomposes to a gold(I) complex of limited solubility. Presumably, the yellow platinum complex is a platinum(II) complex formed by the reduction of platinum(IV) to platinum(II) by xanthate.[13] In tests with platinum, a red-brown precipitate, insoluble in chloroform, formed in the aqueous phase on standing.

Palladium(II) is completely extracted from 0.1–8*M* sulphuric acid. Complete extraction is also obtained from 0.1–10*M* hydrochloric acid.[2]

Rhodium

Table 2 shows that rhodium(III) is slightly extracted from 0.1–8*M* sulphuric acid. It is not extracted from 0.1–10*M* hydrochloric acid.[2] An additional test carried out at ~pH 3 showed that, at the 1-mg level, ~15% of the rhodium(III) present was extracted into chloroform when the aqueous phase was allowed to stand for ~1 hr after the addition of xanthate solution. This suggests that the rate of formation of the complex is slow. The formation of a yellow rhodium(III) xanthate complex has been reported previously.[14]

Vanadium and uranium

The extraction of vanadium and uranium from sulphuric acid media is consistent with that reported for hydrochloric acid media.[2]

Arsenic, antimony and bismuth

Figure 1 shows that arsenic(III) can be completely extracted into chloroform from 0.1–8*M* sulphuric acid and, as found previously,[2] from 0.1–10*M* hydrochloric acid. However, the extraction of arsenic, initially present as arsenic(V), from sulphuric acid solutions is not entirely consistent with that found for hydrochloric acid solutions. From sulphuric acid solutions, more arsenic is extracted at low acidities, and less from ~5–8*M* solutions. Previously,[2] it was considered that the increase in extraction from ~5–10*M* hydrochloric acid was caused by the reduction of

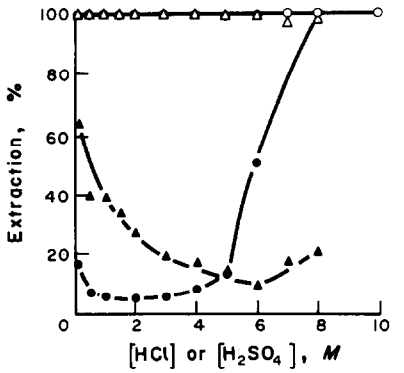

Fig. 1. Extraction of As(III) (open symbols) and As(V) (filled symbols) as a function of the HCl (circles) or H_2SO_4 (triangles) concentration, respectively.

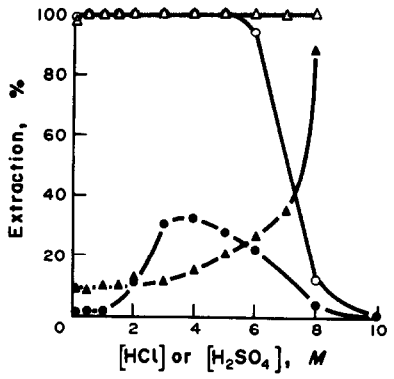

Fig. 2. Extraction of Sb(III) (open symbols) and Sb(V) (filled symbols) as a function of the HCl (circles) or H_2SO_4 (triangles) concentration, respectively.

arsenic(V) by chloride ions and its subsequent extraction as either arsenic(III) xanthate or as the chloro-complex. The extraction profile shown in Fig. 1 for arsenic(V) extracted from sulphuric acid solutions definitely suggests that the increase in extraction from the ~ 6–$8M$ acid (*i.e.*, in the absence of chloride ions) can only be caused by the extraction of arsenic(III) xanthate resulting from the reduction of arsenic(V) to arsenic(III) by xanthate. Tests showed that no arsenic(V) was extracted from sulphuric acid solutions in the absence of xanthate. However, the fact that considerably more arsenic is extracted from ~ 5–$8M$ hydrochloric acid than from 5–$8M$ sulphuric acid suggests that, in hydrochloric acid media, the increase is most probably caused by the reduction of arsenic(V) by both chloride ions and xanthate. The degree of extraction at both low hydrochloric and sulphuric acid concentrations must also be due to partial reduction of arsenic(V) by xanthate. Possibly xanthate reduces arsenic(V) more readily in both dilute and strongly acidic media than at intermediate acidities in the range ~ 2–$5M$.

Figure 2 shows that antimony(III) can be extracted quantitatively as the ethyl xanthate complex from 0.1–$8M$ sulphuric acid, whereas, in hydrochloric acid media, complete extraction is only obtained from 0.1–$5M$ solutions.[2] The decrease in extraction from $\geq 6M$ hydrochloric acid is probably caused by the formation of stronger chloro-complexes. Previously,[2] it was considered that the increase in the extraction of antimony, initially present as antimony(V), from ~ 2–$6M$ hydrochloric acid was caused by the extraction of antimony(V) as the chloro-complex. However, as shown in Fig. 2, antimony present as antimony(V) is also extracted from sulphuric acid solutions and the degree of extraction increases considerably from $\geq 6M$ sulphuric acid. This shows that antimony(V) is partly reduced to antimony(III) by xanthate in sulphuric acid media. Consequently, in hydrochloric acid solutions, the increase in the extraction from ~ 2–$6M$ hydrochloric acid is probably due both to the partial extraction of antimony(V) as the chloro-complex and to the extraction, as the xanthate, of some antimony(III) produced by reduction of antimony(V) with xanthate. However, the fact that very little antimony, present as antimony(V), is extracted from $8M$ hydrochloric acid compared with that extracted from $8M$ sulphuric acid suggests strongly that the decrease in extraction at high hydrochloric acid concentrations is probably due to the formation of unreactive hydrolysis products of antimony(V).[15]

Figure 3 shows that bismuth is completely extracted into chloroform as the xanthate over the whole range of sulphuric acid concentration investigated. However, in hydrochloric acid media, the extraction is only quantitative from ~ 0.1–$3M$ hydrochloric acid.[2] The decrease in extraction from $> 3M$ hydrochloric acid is considered to be due to the formation of stronger chloro-complexes.

Molybdenum, rhenium and chromium

The extraction profiles for the extraction of molybdenum(VI)—which is reduced to molybdenum(V) by xanthate[1]—from both sulphuric and hydrochloric acid media[2] are shown in Fig. 4. The anomalous results obtained for sulphuric acid solutions were confirmed in several additional tests. The "hump" in the extraction profile at $\sim 4M$ sulphuric acid and the increase in the degree of extraction at $\sim 8M$ sulphuric acid are considered to be caused by the formation of

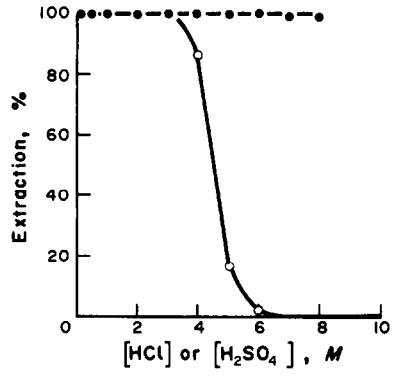

Fig. 3. Extraction of Bi as a function of the HCl (○) or H_2SO_4 (●) concentration.

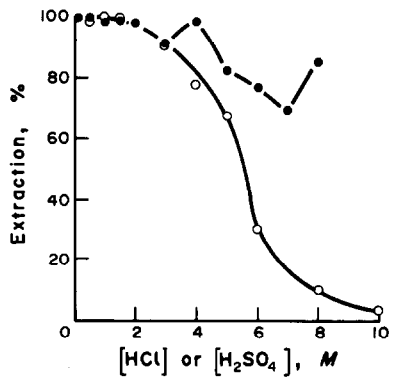

Fig. 4. Extraction of Mo(VI) as a function of the HCl (○) or H_2SO_4 (●) concentration.

different xanthate complexes, since there is a change in the colour of the extracts. Those from 0.1–2*M* sulphuric acid were reddish-purple, and those from 4 and 8*M* solutions were brownish-red and bluish-red, respectively. Changes in the colour of the extract were not observed in earlier work involving the extraction of molybdenum from hydrochloric acid media.[2] Previous investigators have reported that molybdenum forms different xanthate complexes.[16, 17] The lower degree of extraction from $>3M$ hydrochloric acid than from sulphuric acid is considered to be due to the formation of stronger chloro-complexes.

Table 2 shows that the extraction of rhenium, initially present as rhenium(VII), increases from $\sim$2–8*M* sulphuric acid. This is reasonably consistent with its extraction from hydrochloric acid solutions.[2] Because it is rhenium(III) that is considered to react with xanthate,[2] the results obtained for sulphuric acid media suggest that rhenium(VII) is reduced to rhenium(III) by xanthate. Rhenium is not extracted from either sulphuric acid or hydrochloric acid solutions in the absence of xanthate.

Previously[2] it was found that neither chromium(VI) nor chromium(III) is extracted as a xanthate from hydrochloric acid solutions. However, Table 2 shows that small amounts (μg-quantities) of chromium(VI) are extracted from dilute sulphuric acid solutions. Chromium(III) is not extracted. Because chromium(VI) and, particularly, chromium(III) react very slowly with xanthate in weakly acidic solutions,[18] and at hydrochloric acid concentrations above about 2*M*, because chromium(VI) is reduced to chromium(III) by chloride, neither of these ions would be expected to be extracted from hydrochloric acid media.

Selenium and tellurium

The results in Table 2 show that both selenium(IV) and tellurium(IV) are completely extracted as xanthate complexes from 0.1–8*M* sulphuric acid. These findings are consistent with those reported previously for hydrochloric acid media.[2] However, although in hydrochloric acid solutions, the extraction of these elements, when present as selenium(VI) and tellurium(VI), gradually increases with an increase in the hydrochloric acid concentration to $\sim$100% from $\geq 8M$ and $\geq 10M$ hydrochloric acid, respectively, no extraction of these ions occurred from sulphuric acid solutions. Consequently, the increase in extraction from hydrochloric acid must be due to the reduction of selenium(VI) and tellurium(VI) to selenium(IV) and tellurium(IV) by chloride ions—not by xanthate ions.

DISCUSSION

The results obtained in this work and those obtained previously[2] have led to a better understanding of the processes involved in the extraction of various elements as ethyl xanthate complexes from sulphuric and hydrochloric acid media, particularly those elements that form strong chloro-complexes. The results also show that, in some instances, it may be more advantageous to extract from sulphuric acid solutions than from hydrochloric acid solutions, and *vice versa*. The separations of selenium(IV) and tellurium(IV) from selenium(VI) and tellurium(VI), respectively, are possible by extracting quadrivalent selenium and tellurium from $\sim$0.1–8*M* sulphuric acid. However, a strongly acidic hydrochloric acid medium, or a mixture of hydrochloric and sulphuric acids, is preferable for the separation of total selenium and tellurium, because the chloride ions present function as the reductant.[3, 5] Bismuth and antimony(III) can be quantitatively extracted as the xanthates over a much wider range of sulphuric acid concentration ($\sim$0.1–8*M*) than hydrochloric acid concentration ($\sim$0.1–3*M* and $\sim$0.1–5*M*, respectively). For the separation of arsenic(III), 10*M* hydrochloric acid is preferable to 8*M* sulphuric acid because, in general, fewer other elements are co-extracted from hydrochloric acid solutions. In dilute acid solutions, less gallium, thallium(I) and thallium(III) will be extracted from sulphuric acid than from hydrochloric acid of the same concentration. The group separation of cobalt, nickel, indium, tin, palladium, molybdenum, bismuth and possibly antimony(III) and arsenic(III)—after suitable reduction of antimony(V) and arsenic(V)—should be possible by extraction from $\sim$0.1*M* sulphuric acid. As mentioned previously,[2] the co-extraction of iron(III) and copper(II) can be avoided by reduction with ascorbic acid and complexation with thiourea, respectively. Tin can be prevented from extraction by complexing it with hydrofluoric acid[7] and the extraction of thallium(III) can be minimized by reducing it to thallium(I) with sulphurous acid.[6]

In this work, tests showed that neither ruthenium(III) nor iridium(IV) is extracted from 0.1–8*M* sulphuric acid. Previous work[2] showed that they are also not extracted from 0.1–10*M* hydrochloric acid. However, in an additional test with ruthenium at $\sim$pH 3 in the presence of tartaric acid to keep it in solution, a green extract was obtained when the aqueous phase was allowed to stand for $\sim$1 hr after the addition of xanthate solution. This extract contained $\sim$18% of the ruthenium initially added (500 μg). This shows that ruthenium forms a xanthate complex and that the rate of formation of the complex is slow. Recently, ruthenium has been determined by AAS after the extraction of the ruthenium(III) xanthate complex into methyl isobutyl ketone at pH 7–8.[19] No iridium(IV) was extracted in a similar test at $\sim$pH 3.

As mentioned previously,[2] care should be taken in applying the results given in this paper to specific analytical problems, because the extraction profiles of the elements may change somewhat with factors such as the amount of the species to be extracted, the time allowed for complex formation, the amount of matrix elements present, the presence of complexing agents and the amount of potassium ethyl xanthate and the volume of chloroform used for extraction.

It should be emphasized that because of the toxic nature of xanthates, weighing of xanthate compounds, extractions and all other operations involving their use should be prepared in a fume hood. Xanthate solutions should be added by pipette with the aid of a suction bulb or by using a graduated or marked medicine dropper. The aqueous phase remaining after the extraction and any excess of xanthate solution should be treated with concentrated nitric acid and boiled vigorously to decompose the xanthate before disposal of the solution. Recent studies of the health of workers in industrial plants involved in the production of xanthates and other organic sulphur compounds, in which the air contains carbon disulphide and xanthate vapour, have shown that prolonged exposure to these vapours causes a high rate of respiratory illnesses, dermatitis, headaches, fatigue, insomnia, marked changes in liver functions, disorders of the nervous and cardiovascular systems and other related disorders.[20–23] The authors can attest to allergic reactions such as severe sneezing and nasal congestion.

VARIABILITY OF SELECTIVITY COEFFICIENTS OF SOLID-STATE ION-SELECTIVE ELECTRODES

ADAM HULANICKI and ANDRZEJ LEWENSTAM
Department of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 7 *September* 1981. *Revised* 22 *January* 1982. *Accepted* 11 *February* 1982)

Summary—The generalized model for the selectivity mechanism of solid-state ion-selective electrodes has been experimentally verified. The experimental parameters investigated were the concentration of interfering ion, temperature and stirring. Among the systems studied were electrodes sensitive to chloride (bromide, iodide), bromide (chloride, iodide), iodide (chloride, bromide), silver (copper, lead), copper (silver, lead) and lead (silver, copper), the species given in brackets being considered as the interferents. The model has been confirmed except for cases where the concentration of ions formed at the electrode surface by metathesis is too small to be the factor that dictates the electrode potential.

The literature data and our own measurements of the selectivity coefficients of a number of ion-selective electrodes have pointed out discrepancies which should be explainable on the basis of an adequate model of electrode function and mechanism of interference. Such differences were found for both liquid-state and solid-state electrodes. The latter were studied in this work.

In previous papers[1,2] we have reported an important role of diffusion processes which are a consequence of metathesis at the interface between the electrode material and the electrolyte solution. In the processes a significant part is played by the nature of the products formed as the result of an exchange reaction, and by their activity or inactivity in the electrode phenomena. From consideration of both the diffusion processes and the thermodynamic equilibrium we have proposed a generalized model of electrode interferences.[3]

The principal assumptions of the generalized model are (*a*) zero-current conditions, (*b*) total electroneutrality, (*c*) rapidity and reversibility of the ion-exchange processes, (*d*) constancy of the appropriate chemical standard potentials, (*e*) constancy of the diffusion coefficients in the solution.

For a reasonable mathematical description of the processes, the following simplifications have been introduced: (*a*) electrochemical potentials change only in the direction perpendicular to the macroscopic membrane surface, (*b*) concentrations of ions change linearly within the diffusion region, (*c*) steady-state distribution exists at the membrane interface, (*d*) activities are equal to concentrations, (*e*) other processes, such as redox, adsorption, *etc.*, are negligible.

The treatment presented below deals with solid-state electrodes for which it can be assumed that the mobility of interfering ions in the membrane phase is negligible. The opposite case has previously been considered,[3,4] a typical example being attack of hydroxide on the fluoride electrode.

In the case of the electrodes considered the assumptions mentioned have led to an equation describing the electrode potential in a system where the following metathetic reaction occurs:

$$AB + C \rightleftharpoons AC + B$$

where B and C denote the main and interfering ions, respectively, and A the active membrane site.

At this point it must be noted that the product of the exchange reaction, depending on the conditions of its formation, may be electrode-active (mixed phase formation) or electrode-inactive (dissolution–precipitation).

The electrode potential is generally described by the equation:[3]

$$E = \text{constant} \pm \frac{RT}{F} \ln \frac{K_{B,C}}{S\frac{D_C}{D_B} + (1 - S)K_{B,C}} \left([B] + \frac{D_C}{D_B}[C]\right) \quad (1)$$

where D_B and D_c are the diffusion coefficients of B and C, respectively, $K_{B,C}$ is the equilibrium constant of the metathetic reaction and S is the apparent coverage factor. S may be evaluated from equation (1) by using measured potential values and literature data for the thermodynamic equilibrium constants and diffusion coefficients (Table 1). These data are mostly reliable, but discrepancies in data found in the literature indicate that in some cases their accuracy may be questioned. The sign preceding the logarithmic term depends on whether the electrode is cation or anion selective.

With proper approximations the generalized equation is reduced to that given by the total equilibrium model of Pungor and Tóth.[5]

$$E = \text{constant} \pm \frac{RT}{F} \ln([B] + K_{B,C}[C]) \quad (2)$$

Table 1. The constants used in the calculations

AgCl	9.8	6	Cl^-	2.03	8

based on mixed-phase formation, for which the selectivity coefficient is the ratio of the solubility products of both solid phases. Otherwise the generalized equation is reduced to that postulated by the diffusion model suggested previously:[1,2]

$$E = \text{constant} \pm \frac{RT}{F} \ln\left[\frac{K_{B,C}}{K_{B,C} + D_C/D_B}\left([B] + \frac{D_C}{D_B}[C]\right)\right] \quad (3)$$

which considers only the dissolution–precipitation mechanism, for which the selectivity coefficient is the ratio of the corresponding diffusion coefficients when $K_{B,C} \gg 1$ or equal to the ratio of the solubility products when $K_{B,C} \ll 1$. These two models assume invariable values of the selectivity coefficients, while in the generalized model the values are variable, which can explain a number of discrepancies found among the literature data.

The aim of this study was to confirm the validity of our model for several electrode systems. It was expected that under properly chosen experimental conditions it would be possible to find values of selectivity coefficients which correspond to the two limiting cases as well as to the intermediate range, in which the selectivity coefficients are time-dependent.

Among the systems studied were: chloride electrode with bromide and iodide interferences, bromide electrode with chloride and iodide interferences, iodide electrode with chloride and bromide interferences, silver electrode with copper and lead interferences, copper electrode with silver and lead interferences, and lead electrode with silver and copper interferences.

EXPERIMENTAL

The electrodes used were the Cl 101 chloride electrode (Mera, Poland), OP-Br-7111-C bromide electrode (Radelkis, Hungary), OP-I-7112-C iodide electrode (Radelkis), 94-16 silver electrode (Orion, U.S.A.), 94-29 A copper electrode (Orion), and 94–82 A lead electrode (Orion).

All reagents used were of analytical grade. Solutions were always made in 1*M* potassium nitrate (in doubly distilled water). The measuring cell temperature was controlled to within ±1°.

The selectivity coefficients were evaluated by the method of separate solutions.

RESULTS AND DISCUSSION

Two main cases were considered, according to whether the equilibrium constant for the exchange reaction was larger or smaller than unity. As an example of the former case the results for iodide interference with the chloride electrode are discussed in detail.

The effect of changing the iodide concentration in the range from 10^{-4} to $10^{-1}M$ indicates that the lowest concentration reflects the diffusion model only and even over a period of several hours the selectivity coefficient is close to the ratio of the diffusion coefficients of both ions. The highest concentration results in a nearly immediate potential drop, the final value corresponding to a selectivity coefficient expressed by the ratio of the solubility product of AgCl to that of AgI. Intermediate concentrations produce, after a diffusion-controlled period, a drop in potential to that for the total equilibrium state (Fig. 1). Experimental conditions such as temperature and stirring influence

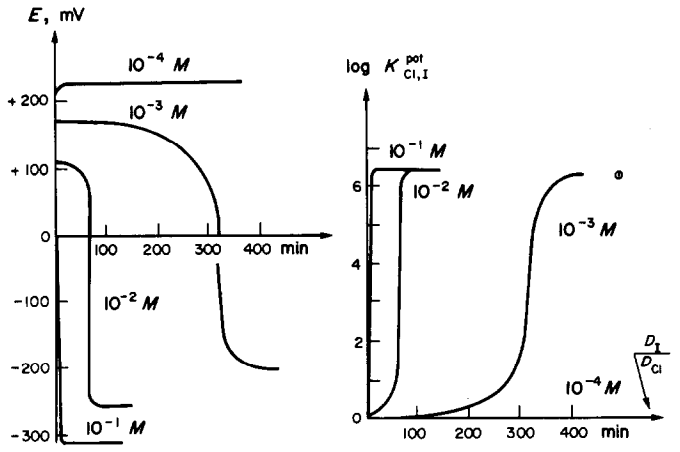

Fig. 1. The effect of concentration of interfering iodide on the potential response of the chloride-selective electrode and on the selectivity coefficient. Temperature 25°C; unstirred solution. The point ⊙ indicates the value of the equilibrium constant calculated on the basis of data given in Table 1.

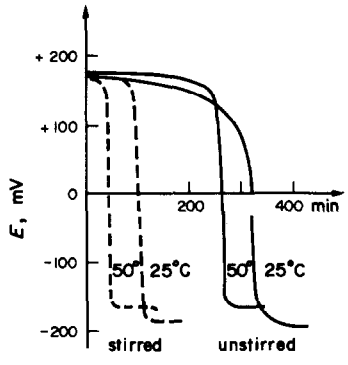

Fig. 2. The effect of stirring and temperature on the potential response of the chloride-selective electrode in presence of $10^{-3}M$ iodide.

this behaviour, shortening (for a given concentration) the diffusion-controlled period (Fig. 2).

Similar behaviour has been observed in other cases, such as the chloride electrode in bromide solution,[3] bromide electrode in iodide solution, copper electrode in silver solution and lead electrode in silver and copper solutions (Fig. 3).

It is obvious that in all instances the selectivity coefficients evaluated fall within the limits defined by both models. However, in some systems the limiting values indicated on the figures are not reached during the experiment. This fact may be interpreted, according to the present model, as due to a slow approach towards the total equilibrium state. On the other hand, it could be assumed that equilibrium is really attained but the equilibrium constants for the given experimental conditions are not known with sufficient accuracy.

As an example of the equilibrium constant being smaller than unity the iodide electrode in bromide solution will be discussed in more detail (Fig. 4). At a bromide concentration of $0.1M$, the equilibrium is rapidly established and corresponds to an iodide concentration of about $10^{-4}M$ at the membrane surface.

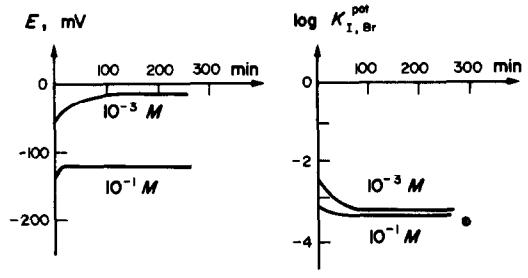

Fig. 4. The effect of concentration of interfering bromide ion on the potential response and selectivity coefficient of the iodide-selective electrode. Temperature 25°C; unstirred solutions. Point ⊙—see Fig. 1.

When the bromide concentration is $10^{-3}M$ the iodide concentration after equilibration is about $10^{-6}M$. At this level the equilibrium is established rather slowly[9] and some parasitic processes may occur. However, the final potential value reflects the expected equilibrium state fairly well. As before, even a small uncertainty in the solubility products may result in the selectivity coefficient changing by up to one order of magnitude. If this is allowed for, the correlation with the expected final value of the selectivity coefficient is quite good.

Similar behaviour was found in the case of chloride attack on the bromide membrane.[3] Such a potential response is due to the exchange reaction proceeding according to the dissolution–precipitation mechanism, for which the selectivity coefficient is given by the ratio of the two solubility products.

The behaviour of the iodide electrode in chloride solution should result in a selectivity coefficient equal to the solubility product ratio, but this is not quantitatively the case, because the iodide concentration in $10^{-1}M$ chloride solution is close to $10^{-7}M$, which corresponds to the range of the calibration curve where parasitic processes may influence the electrode response.[9] We have noted, for example, a significant dependence of the evaluated selectivity coefficient on the electrode pretreatment (Fig. 5).

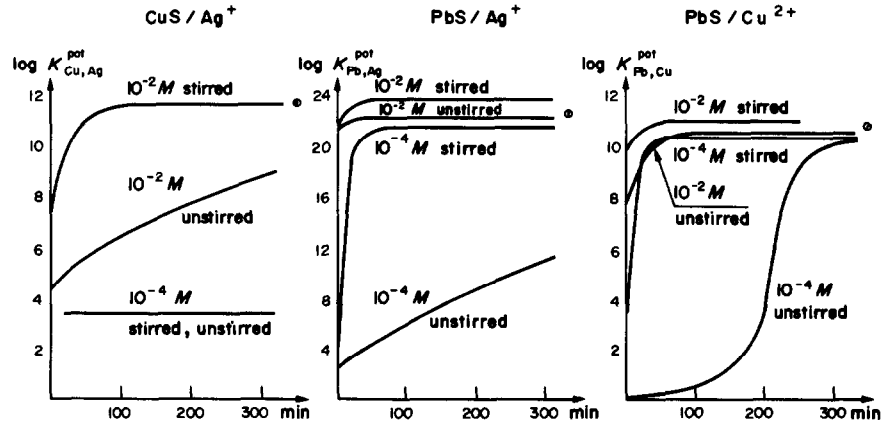

Fig. 3. The effect of concentration of interfering ion and stirring on the selectivity coefficient of metal-selective electrodes. Temperature 25°C. The point ⊙—see Fig. 1.

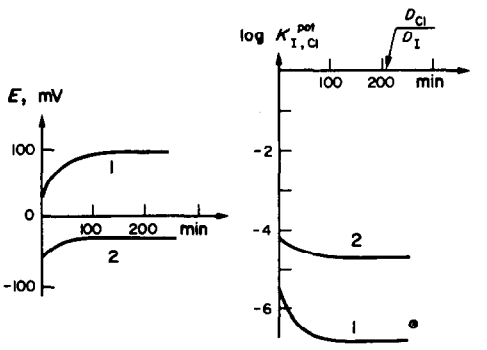

Fig. 5. The effect of iodide-selective electrode pretreatment on the potential response and selectivity coefficient in presence of $10^{-1}M$ chloride. Temperature 25°C; unstirred solutions. 1—Electrode soaked 10 min in $0.1M$ $AgNO_3$, 2—electrode soaked 10 min in $0.1M$ KI. Point ⊙—see Fig. 1.

When the equilibrium constant is significantly smaller, as happens for the attack of lead ions on the copper or silver electrode, as well as for copper attack on the silver membrane, the main ion concentration at the electrode surface is much smaller than that which corresponds to the practical limit of detection. This means that our model cannot then be applied to interpretation of the electrode behaviour because a number of other factors define the electrode potential.[10] Those factors may be adsorption, redox reactions or the level of uncontrolled trace contaminants. Selectivity coefficients can be formally calculated but they have no physical meaning in our model.

We are convinced that the examples presented cover all practical situations that may be met in discussing the selectivity coefficients of solid-state electrodes.

CONCLUSIONS

The investigations presented indicate that in evaluation of selectivity coefficients a number of precautions should be kept in mind. Hitherto, these were intuitively obvious to many workers experienced in the field of ion-selective electrodes. Obtaining reasonable numerical values for selectivity coefficients requires compliance with such experimental conditions as proper ion concentrations, temperature, and stirring. The numerical values obtained fall within the limits given by the limiting models of interference based on the two mechanisms described as dissolution–precipitation and mixed-phase formation. Such a treatment enables us to explain at least some of the existing discrepancies in the selectivity coefficient data in the literature.

We are, however, aware that the model is in some respects an idealized one, and that it does not take into account some of the more complicated effects such as non-ideal miscibility of solid phases, occurrence of chemical reactions more complicated than simple metathesis, irreversibility of processes and slowness of reactions, non-linearity of transport phenomena, mutual interactions of diffusion processes, effect of the microscopic membrane surface and the existence of other parasitic processes.

Quite apart from the detailed considerations of physical and chemical processes it should be firmly stated that thermodynamics and kinetics both contribute to the selectivity of ion-selective electrodes.

(*Received* 23 *November* 1981. *Accepted* 3 *February* 1982)

Summary—Electrothermal atomic-absorption spectrophotometry (AAS), by use of a graphite furnace, in conjunction with sample pretreatment by homogenization, was evaluated as a rapid method for the determination of bismuth, thallium and vanadium in sewage sludge. This method was compared with use of flame, electrothermal and hydride-generation (for bismuth) AAS in conjunction with conventional acid digestion and dry-ashing pretreatments and was found to be applicable to this type of sample. Comparisons were also made between flame and hydride-generation AAS in conjunction with an acid digestion pretreatment for the determination of antimony, arsenic and tellurium in sewage sludge. The hydride-generation technique was considered the better for waste-water samples because of its greater sensitivity.

The disposal of sewage sludge on agricultural land is a common practice in the U.K. Application of the sludge to agricultural land may have beneficial effects,[1,2] but there is a risk of toxic elements accumulating in the soil.[3] This has caused concern because of the potential hazards associated with the contamination of soil, crops and ground water, leading to mobilization of toxic elements in food-chains.[4]

The behaviour of certain toxic elements in waste-water treatment processes has been studied only to a limited extent.[5–7] Concentrations of arsenic,[8,9] bismuth[10] and antimony[8,9] in sewage sludge may be of the order of 30 μg/g, vanadium concentrations as high as 400 μg/g,[9,10] and tellurium and thallium, which have rarely been reported, occur at much lower concentrations.[8]

Various methods have been employed for the determination of elements in waters, waste-waters and sewage sludges;[11–13] atomic-absorption spectrophotometry (AAS) is probably the most widely applicable for environmental samples.[14] Flame AAS is considered the traditional mode of analysis for most elements.[12] The hydride-generation technique is applicable to those elements producing hydrides (which include arsenic, antimony, tellurium and bismuth),[12] especially when they are present at low concentrations. Flameless AAS in conjunction with a rapid pretreatment method has recently been developed for routine metal determination in waste-water samples.[14]

Most analytical methods require a liquid sample; a pretreatment is therefore necessary to dissolve the metal species and destroy the organic matter. Various methods have been used, including ashing procedures and acid digestions.[15]

Sulphuric acid and hydrogen peroxide have been used to digest fish tissue[16] and organic material[17] for analysis for arsenic, and in the determination of vanadium in biological tissue.[18] Nitric acid, sulphuric acid and hydrogen peroxide have been employed to digest seaweed[19] and organic material[20] before arsenic determination. A nitric and perchloric acid digestion for soil and plants[21] and for sludges[22] has also been reported. Nitric, sulphuric and perchloric acids have been employed in the digestion of biological tissue for tellurium, antimony and arsenic determinations.[23] A nitric–sulphuric acid mixture is recommended for antimony in organic matter.[24] A perchloric–hydrofluoric acid mixture has been used for vanadium in geological samples[25,26] and a nitric–perchloric–hydrofluoric acid mixture for vanadium in sediments.[27] Dry ashing has been reported for vanadium determinations in biological tissue.[28]

The experiments reported here were undertaken in order to compare the applicability of flame, electrothermal and hydride-generation AAS, in conjunction with various sample pretreatments, for the determination of arsenic, antimony, bismuth, tellurium, thallium and vanadium in sewage sludge.

EXPERIMENTAL

Instrumental

A Perkin–Elmer model 5000 atomic-absorption spectrophotometer fitted with standard burner heads was used for all flame atomic-absorption determinations. The same spectrophotometer, fitted with a Perkin–Elmer HGA 500 heated graphite atomizer, and a model 603 atomic-absorption spectrophotometer fitted with an HGA 400, were used for flameless determinations. A Perkin–Elmer MHS-1 hydride-generation system was used in conjunction with the model 603 spectrophotometer for the determination of the

hydride-forming elements (arsenic, antimony, bismuth and tellurium). The use of electrodeless discharge lamps (EDLs) has been reported to be of benefit in terms of sensitivity and lamp life.[29] EDLs were used for arsenic, bismuth, antimony, tellurium and thallium. A hollow-cathode lamp was used for vanadium. Instrumental parameters are detailed in Table 1.

In-situ *pyrolytic coating of graphite tubes*

For flameless atomic-absorption determinations of vanadium, pyrolytically coated graphite tubes were used. The coating was performed *in situ* by passage alternately of argon and of a methane–argon mixture (1:9 v/v) under temperature and gas flow conditions optimized to ensure uniform pyrolysis of the methane, thus producing an even coating. The conditions are summarized in Table 2. Pyrolytic coating extended the tube life, improved sensitivity and reduced memory effects, the last being the most pertinent in the determination of vanadium.

Reagents

The following reagents were all BDH "Aristar" grade: nitric acid (s.g. 1.42), sulphuric acid (s.g. 1.84), hydrochloric acid (s.g. 1.18), perchloric acid (s.g. 1.54), hydrofluoric acid (s.g. 1.15) and hydrogen peroxide (100 volume).

Standard solutions

Stock solutions were prepared from the following analytical-grade chemicals: arsenic trioxide, antimonyl potassium tartrate, tellurium, thallium(I) nitrate and ammonium metavanadate. The bismuth stock solution was a commercially available atomic-absorption standard (BDH).

Working standards were prepared by serial dilutions of stock solutions, and contained 1% v/v nitric acid.

Glassware

Borosilicate glassware was used throughout, and was cleaned by soaking for 24 hr in 5% v/v Decon 90 detergent and then 24 hr in 10% v/v nitric acid. PTFE beakers and polypropylene apparatus were similarly cleaned.

Sampling

Sludge samples were collected in polyethylene jerry-cans (cleaned as for glassware) and immediately acidified to a concentration of 1% v/v nitric acid.[30]

Homogenization

The sludge was diluted tenfold with 1% v/v nitric acid. An Ultra Turrax (Scientific Instrument Co., London), fitted with a titanium shaft was used to homogenize the samples as described previously.[31]

Decomposition procedures

Nitric acid–sulphuric acid digestion. A modified version of a recommended digestion[11] was used, as reported before.[32] To undiluted sludge were added 30 ml of concentrated sulphuric acid and 50 ml of concentrated nitric acid; the mixture was heated at 120° and successive 20-ml portions of nitric acid were added until digestion was complete. The digest was filtered and then made up to volume in a 100-ml standard flask.

Nitric acid–hydrogen peroxide digestion. A modification of a previous method[33] was used. Preliminary oxidation with nitric acid ensured a controlled reaction.[34] An addition of 75 ml of nitric acid was made to 50 ml of sludge in a PTFE beaker; further 25-ml portions of nitric acid were added, followed by 10-ml additions of hydrogen peroxide until the digestion was complete. The digest was filtered and made up to volume in a 100-ml standard flask.

Nitric acid–perchloric acid digestion. The recommended method[11] was used with some modification. PTFE beakers each containing 50 ml of sludge were heated at 120°, with several 30-ml additions of nitric acid. Perchloric and nitric acids were added to the cooled reaction mixture, which was then heated to about 200°. Successive additions of perchloric and nitric acids were made until completion of the digestion. The digest was filtered before being made up to 100 ml.

Nitric–perchloric–hydrofluoric acid digestion. The method used was similar to that previously employed[27] and is an extension of the nitric–perchloric acid digestion described above, hydrofluoric acid being added as a final stage, before filtration and making up to 100 ml.

Dry ashing. The ashing procedure adopted was as reported previously.[32] The sludge (50 ml) was charred in covered Pyrex beakers at 200° for 1 hr in a muffle furnace. The temperature was then increased to 450° and kept there for 14 hr. After cooling and the addition of 5 ml of concentrated nitric acid, the ashing was continued for a further hour. The residue was boiled with extraction acids before filtration and making up to 100 ml.

Nitric acid–sulphuric acid–hydrogen peroxide digestion. The method was essentially that described elsewhere.[20] The sludge was charred with sulphuric acid; the digestion was continued with nitric acid and was completed by the addition of hydrogen peroxide. The digest was then filtered and made up to 100 ml.

Prereduction for tellurium, arsenic and antimony

Before hydride generation, reduction of the sample is sometimes required to ensure that the determinand is in the correct oxidation state.[35] To convert all tellurium into tellurium(IV), boiling for 2 min with concentrated hydrochloric acid[35] or boiling for a longer period with *aqua regia*[36] have been proposed. The latter method was used; equal volumes of *aqua regia* (3:1 v/v hydrochloric acid–nitric acid) and digested sample were boiled together for 15 min. Standard solutions were treated in the same manner.

Similarly, the oxidation states of arsenic and antimony affect the sensitivity of the hydride-generation method.[35] Arsenic(V) gives lower sensitivity than arsenic(III).[35] Potassium iodide[21] and sodium iodide[23] have been used to ensure that the arsenic is in oxidation state (III).

Antimony is also reduced with potassium iodide[35] or sodium iodide.[24] Antimony(V) gives only half the sensitivity given by antimony(III).[35] As the reduction is instantaneous, the determination should be performed immediately; delay allows the formation of iodine from the acid solution, which may cause interference in hydride generation.[35]

Statistical treatment

For each pretreatment (acid digestion, dry ashing and homogenization) five replicates and two blanks were used in order to validate the statistical analysis. The results were statistically treated; mean values, within-group relative standard deviation and analysis of variance by the *F*-test were obtained.[37] Tukey's test[37] was used to indicate which means were statistically different at the 0.05 (5%) significance level.

RESULTS AND DISCUSSION

Bismuth

Flame atomic-absorption was used to determine bismuth concentrations in the acid-digested and dry-ashed samples. Electrothermal atomic-absorption was used to analyse the homogenized sludge samples for bismuth, by direct comparison with standards. The acid-digested and dry-ashed samples were also analysed for bismuth by the hydride-generation technique. The values obtained and the statistical analysis of the results are shown in Table 3, and indicate that no significant difference was found between treatments, except for flame atomic-absorption of the perchloric acid digest, and hydride-generation from the hydrogen peroxide digest, the first giving low and the second high results. No results were recorded for the

nitric–sulphuric acid digests, because of severe background interference, but the limit of detection was approximately 0.1 μg/ml.

In the hydride-generation method, prereduction was considered unnecessary since bismuth(III) is virtually the only oxidation state occurring naturally.[35]

The detection limits of the electrothermal and hydride-generation methods were comparable, about 1 ng/ml.

Vanadium

Vanadium in the acid-digested and dry-ashed samples was determined by flame atomic-absorption. The standard-addition method was used to determine vanadium in the homogenized sludge samples by electrothermal atomic-absorption since reproducibility was poor for direct comparison with standards. The results and statistics are shown in Table 4. The relative standard deviations for the flame AAS determinations were all lower than that for the electrothermal determination. However, the results showed agreement statistically, with the exception of the nitric–perchloric acid digest, which gave lower vanadium recoveries than any other pretreatment.

Owing to difficulties in obtaining reproducible signals from electrothermal atomic-absorption for vanadium, and because the relative standard deviations obtained were higher than those of other analytical methods, the reproducibility was examined by having three analysts determine vanadium in five replicate subsamples independently. The comparison in Table 5 indicates that the relative standard deviations differed slightly but not significantly.

Table 5. Influence of change of operator on the reproducibility of vanadium determination in homogenized samples by electrothermal atomic-absorption

Analyst	Mean concentration,* μg/ml	Relative standard deviation, %

3	14.3	13

* The means do not differ at the 0.05 level of significance.

The results for dry ashing and flame atomic-absorption were rather low, probably owing to incomplete mineralization at the temperature used. Ashing at 650° has beeen recommended for vanadium determination.[28] The low recovery from the nitric–perchloric acid digestion could be due to loss during the boiling of acids or interference caused by perchloric acid in the flame atomic-absorption.

Thallium

Thallium concentrations in the homogenized sludge samples were determined by electrothermal AAS with direct comparison with standards and by a standard-additions method. Electrothermal AAS was also employed to determine thallium in the acid-digested and dry-ashed samples (by the standard-additions method) since flame AAS was insufficiently sensitive to detect any thallium. The results are presented in Table 6. No values above the detection limit for thallium were obtained for the dry-ashed samples, possibly because of volatilization of thallium during the heating at 450°. Wet oxidation has been reported as a generally more reliable decomposition method than dry ashing.[15] Although the recovery of thallium from the homogenized samples was comparable with the recoveries from the nitric acid–sulphuric acid, nitric acid–perchloric acid–hydrofluoric acid and nitric acid–perchloric acid digestions, but the nitric acid–hydrogen peroxide digestion gave higher recoveries. It is unlikely that this digestion would cause dissolution of more metal than perchloric or hydrofluoric acid would, and the higher recovery may have been due to high background signals, caused by incomplete destruction of the matrix.

Arsenic

The sludge sample obtained contained arsenic at a concentration too low to be determined by flame

Table 6. Comparison of results for thallium in sewage sludge, obtained by electrothermal atomic-absorption analysis of homogenized, acid-digested and dry-ashed samples

atomic-absorption. To enable this method to be included for comparison, the sludge was spiked with a standard solution of arsenic to give a concentration which would favour all the analytical methods equally. The spiked sludge, digested by the nitric acid–sulphuric acid–hydrogen peroxide method, was analysed for arsenic by flame AAS and the hydride-generation technique. The recovery of arsenic was good and the analytical methods essentially yielded the same result, as expressed in Table 7. Electrothermal AAS of the homogenized sludge samples produced high results (approximately 4 μg/ml) which, if correct, should have been obtained by flame AAS (sensitivity 0.8 μg/ml) analysis of acid-digested samples, but were not. Electrothermal atomic-absorption has been employed previously for the determination of arsenic, although with difficulty.[38] It has been suggested that matrix modification can eliminate depression or enhancement caused by sample components,[39] but it seems that the nature of the homogenized sludge caused interference that could not be compensated by matrix modification and gave erroneously high results. Such molecular spectral interference has already been reported.[40]

No pretreatment of arsenic was thought necessary, because of the agreement between the results of the analytical methods, indicating that all the arsenic was already in the oxidation state (III) needed for hydride generation. Other possible reasons for the concordance of the results include the pH being sufficiently low to ensure that both arsenic(III) and (V) gave the same response,[20] or that the sodium borohydride concentration was high enough to produce an arsenic(V) signal equivalent to 90% of an arsenic(III) signal.[36]

Antimony

Antimony concentrations in the sludge sample were too low to be determined by flame atomic-absorption. To permit a comparison of flame AAS with hydride generation, the sludge was spiked with antimony, as for arsenic. The values obtained are shown in Table 8. A sulphuric acid–hydrogen peroxide digestion has previously been reported to give good recoveries for antimony.[17]

The hydride-generation technique gave better results than flame atomic-absorption. Owing to the virtually total recovery of antimony by the hydride method, no prereduction of antimony was deemed necessary. When sodium iodide was used as a prereductant for antimony the signal response was decreased, possibly because of iodine formation.

† *Aqua regia* also added in digestion.

Tellurium

For the same reasons as for arsenic and antimony, the sludge sample was spiked before digestion with nitric and sulphuric acids and hydrogen peroxide. The values obtained from flame atomic-absorption and hydride generation are presented in Table 9.

The mean recoveries from both analytical methods suggest incomplete recovery or loss during the digestion, although previously a similar digestion was demonstrated to be applicable to tellurium.[17]

As the hydride method produced a little lower mean recovery than the flame AAS method did, the oxidation state of the tellurium was investigated. Treatment of digests with *aqua regia* slightly increased the mean recovery, but the range of values obtained was similar to that obtained without this treatment, and statistical analysis showed that there was no significant difference between the results of flame AAS or hydride-generation AAS, with or without prereduction.

CONCLUSIONS

From the comparison of flame, electrothermal and hydride-generation AAS for the determination of bismuth in sewage sludge, the most suitable method appeared to be electrothermal AAS of the homogenized samples by direct comparison with standard solutions.

For vanadium determination, electrothermal AAS was best, but the standard-additions method was required. The same applies to determination of thallium.

For arsenic, antimony and tellurium, flame AAS has been shown to be insufficiently sensitive to detect environmental concentrations. Hydride generation is, therefore, the method of choice, but is subject to many interferences,[41,42] which may have contributed to the high relative standard deviations, *e.g.*, for tellurium. This effect was limited by using a large ratio of acid volume (20 ml of 3% v/v hydrochloric acid) to digest volume (20–100 μl). Since volatilization of the tellurium hydride separates it from the majority of the matrix components, except other hydride species, interferences are then expected to be small.[23] It has been reported that residual nitric acid and perchloric acid do not cause interference,[23] the major cause being incompletely oxidized organic matter.

(*Received* 6 *November* 1981. *Accepted* 2 *March* 1982)

Summary—A new procedure for the titration of vanadium(IV) with cerium(IV) sulphate, with ferroin as indicator, in aqueous alcohol medium, is reported. The visual titration gives accurate results but potentiometric titration fails in this medium; this failure is attributed to the sluggish indicator electrode behaviour. Experimental conditions for preliminary quantitative photochemical reduction of vanadium(V) with alcohol have been established.

The titration of vanadium(IV) with cerium(IV) sulphate, with ferroin as indicator, is not possible in dilute sulphuric acid medium because of the sluggish ferriin–vanadium(IV) reaction but the potentiometric titration gives good results.[1] We have reported earlier that the titration with ferroin as indicator is satisfactory if the titration medium contains acetic acid[2] or acetone[1] in addition to mineral acid; under these experimental conditions the end-point can also be detected potentiometrically. The failure of potentiometric titration of vanadium(IV) with cerium(IV) sulphate in the presence of even a small amount of ethanol, however, has prompted us to investigate the use of ferroin in aqueous alcohol as titration medium.

EXPERIMENTAL

Reagents

Vanadium(IV) sulphate solution (0.05*M*) and cerium(IV) sulphate solution (0.05*M*) were prepared in 1*N* sulphuric acid and standardized as described by Rao and Dikshitulu.[3] Sodium vanadate solution (0.05*M*) was prepared by treating the requisite amount of ammonium metavanadate with a slight excess of sodium carbonate solution, boiling until free from ammonia, then making up to the desired volume; it was standardized with ferrous ammonium sulphate solution by the procedure of Walden *et al.*[4] A 0.01*M* ferroin solution was used. All chemicals were of analytical reagent grade.

Apparatus

A quinhydrone electrode in 1*M* sulphuric acid (E_0 0.696 V *vs.* NHE),[5] bright platinum electrodes, and a salt-bridge consisting of an inverted U-tube with porcelain discs at the ends and filled with 1*M* sulphuric acid, were used in the potentiometric investigation.

Potentiometric investigation

Vanadium(IV) can be titrated potentiometrically with cerium(IV) sulphate solution in dilute sulphuric acid medium, but the electrode equilibration is slow, taking 5–6 min in the vicinity of the equivalence point (though only 1 min earlier in the titration). The potentiometric titration fails to give accurate results if an alcohol is present, although there is no difficulty in attaining an apparently stable potential with the indicator electrode used. The effect of varying alcohol content is shown graphically in Fig. 1 for methanol and ethanol. Isopropyl alcohol behaves similarly but more is needed to affect the result adversely.

Visual titration

In the titration of vanadium(IV) with cerium(IV) sulphate in dilute sulphuric acid, ferroin gives a premature end-point because reduction of the oxidized indicator by vanadium(IV) is slow. However, in a medium of 0.5–2.5*N* sulphuric acid or 1*M* hydrochloric acid containing 40–60% of alcohol, the titration is satisfactory (the indicator reaction is sluggish at other alcohol concentrations).

Procedure

A solution containing 2.5–25 mg of vanadium(IV) and enough 10*N* sulphuric acid to give an overall final acidity of 0.5–2.5*N* was diluted with water to 25 ml and 20–25 ml of alcohol were added. The mixture was cooled to room temperature, 2 drops of 0.01*M* ferroin were added and the solution was titrated with 0.05*M* cerium(IV) sulphate at the usual speed until near the end-point, a 10-sec delay then being allowed between additions. At the end-point the colour changed sharply from orange-red to bright yellow and was permanent for 3–4 min. An indicator correction of 0.02 ml of 0.05*M* cerium(IV) was needed. Typical results are given in Table 1.

Interferences

Amounts of 55 mg of iron(III), 25 mg of chromium(III), 200 mg of cerium(III), 30 mg of vanadium(V), 300 mg of zinc, 70 mg of nickel, 60 mg of copper and 160 mg of manganese(II) were found not to interfere.

The reverse titration under similar conditions was unsuccessful, premature end-points being obtained.

Differential titration of iron(II) and vanadium(IV)

By combination of the procedure above with that of Walden *et al.*,[4] iron(II) and vanadium(IV) can be determined differentially, with ferroin as indicator. One aliquot is titrated with cerium(IV) sulphate in 10–12*N* sulphuric acid medium to obtain the iron(II) content. Another aliquot is titrated as described for vanadium(IV) to obtain the

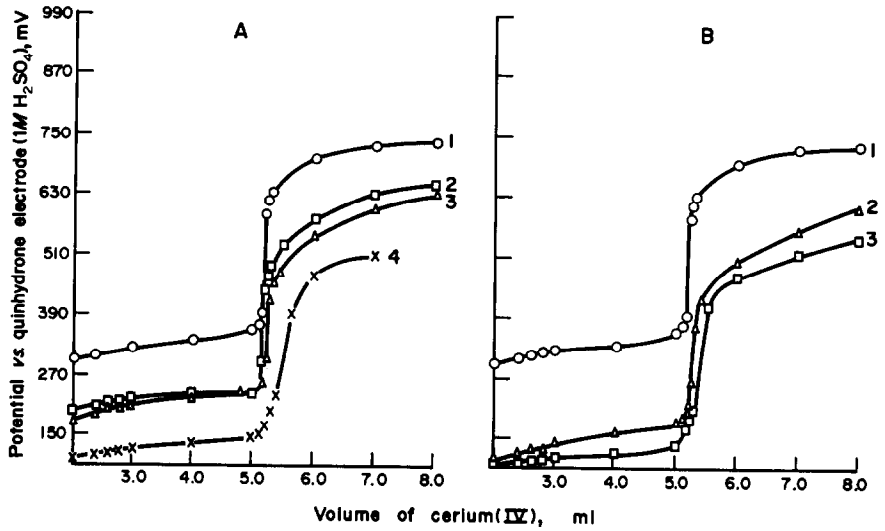

Fig. 1. Potentiometric titration with cerium(IV) sulphate at 28°C: 5.0 ml of 0.052*M* vanadium (IV) in 50 ml of 1*N* H_2SO_4 containing (A) *x*% v/v methanol; (B) *x*% v/v ethanol. (A) 1, O——O $x = 0$; 2, □——□ $x = 2$; 3, △——△ $x = 5$; 4, ×——× $x = 50$.
(B) 1, O——O $x = 0$; 2, △——△ $x = 2$; 3, □——□ $x = 10$.

total of iron(II) and vanadium(IV). Typical results are given in Table 2.

Spectrophotometric investigation

The absorption spectra of vanadium(IV) and (V) in 1*N* sulphuric acid without and with methanol (50% v/v) present were recorded against reagent blanks and are shown in Fig. 2. The methanol had only a small effect on the vanadium(IV) spectrum but a large effect on that of vanadium(V).

Photochemical reduction of vanadium(V)

Preliminary experiments showed that reduction of vanadium(V) by alcohol is quantitative in 2–3*N* sulphuric acid containing 60–70% v/v alcohol on exposure to bright sunlight for about 90 min. The vanadium(IV) can be titrated with cerium(IV) to a visual end-point (the potentiometric end-point gives an inconsistently high result).

Procedure

A solution containing 5–25 mg of vanadium(V) was treated in a 100-ml iodine flask with enough 10*M* sulphuric acid and methanol/ethanol to make it 2–3*N* in sulphuric acid and 60–70% v/v in alcohol when diluted to 40 ml. The flask was stoppered and the solution exposed to bright sunlight for 90 min. During this time the colour changed from bright yellow to blue. The solution was diluted to 50 ml with water and titrated as already described. Typical results are given in Table 3.

Determination of vanadium in ferrovanadium

About 1.0 g of sample (accurately weighed) is treated with 80 ml of 4*M* sulphuric acid and 40 ml of nitric acid (1 + 1) in a 600-ml beaker. When the reaction has abated, the solution is evaporated to dense white fumes, cooled, diluted and again heated to dissolve the salts. The solution is cooled, transferred to a 250-ml standard flask, made up to the mark with distilled water, and titrated by one of the following methods.

Reduction with iron(II). A 5.0-ml aliquot is treated with 5 ml of ~0.1*M* iron(II) and the unreacted iron(II) is titrated with cerium(IV) sulphate in 5*M* sulphuric acid to a ferroin end-point. Enough water and alcohol are then added to make the solution 2*N* in sulphuric acid and 40–50% in alcohol content. The red colour of ferroin is restored, and the solution is titrated with 0.05*M* cerium(IV) sulphate. The second titration gives the content of vanadium.

Reduction with alcohol. A 5.0-ml aliquot is mixed with 3 ml of concentrated sulphuric acid and 8 ml of alcohol and is heated for 10 min on a boiling water-bath, then cooled to room temperature; 20–25 ml each of water and alcohol and 2 drops of 0.01*M* ferroin are added and the mixture is

titrated with 0.05*M* cerium(IV) sulphate. The mean of five analyses of EURO-Standard 577-1 (V 50.16%) was 50.2 by the iron(II) method and 50.1% by the alcohol method.

Analysis of a vanadium complex

Bis(1,10-phenanthroline)oxovanadium(IV) sulphate, prepared as described by Selbin and Holmes,[8] was analysed by the following procedure.

About 0.1 g of complex (accurately weighed) is mixed with 15 ml of 1.5*M* sulphuric acid and heated on a boiling water-bath to assist dissolution, then cooled to room temperature; 20 ml of alcohol are added, followed by 2 drops of 0.01*M* ferroin. The mixture is titrated with 0.05*M* cerium(IV) sulphate.

The average of three determinations for the VO content, 13.1%, was in good agreement with the value of 12.80% calculated for $VO(C_{12}H_8N_2)_2SO_4$. The phenanthroline was found not to interfere, which greatly simplified the procedure, since there was no need to destroy the organic moiety.

DISCUSSION

The possible cerium(IV)–alcohol reaction does not seem to affect the vanadium(IV)–cerium(IV) titration in aqueous alcohol medium, with ferroin as indicator; presumably the vanadium(IV)–cerium(IV) reaction is much faster, and the vanadium(V)–alcohol reaction is very slow. The failure of the potentiometric titration of vanadium(IV) with cerium(IV) sulphate in the presence of methanol or ethanol or isopropyl alcohol is, however, interesting. Such behaviour was not observed for titrations in aqueous acetone[1] or acetic acid[6] medium. The delayed end-point was originally thought to be due to the simultaneous oxidation of alcohol, but the ferroin end-point gives correct results, so this cannot be the case. Even when the potentiometric titration is done with ferroin present there is no change in the results, *i.e.*, the ferroin end-point is correct while the potentiometric end-point is erroneous. Evidently the platinum of the electrode does not catalyse oxidation of the alcohol. Moreover, if the erroneous potentiometric result is caused by abnormal electrode behaviour, ferroin does not correct this even though it is a good electron-transfer catalyst.[7] The effect is also not related to the presence of vanadium since alcohol also causes high results for iron(II) when the titrant is cerium(IV). However, a fresh platinum electrode introduced just after the ferroin end-point has been reached registers a potential high enough to indicate the presence of excess of cerium(IV), and ferroin added at this stage is oxidized. The error in the potentiometric result must therefore be attributed to non-Nernstian behaviour of the electrode response to the cerium(IV)/cerium(III) couple in alcohol medium.

Figure 1 shows that there is a decrease in the vanadium(V)/vanadium(IV) standard potential when alcohol is present. This indicates formation of a more stable complex of alcohol with vanadium(V) than with vanadium(IV), which is confirmed by the effect of alcohol on the absorption spectra (Fig. 2).

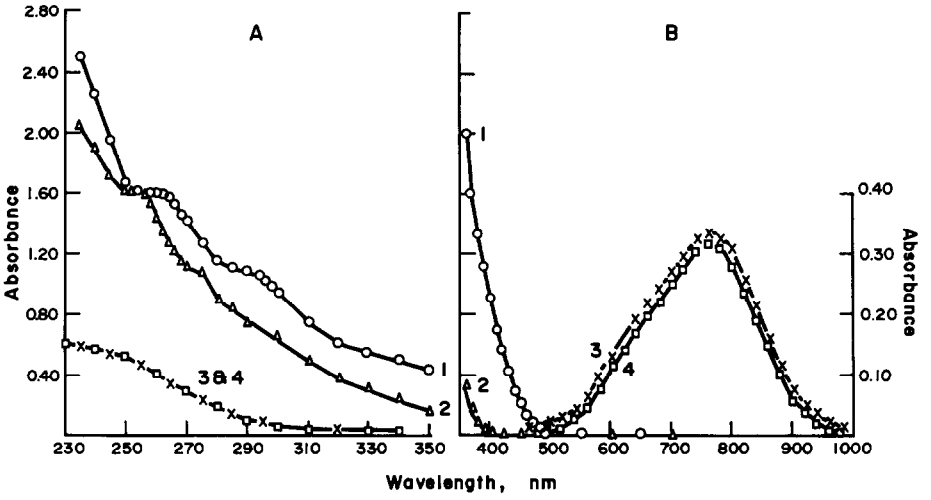

Fig. 2. Absorption spectra. (A) 1, O——O 1.06 × 10^{-3}*M* vanadium(V) in 1*N* H_2SO_4 containing 50% v/v methanol; 2, △——△ 1.06 × 10^{-3}*M* vanadium(V) in 1*N* H_2SO_4; 3, □——□ 2 × 10^{-3}*M* vanadium(IV) in 1*N* H_2SO_4 containing 50% v/v methanol; 4, ×——× 2 × 10^{-3}*M* vanadium(IV) in 1*N* H_2SO_4.

(B) 1, O——O 5 × 10^{-3}*M* vanadium(V) in 1*N* H_2SO_4 containing 50% v/v methanol; 2, △——△ 5 × 10^{-3}*M* vanadium(V) in 1*N* H_2SO_4; 3, ×——× 2 × 10^{-2}*M* vanadium(IV) in 1*N* H_2SO_4 containing 50% v/v methanol; 4, □——□ 2 × 10^{-2}*M* vanadium(IV) in 1*N* H_2SO_4. For curves 3 and 4 in (B), the absorbance scale is given on the right-hand side.

The reaction between vanadium(V) and alcohol in dilute sulphuric acid medium is slow but can be accelerated by exposing the reaction mixture to bright sunlight. Ethanol or methanol is recommended as the reductant because the reaction with isopropyl alcohol is rather slow even in the presence of sunlight.

SEQUENTIAL TITRATION OF IRON(II) AND VANADIUM(IV) MIXTURES WITH CERIUM(IV) SULPHATE, WITH FERROINS AS INDICATORS

K. SRIRAMAM, B. S. R. SARMA, N. RAMABRAHMA SASTRY and A. R. K. VARA PRASAD
Department of Chemistry, Nagarjuna University, Nagarjunanagar—522510 (A.P.), India

(*Received* 1 *September* 1981. *Revised* 5 *January* 1982. *Accepted* 26 *February* 1982)

Summary—The titration of vanadium(IV) with cerium(IV) sulphate, with nitroferroin as indicator, is proposed. Unlike ferroin, the indicator does not need a catalyst in this system. By suitable choice of experimental conditions iron(II) can be titrated first to a ferroin end-point and then vanadium(IV) to a nitroferroin end-point.

The analysis of vanadium or chrome–vanadium steels usually involves preliminary oxidation of the alloying elements to their highest oxidation states, followed by titration with iron(II) in acid solution. It is convenient to do the analysis with a single sample and this is possible if the vanadium(IV) and the excess of iron(II) can be determined sequentially with one titrant. Cerium(IV) is a suitable titrant. Smith and Getz[1] proposed a potentiometric titration in 8*M* perchloric acid medium; Furman,[2] and Dikshitulu and Rao,[3] used dilute sulphuric acid medium, though under different experimental conditions. There seem to be no visual end-point methods for such a sequential titration. We report here the use of ferroin and 5-nitroferroin as indicators for detection of the iron(II) and vanadium(IV) end-points respectively.

The vanadium(IV)–cerium(IV) reaction is considered to be slow, needing elevated temperature when the end-point is detected potentiometrically.[2,4] Rechnitz and Rao,[5] however, inferred from kinetic studies that the reaction is fast and the apparent sluggishness arises in the end-point detection system, *e.g.*, from slow potential equilibration at the platinum electrode. Recently some visual indicator methods[6–8] have been proposed for this titration, with use of a suitable solvent medium or a catalyst. Most of the procedures do not work if the concentration of sulphuric acid in the titration medium exceeds 0.5*M*. Obviously, this places a restriction on extending these procedures to the determination of vanadium(IV) in a test solution containing iron(II). Under the conditions prescribed for the titration of vanadium(IV), iron(II) also reacts with the oxidant, so the sum of the two is obtained. However, the iron(II) alone can be titrated with cerium(IV) sulphate in 5.0*M* sulphuric acid medium with ferroin as indicator, as the vanadium(V)/vanadium(IV) conditional standard potential is then too high for competitive titration of the vanadium. For determination of the vanadium(IV), the acidity must be lowered and a catalyst added. However, the titration is not satisfactory because of the sluggishness of the indicator reactions. In the method reported here, the titration of vanadium(IV) can be completed with 5-nitroferroin as indicator if the solution is diluted with about an equal volume of water.

EXPERIMENTAL

Reagents

Iron(II), vanadium(IV) and cerium(IV) sulphate solutions were prepared and standardized as described earlier.[7] The ferroin and 5-nitroferroin solutions were both 0.01*M*.

Procedures

Titration of vanadium(IV). Between 8 and 30 mg of vanadium(IV) is treated with enough 10*M* sulphuric acid to give an acid concentration of 0.5–2.5*M* on dilution to 45 ml. The mixture is titrated with 0.05*M* cerium(IV) sulphate after addition of one drop of 5-nitroferroin indicator. Near the end of the titration, the titrant must be added dropwise with a 10–15 sec wait after each addition, to allow return of the nitroferroin colour. As the titration proceeds, the masking of the red colour of the indicator by vanadium(IV) decreases. At the end-point the colour changes from red to greenish yellow. Some typical results are given in Table 1.

Amounts of 28 mg of iron(III), 25 mg of chromium(III), 33 mg of manganese(II), 200 mg of zinc, 17 mg of Ag, 875 mg of Cl^- or 700 mg of PO_4^{3-} (examined separately) did not interfere in the titration. Larger quantities of phosphate, however, retarded the indicator oxidation, resulting in overstepped end-points; in the presence of tungstic acid, the colour change is not sharp.

The transition potential of 5-nitroferroin was found to be 1.28–1.25 V under the conditions of the titration (1–2*M* sulphuric acid).

Sequential titration of iron(II) and vanadium(IV). The titrand, containing 8–30 mg each of iron(II) and vanadium(IV), is treated with 10*M* sulphuric acid to give a concentration of 5*M* at the iron(II) end-point. The solution is diluted to 45 ml and a drop of ferroin is added. The solution is titrated with 0.05*M* cerium(IV) sulphate solution till the red colour of ferroin is completely discharged.

Table 2. Determination of iron(II) and vanadium(IV) in mixtures

Taken, *mg*		Found, *mg*	
Fe(II)	V(IV)	Fe(II)	V(IV)
23.63	10.56	23.58	10.53
14.95	20.59	14.92	20.54
12.71	23.36	12.71	23.26
18.28	18.98	18.24	18.92
9.69	23.05	9.66	22.95

The solution is then diluted with 50–60 ml of water and cooled, 1 or 2 drops of 5-nitroferroin solution are added and the titration is continued to the vanadium(IV) end-point. Some typical results are given in Table 2.

Analysis of ferrovanadium

About 1.0 g of the ferrovanadium sample (accurately weighed) is treated with 40 ml of sulphuric acid (1 + 1) and 40 ml of nitric acid (1 + 1) and heated. When the reaction has abated, the solution is evaporated to dense white fumes, cooled to room temperature and diluted to the mark with water in a 250-ml standard flask. A 5.0-ml aliquot is treated with 10 ml of 0.05*M* iron(II) solution and analysed for excess of iron(II) and the vanadium(IV) content according to the procedure described above. Typical results are given in Table 3.

Table 3. Determination of vanadium in ferrovanadium

Sample	Certified value, %	Found, %
EURO-standard 577-1	50.16	50.17

DISCUSSION

The titration of iron(II) with cerium(IV) sulphate in 5*M* sulphuric acid with ferroin as indicator is free from interference by vanadium(IV). The vanadium(IV) can then be titrated in 0.5–2.5*M* sulphuric acid with 5-nitroferroin as indicator. Ferroin is useless for the latter titration because its redox potential is too low and there is a premature end-point, and the indicator reaction is slow.

SIMULTANEOUS DETERMINATION OF BROMIDE AND CHLORIDE IN NATURAL WATERS BY ION-EXCHANGE CHROMATOGRAPHY AND DIRECT POTENTIOMETRY WITH AN ION-SELECTIVE ELECTRODE

H. AKAIWA, H. KAWAMOTO and M. OSUMI
Department of Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376, Japan

(*Received* 8 *February* 1982. *Accepted* 16 *February* 1982)

Summary—A method has been developed for the sequential determination of bromide and chloride in natural waters by use of ion-exchange chromatography and an ion-selective electrode. Hydrous zirconium oxide has successfully been used as the ion-exchanger.

Titrimetric methods using ion-selective electrodes for end-point detection have been applied for the determination of halides in naturally occurring samples.[1–3] Recently, an ion-selective electrode was used as a detector in chromatography.[4] We have reported a method for determination of chlorine and bromine in silicate rocks by ion-exchange chromatography followed by direct potentiometry with an ion-selective electrode,[5,6] but the sequential determination of the two elements was not successful because of the peculiar response behaviour of the silver halide electrode. In the present work, this problem is overcome by reversing the elution order of the halide ions by using an inorganic ion-exchanger, *viz.* hydrous zirconium oxide.[7,8] The method is then suitable for sequential determination of bromide and chloride in natural waters.

EXPERIMENTAL

Reagents

Redistilled water and guaranteed reagent-grade inorganic chemicals were used throughout. The hydrous zirconium oxide was prepared according to the literature[7,8] and conditioned by immersion for one day in 0.5*M* sodium nitrate at about pH 2 before use.

Apparatus

An Orion Model 94-17 silver chloride electrode, Model 94-35 silver bromide electrode, Model 94-53 silver iodide electrode and Model 90-02 double-junction reference electrode were used, and an Orion Model 701 digital pH-meter combined with a Shimadzu R-111M type recorder. The chromatographic column was 6 mm in bore and 11 cm long. The apparatus for ion-exchange chromatography has already been described.[5]

Preparation of the sample solution

A suitable volume of sample solution is taken in a 50-ml standard flask, and 5.0 ml of 5.0*M* sodium nitrate and 1.0 ml of 0.7*M* nitric acid are added to adjust the ionic strength and pH, and the sample solution is diluted to volume. A standard solution is prepared in the same way, with a known amount of bromide and chloride solution.

Procedure

About 5 ml of the sample solution are injected into the column by syringe. Bromide and chloride are eluted in that order with 0.5*M* sodium nitrate adjusted to about pH 2 at a flow-rate of 0.55 ml/min. Bromide and chloride are determined by comparing the peak heights of the chromatograms of the sample and the standard.

Pond water Kezouji park)	31	19.3	35	18.5
Tap water (Nitta Town)	—	38.5	—	39.0
Tap water (Gunma Univ.)	—	9.5	—	9.0

RESULTS AND DISCUSSION

Since hydrous zirconium oxide acts as an anion-exchanger in acidic solution,[7] the pH of both the eluent and the sample solution is adjusted to *ca.* 2. Under the conditions described, bromide and chloride can be quantitatively separated, and the separation is not affected by variation of the pH in the range 1.5–2.5.

The response of the three silver halide electrodes in the chromatography of a mixture of iodide, bromide and chloride is shown in Fig. 1. The silver chloride electrode gave poor response to iodide and bromide, and so did the silver bromide electrode to iodide. Although the silver iodide electrode responded to all three halides, the peaks are not sufficiently resolved and they are asymmetric. Further, there was a drift of the base-line after detection of a halide ion which was not a component of the electrode, and this drift caused disturbance in the following peak. This electrode behaviour was the reason for our failure to determine bromide and chloride sequentially by separation with a gel-type ion-exchange resin:[5,6] the bromide could not be detected with the silver chloride electrode, and when the bromide electrode was employed, the bromide peak height was influenced by the preceding peak of the chloride eluted preferentially from the anion-exchanger. This difficulty has now been eliminated by using hydrous zirconium oxide instead of the anion-exchange resin for the chromatography, since it reverses the elution order for halide ions. The silver bromide electrode is then the most suitable as the detector for both bromide and chloride. Iodide up to 200 ng/ml does not interfere.

The calibration graphs obtained by plotting peak height against concentration are linear over the range of 10–100 ng/ml for bromide and 1.0–9.0 μg/ml for chloride, as expected theoretically,[9] but at higher concentrations tend towards Nernstian response, *i.e.* peak height $\propto \log [X^-]$.

Reproducibility was tested by using a pond water sample from the Gunma University campus, and average values of 27 ng/ml bromide and 8.6 μg/ml chloride were obtained from 5 determinations, the coefficients of variation being 3.6 and 1.6% respectively.

The standard-additions method was used for accuracy tests. Table 1 shows very good agreement of the values obtained by the calibration method with those from the addition method. The results show that the method is satisfactory for the sequential determination of bromide and chloride in natural water samples.

SOME APPLICATIONS OF LIGAND-EXCHANGE—II

SEPARATION OF PHENOLIC COMPOUNDS*

B. M. PETRONIO, E. DE CARIS and L. IANNUZZI
Istituto di Chimica Analitica dell'Università, Rome, Italy

(*Received* 27 *October* 1981. *Accepted* 25 *February* 1982)

Summary—The separation of phenol, 2-nitrophenol, 2,4-dichlorophenol and pentachlorophenol by ligand-exchange chromatography was studied with Chelex 100 resin in the Fe^{3+} form as stationary phase and sodium hydroxide solution (pH 7.5, 11.5, 12) as the mobile phase.

Ligand-exchange chromatography[1] is a technique used to separate compounds which can form complexes with metal ions. Siegel *et al.*[2] have described such a method for the determination of amino-acids in sea-water, Carunchio *et al.*[3] have applied the technique for determination of non-ionic surfactants, and a recent paper[4] describes the quantitative trapping of phenolic compounds by a ligand-exchange process involving a chelating resin in the iron(III) form. The phenols retained may be eluted with sodium hydroxide solution, because of differences between the strength of the metal-binding to the phenol and to hydroxide ion.

The purpose of the present work is to apply the ligand-exchange reaction to the separation of phenols retained on the exchanger, by exploiting differences in the stabilities of iron–phenol complexes. Since the stability constants of some iron(III)–phenol complexes are unknown and the resin matrix determines the strength of the binding of a particular ligand,[5] we have studied the effect of pH (sodium hydroxide concentration) on the distribution coefficients of some monohydric phenols.

EXPERIMENTAL

Reagents

Standard solutions (1 mg/ml) of phenol, 2-nitrophenol, 2,4-dichlorophenol and pentachlorophenol were prepared by dissolving weighed amounts of the pure phenols in acetone. Portions of these solutions were then diluted with distilled water to give the test solutions. All chemicals were analytical grade.

Chelex resin in the iron(III) form. An exchanger of the polystyrene–iminodiacetic acid type (Chelex 100, Bio-Rad) was used. The resin (100–200 mesh) in the sodium form was converted into the iron(III) form by mechanical shaking for 12 hr with 100 ml of 1*M* iron(III) chloride. After equilibration was complete the solution was decanted, and the resin was washed with distilled water until the washings were free from iron(III).

Analytical procedures

Rate of sorption. Weighed quantities of dried resin (3 g) in the iron(III) form were placed in 300-ml glass bottles. To each bottle 100 ml of water containing 0.5 μmole of a phenol were added. The bottles were stoppered and rotated in a thermostat at 20°. At intervals of 1, 2, 3, 5, 10, 20 and 30 min the aqueous phase was separated and the concentration of the phenol in it was determined from its absorbance at 270 nm (phenol), 283 nm (2,4-dichlorophenol), 277 nm (2-nitrophenol) or 250 nm (pentachlorophenol), measured with a Perkin–Elmer 320 spectrophotometer and 1.0-cm cells.

Effect of hydroxide concentration on adsorption. Three g of resin in the iron(III) form and 100 ml of water containing 0.5 μmole of a phenol were placed in a glass bottle and equilibrated for 20 min. The aqueous phase was then decanted and the resin was washed with distilled water and equilibrated with 100 ml of sodium hydroxide solution. The resin was filtered off on a sintered-glass filter and the concentration of the phenol in the aqueous phase determined spectrophotometrically as before. The pH of the aqueous phase was also measured.

The distribution coefficient K_d was calculated from

$$K_d = \frac{\text{mg of phenol in resin–iron(III) phase/g of dry resin}}{\text{mg of phenol in solution phase/ml of solution}}$$

The experiment was repeated with various concentrations of sodium hydroxide.

Separation of phenols. An aqueous solution containing 50 ng of each phenol per ml was passed through a column of Chelex resin in iron(III) form. The phenols retained on the exchanger were sequentially displaced by passing through the column solutions of sodium hydroxide at increasing pH values (appropriate to the K_d values), at a flow-rate of 1 ml/min. The phenols obtained by this stepwise elution were determined spectrophotometrically in successive 10-ml fractions of eluate and also by gas chromatography. Portions of the eluate were acidified and extracted with methylene dichloride, then 1-μl samples of the extracts were injected together with *o*-cresol or 2,3,4,5-tetrachlorophenol as internal standards into a 9-m persilaned glass capillary coated with SP 2100, the injector temperature being 300°. The carrier gas was hydrogen and a flame-ionization detector was used.

*Work carried out on a grant from the National Council of Research, Italy.

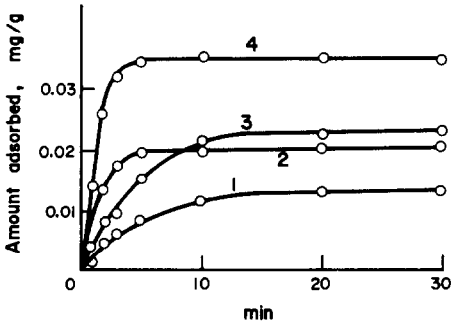

Fig. 1. Rate of adsorption of phenols from aqueous NaOH at 20°: 1, phenol; 2, 2-nitrophenol; 3, 2,4-dichlorophenol; 4, pentachlorophenol. Resin, Chelex 100, Fe^{3+} form; solvent: NaOH at pH 7.5.

RESULTS AND DISCUSSION

Results for sorption equilibria are shown in Fig. 1, which shows that at pH 7.5 2-nitrophenol and pentachlorophenol are adsorbed faster than phenol and 2,4-dichlorophenol. From Fig. 1 the capacity of the resin can be determined; a value of 0.1 μmole/g was obtained for all the phenols tested.

Figure 2 shows that the K_d values for the various phenols decrease with increasing pH. The elution order for these phenols (phenol > 2-nitrophenol > 2,4-dichlorophenol > pentachlorophenol) is independent of pH. This behaviour is in disagreement with the values of the formation constants reported by Sillén and Martell:[6] iron(III)–phenol (log K = 7.78) and iron(III)–2-nitrophenol (log K = 5.59); the first-named is retained less strongly on the resin in the Fe^{3+} form. However, it may be roughly correlated with the pK_a values for the phenols.

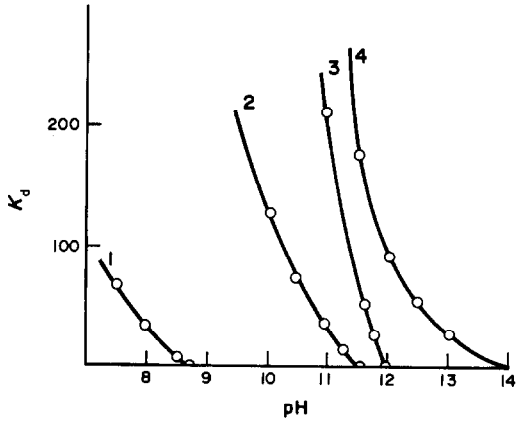

Fig. 2. Effect of pH (NaOH concentration) on the distribution coefficients of phenols: 1, phenol; 2, 2-nitrophenol; 3, 2,4-dichlorophenol; 4, pentachlorophenol. Resin, Chelex 100, Fe^{3+} form.

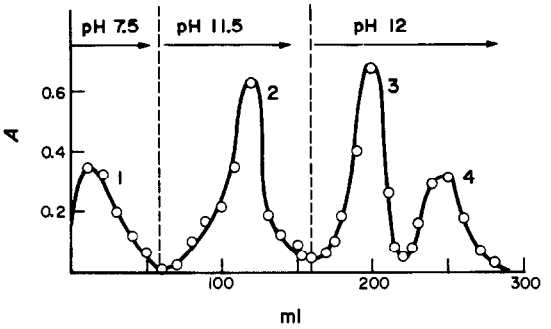

Fig. 3. Elution curves: 1, phenol; 2, 2-nitrophenol; 3, 2,4-dichlorophenol; 4, pentachlorophenol. Column 10 × 70 mm; resin Chelex 100, Fe^{3+} form; eluent NaOH solution; flow-rate 1 ml/min.

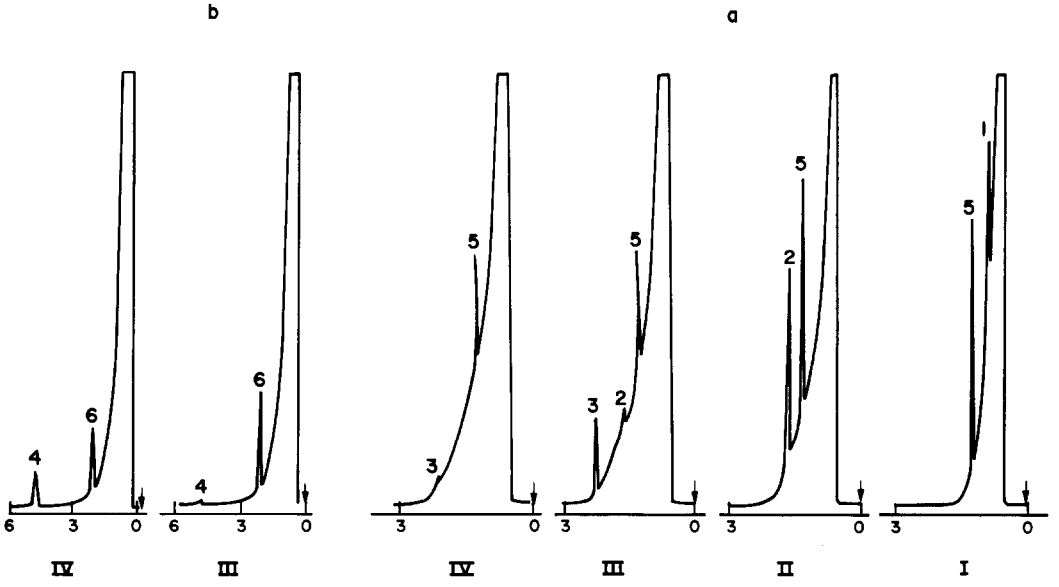

Fig. 4. Gas chromatograms of extracts from NaOH eluates. I = 60 ml, pH 7.5; II = 100 ml, pH 11.5; III = 60 ml, pH 12; IV = 70 ml, pH 12. 1, Phenol; 2, 2-nitrophenol; 3, 2,4-dichlorophenol; 4, pentachlorophenol; 5, *o*-cresol (internal standard); 6, 2,3,4,5-tetrachlorophenol (internal standard); (*a*) column temperature 60°, $\bar{u}$ = 37.5 cm/sec; (*b*) column temperature 130°, $\bar{u}$ = 37.5 cm/sec.

The separation factor calculated from the K_d values of phenol and the substituted phenols is large enough to permit quantitative separation of phenol in the pH range 7.5–10. When sodium hydroxide solution (pH 7.5) is passed through the column at a flow-rate of 1 ml/min, 2-nitrophenol, 2,4-dichlorophenol and pentachlorophenol are quantitatively retained, while phenol passes into the eluate. For pH values > 11, the complex Fe^{3+}–hydroxide in the resin becomes more stable than the complexes iron(III)–2-nitrophenol, iron(III)–2,4-dichlorophenol and iron(III)–pentachlorophenol. The difference in the three K_d values is not large, but it is possible to carry out the separation (Figs. 3 and 4) with different portions of sodium hydroxide solution at pH 11.5 and 12 as eluents.

CONCLUSIONS

The ligand-exchange technique, using a Chelex resin in the iron(III) form, can be applied to trap trace amounts of phenolic compounds from water, and the retained phenols can be separated with an appropriate eluent, provided that there is a sufficiently large difference in the stability of the complexes.

From the distribution coefficients of the phenols between the resin phase and the eluent, it is possible to predict the course of the separation and the optimum conditions.

TITRIMETRIC DETERMINATION OF CHLORAMINE-T AND SOME ALDOSES BY AMPLIFICATION REACTIONS

D. AMIN, K. Y. SALEEM and W. A. BASHIR
Department of Chemistry, College of Science, Mosul University, Mosul, Iraq

(*Received* 27 *April* 1981. *Revised* 30 *November* 1981. *Accepted* 22 *February* 1982)

Summary—A titrimetric method with amplification has been worked out for the determination of chloramine-T and certain aldoses. It is based on Leipert determination of iodide produced in the case of chloramine-T by reduction of the determinand with excess of iodide, and extraction and subsequent reduction of the iodine liberated. In the other case, the aldoses are oxidized with iodine, the surplus oxidant is extracted, and the residual iodide is determined. The method is applicable to chloramine-T in the range 0.01–3 mg, with a relative error between −3.0 and −0.4% and a relative standard deviation of 0.6–0.8%, depending on the amount present, and to 0.05–1 mg of glucose, galactose or arabinose, or 0.1–2 mg of lactose or maltose, with a relative standard deviation of 1.4% for >0.5 mg of aldose.

We have recently reported[1] an application of the so-called Leipert amplification reaction[2] in which an iodine solution in chloroform was used for oxidation of chloral hydrate, and after extraction of the surplus iodine, the iodide produced was determined by the Leipert procedure. We have now extended this technique to determination of some aldoses, and developed a variant of it by which we can determine chloramine-T.

In the new variation, the chloramine-T is reduced by excess of iodide, and the iodine produced is extracted into chloroform, then reduced back to iodide, which is determined by the Leipert procedure with either 6- or 36-fold amplification.[3]

EXPERIMENTAL

Reagents

Chloramine-T solution (*1 mg/ml*). Prepared in distilled water. The chloramine-T was freed from possible contamination with dichloramine-T by washing it several times with carbon tetrachloride, and was dried in a vacuum desiccator over calcium chloride.[4] The purity of the compound was determined iodometrically,[5] on the basis of its active chlorine content. Less concentrated solutions were prepared by dilution.

Iodine solution. Prepared weekly by dissolving 0.3 g of pure iodine in 250 ml of pure dry chloroform, and stored in an amber bottle.

Iodide solution, 1 mg/ml.

Sodium thiosulphate solutions, 0.01 and 0.001*N*. Standardized against potassium iodate solutions of similar normalities.

Sodium sulphite solution, 1%. Prepared fresh daily.

Procedure for chloramine-T

In a 50-ml separating funnel, place 0.2–3 ml of chloramine-T solution (0.01–3 mg), 5 ml of iodide solution, 1 ml of 2*M* hydrochloric acid, and distilled water to make a total volume of 10 ml. Extract the liberated iodine with two 10-ml portions of chloroform. Collect the extracts in another funnel, and shake them with 10 ml of water containing 0.5 ml of 1% sodium sulphate solution to reduce the iodine to iodide. Transfer the aqueous (upper) layer to a 100-ml Erlenmeyer flask, and determine the iodide by one of the following methods. Run a blank determination.

6-Fold amplification. To the iodide solution obtained, add 2 ml of saturated bromine water. Stopper the flask and stir the solution for 5 min. Destroy the excess of bromine by adding 5 ml of 80% v/v formic acid solution, shaking till colourless. Add about 0.5 g of potassium iodide and titrate the liberated iodine with thiosulphate in the usual way.

36-Fold amplification. Transfer the iodine, formed as for the 6-fold amplification, to a 50-ml separating funnel. Extract the iodine with four 10-ml portions of chloroform. Collect the extracts in a 100-ml separating funnel. Wash the combined extracts with 5 ml of water to remove any iodide carried over. Shake the iodine solution with 10 ml of water containing 1 ml of 1% sodium sulphite solution, to reduce iodine to iodide. Transfer the aqueous (upper) layer, containing the iodide, to a 100-ml conical flask, then oxidize it with bromine water and complete the determination in the same way as for the 6-fold method.

Procedure for aldoses

In a 50-ml separating funnel, place a suitable volume (1–2 ml) of the aldose solution (0.05–2 mg of aldose) and dilute to about 10 ml with distilled water. Add the iodine solution (0.3 ml for each 0.1 mg of aldose compound), then add, with shaking, 0.01*M* sodium hydroxide (0.5 ml for each 0.1 mg of the aldose compound). Allow the flask to stand for 15 min (20 min for lactose and maltose) with occasional shaking, then acidify with 0.5 ml of 1*N* sulphuric acid. Extract the excess of iodine with two 10-ml portions of chloroform. Transfer the aqueous phase quantitatively to a 100-ml conical flask, add 3 ml of saturated bromine water and stir for 5 min. Destroy the excess of bromine with 4 ml of 80% v/v formic acid solution. Add about 0.5 g of potassium iodide and titrate the liberated iodine with 0.01*N* thiosulphate, using starch as indicator (for less than 0.5 mg of aldose, use 0.001*N* thiosulphate). Run a blank determination.

1 ml of 0.01*N* thiosulphate ≡ 150.1 μg of glucose or galactose, 125.1 μg of arabinose or 300.3 μg of maltose or lactose.

Table 1. Accuracy and precision of the method

Amount of CAT taken, *mg*	Relative error, % 6-fold	36-fold	Relative standard deviation, % 6-fold	36-fold
0.01	—	−3.0	—	0.8
0.05	−1.5	−1.8	0.6	0.7
0.10	−0.4	−1.2	1.0	0.5
1.00	−0.2	−3.0	0.1	0.6
3.00	−0.9	—	0.9	—

RESULTS AND DISCUSSION

Chloramine-T

The oxidation of iodide to iodine by chloramine-T is a function of many parameters, which have to be optimized. The conditions reported refer to 1 mg of chloramine-T.

Effect of acidity. The reaction is known to proceed rapidly and quantitatively in acidic medium. Experiment showed that the reaction was instantaneous and quantitative in 0.05–0.4*M* hydrochloric acid medium. Higher concentrations of the acid give a high blank because the iodide becomes sensitive to aerial oxidation, and lower concentrations of the acid result in incomplete reaction. Sulphuric acid can be used instead of hydrochloric.

Amount of iodide. For quantitative reaction, for 1 mg of chloramine-T, at least the stoichiometric amount of potassium iodide is needed and up to 5 mg can be safely added. Higher amounts of iodide do not affect the determination, but result in a high blank owing to aerial oxidation or iodide.

Aqueous phase volume. The optimal volume is 10–12 ml. Larger volumes give low recoveries because of the phase volume ratio effect.

Solvent. Chloroform is preferred; although benzene is more efficient, it is regarded as a potential toxic hazard. Two 10-ml portions of chloroform are sufficient for complete extraction of iodine in the 6-fold method, but four are required for the 36-fold procedure; amounts of chloramine-T larger than 1 mg can be determined provided the amount of iodine liberated can be extracted with the volumes recommended.

Formic acid. As this acid serves both for destroying the excess of bromine and for the iodate/iodide reaction in the final step, 5 ml of its 80% solution are used.

Accuracy and precision of the method

The results in Table 1 indicate that the method is satisfactory for determination of small amounts of chloramine-T.

For amounts of chloramine-T below 0.05 mg and for the blank, titrate with 0.001*N* thiosulphate. The conversion factors are:

1 ml of 0.01*N* thiosulphate
≡ 205.8 μg of CAT (6-fold amplification)
≡ 36.0 μg of CAT (36-fold amplification)

The procedures described here are more sensitive than previously published methods.[5,8–12] The 6-fold procedure is faster but the 36-fold method is more sensitive.

Aldoses

The conventional method for determination of aldose compounds involves oxidation with excess of aqueous iodine solution and back-titration with thiosulphate:[6]

$$RCOH + I_2 + 3NaOH \rightarrow RCOONa + 2NaI + 2H_2O$$

The equation shows that two iodine atoms are reduced by one molecule of aldose to two iodide ions which can then be dealt with by the Leipert 6-fold amplification procedure. Hence one molecule of aldose is equivalent to 12 iodine atoms, instead of the 2 in the normal reaction, so the overall amplification is 6-fold.

Preliminary studies confirmed that the amount of sodium hydroxide must be carefully controlled[7] to prevent conversion of part of the iodine into iodate. For 1 mg of sample, 5 ml of 0.01*N* sodium hydroxide will give the optimum concentration. For lower

Table 2. The iodometric determination of aldoses

*Average of 5 determinations.

amounts of aldose, proportionately smaller amounts of hydroxide are used. The second factor is the amount of iodine, and a 1.5–4-fold excess has been found essential for rapid and quantitative oxidation. Larger excesses of iodine should be avoided in order to decrease the number of extractions necessary, since these increase the risk of mechanical loss of aqueous phase, which would cause low results.

The working procedure developed has been applied successfully to the analysis of 0.05–2 mg amounts of aldose compounds. For sample weights lower than 50 μg, inconsistent errors (about ±6%) were obtained, which may be attributed to mechanical losses in the extraction, separation and transfer processes. On the other hand, for sample weights greater than 1 mg, low recoveries were obtained and may be due either to volatilization of some of the iodine produced in the amplification reaction, or to mechanical loss of the aqueous iodide solution during the extraction.

Table 2 shows the recoveries obtained for 5 aldose compounds. They range between 97.0 and 99.2%.

EXTRACTION CHROMATOGRAPHY WITH MACRORETICULAR POLYMER BEADS IMPREGNATED WITH MONOTHIODIBENZOYLMETHANE SOLUTION

ATSUSHI SUGII, NAOTAKE OGAWA and HISASHI YAMAMURA
Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-honmachi, Kumamoto 862, Japan

(*Received* 31 *December* 1981. *Accepted* 9 *February* 1982)

Summary—Extraction chromatography using macroreticular ethylstyrene–divinylbenzene beads impregnated with monothiodibenzoylmethane (SBB) solution has been investigated. Of the solvents used as the stationary phase, heptan-1-ol showed the highest rate of metal extraction, and loading with 0.5 ml of the solvent per g of resin was found to be the optimum. A column packed with such loaded beads can be used for the separation of nickel(II), iron(III) and cobalt(II).

In extraction chromatography, selection of the support is very important in connection with the function of the stationary phase. Although many polymeric substances, including silica,[1] fluorine polymers,[2] polyethylene,[3] polyurethane,[4] polystyrenes[5] and celluloses,[6] have been used as supports, these have individual advantages and disadvantages. We have been interested in macroreticular (MR) polystyrene-based co-polymer beads for use as supports because beads with different physical properties are easily prepared by varying the composition of the monomers and the diluent. Parrish[7] has reported extraction chromatography with commercially available MR polymer beads impregnated with liquid ion-exchanger and pointed out the consequence of hydrophilicity of the supports in the extraction system. We have also reported an extraction chromatographic system based on MR co-polymer beads and a dibutyl phthalate solution of dithizone, and shown that effective metal extraction is markedly dependent on the physical properties of the beads.[8] An analogous extraction system for the separation of inorganic and organic mercury was later reported by Howard and Arbab-Zavar.[9] In these methods using dithizone as the extractant, the most serious disadvantage is the instability of dithizone.

In this paper, an extraction system based on ethylstyrene and divinylbenzene co-polymer beads and monothiodibenzoylmethane (which is more stable than dithizone and shows high affinity for some heavy metals) is investigated. The proposed system is applied to the separation of some metals.

EXPERIMENTAL

Reagents and apparatus

Commercial divinylbenzene (DVB) solution (nominally about 50% weight of DVB isomers, the remainder being ethylstyrene) was used after removal of the phenolic inhibitor. Monothiodibenzoylmethane (SBB) was prepared and purified by the method reported by Yokoyama *et al.*[10] Radioisotopes, ^{59}Fe, ^{60}Co, ^{65}Zn, ^{109}Cd and ^{203}Hg (as chloride or nitrate) were purchased from the New England Nuclear Corp., U.S.A., and the Radiochemical Centre, Amersham, England. All other reagents were reagent-grade materials and were used without further purification. The radioactivity was determined with a scintillation counter equipped with a well-type sodium iodide crystal detector. Copper(II) and nickel(II) were determined by atomic-absorption.

Polymer beads

Spherical beads of MR ethylstyrene–DVB co-polymer were prepared as reported previously.[8] The 35–60 mesh fraction was collected, washed with benzene and dried *in vacuo*. The physical properties of the beads were as follows: specific surface area 378 m^2/g, pore volume 1.44 ml/g, average pore diameter 15.2 nm, water regain[11] 1.40 ml/g, hexane regain[11] 1.46 ml/g.

Coating the beads

The polymer beads (6 g) were immersed for 1 hr in an appropriate amount of solvent and 30 ml of ethyl acetate containing the required amount of SBB, and the ethyl acetate was then evaporated by means of a rotary evaporator at 30–40°. The beads thus obtained contain 4 μmole of SBB per 100 mg of the solvent-loaded beads, and can be stored for at least one week without deterioration.

Batch operation

One hundred mg of the beads impregnated with the stationary phase containing 4 μmole of SBB were put in a glass-stoppered tube (18 × 180 mm), and 10 ml of metal-ion solution (at various pH values) were added. After a given period of mechanical agitation (320 strokes/min with an amplitude of 40 mm), the concentration of metal ion in the aqueous phase was determined.

Column operation

Beads (3 g) impregnated with the stationary phase were packed into a column. The column (10 × 100 mm) was conditioned with 50 ml of 1*M* perchloric acid and then washed with water until the effluent was neutral. Then 2 ml of sample solution [a mixture of equal volumes of $1 \times 10^{-3}M$ iron(III), cobalt(II) and nickel(II) spiked with iron and cobalt radioisotopes] were added to the column and the metals were eluted with buffer, acid solution or organic solvent at a flow-rate of 1 ml/min.

RESULTS AND DISCUSSION

Thiosubstituted β-diketone derivatives such as thiothenoyltrifluoroacetone (STTA) and monothiodibenzoylmethane (SBB) are efficient reagents in inorganic analysis and have been widely used for the extraction and spectrophotometric determination of many metals. Generally, SBB is more stable than STTA in acidic media,[12] and can be stored in the crystalline state for long periods at room temperature. We thought that the stability of the extracting agent was a dominant factor, and therefore employed SBB in this investigation. On the other hand, Parrish[7] pointed out that a certain minimum surface area and pore diameter of the support were necessary in extraction chromatography, and Amberlite XAD-7 (polyacrylic ester) having high water regain was favourable as the support. The MR DVB–ethylstyrene co-polymer beads prepared in our laboratory have fairly high water regain (1.40 ml/g), so the beads are expected to be an efficient support.

The extraction of metal ions at different pH by batch operation is shown in Fig. 1. Dibutyl phthalate (DBP) was used as the solvent in the stationary phase, because it is a stable high-boiling solvent and has poor solubility in aqueous media. Mercury(II) and copper(II) are extracted effectively in the lower pH region. In terms of $pH_{\frac{1}{2}}$ for extraction of metals, the order of extraction is mercury(II) > copper(II) > iron(III) > zinc(II) > cadmium(II) > cobalt(II) > nickel(II). However, cobalt(II) seems to be extracted as the cobalt(III) complex in the extraction system, as described later. This order corresponds essentially to the magnitude of the stability constants and the behaviour of the SBB complexes in liquid–liquid extraction.[13,14] When the beads hold only SBB without any solvent, the metal extraction is markedly decreased. In the proposed extraction system, the solvent plays a very important role. Beads impregnated with only solvent, without any SBB, showed no metal extraction below pH 7.

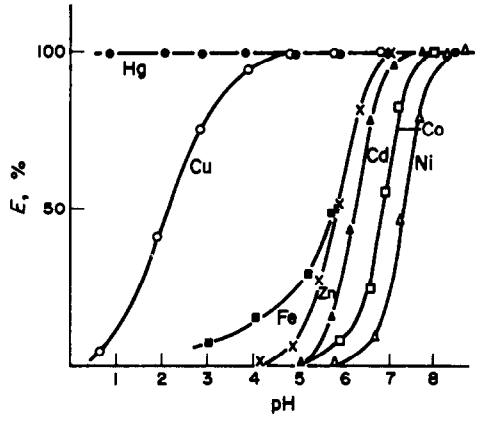

Fig. 1. Extraction of metal ions with SBB–DBP beads. Beads containing stationary phase 100 mg; metal-ion solution 4 × $10^{-5}M$; shaking time 3 hr; solvent loading 0.5 ml/g.

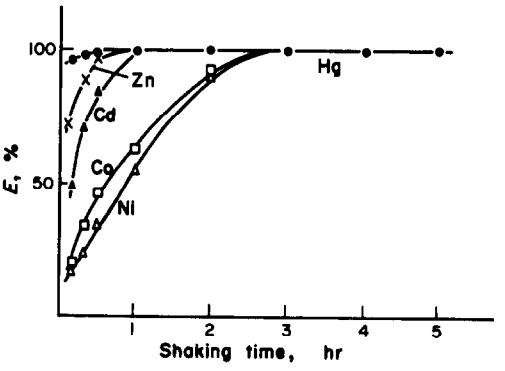

Fig. 2. Effect of shaking time on the extraction of metal ions at pH 8 with SBB–DBP beads. Conditions as for Fig. 1.

The extraction rate for the selected metal ions at pH 7 was determined, and the result is shown in Fig. 2. The extraction of mercury(II), zinc and cadmium reached equilibrium within 30–60 min, but that of cobalt(II) and nickel required about 180 min in the case of SBB–DBP beads. As pointed out by Chaston and Livingstone[15] and by Honjo and Freiser,[14] the slow rate of establishment of extraction equilibrium of the nickel chelate may be due to the change from an octahedral monochelated species $[Ni(H_2O)_4SBB]^+$ to a square-planar species $[Ni(SBB)_2]$.

Although DBP is an interesting solvent to use in the experiment above, its main disadvantage is lack of hydrophilicity. The use of hydrophilic solvents should be more effective in the extraction of metals. The effect of other solvents in this extraction system was investigated and the results are shown in Table 1. To minimize loss of solvent by evaporation during the coating process, solvents having relatively high boiling points were chosen. In addition, solvents giving

lower swelling of the beads were used in order to utilize the characteristic physical properties of the beads. Alcoholic solvents showed higher efficiency for metal extraction than the other solvents. Among the alcohols used, heptan-1-ol was the most effective in the extraction of zinc. In the present extraction system, alcohols seem to contribute to increasing the hydrophilicity, which in turn is related to the extraction kinetics.

The effect of the loading on the extraction of the metal ion was also examined, with heptan-1-ol as the solvent (Table 1). A loading of 0.5 ml/g gives the best results. With lower loading, the surface of the bead is not fully covered with solvent, but with too high a loading the advantage of the characteristic physical nature of the MR beads is lost.

For extraction with the SBB–heptan-1-ol (0.5-ml/g loading) beads, the $pH_{\frac{1}{2}}$ values for extraction of iron(III), cobalt(II) and nickel were 4.4, 4.9 and 6.7, respectively, and nickel was not extracted below pH 5 under the conditions indicated in Fig. 1. Separation of the three metals is shown in Fig. 3. Each metal ion is separated quantitatively by using stepwise elution, in which cobalt is washed out with acetone as well as the extraction system with STTA[16] because cobalt(II) reacts with SBB to form the stable SBB–cobalt(III) complex.[17]

Acknowledgement—The authors are grateful to Professor H. Tanaka, Kyoto University, for his useful suggestions for the extraction system.

POLLUTION-FREE METHOD FOR THE DETERMINATION OF IRON IN IRON ORE

S. KALLMANN and E. KOMARKOVA
Ledoux & Company, Teaneck, NJ 07666, U.S.A.

(*Received* 8 *December* 1981. *Accepted* 9 *February* 1982)

Summary—A method for the determination of total iron in iron ores and concentrates is described which avoids the use of mercuric chloride. The sample is decomposed either by an acid attack or by fusion with sodium peroxide. The hot sample solution in about 6*M* hydrochloric acid is treated with hot 10% stannous chloride solution till pale yellow, followed by addition of a slight excess of 2% titanous chloride solution; the excess is then oxidized with perchloric acid (1 + 1). The solution is rapidly cooled in ice-water, and the iron (II) is titrated with potassium dichromate (sodium diphenylsulphonate as indicator). The results show the same degree of precision, accuracy, and degree of interference as those obtained by the standard stannous chloride–mercuric chloride method.

Iron ore ranks second only to crude oil as a commodity in commerce and industrial use. A shipment of iron ore may weigh as much as 100,000 tons and its evaluation may be based on just a few analytical samples. The accurate determination of iron in iron ore is therefore of considerable economic importance.

No instrumental method has been found accurate enough for the determination of iron in iron ores, although many routine iron determinations are carried out by XRF.

Two titrimetric methods have been recommended by ASTM and ISO for the determination of total iron in iron ores and concentrates.[1–3] They differ only in minor details. The ASTM methods are based on a dry sample, and the ISO methods prescribe an "as received" sample and a separate moisture determination.

One of the methods recommended by both ASTM and ISO uses hydrogen sulphide as reductant, the other uses stannous chloride. In the latter case, a solution of mercuric chloride is used to oxidize the excess of stannous chloride. Both methods therefore involve reagents which in many countries are increasingly rejected for environmental reasons.

The search for pollution-free methods has led ISO Committee TC-102/SC-2 to form two task forces. One of these[4] is considering the use of silver as the reducing agent.[5] Some objections that have been made have prevented this method from being more widely used. One is of a practical nature; the reductor must be prepared, cared for and regenerated, a fact which makes the method less attractive for large-scale routine determinations. The second objection involves the possible formation of hydrogen peroxide. There is also uncertainty regarding possible interference from copper.

The other task force is investigating the reduction of most of the iron(III) with stannous chloride, followed by addition of a slight excess of titaneous chloride. The excess of titanium(III) is removed by a delicate procedure requiring a precise titration (with Indigo Carmine solution as indicator) prior to the titration of the iron(II) with potassium dichromate.[6]

The procedure proposed here avoids the titration of the excess of titanium (III); instead the titanium(III) is oxidized in boiling solution with perchloric acid (which is reduced to chloride). This reaction has been previously used for the determination of perchlorate,[7] but not, to our knowledge, for the oxidation of titanium(III).

Under the conditions described in the procedure, the iron(II) is not oxidized.

EXPERIMENTAL

Reagents

Ferrous ammonium sulphate solution (approx. 0.1*N*). Dissolve 40 g of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$ in 400 ml of sulphuric acid (5 + 95). Transfer to a 1000-ml standard flask, dilute to volume with the same acid, and mix.

Perchloric acid, 70% diluted 1:1.

Phosphoric acid–sulphuric acid mixture. Pour 150 ml of concentrated phosphoric acid into 400 ml of water, with stirring. Add 150 ml of concentrated sulphuric acid, with stirring. Cool and dilute to 1000 ml with water.

Potassium dichromate solution 0.1N. Pulverize about 6 g of standard-grade reagent in an agate mortar, dry in an oven at 105° for 3–4 hr, and cool to room temperature in a desiccator. Dissolve 4.904 g of the dry reagent in 300 ml of water, transfer to a 1000-ml standard flask, dilute to volume, and mix.

Potassium permanganate solution, 25 g/l.

Sodium diphenylaminesulphonate indicator solution. Dissolve 0.2 g of the reagent in water and dilute to 100 ml.

Stannous chloride solution, 10%. Dissolve 20 g of $SnCl_2 \cdot 2H_2O$ in 40 ml of concentrated hydrochloric acid by warming. Dilute to 200 ml with water. Prepare fresh as needed.

Titanium(III) chloride solution, 2%. On a steam-bath warm 1 g of titanium sponge with about 30 ml of concentrated hydrochloric acid until dissolved. Dilute to 50 ml with water. Prepare fresh as needed. If preferred, dilute 1 volume of commercial titanous chloride solution (about 15% w/v) with 7 volumes of hydrochloric acid (1 + 1).

Preparation of sample solution

(*a*) *Acid decomposition.* Transfer 0.4 g of dried 100-mesh sample (weighed to 0.1 mg) to a 400-ml beaker and decompose with hydrochloric acid with addition of a small amount of stannous chloride solution. Filter off and wash the residue, ignite it, then treat the cooled product with hydrofluoric and sulphuric acids. Take up the residue with hydrochloric acid and add to the filtrate, which is then ready for reduction and titration. For details of the acid decomposition step see references 1 and 2. If preferred, analyse the sample on an "as received" basis and determine the hygroscopic water on a separate portion of the sample.[7] This method is limited to samples containing less than 0.1% vanadium or molybdenum.

(*b*) *Fusion decomposition.* Fuse 0.4 g of sample in a zirconium or vitreous carbon crucible with 1.3 g of sodium carbonate and 2.7 g of sodium peroxide, in a muffle furnace at 700° until decomposed. Place the cold crucible in a 400 ml beaker, add about 20 ml of water to the crucible and cover the beaker with a watch-glass. After the reaction has ceased, wash the contents of the crucible into the beaker. If the sample contains more than 0.1% of vanadium and/or molybdenum, filter the alkaline solution and dissolve the iron hydroxide off the filter with hydrochloric acid. If the sample contains less than 0.1% vanadium and/or molybdenum, carefully add 20 ml of concentrated hydrochloric acid to the beaker and mix to dissolve the ferric hydroxide. Rinse the crucible with hot hydrochloric acid and add the washings to the beaker. Evaporate the solution to about 50 ml. For more details see reference 6.

Reduction of iron (III)

Add to the sample solution 1 ml of potassium permanganate solution and boil for about a minute. To the hot solution add 10% stannous chloride solution dropwise until only a light yellow colour remains. It is essential that some iron(III) is left unreduced. If all the iron is inadvertently reduced, reoxidize a little with a drop of permanganate solution.

Reduce the remaining iron(III) by adding 2% titanous chloride solution dropwise until the solution is colourless, then add an additional 3–5 drops.

Rinse the walls of the beaker with water and heat to near boiling. Remove from the source of heat and immediately add—all at once—5 ml of perchloric acid (1 + 1). Mix well by swirling for 5 sec. Cool rapidly in ice-water. Rinse the cover and the walls of the beaker. Add 25 ml of phosphoric acid–sulphuric acid mixture and 0.25 ml of sodium diphenylaminesulphonate solution.

The volume at this stage should be between 100 and 125 ml. Titrate with 0.1*N* potassium dichromate to a deep violet.

Determine the blank, using the same procedure and the same amounts of all reagents used in analysis of the sample, but in the reduction step use only 3–5 drops of the titanous chloride solution. To the cold solution thus prepared add 1.0 ml of 0.1*N* iron(II) solution. Titrate with the 0.1*N* dichromate solution (B_2 ml). In another 400-ml beaker place the same volume of hydrochloric acid (1 + 9) as the volume of the blank solution. Add 1.0 ml of 0.1*N* iron(II) solution, 25 ml of the acid mixture and 0.25 ml of indicator solution. Titrate with the 0.1*N* dichromate solution (B_1 ml). The difference between B_2 and B_1 is the blank value for the reagents.

Calculation of iron content

$$\text{Fe}\,\% = \frac{(V + B_1 - B_2)f}{m} \times 0.005585 \times 100$$

where V ml is the volume of $f \times 0.1N$ dichromate required for titration of the iron in m g of sample.

DISCUSSION

Oxidation of excess of $TiCl_3$ with perchloric acid

Six iron solutions were prepared by decomposition of 0.4000-g portions of NBS No. 690 (66.85% Fe), three by acid decomposition and three by fusion, as outlined in the procedure. The iron(III) was partially reduced with stannous chloride, then titanous chloride solution was added in slight excess.

To test the rate and completeness of the oxidation of titanium(III) by perchloric acid, the excess of titanous chloride solution added was varied from 1 drop to 2 ml. In all six cases, the volume of 0.1*N* potassium dichromate solution required to oxidize the iron was identical (within ±0.1 ml) with that needed for control titrations of solutions obtained by using stannous chloride as sole reductant and mercuric chloride as oxidant for the excess of stannous chloride.[2] This indicates that titanium(III) is efficiently oxidized by 5 ml of perchloric acid (1 + 1). It was further found that this oxidation is almost instantaneous if the perchloric acid is added to the solution at or near the boiling point. At 75° the oxidation is more sluggish. Rapid oxidation of the titanium(III) is important, since the subsequent titration of the iron(II) with potassium dichromate should be carried out expeditiously.

Stability of the iron(II) solution

After the oxidation of the titanium(III) with perchloric acid, the hot solution containing the iron(II) is rapidly cooled. During initial tests, the solutions were cooled under a blanket of carbon dioxide generated by the addition of a saturated sodium bicarbonate solution.

When the cooling and standing period was varied from 4 to 25 min, no change in the volume of titrant needed was noted, thus indicating that the iron(II) was stable under the experimental conditions used. When the addition of bicarbonate was omitted, a slight degree of aerial oxidation of the iron(II) was noted after half an hour of standing, amounting to about 0.05–0.1 ml (total titration ~47 ml) of 0.1*N* potassium dichromate solution.

Verification of procedure

The proposed method was applied to the determination of iron in a variety of iron ores of known composition. The results, along with those obtained by the conventional stannous chloride–mercuric chloride method, are presented in Table 1. The results

of a previous round-robin testing programme[2] indicated that the relative standard deviation of the stannous chloride procedure is approximately 0.15%.

The method was applied by U.S. Steel, Monroeville, Pa., to the determination of iron in a number of iron ore samples, with use of the fusion technique. Mr. J. Selvaggio of U.S. Steel obtained the results in Table 2.

Table 3. Results obtained by Andrew S. McCreath & Sons, Inc.

Fe % $TiCl_3$ procedure	Fe % $SnCl_2$ procedure	Fe % $TiCl_3$ procedure	Fe % $SnCl_2$ procedure
66.16	66.03	63.88	63.85
64.63	64.63	61.87	61.93
66.20	66.21	65.96	66.03
64.66	64.62	67.37	67.36
68.52	68.55	64.90	64.77
65.96	65.97	64.58	64.61
65.99	65.97	65.99	65.96
64.66	64.62	13.15	13.17
65.96	65.97	2.95	2.91
68.99	68.92	3.27	3.35

The method was also examined by Andrew S. McCreath & Sons, Inc., Harrisburg, Pa. Mr. F. A. Pennington, Jr. submitted the set of averages of duplicate results in Table 3 for a variety of iron ores (the acid-decomposition procedure was used).

DETERMINATION OF THIURAM DISULPHIDES AND ANALYSIS OF THIURAM DISULPHIDE–DITHIOCARBAMATE MIXTURES

BALBIR CHAND VERMA,* HARMOHINDER SINGH SIDHU and RAJNISH KUMAR SOOD
Chemistry Department, Himachal Pradesh University, Simla-5, India

(*Received* 2 *December* 1981. *Accepted* 6 *February* 1982)

Summary—Potassium trithiocarbonate is used as reductant for the titrimetric determination of thiuram disulphides in dimethylformamide–water media. The method is based on reductive cleavage of the disulphide linkage to yield the corresponding dithiocarbamates. In visual titrations, the end-point is marked by appearance of a yellow colour with the first drop of reagent added in excess. The method is simple, accurate, reliable and of wide applicability. It has been successfully extended to the analysis, in the same sample solution, of thiuram disulphide–dithiocarbamate mixtures.

Thiuram disulphides (II) are the products of mild oxidation of dithiocarbamates (I).

(I) (II)

The lower tetra-alkyl thiuram disulphides are among the most important thiocarbonyl compounds. They are used in pesticide formulations, most often as fungicides. They also find applications as accelerators in rubber vulcanization. These compounds also possess biological activity.

The methods commonly used for determination of thiuram disulphides are based on their acid hydrolysis, or abstraction of a sulphur atom from the disulphide linkage, or reduction to dithiocarbamates.

Acid hydrolysis, leading to formation of the parent amine and evolution of carbon disulphide is the key reaction used for the analysis of thiuram disulphides,[1] but the methods are time-consuming and require special apparatus. Moreover, the stoichiometry of the reaction is not well established.

The sulphur abstraction methods are based on the reaction of thiuram disulphides with potassium cyanide.

(III)

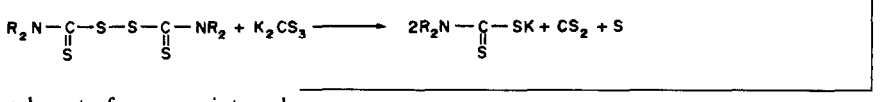
The thiocyanate formed is determined either by titration with silver nitrate[2,3] or by oxidation with bromine to cyanogen bromide, which is determined iodometrically.[4] However, the reaction mixture must be shaken for 30 min to ensure completion of the abstraction reaction, and the thiuram monosulphide (III) must be removed (by extraction with benzene) before the thiocyanate is determined.

Reduction of thiuram disulphides to the corresponding dithiocarbamates is obviously an important approach to the analysis of these compounds. It opens up two pathways for the analysis, one involving reduction followed by determination of the resulting dithiocarbamates, and the other involving direct titration with a suitable reductant. Efforts[5–8] have been made to use the first pathway, but the second appears to have attracted little attention. Scheele and Gensch[9] have described conductometric titrations of tetramethylthiuram disulphide with copper sulphate after reduction with hydroquinone. Lowen[10] attempted to determine tetramethylthiuram disulphide in ferric dimethyldithiocarbamate by potentiometric titration with sodium sulphite as reductant. Potassium fluoride was added to prevent interference from iron(III) during the titration, and a nitrogen atmosphere was used to avoid any oxidation of dithiocarbamate during the titration.

The present communication reports for the first time the use of potassium trithiocarbonate as reductant for the direct titrimetric determination of

*To whom correspondence should be addressed.

thiuram disulphides, the dithiocarbamates being formed



Since potassium trithiocarbonate forms an intensely yellow solution, the end-point can be detected by appearance of the yellow colour. The equivalence point in potentiometric titrations is marked by a sharp drop in potential. The method can be extended to the analysis, in the same sample solution, of mixtures of thiuram disulphide and dithiocarbamate. The mixture (in dimethylformamide–water medium, in which this group of compounds is readily soluble) is first titrated with potassium trithiocarbonate to determine the thiuram disulphide, and then further titrated with iodine. The solution becomes colourless immediately on addition of the first drop of iodine, and the end-point is signalled by appearance of a yellow colour (due to iodine) in visual titrations, or a sharp jump in potential in potentiometric titrations. The iodimetric titration corresponds to the total amount of dithiocarbamate (the original amount plus that formed in the first titration). The amount of dithiocarbamate originally present is found by difference.

The methods are simple, rapid, accurate and reliable, and have wide applicability.

EXPERIMENTAL

Reagents

Potassium trithiocarbonate, 0.01M. The compound was prepared[11] by saturating an alcoholic solution of potassium hydroxide with hydrogen sulphide and adding an absolute alcohol solution of carbon disulphide, and was collected by filtration and kept in a desiccator. The solution was prepared by dissolving a little more than the calculated amount in doubly distilled water, and standardized iodimetrically, with starch as indicator. A 0.025*M* solution, when stored in tightly closed amber-coloured bottles, retains its titre for about a week.

Iodine, 0.02N. Prepared and standardized as usual.

Thiuram disulphides. The tetramethyl, tetraethyl, tetra-n-propyl, tetraisopropyl and tetrabenzyl compounds were prepared[12] from the respective dithiocarbamates through reaction with iodine, and recrystallized from suitable solvents.

Dithiocarbamates. Sodium diethyldithiocarbamate was recrystallized before use. The sodium dimethyl, potassium di-n-propyl, potassium di-isopropyl and potassium dibenzyl dithiocarbamates were prepared and purified as described earlier,[13] and checked by known methods.

Procedures

Determination of thiuram disulphides. Aliquots of dimethylformamide solutions of each thiuram disulphide were taken in titration vessels, diluted to 35 ml with dimethylformamide and mixed with 15 ml of water, then titrated at room temperature (~25°) visually or potentiometrically with 0.01*M* potassium trithiocarbonate from a microburette till appearance of a yellow colour and/or a sharp drop in potential. The results are recorded in Table 1.

Analysis of mixtures of thiuram disulphide and dithiocarbamate. Aliquots of dimethylformamide solutions of synthetic mixtures containing different ratios of dithiocarbamate and thiuram disulphide were taken in titration vessels and treated as described above for determination of the thiuram disulphide. The titrated solution was then further titrated with 0.02*N* iodine. The solution became colourless immediately on addition of the first drop of iodine solution, and yellow again at the end-point. The end-point was also located potentiometrically (sharp rise in potential). The difference between the amounts of trithiocarbonate and iodine consumed gave the amount of dithiocarbamate in the mixture. The results are recorded in Table 2. In the potentiometric titrations, however, since it is necessary to titrate with trithiocarbonate to beyond the first equivalence point, the surplus trithiocarbonate added must be calculated, and an equivalent volume of iodine deducted from the second titration value, because the excess of trithiocarbonate is also oxidized by iodine.

RESULTS AND DISCUSSION

Potassium trithiocarbonate, on mild oxidation, yields carbon disulphide and sulphur.[14]

$$K_2CS_3 \rightarrow 2K^+ + CS_2 + S + 2e^-$$

It is this reducing property which is responsible for the reductive cleavage of the disulphide linkage of thiuram disulphides. The proposed method, besides being direct, convenient, accurate and reliable, possesses the following advantages.

(*i*) No additional indicator is needed.

(*ii*) The reduction is smooth and rapid at room temperature.

(*iii*) The reaction products do not interfere.

(*iv*) The reagent is easily prepared, and its solution, if stored properly, shows good stability.

(*v*) The potential stabilizes immediately on addition of each increment of reagent and the inflection point is marked by a sharp drop in potential.

The results in Table 1 show that the overall standard deviations calculated from the pooled data for the visual and potentiometric titrations were 0.037 and 0.034 mg respectively. For 10 mg of each compound, the values were 0.063 and 0.060 mg respectively. In the potentiometric titrations, a sharp drop in potential by about 100 mV for addition of 0.05 ml of 0.01*M* reagent was observed at the equivalence point.

The method has been successfully extended to the analysis of mixtures of thiuram disulphide and dithiocarbamate. Since thiuram disulphides are prepared through the oxidation of dithiocarbamates, such mixtures may be commonly encountered. Synthetic mixtures of tetramethylthiuram disulphide and sodium dimethyldithiocarbamate with ratios from 1:4 to 4:1 were analysed, with relative standard deviations of 1% for both components (Table 2) and gave similar precision and accuracy for mixtures of other thiuram disulphides with their parent dithiocarbamates.

§Amount taken, 10 mg.

Table 2. Determination of sodium dimethyldithiocarbamate and tetramethyl thiuram disulphide

Sodium dimethyldithiocarbamate		Tetramethylthiuram disulphide	
Taken, *mg*	Found,* *mg*	Taken, *mg*	Found,* *mg*
3.00	3.02 (0.03_2)	3.00	3.04 (0.03_5)
3.00	3.04 (0.03_4)	6.00	5.96 (0.06_7)
3.00	3.01 (0.04_1)	9.00	9.06 (0.06_2)
3.00	2.97 (0.03_9)	12.00	12.08 (0.09_1)
6.00	5.92 (0.04_8)	3.00	3.03 (0.03_0)
9.00	8.93 (0.07_0)	3.00	3.01 (0.04_3)
12.00	12.10 (0.06_8)	3.00	2.97 (0.03_8)

*Mean of 10 determinations, standard deviation in brackets.

The proposed method for the analysis of mixtures, besides being simple and accurate, has the added advantage that the same sample solution is used, resulting in saving of time and effort. The potentiometric method is useful when the sample solution is coloured, or for very dilute solutions.

ANALYTICAL DATA

A PHOTOMETRIC STUDY OF THE COMPLEXATION REACTION BETWEEN ALIZARIN COMPLEXAN AND ZINC(II), NICKEL(II), LEAD(II), COBALT(II) AND COPPER(II)

WU XING* and FOLKE INGMAN

Department of Analytical Chemistry, The Royal Institute of Technology, S-100 44 Stockholm 70, Sweden

(*Received* 21 *December* 1981. *Accepted* 24 *February* 1982)

Summary—The complexation reaction between Alizarin complexan ([3-*N*,*N*-di(carboxymethyl)aminomethyl]-1,2-dihydroxyanthraquinone; H_4L) and zinc(II), nickel(II), lead(II), cobalt(II) and copper(II) has been studied by a spectrophotometric method. All these metal ions form 1:1 complexes with HL; 2:1 metal:ligand complex were found only for Pb(II) and Cu(II). The stability constants are (ionic strength $I = 0.1$, 20°C):

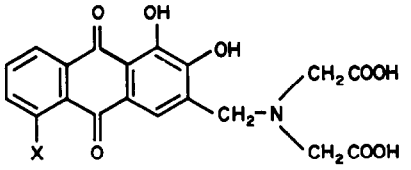
$$Zn^{2+} + HL^{3-} \rightleftharpoons ZnHL^- \quad \log K \pm 3\sigma(\log K) = 12.19 \pm 0.09 \ (I = 0.5)$$
$$Ni^{2+} + HL^{3-} \rightleftharpoons NiHL^- \quad \log K \pm 3\sigma(\log K) = 12.23 \pm 0.21$$
$$Pb^{2+} + HL^{3-} \rightleftharpoons PbHL^- \quad \log K \pm 3\sigma(\log K) = 11.69 \pm 0.06$$
$$PbHL^- + Pb^{2+} \rightleftharpoons Pb_2L + H^+ \quad \log K \approx -0.8$$
$$Co^{2+} + HL^{3-} \rightleftharpoons CoHL^- \quad \log K \pm 3\sigma(\log K) = 12.25 + 0.13$$
$$Cu^{2+} + HL^{3-} \rightleftharpoons CuHL^- \quad \log K \pm 3\sigma(\log K) = 14.75 \pm 0.07$$
$$Cu^{2+} + CuHL^- \rightleftharpoons Cu_2L + H^+ \quad \log K \approx 3.5$$

The solubility and stability of both the reagent and the complexes and the closeness of the values of the stability constants make this reagent suitable for the photometric detection of several metal ions in the eluate from an ion-exchange column.

Two quite different kinds of philosophy may be applied to the choice of reagents used in photometric analysis. By far the most common one is that the reagent should be as selective as possible for the analyte, to allow interference-free determinations.

However, a fairly non-selective reagent can be given a desired selectivity by use of masking agents, and/or pH-control, generally along with extraction of the coloured species formed; the most common reagents used in this way are probably dithizone and oxine. The same reagent may then be used for the determination of many different metal ions. The role played by the reagent is in this case similar to the role of EDTA in complexometry.

Few chromogenic reagents in aqueous solution display selectivity properties similar to those of EDTA. Such a reagent would have to be a chelating agent of structure not far removed from that of EDTA. Examples are Alizarin complexan (Alizarin Fluorine Blue, [3-*N*,*N*-di(carboxymethyl)aminomethyl]-1,2-dihydroxyanthraquinone, AFB)[1] and sulphonated Alizarin complexan (AFBS, [3-*N*,*N*-di(carboxymethyl)-aminomethyl]-1,2-dihydroxyanthraquinone-5-sulphonic acid).[2]



AFB: X = H
AFBS: X = $SO_3^-K^+$

The main use of these two reagents results from their lanthanum or cerium salts giving the only known positive colour reactions with fluoride ions in aqueous solution, and their use as reagents for fluoride is by now well established. However, they form complexes with many other bi- and tervalent metal ions, and could thus be used for selective photometric determination of these ions, *e.g.*, aluminium(III) in the presence of iron(III).[3]

As is well known from complexometry, equilibrium

*On leave from the Education Department, General Research Institute for Non-ferrous Metals, MMI, Beijing, China.

calculations are an extremely valuable aid in working out analytical procedures. If all the relevant stability constants are known, the calculations can be done either by the simple concept of conditional constants and side-reaction coefficients introduced by Ringbom[4] or by computer methods such as the HALTAFALL program.[5]

The aim of this work was to provide more data on the equilibria of Alizarin complexan with cobalt(II), copper(II), nickel(II), lead(II) and zinc(II) in order to facilitate such equilibrium calculations. During the course of the work we also studied the influence of several common buffer substances, to exclude the possibility that ternary complexes are formed.

METHOD

The equilibria were studied in 0.1*M* or 0.5*M* sodium nitrate medium spectrophotometrically. Since the complexes are rather stable it was necessary to use competitive complexing agents to make the reaction with Alizarin complexan incomplete. The stability constants of the metal complexes with Alizarin complexan were then evaluated by using Ringbom's concepts,[4] after determination of the conditional constants by plotting A against $(A_L - A)/[M']$, where, A_L is the absorbance of a solution containing only uncomplexed dye at total concentration c_L, A is the absorbance of a solution containing a mixture of dye and complex at a total dye concentration c_L, and $[M']$ is the concentration of metal ions that have *not* reacted with the dye according to the main reaction. The conditional stability constant K' is then obtained as the reciprocal of the slope of the plot.

EXPERIMENTAL

Reagents

Alizarin complexan was purified as described earlier.[6] All other chemicals were of reagent grade. Distilled water was used throughout.

Procedure

Sets of solutions containing equal concentrations of the dye but increasing concentrations of the metal ion in question were buffered to an appropriate pH and the ionic strength was adjusted to 0.1*M* (except for Zn^{2+}, where the ionic strength was 0.5*M*) with sodium nitrate. Complete spectra for the wavelength range 350–700 nm were recorded with a Varian–Cary model 219 recording spectrophotometer. In addition, some of the continuous-variations measurements were made at two different wavelengths in order to ascertain that only one complex was being formed in the solutions. All experiments were done at 20 ± 1°. About ten data points were used for each determination of a stability constant. As an example, a complete set of data is shown in Table 1.

RESULTS

Influence of reagents and buffer substances

Boric acid is known to form a complex with Alizarin complexan.[6] To decide whether any other reagents used as auxiliary complexing agents or buffer substances would influence the absorbance of the dye we made a rough check of the influence of phthalic acid, acetic acid, EGTA [ethyleneglycol-bis(2-aminoethyl ether)tetra-acetic acid] and NTA (nitrilotriacetic acid) at various concentrations up to about 0.1*M*. The spectra recorded showed that, though there may be an influence at very high concentration levels, it is so small as to be within the experimental error at the concentrations and pH ranges used here (pH 5–6).

Stability of the metal complexes

Zinc(II). The continuous-variations investigation confirmed the suggestion by Leonard and West[7] that zinc(II) forms a 1:1 complex with the dye. One of the protons of Alizarin complexan (H_4L) does not take part in the complexation (this is supported by the bathochronic shift occurring on complexation). The reaction may thus be written:

$$Zn^{2+} + HL^{3-} \rightleftharpoons ZnHL^{-}$$

We determined the stability constant for this complex by using thioglycollic acid (TGA) as auxiliary complexing agent. The stability constants for the Zn–TGA complexes and the acid constants of TGA were taken from the work of Anderegg and Malik,[8] recalculated for 0.5*M* ionic strength by use of Debye–Hückel theory. Absorbances were measured at 490 nm.

Table 1 shows the results of the six determinations that were made.

No tendency for zinc(II) to form polynuclear com-

				log $K \pm 3\sigma(\log K)$ =	12.23 ± 0.21

plexes was observed at the concentrations studied. Although the pH range that could be studied was rather narrow, the results seem to confirm that the complexation takes place according to the equation given.

Nickel(II). According to Leonard and West,[7] Ni(II) forms a 1:1 complex with Alizarin complexan, and this was confirmed by a continuous variations plot. The auxiliary complexing agent in this case was EGTA. Ringbom and Saariaho's stability constants[4] were used in the calculations. The data were best explained by the reaction

$$Ni^{2+} + HL^{3-} \rightleftharpoons NiHL^{-}$$

and there was no indication of the formation of other species in the solution within the ranges of pH and concentration studied. The measurements were made at 505 nm, since at this wavelength the absorptivities of both Ni^{2+} and the Ni^{2+}–EGTA complex are zero, whereas the absorptivity of the Ni^{2+}-AFB complex is at its maximum. The results are given in Table 2.

Lead(II). Two different species are formed when lead(II) is added to a solution containing AFB. With the dye in excess, only a 1:1 species is formed, and it can be described as PbHL. At higher lead(II) concentrations, a precipitate is formed. The data may be reasonably well explained by assuming that the precipitate is the uncharged Pb_2L. Moreover, the spectrum of the colloidal solution resembles that of the completely deprotonated dye (Fig. 1), and this seems to support the suggested composition. The auxiliary complexing agent was EGTA, and the stability constants determined by Ringbom and Saariaho[4] were used. The results of the five determinations of the stability constant for the formation of the first complex are given in Table 3, which also shows the pH and concentration ranges employed. The wavelength was 490 nm.

In analytical applications, the dye is always in excess, so the binuclear complex will not normally be formed, except perhaps in an interfering side reaction. We therefore made only a rough determination at

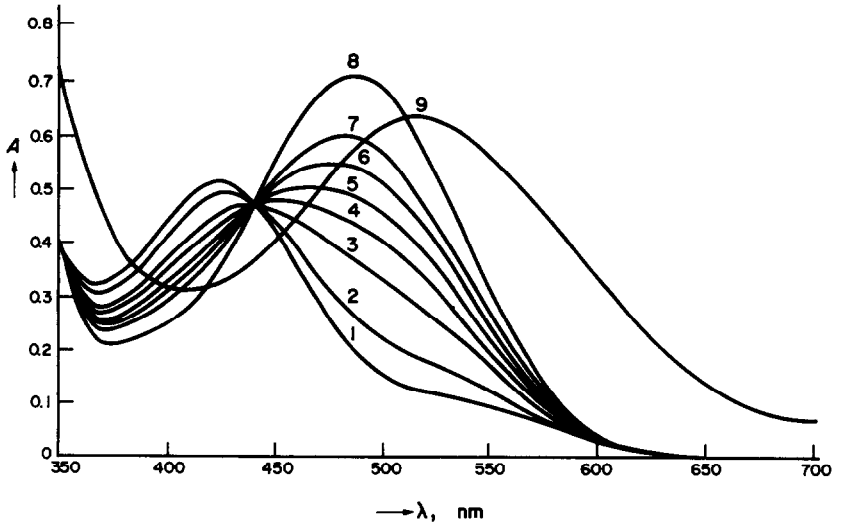

Fig. 1. Absorption spectra of solutions with constant Alizarin complexan concentration, 0.100 mM, and various Pb^{2+} concentrations: 1, 0M; 2, 0.100 mM; 3, 0.300 mM; 4, 0.500 mM; 5, 0.700 mM; 6, 1.00 mM; 7, 1.50 mM; 8, 5.00 mM; 9, 4.00 mM. All solutions except no. 9 had an EGTA concentration of 5 mM. The ionic strength was 0.100M ($NaNO_3$) and the pH was 4.8 (acetate buffer 0.05M).

630 nm of the stability constant for the reaction

$$PbHL + Pb \rightleftharpoons Pb_2L + H^+ \quad \log K \approx -0.8.$$

Cobalt(II). Spectra for the system cobalt(II)–AFB–EGTA in acetic acid–acetate buffer were recorded and show that only one complex species is formed. The ratio of metal ion to dye is 1:1 and the data fit the model

$$Co^{2+} + HL^{3-} \rightleftharpoons CoHL^-.$$

EGTA was used as auxiliary complexing agent, and Anderegg's constants[9] were used in our calculations. The maximum absorbances were measured at 490 nm. Six determinations were made, and the results are shown in Table 4.

One of the determinations (the third listed) was made at I = 0.2M and the constant was recalculated to I = 0.1M by using the Debye–Hückel equation.

Copper(II). Copper(II), like lead(II), seems to form two complexes with Alizarin complexan. The second complex is formed in solutions containing excess of copper(II) but, unlike the corresponding lead(II) complex, the copper complex is soluble. However, no further study of this complex was undertaken, since Alizarin complexan will always be present in excess in analytical applications. At first, EGTA was used as auxiliary complexing agent, yielding the first two values for the stability constant shown in Table 5, but the copper(II)–EGTA complex was too strong to allow Alizarin complexan to compete very effectively, so the experiments were continued with NTA as auxiliary complexing agent. Absorbances were measured at 480 nm. As can be seen from Table 5, the results show a slight difference, according to which auxiliary complexing agent is used. This is to be expected since the stability constants of the Cu–

EGTA and the Cu–NTA complexes were determined by different workers by slightly different methods.[9] For EGTA, Anderegg's values[9] were used, and for NTA the values determined by Ringbom and Saariaho.[4]

The results lead us to conclude that copper forms a complex with Alizarin complexan according to

$$Cu^{2+} + HL^{3-} \rightleftharpoons CuHL^{-} \quad \log K = 14.75$$

We determined the order of magnitude of the stability constant for the reaction

$$CuHL^{-} + Cu^{2+} \rightleftharpoons Cu_2L + H^{+} \quad \log K \approx -3.5$$

DISCUSSION

The results presented support the statement in the introduction about the simplicity of Alizarin complexan chemistry. Moreover, the values for the stability constants show that there is potential for use of AFB as a reagent for the detection of several metal ions, *e.g.*, in the eluate from an ion-exchange column. Other workers have used pyridylazo compounds such as PAR for this purpose.[10] In comparison with such reagents, AFB has the advantages of being relatively soluble in water and stable in aqueous solution. Also, the sensitivities of the reactions with different metal ions are similar, which simplifies the calibration procedure. Work is therefore in progress at this laboratory to study the utility of AFB as a reagent in an ion-chromatography detection system.

ANNOTATIONS

AN EVALUATION OF CELLULOSE AS A SUBSTRATE FOR ROOM-TEMPERATURE PHOSPHORESCENCE*

R. P. BATEH and J. D. WINEFORDNER
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(*Received* 7 *January* 1982. *Accepted* 18 *February* 1982)

Summary—Cotton-linter pulps, wood pulps and several filter papers have been evaluated as substrates for room-temperature phosphorescence. A variety of chemical treatments of one filter paper is discussed in terms of reducing the background phosphorescence of the cellulose and in evaluating possible trace contaminants in cotton fibres. In order to account for uniformity of filter paper used in room temperature phosphorescence, a final evaluation of several different lots of one type of filter paper is presented.

Though room-temperature phosphorescence (RTP) has received considerable attention in drug and polynuclear aromatic hydrocarbon analysis during the past decade, the ultimate success of the method depends on selection of a suitable support material. In recent years, supports such as cellulose, silica gel and sodium acetate have been used in RTP measurements of a variety of organic compounds.[1-3] Of the three major support materials, cellulose appears to offer a considerable advantage because of the wide range of special papers with varied characteristics. The major disadvantage of cellulose is the presence of a broad-band phosphorescence background (at ~400–600 nm).[4-6] We have tested several types of filter paper, but our attempts to minimize the phosphorescence background of the papers by physical and chemical treatments have been unsuccessful.[7,8] In the present study,† several cellulose pulps have been examined as supports to determine whether there is a successful combination of physical/chemical characteristics of cellulose pulp for RTP; treated filter paper has also been examined to find a possible source of the background phosphorescence.

EXPERIMENTAL

Apparatus

All RTP measurements were made with an Aminco-Bowman spectrophotofluorimeter fitted with a Canrad–Hanovia 150-W xenon arc lamp, a laboratory-constructed phosphoroscope[9] for bar-RTP,[10] and a potted Hamamatsu 1P21 photomultiplier tube. An Aminco ratio photometer supplied high voltage to the photomultiplier tube in addition to serving as a d.c. amplifier. All line voltages were regulated with a Sorenson 1001 a.c. regulator.

Reagents and materials

The following companies kindly provided the materials mentioned: Buckeye Cellulose (grade 503 cotton-linter pulp); ITT Rayonier (Cellunier-P wood pulp); Southern Cellulose (grades 270, 277, and 282-R cotton-linter pulps); Eaton-Dikeman (613 and 631 filter papers); Schleicher & Schuell (903 filter paper, lots W01, W02, W12, W92, W93, W94). Diethylenetriaminepenta-acetic acid (DPTA) (Sigma Chemical Co.) was used without further purification. All other reagents were of analytical grade.

Procedure

Following the selected treatments (Table 1), the sheets of S & S 903 were allowed to air-dry in a photographic darkroom for 12 hr. Next, 0.25-in. diameter paper discs obtained with a standard office paper punch were placed under the cover plate of the bar, and the plate was screwed down onto the discs. With a "Micropettor" (Scientific Manufacturing Industries), 5 μl of blank (1*M* potassium iodide/1*M* sodium hydroxide in 50/50 v/v ethanol/water) or 5 μl of analyte [50-ppm *p*-aminobenzoic acid (PABA) in 50/50 v/v ethanol/water] were spotted onto the paper discs. The bar was then placed in the sample compartment where the discs were allowed to dry for 7 min in a flow of dry nitrogen. For each evaluation, 8 or 16 independent measurements were made for both blank ($\lambda_{ex}/\lambda_{em}$, 320/475 nm) and PABA ($\lambda_{ex}/\lambda_{em}$, 296/432 nm). The blank excitation and emission wavelengths were chosen to maximize the signals (which behaved like the substrate background phosphorescence).[6] Blank signals were ~40% lower at the wavelengths used for the PABA.

For the "lot"-analysis (Table 4) of S & S 903 filter paper, all "lots" were soaked in DTPA solution for 24 hr, rinsed for 3 min in water, and allowed to air-dry for 12 hr in a photographic darkroom.

For the handsheet evaluation (Table 2), two handsheets (basis weight 190 g/m² ± 3%, thickness 0.5 mm ± 5%) were made from each source of cellulose pulp. The first

*This research was supported by NIH grant GM-11373-19 and by University of Florida Biomedical Research Support Grant.

†Part of this study contains proprietary information and at the request of the participating companies, no specific details of the manufacture process can be given with respect to each grade of cellulose. For the reader's convenience, an appendix is included to explain terms (used in this article) common to the pulp and paper industry but otherwise unfamiliar to the layman.

Table 1. Summary and results of treatment of S & S 903

Nature of treatment	Time of treatment, *hr*	Change in mean relative signal* Blank	PABA

0 no change in signal.
+1 signal increased by ≈50%.
+2 signal increased by ≈100%.
†no net signal observed.

handsheet was made from a sample of pulp as received from the processing plant. The second was made from a pulp sample that had been mechanically beaten for 1 hr.

The sampling procedure for the "lot"-analysis and handsheet evaluation followed the sequence described above.

RESULTS AND DISCUSSION

Background on papermaking

To understand the results obtained, it is necessary to have a basic knowledge of the papermaking process and more specifically, a knowledge of the types of cellulose used in making filter-paper products. A detailed description of papermaking is beyond the scope of this article, but is readily available,[11–14] and so is up to date information on the procedures used in paper analysis.[15–17]

Generally speaking, purified cellulose can be obtained from two major sources—cotton and wood. Wood is comprised mainly of cellulose (~55%) and hemicellulose and lignin (the fractions of each depending on the type of wood). Cellulose is essential for papermaking, and the hemicelluloses can be beneficial; lignin, on the other hand, is undesirable and is removed during chemical pulping and bleaching. The final proportion of cellulose found in wood pulps can reach 90% with certain pulping methods. Cotton fibres are approximately 95% cellulose, with minor amounts of waxes and pectins and very little lignin. Chemical processing of cotton fibres can give yields of >99% cellulose.

Two broad classes of woods of commercial value to the pulp and paper industry are softwoods (pines, spruces, firs and cedars) and hardwoods (oaks, gums, beeches, birches and eucalypti). The major types of fibre found in softwood trees are the spring-wood fibres and the summer-wood fibres. Paper sheets made with a high percentage of spring-wood fibres (flexible fibres with flat surfaces that pack more closely together) are relatively stronger, denser and less porous. The best source of spring-wood fibre is central Canadian softwood pulp (~75% springwood). Hardwoods have much shorter fibres than softwoods and as a result do not bond well (the sheets have low tensile strength), but they do promote good sheet formation (fewer gaps in the sheet).

The two types of fibre found in most varieties of cottonseeds are the lint (staple) fibres and the linters. Lint fibres are used mostly in the textile industry,

Table 2. Results of handsheet evaluation*

Sample	Mean relative signal† Blank H_1	Blank H_2	PABA H_1	PABA H_2	S_A/S_B‡ H_1	S_A/S_B‡ H_2

while cotton linters are processed into pulp for paper-making or for chemically derived products. Comparisons of the two types of cotton fibre show distinct differences. The lint fibres can grow up to 30 mm in length with cell wall thicknesses of up to 3 μm; cotton linters average 4 mm in length with cell wall thicknesses of up to 10 μm. Lint fibres with thin cell walls and wide lumens collapse when dried and thus add strength and density to a sheet of paper. Cotton linters, on the other hand, with thick cell walls, remain round on drying and impart bulk and porosity to paper. Because of these characteristics, cotton-linter pulp is used extensively for filter paper making.[18]

Diagnostic studies on cellulose products

This study began with a selection of cellulose products with properties appearing to accord with the theories[2] that hydrogen bonding and/or electrostatic interactions give rise to rigid adsorption of organic molecules on the surfaces of solid supports, and that RTP of the compounds can then be observed. The selection included an extremely "pure" wood pulp (Cellunier-P), an equally "pure" cotton-linter pulp (503), additional cotton-linter pulps (270, 277, 282-R) with tailored properties, and several "good" commercially available filter papers (613, 631, and 903).

Background phosphorescence

The first set of experiments (Table 1) was set up to evaluate the background phosphorescence of cellulose. Contrary to popular belief, the vast majority of filter-paper companies marketing products in the clinical fields do *not* add special (luminescent) chemicals (optical whiteners, sizing agents, *etc.*) to their pulps. The desired characteristics of the papers are met through chemical treatment (caustic cooking/extracting and inorganic bleaching followed by extensive washing with purified water) and physical manipulation (refining, beating, *etc*) of the pulps.[19] Thus filter papers are relatively pure, with the cellulose content approaching 100%. However, the question arises of the magnitude of the phosphorescence of "bone-dry" cellulose. [6] Lloyd and Miller[20] have observed that highly purified cotton does not phosphoresce and that any phosphorescence may be attributed to trace contaminants sorbed on the cotton. Similarly, Atalla and Nagel[21] have observed that trace amounts of transition metals incorporated into the crystalline domains of cellulose fibres may be responsible for laser-induced fluorescence in cellulose. More recently, Timell,[22] Huwyler *et al.*,[23,24] Delmer and co-workers,[25–28] Waterkeyn[29] and others[30,31] have pointed out that filter paper cannot be "pure" cellulose because the cotton fibres still contain trace amounts of hemicelluloses and lignin. These hemicellulosic fractions (mainly β-1,3-glucans) increase at the onset of secondary wall formation and contain species that luminesce.

The various soaking treatments (results in Table 1) were designed to deal with trace metals and hemicelluloses and/or lignin in cellulose pulp. The chelating agent DTPA was used in an attempt to remove trace amounts of transition metals that might contribute to the phosphorescence background of the filter paper. Though the background phosphorescence of the blank was reduced only slightly, the analyte signal improved significantly. This treatment gave no improvement for blank levels over past procedures.[8] The effect on the analyte signal is attributed to interaction of the DTPA with PABA, and to the gaps in the paper structure being filled. Unfortunately, the results do not indicate whether trace metals were involved in the phosphorescence background of the cellulose.

Following Millson's work,[4] an Eimac lamp and sunlight were used to try to bleach out "impurities" in the filter paper, but the illumination was actually detrimental, as the analyte signals decreased, possibly because of disruption of the surface structure.

The remaining treatments were used to test for the presence of extractable hemicelluloses (and/or lignin) in cellulose pulp. While none of the treatments unequivocally confirmed the presence of such materials, the soaking with dioxan indicated (by the large decrease in background phosphorescence) that an extractable hemicellulosic (and/or lignin) fraction may have been present. Periodic acid oxidation[29] almost completely destroyed the surface hydroxyl groups (forming aldehyde groups), and no net analyte signal or background was observed. Thus, while hemicelluloses (and/or lignin) appear to be responsible for the background phosphorescence, complete removal of these groups apparently disrupts the surface structure, and then analyte phosphorescence also does not occur.[28]

Fibrillation study and handsheet evaluation

In the fibrillation study (Table 2), two handsheets (one more highly fibrillated than the other) were made from unbeaten and beaten pulps. Beating cellulose pulps over a period of time decreases the average fibre length and increases the average exposed surface area. Therefore, with more hydroxyl groups exposed on the surface, a more complete adsorption of organic molecules on the support material takes place and an enhancement in phosphorescence should be seen. At the same time, however, fibrillation increases the exposure of the hemicellulosic material located in the inner matrix of the cellulose fibres. As a result, a larger phosphorescence background should also be seen. In fact, the results (Table 2) obtained for Cellunier-P, 503, 2570, 277, and 282-R appear to confirm these generalizations. Though the degrees of fibrillation have not been confirmed for Cellunier-P and grade 503, the latter would be expected to be more fibrillated than the former. For the three Southern Cellulose pulps the degree of fibrillation appears to increase in the order grade 270 < grade 277 < grade 282-R.

Table 3. Results of filter paper comparison

Filter paper*	Mean relative signal† Blank	PABA	S_A/S_B

*Mean relative signals and relative standard deviations calculated from 16 measurements of blank and PABA. S_A (mean relative signal of PABA); S_B (mean relative signal of blank).

Comparison of filter paper

Eaton-Dikeman filter papers 613 and 631 were compared with S & S 903 (see Table 3) to determine whether paper porosity affects the interaction of the cellulose surface groups with analyte molecules. Optimally, the filter paper should allow the bulk of the analyte to remain on the surface, to provide more effective adsorption and/or interaction. Thus "slow" filter papers are the best choices. The 613 and 631 papers gave larger analyte signals than the untreated 903 paper, but the DTPA-treated 903 gave even higher signals. The suggestion that DTPA fills in the gaps of S & S 903 now seems confirmed (by the larger signals), if the analyte molecules are regarded as "trapped" in the DTPA–cellulose matrix.[32]

Comparison of various lots of filter papers

The various lots (see Table 4) of S & S filter paper 903 are consistent in quality for use in RTP applications. On a statistical basis (Duncan's multiple range procedure with $\alpha = 0.01$), the W94 (1980) and W93 lots are significantly different for analyte signals, and the W94 (1980) and W12 lots are significantly different for blank signals. In general, the RSD for blank determinations is larger than for analyte determinations, but no correlations were performed for the signal levels and their respective standard deviations.

CONCLUSION

In view of the results obtained in this study, it is clear that cellulose-based support materials vary considerably; nevertheless, for RTP applications, it is practical to assume that the difference in performance between the poorest paper and the best paper is considerably less than an order of magnitude. Thus, researchers evaluating RTP for analytical studies should select support materials giving the highest signal-to-noise ratio. If filter papers are used (for convenience or because of ready availability), then a pretreatment is recommended to enhance the adsorption characteristics. If the background phosphorescence of cellulose-based products indeed cannot be reduced (and it seems unlikely that it *can* be reduced), time-resolved phosphorimetry may effectively correct for such interferences. We shall shortly evaluate use of the Perkin-Elmer LS-5 for this purpose.

Acknowledgements—The authors are indebted to Mr. Whitten Bell (Buckeye Cellulose, Memphis, TN), Mr. Fred Mathis (Southern Cellulose, Chattanooga, TN), and Mr. Harvey Wilson (ITT Rayonier, Stamford, CT) for samples of cotton linters and wood pulps and for technical information and advice. Gratitude is expressed to Mr. Steve Ritchie and to Mr. Bob Edwards (ITT Rayonier, Fernandina Beach, FL) for samples of wood pulps and for an informative tour of the pulp mill. Special thanks are given

to Mr. Bradd Levine (Eaton-Dikeman, Mt. Holly Springs, PA) and to Mr. Lothar Jeschke (Schleicher & Schuell, Keene, NH) for samples of filter paper. The authors are also indebted to Mr. John Baumgardner (Eaton-Dikeman) for making the handsheets of paper, to Dr. Rajai Atalla (Institute of Paper Chemistry, Appleton, WI), and especially to Dr. Ralph Berni (USDA–Southern Regional Research Center, New Orleans, LA) for paper analysis and for helpful suggestions. An additional note of appreciation is extended to all others in the pulp and paper industry for their co-operation in this project.

APPENDIX

Basis weight. The mass per unit area (g/m^2) of paper. In the U.S. paper industry it is generally the weight (lb) of a ream (usually 500 sheets) of paper.

Fibrillation. A pulp-refining technique resulting in loosening of threadlike "elements" from the fibre wall to give greater surface area for forming fibre-to-fibre bonds.

Gap. Voids caused by random fibre orientation during sheet formation.

Handsheet. A sheet of paper made by draining a suspension of fibres in water, on a stationary mould. It is used for testing the physical and chemical properties of a pulp, and is made in accordance with standard procedures.

Hemicelluloses. Various cell-wall polysaccharides, usually not extractable by water or most organic solvents but gradually extracted by dilute ($\sim 10\%$) aqueous alkali.

Lignin. The non-carbohydrate portion of cell walls; it is amorphous, with high molecular weight, predominantly aromatic in nature, and built up of phenylpropane units. It is not a compound, and varies in composition with method of isolation and with species, age, *etc.* of the plant or tree. It is almost completely removed during chemical pulp-processing.

Lint. The ginned cotton textile fibre.

Linters. Short fibres adhering to the cottonseed after ginning.

Pulp. Fibre material, classified according to type (wood, rag, cotton linters, etc.) and manufacturing process.

Thickness. Refers to a single sheet of paper under specific conditions of area and pressure.

THE SOLVENT EXTRACTION OF Cu(II), Ni(II) AND Co(II) WITH BENZIL MONO(2-QUINOLYL)HYDRAZONE*

SELMAN A. BERGER

City University of New York, John Jay College of Criminal Justice, 445 West 59 Street, New York, NY 10019, U.S.A.

(*Received* 23 *June* 1981. *Revised* 21 *January* 1982. *Accepted* 9 *February* 1982)

Summary—Benzil mono(2-quinolyl)hydrazone, BmQH, has been studied as an extracting agent for Cu(II), Ni(II), and Co(II). Though the uncomplexed ligand remains undissociated in the pH range 3.5–10, it can lose a proton on complexation with metals, owing to the electron-withdrawing effects of neighbouring groups. The dependence of degree of extraction on pH indicates that complexes of both Cu^{2+} and $Cu(OH)^{+}$ are extracted. $Cu(BmQH)_2$ and Cu(OH)BmQH species are extracted into MIBK, and the Cu(OH)BmQH complex is extracted into benzene. In the vicinity of pH 5.5–6, extraction efficiencies greater than 95% can be achieved with both solvents. Both Ni(II) and Co(II) also show dependence of extraction on pH, but precipitation of both metals in the vicinity of pH 6 limits further studies.

The condensation of α-diketones with 2-aza-aryl hydrazines can produce mono and bis products which can act as multidentate ligands. For example, Lions and Martin showed that biacetyl bis(2-pyridyl)hydrazone could serve as a quadridentate ligand; further studies indicated that deprotonation in the hydrazine moiety could explain the formation of neutral complexes.[2,3] However, if the α-diketone contains phenyl or bulkier groups, the formation of the bis product is hindered. The resulting mono products can serve as either bidentate or terdentate ligands.[4]

As these reagents form deeply coloured complexes with transition elements, analytical applications seem feasible, but very few spectrophotometric methods have been developed. Pflaum determined Co(III) with benzil mono(2-pyridyl)hydrazone in water–ethanol mixtures.[5] Cu(II) has been determined after extraction from a pH-6 phosphate buffer into benzene with benzil mono(2-quinolyl)hydrazone (BmQH).[6]

Though these α-diketone mono(2-aza-aryl)hydrazones appear useful for analytical application, their properties as extracting agents have not been widely investigated. In this work, the ligand benzil mono(2-quinolyl)hydrazone is studied as an extractant for Cu(II), Ni(II) and Co(II).

EXPERIMENTAL

Reagents

Stock solutions of Cu(II), Ni(II) and Co(II) perchlorates were prepared from the hexahydrates.

BmQH was synthesized by refluxing benzil with 2-quinolylhydrazone, for 2 hr, in ethanol acidified with 1 or 2 drops of glacial acetic acid. The resulting yellow-orange crystals were recrystallized from ethanol, washed, and dried. The m.p. was 165–167°. The infrared spectrum indicated the absence of an OH group but had a large peak at 1642 cm^{-1} corresponding to the C=O stretching mode and a peak at 3315 cm^{-1} for the N–H bond. Mass spectral analysis indicated the presence of the mono product.

Buffers and the benzene and MIBK were of reagent grade.

Procedures

Extraction studies. Ten ml of $5 \times 10^{-4}M$ metal ion solution were added to a 100-ml separatory funnel and 10 ml of BmQH solution in the concentration range 4×10^{-3}–$1 \times 10^{-2}M$ in either benzene or MIBK were added. The pH was adjusted by dropwise addition of 1–5% sodium hydroxide or perchloric acid solution. When buffers were used, they were added to the stock solution of the metal. The solution was equilibrated by gentle shaking for 2 hr. After settling, the aqueous phase was collected by filtration and its equilibrium pH was measured.

The metal concentration of the aqueous phase was determined by atomic absorption, and that of the organic phase by difference.

Spectrum of ligand as a function of pH. Ten ml of $5 \times 10^{-4}M$ metal ion solution were added to a 100-ml separatory funnel followed by 10 ml of $1 \times 10^{-2}M$ BmQH in MIBK. The pH was adjusted by dropwise addition of 1% sodium hydroxide solution, and the mixture was equilibrated. The pH of the aqueous phase was then measured and the absorption spectrum of a diluted portion of the organic phase was measured against an appropriate blank.

RESULTS AND DISCUSSION

Absorption spectrum of ligand as a function of pH

The spectrum of the ligand in MIBK is shown in Fig. 1, with the $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions at 365

*Presented at the Pittsburgh Conference of Analytical Chemistry, Atlantic City, New Jersey, 12 March 1981.

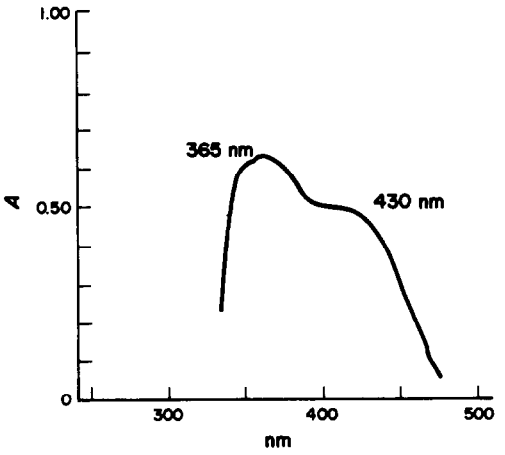

Fig. 1. Spectrum of BmQH *vs.* blank in MIBK.

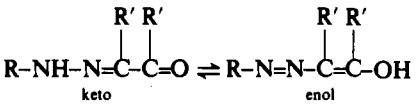
and 430 nm respectively. The positions and intensities of these two maxima do not change with pH over the range 3.5–10, showing the ligand is a very weak acid which remains in the undissociated form throughout this pH range. In very strongly alkaline medium the ligand will react with hydroxide and form a red colour.

Keto-enol tautomerism has been suggested to occur for these compounds:[4]



However, the absence of an absorption maximum at wavelengths longer than 500 nm and of an OH stretching frequency in the infrared indicates that the enol form is not present.

Extraction of Cu(II) as a function of pH

Figure 2 shows plots of log D *vs.* pH for the extraction of Cu(II) with two different initial concentrations of ligand. At the higher ligand concentration, the extraction is more efficient and starts at lower pH. For a ligand concentration of $1 \times 10^{-2}M$, $pH_{0.5} = 4.1$, and for $7.5 \times 10^{-3}M$ reagent $pH_{0.5} = 4.5$. At pH 5, with $[HL]_0 = 1 \times 10^{-2}M$, an extraction efficiency of 97% is observed, and at the same pH, with $[HL]_0 = 7.5 \times 10^{-3}M$, 84% extraction is found. If the total ligand concentration is kept constant and the copper concentration increased, the slope of the log D *vs.* pH plot varies, but not systematically, so presumably no dimeric copper species are extracted.

Extraction of Cu(II) as a function of $[ClO_4^-]$

As perchlorate salts were used in this work, the effect of perchlorate on the extraction was studied. A positive slope in a plot of log D *vs.* log $[ClO_4^-]$ would indicate the formation of extractable ion-association complexes of perchlorate with cationic metal complexes, but no variation in log D was found, so perchlorate is not involved in the extraction.

Equilibrium of extraction

Because the species extracted must be uncharged and perchlorate is not present in it, the charge on the copper ion must be neutralized by dissociated ligand species (and possibly hydroxide ions). Though the ligand, HL, does not dissociate within the pH range 3.5–10, it is well known that complexation enhances the apparent strength of weak acids. Thus, the extraction reaction may be expressed as follows:

$$M_{aq}^{n+} + n[HI]_0 \rightleftharpoons [M(HL)_n^{n+}]_{aq} \rightleftharpoons [ML_n]_0 + nH_{aq}^+. \quad (1)$$

Since the pH range for extraction is sufficiently basic to allow partial hydrolysis of the metal ion, the following reaction is also possible:

$$[M(OH)^{(n-1)}]_{aq} + m[HL]_0 \rightleftharpoons [M(OH)(HL)_m^{(n-1)+}]_{aq} \rightleftharpoons [M(OH)(L)_{n-1}(HL)_{m-n+1}]_0 + (n-1)H_{aq}^+. \quad (2)$$

The overall equilibrium expressions are

$$K_{ex} = \frac{[ML_n]_0[H^+]_{aq}^n}{[M^{n+}]_{aq}[HL]_0^n} \quad (3)$$

for reaction (1) and

$$K'_{ex} = \frac{[M(OH)(L)_{n-1}(HL)_{m-n+1}]_0[H^+]_{aq}^{n-1}}{[M(OH)^{n-1}]_{aq}[HL]_0^m} \quad (4)$$

for reaction (2). The distribution coefficients are

$$D = \frac{[ML_n]_0}{[M^{n+}]_a} \quad (5)$$

and

$$D' = \frac{[M(OH)(L)_{n-1}(HL)_{m-n+1}]_0}{[M(OH)^{(n-1)+}]_{aq}} \quad (6)$$

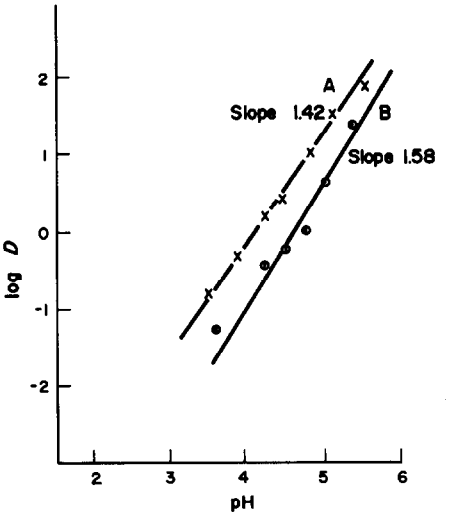


Fig. 2. Plot of log D *vs.* pH for the extraction of Cu^{2+} into MIBK. A: $[HL]_{in} = 1 \times 10^{-2}M$, $[Cu^{2+}]_{in} = 5 \times 10^{-4}M$. B: $[HL]_{in} = 7.5 \times 10^{-3}M$, $[Cu^{2+}]_{in} = 5 \times 10^{-4}M$.

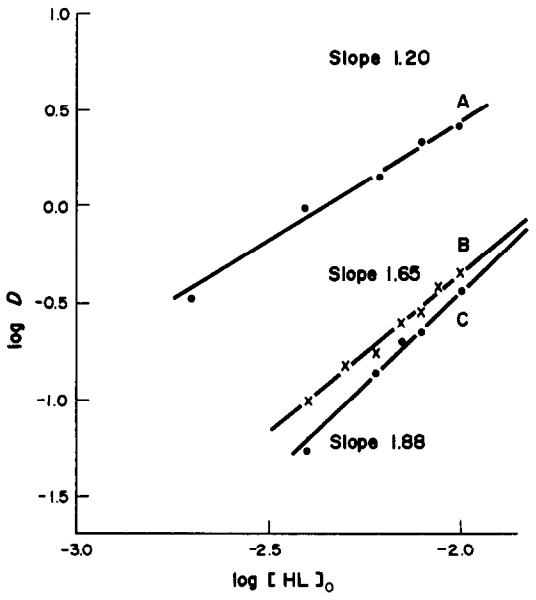

Fig. 3. Plot of log D *vs.* log $[HL]_0$ for extraction of $5 \times 10^{-4}M$ Cu in $0.005M$ biphthalate buffer, pH 5. A: 2×10^{-3}–$1 \times 10^{-2}M$ [HL] in benzene. B: 4×10^{-3}–$1 \times 10^{-2}M$ [HL] in MIBK. C: 2×10^{-3}–$1 \times 10^{-2}M$ [HL] in MIBK.

respectively. Substitution, solving for D and taking logarithms gives:

$$\log D = \log K_{ex} + n \log[HL]_0 + n\text{pH} \quad (7)$$

and

$$\log D' = \log K'_{ex} + m \log[HL]_0 + (n-1)\text{pH}. \quad (8)$$

For Cu(II), slopes of 2 and 1 for log D *vs.* pH would correspond to the extraction of Cu^{2+} and $Cu(OH)^+$, respectively. The slope of 1.4–1.6 (Fig. 2) indicates the extraction of both forms of Cu(II).

Extraction as a function of ligand concentration

Plotting log D *vs.* log $[HL]_0$ at constant pH yields a slope equal to the ligand:metal ratio in the extracted species. Plots for the extraction of Cu(II) into benzene of MIBK are given in Fig. 3. In both instances, the pH was maintained at 5 with a potassium phthalate buffer.

For MIBK, slopes of 1.65 and 1.88 were observed, suggesting extraction of both $[CuL_2]$ and [Cu(OH)L], with the first predominant. For benzene the slope was 1.2, suggesting that the second species predominates in this system, the stoichiometry corresponding to that observed[6] for phosphate-buffered medium at pH 6.

The extraction efficiency is about 2.5 times greater with benzene than with MIBK. This is perhaps because the MIBK is sufficiently polar for the very bulky complex to experience more difficulty in creating "holes" in the MIBK structure than in benzene.

It is also interesting that use of the potassium phthalate buffer diminishes the extraction of copper into MIBK by a factor of 3–5, in comparison with the unbuffered system at the same pH. The phthalate presumably brings about a competing equilibrium which reduces the degree of extraction. Use of unbuffered media and plotting log D *vs.* log $[HL]_0$ (corrected for pH) generated a slope of 1.9, in agreement with that found for the buffered media.

Extraction of nickel and cobalt

Both metals form extractable complexes, but there is precipitation at pH above about 6, so meaningful results can be obtained only at higher acidity than this, and even then there is considerable non-reproducibility. All that can really be said is that both metals would compete with copper in the extraction system.

Conclusion

The implications of these results for practical analysis are (*a*) that the extract could not be used directly for determination of copper through the properties of the complex, since more than one may be formed, (*b*) that the system could be used for isolation of copper, and (*c*) that nickel and copper would interfere.

DIFFERENTIAL PULSE POLAROGRAPHIC DETERMINATION OF ORTHOPHOSPHATE IN AQUEOUS MEDIA

SUSAN C. HIGHT, FREDRICK BET-PERA and BRUNO JASELSKIS
Loyola University of Chicago, Chicago, Illinois 60626, U.S.A.

(*Received* 7 *January* 1982. *Accepted* 14 *April* 1982)

Summary—The determination of orthophosphate in aqueous media by differential pulse polarography is described. It is based on determination of the molybdenum in 12-phosphomolybdic acid. High sensitivity is achieved by measuring the polarographic wave due to the catalytic reduction of perchlorate or nitrate in the presence of molybdenum(VI). The method is suitable for samples as small as 3.5 ml which contain as little as 9 ng of phosphorus per ml. The average relative deviation is 3.0% at the 0.045 mg/l. phosphorus level and 1.6% at the 1.2 mg/l. level. Results for the analysis of EPA quality-control water and real surface-water samples are reported.

Various methods for the indirect determination of orthophosphate by measurement of the molybdenum in 12-phosphomolybdic acid have been reported. Atomic-absorption methods[1,2] provide a sensitivity of about 1 mg/l. for phosphorus. A sensitivity of about 20 μg/l. has been achieved by X-ray fluorescence.[3] Bazzi and Boltz[4] developed a d.c. polarographic method with a detection limit of about 1 mg/l. Fogg and Yoo[5] obtained a sensitivity of about 0.1 mg/l. by differential pulse polarography.

Increasingly sensitive methods for polarographic determination of molybdenum have been developed, based on measurement of the polarographic wave resulting from catalytic reduction of perchlorate in the presence of molybdenum.[6–8] By combining the sensitivity of differential pulse polarography with the catalytic effect of molybdenum on the polarographic reduction of perchlorate or nitrate, the procedure developed in this study achieves a sensitivity of 9 μg/l. for phosphorus. Not only does this procedure provide greater sensitivity than previous methods, it also requires less sample and involves fewer steps.

EXPERIMENTAL

Apparatus

Differential pulse polarograms were recorded on a Princeton Applied Research Electrochemical System Model 170 equipped with potentiostatic control and a mechanical drop-detachment device. A dropping mercury electrode working electrode, a saturated calomel (SCE) reference electrode and a platinum-wire counter-electrode were used. The polarographic cell, drop-detachment device and mercury column with its reservoir were placed inside a grounded aluminium cage to prevent pick-up of extraneous electrical signals from the laboratory surroundings. Solutions were deaerated with nitrogen purified by passage through vanadium(II) chloride solution, and a blanket of the nitrogen was kept over the solutions during the recording of polarograms.

Reagents

All chemicals were either analytical or primary standard grade. No further purification was necessary. Demineralized water was used to make all solutions.

Glassware

All glassware was washed with 6*M* hydrochloric acid and rinsed thoroughly with demineralized water. Polyethylene stoppers were washed in 6*M* hydrochloric acid, rinsed with demineralized water, then washed in 8*M* nitric acid and again rinsed with demineralized water.

Standard solutions

Stock molybdenum solution. Prepared monthly by dissolving 17.66 g of ammonium molybdate tetrahydrate, $(NH_4)_6Mo_7O_{24}\cdot 4H_2O$, in 1 litre of demineralized water, stored in a polyethylene container, and standardized monthly. Working solutions of lower molybdenum concentration were prepared daily by dilution.

Stock phosphate solution. Prepared monthly by dissolving 1.3609 g of oven-dried (2 hr at 100°) primary-standard grade potassium dihydrogen phosphate, KH_2PO_4, in 1 litre of demineralized water, and stored in a polyethylene container. Working solutions of lower phosphate concentrations were prepared daily by dilution.

Procedures

Standardization of molybdenum solution. A 6 × 1 cm column of freshly amalgamated zinc was activated by passing 20 ml of 1.44*M* hydrochloric acid (12 ml of concentrated acid diluted to 100 ml) through it at a rate of 1 drop/sec. A 0.01*M* molybdenum solution in 1.44*M* hydrochloric acid was prepared by diluting 10.00 ml of stock molybdenum solution and 12.0 ml of concentrated hydrochloric acid to 100.0 ml with demineralized water. Ten ml of iron(III) solution [prepared by dissolving 15.06 g of ferric ammonium sulphate, $FeNH_4(SO_4)_2\cdot 12H_2O$ in 5% v/v sulphuric acid] were diluted to about 100 ml with demineralized water and placed in the receiving beaker. This beaker was covered with a sheet of "Parafilm". The tip of the Jones reductor was placed below the "Parafilm" cover

and the receiving beaker was continuously flushed with nitrogen during the reduction and titration.

Exactly 15.00 ml of the acidic 0.01*M* molybdenum solution were passed through the Jones reductor at a rate of 15 drops/min, and the reductor was rinsed with 10.0-ml of demineralized water. The reduced solution and the rinsings were collected in the receiving beaker and the iron(II) produced was titrated with the 0.1*N* permanganate (previously standardized with arsenic trioxide[9]). A blank solution of 15.00 ml of 1.44*M* hydrochloric acid was treated similarly.

Standardization of molybdenum solutions by differential pulse polarography. Exactly 5.00-ml portions of 4.0*M* perchloric acid and various known microlitre amounts of standard 0.0143*M* molybdenum solution were pipetted into a series of 10.00-ml volumetric flasks and diluted to volume with 0.125*M* sodium hydroxide. The solutions were analysed by differential pulse polarography, after deaeration with nitrogen for 5 min immediately before polarography. The voltage was scanned from +0.20 V to −0.60 V *vs.* SCE. The solutions were maintained at 22 ± 0.5°.

Determination of phosphate in low concentration range. Standard solutions for phosphate concentrations in the range 3×10^{-7}–$3 \times 10^{-6}M$ (P 9–90 μg/l.) were prepared by pipetting 60–600 μl of standard $2.52 \times 10^{-4}M$ phosphate solution into a series of 50-ml standard flasks and diluting to the mark with demineralized water.

Then 3.50 ml of a solution to be analysed were pipetted into a 1.5 × 15 cm Pyrex test-tube fitted with a high-density polyethylene or glass stopper. Next, 500 μl of 4.24% ammonium molybdate solution were added, followed by 1.00 ml of 3.33*M* hydrochloric acid (27.8 ml of concentrated acid diluted to 100 ml). Two min later, 5.00 ml of isobutyl acetate were added, the test-tube was stoppered and the contents were vigorously shaken for 1 min. Then 4.00 ml of the organic (upper) phase (containing the phosphomolybdic acid) were transferred to a 100-ml beaker and the solvent was evaporated by placing the beaker in a laboratory hood providing a strong draught. The residue was dissolved in 5.00 ml of 0.125*M* sodium hydroxide. This solution was then acidified with 5.00 ml of 4.0*M* perchloric acid, transferred to the polarographic cell and analysed by differential pulse polarography. A blank solution containing no phosphate was analysed similarly.

Determination of phosphate in high concentrations. Standard solutions for high phosphate concentrations in the range from 1×10^{-6} to $6 \times 10^{-5}M$ were prepared by pipetting 10–500 μl of 0.01*M* standard phosphate solution into 50-ml standard flasks and diluting to the mark with demineralized water. Then 1 ml of the diluted phosphate solution was placed in the test-tube, followed by 0.50 ml of 0.1*M* molybdate and 1.0 ml of 1.65*M* hydrochloric acid. Two min later, 2.0 ml of isobutyl acetate were added and the tube was shaken vigorously. Exactly 1 ml of the organic phase was transferred into a beaker. The isobutyl acetate was evaporated and the residue dissolved in 5.0 ml of 0.125*M* sodium hydroxide. This solution was acidified with 5.0 ml of 4.0*M* perchloric acid or 1.0 ml of 2*M* sulphuric acid, followed by addition of 4.0 ml of 5.0*M* sodium nitrate. The resulting solution was transferred into a polarographic cell and was analysed for molybdenum content by differential polarography. The magnitude of the catalytic peak was measured and compared with that for the blank.

The amount of phosphate in aqueous samples was determined by extraction of 12-phosphomolybdic acid, and measurement of the catalytic perchlorate current in the presence of molybdenum(VI). Extraction efficiencies were obtained by comparing the peak currents for the extracted 12-phosphomolybdic acid with the peak currents for molybdenum(VI) concentrations corresponding to the theoretical concentrations of 12-phosphomolybdic acid.

Analysis of EPA orthophosphate quality-control sample. The EPA quality-control sample was analysed by taking 3.50 ml of this solution and following the procedure described for phosphate levels below $3.0 \times 10^{-6}M$. A "spiked" EPA sample was prepared by pipetting 100 μl of $2.52 \times 10^{-4}M$ phosphate solution into a 25.00-ml standard flask and diluting the contents to the mark with the EPA sample. A 3.5 ml sample of the spiked EPA solution was analysed in the same manner as the unspiked sample.

Analysis of real surface water. A surface water sample was placed in an acid-washed Nalgene container and immediately cooled on ice. The sample was filtered through a 0.45-μm membrane filter. A spiked surface water sample was prepared by pipetting 10 μl of standard $1.01 \times 10^{-2}M$ phosphate solution into a 10.00-ml standard flask and diluting to the mark with surface water. The spiked surface water was then analysed by the procedure for phosphate levels greater than $3.0 \times 10^{-6}M$.

DISCUSSION AND RESULTS

Phosphate in synthetic samples as well as in EPA and natural water samples is determined by an indirect method utilizing 12-phosphomolybdic acid. In this method, molybdate reduction is monitored by the differential-pulse polarographic method and the peak current is then related to the phosphate concentration in the aqueous solution before the extraction with isobutyl acetate.

The overall procedure is evaluated by measuring peak currents for molybdenum(VI) alone in 2.0*M* perchlorate or 2.0*M* nitrate media and comparing them with the values obtained for known phosphate solutions by extraction and polarographic analysis of 12-phosphomolybdic acid. The results are summarized in Tables 1 and 2. Analysis results for the EPA quality-control sample with very low concentration of phosphate and for natural water samples are presented in Table 3.

Determination of micro amounts of orthophosphate as 12-phosphomolybdic acid involves: (1) formation of the heteropoly acid in the aqueous phase, (2) extraction with isobutyl acetate and (3) detection. The conversion of orthophosphate into 12-phosphomolybdic acid proceeds by the reaction

$$PO_4^{3-} + 12MoO_4^{2-} + 27H^+ \rightarrow H_3PO_4(MoO_3)_{12} + 12H_2O$$

and depends not only on the concentration of acid but also on the ratio of molybdenum(VI) to phos-

Table 1. Peak current as a function of molybdenum(VI) concentration in perchlorate or nitrate solutions*

Molybdenum(VI) concentration, μ*M*	Peak current, *nA*† Perchlorate	Nitrate
0.99	71 ± 5	208 ± 6
1.99	145 ± 7	420 ± 10
4.97	376 ± 10	1004 ± 20
9.95	770 ± 15	1920 ± 25

* Perchlorate concentration is 2.0*M* and that of hydrogen ion 1.94*M*. Nitrate concentration is 2.0*M* and that of hydrogen ion 0.14*M*.

† Polarographic settings are: scan-rate 5 mV/sec, drop-time 1 sec/drop, pulse-amplitude 25 mV, sampling time 15 msec.

Table 2. Current as a function of phosphate concentration*

Amount of phosphate in aqueous phase, *ng*	Peak current,† *nA*	Molybdenum(VI) in polarographic cell, *μM* Found§	Expected
In 2.0*M* perchlorate			
0.00	54 ± 5		
155	200 ± 7	2.5	3.00
310	390 ± 10	5.1	6.00
620	760 ± 15	10.0	12.00
1240	1500 ± 20	20.6	24.00

155	570 ± 15	2.75	3.00
310	1060 ± 20	5.40	6.00

* Samples are prepared by taking 1.00 ml of the secondary standard and diluting it with 0.50 ml of 0.1*M* Mo(VI) and 1.0 ml of 1.65*M* HCl. Heteropoly acid is extracted into 2.00 ml of isobutyl acetate and 1.00 ml of the organic phase is analysed.

† Polarographic settings as for Table 1.

§ Molybdenum(VI) concentration is obtained by comparison of the peak currents with those for aqueous molybdate (Table 1).

‡ Obtained by multiplying the 12-phosphomolybdate concentration by 12, assuming conversion and extraction to be complete.

phate. The hydrochloric acid concentration in the aqueous phase is kept to 0.66*M*, which ensures not only rapid formation of 12-phosphomolybdic acid but also enables selective extraction of this acid, thus avoiding the possible interference of silicate and arsenate, which remain in the aqueous phase. In this step, the concentration of molybdate must not be less than 0.02*M*. This provides a molybdate to phosphate ratio

*Sample analysed by taking a 3.50-ml aliquot, 0.50 ml of 0.24*M* Mo(VI) and 1.00 ml of 3.33*M* HCl. The 12-phosphomolybdic acid is extracted with 5.0 ml of isobutyl acetate and 4.00 ml of the organic phase are analysed.

† Polarographic settings: scan-rate 5 mV/sec, pulse-amplitude 25 mV, drop-time 1 sec/drop, sampling time 5 msec. Peak currents are the average values of three measurements.

§ EPA quality-sample water is spiked with 0.100 ml of $2.4 \times 10^{-4}M$ phosphate per 25 ml of sample and surface water is spiked with 0.010 ml of 0.0101*M* phosphate per ml of sample.

of 400 or more. Under these conditions, formation of 12-phosphomolybdic acid is rather fast and it can be extracted after 2 min. However, if the molybdate concentration is reduced to 0.01*M*, the extraction efficiency falls to below 50%. Also, if the aqueous-phase phosphate concentration is low, less than the expected amount of molybdenum is recovered in the polarographic cell, and the extraction of phosphomolybdic acid is incomplete. Nevertheless, linear calibration graphs can be obtained even when the aqueous-phase phosphate concentration is as low as $3 \times 10^{-7}M$. Since the amount of phosphomolybdic acid extracted depends on the aqueous-phase phosphate concentration, it is necessary to use standard phosphate solutions that bracket the concentration of the sample. Because of the small amount of free molybdate extracted in the blank, it is also necessary to analyse a blank (for the whole procedure) along with the standard phosphate solutions.

The efficiency of various organic solvents for extracting heteropoly acids has been investigated by Wadelin and Mellon.[10] Their studies showed that organic oxygen-compounds are good extractants. Isobutyl acetate not only selectively extracts 12-phosphomolybdic acid from arsenomolybdic and silicomolybdic acids as reported by Paul[11] but also provides a rather high efficiency for the preconcentration of 12-phosphomolybdic acid.

Before the polarographic analysis, it is preferable to evaporate the isobutyl acetate and it is essential to dissolve the residue in dilute sodium hydroxide solution, followed by acidification with perchloric acid. The dissolution in alkali ensures complete solubilization and recovery of molybdic acid.

The phosphate is then determined indirectly by measuring the catalytic current of perchlorate or nitrate in association with molybdenum(VI). The polarographic behaviour of molybdenum(VI) in various supporting electrolytes has been studied by Boltz *et al.*[12] and Johnson and Robinson.[13]

Molybdenum(VI) is reduced stepwise from Mo(VI) to Mo(V) and from Mo(V) to Mo(III). However, in some of these studies more than two steps have been observed and exact interpretation of these observations is lacking. Recently, Von Henrion *et al.*[14] appear to have elucidated the molybdenum(VI) reduction.

In the presence of perchlorate or nitrate, the second reduction step for molybdenum(VI) is greatly enhanced, as observed by Holtje and Geyer.[6] This behaviour has been investigated further by Stach and Schone,[8] Haight,[7] and Kolthoff and Hondara,[15] and has been used for the determination of small amounts of molybdenum.

The catalytic current is affected not only by the molybdenum(VI) concentration but also by the perchlorate or nitrate concentration. Thus, throughout these experiments the concentration of perchlorate or nitrate is kept constant while the molybdenum(VI) concentration varies directly with the phosphate concentration of the aqueous solution.

The catalytic current increases as the square root of the perchlorate or nitrate concentration, up to approximately 1*M* concentration of these ions. However, with increasing concentration of perchlorate the background noise also increases and perchlorate or nitrate concentrations higher than 2*M* are undesirable.

The hydrogen-ion concentration affects not only the half-wave potential for the catalytic wave, but also (at pH < 1) the magnitude of the catalytic wave, which decreases with increasing pH; for perchlorate medium the hydrogen-ion concentration can be in the range from 0.2 to 2.0*M* while for nitrate medium the optimum range is 0.2–0.4*M*.

Results for the analysis of synthetic EPA and surface water samples show that the current can be reproduced with a relative deviation ranging from 5 to 1% with increasing amount of phosphate. The relative average deviation of the method for the EPA sample is 3.0% at the 0.046 mg/l. phosphorus level and the average recovery for the replicates is 92%. When the phosphate concentration in the starting solutions is less than 30 ng/ml, then the observed values are consistently lower by 6–10% than the expected values. This can in part be attributed to lack of linearity in the calibration graph and to a relatively high contribution from the blank.

ANALYSIS OF VARIANCE APPLIED TO DETERMINATIONS OF EQUILIBRIUM CONSTANTS

A. BRAIBANTI,* F. DALLAVALLE, G. MORI and B. VERONI
Institute of Pharmaceutical Chemistry, Physical Chemistry Section,
University of Parma, Parma, Italy

(*Received* 14 *January* 1982. *Accepted* 9 *April* 1982)

Summary—The statistical analysis of variance has been applied to the values of the equilibrium constants of the glycinate–proton and glycinate–nickel systems, determined in different laboratories by pH-titration in aqueous solution. The analysis shows how the main part of the error derives from the variability from one titration to another even in the same laboratory. Therefore the data for a single titration (k) must be processed separately, thus yielding a mean value for the equilibrium constant $\overline{\log \beta_{pqr}}(k)$ of the species $M_pH_qL_r$; from these mean values for different titrations in each laboratory l, a within-laboratory grand average, $\overline{\overline{\log \beta_{pqr}}}(l)$, can be calculated; the variance of this grand average measures the experimental error. A further analysis of the data from the different participating laboratories shows that there were no significant differences between laboratories for the constants reported. From these results it can be inferred that all the values of the mean constants $\overline{\log \beta_{pqr}}(k)$ for one species, as determined separately for each titration in four laboratories, belong to the same population. A χ^2 analysis of these populations demonstrates that the stability constants of the species HL, H_2L^+, NiL^+, NiL_2 (with L^- = glycinate) are normally distributed, but not that for NiL_3^-. Therefore, general mean values of the first four constants can be calculated and proposed as reliable standard values at 25° and I = 1.0M Na(Cl): protonation of glycinate, $\log \beta_{011}$ = 9.651(12), $\log \beta_{021}$ = 12.071(26); nickel-glycinate complexes, $\log \beta_{101}$ = 5.615(35), $\log \beta_{102}$ = 10.363(62). These values indicate that the standard deviations are rather higher than those often reported in the literature.

LIST OF SYMBOLS

i = index of one measured point, ml_i, pH_i
k = index of titration
l = index of laboratory
n_k = number of points for species $M_pH_qL_r$ in titration k ($\equiv i_{max}$)
$n_l = \sum_k n_k$ = number of points for species $M_pH_qL_r$ in titrations of laboratory l
$\bar{n}$ = mean value of n_k
m = number of titrations ($\equiv k_{max}$)
m_l = number of titrations in laboratory l ($\equiv k_{max}$ of lth laboratory)
$\bar{m}$ = mean value of m_l
m' = number of laboratories ($\equiv l_{max}$)
β_{pqr} = cumulative formation constant of the species $M_pH_qL_r$
$\log \beta_{pqr}(i,k)$ = log of formation constant calculated from data of point i of kth titration
$\overline{\log \beta_{pqr}}(k)$ = mean value of $\log \beta_{pqr}(i,k)$ for kth titration
$\sigma^2(k)$ = variance of $\log \beta_{pqr}(k)$ as calculated by the computer program
$\sigma_i^2 = \sum_k \sigma^2(k)/m$ = mean variance of $\log \beta_{pqr}$ for any point (estimated)
$\overline{\overline{\log \beta_{pqr}}}$ = average $\overline{\log \beta_{pqr}}(k)$ from one laboratory
σ_{av}^2 = variance of $\overline{\overline{\log \beta_{pqr}}}$
$\overline{\overline{\log \beta_{pqr}}}(l)$ = average of $\overline{\log \beta_{pqr}}(k)$ in laboratory l [$\equiv \log \beta_{pqr}(l)$]
$\overline{\log \beta_{pqr}}(l)$ = $\overline{\overline{\log \beta_{pqr}}}$ in laboratory l
$\sigma^2(l)$ = variance of $\overline{\log \beta_{pqr}}(l)$
σ_{tit}^2 = variance between titrations
$(\overline{\overline{\log \beta_{pqr}}})_{g.av}$ = general grand average of $\overline{\log \beta_{pqr}}(l)$ from m' values
$w(l) = 1/\sigma^2(l)$ = weight of $\overline{\log \beta_{pqr}}(l)$
$\sigma_{g.av}^2$ = variance of $(\overline{\overline{\log \beta_{pqr}}})_{g.av}$
σ_{lab}^2 = variance between laboratories
σ_{pqr}^2 = variance of $\log \beta_{pqr}$ (determined)

The determination of equilibrium constants for aqueous solutions by pH measurements with a glass electrode is widely used.[1,2] It is a recommended and generally accepted usage to perform several titrations in order to average out the errors inherent in single titrations. There is, however, no precise indication as yet whether the processing of the data to get equilibrium constants, particularly by computer programs, should be applied either to single titrations followed by averaging the results or to the whole set of data taken together. It is the purpose of this note to show, by means of analysis of variance, how the right procedure can be identified and followed. This will help to clarify the debate on the assessment of the reliability of the equilibrium constants and their standard deviations.[3]

As to whether the equilibrium constants or their logarithms ought to be handled, we have chosen in principle to use the logarithms because: (*i*) the potentiometric experimental measurements are on the logarithmic scale, *i.e.*, on the free-energy scale, and (*ii*) the logarithms of equilibrium constants are usually re-

*To whom correspondence should be addressed.

ported in collections of stability constants. At any rate the numerical differences between the averages of the constants and those of their logarithms are negligible in the case at hand. The term "stability constant" in this paper is very often employed to mean "logarithm of stability constant".

Analysis of variance

The experimental data consist of the data-points, i, (ml_i, pH_i), $(i = 1, 2, 3, \ldots, n_k)$ for each titration k $(k = 1, 2, 3, \ldots, m)$. The analytical concentrations of metal, hydrogen ion and ligand are also known. It is therefore possible to determine a value $\log \beta_{pqr}(i, k)$ for each data-point (i, k). These values can be ordered in an array (Table 1) in which the m columns correspond to the titrations, each with n_k points. Each array as a whole is representative of a single formation constant $\log \beta_{pqr}$ and for simplicity of description we assume that only one type of complex, $M_pH_qL_r$, is formed at the measured points.

Usually the values of the cumulative constants

$$\beta_{pqr} = [M_pH_qL_r]/[M]^p[H]^q[L]^r$$

are refined by computer programs (*e.g.*, MINIQUAD,[4] SCOGS,[5] LETAGROP[6]) by non-linear least-squares methods. The treatment of the data by these programs is implicitly equivalent to forming the array of Table 1. The programs are able to process several arrays at the same time, which means that points representing more than one species can also be handled. Hence the arguments used in the present paper, even if they concern a single species, could be applied to the general case of simultaneous equilibria.

If all the points of every titration belonged to the same population of data, then it should be permissible to calculate the total average by refining all the points together. To establish the validity of this assumption, each set of titration data is refined separately, thus obtaining for each column k a mean value $\overline{\log \beta_{pqr}}(k)$ with variance $\sigma^2(k)$ and n_k-1 degrees of freedom. From m mean values the grand average $\overline{\overline{\log \beta_{pqr}}}$, with variance σ^2_{av} is calculated. If σ^2_{av} is nearly equal (H_0 hypothesis) to the estimated variance between points, σ_i^2/n, the assumption that all the points belong to the same population is proved. If on the contrary some difference between one titration and another exists (H_1 hypothesis), then $\sigma^2_{av} > \sigma_i^2/n$ and the assumption is false (Table 2). The F-test table is used to assess the hypothesis, at a given significance level.[7]

If the H_0 hypothesis is accepted, then the variability between titrations, σ^2_{tit}, is approximately zero, *i.e.*, no real difference exists between the titrations, and the data as a whole can be used as a single batch for the refinement of $\log \beta_{pqr}$. On the other hand, if H_1 is accepted, then $\sigma^2_{tit} > 0$ and the *refinement* must be

Table 2. Analysis of variance as applied to n points* of the kth titration in the same laboratory

$$\sigma^2_{av} = (\sigma_i^2/n) + \sigma^2_{tit}$$

H_0 hypothesis

$$F = (n\sigma^2_{av}/\sigma_i^2) \simeq 1;\ \sigma^2_{tit} \simeq 0$$

H_1 hypothesis

$$F = (n\sigma^2_{av}/\sigma_i^2) > 1;\ \sigma^2_{tit} > 0$$

*The number of points, n, specifies the size of the experiment and it should be constant throughout all the experiments. It is impossible, however, to foresee how many points, n_k, contribute to the definition of $\log \beta_{pqr}$. A mean value, $\bar{n} = 10$, will be assumed in the application.

Table 1. Array of data* for the determination of a constant $\log \beta_{pqr}$ in one laboratory (pqr omitted)

Data point i	Titration k				
	1	2	3	m	
1	$\log \beta(11)$	$\log \beta(12)$	$\log \beta(13)$	.	
2	$\log \beta(21)$	$\log \beta(22)$	$\log \beta(23)$	.	
3	$\log \beta(31)$	$\log \beta(32)$	$\log \beta(33)$	.	
.	.	.	.	.	
.	.	.	.	.	
n_k	.	.	.	.	
$\overline{\log \beta_{pqr}}(k)$	$\overline{\log \beta}(1)$	$\overline{\log \beta}(2)$	$\overline{\log \beta}(3)$	$\overline{\log \beta}(m)$	$\overline{\overline{\log \beta_{pqr}}}$
$\sigma^2(k)$	$\sigma^2(1)$	$\sigma^2(2)$	$\sigma^2(3)$	$\sigma^2(m)$	σ^2_{av}

$\sigma^2(k)$ = variance of $\overline{\log \beta_{pqr}}$ among points of kth titration, as calculated by the computer program.

$\sigma_i^2 = \Sigma\sigma^2(k)/m$ = variance of $\overline{\log \beta_{pqr}}$ among points for any titration, estimated.

$\sigma^2_{av} = \sum_k [\overline{\overline{\log \beta_{pqr}}} - \overline{\log \beta_{pqr}}(k)]^2/(m-1)$ = variance of the grand average

$\overline{\overline{\log \beta_{pqr}}} = \sum_k \overline{\log \beta_{pqr}}(k)/m.$

*One value of $\log \beta_{pqr}(i, k)$ from each data-pair (ml, pH).

done *separately for each titration*. On the assumption that the values of $\overline{\log \beta_{pqr}}(k)$ belong to a normally distributed population, $\overline{\overline{\log \beta_{pqr}}}$ is the central point of the distribution, with variance $\sigma^2_{av} \simeq \sigma^2_{iit}$.

As a further step, when data for the same system are available from different laboratories, a search can be made for differences between laboratories.

Consider the case that $\sigma^2_{iit} \simeq 0$ in all the laboratories. Then an array similar to that of Table 1 can be composed by putting all the

$$n_l = \sum_k n_k$$

points from one laboratory in the same column, each column l ($l = 1, 2, 3, \ldots, m'$) now representing one laboratory. At the bottom of each column we have one laboratory mean value, $\overline{\log \beta_{pqr}}(l)$, with variance $\sigma^2(l)$. The general grand average, $(\overline{\log \beta_{pqr}})_{g.av}$ is calculated for the m' laboratories and, with the same procedure as before, the analysis of variance applied to the function $\sigma^2_{g.av} = (\sigma^2(l)/n) + \sigma^2_{lab}$. In the case $\sigma^2_{lab} > 0$ (remembering that $\sigma^2_{iit} \simeq 0$), differences in apparatus or procedures of different laboratories must be searched for, the data being grouped according to common features and the possible factors of variance being analysed.

On the other hand, consider the case that $\sigma^2_{iit} > 0$ (with $\sigma^2_i/n \simeq 0$). Then the elements in one column of the array can be thought of as m_l mean values $\overline{\log \beta_{pqr}}(k)$ for each titration, with $k = 1, 2, 3, \ldots, m_l$, while each column (l) represents one laboratory. The statistical analysis is then carried out by putting $\sigma^2_{g.av} = (\sigma^2_{iit}/m) + \sigma^2_{lab}$. A mean number of titrations, $\overline{m}$, can be employed instead of m, if the laboratories do not perform equal numbers of titrations. If the H_0 hypothesis holds, then $\sigma^2_{lab} \simeq 0$ and all the $\overline{\log \beta_{pqr}}(k)$ values from each laboratory, obtained by refining each titration separately, belong to the same population and a general mean and variance can be calculated.

If the H_1 hypothesis is accepted both among titrations and among laboratories ($\sigma^2_{iit} > 0$, $\sigma^2_{lab} > 0$), then the differences between laboratories are significant as well as those between titrations, and the search for causes of error, with possible covariances, becomes a very difficult task.

EXPERIMENTAL

The experimental data are taken from the report of the so-called "Nickel–glycine Project". In that project, promoted by the Italian Group of Thermodynamics of Complexes, seven laboratories agreed to determine the equilibrium constants for the glycinate–proton and glycinate–nickel(II) systems.[8] The standard conditions required were the following: (*i*) temperature 25°, (*ii*) ionic strength $I = 1.0M$ Na(Cl), (*iii*) various Ni^{2+} concentrations, and total concentration of the reagents not more than $0.1M$ and (*iv*) other details left to free choice by the laboratories, which generally used their customary procedures and apparatus for determination of equilibrium constants. In this way the methods were varied enough to represent a significant test of the different procedures usually reported in the literature.

The methodological peculiarities of four laboratories out of the seven are reported in Table 3. These four laboratories have been chosen because their data can be treated by the same computer program. The experimental data can be found in the original publication[8] or will be supplied by the authors of this paper upon request.

RESULTS

Application of the analysis of variance

We have reprocessed the data with the computer program MINIQUAD,[4] by refining the constants separately for each titration. The results of the refinement for the glycinate protonation constants are reported in Table 4 and for the Ni(II) complex-formation constants in Table 5.

$\overline{\overline{\log \beta_{101}}}$	5.631(10)
$\overline{\overline{\log \beta_{102}}}$	10.399(10)
$\overline{\overline{\log \beta_{103}}}$	13.907(23)

$$(\overline{\overline{\log \beta}})_{g.av} = \frac{\Sigma w(l) \cdot \overline{\log \beta(l)}}{\Sigma w(l)}; \quad w(l) = \frac{1}{\sigma_{tit}^2}$$

$$\sigma_{g.av}^2 = \frac{1}{m' - 1} \cdot \frac{\Sigma w(l) \cdot [(\overline{\overline{\log \beta}})_{g.av} - \overline{\log \beta(l)}]^2}{\Sigma w(l)}$$

The analysis of variance as applied to the titrations of each laboratory is reported in Table 6 for the protonation constants, and in Table 7 for the complex-formation constants. This analysis shows unequivocally that for every constant the differences between titrations are larger than the variability within one titration, *i.e.*, in every case the H_1 hypothesis is accepted ($\sigma_{tit}^2 > 0$). If it is assumed that the $\overline{\log \beta_{pqr}}(k)$ values are normally distributed, then since the variability within points, σ_i, is much smaller than σ_{tit}, the latter can be considered as the standard deviation of $\log \beta_{pqr}$ from one laboratory.

The correct procedure for refining the equilibrium constants in this case is therefore to refine the constants separately for each titration and then average the values of different titrations.

The analysis of variance has also been applied to the possible differences between laboratories. If weighted averages are considered (Table 8), the differences between laboratories turn out to be insignificant ($\sigma_{lab}^2 \simeq 0$) both for the protonation and the complex-formation constants. The laboratories have been assigned the weightings $w(l) = 1/\sigma_{tit}^2$.

DISCUSSION AND CONCLUSIONS

The main inferences from this analysis are: (*i*) the single experimental points of the titrations do not belong to the same universe and they cannot be treated together in the refinement of the constants, (*ii*) the major source of errors is seen to be the parameters specific for each titration (E_0, standard potential, E_j, liquid-junction potential, concentrations of the reagents, *etc.*), and (*iii*) the mean values of each titration, $\overline{\log \beta_{pqr}}(k)$, belong to the same universe, in whichever laboratory. Hence the true values of the equilibrium constants can be calculated as the mean values among all the titrations of all the laboratories (Table 9). The mean values, as expected, do not differ significantly from the general grand averages of Table 8, but the standard deviations indicate a rather high experimental error. This means, from an analytical point of view, that the concentrations of the species are obtained with a lower precision than is usually assumed.

The sets of values of the equilibrium constants have been analysed to check whether they were normally distributed around the mean. The comparison was done by constructing histograms from the data of Tables 4 and 5, and testing them by means of χ^2-tables with reference to a normal distribution of $\overline{\log \beta_{pqr}}$ with mean μ and standard deviation σ_{pqr} (Table 9). The normality of the distribution has also been confirmed by other tests.[9]

The two protonation constants of glycinate ($L^- = H_2NCH_2COO^-$) and the first two of the complex-formation constants (NiL^+, NiL_2) are normally distributed. The only exception to normality is $\log \beta_{103}$ (NiL_3^-); several suggestions can be put forward to explain this, but only a thorough multifactor analysis of variance could perhaps offer a meaningful explanation.

It can be concluded that the stability constants obtained by the statistical analysis of the experimental data of the "Nickel–glycine Project" can be chosen as reference standard values. They indicate that the error in the equilibrium constants is notably higher than the precision usually reported in the literature. The

ϕ = degrees of freedom; $\chi^2 = \dfrac{\Sigma(\text{observed} - \text{expected})^2}{\text{expected}}$

explanation is that the errors usually quoted are actually σ_i^2, whereas since $\sigma_{pqr}^2 = \sigma_i^2 + \sigma_{iit}^2 + \sigma_{lab}^2 + \Sigma$ covariances, a better approximation would be $\sigma_{pqr}^2 \simeq \sigma_{tit}^2$, as shown by the present analysis of variance.

At any rate, these standards offer the researcher the possibility of checking either the improvement of his experimental procedures or the dependability of a new potentiometric system. One possible way towards amendment of the experimental causes of error is to isolate the individual factors. These seem to be: (*i*) the reversibility of the glass electrode over the entire pH range and in high ionic strength solutions, (*ii*) the reproducibility of the liquid-junction potential, (*iii*) the correctness of the model to be refined, *i.e.*, the number and formulae of the species supposed to be present, (*iv*) the precision in reagent concentrations, *etc.* Some of these factors have been critically examined by the authors of the project,[8] but a precise evaluation of their possible effects on the refined constants deserves further endeavour in connection with the correctly assessed values of the standard deviations.

DIFFUSION COEFFICIENTS AND COMPLEX EQUILIBRIA IN SOLUTION—I

THEORY: DIFFUSION COEFFICIENTS OF COMPLEX SPECIES

D. R. CROW
Department of Physical Sciences, The Polytechnic, Wolverhampton, England

(*Received* 16 *October* 1981. *Revised* 31 *March* 1982. *Accepted* 9 *April* 1982)

Summary—It is shown that in principle it is possible to obtain values of the formation constants of metal complexes in solution from values of diffusion coefficients. It is also confirmed that, in a system of successively formed complexes, there is a linear relationship between the square root of the diffusion coefficients and the co-ordination numbers of the complexes formed. In some instances such analysis has shown that revision of some previously reported formation constant data is required.

In an earlier paper[1] it was shown that the change in polarographic diffusion current (Δi_d) of a metal ion, induced by the presence of increasing concentrations of a complexing agent ([X]), was related to the mean ligand number ($\bar{n}$) by the relationship:

$$\bar{n} = k\,\Delta i_d \qquad (1)$$

where k is a constant for a given metal–ligand system.

Equation (1) was derived theoretically by considering the effective volume change induced in an aquo-complex by successive replacement of water molecules by other ligands. The consequent change in radii of diffusing particles was related to the change in diffusion coefficient by means of the Stokes–Einstein equation and, in turn, to the change in diffusion current by means of the Ilkovič equation. The relationship was verified for a number of systems by a satisfactory comparison of mean ligand numbers $\bar{n}$, obtained by its means, with those calculated from independently determined values of formation constants covering some six orders of magnitude.

If k is determinable, data pairs $\bar{n}$, [X] become available which can, in principle, lead to estimation of the formation constants of the various complexes formed, if these are mononuclear. Further, diffusion currents are less difficult than half-wave potentials to measure directly and unlike the latter, do not depend on reversibility of the electrode processes. If equation (1) may be exploited, indicator-ion methods are not needed, and formation constants may be evaluated under exactly those voltammetric conditions used for investigating the kinetics of electrode processes. Thus, equation (2), applicable to the wave of a totally irreversible process characteristic of a particular system of complexes, can be used to estimate directly the values of the rate constant, k_e.

$$\frac{i}{i_d - i} = \frac{0.886 k_e t^{1/2}}{D^{1/2}(k_N k_{N-1} \cdots k_{K+1})[X]^{N-K}} \qquad (2)$$

where k_N, *etc.* are the stepwise formation constants for the species with co-ordination numbers N *etc.*, K being the co-ordination number of the species reacting directly with the electrode; t and D are the drop-time of the mercury electrode and the diffusion coefficient of the complex species, respectively.

If a single complex is formed, equation (3) can be used to determine its formation constant:

$$\bar{D} = \frac{D_M + D_{MX}\beta_{MX}[X]}{1 + \beta_{MX}[X]} \qquad (3)$$

where $\bar{D}$, D_M and D_{MX} are respectively the mean diffusion coefficient of simultaneously diffusing "free" (aquo) and complexed metal ions, the diffusion coefficient of the uncomplexed ion, and the diffusion coefficient of the complex; [X] is the free ligand concentration and β_{MX} the formation constant of the complex. Equation (3) is the limiting form of the general equation expressing the mean value of some parameter for simple and complexed species, and which is a function of [X], expressed in terms of the overall formation constants, β_{MX_j}, of a series of complexes, *viz.*

$$\bar{D} = \frac{\sum_0^N D_{MX_j}\beta_{MX_j}[X]^j}{\sum_0^N \beta_{MX_j}[X]^j} = \frac{\sum_0^N D_{MX_j}\beta_{MX_j}[X]^j}{1 + \sum_1^N \beta_{MX_j}[X]^j} = \frac{\sum_0^N D_{MX_j}\beta_{MX_j}[X]^j}{F_0[X]} \qquad (4)$$

For a system for which the β_{MX_j} values are known from independent experiments, and for which $\bar{D}$ values over the experimental ligand concentration range have been determined, equation (4) may be used to estimate values of the individual diffusion coefficients for all species by rearrangement as follows,

$$\bar{D}\left(1 + \sum_{1}^{N}\beta_{MX_j}[X]^j\right) = \sum_{0}^{N} D_{MX_j}\beta_{MX_j}[X]^j$$

$$= D_M + D_{MX}\beta_{MX}[X] + \cdots + D_{MX_N}\beta_{MX_N}[X]^N. \quad (5)$$

The function on the left of equation (5) may be designated $F([X], \bar{D})$ to indicate that it is a function of both the free ligand concentration and of the mean diffusion coefficient. The derived function $F_1([X], \bar{D})$, given as $\left\{\bar{D}\left(1 + \sum_{1}^{N}\beta_{MX_j}[X]^j\right) - D_M\right\}/[X]$, together with the further derived functions $F_2([X], \bar{D}), \ldots, F_N([X], \bar{D})$ may be plotted against [X], and the various products, $D_{MX_j}\beta_{MX_j}$, determined. Such an analysis closely follows that of Leden[5] and DeFord and Hume.[6] With β_{MX_j} known, the diffusion coefficient of each complex species may be estimated, provided that D_M is known.

If equation (1) is valid, there should be a linear relationship between $D_{MX_j}^{1/2}$ and j; this is indeed the case, as will be demonstrated.

In principle, it is possible to use equation (5) in the interrelated forms

$$\bar{D} + \bar{D}\beta_{MX}[X] + \ldots + \bar{D}\beta_{MX_N}[X]^N = D_M + D_{MX}\beta_{MX}[X] + \ldots + D_{MX_N}\beta_{MX_N}[X]^N \quad (6)$$

and

$$(D_M - \bar{D}) = (\bar{D} - D_{MX})\beta_{MX}[X] + \ldots + (\bar{D} - D_{MX_N})\beta_{MX_N}[X]^N \quad (7)$$

to obtain values of $\beta_{MX}, \ldots \beta_{MX_N}$ for a system for which values of $(\bar{D} - D_{MX}) \ldots (\bar{D} - D_{MX_N})$ may be estimated.

There are, however, two obstacles to this procedure. (*i*) The first derived function which follows from equation (7), *viz.*

$$\frac{D_M - \bar{D}}{[X]} = (\bar{D} - D_{MX})\beta_{MX} + \cdots + (\bar{D} - D_{MX_N})\beta_{MX_N}[X]^{N-1}, \quad (8)$$

varies particularly sharply with [X] as $[X] \rightarrow 0$. This makes it very difficult to obtain a reliable intercept from the graph of $(D_M - \bar{D})/[X]$ *vs.* [X]. The steep curvature arises from the fact that the function on the left of equation (8) is dependent not only on [X] but also on the various $(\bar{D} - D_{MX_j})$ terms, which vary sharply at low values of [X]. (*ii*) It is necessary to have some means of reliably assessing the values of the $(\bar{D} - D_{MX_j})$ terms. Since $\bar{D}$ values are determinable experimentally, the problem amounts to the assignment of values for the diffusion coefficients for individual complexes but *independently of data for the formation constants.*

An *approximate* assessment may sometimes be made in terms of the limiting (or near-limiting) value of $\bar{D}$ observed at the highest concentrations of ligand used, if these correspond to the region in which the maximum degree of complexation occurs. However, it is frequently not possible to obtain a limiting value of $\bar{D}$ reliably, the highest complex formed may not be known, and the extent of its formation, even at the highest ligand concentrations accessible, may be small. In other words, the lowest recorded value of $\bar{D}$ may not be assumed to be approaching the value of the diffusion coefficient of the highest complex formed. In any case, it is desirable to develop a method which is not dependent on values of N implied by other techniques or suggested by data for similar systems.

Since $\bar{n} = k\Delta i_d$ for any concentration of ligand, it is possible to write

$$\frac{d \ln F_0[X]}{d \ln [X]} = \bar{n} = k\Delta i_d \quad (9)$$

or

$$\frac{d \ln F_0[X]}{k\, d \ln [X]} = \frac{d \ln F_0'[X]}{d \ln [X]} = \Delta i_d \quad (10)$$

where $F_0[X]$ is the Leden function, given approximately (neglecting the appropriate activity coefficients) by

$$F_0[X] \sim 1 + \beta_1[X] + \ldots + \beta_N[X]^N \quad (11)$$

Since integration of a graph of $\bar{n}$ *vs.* ln[X] (the formation curve) provides $F_0[X]$ data, it is clear that if k can be found, approximate values of formation constants may be determined from the data $(\bar{n}, [X])$. More significantly, if k were known, $\bar{n}_{max}$ (*i.e.*, N) would be implied and, since there is known to be a linear relationship between $D_{MX_j}^{1/2}$ and j, values of the functions $(\bar{D} - D_{MX_j})$ would follow, allowing direct application of equation (7).

Approaches to the evaluation of k

(*i*) If the graph of Δi_d *vs.* [X] *clearly* reaches a limit at high [X] and if $\bar{n}_{max}$ may be inferred, by whatever means, then approximate values of $\bar{n}$ may be assigned to each value of [X]. This is not to be regarded as of general applicability or reliability.

(*ii*) The "pseudo-formation curve", *i.e.*, the graph of Δi_d *vs.* ln[X], may be integrated to provide $F_0'[X]$ data for the range of values of [X]; see equation (10). A series of Leden graphical analyses may then be performed at chosen integral (or intermediate) values of k to establish which gives a sensible family of derived curves. By these means it will be shown that it is possible to establish k to, at least, the nearest half-integral value. Any significant error in k would add to

the inherent cumulative errors involved in the estimation of higher β values. Such analysis, however, is capable of giving a reliable indication of the number of complex species formed.

(*iii*) From equations (9) and (10) it follows that

$$\left[\frac{\mathrm{d}\ln F_0[\mathrm{X}]}{\mathrm{d}\ln[\mathrm{X}]}\right]_{\max} = \bar{n}_{\max} = N \qquad (12)$$

and

$$\left[\frac{\mathrm{d}\ln F_0[\mathrm{X}]}{k\,\mathrm{d}\ln[\mathrm{X}]}\right]_{\max} = \frac{\bar{n}_{\max}}{k} = \left[\frac{\mathrm{d}\ln F_0'[\mathrm{X}]}{\mathrm{d}\ln[\mathrm{X}]}\right]_{\max}. \qquad (13)$$

Thus the limiting slope of the plot of $\ln F_0'[\mathrm{X}]$ *vs.* $\ln[\mathrm{X}]$, at the highest values of [X], provides an estimate of k when $\bar{n}_{\max}$ is known. Further, it indicates the range of values of [X] where $n_{\max}$ is most closely approached, which is also implied by (*ii*).

In this paper attention is confined to the verification and implications of the linear relationship between the square root of the diffusion coefficient of a complex and its co-ordination number with respect to the ligand used.

In subsequent papers of this series the assessment of k values for a range of metal–ligand systems and the direct evaluation of overall formation constants will be described. Such an analysis will be shown to be a necessary preliminary to the exploitation of equations (7) and (8), both graphically and analytically, by means of $(\bar{D} - D_{\mathrm{MX}_j})$ data.

EXPERIMENTAL

In a number of instances, mean diffusion coefficient data estimated from diffusion current values reported in the literature for metal–ligand systems have been used. In other cases, values of diffusion current and capillary characteristics measured by manual polarography at a working temperature of 25° were used. Analytical-grade metal salts (preferably nitrates) were used, and reagent-grade ligands. The metal ion concentration was $5 \times 10^{-4} M$, and the concentration range of the various ligands was dictated by both their strength as co-ordinators and their solubility in water (for benzimidazole 50% v/v aqueous methanol was used as solvent). Potassium nitrate solution (0.1 *M*) was used as supporting electrolyte throughout. Further details of the current and potential measurements were given in an earlier paper.[1]

RESULTS AND DISCUSSION

Determination of diffusion coefficients for individual complexes

Cadmium–benzimidazole. The various functions and derived functions are presented in Table 1. The values of the stability constants quoted are those reported previously,[1] which were calculated from the measured shift in half-wave potential.

Cadmium–thiourea (and substituted thioureas). For these systems the smoothed diffusion current data reported by Lane *et al.*[7] were used in order to estimate the various $\bar{D}$ values for the range of concentrations of ligand. The values of the function

$$\left(1 + \sum_{1}^{N} \beta_j [\mathrm{X}]^j\right)$$

were taken as the $F_0[\mathrm{X}]$ values obtained by Lane from shifts in half-wave potential of the cadmium ion. In some instances the stability constant values used in the estimation of the diffusion coefficients were those obtained by re-analysis of Lane's potential data, and these were rather different from those reported earlier. This point is enlarged upon later.

The linearity of the plots of $D_{\mathrm{MX}_j}^{1/2}$ *vs.* j for the five systems studied is shown in Fig. 1. A comparison of the estimated values of D for the highest complexes formed and those of the limiting values of $\bar{D}$ in each system is worthwhile (Table 2). Whereas for the complexes with the various thioureas these values of D and $\bar{D}$ are a close match, this is clearly not so for benzimidazole. For the latter case, not only is there no *a priori* reason for assuming that $\bar{n}_{\max} = 3$, but the limiting value of $\bar{D}$, in fact, lies much closer to the

value of D for the complex with co-ordination number 2. This would suggest that at the highest values of ligand concentration, the species MX_2 predominates over MX_3. Calculation of $\bar{n}$ at the highest ligand concentration from *known* stability constants bears this out, a value slightly in excess of 2 being obtained.

A fairly stringent test of the validity of the equations involving $\bar{D}$ would be to estimate the values of $\bar{D}$ expected on the basis of independently determined $F_0[X]$ data. For the systems reported here, $F_0[X]$ data are available from half-wave potentials, since in all cases reversible reductions occur. In turn, recalculations of $F_0[X]$ data from the values of formation constants obtained by graphical analysis give some indication of the validity of the slopes and intercepts judged from the graphical analysis. For the cadmium–benzimidazole system, good agreement (Fig. 2) is obtained between the values of $\bar{D}$ obtained from diffusion currents, and the values estimated from D_{MXj} and $F_0[X]$ data by means of equation (4).

Such good agreement was not found for the cadmium–thiourea system (Fig. 3) when it was treated in this manner; there were large discrepancies, particularly in the ligand concentration range 0.1–0.4*M*. When Lane's values for the formation constants were fed back into the defining equation for $F_0[X]$, there were again large discrepancies (Table 3). This indicates either that the values of some lower constants were in error (and mere inspection suggests that the sequence $\beta_1 = 24$; $\beta_2 = 51$; $\beta_3 = 40$; $\beta_4 = 3590$ reported by Lane is rather unusual) or that the $F_0[X]$ data were in error, which implies significant error in $\Delta E_{1/2}$. The latter would seem unlikely on two counts. (*i*) The overall shifts in half-wave potential reported by Lane are quite large, so significant errors are less likely for this system than for many others; in any case the larger and hence more precisely determinable shifts are always observed for lower ligand concentrations and it is just here that the largest discrepancies occur. (*ii*) The limiting linear section of the $\Delta E_{1/2}$. *vs.* log[X] graph provides a value of 3300 for β_4, which agrees quite favourably with Lane's figure.

Graphical re-analysis of Lane's $\Delta E_{1/2}$ data gave $\beta_1 = 20$; $\beta_2 = 100$; $b_3 = 400$; $\beta_4 = 3000$ (with estimated maximum errors of ± 5; ± 40; ± 100; ± 800 respectively). $F_0[X]$ data recalculated with these revised figures were closer to those obtained experimentally. When these β data, combined with interpolated values of D_{MX_j} and the values of $F_0[X]$ estimated from $\Delta E_{1/2}$, were used to obtain values of $\bar{D}$,

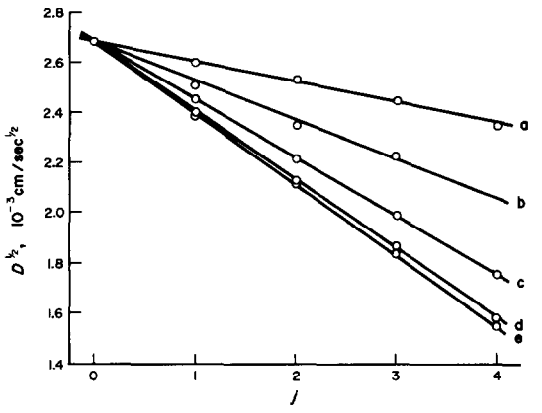

Fig. 1. Graphs of square root of diffusion coefficient of complexes as a function of the number of ligands, *j*, bound to the central metal ion (Cd^{2+}). (*a*) Thiourea; (*b*) benzimidazole; (*c*) methylthiourea; (*d*) dimethylthiourea; (*e*) ethylthiourea.

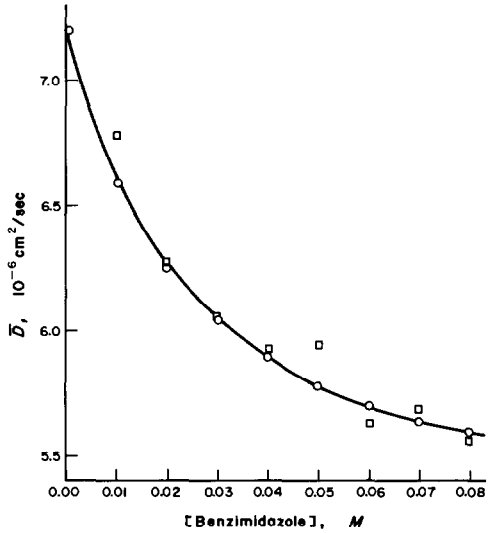

Fig. 2. Comparison of variation of $\bar{D}$ values with concentration of benzimidazole: ○ from observed diffusion currents; □ calculated by means of equation (4).

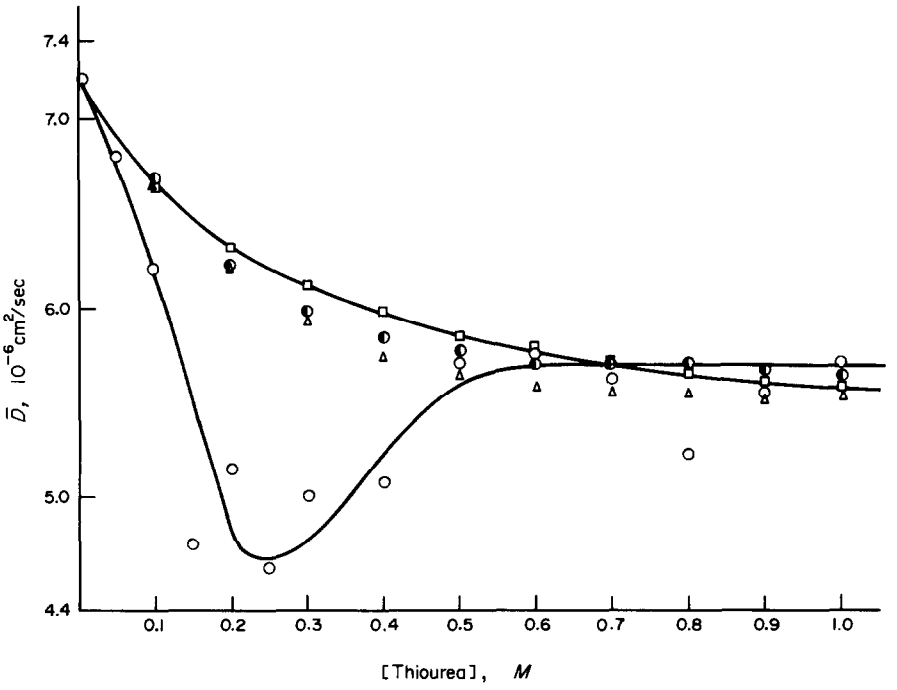

Fig. 3. Comparison of values of $\bar{D}$ for the system cadmium–thiourea, obtained by various means: ○ from F_0 and β data (after Lane *et al.*);[7] △ from F_0 data (after Lane *et al.*)[7] and recalculated β data; □ from diffusion currents measured experimentally; ◑ from F_0 and β data (after Crow).

closer agreement with experimental values was obtained (Fig. 3). It is clear that for the limited number of systems investigated, the stepwise replacement of water molecules in an aquo-complex by other ligands produces a regular decrease in diffusion coefficient. However, to exploit equation (7) for the estimation of formation constants, it is clearly necessary to be able to estimate D_{MX_j} values without prior assumptions regarding the degree of co-ordination. The case of benzimidazole shows how misleading such assumptions might be.

In the most general case where irreversible reductions are encountered and $\Delta E_{1/2}$ data are without thermodynamic significance, only diffusion currents or related parameters are available for manipulation. Clearly it is necessary to obtain at least preliminary values of (*i*) the maximum degree of co-ordination and (*ii*) the *actual* degree of co-ordination at the highest ligand concentrations used experimentally. In essence, this comes down to estimating the value of k [equations (9) and (10)] for given systems; this will be discussed in subsequent papers in this series.

Table 3. Comparison of various values of F_0[X] for the system cadmium–thiourea: 1, from $\Delta E_{1/2}$, 2, calculated from β values due to Lane; 3, calculated from values reassessed by Crow

DIFFUSION COEFFICIENTS AND COMPLEX EQUILIBRIA IN SOLUTION—II

APPROXIMATE EVALUATION OF FORMATION CONSTANTS

D. R. CROW
Department of Physical Sciences, The Polytechnic,
Wolverhampton, England

(*Received* 16 *October* 1981. *Revised* 31 *March* 1982. *Accepted* 9 *April* 1982)

Summary—It is shown, for four systems containing complexes of widely differing stabilities, that a very fair assessment of the values of formation constants is obtainable from the data pairs Δi_d, log [X] (the pseudo-formation curve). This is seen as a preliminary exercise to the more precise analysis which is possible in terms of mean diffusion coefficients which feature in equations reported earlier.

In the previous paper[1] the linear relationship between the square root of the diffusion coefficient of a complex species and its co-ordination number with respect to the ligand used, was verified (at least for the case of uncharged ligands). In this paper attention is focused on the problem of assessing $F_0[X]$ functions from changes in the diffusion current of a metal ion in the presence of increasing amounts of complexing agent.

The four systems analysed have the common feature that nearly reversible reductions take place at the dropping mercury electrode under all conditions used. Thus, values of formation constants for comparison purposes are available from independently determined half-wave potentials. Further, the systems all show the development of a maximum co-ordination number of four but differ very considerably in the *range* of β_4 values, which cover some seven orders of magnitude.

The experimental conditions used were those given in the earlier paper.[1]

The approximate calculation of formation constants by the method described is a necessary preliminary in the more precise analysis which is possible in terms of diffusion coefficients,[1] but requires a reliable indication of the extent of complexation at the highest ligand concentrations used. This makes it possible to assess k in the relationship

$$\frac{\mathrm{d}\log F_0[X]}{k\,\mathrm{d}\log[X]} = \Delta i_d = \frac{\mathrm{d}\log F'_0[X]}{\mathrm{d}\log[X]} = \frac{\bar{n}}{k} \qquad (1)$$

RESULTS AND DISCUSSION

Figure 1 shows the variation of Δi_d with log[ligand] for the four systems investigated. It is the *relative* variation of Δi_d with log[ligand] that reflects the magnitudes of the formation constants characteristic of a given system. This is most clearly shown by comparing the relative positions of the pseudo-formation curves for a lead–thiourea system (showing the weakest complexes) and the cadmium–imidazole system (showing the strongest complexes).

The units in which i_d and Δi_d are measured are quite arbitrary, since the product $k\Delta i_d$ is dimensionless.

Cadmium–thiourea

Figure 2 shows plots of $k\log F'_0[X]$ *vs.* log[X] for integral values of k from 1 to 4, $\log F'_0[X]$ being estimated from integration of the pseudo-formation curve. In the graph for $k = 1$, the limiting slope at log[thiourea] = 0 is ~ 1.1; if it is assumed that at this ligand concentration maximum co-ordination is achieved, then from equation (1) the limiting slope is $\sim n_{max}/k$, so if $n_{max} = 4$, $k \sim 3.6$.

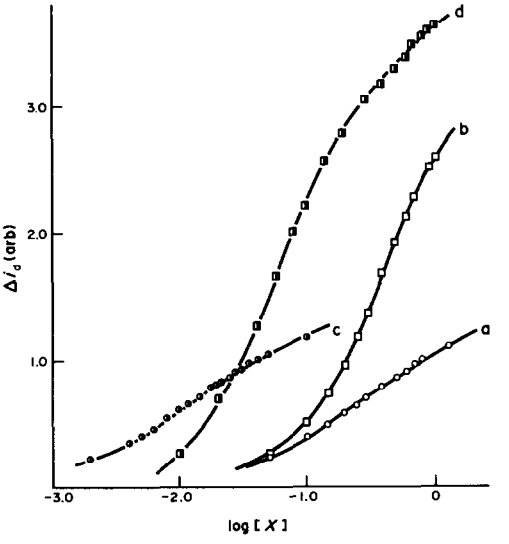

Fig. 1. Variation of Δi_d with log[ligand] (pseudo-formation curves) for the systems: (a) cadmium–thiourea, (b) lead–thiourea, (c) cadmium–imidazole, (d) cadmium–ethylthiourea (arbitrary unit for $\Delta i_d \approx 1$ μA).

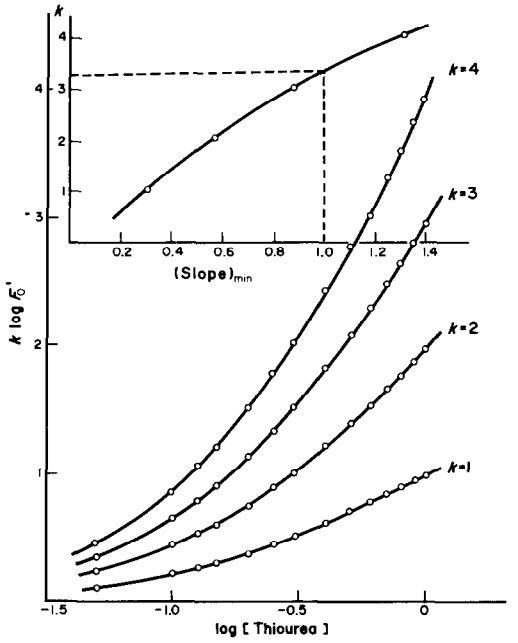

Fig. 2. Variation of $k\log F'_0[X]$ with log[thiourea] for integral values of k from 1 to 4. Inset shows graph of k *vs.* limiting slope at log[thiourea] = −1.3.

If it may be assumed that only the first complex predominates at the lowest ligand concentrations used, then in the region of log[thiourea] ~ −1.3, $\bar{n}$ is ~1. If k is plotted *vs.* the minimum slopes of the four $kF'_0[X]$ plots, the operative k value may be taken as that at which the minimum slope is approximately unity. Such a plot is inset in Fig. 2, and indicates that k is ~3.3. Clearly the consistency of these estimates at least suggests that the value of k lies between 3 and 4.

Consequently, a Leden-type analysis can be made for the $kF'_0[X]$ functions obtained with values of k in the range 3–4; the various derived functions are plotted in Figs. 3–6. At the stage of the F_3 plots (Fig. 5) it is much clearer where the true value of k lies. Here there is increasing positive and negative divergence from linearity on either side of the approximately straight line corresponding to $k = 3.63$. The same

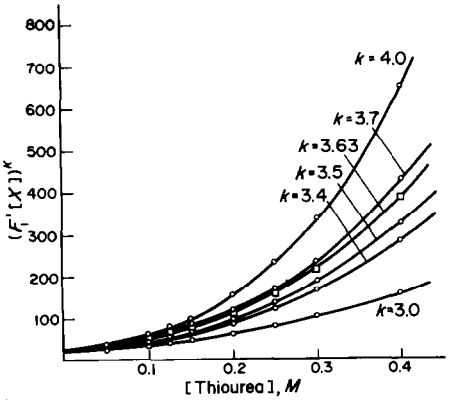

Fig. 3. $(F'_1[X])^k$ *vs.* [thiourea] curves for k values between 3 and 4.

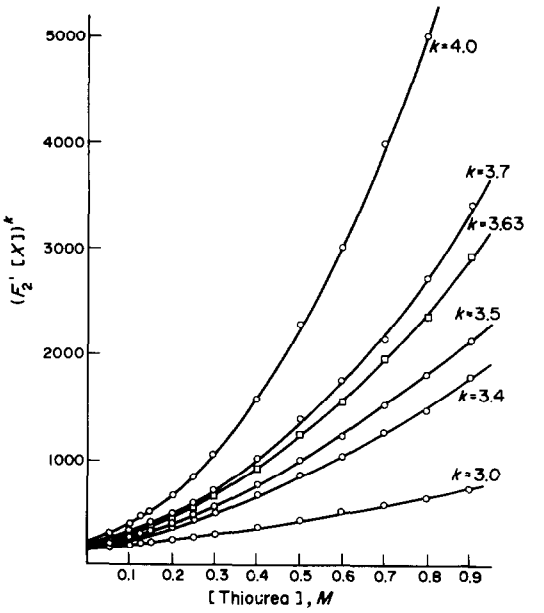

Fig. 4. $(F'_2[X])^k$ *vs.* [thiourea] curves for k values between 3 and 4.

trends are even more clearly seen in the F_4 plots (Fig. 6).

Clearly the assignment of a precise value of k before the Leden analysis is often not possible, but neither is it crucial. Though a rough guide to the value of k is initially helpful, a series of analyses covering a range of values of k is more useful, giving clearer resolution of the more nearly correct k-values and aiding assessment of the relative errors of the β-values obtained. The β-values obtained in this way and those reported in the previous paper[1] (and recalculated from Lane's half-wave potential data[2]) are given in Table 1.

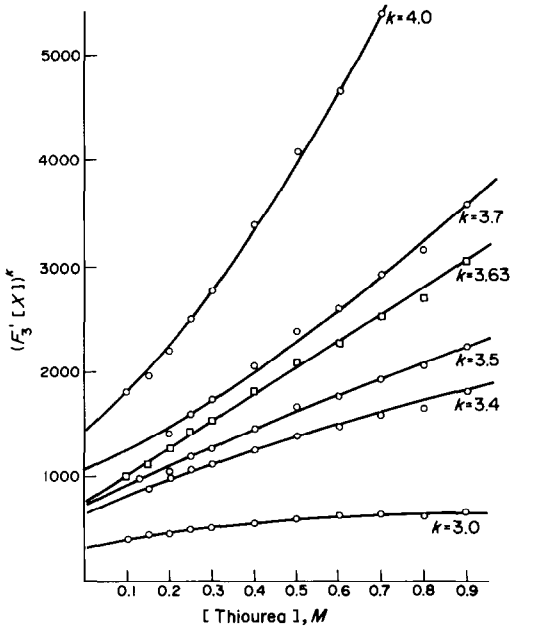

Fig. 5. $(F'_3[X])^k$ *vs.* [thiourea] curves for k values between 3 and 4.

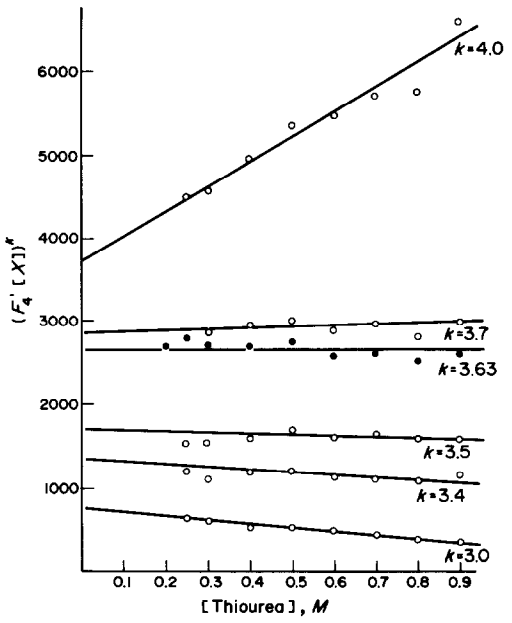

Fig. 6. $(F'_4[X])^k$ *vs.* [thiourea] curves for k values between 3 and 4.

Lead–thiourea

Although the β-values are expected to be considerably lower than those for the corresponding cadmium complexes, as indicated by the very small $\Delta E_{1/2}$ values reported by Lane, the variation in i_d over the same ligand concentration range is almost three times that observed for cadmium (Fig. 1). On the assumption that a maximum co-ordination number of 4 is approached at the highest ligand concentration, a value of 1.44 is estimated for k. The β-values agree favourably with those obtained by Lane (Table 1).

Cadmium–ethylthiourea

This system gave the largest changes in diffusion current, yielding a proportionately smaller value of 1.11 for k. Although the value of β_4 obtained was of the same order as that reported by Lane,[2] the other constants differed considerably from the earlier values. No re-examination of the earlier calculations, using half-wave potential data, has been attempted for this case, but it is perhaps worth comparing the stepwise constants obtained by the two methods (Table 2). The data resulting from the diffusion-current calculations show a more consistent trend.

Cadmium–imidazole

Relatively small current changes were observed, but it is immediately clear from the position of the pseudo-formation curve that the formation constants considerably higher than those of the other systems investigated. The stepwise constants (Table 2) are seen to compare very favourably with those reported by Tanford and Wagner.[3]

CONCLUSIONS

The general validity of this method of analysing pseudo-formation curves has been demonstrated for neutral ligands. The most obvious application is to systems giving irreversible diffusion-controlled polarographic waves and this will be reported on later. Further, the way is now clear to apply the equations[1] based on mean diffusion coefficients. It will be shown that the serious cumulative errors which are inherent in the Leden analysis may be substantially reduced. A practical limitation to this application is the lack of precision in the available diffusion-current data in the literature and indeed in those obtained by the author

with conventional methods. This is because many more data points are required—the minimum is 20, covering the range of ligand concentration, particular importance being attached to those at lower ligand concentrations—and it is necessary to measure changes in diffusion current to ± 1 nA. A technique for accomplishing the necessary precision has been devised and will be reported in a later communication.

In this way it is possible not only to obtain results which are clearly superior to those obtained from half-wave potentials but also to obtain results when $E_{1/2}$ data cannot be used because of irreversibility of the electrode process.

SELECTIVE EXTRACTION OF METAL IONS ASSOCIATED WITH HUMIC ACIDS

J. SLAVEK, J. WOLD and W. F. PICKERING
Chemistry Department, University of Newcastle, N.S.W. 2308, Australia

(*Received* 22 *September* 1981. *Revised* 1 *April* 1982. *Accepted* 9 *April* 1982)

Summary—The ability of a range of electrolyte solutions to release metal ions (Cu, Pb, Cd, Zn) presorbed on two samples of humic acid has been investigated. Though treatment with mineral acid or a chelating agent released a high proportion of the retained metal ion, recoveries were never total. Concentrated salt solutions displaced about 80% of the retained Cd or Zn, and about half of any Cu or Pb held by the organic matter, which indicates that most of the adsorbed metal ion is exchangeable, the extraction efficiency being controlled by competing equilibria. The effect of added clay suspensions was also examined. Analytical procedures for fractionating the total metal content of soils into subgroups have been assessed against the observed extraction behaviour.

Only a fraction of the total metal content of soils and sediments tends to be available for uptake by plants or biota. This fraction is generally associated with the "colloidal" material (*i.e.*, clay minerals, hydrous oxides and organic matter), but views differ on the relative effects of the individual components. Opinions also vary in respect of the most suitable procedure(s) for evaluating "available" levels. A widely adopted approach is extraction with a chemical solution, and a wide variety of active constituents has been proposed, ranging from acids (strong or weak) to complexing agents or salt solutions of different types. Further, as reported in a recent review,[1] the correlations obtained between extraction values and plant uptakes tend to be sensitive to the species of plant grown and type of soil used. There is also uncertainty about whether different reagents release metal ions from the same or from different types of binding sites.

By making arbitrary assumptions about the behaviour of metal ions associated with different components of a sample, when exposed to solutions of varying reactivity, it is possible to propose sequential procedures which theoretically fractionate the total metal content into subcategories. Some investigators have been satisfied with a simple division (*e.g.*, between detrital and non-detrital) while others[2–7] have been more ambitious and have sought to identify several fractions, loosely classified as ion-exchangeable, weakly adsorbed, associated with organic matter, precipitated, retained by hydrous oxides, *etc.* The order of attack adopted varies between authors, owing, in part, to limited understanding of some or all of the competing equilibria involved.

The relative efficiency of various reagents in retrieving Cu, Pb, Cd or Zn ions presorbed onto clay suspension has been investigated.[8] It was found that a few extractants (*e.g.*, EDTA, oxalic acid) recovered all the adsorbed metal ion, but in most of the systems examined the extraction yield varied with the type of clay, the metal ion, and the pH and concentration of the extractant, as well as with the pH during the initial sorption stage.

Recent studies have shown that the adsorption capacity of a common organic component (humic acid) can exceed that of clay minerals. A change in pH can cause marked changes in the uptake of metal ions by such humic acids[9] or humic acid–clay mixtures[10], and we therefore deemed it appropriate to examine the effect of various electrolytes on the organic acid–metal ion equilibria, with a view to clarifying the situation.

EXPERIMENTAL

Humic acid samples

The solids used in the experiments were technical grade products purchased from Fluka AG (HA I) and Aldrich Chemical Co. (HA II). Uptake of hydrogen ions by HA I was small but about 0.8 mole/kg for HA II. Acid washing of HA I (13% ash) and HA II (20%) ash released cations to the following extent (expressed as mmole/kg, HA II values in parentheses): Na^+ 420 (13); Al^{3+} 67 (280); Ca^{2+} 38 (460); Mg^{2+} 20 (80); Fe^{3+} 6 (22); Zn^{2+} 0.2 (3). The adsorptive capacity of the two organic acids for metal ions varied with pH, but at around pH 5 the values (mole/kg) obtained[9] for HA I and HA II respectively were Pb^{2+} 1.0 and 0.7, Cu^{2+} 0.8 and 0.5, Zn^{2+} 0.6 and 0.3, Cd^{2+} 0.5 and 0.25. At pH > 8, the metal–humate complexes of HA I tended to become soluble. Higher pH values were required for dissolution of metal–HA II species.

Extraction studies

Aqueous suspensions of the two humic acids were prepared, and aliquots (5.0 ml, containing about 3 mg of solid) were transferred into clean, acid-washed 30-ml glass vials followed by 10.0 ml of $5 \times 10^{-4} M$ metal nitrate solution and enough doubly demineralized water to give a final volume of 30.0 ml. The vials were sealed and transferred into an end-over-end stirrer device immersed in a water-bath held at 25°. After 24 hr of mixing and equilibration, the contents of the vials were filtered with 25-mm diameter 0.45-μm pore membrane filters. The metal contents of the

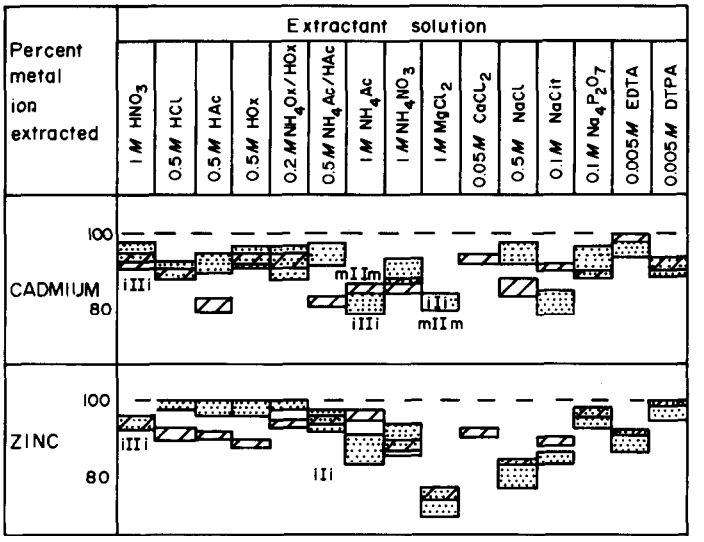

Fig. 1. Percentage of adsorbed Cd or Zn ions extracted from humic acid suspensions by electrolyte solutions. ▨ Humic acid I; ▩ Humic acid II. Symbols indicate mean ± S.D. The lettered entries indicate systems in which addition of clay particles (i = illite, m = montmorillonite) altered the recovery level.

filtrates were then determined (by atomic-absorption spectrometry under appropriate conditions) in order to ascertain the amounts of metals retained by the solid.

The filters were carefully transferred back into the original vials, and 30.0 ml of the chosen extractant were added. The vials were again sealed, transferred to the stirrer and allowed to equilibrate for 24 hr before filtration of the contents with fresh 0.45-μm membranes, Analysis of the filtrates permitted calculation of the percentage of adsorbed material released.

To permit statistical examination of the data, and allow for occasional leakages or losses, replicate studies (generally 10) were made for each of the 16 extractant solutions.

Since the extractants (listed in Figs. 1 and 2) varied greatly in chemical composition and concentration, individual calibration curves were prepared for each extraction system. The atomic-absorption spectrometer used (an updated Varian-Techtron AA5) had background-correction facilities which compensated for some salt effects, but the solution matrix had a significant influence on the slope of Cu and Pb calibration graphs, in particular.

Total loading effects

In another series of studies, the pH of the humic acid suspensions was increased by adding sodium hydroxide. This led to greater uptake of metal ion by the solids in the adsorption stage, as shown in Table 1, but few changes in the degree of extraction by a selected range of solutions. The reverse effect, *i.e.*, smaller total uptake, was achieved by having less metal ion present in solution during the adsorption step, *viz.* by using solutions which were initially 0.5 or 1.0×10^{-4} *M* in metal nitrate, instead of the 1.67×10^{-4} *M* used in the majority of tests.

Clay–humic acid mixtures

Since the adsorptive capacity of clay–humic acid mixtures is not always additive,[10] extraction studies were also made with solid suspensions which contained both components (*i.e.*, 5.0 ml containing 2.5–2.8 mg of humic acid and *ca.* 10 mg of Na^+-form montmorillonite or illite). The presence of the clay increased the time required for filtration, but had little effect on the precision achieved or the percentage of total sorbed metal ion extracted (*cf.* Figs. 1 and 2).

Destructive oxidation

Portions of humic acid (*ca.* 3 mg of solid) and metal nitrate solution (5 μmole of M^{2+}) were treated with 10 ml of 1*M* nitric acid and two successive 5-ml volumes of 30% hydrogen peroxide, with warming to ensure rapid oxidation of the organic matter. The resultant clear solutions were then filtered and analysed for metal content.

RESULTS AND DISCUSSION

Extraction of zinc and cadmium

It can be observed from Fig. 1, that most of the extractants tested displaced more than 80% of the presorbed Zn or Cd ions.

Humic acid I (symbol ▨) retained the sorbed material to a slightly greater extent in acid media, but released marginally greater amounts to the complexing agents. The alkaline complexing solutions (*i.e.*, citrate, pyrophosphate, EDTA, DTPA) appeared to dissolve or colloidally disperse the humic acids, but there was a residual > 0.45-μm fraction which retained a measurable amount of the sorbed ion (this observation is consistent with adsorption/pH trends observed in earlier studies[9]).

No attempt was made to reduce the ash content of the humic acid samples, since drastic purification methods can cause abnormal changes in humate characteristics, and it was believed that most organic acids in their natural environment would be in salt form and associated with other colloidal matter. Though competition from displaced cations may have contributed to the smaller uptake by HA II in the adsorption stage (as shown in Table 1) any residual counter-ions should have had little effect on the metal-ion extraction step.

The two humic acids released different proportions of the adsorbed metal ions into most of the extrac-

*With $[M^{2+}]$ initially $1.67 \times 10^{-4}M$, 100% adsorption with HA alone corresponds to *ca.* 1.85 mole of M^{2+} per kg of HA. Each 10% increase in sorption due to presence of clay (similar pH) corresponds to *ca.* 45 mmole of M^{2+} sorbed per kg of clay.

†2.6–2.8 mg of HA added to 30 ml of M^{2+} solution.

§Weight of clay present: 10 mg (illite) or 11 mg (montmorillonite).

tants studied (*cf.* Fig. 1 and 2) but these variations have been attributed to differences in chemical structure, that is, the type and spatial location of the functional groups attached to the organic moeity. The chemical reactivity of humic acid samples is usually attributed to constituent carboxylic acid groupings, in particular these located *ortho* or *meta* to phenolic groups or a second carboxylic acid group, with contributions from other functional groups such as $-NH_2$ or –SH. Interaction between metal ions and humic acids has been shown to yield both 1 : 1 species and 1 : 2 complexes.[11–13] In the 1 : 1 forms, the metal ion is either retained through a salt-type linkage (*i.e.*, $RCOO^-M^{2+}\ldots$) or co-ordinated to appropriately

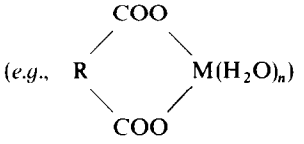
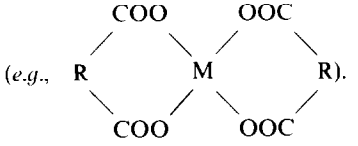
located pairs of functional groups



In the 1:2 complexes, the metal ion becomes fully co-ordinated to functional groups



Because of the polyfunctional nature of the humic materials, extended chains can also develop. Experimental conditions can influence the amount of each type formed, which partially explains why views differ on the relative order of stability for metal humate complexes. Proposed sequences include Cu > Pb ≫ Cd > Zn;[12,14] Pb > Cu > Ni > Cd;[15] and Cu ≫ Zn > Pb.[16]

In an earlier study,[9] which involved reactant ratios similar to those used in this investigation, it was found that every μmole of M^{2+} sorbed by the organic sample released either 1.3 μmole of H^+ (HA I) or 1.1 μmole (HA II). These values imply that the predominant reaction is formation of 1:1 species, a conclusion supported by the effectiveness of salt solutions in displacing the adsorbed metal ions.

As noted above, Cd and Zn humate complexes are less stable than those of Cu and Pb, and comparison of Figs. 1 and 2 shows that this was reflected in the amount displaced by the different reagents. The bonding of the Cd and Zn appears to be predominantly electrostatic (*i.e.*, salt-type linkages), since most of the adsorbed material was displaced by competing cations (*i.e.*, NH_4^+, Na^+, Ca^{2+}, Mg^{2+}). Protons from acid solutions were slightly more effective (owing to their greater affinity for the functional groups involved) and solutions containing chelating agents also gave higher recoveries (partly because of the stability of the metal chelates formed, and partly owing to dissolution of the solid). The marginal differences in the amount of Cd or Zn extracted by many of the displacing reagents imply that Zn was not quite as strongly bonded as Cd.

The total, or near total, recoveries achieved in a limited number of systems demonstrated that the lower values were real, and not an artefact of the experimental procedure. The blocks shown in Figs. 1 and 2 represent the mean value ± the calculated standard deviation (for 8–10 determinations). It was found that the relative standard deviations rarely exceeded 4%, and in nearly two-thirds of the systems studied the precision achieved was better than ± 2%. Careful calibration and manipulation were required to achieve this limited spread, because the procedure involved two filtration steps and analysis of solutions having different chemical compositions.

Extraction of copper and lead

The greater affinity of humic acids for Cu or Pb ions is clearly reflect in the extraction values reported in Fig. 2. In particular, far less of the adsorbed material was displaced by the salt solutions. The amount of lead retrieved by these extractants, and also with the mineral acids and buffer solutions, exceeded the copper recoveries, so copper appears to be more firmly bound than lead on the humic acid samples studied.

As with Cd and Zn, the amount released by chelating agents such as DTPA and EDTA was > 90%, but not total, which again indicates strong bonding of some of the metal ion to residual solids. Increasing

the chelate concentration tenfold (i.e., to 0.05*M* EDTA) had little measurable effect. Behaviour in the presence of acids was somewhat variable, lead recovery in the presence of oxalic acid being quite low. This has been attributed to conditions favouring the formation of sparingly soluble lead oxalate. The addition of ammonium oxalate, however, favoured formation of soluble oxalato-complexes and the lead extraction values then exceeded 90%.

The electrolyte extractants (NH_4NO_3, NaCl, $MgCl_2$, $CaCl_2$) displaced only about half of the sorbed ions (with less from HA I than HA II), which indicates that a higher proportion of Cu and Pb ions become co-ordinated to the organic solid.

Effect of clay suspensions

Natural systems may contain mixtures of clays and organic acids. To assess the effect of greater contamination with silicate material, studies were made with systems in which the clay content was 3–4 times the amount of humic acid added. The extractants used in these comparison studies were nitric acid, ammonium acetate, magnesium chloride and EDTA. Two different types of clay were used, namely montmorillonite (which has a high adsorption capacity and retains metal ions mainly through electrostatic attraction) and illite (with a lower capacity and a tendency to bind some ions specifically, particularly lead).

It was found that in over three-quarters of the systems studied, the amount extracted was similar to that in the absence of the clay. For recoveries differing from that for humic acid alone by > 5% (absolute), the observed values are recorded in Figs. 1 and 2 and indicated by symbols such as m II m (montmorillonite/HA II mixture) or i I i (illite/HA I).

A previous study[10] indicated that interaction between illite and HA I and HA II is limited, and that the adsorption capacity of the mixtures for metal ions is additive, whereas with montmorillonite (or kaolinite) the uptake can be less than the sum of the individual uptakes. It has also been observed[8] that the ability of electrolyte solutions to release metal ions sorbed on clays varies with the metal involved, the type of clay, and reagent used. In summary, chelating agents tend to displace presorbed metal ions totally, mineral acids release > 90%, and ammonium acetate or sodium or calcium chloride solutions displace as little as half of the retained matter.

Most of the variations noted in the clay–humic acid extraction studies can be attributed to extraction values for the clay component being higher, or lower, than those for the humic acids. The highest proportion of varied responses occurred for Pb with ammonium acetate or magnesium chloride solution, these being the two extractants most sensitive to changes in bond strength or bonding mode.

Since the addition of excess of clay only slightly varied the extraction behaviour, the contribution of the inorganic contaminants present in the humic acids used (*i.e.*, the ash fraction) was probably quite small.

Effect of surface loading levels

As shown in Table 1, the amount of metal ion initially retained by the humic acids could be varied by either increasing the system pH, or by reducing the initial metal ion concentrations.

The number and type of metal–humate complexes formed has been reported to be influenced by the total metal: humate ratios, so a few studies were made with HA II to ascertain whether small changes in total loading affected extraction behaviour. It was found that increasing the uptake by increasing the pH led to slightly higher extraction percentages, *i.e.*, proton abstraction appears to create more negative sites, to which metal ions might be electrostatically attracted. Reducing the amount sorbed by using more dilute initial solutions also led to higher extraction values, which implies that formation of 1:1 species with salt-type linkage could be the preferred initial form of bonding. Both these findings indicate that the fraction extracted is influenced by environmental conditions at the time of metal ion retention.

Peroxide oxidation of humic acid

To release metal ions bound to organic matter, destruction of the organic phase has regularly been recommended, and oxidation with hydrogen peroxide has been one of the preferred methods (*c.f.* Table 2). It was found in this study that peroxide treatment of solutions containing metal salt and humic acid yielded 99% recoveries of Zn^{2+}, 97–98% of Cd^{2+} and 95% of the initial Cu^{2+} but only 67% (HA II)–75% (HA I) of the added Pb^{2+}.

It has been noted that though peroxide treatment can make soils incapable of chelating metal ions (*e.g.*, Zn^{2+}), not all the organic matter is necessarily destroyed.[17] Oxalic acid has been identified[18] as the major product formed on treating soil organics with hydrogen peroxide, and the oxalates of calcium,[19] iron and aluminium[20] have been observed in soil samples pretreated with this reagent. It is therefore assumed that the low Pb recoveries noted above are due to the formation of lead oxalate (*cf.* extraction behaviour with oxalic acid, Fig. 2).

Other oxidants may yield different products, and the possible effect of these on metal ion recoveries warrants further investigation.

ANALYTICAL IMPLICATIONS

Hydrochloric acid (0.1*M*),[21] 1*M* ammonium chloride[22] or acetate,[3] and 0.05*M* calcium[2] or 1*M* magnesium chloride[6,23–25] have all been proposed as suitable extractants for the evaluation of the "available" or "exchangeable" fractions of the total metal content of soils.

It may be seen from Figs. 1 and 2, however, that reagents such as these extract differing amounts of metal ion from humic acids, a result similar to that noted earlier for clay suspensions.[8] The preferred re-

agents, magnesium and calcium chlorides, displace, in general, less than the other proposed reactants, but the amount released by each system tends to be quite variable, depending, *inter alia*, on the type of humic acid, surface loading, equilibrium pH, and type of clay present (if any).

Variations between reagent responses may be of minimal concern if the analytical data are intended solely to indicate major differences in soil behaviour (*i.e.*, for comparative studies) and no special significance has to be placed on the assignment terminology used, although the influence of other variables on extraction values probably contributes to the correlation problems associated with plant pot-trials.

However, where sequential extraction steps are to be adopted, with the aim of fractionating the total content into specific categories (*e.g.*, exchangeable, weakly adsorbed, associated with organic matter) improved understanding of the chemical equilibria associated with the extractant–solid interactions becomes highly desirable.

A summary of the sequential approach proposed by four different groups is provided in Table 2, and this can be used to illustrate the complexity of the problem.

It can be seen that the determination of the fraction bound to organic matter occurs at different stages of the various sequences. In one case,[7] the initial step is destruction of organic matter with sodium hypochlorite at pH 9.5. At this pH most types of metal ions released should precipitate as hydroxide species, and retrieval of this group will be deferred to the next stage, namely, acidification with hydrochloric acid (this reagent will also dissolve metal carbonates, displace cations from clay surfaces, *etc.*). Hence any metal ion identified in the alkaline centrifugate may thus provide a poor indication of the material initially associated with the organic matter (or present as sulphides). The source of the analytical result could be colloidal dispersions or metal-organic species not fully oxidised by the reagent used. In the other three systems,[2,5,6] the soil is first treated with calcium or magnesium chloride solution, and as shown in Figs. 1 and 2, this can displace 50–80% of any Cu, Pb, Cd or Zn associated with the humic acid component. Subsequent steps in the sequences (*e.g.*, treatment with acetic acid,[2] or acetate buffer and dithionite/citrate[5]) are capable of displacing further fractions of the metal initially associated with the organic acids. Accordingly, only the fraction most firmly co-ordinated to the organic component will be released on destroying the organic matter with hydrogen peroxide. The use of this reagent can also introduce side-effects, however. For example, low lead recoveries have been noted in this paper, and are thought to be probably due to lead oxalate formation. Any oxalic acid formed in this way could also aid dissolution of hydrous oxide layers (releasing associated metal ions) and addition of peroxide may result in some dissolution of manganese oxide particles.

It may therefore be concluded that if the same soil were subjected to each of the four sequences proposed, the analytical result reported for "bound to organic matter" could be different in each case. It seems likely that development of valid sequential systems may have to await completion of more basic studies, for example, investigation of the extraction of metal ions presorbed on hydrous oxides, or side-effects in oxidation procedures.

Other soil scientists have preferred to determine "non-detrital" or "available" metal ion levels by means of a chelating agent, such as DTPA,[26,27] but the efficiency of these methods can also be influenced by reaction parameters. For example, it has been observed that the amount of metal ion released can be increased by increasing the shaking time,[28,29] extractant concentration,[29] solution pH (from 4.8 to 8.5)[29] or the duration of the initial sample-grinding period.[26]

With organic-rich natural soils some of the metal ions displaced by salt solutions may be present as solubilized metal–humate complexes. The two humic acids studied in this investigation required a high pH for solubilization, but two forest soil acids previously used[9] formed water-soluble complexes at pH > 6 (Cu, Pb) or 7 (Cd, Zn).

In summary, examination of metal ion recoveries from humic acid samples by different chemical extractants has confirmed that in any extraction procedure very careful consideration must be given to the associated chemical equilibria and the impact of competing reactions.

(*Received* 18 *November* 1981. *Revised* 17 *February* 1982. *Accepted* 23 *March* 1982)

Summary—Construction details and voltammetric characterization of a long-lasting sessile-drop mercury electrode are reported. The results obtained in the fully automated differential pulse anodic-stripping voltammetric determination of cadmium in a simple purified electrolyte as well as of zinc, cadmium and lead in sea-water samples suggest that this new kind of semi-stationary mercury electrode may be employed in voltammetric trace and ultratrace analysis of natural waters for metal ions.

In recent years, under the thrust of environmental problems, the determination of trace and subtrace (down to 50 ng/l)[1] metal concentrations in natural waters, sea-waters, industrial effluents, biomatrices, *etc.* has received increasing attention. This is mainly because it has been found that some heavy metals (such as cadmium, lead and mercury) have toxicological action, even at very low concentrations, while other metals (such as copper, chromium and zinc) at concentrations below their respective critical threshold levels are essential to man and other organisms.[1–3] Among the various analytical methods currently used in such investigations, electrochemical stripping analysis is of particular interest, because of its intrinsic simplicity, sensitivity and flexibility in operation. Differential pulse anodic-stripping voltammetry (DPASV) is one of the instrumental techniques which appears particularly well suited to the determination of traces of copper, zinc, cadmium and lead. This technique, which requires only simple and inexpensive apparatus, involves cathodic deposition on a stationary or semi-stationary electrode at an appropriate potential and for a given time. The solution is usually stirred in this period to increase the sensitivity of the method, since during the deposition from a solution with a very low bulk concentration of metal, a substantial preconcentration on the working electrode is achieved. At the end of the programmed deposition process, the stirring is stopped and in the following rest period the solution comes to rest so that the mass transfer in the subsequent stripping stage takes place by diffusion only. Finally, an anodic stripping of the deposited metal yields the current signal used for the quantitative determination. In the stripping stage, a sequence of pulses of small amplitude and duration is superimposed on the voltage sweep while the current flowing through the cell is sampled twice, just before the rise and the fall of each pulse.[4–6] Impregnated graphite electrodes,[7,8] glassy-carbon electrodes,[9] noble metal electrodes,[10] mercury-film electrodes,[1,11–13] and Kemula's hanging-drop mercury electrodes[14–21] have been employed as working electrodes. Of these, the mercury-film and the hanging-drop mercury electrode have provided the best results in the determination of trace metals by DPASV. Kemula's electrode, a truly sensitive tool is difficult to manipulate, however, since it must be renewed manually for each determination, with consequent poor repeatability and waste of time. Mercury-film electrodes, which unlike Kemula's electrodes can be operated in a fully automated sequence, require great care in preparation of the surface (where the mercury film will be deposited) as well as long and tedious conditioning before the analysis. Ordinary capillary electrodes with a long drop-time (60–80 sec) have also been employed for the determination of zinc, cadmium and lead in sea-water samples by DPASV.[6,22] However, with such electrodes the deposition time must be quite short (30–40 sec) while the voltage range cannot be larger than 500 mV at a scan-rate of 20 mV/sec.

In a previous paper[23] we have proposed a new kind of semi-stationary mercury electrode: the long-lasting sessile-drop electrode (LLSDME) which allows a longer electrolysis time with more vigorous stirring, a longer rest time to obtain a quiescent solution, a larger potential range at slower scan-rates and lastly, a higher current response. The results obtained in the determination of zinc either in a simple purified electrolyte or in sea-water samples with a semi-automated sequence (the drop was dislodged manually at the end of each anodic scan) and a non-analytical multipolarograph suggested that after optimization of the parameters which affect the sensitivity of the method, the

LLSDME could be suitable for the determination of metals at subtrace levels by DPASV.

In the present paper we report more detail of the construction of LLSDME as well as the results obtained in evaluating the influence of some parameters (namely electrolysis time, rate of stirring, amplitude of superimposed pulse) on the peak current for cadmium in potassium chloride solution. The current was recorded with fully automated equipment, which mechanically dislodged the drop and also controlled both the deposition and rest times. To illustrate the potential analytical applications of the LLSDME, the simultaneous determination of zinc, cadmium and lead in sea-water samples is reported.

EXPERIMENTAL

Construction of the LLSDME

The electrodes were made from ordinary polarographic capillaries (Sargent, drop-time 6–12 sec; Amel, 10–15 sec, 21–22 cm long) as shown in Fig. 1. A 2–3 cm length about 5–6 cm from one end was rotated in a slot-type flame (Fig. 1a) until red-hot and then gently drawn out to reduce its external diameter to about 2 mm (Fig. 1b). The capillary was then cut off about 1–2 cm from the end (Fig. 1c), and the tip ground to a truncated cone (Fig. 1d) with a diamond grindstone. The narrow portion was then bent into a hook, in a small Bunsen flame (Fig. 1e). The capillary was connected to the self-levelling mercury reservoir as shown in Fig. 2, then filled with mercury by means of a vacuum pump or by squeezing the Tygon tubing. When immersed in 0.1*M* potassium chloride (stirred at 800 rpm) with −1.3 V applied in a closed circuit the electrodes gave drop-times of 6–10 min. To avoid blocking, the mercury should be dropping continuously. Some electrodes more than 7 months old are still functioning satisfactorily.

Apparatus

An Amel 472/WR multipolarographic analyser, Amel 862/D X-Y recorder and a synchronized electromagnetic knocker were used. The apparatus was modified to allow the electrolysis and rest times to be varied up to 999 and 100 sec respectively.

Procedure

At the push of a "start" button the mercury drop is dislodged by the knocker, the solution (60–80 ml) is stirred (at 200–800 rpm) while the drop is polarized at a preset potential (*e.g.* −1.20 V for zinc, −0.85 V for cadmium and lead). After 120–360 sec the stirring is stopped, and after a further 12–30 sec rest period the anodic voltamperogram is recorded at 5 or 10 mV/sec. At the end of the scan the knocker dislodges the drop and a new sequence begins automatically. All the determinations were performed at 25° in a Teflon or fused silica cell with an SCE (Ingold) and a platinum ring (Ingold) as reference and counter-electrode, respectively. The reference electrode was filled with saturated potassium chloride solution and connected to the test solution by a tube filled with 1*M* potassium chloride solution and fitted with a sintered-glass disc. The test solution was stirred by a magnetic stirrer and a Teflon-covered iron bar with a Teflon ring fitted over it (Fig. 3). The standard solutions were added from automatic microlitre pipettes (Gilson). The sea-water samples were collected and stored in polyethylene bottles, previously cleaned as described in the literature.[24,25]

Chemicals

Potassium chloride (Merck, Suprapur) and nitric acid, 65% w/w (Merck, Suprapur or BDH, Aristar) were used, as received, to prepare the supporting electrolyte and the cleaning solutions, respectively. The cadmium, lead and zinc standard solutions were prepared by diluting stock solutions of their nitrates (Fluka or BDH, for atomic spectroscopy). Argon (99.99% pure) was used to deoxygenate the solutions. For cleaning purposes and for preparing the standard solutions two different water supply systems were employed. The first was a Millipore Q-system, the second used multiple distillation in glass and then double distillation in quartz. To check the presence of contaminating metals in the mercury used for the tests, voltamperograms were recorded for an anodic voltage scan (from −1.20 to −0.20 V) on the mercury drop in 0.01*M* potassium chlor-

ide after the drop had grown for 390 sec in open circuit and non-stirred solution. Mercury with a concentration of heavy metals less than our limit of detection was obtained by the following procedure. Mercury (C. Erba, pure for analysis) was scrubbed several times by passing it through a funnel (with a sintered-glass disc in its neck) into a glass tube (100 cm height, 4.5 cm diameter) containing 15% w/w nitric acid; it was then washed with ultrapure water (in a similar column), and dried and distilled under reduced pressure. The intermediate fraction was collected, again scrubbed with 12% v/v nitric acid, washed, dried and lastly redistilled four times under reduced pressure.

RESULTS AND DISCUSSION

Optimization of some parameters affecting the sensitivity

In DPASV, the peak current depends mainly on the electrolysis time, stirring rate, electrode size, pulse amplitude, pulse repetition time and scan-rate. To optimize some of these parameters, we examined the influence of electrolysis time, stirring rate, pulse amplitude and potential scan-rate on the peak current for cadmium in potassium chloride solution (Figs. 4–7). The pulse repetition time was kept constant at 0.1 sec since it is an instrumental characteristic of the polarograph used.

The peak current rises with increase in stirring rate (from 0 to 800 rpm) as shown in Fig. 4a. Thus, vigorous stirring enhances the mass transfer of cadmium ions towards the electrode.

The peak current decreases when the anodic voltage scan-rate is increased (from 5 to 50 mV/sec), as shown in Fig. 4b. This depends on the fact that if the anodic scan-rate is increased the duration of each measurement is reduced and the number of samplings distributed along a voltamperogram decreased (the pulse duration is constant). In other words the number of current differences which add up to give the amplitude of the voltamperogram will also decrease. Moreover, at slow anodic scan-rates a second-order effect becomes evident: though at slow scan-rates the variation of potential during a pulse can be regarded as negligible, at fast scan-rates it can not, and it adds a contribution to the charging current.[6] Therefore, the sensitivity and the resolution of the method will be rather impaired at fast scan-rates since the peaks will be smaller and broader.

Figure 4c shows the influence of the electrolysis time on the peak current, which increases when the deposition time is made longer (from 60 to 360 sec).

Finally, Fig. 4d shows that increasing the modulation amplitude (from 10 to 100 mV) of the superimposed pulse at first increases ($\Delta E \leqslant 80$ mV) and then ($\Delta E > 80$ mV) decreases the peak current.

Thus, to obtain a higher sensitivity in DPASV with an LLSDME a long electrolysis time (300–360 sec), a fast stirring rate (800 rpm), a high pulse modulation amplitude (50–80 mV) and a slow scan-rate (5 or 10 mV/sec) are to be preferred.

Linearity of response and repeatability

The linearity between peak current and concentration was checked by the standard addition method. For this purpose, various volumes of a $10^{-6}M$ standard cadmium solution were added to $0.01M$ potassium chloride. The repeatability was tested at different cadmium concentrations on consecutive mercury drops. The choice of cadmium was suggested by its low abundance in the environment and therefore by the highly unlikely occurrence of accidental pollution of the solutions during the required manipulations.

Fig. 4. Effect of stirring rate (a), anodic sweep-rate (b), electrolysis time (c) and pulse modulation amplitude (d) on peak current for an LLSDME. Solution (84 ml) 1.64 × $10^{-9}M$ Cd in 0.01M KCl; electrolysis potential = −0.85 V; electrolysis time = 300 sec (d) or 360 sec (a, b); stirring rate = 800 rpm (b, c, d); rest time = 30 sec; pulse modulation amplitude = 20 mV or 50 mV (a, c); sweep rate = 10 mV/sec (a, c, d); 25°C.

Typical voltamperograms relative to two (6th and 7th) successive mercury drops are shown in Fig. 5, and the peak currents (i_p) at different cadmium concentrations (C) obtained on seven consecutive drops are reported in Table 1. From Table 1 it follows that over the concentration range examined (10^{-10}–$10^{-9}M$) satisfactory linearity between i_p and C can be obtained. Moreover, from curves a–e and a′–e′ in Fig. 8 or the data reported in Table 1 it is evident that the cadmium peak gives good repeatability (3%, Table 1) even at the lowest concentration examined. Finally, from Table 1 it is possible to calculate by linear regression the concentration of cadmium in the 0.01M potassium chloride solution; it is 1.72 ng/l.

Determination of zinc, cadmium and lead in sea-water

The simultaneous determination of zinc, cadmium and lead in a sea-water sample by DPASV with an LLSDME is shown in Figs. 6 and 7. The sample was

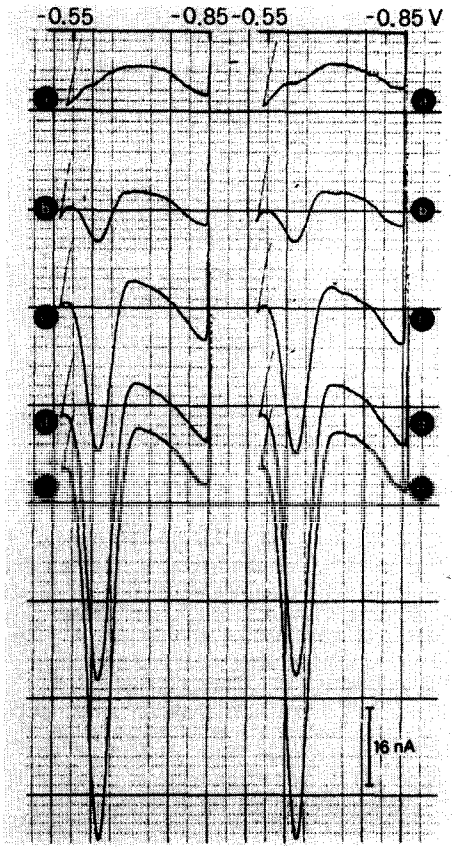

Fig. 5. Anodic stripping voltamperograms of cadmium in KCl solution. (a) 84 ml of 0.01M KCl; electrolysis potential = −0.85 V; electrolysis time = 360 sec; stirring rate = 800 rpm; rest time = 30 sec; pulse modulation amplitude = 50 mV; sweep-rate = 10 mV/sec; mercury head = 57 cm; 25°C; (b–e) as for (a) after addition of (b) 14.1, (c) 56.5, (d) 98.9 and (e) 141.1 ng of cadmium per litre. Voltamperograms a–e and a′–e′ refer to the sixth and seventh mercury drops, respectively (see Table 1). Every voltamperogram is recorded on a "fresh" mercury drop (see text).

§The roman numeral refers to the mercury drop number.

collected by us in the Tyrrhenian sea about 4 miles off the mouth of the harbour-canal of Castiglione della Pescaia (Grosseto, Italy). Two typical explorative voltamperograms are shown in Fig. 6, and some relative to the determination of cadmium and lead are shown in Fig. 7. From curves a–c and a′–c′ in Fig. 7, and curves recorded for the zinc determination, it is evident that every peak gives satisfactory repeatability. From the corresponding i_p–concentration plot (regression line) the concentrations of zinc, cadmium and lead in the sea-water sample were evaluated as 1560, 24 and 366 ng/l., respectively.

Two other sea-water samples were collected by the researchers of the Thalassographic Institute of CNR, Trieste (Italy), in the North Adriatic sea (stations GT 5 and GT 9), during a cruise of the oceanographic ship "Marsili". The samples were stored at low temperature (−5°) and analysed by us after about 4 months. The concentrations of cadmium and lead in the two samples were evaluated as 70 and 510 ng/l. for GT 5, and 17.8 and 418 ng/l. for GT 9.

CONCLUSIONS

The experimental results reported so far, as well as those obtained with some other electrodes of the same kind, suggest that the LLSDME may be employed very satisfactorily for the determination of metals at trace and subtrace levels in natural waters, industrial effluents, biomatrices, *etc.* by the DPASV technique. The LLSDME, easily prepared from an ordinary capillary and usable without precautions over a long period, can be used in fully automated equipment. Moreover, each measurement is performed with a fresh and highly reproducible mercury drop, a condition less likely to be met by stationary electrodes.

Work is in progress in our laboratories to improve the sensitivity (in the work on sea-water reported here we have reached a repeatability of about 3% with a detection limit of about $10^{-10}M$). We intend to modify both the capillary and the polarographic apparatus. A modified capillary design could allow more vigorous stirring of the test solution without detaching the mercury drop, and thus shorter deposition times even for subtrace analyses. Modification of the analyser to allow use of subtractive differential pulse anodic-stripping voltammetry (SDPASV) would cancel the current contribution related to the drop growth. Thus, an appropriate signal recorder could be synchronized with our analysis apparatus so that the current related to the drop growth, recorded for a quiescent solution, is memorized and subtracted from

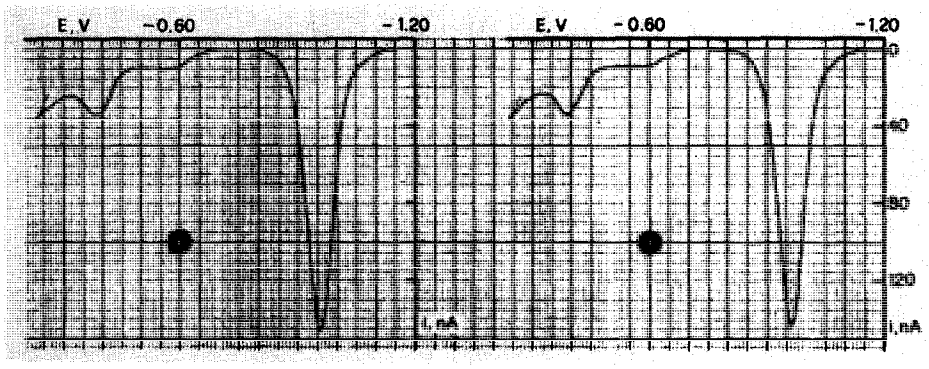

Fig. 6. Explorative voltamperograms from two consecutive mercury drops (a and a′), for a Tyrrhenian sea-water sample (see text). Sample volume = 82 ml; stirring rate = 800 rpm; rest time = 30 sec; pulse modulation amplitude = 50 mV; mercury head = 56 cm; 26°C. Each voltamperogram is recorded on a "fresh" mercury drop (see text). Electrolysis potential = −1.20 V; electrolysis time = 300 sec; rest time = 30 sec; sweep-rate = 10 mV/sec.

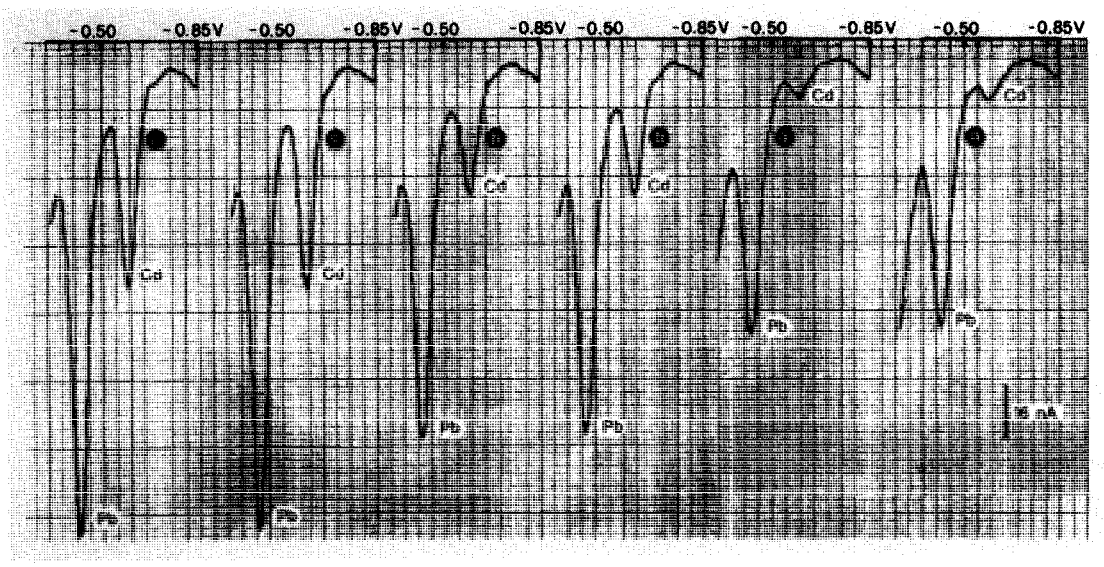

Fig. 7. Determination of cadmium and lead. Electrolysis potential = −0.85 V; electrolysis time = 390 sec; rest time = 30 sec; sweep-rate = 5 mV/sec. (a) Blank; (b) and (c) the same as (a) after addition of 20 μl (b) and 40 μl (c) of $3.56 \times 10^{-6} M$ cadmium and $2.90 \times 10^{-6} M$ lead standard solutions. Curves a′–c′ refer to the results obtained with the next mercury drop.

the currents recorded for subsequent drops in stirred solutions. Therefore, the SDPASV technique may allow improved accuracy and repeatability with an LLSDME.

Finally, we think that this new type of electrode may have many applications in oscillopolarography and in d.c. or a.c. polarography, mainly where decomposition of the medium may occur at very negative potentials, where the performance of Kemula's hanging mercury drop electrodes and the usual dropping mercury electrodes is no longer reliable.

(*Received* 25 *June* 1981. *Revised* 19 *November* 1981. *Accepted* 23 *March* 1982)

Summary—The role of anion-exchange resin beads in the initiation of reactions of tertiary amines with 2,4-dinitrophenylhydrazine has been explored. This reagent has been used for the selective detection and determination of aliphatic amines. Radiochemical studies have been performed to show that the coloured species is adsorbed but not exchanged on ion-exchange beads. A model for the interaction is proposed.

Ion-exchange resin beads were first used as detection media by Fujimoto.[1] The term "resin spot-test" was later coined by him[2] to describe the detection of a substance by conversion into a coloured species which could be taken up on resin beads. In this way the selectivity and sensitivity of the test were improved and the stability of the colour was enhanced. These tests[3] were mostly used for the detection of inorganic species on the basis of known colour reactions. West *et al.*[4] were the first to develop new resin spot-tests for the detection of organic functional groups such as esters, amides, imides and anilides. In these tests the beads were used as carrier for the ions taking part in the reaction, and could be separated from the reaction medium after the reaction was over.

However, no investigations have so far been reported on whether the uptake of the coloured species by the resin beads is due to ion-exchange or adsorption and no effort has hitherto been made to explore the use of resin beads as a substrate for reactions which apparently do not occur in solution. These aspects are now explored, with reference to detection of amines.

Numerous methods have been proposed for the colorimetric detection and determination of amines. Menzie[5] reported that in non-aqueous media *p*-dimethylaminobenzaldehyde (*p*-DAB) gives interesting colours with amines and heterocyclic nitrogen compounds, but as the colours produced with *p*-DAB are unstable this reaction was not used for the spectrophotometric determination of amines. Qureshi and Khan[6] used *p*-dimethylaminocinnamaldehyde (*p*-DAC) for the detection and determination of primary and secondary aromatic amines, as the colour produced is stable. A colorimetric method for secondary amines was proposed by Umbreit[7] and extended by Karweik and Meyers.[8] Rawat and Singh[9] proposed a sensitive method for the spectrophotometric determination of primary, secondary and tertiary amines. A rather unselective photometric determination of low molecular-weight aliphatic amines was proposed by Korenman and Shermarova,[10] and Toome and Manhart[11] developed a simple simultaneous colorimetric determination of primary and secondary aliphatic amines with fluorescamine.

Nitro compounds are known to give interesting but unstable colours with aliphatic amines.[12] The present study had four objectives: (*i*) to explore the conditions for stabilization of the colour of the nitro-compound/amine reaction products; (*ii*) to develop an ion-exchange method for the selective and sensitive detection of aliphatic amines; (*iii*) to determine aliphatic amines by a simple colorimetric method; (*iv*) to identify the mechanism of the resin-bead reaction. A novel feature was a radiochemical study which showed that the coloured species are adsorbed but not exchanged on the resin surface, so doubt arises whether ion-exchange mechanisms operate in those reactions in which colourless resin beads become coloured[1–4,6,9,13,14] when kept in contact with a coloured solution. The present study shows that in at least some cases no ion-exchange occurs, and these reactions should therefore be reinvestigated.

EXPERIMENTAL

Reagents

Solutions of amines were prepared in conductivity water for detection and in dimethylsulphoxide (DMSO) for determination. A 0.1% ethanol solution of 2,4-dinitrophenylhydrazine (DNPH, Merck guaranteed reagent) was used for detection and a 0.02*M* solution in DMSO for determination.

The resins used were Amberlite IRA-400 (Cl^- form) and Dowex 50W-X8 (Na^+ form).

Procedure for detection

Place 4 or 5 Amberlite resin beads (Cl^- form) in the depression of a white spot-plate. Add 0.01 ml of the amine solution to the beads followed by 0.01 ml of reagent sol-

ution. An immediate green colour on the resin surface confirms the presence of an amine.

Procedure for determination

To 1 ml of solution containing an appropriate amount of the amine in DMSO (see Table 4) add 5 ml of 0.02*M* DNPH in DMSO and make up to volume in a 10-ml standard flask with DMSO. Measure the absorbance in a 1-cm cuvette at 640 nm against a blank prepared in the same way and at the same time as the sample solution. The colour is stable for about 4 hr.

Radiochemical studies

In these exploratory tests, 2 g of Amberlite IRA-400 (Cl^- form) were treated with 0.1*M* chloride-labelled sodium chloride solution. The radio-chloride retained on the resin after repeated washing was measured by β-counting. The labelled resin was then treated with a concentrated solution of the DNPH–amine product, by the batch method. After several hours the liquid phase was tested for radio-chloride. The test was repeated with DMSO, ethanol, aqueous DMSO, aqueous ethanol and ethanolic DMSO as media, for times between 2 and 24 hr, and also with a cation-exchanger (Cs^+ form, γ-counting with a scintillation counter).

DISCUSSION

The colours produced when a base is added to the solution of a polynitro-aromatic have been attributed to a variety of interactions. Three noteworthy reviews[15–17] summarize the work up to 1970.

The interaction of 2,4-dinitroaniline with bases was first studied by Crampton and Gold.[18] Proton transfer from the aniline to the base was shown to be responsible for the colour, and this has recently been confirmed by Crampton and Wilson.[19]

Since DNPH is a derivative of 2,4-dinitroaniline it will also probably react by proton loss. *In solution*, however, DNPH apparently does not react with tertiary amines although these would presumably be quite efficient proton acceptors. If proton loss is the major mode of interaction, which proton of DNPH is lost—that from N^1 or N^2 (Scheme 1)?

Buncel *et al.*[20] have shown that DMSO stabilizes the conjugate base of polynitroaniline derivatives with respect to the sigma complex with a species such as methanol. We expect a similar effect here, *e.g.*, structure (3) in Scheme 1. This view is supported by Crampton and Wilson.[19] Since our studies were carried out in pure DMSO, there will be a negligible amount of the sigma complex. Buncel *et al.*[20] further state that sigma complexes have two maxima in the visible region while in our case there is only one maximum in the visible region, at 640 nm. Case III therefore seems excluded.

Moreover the stoichiometry of DNPH to amine in (3) would be 1:2, but a Job plot for the stabilized complex shows a stoichiometry of 1:1.

The species (2) is a spiro Meisenheimer complex, the instability of which, according to Bernasconi *et al.*,[21] is governed by two factors, ground-state resonance stabilization and ring strain. In cases I and II the first of these is a common parameter. Furthermore all known spiro Meisenheimer complexes are stable when there is a five-membered ring, and the stability decreases with increase in ring size, which has been recently confirmed by Crampton *et al.*[22] A typical spiro Meisenheimer anion is shown in Fig. 1. In (2) there is a three-membered ring and the strain of such a ring would definitely be prohibitive. This leaves case I as the sole possibility.

There may be two reasons why tertiary amines apparently do not react in solution.

(*a*) The solubility of tertiary amines in DMSO is much lower than that of primary and secondary amines because tertiary amines cannot hydrogen-bond to DMSO.[23]

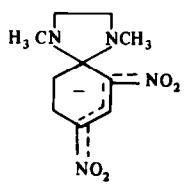

Fig. 1. A typical spiro Meisenheimer complex.

(*b*) There is a marked decrease in the basicity of tertiary amines in DMSO,[24] the sequence being primary > secondary ≫ tertiary.

The results in Tables 1–3 show that the ion-exchange method is selective and sensitive for aliphatic amines. Compounds with similar functional groups, *i.e.*, aromatic amines, amides, anilides, ureas and thioureas, do not interfere. This selectivity arises from the fact that only aliphatic amines form anionic complexes with DNPH. The aromatic amines form charge-transfer complexes which are not as intensely coloured as the reagent and hence do not interfere. The radiochemical studies were performed to pinpoint the role of the resin beads. We had expected exchange to take place and an equivalent quantity of Cl^{-}* or Cs^{+}* to be released, depending on the charge on the coloured species. However, to our surprise, despite repeated efforts no exchange could be detected (results are omitted to save space). It follows that when resin beads become coloured on contact with a coloured solution it cannot be assumed that ion-exchange has necessarily occurred.

The reaction of tertiary amines is interesting. When a tertiary amine is added to the DNPH solution no colouration is observed. However, on the addition of anion-exchange resin beads, the beads are coloured green. The reaction may be explained thus: let us suppose that the tertiary amine (A) reacts with DNPH (B) to form the complex (C), and that the reaction may be represented as

$$A + B \rightleftharpoons C$$

As the solution is not coloured green it is reasonable to assume that initially there is a very small concentration of C, or that C is a transient intermediate. On addition of the resin beads the coloured species is adsorbed by the beads and as a result of this irreversible adsorption the equilibrium shifts to the right and this process continues till the beads are strongly coloured.

In the resin-bead tests this role of the ion-exchanger needs further study. It may, however, be pointed out that this test allows us to distinguish tertiary amines

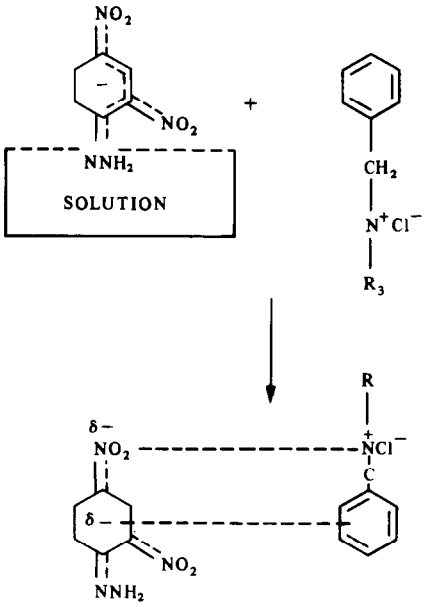

Fig. 2. The model of the interaction of the anionic DNPH–aliphatic amine species with the anion-exchange resin bead.

from primary and secondary amines, as well as from all other organic substances, provided only one species is present. If both the solution and the resin beads are coloured green the solution contains a primary or a secondary amine. On the other hand if the solution is colourless and the resin beads are coloured green then the solution contains only a tertiary amine. In the absence of primary and secondary amines it becomes a specific test for tertiary amines.

A quantitative theory of non-electrolyte sorption by ion-exchangers has not yet been developed. However, sorption of organic non-electrolytes with hydrocarbon groups by ion-exchange resins with hydrocarbon matrices is likely to be affected by London interactions and dipole–dipole interactions.[25] The consequence of such interactions is that the hydrocarbon groups tend to coagulate or to be squeezed out of the polar solution onto a phase boundary. In solution this effect is strikingly demonstrated by soap micelle formation and detergent action. Both the London and the dipole interactions favour local adsorption of the hydrocarbon groups of the solute on the matrix and thus enhance sorption of the non-electrolyte. London forces are specific interactions and depend on the molecular structure of the solute and the matrix. According to the ancient rule "*similia similibus solvuntur*", a high affinity and thus strong sorption may be expected when the chemical configurations of the solute and the matrix are similar. A simple model of the interactions is given in Fig. 2.

DNPH has been very widely used for the detection and determination of aldehydes and ketones, but it has not previously been used for the detection and determination of aliphatic amines. Feigl[26] has presented numerous methods for the detection of amines, but none is selective for aliphatic amines. Also, the sensitivity of these methods is much less (usually 6 μg) than that of the method proposed here.

As DNPH does not form a coloured product with amides, aromatic amines *etc.*, no effort was made to determine aliphatic amines in the presence of such substances, but it appears that there will be practically no interference in the spectrophotometric determination of aliphatic amines by the proposed method.

The coloured species formed by the reaction of DNPH with aliphatic amines is unstable in alcoholic media, but it can be stabilized by replacing the alcohol with DMSO and adding an excess of DNPH.

EXTRACTION-SPECTROPHOTOMETRIC DETERMINATION OF NIOBIUM WITH DIBENZO-18-CROWN-6 AND THIOCYANATE

D. BLANCO GOMIS, S. ARRIBAS JIMENO and A. SANZ-MEDEL
Departamento de Química Analítica, Facultad de Ciencias, Universidad de Oviedo, Oviedo, España

(*Received* 4 *November* 1981. *Revised* 27 *January* 1982. *Accepted* 21 *March* 1982)

Summary—A method is described for the direct spectrophotometric determination of micro-amounts of niobium by extraction into a benzene solution of dibenzo-18-crown-6 (L) from 3*M* hydrochloric acid containing potassium thiocyanate. The molar absorptivity of the extracted complex is $3.85 \pm 0.03 \times 10^4$ $l.mole^{-1}.cm^{-1}$ (relative standard deviation 0.8%). Co-ordinatively unsaturated complexes of the type $[NbO(SCN)_3]_2L$ and $NbO(SCN)_3L$ are extracted, along with ion-pairs, especially when small amounts of L are used for extraction. The ion-pair complex $[NbOCl_2(SCN)_3][(LK)_2]$ seems to be the main species formed in the organic phase.

Pedersen[1] was the first to report the potential selectivity of crown ethers, L, as ligands complexing most strongly those metal cations having ionic radii which best match the radius of the cavity formed by the polyether ring. The positively charged complex is usually not coloured or fluorescent, although a colorimetric[2] or fluorimetric[3] determination of the cation is possible by solvent extraction of the ion-association species formed by the cationic complex and a coloured or fluorescent organic anion.

We have previously reported the impressive sensitivity and selectivity that can be achieved by using this principle in the fluorimetric determination of potassium with 18-crown-6 and eosin.[4] In continuance of our studies on the analytical application of crown ethers a different approach has been investigated: the use of cationic alkali metal–crown ether complexes for extraction of anionic species containing the cation to be extracted or determined. In this type of extraction, ion-association species L of the type $[LK^+][MX_n^-]$ can be expected in the organic phase.[5,6]

We are also engaged in the search for improved analytical methods for determination of niobium[7–9] and as this element forms anionic thiocyanate complexes[10] its extraction into an organic phase might be accomplished by addition of a cationic crown ether complex, and the extraction followed spectrophotometrically.

The spectrophotometric determination of niobium with thiocyanate, with and without extraction, has become very popular although the reagent concentrations are critical.[11] Affsprung[12] reported that this determination was improved by use of tetraphenylarsonium counter-ions for extraction of the anionic thiocyanatoniobate complex into a chloroform–acetone mixture.

In the present work the potassium complex of dibenzo-18-crown-6 is used to extract the thiocyanatoniobate complexes (from hydrochloric acid medium) into benzene (in chloroform the extracted species precipitate, although partially halogenated hydrocarbons such as 1,2-dichloroethane can be used for the extraction). Investigation of the optimal conditions and the nature of the extracted species has allowed us to establish a new extraction–spectrophotometric determination of niobium and has shown the involved mechanism of this extraction process.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade.

Nb(V) standard solution (10 μg/ml). Stock solution (200 μg/ml), prepared as described previously,[7] diluted with 2% tartaric acid solution.

Potassium thiocyanate solution, 3*M*. Prepared daily to avoid thiocyanic acid polymerization.

Dibenzo-18-crown-6, solution in benzene, $5 \times 10^{-3}M$.

Tartaric acid solution, 3*M*.

Ascorbic acid solution, 10%. Freshly prepared.

General procedure

Pipette a portion of the sample containing up to 20 μg of niobium into a 100-ml separating funnel, add 5 ml of 6*M* hydrochloric acid and 3 ml of 3*M* potassium thiocyanate, and dilute to 10 ml with redistilled water. Add 10 ml of the crown-ether solution and extract the niobium by mechanical shaking (5 min) to achieve a rapid distribution of the extraction reagent between the two phases. Allow the phases to separate, filter the benzene solution through a dry filter paper and measure the absorbance at 398 nm against benzene.

RESULTS AND DISCUSSION

Spectral characteristics of the complex

The absorption spectra of the extracted species and the reagent blank are given in Fig. 1. The absorbance of the blank is very small at the wavelength of the

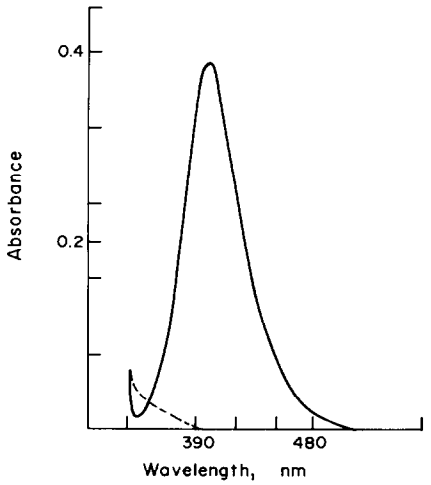

Fig. 1. Absorption spectrum of the niobium complex in benzene (dashed line corresponds to the reagent blank).

absorbance maximum of the complex, so benzene can be used as reference. The calibration graph is linear over the range 1–20 μg of niobium, and the molar absorptivity at 398 nm is 3.85×10^4 l.mole^{-1}.cm^{-1}. The relative standard deviation (10 replicates, 10 μg of niobium) is 0.8%.

Effect of reagent concentrations

The optimization studies were done with a fixed amount of 10 μg of niobium and a single extraction step. Figure 2 shows that the optimum concentrations are 2–4*M* hydrochloric acid and not less than 0.3*M* thiocyanate and 0.004*M* crown ether.

Extraction conditions

The extraction is maximal after 4 min shaking time, and the yellow colour produced remains constant for at least 1 hr. The efficiency of the extraction was determined by stripping the extracted niobium and determining it; a single extraction was found to be 99.4 ± 0.4% complete.

Interference studies

The effect of various metals (those most frequently associated with niobium in steels and niobium ores) on the determination is shown in Table 1. Table 2 gives the influence of some common anions that mask niobium.

As can be seen from Table 1, some elements interfere even at low levels (W, V, Ti, Sn and Cu) but their interference may be reduced by addition of ascorbic acid, tartaric acid or both as shown in Table 1.

Mo(VI) interference can be eliminated by a preextraction step, introduced into the general procedure, consisting of addition of potassium fluoride to the aqueous phase to prevent extraction of Nb(V) while the Mo(VI) is extracted with the crown ether. After this step, boric acid is added to the aqueous phase to demask Nb(V) and allow it to be extracted with a further portion of crown-ether solution.

In general, the extraction is fairly selective, and the method could be especially advantageous for niobium ores containing rare earths.

As shown in Table 2, fluoride is the most efficient masking agent for Nb(V), but the effect of up to 14.7

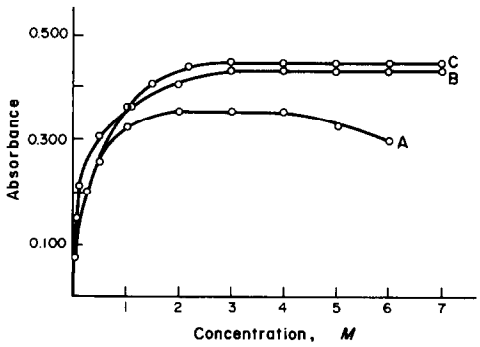

Fig. 2. Extraction efficiency as a function of reagent concentration: (A) molar concentration of HCl in the aqueous phase; (B) molar concentration ($\times 10^3$) of dibenzo-18-crown-6 in the organic phase; (C) molar concentration ($\times 10$) of KSCN in the aqueous phase.

mg of fluoride in 10 ml of aqueous phase can be eliminated by adding 85 mg of boric acid for demasking.

Nature of the extracted species and mechanism of the extraction

The stoichiometry of the potassium dibenzo-18-crown-6 complex has been clearly established[13–15] as 1:1 (LK^+). As the anionic complexes of niobium and thiocyanate are of the type[10] $NbOX_n(SCN)_m^-$ or $NbO(SCN)_5^{2-}$, the expected Nb/L ratio should be 1:1 or 1:2 for neutralization of the charge.

Experimental results from investigation of the Nb/SCN ratio by the Asmus and equilibrium-shift methods invariably gave a value of 1:3 (Figs. 3 and 4). The experimental Nb/L ratio obtained by the same methods unexpectedly gave a value of 0.5 by the Asmus method. The equilibrium-shift method gave 0.45 at low L concentration but 0.77 at higher L concentration (Figs. 3 and 4).

It seems unlikely that the formation and extraction of any $NbO(SCN)_n$–LK^+ ion-pair could correspond to the Nb/L ratio observed. Thus it appears that neutral adducts of the type[16,17] $Nb_2Cl_{10}L$ and $NbCl_5L$ might be formed.

On this basis, the equilibrium between an aqueous solution containing niobium and thiocyanate, and an organic solution containing a cyclic polyether (L) could be simply expressed as

$$m\mathrm{Nb} + n\mathrm{SCN} + p\mathrm{L}_{org} \overset{K_c}{\rightleftharpoons} [\mathrm{Nb}_m(\mathrm{SCN})_n\mathrm{L}_p]_{org}$$

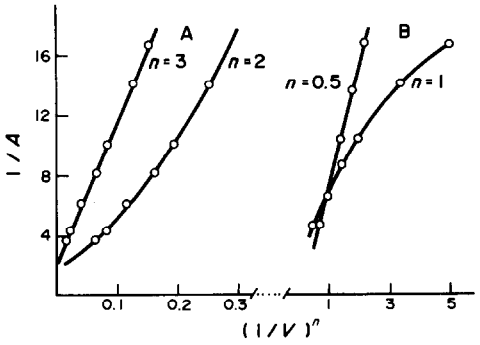

Fig. 3. The Asmus method applied to the Nb–L–SCN system. (A) Relationship Nb/SCN, Nb = 1.08 × $10^{-5}M$, L = 5 × $10^{-3}M$; (B) relationship Nb/L, Nb = 1.08 × $10^{-5}M$, SCN = 0.9M. A = absorbance, V = volume (ml).

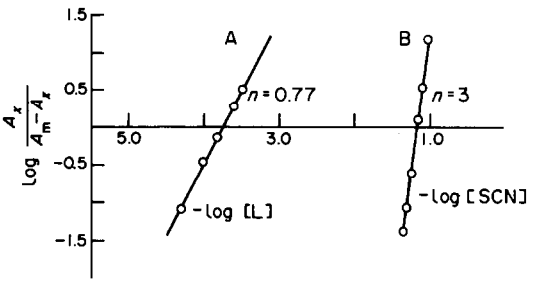

Fig. 4. Equilibrium-shift method applied to the Nb–L–SCN system. Nb = 1.08 × $10^{-5}M$. (A) Relationship Nb/L, SCN = 0.9M; (B) relationship Nb/SCN, L = 5 × $10^{-3}M$. A_x = absorbance of mixture, A_m = saturation absorbance with excess of reagent present.

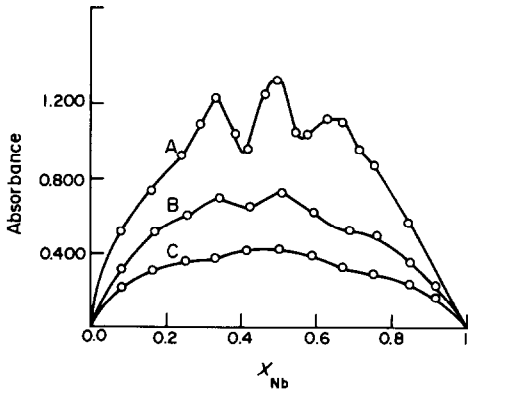

Fig. 6. Continuous-variations study of Nb–L systems. (A) Total concentration of Nb + L = 2.4 × $10^{-4}M$; (B) Nb + L = 1.8 × $10^{-4}M$; (C) Nb + L = 1.2 × $10^{-4}M$; wavelength = 398 nm, 1.00-cm cells.

where the subscript org refers to the benzene phase, and charges are omitted for simplicity. The extraction constant is

$$K_c = [\mathrm{Nb}_m(\mathrm{SCN})_n\mathrm{L}_p]_{org}/[\mathrm{Nb}]^m[\mathrm{SCN}]^n[\mathrm{L}]^p_{org} \quad (1)$$

and assuming that only one species is formed in a given range of reagent concentrations, we may write:

$$[Nb_m(SCN)_nL_p]_{org} = A/\epsilon l \quad (2)$$

where ϵ = molar absorptivity and l = cell path-length. Substituting (2) into (1) and simplifying gives

$$\log A = m\log[Nb] + n\log[SCN] + p\log[L]_{org} + \log K_c\epsilon l$$

It is possible to determine m, n or p by maintaining all concentrations constant except that of the appropriate component. The values found in this way were $m = 1.02$ and $n = 2.8$, but for p two values were obtained, 0.54 at low L concentration and 0.94 at high L concentration (Fig. 5).

Moreover Job plots ([Nb] and [L] varied, their sum being constant) showed three absorption maxima, located at $X_{Nb} = 0.33$, 0.5 and 0.66 (corresponding to 1:2, 1:1 and 2:1 stoichiometries) (Fig. 6).

To get more information about the nature of the extracted complexes, attempts were made to isolate them from the benzene extract. The procedure already described was applied to 0.5 mg of niobium in 10 ml of aqueous phase, and a yellow-orange crystalline compound was obtained. This was filtered off, rinsed with pure benzene to eliminate the excess of LK^+SCN^- and LK^+Cl^- present, and finally dried at 100°. Elemental analysis gave the results in Table 3, which agree with the values calculated for a complex of formula $[NbOCl_2(SCN)_3]^{2-}$ $(LK^+)_2$. This formulation is supported by comparative conductivity measurements on $10^{-4}M$ acetonitrile solutions of this species, L and LK^+Cl^-. The observed specific conductance of the solution of the complex is about 50 times that of the L solution and only slightly lower than that of the $LK^+ \cdot Cl^-$ solution.

DISCUSSION

The results obtained can be explained in terms of an extraction process dependent on the concentration of L. If this concentration is low, the most probable species formed is a neutral adduct $[NbO(SCN)_3]_2L$ analogous to $(NbCl_5)_2L$ (recently demonstrated in the reaction of $NbCl_5$ with L[17] or with cyclic polythiaethers).[16] When excess of L is used, the species $NbO(SCN)_3L$ would also be formed (cf. formation of $NbCl_5L$[17]). Simultaneous formation of both compounds explains the slope of 0.77 obtained for the Nb/L ratio by the equilibrium-shift method (Fig. 4). Under the conditions of the procedure, during the shaking L is mostly changed into the cationic LK^+ complex, which could be responsible for the formation of the ion-pair $NbOCl(SCN)_3^- LK^+$. With a large excess of L, as in the analytical procedure, the species formed in the organic phase could be ion-association complexes having a higher content of L, such as $NbOCl_2(SCN)_3^{2-}(LK^+)_2$, as demonstrated by the analysis of species isolated, supported by the Nb:L ratio of 1:2 found in the continuous-variations experiments.

Table 3. Analysis of the isolated complex

	Experimental, %	Theoretical,* %
C	44.8	45.34
N	3.7	3.69
H	4.2	4.25
Nb	7.8	8.16
Cl	6.6	6.22
K	7.1	6.86

*For $NbOCl_2(SCN)_3^{2-}(LK^+)_2$.

Table 4. Determination of niobium

Sample	Niobium present, %	Niobium found, %			
Stainless steel BCS 261/1	0.91	0.91_3	0.91_4	0.90_7	0.90_9
Pyrochlore OKA-1	0.36	0.34_9	0.35_6	0.34_7	0.35_2

The proton NMR data reported[16,17] for such adducts suggest a weak bond between the Nb(V) and the available oxygen co-ordination sites of the polyether. The low dielectric constant of the organic solvent, its solvating properties and especially the large excess of L (as LK^+) would promote further stabilizing ion-association reactions of such adducts in the organic phase.

Conclusion

The mechanism of extraction anionic metal complexes with cationic crown-ethers becomes quite involved when the metal has great affinity for the oxygen atoms of the polyether. In such cases the species extracted may be neutral adducts of the unsaturated co-ordination type[18] which are extracted along with the expected ion-pair $LK^+MX_n^-$.[5,6]

For the system studied here, it seems that further reaction can take place in the organic phase between the excess of L and the ion-association species containing the cation to be determined, so that species such as $NbO(SCN)_3Cl_2(LK)_2$ are the final species responsible for the absorption properties of the organic extract.

To assess the reliability and utility of the method, a stainless steel (B.C.S. 261/1) and a niobium pyrochlore ore from OKA (Canada) were analysed. The steel was dissolved by the method proposed by Sanz-Medel *et al.*[19] and the ore sample by a modification of Faye's method.[9] The results agreed very well with the expected values (Table 4).

A NEW GRAPHICAL METHOD BASED ON STOICHIOMETRIC DILUTION FOR THE CLASSIFICATION OF BINARY COMPLEXES WITH MOLE RATIO 1:1

HE XI-WEN* and DONALD P. POE†
Department of Chemistry, University of Minnesota, Duluth, Minnesota 55812, U.S.A.

(*Received* 31 *December* 1981. *Accepted* 20 *March* 1982)

Summary—A simple approach to the treatment of spectrophotometric data obtained by stoichiometric dilution is presented for complexes of the type M_mB_n and $m/n = 1$. The values of m and n are obtained by matching the slope of a straight line with a mathematically predicted value. The method can be applied to moderately strong complexes, the concentration of which can be determined by absorbance measurements, and allows calculation of the formation constant as well.

Various methods have been reported for the characterization of metal complexes in solution.[1,2] In many cases the existence of several complex species must be assumed, and a large amount of very precise data must then be obtained, usually by potentiometric titration or polarography, and the data must be treated by computer for the values of the average ligand number, $\bar{n}$, and the formation constants to be obtained. The distribution of species under a given set of conditions may then be calculated. The study of such a system can be a very time-consuming task. The interested reader should refer to the work by Rossotti and Rossotti.[1] If, however, it is evident that only a single complex is formed, the study can be greatly simplified. Such chemical systems are commonly encountered in spectrophotometric analysis, in which conditions are adjusted to ensure the formation of a single complex. These systems are most conveniently studied by molecular absorption spectrophotometry.

Spectrophotometric methods for differentiating mononuclear and polynuclear complexes depend on the tendency of a complex to dissociate in solution at low concentrations. For a general equilibrium reaction

$$mM + nB \rightleftharpoons M_mB_n \qquad (1)$$

where M_mB_n is the only significant complex formed, three general approaches have been used. In the log ratio (or fixed logarithm) method,[3] the absorbance is measured as small amounts of one reactant are added to a large fixed amount of the other under such conditions that most of the reagent added remains uncomplexed. A second approach developed by Klausen and Langmyhr[4,5] depends on the presence of inflection points in a continuous variations plot to characterize complexes with mole ratio 1:1. A third and most useful approach depends on the degree of dissociation of the complex when the reactants are mixed in the stoichiometric ratio. Budĕšínský[6–10] has referred to this as the method of stoichiometric dilution, and it has been employed by several workers.[11,12] Recently several new mathematical treatments of data obtained by the method of stoichiometric dilution have been reported,[13,14] including one which can be applied to mixed-ligand complexes.[15] These methods allow the calculation of formation constants for moderately strong complexes, but are limited by the requirement that only a single complex must be formed. An alternative but similar approach, which might be called non-stoichiometric dilution, allows the calculation of formation constants of very weak complexes and can be used if more than one complex is formed.[16]

The present paper describes a new approach to the differentiation of mononuclear and polynuclear complexes with mole ratio 1:1, employing the method of stoichiometric dilution. It also yields the formation constants of moderately strong complexes.

THEORY

Consider the equilibrium reaction in equation (1) where M_mB_n is a coloured metal complex, the concentration of which can be measured spectrophotometrically, and for which the mole ratio has been previously determined by the usual methods and found equal to unity.[17–19] The degree of complex formation (α_c) is defined by

$$\alpha_c = \frac{m[M_mB_m]}{C_M} = \frac{A_{M_mB_m}}{A^{max}_{M_mB_m}} \qquad (2)$$

*On leave from Chemistry Department, Nankai University, Tianjin, People's Republic of China.
†Author to whom correspondence should be addressed.

where C_M = total metal ion concentration, $A_{M_mB_m}$ is the absorbance due to the complex M_mB_m, and $A^{max}_{M_mB_m}$ is the absorbance due to M_mB_m for 100% complexation of the metal ion. If M_mB_m is the only complex formed between M and B, the total absorbance $A = A_{M_mB_m} + A_B$, where A_B is the absorbance due to uncombined B. Correction for the absorbance due to uncomplexed reagent can be made by successive approximations, beginning with $A_{M_mB_m} \sim A$ in equation (2), and recalculating $A_{M_mB_m}$ after application of the relation $A_B = \epsilon_B(C_B - \alpha_c C_M)$, where ϵ_B is the molar absorptivity of B and C_B is the total concentration of B.

The fraction of uncomplexed metal ion, α_M, is defined by

$$\alpha_M = \frac{C'_M}{C_M} \tag{3}$$

where C'_M is the total concentration of uncomplexed metal ion. If M_mB_m is the only complex formed between M and B under the conditions of the experiment, then

$$C_M = m[M_mB_m] + C'_M \tag{4}$$

and dividing through by C_M yields

$$1 = \alpha_c + \alpha_M \tag{5}$$

The conditional formation constant for reaction (1) is

$$K' = \frac{[M_mB_m]}{(C'_M)^m(C'_B)^m} \tag{6}$$

where C'_B is the total concentration of uncomplexed B. If the experimental conditions are arranged so that $C_M = C_B$, then substitution of either α_M or α_c into equation (6), followed by a simple algebraic modification, will yield linear equations, which directly yield the value of m.

Substitution of α_c

Rearrangement of equation (2) gives

$$[M_mB_m] = C_M\alpha_c/m$$

Combination of equations (2) and (4) yields

$$C'_M = C_M(1 - \alpha_c)$$

Under the experimental constraints, $C'_M = C'_B$, and equation (6) becomes

$$K' = \frac{C_M\alpha_c}{mC_M^{2m}(1 - \alpha_c)^{2m}} \tag{7}$$

which on rearrangement and taking of logarithms gives

$$\log \alpha_c/(1 - \alpha_c)^{2m} = \log mK + (2m - 1)\log C_M \tag{8}$$

Thus a plot of $\log \alpha_c/(1 - \alpha_c)^{2m}$ *vs.* $\log C_M$ yields a straight line with slope $2m - 1$ and intercept $\log mK$. Selection of different values of m will yield straight lines with different slopes, but only the correct value of m will yield a slope which is equal to the value predicted by equation (8).

Substitution of α_M

The same results can be achieved by substituting appropriate expressions involving α_M into equation (6). Alternatively, substitution of equation (5) directly into (8) yields

$$\log(1 - \alpha_M)/\alpha_M^{2m} = \log mK + (2m - 1)\log C_M \tag{9}$$

Thus a plot of $\log(1 - \alpha_M)/\alpha_M^{2m}$ *vs.* $\log C_M$ will yield the same results as equation (8).

Calculation and precision of the formation constant

After the value of m has been determined, the value of the conditional formation constant can be obtained from the intercept according to equation (8), or by direct calculation from equation (7). The intercept method is likely to produce poor results because it involves a long extrapolation. Calculation of K' from equation (7) is preferable.

The relative error in the value of K' can be ascertained by differentiating equation (7) with respect to α_c, which yields

$$\frac{\delta K'}{\delta \alpha_c} = \frac{K'[1 + (2m - 1)\alpha_c]}{\alpha_c(1 - \alpha_c)}$$

Rearranging, converting to finite differences, and replacing $\Delta\alpha_c/\alpha_c$ with $\Delta A/A$, yields

$$\frac{\Delta K'}{K'} = \frac{\Delta A}{A}\left(1 + \frac{2m\alpha_c}{1 - \alpha_c}\right) \tag{10}$$

for a system in which the reagent blank is insignificant, that is, $A \sim A_{M_mB_m}$. The same expression was reported earlier for a similar approach[15] along with several curves to illustrate the relative error in K' for various values of m and α_c. Note that $\Delta K'/K'$ becomes very large as α_c approaches unity (complete complex formation), and approaches $\Delta A/A$ for small values of α_c.

RESULTS

Copper–orotic acid system

Earlier studies showed[13,16] that Cu(II) and orotic acid combine to form a 1:1 complex with $m = n = 1$, $\epsilon = 7.20 \times 10^3$ l.mole^{-1}.cm^{-1}, and $\log K' = 4.85$ in pH 5.01 acetate buffer. Table 1 shows calculation of the values of α_c from the equation

$$\alpha_c = A_{M_mB_m}/\epsilon' l C_M \tag{11}$$

where ϵ' is the apparent molar absorptivity calculated for $m = 1$ (this can be done without knowing the value of m, since C_M is used in the expression rather than the maximum concentration of the complex). Values of $\log \alpha_c/(1 - \alpha_c)^{2m}$ were calculated for m values from 1 to 4. Straight lines with correlation coefficients of 0.998 or better were obtained for each m

Table 1. Copper–orotic acid system*

C_{Cu}, μM	A	α_c	log $K'(m = 1)$
20	0.064	0.444	4.86
40	0.162	0.563	4.87
60	0.265	0.613	4.83
80	0.385	0.668	4.88
100	0.498	0.692	4.86
140	0.735	0.729	4.85
200	1.095	0.760	4.82

Assumed m	Predicted slope	Observed slope	Δslope	Δ^2slope
1	1	0.997 ± 0.02	−0.02	1.26
2	3	1.72 ± 0.04	−1.28	1.26
3	5	2.46 ± 0.05	−2.54	1.26

*Data taken from reference 13.

value (Fig. 1), but only for $m = 1$ did the observed slope agree with the predicted slope. This was in agreement with previous results.

The formation constant calculated from equation (7) for the seven cases is log $K' = 4.85 \pm 0.02$, in excellent agreement with the previously reported result.[13]

Iron–Chrome Azurol S system

In a recent paper[15] we reported (in agreement with earlier studies[4,5,13]) that iron(III) combines with Chrome Azurol S (CAS) at pH 3.4 to form a single complex, with $m = n = 2$, a molar absorptivity at 570 nm equal to 4.60×10^4 l.mole^{-1}.cm^{-1}, and a formation constant log $K' = 17.88$ in 0.01M potassium chloride. Treatment of our previous results according to the present approach yields the results shown in Table 2. Values of α_c were calculated from equation (11), with $\epsilon' = 2.30 \times 10^{-4}$ l.mole^{-1}.cm^{-1}. The predicted and observed slopes agree for $m = 2$ (Fig. 2), corresponding to the composition $Fe_2(CAS)_2$. The average value of the formation constant calculated from equation (7) is log $K' = 17.89 \pm 0.05$, in agreement with 17.88 found in our previous study.[15]

Treatment of the data reported by Garcia *et al.*[13] yielded similar results. For $m = 1$, the predicted slope was 1 and the observed slope 1.67. For $m = 2$, the predicted slope was 3 and the observed slope 3.02, confirming the composition $Fe_2(CAS)_2$. The conditional formation constant, in this case at pH 3.40 and in 0.1M potassium chloride, was log $K' = 16.55$.

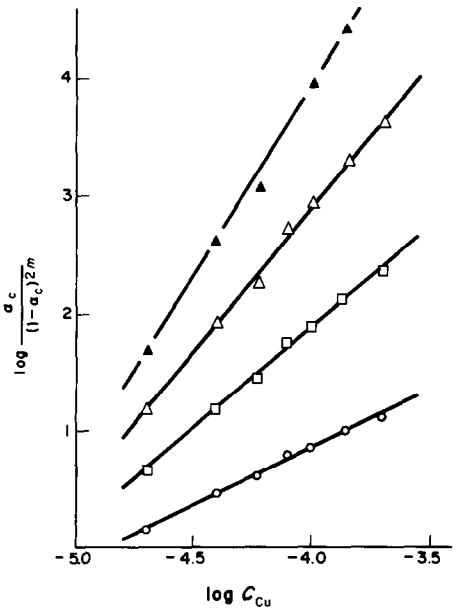

Fig. 1. Plots of log $\alpha_c/(1 - \alpha_c)^{2m}$ *vs.* log C_M for the copper–orotic acid system, assuming different values of m. ○, $m = 1$; □, 2; △, 3; ▲, 4.

DISCUSSION

The proposed method has been shown to yield the correct results for two well-studied systems. Its application is very straightforward, and although it is experimentally similar to previously described approaches,[7–15] its mathematical simplicity makes it particularly attractive. The success of this new approach depends on several factors as discussed below.

Since the degree of complexation is calculated from absorbance measurements, the apparent molar absorptivity of the complex must be obtained experimentally. Usually this means that excess of ligand must be added to a known concentration of metal ion to make complexation practically 100% complete. This raises the possibility that higher complexes will be formed, with a resultant error in the molar absorp-

Table 2. Iron–Chrome Azurol S system*

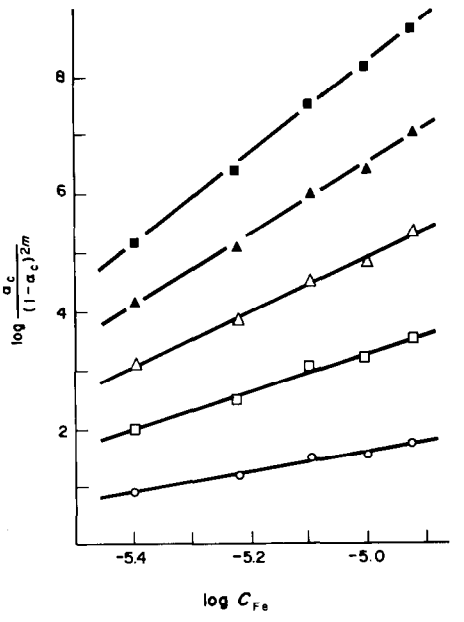

Fig. 2. Plots of log $\alpha_c/(1-\alpha_c)^{2m}$ *vs.* log C_M for the iron–Chrome Azurol S system, assuming different values of *m*. ○, *m* = 1; □, 2; △, 3; ▲, 4; ■, 5.

tivity. For this reason it is important to make a complete mole-ratio study in which the metal concentration is held constant and the concentration of ligand is increased. An absorbance *vs.* added ligand concentration graph giving two straight-line portions connected by a smooth curve is indicative that additional ligand molecules are not incorporated into the complex. The molar absorptivity determined in this experiment can be applied to solutions in which the reactants are mixed in the stoichiometric ratio. Such a study was performed for the iron–Chrome Azurol S system, and no evidence was found for formation of higher complexes.

Further evidence for the existence of only a single major complex in solution can be obtained from absorption spectra. If only one complex exists, the background-corrected spectrum obtained for the stoichiometric solution will be identical (except in amplitude) to the spectrum of the solution containing excess of ligand (provided the ligand itself does not absorb in the region examined).

The uncertainty in the formation constant for various values of $m + n$, A, and α_c, which was illustrated by graphs in the previous report,[15] also applies to this method. In general it is desirable to keep $\alpha_c < 0.5$ and $0.1 < A < 0.8$. Under these conditions the relative error in K' due to uncertainty in the absorbance measurement will be less than 10% for $m \leq 2$. The error becomes larger for $m > 2$, but such complexes are rarely encountered.

It is interesting to note that if the difference (Δ slope) between the observed and predicted slope is taken for each *m* value, and the difference between successive Δ slope values is then taken,

$$\Delta^2\text{slope} = (\Delta\text{slope})_{m+1} - (\Delta\text{slope})_m$$

the values of Δ^2slope are constant for a given system (Tables 1 and 2). A plot of the observed slope *vs.* assumed *m* value must therefore yield a straight line of the general form

$$y = ax + b \tag{12}$$

where y = observed slope and x = assumed *m* value. There can be only one correct pair of x and y values for a specific system, given by the equation for the predicted slope line

$$y = 2x - 1 \tag{13}$$

where in this case x = true *m* value and y is the correct predicted slope. It follows that the correct solution will be given by the intersection of the lines corresponding to equations (12) and (13). In Fig. 3 the observed slopes obtained for the two systems studied are plotted against the assumed *m* values. The point of intersection can be estimated from the graph, or calculated exactly by solving equations (12) and (13) for x. For the copper–orotic acid system equation (12) is $y = 0.741x + 0.237$, which yields $x = m = 0.98$. For the iron–Chrome Azurol S system, equation (12) is $y = 1.460x + 0.190$, which yields $x = m = 2.20$. Treatment of the data of Garcia *et al.*[13] gives $m = 1.94$.

Figure 3 suggests that as the true value of *m* increases, the line for the observed slope *vs.* assumed *m* and the predicted slope line will tend to merge, leading to larger uncertainties in the point of intersection. It follows that the best precision is obtained for small values of *m*.

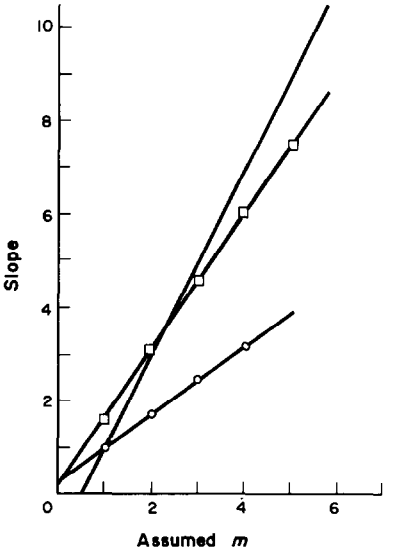

Fig. 3. Observed slope *vs.* assumed *m* for the copper–orotic acid (○) and iron–Chrome Azurol S (□) systems. Unbroken line is the predicted slope line.

The requirement that the complex must undergo significant dissociation limits the application of this method to complexes that are not extremely stable. Various allowable combinations of formation constants and molar absorptivities can be calculated from equations (6) and (11).

A COMPARISON BETWEEN SECONDARY-ION MASS-SPECTROMETRY AND SPARK-SOURCE MASS-SPECTROMETRY FOR THE QUANTITATIVE ANALYSIS OF STEEL WIRE

M. VAN CRAEN, J. VERLINDEN, R. GIJBELS and F. ADAMS
Department of Chemistry, University of Antwerp (U.I.A.), Universiteitsplein 1, B-2610 Wilrijk, Belgium

(*Received* 4 *November* 1981. *Accepted* 10 *March* 1982)

Summary—A comparison has been made between the results of the matrix-ion species ratio (MISR) method for quantification of secondary-ion mass-spectrometry data and spark-source mass-spectrometry analysis using photoplate detection for analysis of the steel basis of Al–Zn coated wire products. For SIMS quantification a suitable set of sensitivity factors, corrected for the actual surface sampling condition, was used. The results of both methods compare well. The SIMS results were, for most elements, within 25% of the concentration determined by SSMS. This could indicate that reasonably accurate results can be obtained by using the matrix-ion species ratio method for SIMS.

Secondary-ion mass-spectrometry (SIMS) is a powerful technique for the surface analysis of solid samples. The surface is bombarded with a beam of primary ions of several keV energy. As a result of the impact, surface particles are sputtered as atoms or ions. These ions are extracted from the target region and passed through a mass analyser, where they are separated according to their mass-to-charge ratio. These secondary ions are detected by suitable means.

The ability of SIMS to produce quantitative results is hampered by the large variations in sensitivity for different elements. Although the primary utility of SIMS is the possibility of performing both elemental distribution mapping of surfaces (in the ion microprobe or ion microscope version) and depth profile analysis, quantitative information is also often required.

The elemental sensitivities range over five orders of magnitude for various elements and moreover are sensitive to the matrix composition. Thus a set of sensitivity factors (SF) has to be determined for each element in each matrix. Smith and Christie[1] made a comparison of a theoretical model and SF determinations for quantification of SIMS data for glass and iron standard reference materials. Their experimental results based on use of SF were within a factor of 2 of expectation for 85% of the elements determined whereas for the theoretical approach, using the Anderson and Hinthorne model,[2] this level of agreement was achieved for only 55% of the elements.

More accurate quantitative results can be obtained, however, for SIMS data by using the matrix-ion species ratio (MISR) method described by Ganjei *et al.*[3] This method consists essentially of the use of a ratio of matrix-ion intensities (*e.g.*, M^+, MO^+, M_2^+, M_2O^+) to calibrate the elemental SF. Through admission of oxygen into the sample chamber during analysis of an external standard, a series of SF-values is generated as a function of the matrix-ion ratio. This ratio effectively indexes the sampling environment. The relative error of the MISR method, for different metallic matrices, is about 10–20%.

In this study, quantitative SIMS analysis using the MISR procedure is compared with results obtained with spark-source mass-spectrometry (SSMS). The latter technique is based on the formation of ions from a solid sample by a radiofrequency spark. The positive ions generated are accelerated and separated in a high-resolution double-focusing mass spectrometer. They are finally detected either simultaneously as a line spectrum on an ion-sensitive emulsion, or separately by a suitable dynode of an electron multiplier. SSMS has a distinct advantage for general analytical work on conducting solids, because it is possible to prepare two specimens of the sample for use as a pair of electrodes. This reduces the possibility of contamination. Some important advantages of SSMS in comparison with other methods are the possibility of detecting almost all elements simultaneously, the very low detection limits down to the ng/g level, an approximately equal sensitivity for all elements and the absence of matrix effects.[4]

EXPERIMENTAL

Samples

The samples investigated consisted of transverse cuts of the steel base of 55% Al–Zn coated steel wires (Bekaert N.V., Zwevegem, Belgium). As a standard sample, NBS SRM 467 low-alloy G steel was used, the composition of which closely corresponds to that of the steel wire.

For SIMS measurements the samples were mounted in the sample holder and embedded in a conducting resin.

They were subsequently wet-polished with 280 and 400 mesh abrasive paper and fine-polished with 25-μm, 15-μm, 3-μm and 1-μm metallurgical diamond paste used successively. They were presputtered during at least 15 min over a 1 × 1 mm area until stable ion signals were obtained. In this way any contamination due to the pretreatment was removed.

For SSMS analysis, the steel wire (diameter 3.4 mm) was metallographically ground and chemically polished in 20% HNO_3–10% HF solution until the surface coating was entirely removed. The resulting samples had a mirror-bright appearance and 10-mm long pieces were used as electrodes. They were presparked for at least 30 min, before SSMS analysis.

SIMS analysis

Measurements were performed with a CAMECA IMS-300 ion analyser, equipped with an electrostatic sector analyser for energy discrimination of the secondary ions. The apparatus was automated for spectral data acquisition and processing. The computer system used and program possibilities are described elsewhere.[5,6] The experimental SIMS measurements are summarized in Table 1. For quantitative analysis by the MISR method a series of SF is generated as a function of the reactive-gas adsorption on the NBS standard sample surface by progressively admitting oxygen into the sample chamber to increase the pressure from 2×10^{-7} to 7×10^{-5} mmHg. In this way a large range of secondary-ion yields is obtained, with only one external standard. Its homogeneity was investigated earlier.[7] The sampling constants provided a means for estimating the number of analyses needed for achieving a precision of 10%. They are listed in Table 2. Therefore at least five measurements were performed after each pressure increment, several minutes being allowed for stabilization between sputtering and adsorption. The actual surface sampling condition was thus measured by the ratio of two matrix ions which react differently upon adsorption of oxygen. The Fe_2^+/Fe^+ ratio was chosen in this work. The SF were calculated by using the relation:

$$SF_x = \frac{I_{x_i}}{I_{Fe_j}} \times \frac{C_{Fe}}{C_x} \times \frac{f_i}{f_j} \qquad (1)$$

where I_{x_i} and I_{Fe_j} denote the secondary-ion intensities of the ith isotope of the element in question and the jth isotope of the reference element Fe, while f_i and f_j symbolize the respective abundances of the chosen isotopes. Since the $^{56}Fe^+$ signal was too high to be measured ($> 3 \times 10^6$ cps) and since $^{57}Fe^+$ and $^{58}Fe^+$ were interfered with by $^{56}FeH^+$ and $^{58}Ni^+$ respectively, $^{54}Fe^+$ was chosen as the reference ion. The spectral interferences of $^{54}Fe^{2+}$ with $^{27}Al^+$ and of $^{56}Fe^{2+}$ with $^{28}Si^+$ were eliminated by applying high mass-resolution ($M/\Delta M = 3000$), while the interference of $^{54}FeH^+$ with $^{55}Mn^+$ could be sufficiently reduced by energy discrimination against secondary ions with kinetic energy less than 100 eV. For all other elements in the standard interference-free isotopes could be chosen, or the interference could be proved to be insignificant.

Table 1. Experimental SIMS conditions

Primary ion type	$^{40}Ar^+$
current density	~0.3 mA/cm²
energy	6 keV
source working pressure	1.5×10^{-4} mmHg
beam diameter	250 μm
Immersion lens aperture	55 μm
Magnetic field diaphragm	750 μm
Electrostatic analyzer energy window	4 eV
Working O_2-pressure in sample chamber	$\sim 2 \times 10^{-5}$ mmHg

Table 2. Number of analyses needed for achieving a 10% precision with a 0.05 probability of exceeding this error, for the NBS SRM 467 standard (area analysed = 0.02 mm²)

Element	Number of analyses
Al	2
Si	4
Ti	5
V	1
Cr	3
Mn	3
Co	2

The SF were fitted as a function of the matrix-ion ratio according to

$$SF_x = a(Fe_2^+/Fe^+)^b \qquad (2)$$

The sensitivity curves for V, Cr, Co and Mo are shown in Figs. 1 and 2 as an example. Table 3 lists the coefficients a and b and the correlation coefficient r for the sensitivity curves of the elements detected in the SRM.

The logarithm of SF at a given matrix-ion ratio is linearly related to the first ionization potential, as appears from Fig. 3. For the elements for which no SF can be determined because they are not detectable in the standard,

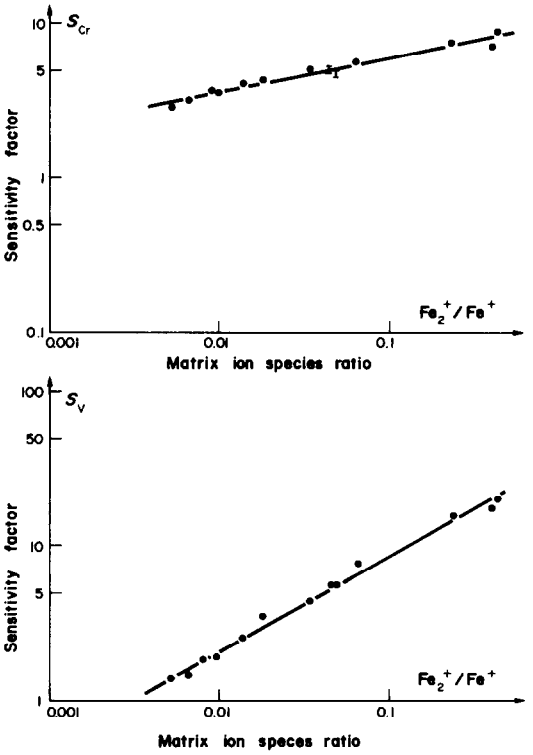

Fig. 1. Sensitivity factors for V and Cr as a function of the surface sampling condition (matrix-ion ratio Fe_2^+/Fe^+).

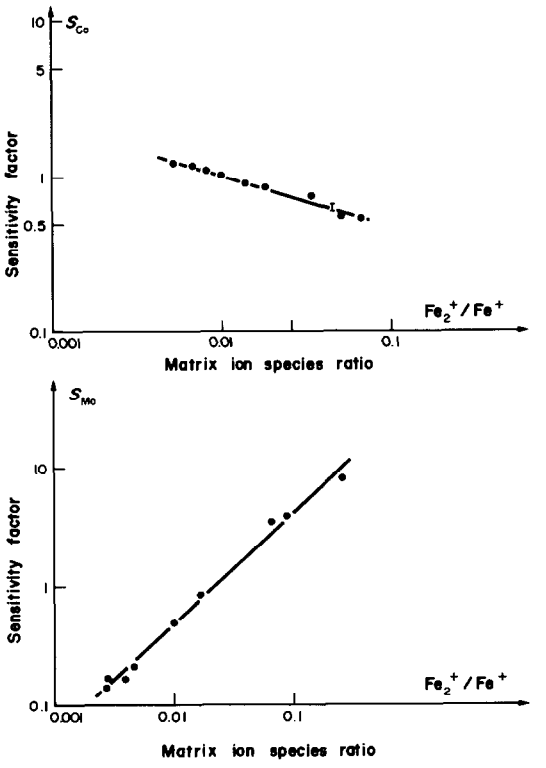

Fig. 2. Sensitivity factors for Co and Mo as a function of the surface sampling condition (matrix-ion ratio Fe_2^+/Fe^+).

namely Na, Mg, K, Ca, Zn, Ga and Sb, at least semiquantitative results can be obtained by using this relationship. From Fig. 3, the error expected from use of this procedure should be less than a factor of 2.

SSMS analysis

The instrument used was a Jeol JMS-01-BM-2 double-focusing mass spectrometer, incorporating a spherical electrical sector (*z*-focusing). Detection was done with Ilford Q2 ion-sensitive plates. The transmission profiles of the mass lines were stored on magnetic tape after automated densitometry, and the data reduction was performed on a PDP 11/45 computer, following the program developed by Pilate.[8] The SSMS spectrographic conditions are given in Table 4.

The quantitative analysis of the ion-sensitive plates in SSMS is very time-consuming because of the necessity of using several exposures to cover adequately the entire concentration range from the matrix level down to the ppm region.

The transmission profiles were integrated by using the Hull function,[9] and the plate "gamma" was determined by using the isotopic abundances of ^{54}Fe and ^{56}Fe and of ^{52}Cr and ^{53}Cr. The different exposures were correlated by using "calculated" exposures instead of the unreliable coulometer readings. ^{54}Fe was used as an internal standard. The interference of ^{54}Cr was insignificant (<0.01%). For the quantitative analysis only singly-charged ions were used. The following interference-free isotopes were selected: ^{23}Na, ^{24}Mg, ^{27}Al, ^{29}Si, ^{30}Si, ^{31}P, ^{32}S, ^{34}S, ^{35}Cl, ^{37}Cl, ^{39}K, ^{40}Ca, ^{50}Cr, ^{52}Cr, ^{53}Cr, ^{51}V, ^{55}Mn, ^{54}Fe, ^{57}Fe, ^{59}Co, ^{60}Ni, ^{62}Ni, ^{63}Cu, ^{65}Cu, ^{64}Zn, ^{68}Zn, ^{69}Ga, ^{71}Ga, ^{75}As, ^{92}Mo, ^{98}Mo, ^{116}Sn, ^{118}Sn, ^{120}Sn, ^{121}Sb and ^{123}Sb.

Three individual measurements were performed on the sample. Also, in order to compensate for differences in sensitivity of the photoplates, 8 exposures of the sample were compared with 7 exposures of the NBS SRM 467 standard, collected on the same photoplate. For the certified elements the concentrations in the unknown sample could then be directly calculated.

For some uncertified elements an empirical approach was used for the calculation of the elemental sensitivities. For the analysis of steel, Van Hoye[10] found a good agreement between his experimental SF and those calculated by the method of Williardson and Socha,[11] using the relation

$$SF_{(x/y)} = \left[\frac{IP_x}{IP_y}\right]^{3.3} \qquad \text{for } IP_x < IP_z \tag{3}$$

The concentration of the elements Na, Mg, K, Ca and Ga could be calculated by using this method. For S, Cl, Zn and Sb, which cannot be determined by means of equation (3), the approach of Taylor and Gorton[12] was used [equation (4)]

$$SF_{(x/y)_z} = \frac{(IP_x)^2\,(BP_x)^{1/2} M_x}{(IP_y)^2\,(BP_y)^{1/2} M_y} \tag{4}$$

In equations (3) and (4) the indices x and y refer to the unknown element and the reference element respectively, z symbolizes the matrix, BP is the boiling point (K), *M* the mass, and IP the first ionization potential (eV).

Table 3. Coefficients *a* and *b* for the relation between sensitivity factors (SF) and matrix-ion species ratio [$SF = a(Fe_2^+/Fe^+)^b$] and the corresponding correlation coefficients *r* for NBS SRM 467

Element	*a*	*b*	*r*	Number of data points collected
Al	159	0.60	0.989	13
Si	0.71	0.052	0.707	7
P	0.034	0.148	0.800	7
V	35.4	0.617	0.995	13
Cr	9.54	0.214	0.976	13
Mn	2.11	0.073	0.943	12
Co	0.225	−0.329	0.989	10
Ni	7.5	0.458	0.955	8
As	0.0042	−0.446	0.989	8

Sn	5.16	0.624	0.974	10

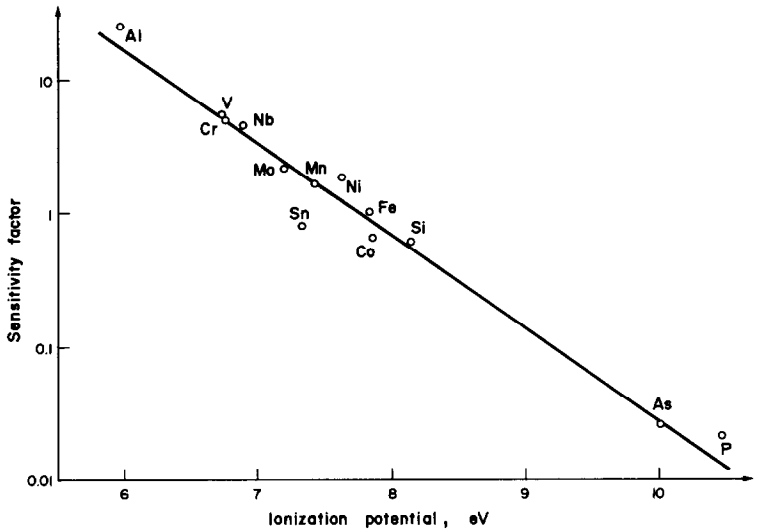

Fig. 3. Linear relationship between the logarithm of the sensitivity factor (SF) and the elemental first ionization potential (IP) for a matrix-ion ratio $Fe_2^+/Fe^+ = 0.047$.

RESULTS

Figure 4 shows the mass spectrum of the steel wire for the region m/e = 20–120. The elements C, Na, Mg, Al, Si, P, K, Ca, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Ga, As, Mo, Sn and Sb are detected (SIMS).

The resulting concentrations, determined by SIMS, are given in Table 5. For Cl, Ca, Zn, Zr and Sb only upper limits can be given, owing either to the absence of detectable ion signals (Cl, Zr) or to the presence of spectral interferences (Ca, Zn, Sb). About 20 analyses were performed for each element, except for Si and Co, for which up to 40 data points were collected, and for Ga, for which significant peaks were obtained in only two mass spectra. The precision is better than 20% for all elements, except for K and Ga, for which the errors amount to 40 and 50% respectively. Silicon was found to be quite heterogeneously distributed. Concentrations ranging from 0.1 to 0.3% were found, averaging around 0.21%.

Table 4. Spark-source mass-spectrographic conditions

Vacuum conditions	
Electrostatic analyser	$<10^{-8}$ mmHg
Magnetic analyser	$<10^{-8}$ mmHg
Source (when sparking)	$\sim 10^{-7}$ mmHg
Spectrometer parameters	
Spark voltage	60 kV
Repetition frequency	3 kHz
Pulse width	20 μsec
Accelerating voltage	29.0 kV
Main slit aperture	20 μm
α,β Slit openings	0.7 mm
Magnet current	4.75 A
Electrostatic analyser	2.9 kV
Exposure range	$0.3–1.5 \times 10^4$ pC
Detector	Ilford-Q_2 glass photographic plate

For the determination of the Al, Si, P, Cl, Ca, V, Cr, Mn, Co, Ni, As, Zr, Mo, Sn and Sb concentrations in the steel-wire sample several analyses were performed on different locations within the presputtered area. The Fe concentration was assumed to be 100%, as the total concentration of impurities as determined by SSMS is less than 1%.

The resulting concentrations, determined by SSMS, are also given in Table 5. The overall precision is 25%.

DISCUSSION

The overall agreement between the concentrations determined by SIMS and SSMS is good, as can be seen from Fig. 5. For 55% of the elements determined by using experimental SF, the difference is smaller than 25% relative error, and for 90% of these elements the error is better than 70%. Only for Sn is a large deviation obtained (factor 2.7); no explanation has yet been found to account for this discrepancy.

Where the concentrations are calculated by empirical methods for the compensation of differences in relative sensitivity, the agreement is less satisfactory, especially for K and Ga (factors 2.1 and 4.5 respectively). This could in principle be due to errors in the standardization of either the SIMS or SSMS. For Ga, heterogeneities and the lack of a sufficient number of data points could be responsible for the lack of accuracy from use of SIMS. For K the sensitivity factor was obtained by extrapolation of the log SF *vs.* IP graph. Taking into account the very low ionization potential of this element, the accuracy might be limited. It can be noted that the use of a similar MISR procedure for analysis of electric furnace dust also provided exceptionally low K concentrations, (low by a factor of 4).[13]

Also, SSMS results might lead to rather large inaccuracies, as Van Hoye[10] showed that differences in

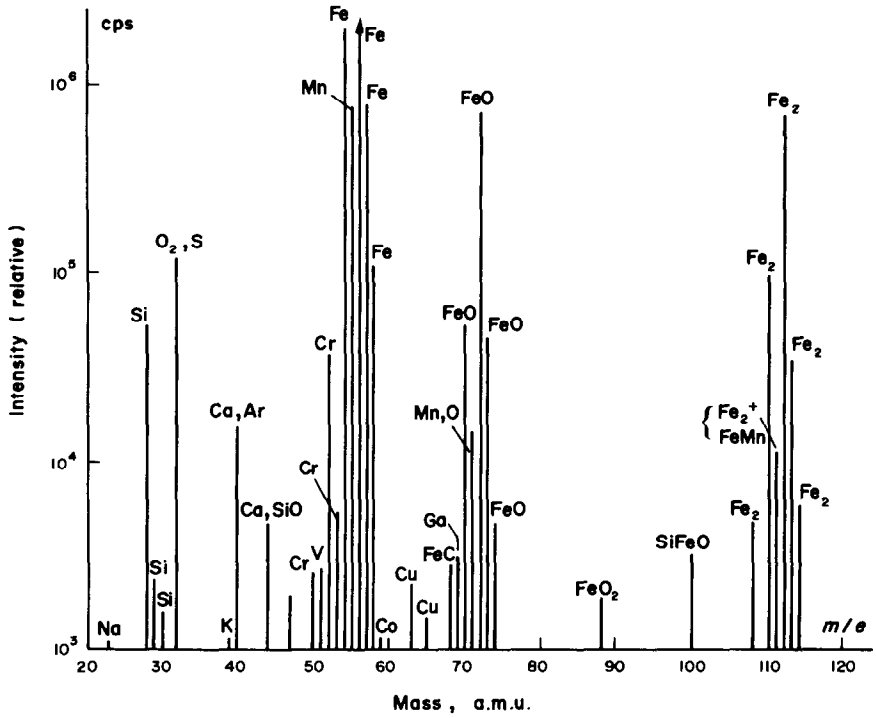

Fig. 4. Positive secondary-ion mass spectrum of the steel wire, for m/e = 20–120.

sparking conditions affect the sensitivities of most elements in steel samples and that the use of empirical formulas for the sensitivity factors might be doubtful.

Considering all this, it can be concluded that the matrix-ion species ratio method leads to reasonably accurate and precise results with SIMS, provided a standard sample with similar composition and adequate homogeneity is used.

o-IODOSOBENZOATE AS AN OXIDIMETRIC TITRANT

KRISHNA K. VERMA and ANIL K. GUPTA
Department of Chemistry, University of Jabalpur, Jabalpur 482001, India

(*Received* 17 *July* 1981. *Revised* 29 *January* 1982. *Accepted* 18 *February* 1982)

Summary—*o*-Iodosobenzoate has been used as a titrant at pH 7 with potassium iodide and starch as indicator, under Andrews' titration conditions with iodine monochloride as preoxidant, and in acid medium with potassium bromide and Methyl Red as indicator. Methods are described for the determination of tetrathionate (through disulphide cleavage by cysteine), hydrogen sulphite, thiosulphate, xanthates, cysteine and glutathione in certain combinations (involving masking of sulphite and thiols with acrylonitrile). Hexacyanoferrate(II) is determined in the presence of arsenic(III), antimony(III) and thallium(I). Sulphathiazole, sulphadiazine and sulphamerazine consume six equivalents of bromine per mole, but phthalation or diazotization of the aromatic amino group prevents disubstitution of bromine in the benzene ring. Chloramphenicol is determined by reduction of its aromatic nitro group to an amino group, followed by bromination. Rutin and vitamin C react with eight and two equivalents of bromine per mole respectively.

The aryl iodoso, iodoxy and related compounds constitute a group of considerable interest. They act as powerful oxidizing agents and are reduced practically irreversibly.[1–3] A number of iodoso compounds can be conveniently synthesized and it is an interesting question whether this series of oxidizing agents will be found of wide analytical value.

o-Iodosobenzoic acid was proposed by Hellerman *et al.*[4] for the specific determination of cysteine, glutathione and other protein thiols. The high results yielded by this method were thought to be due to the iodine liberated in the iodometric titration of the surplus reagent. Modified methods have been proposed that involve back-titration with ascorbic acid[5] or direct titration with *o*-iodosobenzoate[6] (with leuco-2,6-dichlorophenolindophenol and potassium iodide as indicator). Ascorbic acid has been determined in the presence of cysteine and hydrogen sulphite after masking of these two substances with acrylonitrile.[7] Xanthates in neutral solutions and thiols in acid medium have been determined, with starch and potassium iodide as indicator.[8] Chlorpromazine reacts with *o*-iodosobenzoic acid in acid medium, yielding a coloured substance of free radical nature.[9] *o*-Diacetoxyiodobenzoic acid behaves similarly to *o*-iodosobenzoic acid.[10,11]

The oxidation potential of *o*-iodosobenzoic acid has been found to be pH-dependent.[7] Thus, the reagent oxidizes iodide to iodine in neutral solution, and to iodine monochloride under Andrews' conditions, and bromide to bromine in acid medium. These conditions have been used in the present work for the determination of certain mixtures of organic and inorganic substances. On account of its ease of preparation,[12] excellent stability and applicability under various experimental conditions, *o*-iodosobenzoic acid can be recommended as an oxidimetric titrant for a variety of determinations.

EXPERIMENTAL

Reagents

*o-Iodosobenzoate, 0.02*M *solution.* Made by stirring 5.28 g of the free acid with 20 ml of 6% potassium hydroxide solution, diluting to 1 litre with demineralized water, and standardized iodometrically.[12] This solution loses about 1% titre on storage for 8 months. It can be diluted further as required.

*Iodine monochloride, 0.05*M *solution.* Prepared as described previously.[13]

Phosphate buffer, pH 7. Prepared by dissolving 117.7 g of K_2HPO_4 and 44.1 g of KH_2PO_4 in 1 litre of water.

Methyl Red. A 0.04% solution in ethanol.

Samples

Potassium ethyl and butyl xanthates[14] and sodium tetrathionate,[15] prepared and purified by known methods, were dissolved in water and the solutions were standardized, the xanthate solutions by mercurimetry[16] and the tetrathionate solution by periodate oxidation.[17]

Glutathione and cysteine were high-purity biochemicals, and their solutions were standardized by titration with chloramine-T[18] and by tetrathionate oxidation[13] respectively.

Solutions of high-purity salts of antimony(III), arsenic(III), thallium(I), hexacyanoferrate(II), thiosulphate and hydrogen sulphite were standardized by appropriate methods.[19]

All drug samples used were fresh.

Determination of tetrathionate

Mix 10 ml of solution containing up to 12 mg of tetrathionate with 5 ml of phosphate buffer and 10 ml of 0.02*M* cysteine and swirl the mixture for 5 min. Add 2 ml of acrylonitrile and let stand for 10 min. Add 10 ml of water, 100 mg of potassium iodide and 1 ml of 0.5% starch solution and titrate with 0.005*M* *o*-iodosobenzoate to appearance of a blue colour.

$$S_4O_6^{2-}\ (\text{mg}) = 224\ VM$$

where V is the volume (ml) of *o*-iodosobenzoate (molarity M) used.

Analysis of mixtures of xanthate or thiosulphate with hydrogen sulphite

To determine the xanthate or thiosulphate, mix 10 ml of the sample solution with 5 ml of phosphate buffer and 2 ml of acrylonitrile and shake the mixture for 5 min. Add 20 ml of water, 100 mg of potassium iodide and 1 ml of 0.5% starch solution and titrate with 0.01*M* *o*-iodosobenzoate to a blue colour.

$$S_2O_3^{2-} \text{ (mg)} = 224\ VM$$

$$\text{Alkyl xanthate (mg)} = 2\ VM\ w$$

where w is the formula weight of the alkyl xanthate ion. Mix another 10 ml of sample with 5 ml of phosphate buffer, 10 ml of water, 100 mg of potassium iodide and 1 ml of 0.5% starch solution and titrate with 0.01*M* *o*-iodosobenzoate to a blue colour. The amount of hydrogen sulphite is obtained by difference:

$$HSO_3^- \text{ (mg)} = 81\ \Delta VM$$

where ΔV is the difference between the two titration volumes.

The same set of methods can be used to analyse a mixture of a xanthate with cysteine or glutathione. Titration after reaction with acrylonitrile gives the amount of xanthate; the cysteine or glutathione is obtained by difference.

Cysteine or glutathione (mg) = $2\ f\Delta VM$ where f is the appropriate formula weight.

Analysis of mixtures of antimony(III) or thallium(I) with hexacyanoferrate(II)

Mix 10 (or 20) ml of sample with 25 ml of water, 5 ml of carbon tetrachloride and 5 ml of 0.05*M* iodine monochloride in a 250-ml iodine flask, shake the stoppered flask for 2 min, add 20 ml of 6*M* hydrochloric acid and titrate the liberated iodine with 0.02*M* *o*-iodosobenzoate to an Andrews end-point.

Determine the antimony(III) or thallium(I) alone by treating an equal aliquot of sample with 0.5 g of zinc sulphate and 25 ml of water, then applying the procedure above. Hexacyanoferrate(II) is obtained by difference.

$$\text{Sb(III) or Tl(I) (mg)} = aVM$$

where a = atomic weight

$$Fe(CN)_6^{4-} \text{ (mg)} = 424\ \Delta VM$$

Analysis of mixtures of arsenic(III), thallium(I) and hexacyanoferrate(II)

Mix an aliquot with 5 ml of phosphate buffer, 500 mg of potassium iodide and 1 ml of 0.5% starch solution, and titrate with 0.02*M* *o*-iodosobenzoate to obtain the amount of arsenic(III).

$$\text{As(III) (mg)} = 75\ VM$$

Take another aliquot to determine all three components by treating the mixture with iodine monochloride and titrating the liberated iodine to the Andrews end-point (V_1 ml). Treat a third aliquot with 500 mg of zinc sulphate, and then repeat the Andrews titration (V_2 ml)

$$Fe(CN)_6^{4-} \text{ (mg)} = 424\ (V_1-V_2)M$$

$$\text{Tl(I) (mg)} = 204\ (V_2-V)M$$

Analysis of chloramphenicol/sulphadiazine mixtures

Treat a known volume of drug suspension with 10 ml of 4*M* sulphuric acid and 50 ml of water, shaking well. Filter off insoluble matter on a Whatman No. 41 paper and wash it with water. Make up the filtrate and washings to known volume.

To determine the sulphadiazine, mix an aliquot with 200 mg of potassium bromide, 5 ml of 1*M* sulphuric acid and 2 or 3 drops of Methyl Red indicator and titrate with 0.02*M* *o*-iodosobenzoate till the red colour has almost faded, add 2 or 3 drops more indicator and titrate until the indicator is bleached.

$$\text{Sulphadiazine (mg)} = 83.3\ VM$$

Determine the sum of both components by treating another aliquot with two successive 0.25-g portions of zinc dust, heating on a water-bath for 5 min then cooling to room temperature, and titrating as before after adding 200 mg of potassium bromide and the indicator. Chloramphenicol is obtained by difference

$$\text{Chloramphenicol (mg)} = 161.5\ \Delta VM$$

Analysis of rutin/vitamin C mixtures

Stir a known weight of ground sample with 30 ml of water. Filter off insoluble matter on a Whatman No. 41 paper, wash with water, and make up the filtrate and washings to known volume. Treat the residue on the filter paper with two 25-ml portions of methanol and dilute the filtrate to a known volume with methanol.

Analyse an aliquot of the aqueous extract, which contains vitamin C (and any hydrogen sulphite added as preservative) by the method for xanthate.

$$\text{Vitamin C (mg)} = 176\ VM$$

Titrate a portion of the methanolic extract, which contains the rutin, by the method used for sulphadiazine.

$$\text{Rutin (mg)} = 160\ VM$$

Analysis of mixtures of phthalylsulphathiazole and chloramphenicol with sulphamerazine or sulphadiazine

Stir a known weight of finely ground sample with 25 ml of 1*M* potassium hydroxide, for 10 min, dilute to 100 ml with water and filter. Dilute the filtrate to a known volume. Analyse four equal aliquots as follows.

Aliquot 1. Add 5 ml of 2*M* sulphuric acid, 200 mg of potassium bromide, 20 ml of methanol, 2 or 3 drops of Methyl Red indicator and titrate with 0.02*M* *o*-iodosobenzoate to the sharp bleaching of the red colour (V_1 ml).

Aliquot 2. Acidify with 5 ml of 2*M* sulphuric acid; dissolve any precipitated material by adding 20 ml of methanol. Then add 5 ml of 2% sodium nitrite solution with shaking, and 2 min later 1 g of urea. Let stand for 5 min, add potassium bromide and indicator and titrate as for aliquot 1 (V_2 ml).

Aliquot 3. Add 20 ml of 2*M* sulphuric acid and heat on a water-bath for 20 min. Cool, add bromide *etc.* and titrate (V_3 ml).

Aliquot 4. Add 25 ml of 2*M* sulphuric acid and two 0.25-g portions of zinc dust. Heat on a steam-bath for 20 min, cool, add bromide *etc.* and titrate (V_4).

Sulphadiazine or sulphamerazine (mg) = $f(V_1-V_2)M/2$

(f = formula weight)

$$\text{Phthalylsulphathiazole (mg)} = 201.5\ (V_3-V_1)M$$

$$\text{Chloramphenicol (mg)} = 161.5\ (V_4-V_3)M$$

RESULTS AND DISCUSSION

Results obtained by these procedures are given in Tables 1–6 (CV = coefficient of variation). Results obtained by other methods are shown for comparison.

A number of oxidimetric methods have been proposed for determining tetrathionate but they lack specificity.[17,20] Cyanolysis and determination of the thiosulphate or thiocyanate produced has been used

quite extensively.[21,22] In the present work, cysteine has been found to react with tetrathionate at pH 7:

$$S_4O_6^{2-} + 2CySH \rightarrow 2S_2O_3^{2-} + CySSCy + 2H^+$$

At least a twofold molar excess of cysteine should be added. The surplus cysteine is masked by reaction with acrylonitrile at the same pH, to produce *S*-2-cyanoethylcysteine which does not interfere in the titration of the thiosulphate. Sulphite, if also present with tetrathionate, is also masked by acrylonitrile.

$$CySH + CH_2{=}CHCN \rightarrow CySCH_2CH_2CN$$

$$HSO_3^- + CH_2{=}CHCN \rightarrow {}^-O_3SCH_2CH_2CN$$

$$SO_3^{2-} + CH_2{=}CHCH + H_2O \rightarrow {}^-O_3SCH_2CH_2CN + OH^-$$

Thiosulphate interferes, of course, but a mixture containing tetrathionate and thiosulphate can be analysed by titrating the thiosulphate alone with *o*-iodosobenzoate at pH 7 (using potassium iodide and starch), then the sum of the two compounds by using the method given for tetrathionate. The tetrathionate is obtained by difference. Xanthates are not masked by acrylonitrile, and their oxidation yields the dixanthates:

$$2ROC(=S)S^- + OI.C_6H_4.CO_2^- + H_2O \rightarrow (ROC(=S)S)_2 + I.C_6H_4.CO_2^- + 2OH^-$$

Methods have been recommended for sulphite determination that involve reaction with excess of iodine followed by titration of the surplus.[19] Direct titration with iodine gives erratic results, perhaps because acid is also produced in the reaction, since

*Excipients adrenochrome monosemicarbazide (0.5 mg), menaphtheone sodium hydrogen sulphite (10 mg), calcium dihydrogen phosphate (132 mg), calciferol (500 IU).

†Excipient streptomycetin sulphate (125 mg).

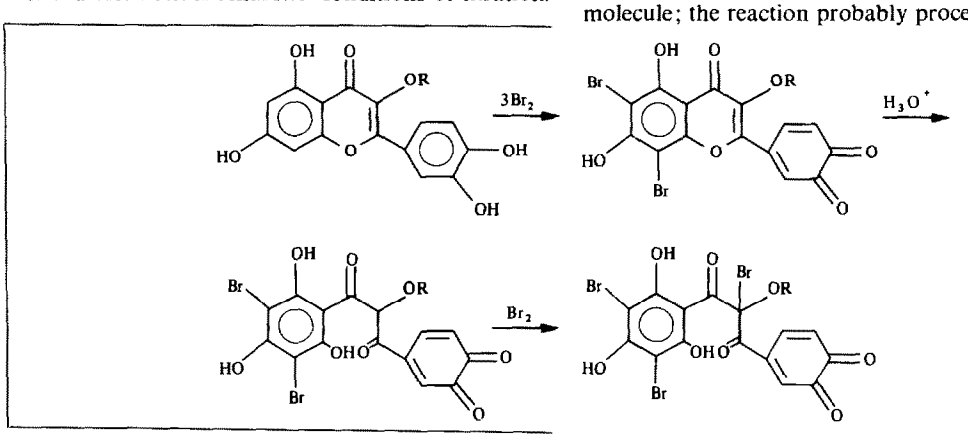
the *o*-iodosobenzoate titration, which does not yield any acid, gives accurate results.

$$SO_3^{2-} + I_2 + H_2O \rightarrow SO_4^{2-} + 2H^+ + 2I^-$$

$$SO_3^{2-} + OI.C_6H_4.CO_2^- \rightarrow SO_4^{2-} + I.C_6H_4.CO_2^-$$

This view is supported by the fact that when sulphite is titrated with iodine in pH-7 phosphate buffer, the results are precise (contrary to those yielded in non-buffered medium) and agree with those from *o*-iodosobenzoate titration (Table 2).

o-Iodosobenzoate oxidizes iodide to iodine monochloride under Andrews' conditions of titration.



Thallium(I), arsenic(III), antimony(III) and hexacyanoferrate(II) are also oxidized. If iodine monochloride is used as a preoxidant the Andrews end-point detection method can be used. Hexacyanoferrate(II) can be masked by precipitation with zinc, allowing analysis of mixtures of hexacyanoferrate(II) with other oxidizable ions.

Sulphonamides have been determined with reagents that produce bromine *in situ*,[23,24] but the stoichiometry changes with the reaction conditions and the substituents attached to the sulphonamide group.[25,26] Sulphadiazine, sulphamerazine and sulphathiazole have been examined in the present work and found to consume six atoms of bromine per molecule. The carbon atom β to a nitrogen atom in the substituent is active towards electrophilic bromination.[27]

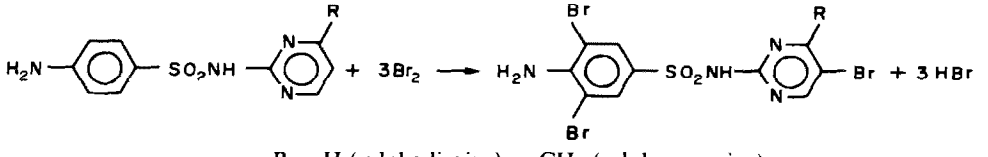
$$OI.C_6H_4.CO_2H + 2HBr \rightarrow Br_2 + I.C_6H_4.CO_2H + H_2O$$

Phthalation of the aromatic amino group prevents substitution at the two *ortho*-positions in the benzene ring, so phthalylsulphathiazole consumes only two atoms of bromine per molecule. The same effect results when the amino group is diazotized. Thus, diazotized sulphathiazole, sulphadiazine and sulphamerazine react with only two atoms of bromine per molecule. Hydrolysis of phthalylsulphathiazole produces sulphathiazole.

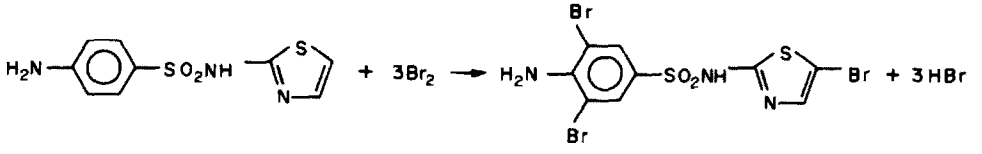
Chloramphenicol does not react with bromide and *o*-iodosobenzoate, but reduction produces an amino group which activates two *ortho*-positions for bromination. Rutin consumes eight atoms of bromine per molecule; the reaction probably proceeds as below:

(R = rotinose)

The methods for tetrathionate, thiosulphate, hydrogen sulphite, xanthates, cysteine and glutathione are unaffected by the presence of up to 20-fold molar excess of thiocyanate, chloride, bromide, acetate, oxalate, citrate, tartrate, formate and ammonium. Sulphide, dithionite and dithiocarbamates interfere severely. Titrations under Andrews' conditions are interfered with by hydrazine, hydroxylamine and similar reducing agents. The methods for the analysis of drugs tolerate glucose, starch, lactose, urea, histidine, glutamic acid, thiamine hydrochloride and iron(II) sulphate, but methionine, cystine, tyrosine, paracetamol, oxyphenbutazone, tryptophan, iodide, resorcinol and thiobarbituric acid interfere severely. Folic acid, phenacetin and acetylsalicylic acid also do not interfere, but if the drug solution is hydrolysed (as in the



R = H (sulphadiazine) or CH_3 (sulphamerazine)



analysis of Chlorosulf and Enteromycetin Sulfa), their interference is severe.

SHORT COMMUNICATIONS

GRAVIMETRIC DETERMINATION OF RHENIUM AS 2,4,6-TRIPHENYLPYRYLIUM PERRHENATE

M. PAVLOVA, M. ANGELOVA and N. JORDANOV
Institute of General and Inorganic Chemistry, Bulgarian Academy of Sciences, Sofia 1040, Bulgaria

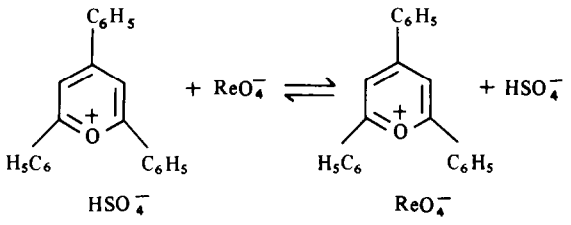
(*Received* 4 *September* 1981. *Revised* 16 *March* 1982. *Accepted* 13 *April* 1982)

Summary—A gravimetric method for determination of rhenium is based on formation of sparingly soluble 2,4,6-triphenylpyrylium perrhenate. The conditional solubility product in 0.1*N* sulphuric acid medium was found to be $(3.72 \pm 0.08) \times 10^{-9}$. The interference of foreign anions (simple or complex) is eliminated by preliminary extraction of perrhenate with acetone from strongly alkaline medium. The method is applied to the determination of rhenium in perrhenates and rhenium alloys.

It is known that 2,4,6-triphenylpyrylium chloride $(C_6H_5)_3C_5H_2O^+$. Cl^- yields sparingly soluble salts with a number of complex anions.[1] This reaction has been used for gravimetric determination of boron, gold, platinum and perchlorate.[1,2] The performance characteristics of these methods show that 2,4,6-triphenylpyrylium chloride is equal or even superior to nitron and tetraphenylarsonium chloride for the purpose.

The present work deals with the gravimetric determination of perrhenate by precipitation with 2,4,6-triphenylpyrylium bisulphate, which has the advantages of being simpler to make and more selective than the chloride salt (in the presence of chloride various anionic chloro-complexes could be formed and interfere).

The precipitate is formed according to the reaction:



EXPERIMENTAL

Reagents

2,4,6-Triphenylpyrylium bisulphate was prepared according to Chadwick.[2] All other reagents were of Merck analytical grade.

Synthesis of 2,4,6-triphenylpyrylium perrhenate

Perrhenate was precipitated with a solution of 2,4,6-triphenylpyrylium bisulphate in sulphuric acid, to yield a lemon yellow substance sparingly soluble in water, m.p. 270–274°. Elemental analysis was in agreement with the composition $C_{23}H_{17}O_5Re$, m.w. 559.6, rhenium content 33.28%.

Determination of the conditional solubility product of 2,4,6-triphenylpyrylium perrhenate

A weighed amount of the salt was stirred continuously with 0.1*N* sulphuric acid at 20 ± 0.1° in a thermostat. Samples of the solution were taken with a submerged filter tube at fixed time intervals and the rhenium content determined spectrophotometrically with thiocyanate.[3]

RESULTS AND DISCUSSION

Solubility product

The solubility of 2,4,6-triphenylpyrylium perrhenate was determined in order to establish whether it would be suitable for the gravimetric determination of rhenium. The dependence of rhenium concentration on contact time with water is shown in Fig. 1, curve 1. The rhenium concentration continuously increases. Taking into consideration the chemical behaviour of the pyrylium cation it seems that the curve is in agreement with the effect of the hydrolysis processes which may occur (causing cleavage of the pyrylium ring). The same experiments were done with 0.1*N* sulphuric acid instead of water (curve 2) to prevent hydrolysis. It is seen that equilibrium was established within 15 min. The solubility began to increase after about 5 hr, but is constant for the duration of the gravimetric determination. The conditional solubility product for 0.1*N* sulphuric acid medium was found to be $(3.72 \pm 0.08) \times 10^{-9}$, very close to that for tetraphenylarsonium perrhenate, $(3.72 \pm 0.2) \times 10^{-9}$.[4]

Interferences

All complex anions forming insoluble triphenylpyrylium salts, such as $AuCl_4^-$, $PtCl_6^{2-}$, ClO_4^-, MnO_4^-, BF_4^-, CrO_4^{2-}, CNS^-, NO_3^-, MoO_4^{2-}, WO_4^{2-}, VO_3^- interfere. The interference of Mo, W, V, Cr (the elements which most often accompany rhenium) can be effectively eliminated by a preliminary extraction of perrhenate with acetone from 5*M* sodium hydrox-

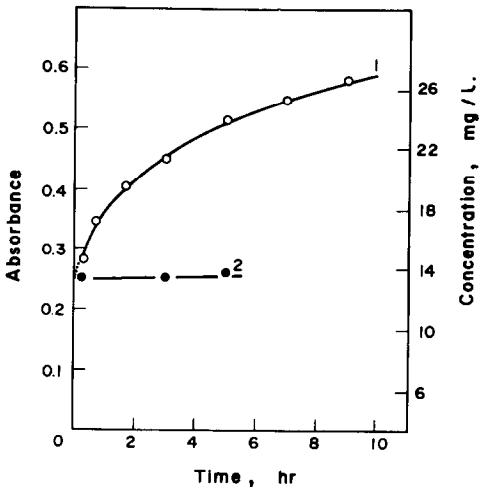


Fig. 1.

ide. The solubility of acetone in the aqueous phase is negligible and good separation of the phases is achieved. The presence of hydroxide precipitates does not interfere with the quantitative extraction of perrhenate. The organic layer is separated and the acetone evaporated by heating on a water-bath. The residue is dissolved in 30 ml of 0.1*N* sulphuric acid and perrhenate precipitated as in the normal procedure.

Procedure

The test solution, containing 20–50 mg of rhenium in 0.1*N* sulphuric acid is treated with a 50–60% excess of 1% solution of the reagent in 0.1*N* sulphuric acid, with stirring. The precipitate is allowed to stand for 30 min at room temperature, then for 1 hr in a refrigerator, and is finally filtered off on a porosity-4 fritted glass filter and washed first with cooled 0.1% solution of the precipitant and finally with small portions of ice-water. The final volume of filtrate should not exceed 50–60 ml.

Applications

The proposed method was applied to the analysis of potassium perrhenate (*p.a.*), ammonium perrhenate (technical grade) and rhenium–molybdenum alloy. The results were as follows.

1. Potassium perrhenate ($KReO_4$) *p.a.*
   Theoretical assay 64.36% Re
   Sample 50 mg
   Found, $\bar{x}_{Re} = 64.35\%$ $n = 14$, $P = 95\%$, $S = 0.25$,
   Re = 64.35 ± 0.15%, where $0.15 = t(n,P)S/\sqrt{n}$.

A parallel analysis was performed with tetraphenylarsonium chloride. The following results were obtained.

$\bar{x}_{Re} = 63.93\%$, $n = 10$, $P = 95\%$, $S = 0.20$,
Re = 63.94 ± 0.14%.

2. Ammonium perrhenate (NH_4ReO_4), technical grade
   Theoretical assay 69.42% Re
   Sample 50 mg
   Found, $\bar{x}_{Re} = 65.03\%$, $n = 4$, $P = 95\%$
   Comparative analyses gave $\bar{x}_{Re} = 64.93\%$, $n = 4$, $P = 95\%$
3. Rhenium–molybdenum alloy

With a model system it was shown that the proposed method can be applied to the analysis of rhenium–molybdenum alloys. Rhenium was separated from molybdenum by extraction with acetone. The model system contained about 10% Re and 90% Mo. With 9.94% Re present, the concentration found was 9.89% Re.

A standard rhenium–molybdenum alloy containing 46.7% Re was analysed. It was dissolved by anodic oxidation in 5*M* sodium hydroxide. The proposed method gave 47.0% Re.

POTENTIOMETRIC AND VISUAL TITRATIONS WITH BROMAMINE-B

H. SANKE GOWDA and H. NOOR AHMED KHAN
Department of Post-graduate Studies & Research in Chemistry,
University of Mysore, Manasa Gangotri, Mysore-570006, India

(*Received* 23 *July* 1981. *Revised* 24 *March* 1982. *Accepted* 2 *April* 1982)

Summary—Bromamine-B is proposed as an oxidimetric titrant for potentiometric and visual end-point titrations of arsenic(II), hexacyanoferrate(II), antimony(III), hydroquinone, semicarbazide hydrochloride, isonicotinic acid hydrazide, hydrazine sulphate, ascorbic acid, phenylhydrazine hydrochloride and metol. Quinoline Yellow, naphthidine, dimethylnaphthidinedisulphonic acid, *o*-dianisidine, diphenylbenzidine, Variamine Blue, α-naphthoflavone, Amaranth, Methyl Orange and Methyl Red are proposed as indicators in macro and micro titrations of the reductants with bromamine-B. The transition potentials of Quinoline Yellow, naphthidine, dimethylnaphthidinedisulphonic acid, and *o*-dianisidine in the titration of ascorbic acid are reported. Arsenic(III) and hexacyanoferrate(II) are suggested for the standardization of bromamine-B solutions.

This communication describes simple and accurate methods for standardization of bromamine-B (BAB) solution, which is proposed for the potentiometric and visual titration of macro and micro amounts of arsenic(III), hexacyanoferrate(II), antimony(III), hydroquinone (HQ), semicarbazide hydrochloride (SCH), isonicotinic acid hydrazide (INH), hydrazine sulphate (HS), ascorbic acid (AA), phenylhydrazine hydrochloride (PHH) and metol, with Quinoline Yellow (QY), naphthidine (N), dimethylnaphthidinedisulphonic acid (DMNS), *o*-dianisidine (ODA), diphenylbenzidine (DB), Variamine Blue (VB), α-naphthoflavone (NF), Amaranth (Am), Methyl Orange (MO) and Methyl Red (MR) as indicators.

EXPERIMENTAL

Indicator solutions

Solutions (0.1%) of QY, DMNS, VB, Am, MO and MR in water, N in glacial acetic acid, ODA in 0.04*N* sulphuric acid, DB in concentrated sulphuric acid and NF in ethanol were prepared.

Standardization of BAB solution with arsenic(III) and hexacyanoferrate(II)

A mixture of 20 ml of 0.05–0.01*N* arsenic(III), 5 ml of 10% potassium bromide solution and 0.5 ml of QY or NF or 0.2 ml of Am or MO was diluted to 40 ml with acid to give 1*M* sulphuric or hydrochloric acid or 2*M* phosphoric acid at the end-point, and titrated with 0.05–0.01*N* BAB solution to the disappearance of the colour or the appearance of a rust-brown, depending on the indicator.

A mixture of 20 ml of 0.05–0.01*N* hexacyanoferrate(II) and 0.1 ml of ODA was diluted to 40 ml with enough phosphoric acid to give a 0.5*M* acid concentration at the end-point, and titrated with 0.05–0.01*N* BAB solution to the appearance of a reddish brown colour.

Potentiometric titrations

Hexacyanoferrate(II), antimony(III), HQ, SCH or INH solution (20 ml, 0.05–0.01*N*) was diluted to 60 ml with enough acid to give 1*M* sulphuric or hydrochloric acid or 2.5*M* phosphoric acid concentration [only phosphoric acid medium for hexacyanoferrate(II)] at the end-point. The mixture was titrated potentiometrically with 0.05–0.01*N* BAB solution, a bright platinum gauze electrode being used. Potassium bromide solution (10%, 5 ml) was added before the titration of SCH and INH.

Visual end-point titrations

A mixture of 10–20 ml of 0.05–0.01*N* antimony(III), SCH, INH, HS, AA or PHH, 3–5 ml of 10% potassium bromide solution and 0.5 ml of QY (except for PHH) or 0.2 ml of Am, MO or MR, was diluted to 25–40 ml with enough acid to give 1*M* sulphuric or hydrochloric acid or 2*M* phosphoric acid at the end-point, and titrated with 0.05–0.01*N* BAB solution to the disappearance of the colour.

HQ was similarly titrated, with 0.1 ml of N, DMNS or ODA indicator: AA was titrated with 0.1 ml of N, DMNS or ODA or 0.5 ml of DB or VB as indicator, HS was titrated with 0.5 ml of NF as indicator, and metol was titrated only in 0.3*M* sulphuric acid medium, with 0.1 ml of ODA indicator.

RESULTS AND DISCUSSION

The transition potentials of QY, N, DMNS and ODA in the titration of AA with BAB vary over the ranges 843–867, 809–797, 744–715 and 766–754 mV respectively over the range of phosphoric acid concentration 2.0–3.5*M*.

BAB solution can be standardized with the primary standard arsenic(III), with QY, NF, Am and MO as indicators, or against hexacyanoferrate(II), with ODA indicator or a potentiometric end-point. QY, NF and ODA act as reversible indicators and Am and MO as irreversible indicators. The results indicate that these methods of standardization give satisfactory agreement but the arsenic(III) method is superior because it uses direct titration of a primary standard.

Potentiometric titrations

In the potentiometric titration of hexacyanoferrate(II), antimony(III), HQ, SCH and INH, the presence

of potassium bromide is desirable only for SCH and INH. Equilibration of the electrode potential takes about a minute. The potential jump at the end-point is 100 mV for hexacyanoferrate(II) in 1*M* phosphoric acid, 116 mV for antimony(III), 180 mV for HQ, 230 mV for SCH and 198 mV for INH in 1*M* hydrochloric acid medium, for addition of 0.1 ml of 0.01*N* BAB. Titrations of hexacyanoferrate(II) in 0.5–1.5*M* phosphoric acid, antimony(III) in 1.0–2.5*M* hydrochloric acid, HQ in 0.5–1.5*M* hydrochloric or sulphuric acid or 1.5–3.0*M* phosphoric acid, and SCH and INH in 0.5–1.5*M* hydrochloric or sulphuric acid or 1.5–2.5*M* phosphoric acid solution containing 0.6–2.5% potassium bromide, give accurate results (Table 1).

Visual end-point titrations

The indicators used in the visual end-point titrations depend on the nature of the indicator, the reductant and the titration medium. For example QY, NF, Am, and MO function in the titration of arsenic(III); QY, Am, and MO in the titration of antimony(III); N, DMNS and ODA in the titration of HQ; QY, Am, MO and MR in the titration of HS; QY, DB, N, DMNS, ODA, VB, Am, MO, and MR in the titration of AA; and Am, MO and MR in the titration of PHH in 0.5–1.5*M* sulphuric or hydrochloric acid [1–2.5*M* for antimony(III)] or 1.5–3*M* phosphoric acid (2–3.5*M* for HQ and HS) containing 0.6–2.5% potassium bromide. ODA gives sharp end-points in the titration of hexacyanoferrate(II) in 0.3–1.5*M* phosphoric acid and in the titration of metol in 0.3*M* sulphuric acid solution containing 0.6–3.7% potassium bromide. The total volume of the titration mixture at the end-point is about 60 ml in the titration of 0.05*N* reductant and 35 ml in the titration of 0.01*N* reductant.

QY, N, DMNS, ODA, DB, VB, and NF give sharp reversible end-points. QY gives a colour change from yellow to colourless and N, DMNS, ODA, DB, VB and NF from colourless to pinkish violet red, reddish brown, blue-violet, purple and rust-brown respectively at the equivalence point. The end-point colour is stable for 2–15 min. Am, MO and MR give sharp irreversible colour changes from red to colourless at the equivalence point.

Table 1. Potentiometric titrations with BAB

Reductant	Range studied, *mg*	Maximum error, %
$Fe(CN)_6^{4-}$	2.5–220	0.2
Sb(III)	7.5–128	0.3
HQ	5.5–150	0.4
SCH	5.3–53	0.1
INH	3.1–76	0.1

Table 2. Titration of arsenic(III), hexacyanoferrate(II), antimony(III), HQ, SCH, INH, HS, AA, PHH and metol with BAB

Reductant	Taken, *mg*	Mean found, *mg*	Relative std. devn., %
As(III)	68.8	68.9	0.1
	3.29	3.28	0.1
$Fe(CN)_6^{4-}$	221.7	222.0	0.3
	2.46	2.45	0.1
Sb(III)	128.2	128.5	0.2
	7.58	7.57	0.2
HQ	150.5	150.4	0.3
	5.54	5.54	0.1
SCH	52.8	52.8	0.2
	5.28	5.27	0.4
INH	76.2	76.2	0.3
	3.13	3.12	0.2
HS	68.3	68.3	0.2
	3.40	3.42	0.1
AA	178.6	178.5	0.2
	21.3	21.3	0.1
PHH	75.2	75.4	0.4
	3.79	3.84	0.1
Metol	164.6	164.5	0.8
	3.96	3.96	0.4

For all the reductants, 0.5–1.5 ml of 0.1% QY, DB, VB and NF, 0.1–0.5 ml of 0.1% N, DMNS and ODA and 0.2–0.8 ml of 0.1% Am, MO and MR indicators are recommended. Smaller amounts of indicator are suitable for titrations of 0.01*N* reductant. The average indicator correction is 0.03–0.05 ml of 0.01*N* BAB for the amounts of indicators recommended in the procedures. The sharpness of the end-point is in the order QY > ODA > N = DMNS > DB > VB > NF > Am > MO = MR.

A large deviation from the permissible ranges of acidity, indicator, and potassium bromide leads to sluggish, premature or overshot end-points.

The titration of AA and INH was used for the determination of AA in vitamin-C tablets and injections and INH in isoniazid tablets and syrup. A synthetic mixture containing 305 mg of starch, 304 mg of gelatin, 255 mg of talc, 285 mg of stearic acid, 270 mg of sodium alginate, 329 mg of citric acid, 242 mg of reserpine, 484 mg of pulvis acaciae and 400 mg of dextrose, sucrose or oxalic acid did not interfere in the determination of 75 mg of AA in 1*M* phosphoric acid or 50 mg of INH in 0.5*M* sulphuric acid. The results of the assay of tablets, injections and syrup compare favourably with those obtained by the standard methods.[1,2]

DETECTION AND SEMIQUANTITATIVE DETERMINATION OF NICKEL WITH DIMETHYLGLYOXIME-LOADED FOAM

A. B. FARAG, A. M. EL-WAKIL and M. S. EL-SHAHAWI
Chemistry Department, Faculty of Science, Mansoura University, Mansoura, Egypt

(*Received* 19 *December* 1981. *Accepted* 24 *March* 1982)

Summary—Rapid, sensitive and selective detection and semiquantitative determination of nickel in aqueous solution can be obtained by using dimethylglyoxime loaded on polyurethane foam, either by batch or column extractions, the detection limits being 0.05 and 0.01 ppm respectively.

Polyurethane foam loaded with water-insoluble reagents which yield coloured reaction products seems very attractive for raising the sensitivity of spot-tests. This method has been tested for the detection of cobalt(II),[1] chromium(VI)[2] and iron(III)[3] with polyurethane foam loaded with Amberlite LA-1, 1,5-diphenylcarbazide and tricaprylamine, respectively. These tests were more sensitive than the normal spot-tests on a spot-plate,[4] on paper impregnated with reagent[4] or with the resin spot-test,[5] and had good selectivity.

They could also be used for semiquantitative determination.

In the present work polyurethane foam loaded with dimethylglyoxime was evaluated as a reagent for detection and semiquantitative determination of nickel.

EXPERIMENTAL

Reagents

All reagents were of analytical-reagent grade unless otherwise specified. Tricaprylamine (Alamine 336), pure grade, was kindly provided by General Mills, Kankakee, Illinois, U.S.A. An open-cell, polyether type polyurethane foam (bulk density 30 kg/m^3) was supplied by Greiner KG, Schaumstoffwerk-Kremsmunster, Austria. The foam material (cubes of 5 mm edge) was washed and dried as previously described.[1,2]

The dimethylglyoxime solution was prepared by dissolving about 0.2 g in 10 ml of Alamine 336. The reagent-foam was prepared by immobilizing the dimethylglyoxime–amine solution on the polyurethane foam by a procedure similar to that described previously.[6]

In the flow experiment, 0.5 g of the loaded foam was packed in a glass tube 5 mm in diameter and 10 cm long, by the vacuum method.[7]

RESULTS AND DISCUSSION

The colour reaction of dimethylglyoxime with nickel is well known. Experience with reagent-loaded polyurethane foam has shown that metal ions at very low concentration in aqueous solution can be collected on the reagent-foam simply by shaking, or by percolating the solution through a foam column at a reasonable flow-rate.

In preliminary experiments, an alcohol solution of dimethylglyoxime was tried for loading the foam, but the results were not satisfactory. A saturated solution of dimethylglyoxime in Alamine 336 proved suitable, however, the reagent not being leached from the foam on shaking vigorously with aqueous solution or on elution at relatively high flow-rates. Evidently, the amine serves a dual purpose, as a suitable solvent for the dimethylglyoxime and as a plasticizer for the foam material.

Shaking one cube (5 mm edge) of the foam for 1–2 min with 2 ml of aqueous nickel solution (pH 7–9), allowed detection of the nickel at relatively very low concentrations (0.05 ppm) by means of the red colour formed on the foam. The sensitivity was superior to that of the normal spot-test on a spot-plate (3.2 ppm) or impregnated paper (0.5 ppm).

It was found possible to detect 1 μg of nickel in the presence of 20 mg of Tl^+, In^{3+}, Hg(I), Cd^{2+}, Zn^{2+}, Ca^{2+}, Ba^{2+}, Rb^+, Mg^{2+}, NH_4^+, PO_4^{3-}, $S_2O_3^{2-}$, SO_4^{2-}, SCN^-, CH_3COO^-, CO_3^{2-}, HCO_3^-, Cl^-, Br^-, I^-, SO_3^{2-}, $B_4O_7^{2-}$, ascorbate or tartrate. Bi^{3+}, Au^{3+}, Pd^{2+} and Pt^{4+} interfere in the same way as in the usual spot-test.

In the presence of some other ions simple modifications of the aqueous solution are needed for the clear and sensitive detection of nickel (Table 1). Iron(II) must be oxidized to iron(III) before addition of fluoride.

Semiquantitative determination is possible by comparison of the colour of the foam cube with standards prepared with 0.05, 0.1, 1, 10 and 50 ppm nickel solutions under the same conditions.

A still lower concentration of nickel (0.01 ppm) can be detected by percolating 100 ml of the nickel solution through 0.5 g of reagent-foam (packed in a column) at a flow-rate of 3–5 ml min. The length of the coloured zone is proportional to the concentration of nickel, which can be estimated by using standards covering the concentration range 10–50 ng/ml.

Table 1. Effect of various ions on the detection of 1 μg of nickel(II) in 2 ml of aqueous solution

Foreign ion	Compound added	Colour of the foam*	Tolerance limit,† μg	Notes
Cu(II)	$CuCl_2$	White	$1:10^4$	Crystals of KI added, followed by $Na_2S_2O_3$ crystals.

EXTRACTIVE-SPECTROPHOTOMETRIC DETERMINATION OF MOLYBDENUM AS MIXED-LIGAND COMPLEXES WITH THIOCYANATE AND AMIDOPYRIDINES

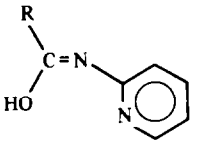
K. S. PATEL* and R. K. MISHRA
Department of Chemistry, Ravishankar University, Raipur-492010, M.P., India

(*Received* 16 *December* 1980. *Revised* 21 *January* 1982. *Accepted* 9 *April* 1982)

Summary—A fairly selective and sensitive method is described for the determination of microgram amounts of molybdenum(V) by means of its reaction with thiocyanate and the enolic form of various amidopyridines and extraction into benzene. The molar absorptivity of the complexes is in the range 1.5–1.9 × 10^4 l.mole^{-1}.cm^{-1} at λ_{max} 470 nm. The method is applicable in 1.5–7*M* hydrochloric acid or 1.2–6*M* sulphuric acid media. Cu^{2+}, Co^{2+}, Mn^{2+}, Zn^{2+}, Ni^{2+}, Cd^{2+}, Fe^{3+}, Al^{3+}, Cr^{3+}, Ti^{4+}, Zr^{4+}, V(V), Nb^{5+}, Ta^{5+}, W(VI) and U(VI) do not interfere.

The classical thiocyanate method is frequently used for the determination of molybdenum in spite of its drawbacks.[1] The spectrophotometric methods based on other reagents[2–12] also suffer from various difficulties, including interference from ions commonly associated with molybdenum, such as Cu^{2+}, Co^{2+}, Ni^{2+}, Fe^{3+}, Bi^{3+}, Ti^{4+}, Zr^{4+}, Nb^{5+}, V(V), W(VI).

We now report on 2-benzamidopyridine and similar compounds as simple and selective reagents for molybdenum in presence of thiocyanate. The organic ligand is believed to behave as a singly charged bidentate chelating agent with the functional grouping shown below.



EXPERIMENTAL

Reagents

Standard molybdenum(VI) solution. Prepared by dissolving 2.04 g of ammonium heptamolybdate tetrahydrate in doubly distilled water and standardized gravimetrically.[13] The working solution was prepared by appropriate dilution.

Amidopyridines. Prepared as described in the literature[14] and used as 1% solutions in benzene.

Ascorbic acid and ammonium thiocyanate solutions. Freshly prepared 10 and 20% solutions respectively.

All solutions used were presaturated with benzene.

Procedure

An aliquot of solution containing 5–100 μg of Mo(VI), 5 ml each of ascorbic acid and ammonium thiocyanate solutions and 12 ml of 10*M* hydrochloric or sulphuric acid were transferred to a 100-ml separatory funnel, diluted to 25 ml with distilled water and shaken with 25 ml of benzene solution of the amidopyridine for 2 min. The organic layer was dried over anhydrous sodium sulphate (2 g) in a 50-ml beaker and its absorbance measured at λ_{max} against a suitable reference.

Analysis of steel

The sample was dissolved in *aqua regia* and the solution evaporated to dryness. The residue was heated with 3 ml of concentrated sulphuric acid till fuming. The digestion procedure was repeated 2 or 3 times. The dried mass was cooled and dissolved in 0.5*M* hydrochloric acid and diluted to known volume with distilled water. An aliquot was taken in a 100-ml separatory funnel and 0.2 g of sodium oxalate (in solution) was added to reduce any V(V). The molybdenum was then determined as described in the procedure above.

RESULTS AND DISCUSSION

Spectral characteristics

The absorption spectra of the metal chelates and 2-benzamidopyridine are shown in Fig. 1. The reagent has negligible absorption at the wavelength of maximum absorption. The metal chelate gives a sharp absorption peak with λ_{max} at 470 nm. Replacing the phenyl group by a 2-furyl group lowers the absorbance of the complex, but the introduction of substituents in the phenyl group only slightly affects the colour intensity (Table 1).

Choice of solvent and reducing agent

Benzene, toluene, chloroform, carbon tetrachloride, ether, ethyl acetate, acetophenone and amyl alcohol were tried as solvents. The complex was extractable into all these, but the molar absorptivity varied considerably. The position of λ_{max} shifts slightly towards shorter wavelengths as the dipole moment of the solvent increases (to 460 nm for alcohol). Benzene was chosen because of the high extractibility of the metal

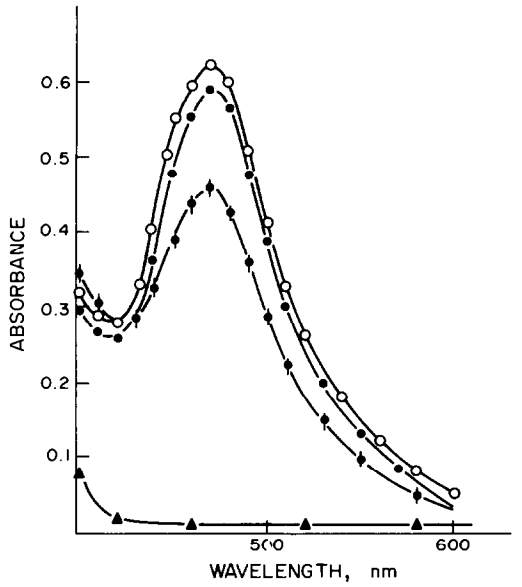

Fig. 1. Absorption spectra. [HCl] 5M; [amidopyridine] 0.05M; [SCN^-] 0.5M; [ascorbic acid] 0.1M. (⊙——⊙) 2-(*p*-toluamido)pyridine complex; (●——●) 2-benzamidopyridine complex; (◆——◆) 2-(*p*-chlorobenzamido)pyridine complex; (▲——▲) 0.05M 2-benzamidopyridine.

chelate into it. Other solvents were unsuitable owing to low absorbance, or slow phase separation or instability of the colour. Ascorbic acid and stannous chloride were tried as reducing agents, but ascorbic acid was chosen because it gave a high absorbance for the complex and the amount to be added was not critical (unlike stannous chloride). The extraction is complete even in the absence of ascorbic acid if the reaction mixture is shaken for at least 30 min.

Effect of variables

Systematic variation of the reagent concentrations indicated that at least 0.015M amidopyridine solution in benzene and 0.3M ammonium thiocyanate were necessary for complete extraction of the metal, but that up to 0.2M amidopyridine and 1.2M thiocyanate did not affect the spectral characteristics of the complex. However, thiocyanate concentrations $>1.2M$ decreased the extraction efficiency. The order of addition of reagents was not critical. A shaking time of 2 min was sufficient for the complete extraction reaction. Variation in temperature from 15° to 35° and in volume of aqueous phase from 15 to 60 ml did not affect the distribution coefficient. The absorbance was constant for at least 2 hr. Salting-out agents had no effect.

Table 1. Spectral data for the ternary complexes in benzene, at λ_{max} 470 nm

R*	[HCl] ([H_2SO_4]) range for extraction, M	ϵ, $l.mole^{-1}.cm^{-1}$
Phenyl	3.0–7.0 (2.0–6.0)	1.90×10^4

p-Chlorophenyl	2.5–6.0 (1.5–6.0)	1.92×10^4
2-Furyl	3.0–7.2 (2.0–6.0)	1.49×10^4

*In RC(OH)N Py.

The acidity of the solutions was adjusted with 10M hydrochloric or sulphuric acid, the optimum acidity ranges being 1.2–7.0M hydrochloric acid and 1.2–6.0M sulphuric acid, which gave the same values of λ_{max} and ϵ for the complex. Higher sulphuric acid concentrations decreased extraction of the metal because of increased miscibility of benzene with the aqueous phase. Hydrochloric acid was preferred because it gave better selectivity. Nitric acid and acetic acid are unsuitable for the extraction. The effect of hydrochloric acid is shown in Fig. 2 and a concen-

tration of 5*M* was chosen because it gave the highest rate of extraction.

Performance characteristics

The calibration graph is linear over a wide concentration range. The optimum range on the basis of a Ringbom plot[15] is 0.5–4.4 ppm Mo. The relative standard deviation (10 replicates, 2 ppm Mo) is 0.8%.

Composition of complex

This was determined by a curve-fitting method,[16] using plots of log *D* *vs.* log $[amide]_o$ or log $[SCN^-]$. The results obtained indicate the mole ratio to be 1:2:1 Mo:thiocyanate:aminopyridine, so the species extracted into benzene is probably $MoO(SCN)_2(RC_6N_2O)$ where RC_6N_2O is the deprotonated enolic form of the amidopyridine, co-ordinated to the metal through the oxygen atom of the amide group and the nitrogen atom of the pyridyl group.

*Average of six determinations.

Effect of diverse ions

The effect of other ions in the determination of 2 ppm of Mo by the procedure given (hydrochloric acid) was examined. Chloride, bromide, nitrate, sulphate or alkali metal up to 2*M* and alkaline-earth elements up to 0.1*M* do not interfere. The tolerable amounts of other ions are tabulated in Table 2.

Applications

The validity of the method was tested with ores, alloy steels and synthetic solutions. The results are shown in Tables 3 and 4.

ANALYTICAL DATA

RADIOCHEMICAL EXTRACTION INVESTIGATION OF THE ION-ASSOCIATION COMPLEX OF Sb(V) WITH THIAZOLYL BLUE IN STRONGLY ACIDIC SOLUTIONS

A. V. ALEXANDROV and S. KOSTOVA
Department of General and Inorganic Chemistry, P. Chilendarski University, 4000 Plovdiv, Bulgaria

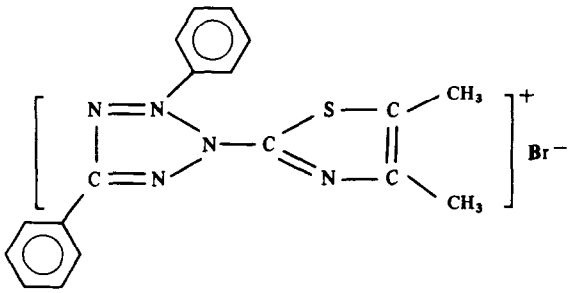
and

J. HÁLA
Department of Inorganic Chemistry, J. E. Purkyně University, 61137 Brno, Czechoslovakia

(*Received* 7 *January* 1982. *Accepted* 4 *April* 1982)

Summary—The interaction between Sb(V) and Thiazolyl Blue (MTT) in 6*M* HCl has been studied by a radiochemical extraction method. It has been proved that the ion-association complex $MTT^+ \cdot SbCl_6^-$ is extracted. The constants characterizing its extraction into $C_2H_4Cl_2$ and a 1:1 $C_2H_4Cl_2/CHCl_3$ mixture have been determined.

It has been established[1] that an extraction-photometric determination of antimony can be based on the formation of an ion-association complex between Sb(V) and MTT (I) in strongly acidic medium [MTT is used here as an abbreviation for Thiazolyl Blue, 3-(4,5-dimethylthiazolyl-2)-2,5-diphenyl-2H-tetrazolium bromide]. Because of the high absorbance of MTT in the organic solvent it was not possible to determine the extraction and association constants in



I

the two-phase extraction system spectrophotometrically. In an earlier work[2] one of us used a radiochemical method to obtain these constants for a similar system. By extending this approach and using Sb tracers it proved possible to determine the constants characterizing the extraction equilibrium in the Sb(V)/HCl/MTT system.

EXPERIMENTAL

MTT (Koch-Light analytical grade) and $SbCl_5$ (Merck-Schuchardt) were used. The hydrochloric acid and all solvents were of reagent grade quality.

The tracers ^{125}Sb (Izotop, USSR) and ^{124}Sb (Institute of Nuclear Research, Poland) were obtained as Sb(III) in 4.1*M* and 0.1*M* hydrochloric acid, respectively. Sb(III) was oxidized to Sb(V) with sodium nitrite in hydrochloric acid medium, and the specific activity was adjusted to 7.4 kBq/ml (0.2 μCi/ml) by adding a solution of antimony(V) chloride. The concentration of antimony was determined iodometrically.

It was found earlier[1] that dichloroethane was the best organic solvent for the extraction of the Sb(V)/MTT complex. In the present study we used both dichloroethane and its 1:1 mixture with chloroform. The extraction procedure was as follows. Either $^{125}Sb(V)$ or $^{124}Sb(V)$ tracer in 6*M* hydrochloric acid, at the desired Sb concentration, was equilibrated with the organic solvent for 30 min, which was found to be sufficient for equilibrium to be reached. The phase volumes were 10 ml. The distribution ratios (organic/aqueous), *D*, were obtained from the count-rate ratios for aliquots of the corresponding phases.

The gamma activity was measured with the scintillation detector of an NP 424 nuclear counter (Hungary) or in the 3-in. well-type NaI(Tl) crystal of the 1185 Automatic Gamma Counting System (Nuclear Chicago).

RESULTS AND DISCUSSION

The values of *D* are plotted in Fig. 1 as a function of the equilibrium concentration of MTT in the

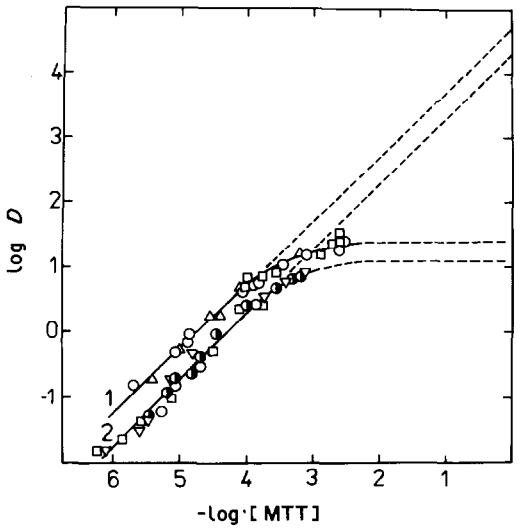


Fig. 1. Distribution ratio of Sb as a function of equilibrium MTT concentration in the aqueous phase. Curve 1: $C_2H_4Cl_2/CHCl_3$ (1:1); Sb(V) concentration: □ 3.0×10^{-5} ○ 5.0×10^{-5} △ 6.0×10^{-5} *M*. Curve 2: $C_2H_4Cl_2$; Sb(V) concentration: ▽ 1.34×10^{-5} □ 2.68×10^{-5} ○ 8.12×10^{-5} ◑ 13.56×10^{-5} *M*.

aqueous phase. The latter was calculated from D and the total Sb(V) and MTT concentrations. The left-hand parts of the plots have a slope of +1 and thus confirm the 1:1 ratio of Sb(V) and MTT in the complex.

The extraction equilibria in the Sb(V)/MTT system can be described by the extraction constant

$$K_{ex} = \frac{[MTT^+ \cdot SbCl_6^-]_{org}}{[MTT^+][SbCl_6^-]} \quad (1)$$

and the equation for the distribution ratio

$$D = \frac{K_D \beta [MTT^+]}{1 + \beta [MTT^+]} \quad (2)$$

where $K_D = [MTT^+ \cdot SbCl_6^-]_{org}/[MTT^+ \cdot SbCl_6^-]$ is the partition coefficient of the ion-association complex and $\beta = [MTT^+ \cdot SbCl_6^-]/[MTT^+][SbCl_6^-]$ is the association constant. The constants are related by

$$K_{ex} = K_D \beta \quad (3)$$

Table 1. Extraction parameters for the Sb(V)/MTT system

Organic phase	K_{ex}	K_D	β
$C_2H_4Cl_2/CHCl_3$ (1:1)	5.0×10^4	25.1	2.0×10^3
$C_2H_4Cl_2$	1.8×10^4	12.5	1.45×10^3

Extrapolation of the curves in Fig. 1 to high MTT concentrations yielded, according to equation (2), the values log $K_D = 1.40$ for the $C_2H_4Cl_2/CHCl_3$ mixture, and approximately 1.10 for $C_2H_4Cl_2$. Following the approach used in earlier papers[2,3] the curves in Fig. 1 were further analysed graphically to yield the constants K_{ex} and β. The constants obtained are summarized in Table 1.

From the constants obtained the log D *vs.* log $[MTT^+]$ curves were back-calculated from equation (2). These are shown as full lines in Fig. 1. The value of K_{ex} for the $C_2H_4Cl_2/CHCl_3$ mixture was also determined by the method of Likussar and Boltz[4] as $K_{ex} = 5.76 \times 10^4$, in good agreement with the description of the equilibria given in this work.

The results show that the Sb(V)/MTT^+ interaction in 6*M* hydrochloric acid is rather strong ($\beta \sim 10^3$.) with the equilibrium markedly shifted towards the formation of the ion-association complex.

ANNOTATIONS

ON THE STORAGE OF THE SODIUM BOROHYDRIDE SOLUTION USED IN THE HYDRIDE-GENERATION ATOMIC-ABSORPTION TECHNIQUE

RAGNAR BYE
Department of Chemistry, University of Oslo, Oslo 3, Norway

(*Received* 25 *January* 1982. *Accepted* 2 *March* 1982)

Summary—A critical examination has been made of the stability of sodium borohydride solutions on storage at room temperature and at 4° in a refrigerator, by comparison of the reductive power for selenium(IV) in a hydride-generator, with that of a freshly prepared solution. No significant change in reactivity appeared to be caused by storage for a period of three weeks, and there seems no need to use freshly prepared solutions for analytical work.

During work with the hydride-generation atomic-absorption technique in this laboratory, it was found that the sensitivity for selenium changed somewhat with the age of the alkaline sodium borohydride solution used. This observation was not at first considered as being very remarkable, as many workers had reported that the solution was unstable on storage. The manufacturer of the hydride-generation assembly also recommended that the borohydride solution should be prepared daily.[1] However, it was discovered that some workers had found that the solution was stable for several weeks if certain precautions were taken, *e.g.*, for at least 8 weeks if the borohydride was dissolved in 2% sodium hydroxide solution and stored in a refrigerator,[2] or if the solution was filtered.[3] These claims did not help to resolve the problem, however, as both addition of sodium hydroxide and filtration are recommended in the Operator's Manual, yet it was still advised to prepare the solution daily. Because quantitative arguments for either statement could not be found in the literature, and it would be advantageous if the solution need not be prepared daily, it was decided to try to clarify the problem.

EXPERIMENTAL

Apparatus and operating conditions

A Perkin–Elmer model 300 atomic-absorption spectrometer was used under the standard conditions for selenium. Deuterium background correction was not used. The hydride-generation assembly was the pneumatically operated Perkin–Elmer MHS-10 system with a T-shaped quartz tube placed in the air–acetylene flame. Argon (99.99%) was used as purging gas. The system was operated according to the Operator's Manual.

Reagents

A 2% sodium hydroxide solution containing 3% sodium borohydride was made by dissolving 40.0 g of sodium hydroxide (Merck, *pro analysi*) in about 500 ml of water, cooling, then dissolving 60.0 g of sodium borohydride (Fluka, *purum*, >97%) in this solution, diluting to about 1800 ml, and filtering into a 2000-ml standard flask, making up to volume and mixing. This solution was divided into two parts, each of 1000 ml, which were stored in screw-cap polypropylene bottles. One solution was stored in the dark at ambient temperature and the other at 4° in a refrigerator. These solutions were used in measuring the signals from aliquots of 0.4*M* hydrochloric acid (Merck, *suprapur*) containing a constant amount of selenium(IV). The signals were compared with those obtained by use of a borohydride "reference" solution prepared just before use, by dissolving 2.00 g of sodium hydroxide and 3.00 g of sodium borohydride in water and making up to 100 ml after filtration. The sodium borohydride powder was delivered in a sealed can, which was furnished with a plastic cap for use after the can was opened the first time. Only one can was used during the experiment.

Procedure

Each borohydride solution was examined in turn, starting with the "reference" solution and ending with the solution that had been stored in the refrigerator, 100 ml being placed in the reductant reservoir. The 100 ml of the solution stored in the refrigerator were transferred to a vessel in the laboratory 1 hr before use, to allow the solution to reach ambient temperature. The 10 ml of 0.4*M* hydrochloric acid were transferred to the reaction vessel and 50 μl of 1-ppm standard Se(IV) solution were added by means of a Hamilton syringe. The reaction vessel was attached to the generation unit and the flame was ignited. After 30 sec the plunger was activated to allow the borohydride solution to be dispensed into the hydrochloric acid solution, and the signal was recorded on a strip-chart recorder operated at 5 mV sensitivity. This procedure was repeated five times for each of the three solutions on the day of the test.

RESULTS AND DISCUSSION

The means ($\bar{X}$) and estimates of the standard deviations (S) of the absorbance values for each of the two test solutions were calculated and compared with

those for the reference solution by means of the equation

$$t = \frac{\bar{X}_{ex} - \bar{X}_{ref}}{\sqrt{\frac{S^2_{ex} + S^2_{ref}}{n - 1}}}$$

where $n = 5$. If the calculated t-values exceeded the t-values from Student's table for 8 degrees of freedom ($2n - 2$) at 90% probability, the mean values were concluded to be significantly different.

Measurements were made on days 1, 3, 5, 9, 11, 15, 19 and 22 after preparation of the test solutions. From the t-test, none of the mean values for the test solution appeared to be different from the mean value for the reference solution obtained each day. The values for the test solutions for the first, third and fifth day appeared to be somewhat higher (more than 1S) than those for the reference solution, but the differences were not significant at the 90% level. This effect can probably be explained as due to the sodium borohydride powder adsorbing some moisture from the air when the can was opened, and hence losing some of its reactivity. This effect should be most pronounced in the first few days after opening of the can. After the fifth day the reactivity of the stored solutions very slowly fell below that of the reference solution, but the differences were never significant.

The reactivity of the solution which was stored in the cold was always slightly better than that of the solution stored at ambient temperature, except for the first three days of storage, but the difference was always very small and less than one standard deviation.

F-tests proved that there were never significant differences between the standard deviations of the five aliquots of the test solutions and the reference solution taken for determination in each set.

From this it might be reasonable to conclude that the sodium borohydride solution used for the hydride generation is stable for at least three weeks, probably longer. It seems there should be of no special need to prepare the solution daily. The main reason for this is probably that the loss of reactivity of the borohydride solution is not much larger than the loss of reactivity of the sodium borohydride powder caused by adsorption of moisture each time the can is opened.

If the solution is stored in the cold, it is important to allow the solution to reach ambient temperature before use, especially when peak heights are to be measured, because the peak heights should be dependent on the reactivity of the borohydride, but the peak areas will probably be much less so.

EFFECT OF WASHING ON THE KINETIC STABILITY OF THE COPPER(II)/APCD/IBMK SYSTEM IN STRONGLY ACIDIC MEDIA

TAKEO TAKADA
Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171, Japan

(*Received* 22 *April* 1981. *Revised* 6 *March* 1982. *Accepted* 14 *March* 1982)

Summary—The extraction behaviour of copper(II) with ammonium 1-pyrrolidinecarbodithioate in isobutyl methyl ketone has been investigated at various acidities of the aqueous phase. The chelate is produced even under strongly acidic conditions (0.01–6*M*), and if the organic phase is washed with water it remains stable for at least 1 hr. The extraction is quantitative over the entire range of acidity.

Low concentrations of copper are often determined by solvent extraction of a copper chelate and a number of chromogenic chelating agents have been proposed. One of the most widely used spectrophotometric reagents for copper(II) is sodium diethyldithiocarbamate (DDTC). However, the disadvantages of this reagent are its instability in acidic media and the narrow pH range for extraction.[1,2] On the other hand, ammonium 1-pyrrolidinecarbodithioate (APCD) is more stable, especially at low pH values, and so is often preferred to DDTC when extractions are performed from acidic solutions.[3,4] Although both chelating agents are decomposed at increased hydrogen-ion concentrations, their half-lives in acidic media are very different (30 sec for DDTC at pH 4 and 26 min for APCD at pH 2).[5] Several reports[4–10] have commented on the kinetic stability of metal–PCD chelates in isobutyl methyl ketone (IBMK). Dellien and Persson[10] reported that the stability in the organic phase increases in the order cadmium < lead < nickel < cobalt. They also observed that the decomposition of the complexing agent and the metal chelates is rapid in the two-phase system IBMK/water. The kinetic stability of the PCD extracts is evidently influenced by experimental conditions such as the contact area between the organic and aqueous phases.

The copper dithiocarbamate complexes exhibit good stability under acidic conditions,[4,6,11] but precise comparison of the results reported is difficult, owing to differences in experimental conditions. Although the experiments were performed on acidic solutions, data for very low pH values (below 0) were not reported. We have studied the change in the kinetic stability of the copper(II)–PCD chelate in IBMK with change in the acidity of the aqueous phase. We have also investigated the effect of washing the organic phase, with the object of improving the stability of the extracts.

EXPERIMENTAL

Reagents

All chemicals used were of reagent grade or better. Water was redistilled from an all-glass apparatus. A 0.1*M* stock solution of copper(II) was prepared by dissolving copper sulphate pentahydrate in water. A working solution was prepared daily by appropriate dilution of the stock with water.

A 0.1% APCD solution was prepared by dissolving 100 mg of ammonium 1-pyrrolidinecarbodithioate in 100 ml of water containing 0.1 ml of concentrated ammonia solution. It was filtered and stored in an amber glass bottle. The reagent was stable for at least 10 days. All solvents were used without further purification.

Procedure

Copper solution (5 ml containing 1 μmole of Cu) was transferred to a 100-ml separatory funnel and 10 ml of 0.1% APCD solution were added. The acidity was adjusted with very dilute hydrochloric acid and the aqueous phase was then diluted to 50 ml with water. The solution was mixed and mechanically shaken vigorously for 5 min with 25 ml of IBMK. The organic/aqueous phase volume ratio was kept constant throughout the experiments. In some experiments, after the aqueous phase had been withdrawn the organic phase was washed with 50 ml of water. In other experiments, the organic phase was washed with 50 ml of hydrochloric acid of the same acidity as the aqueous phase. The absorbance of the copper chelate in the IBMK phase was measured at 435 nm in 10-mm silica cells against a reagent blank prepared in the same manner.

To study the concentration of chelating agent needed for quantitative extraction, various amounts of 0.1% APCD solution were added to a solution containing 1.6×10^{-6} mole of copper. When absorbance measurements were made in 1.0*M* hydrochloric acid solution, the absorbances did not change when the mole ratio of reagent to copper was changed from 100:1 to 1000:1. While this means that the amount of chelating agent used is not critical, a variation in the amount of APCD will affect the degree of extraction of the copper chelate, because the decomposition of APCD is rapid at low pH and the degree of decomposition differs for different pH values. Hence at low pH a large excess of chelating agent is needed to allow for decomposition of the reagent. That is why a volume of 10 ml of 0.1% APCD solution was used in all our studies.

The effect of shaking time on the degree of extraction was examined. Although a 30-sec extraction time appeared to suffice for extraction from 1*M* hydrochloric acid it may not apply for other acidities, because the rate at which the metal chelate is formed and extracted decreases as the pH is reduced,[12] which is why a shaking time of 5 min was selected.

RESULTS AND DISCUSSION

The time stability of the extracts was studied for various acidities of the aqueous phase. The IBMK phase was separated rapidly from the aqueous phase without washing, after drying (filter paper) of the inside of the funnel stem, transferred to a glass bottle and stored. The rate of decomposition of the extract was found by taking samples at various time intervals and measuring the absorbance at 435 nm. The timing was started when the acidity was adjusted by addition of hydrochloric acid. It was found that there was an induction period (the length of which depended on the acidity) during which there was little or no decomposition, and this was followed by more or less rapid decomposition. Table 1 gives the time ($t_{\frac{1}{2}}$) taken for the absorbance of the extract to decrease to half the original value, but most of this time is the induction period. At an acidity of more than 7*M* the chelate readily decomposes during the extraction step. However, at less than 0.1*M* acidity the copper chelate is stable in IBMK and is formed quite readily in the acidity range 2–6*M*. The value of $t_{\frac{1}{2}}$ for 0.01 and 0.1*M* acidity was not determined, but the extracts remain stable for at least 4 hr. Surprisingly, most papers do not provide data on the extraction at high acidity; however, the extracts are fairly stable even in strongly acidic media.

§Decomposed during the 1-min shaking period.

Table 2 shows that the kinetic stability of the copper(II) chelate in IBMK depends on the treatment of the extract. At very low pH, if the extract is separated quickly from the aqueous phase and washed with water, there is no measurable decrease in absorbance in 1 hr, and the extraction is unaffected by the acidity (even > 1*M*). The decomposition of the extract is suppressed, because the free acid in the IBMK phase is removed by the wash water. On the other hand, if the IBMK phase is washed with acid of the same acidity as the aqueous phase, the absorbance decreases rapidly with time, showing that the decomposition is accelerated by increased acidity in the IBMK phase. These results suggest that copper(II) reacts practically quantitatively with APCD even in strongly acidic solution, and that the extract decomposes only slowly if the acid is removed from it.

The effect of washing on the efficiency of extraction was also studied for extraction from 4*M* hydrochloric acid. After the 5-min shaking period the IBMK phase was washed with an equal volume of water and the absorbance of the organic phase was measured. The washing was repeated four times, but the absorbance remained constant, showing that no stripping occurred.

Changing the mixing order of the reagents used had no effect on the efficiency of the extraction except when the acid was added to the APCD before the addition of the copper solution (Table 3).

Figure 1 shows the effect of acidity on the extraction. The IBMK phase was washed with 50 ml of water for 5 min and the measurements were then made directly. Extraction was quantitative in the acidity range 0.01–6*M*, but incomplete at acidities above 6*M*. There is thus no need to adjust the acidity of the aqueous phase if it is less than 6*M* hydrochloric acid. Munro[13] reported that the copper concentration in the organic phase increased with increasing sulphuric acid concentration in the aqueous phase before the extraction. Although precise comparison of the results reported[4,7] is difficult owing to differences in experimental conditions, the present results indicate that APCD is a superior chelating agent under

Table 2. Effect of acidity of washing on the time stability of Cu(II)–PCD chelate extracted from 4*M* HCl (Cu 2 × 10^{-5}*M*, temp. 25°)

	Absorbance				
Washing	20 min	40 min	60 min	2 hr	10 hr
50 ml of 4*M* HCl	0.305	0.140	0.050	0.011	0
50 ml of water	0.540	0.538	0.541	0.512	0.475

Table 3. Effect of order of mixing reagents on absorbances; extraction from 4*M* HCl

Order of mixing					
1	2	3	4	5	Absorbance
Water, 15 ml	Copper, 5 ml	APCD, 10 ml	10*M* HCl, 20 ml	IBMK, 25 ml	0.561
Water, 15 ml	Copper, 5 ml	10*M* HCl, 20 ml	APCD, 10 ml	IBMK, 25 ml	0.561
Water, 15 ml	APCD, 10 ml	10*M* HCl, 20 ml	Copper, 5 ml	IBMK, 25 ml	0.541

The separated organic phase was washed with 50 ml of water.

strongly acidic conditions, and that the copper(II)–PCD extract in IBMK has good stability.

In the method described here, if the extractions from strongly acidic solutions are carried out rapidly with an excess of APCD (to compensate for loss by decomposition) and the hydrochloric acid remaining in the separated IBMK phase is removed by washing, then it is possible to extract the complex regardless of the acidity of the aqueous phase, and the extract remains stable for 1 hr. The method is therefore recommended for the extraction of trace copper from strongly acidic media.

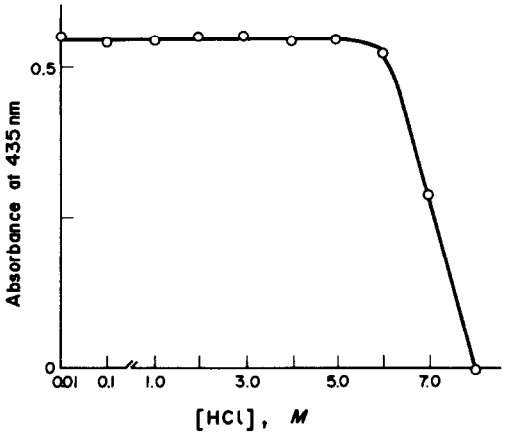

Fig. 1. Effect of acidity on the extraction of Cu(II) with APCD. Aqueous phase, 50 ml; organic phase, 25 ml; Cu(II), $2 \times 10^{-5}M$.

LETTER TO THE EDITOR

SOME ANALYTICAL APPLICATIONS OF CHLORBROMAMINE-B

Sir,

Organic haloamines have received considerable attention as oxidimetric reagents,[1-3] the most recently reported being chlorbromamine-T.[4] The corresponding benzene derivative, chlorbromamine-B (N-chloro-N-bromobenzenesulphonamide, (CBB), also serves as an oxidimetric titrant in acetic acid medium for potentiometric determination of hydrazine, ascorbic acid, hydroquinone, semicarbazide, ferrocyanide, oxine, thallium(I) and antimony(III) and, by back-titration methods, of thiocyanate, thiosemicarbazide, isoniazid and indigo carmine.

The reagent can be prepared by Paterson's method,[5] by dissolving 18 g of benzenesulphonamide in 500 ml of water containing 4 g of sodium hydroxide, cooling to below 5°, adding 8.5 g of bromine dropwise with constant stirring, then when all the bromine has reacted, adding 4 g of sodium hydroxide dissolved in 20 ml of water, cooling to below 5° and passing chlorine through the solution (kept at below 5°), until it is neutral. The lemon yellow precipitate is filtered off, washed with water, dried over phosphorus pentoxide in the absence of light and stored in brown bottles. Yield ~ 100%; m.p. 83°.

CBB is only slightly soluble in water, but fairly soluble in glacial acetic acid (204 g/l. at 30°) and other common organic solvents. Solutions of CBB are light-sensitive and have to be kept in brown bottles. They should be standardized daily as for dichloramine-T.[6] The conditional standard redox potential in glacial acetic acid is +1.31 V at 30°.

Hydrazine sulphate, ascorbic acid, hydroquinone, semicarbazide hydrochloride, ferrocyanide, antimony(III), thiocyanate, thiosemicarbazide, isoniazid, indigo carmine, oxine and thallium(I) can all be titrated potentiometrically [with addition of potassium bromide for titration of semicarbazide, oxine, Sb(III) and Tl(I)], or by a back-titration procedure in which the excess of oxidant is determined iodometrically after 15 min reaction time. Steady potentials are attained almost instantaneously in all the potentiometric titrations. In the back-titration procedure indigo carmine is oxidized to isatin sulphonate. The maximum error was 1% for the potentiometric titrations and 0.8% for the back-titrations.

Assay of ascorbic acid and isoniazid in tablets and injections gave results in good agreement with those obtained by the British Pharmacopoeia[7] and United States Pharmacopoeia[8] methods, the maximum relative difference being about 2% and the average difference 0.6%. Gum acacia, magnesium stearate, citric acid, sodium chloride and reserpin (100 mg) did not interfere

Chlorbromamine-B, like the other organic haloamines, serves as a versatile redox titrant in non-aqueous media.

DERIVATIVE HYDRODYNAMIC-MODULATION VOLTAMMETRY

JOSEPH WANG
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 21 *January* 1982. *Accepted* 20 *May* 1982)

Summary—A technique based on derivative hydrodynamic-modulation voltammetry has been developed for improving the resolution in sensitive analyses of mixtures, at solid electrodes. By simple treatment of the hydrodynamic-modulation data the voltammetric current–potential waves can be transformed into peak-shaped curves, which are frequently more convenient for further data processing. To obtain such curves the rate of change in hydrodynamic-modulation current with potential is plotted against potential. Single and multiple peak systems are evaluated at the micromolar concentration level, by use of stopped-rotation and stopped-flow voltammetry. Dopamine, ascorbic acid, NADH, homovanillic acid and chlorpromazine were used as test compounds. The method is simple and suitable for on-line computerization.

Hydrodynamic-modulation voltammetry (HMV) has been shown to have advantages over other voltammetric techniques for obtaining current–voltage (i–E) data for low concentrations of electroactive species at solid electrodes.[1] For both reversible and irreversible electrode processes HMV produces sigmoidal curves, which give rather poor resolution (*cf.* d.c. and normal pulse polarography). For anodic oxidations at solid electrodes the resolution is even poorer because of the irreversible nature of most of these reactions, *i.e.*, the voltammetric waves are spread out over the potential range; for this reason a separation procedure (usually liquid chromatography) is frequently used before the voltammetric analysis. To improve the resolution of d.c. and normal pulse polarography (at the dropping mercury electrode) it is common practice to plot di/dE against E,[2,3] but this approach has not hitherto been applied to electroanalytical techniques at solid electrodes.

This paper describes the characteristics and applications of this approach, which will be called derivative hydrodynamic-modulation voltammetry (DHMV). It is based on plotting the increments in pulsed convection-current amplitude resulting from increasing the potential in equal steps, as a function of the potential. The resulting DHMV curve has a peak, in contrast to the sigmoidal shape of the conventional hydrodynamic-modulation voltamperogram. This approach is specially suited to HMV, because many of the modulation procedures used (*e.g.*, pulsed rotation[4] or pulsed stirring[5]) are based on pointwise recording of the voltamperogram (*i.e.*, making a 50- or 100-mV change in the applied potential and applying the convection pulse).

A summary of results obtained by such numerical manipulation of raw HMV data is presented in this paper. The DHMV response characteristics of some reversible and irreversible single-peak systems are evaluated, together with applications to batch and flow analyses of mixtures containing various oxidizable species at the micromolar level.

EXPERIMENTAL

Apparatus

The rotating disk electrode assembly, the electrochemical cell and the instrumentation (polarograph, recorder, *etc.*) used in the stopped-rotation (batch) experiments have been described in detail previously.[6] A 0.75-cm glassy carbon disk served as the working electrode.

Pulsed-flow experiments were done with a home-made wall-jet electrode, the details of which have been described elsewhere.[7] A 0.25-cm diameter glassy carbon disk served as the working electrode, with the solution inlet nozzle (0.34-mm diameter) 0.25 mm from the centre of the disk. All potentials are referred to an Ag/AgCl reference electrode. The sample solution was stored in a 250-ml Nalgene beaker, and flowed by gravity to the cell through 0.5-mm bore Teflon tubing.

Reagents

Chemicals and reagents used have been described in detail previously,[6] except as noted. Millimolar stock solutions of dopamine, homovanillic acid and reduced nicotinamide adenine dinucleotide (NADH) were prepared each day.

Procedures

Stopped-rotation experiments. Supporting electrolyte solution (200 ml) was added to the cell and pretreatment of the electrode begun. This consisted of applying potentials of +0.9 and −0.9 V alternately for 8 min, with 1 min wait at each potential. Following this, measurements were made on the blank and analyte solutions by making 25- or 50-mV changes in the applied potential and waiting about 30 sec before applying the rotation pulse. To shorten the overall time of the experiment, only the "off" to "on" part of the pulse was employed, thus eliminating the long decay time that characterizes the "on" to "off" part of the cycle.

Pulsed-flow experiments. After electrode-conditioning (similar to that for the batch analysis described above), current–potential data were obtained by making 50-mV

changes in the applied potential and applying the flow pulse at each potential. The flow was pulsed by raising and lowering the outlet level for the sample solution.

In experiments involving ascorbic acid oxygen was removed from the solution by bubbling nitrogen through it.

Data treatment

The strip-chart current amplitudes were read as described earlier.[6] The current difference Δi, at potential E_1 was subtracted from that at the next potential, E_2. Plots were made of $\Delta i_n - \Delta i_{(n-1)}$ *vs.* E_n.

RESULTS AND DISCUSSION

Single-peak systems

Figure 1 shows DHMV (a) and HMV (b) current–potential curves for the oxidation of 5μM dopamine by stopped-rotation voltammetry. The DHMV curves were obtained by use of potential increments of 25 and 50 mV. Some important characteristics should be noted with respect to Fig. 1. Because the rate of change of current with change in potential is at a maximum at around the half-wave potential, the DHMV peak potential and the HMV half-wave potential are similar, about +0.1 V. The resolution is improved by using the smaller potential increments; the data yield for ΔE = 25 mV a width of about 50 mV at half peak-height, while for ΔE = 50 mV the width is 70 mV. On the other hand, the larger ΔE value gives higher sensitivity and shorter recording time. As ΔE approaches the potential change responsible for the entire HMV wave, no further gain in the sensitivity will be obtained (*i.e.*, the peak current approaches a maximum) but the peak width continually broadens; it seems, therefore, that there should be an optimum ΔE value, which represents the best compromise between resolution, sensitivity and speed, and will differ from one system to another, depending on the reversibility of the reaction and the number of electrons involved (which controls the wave width), as well as on the presence of other species with adjacent redox potentials.

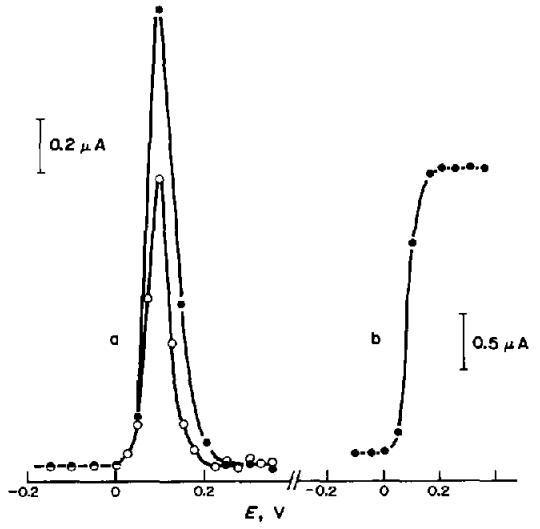

Fig. 1. Derivative (a) and conventional (b) hydrodynamic-modulation voltamperograms for the oxidation of 5μM dopamine in 0.1M phosphate buffer (pH 7.4). Stopped-rotation conditions, rotation on (1600 rpm) for 15 sec. ΔE 25 mV (○) and 50 mV (●).

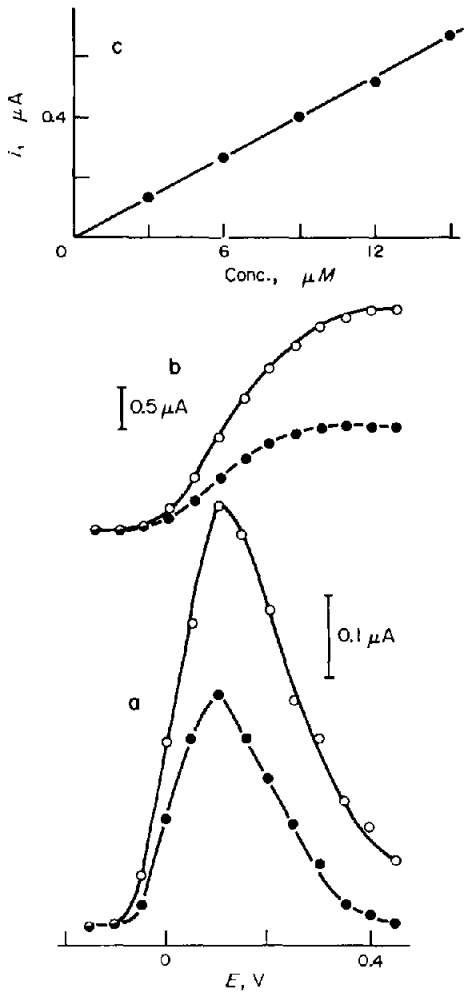

Fig. 2. Characteristic response for ascorbic acid. Derivative (a) and conventional (b) HMV response for 3 and 6μM ascorbic acid. Stopped-rotation conditions, as in Fig. 1; ΔE 50 mV; 0.1M phosphate buffer (pH 7.4).

Figure 2 shows the DHMV and HMV response for ascorbic acid at the micromolar concentration level. As ascorbic acid is oxidized irreversibly at carbon electrodes the hydrodynamic-modulation waves are spread out along the potential axis ($E_{3/4} - E_{1/4}$ about 150 mV), and thus the derivative peaks are wider than those for the reversible oxidation of dopamine (Fig. 1). The width at half peak-height for the two ascorbic acid derivative voltamperograms is about 0.25 V. The DHMV peak potential and the HMV half-wave potential for ascorbic acid are about +0.1 V. The two derivative curves shown in Fig. 2a are from a series of five covering the range 3–15μM ascorbic acid, which gave a linear calibration plot (peak current *vs.* concentration) with a slope of 44 nA.1.μmole^{-1}. The data of Fig. 2 indicate the feasibility of determining

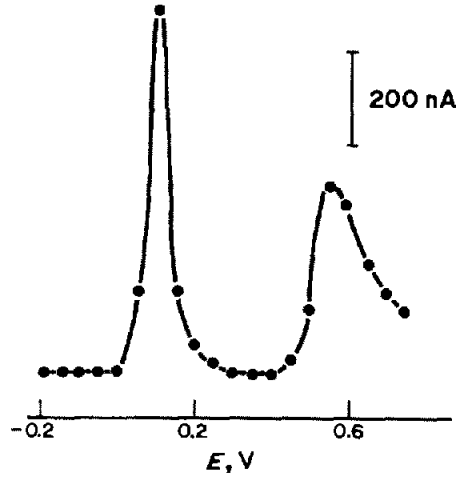

Fig. 3. Simultaneous measurement of 3μM dopamine and chlorpromazine. Conditions as in Fig. 2.

ascorbic acid at the micromolar level by this method, in contrast to differential pulse voltammetry (*e.g.*, ref. 6) which gives poorly-defined peaks for ascorbic acid because of the irreversibility.

Analysis of mixtures

Figure 3 shows a characteristic DHMV response for a mixture of dopamine and chlorpromazine (each at 3μM). The dopamine response is similar to that in Fig. 1. The chlorpromazine peak potential is +0.55 V, with a width of 165 mV at half peak-height, *i.e.*, the oxidation is more irreversible than that of dopamine.

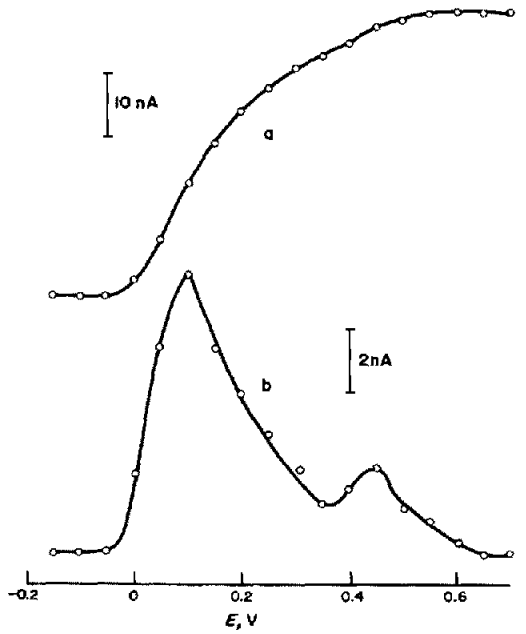

Fig. 4. Consecutive measurement of 2.5μM NADH and 5μM ascorbic acid in a flowing solution. Conventional (a) and derivative (b) pulsed-flow voltamperograms. Pulsed-flow conditions. 1.8 ml/min for 10 sec, 3.0 ml/min for 10 sec; 0.1M phosphate buffer (pH 7.4).

The decreased DHMV sensitivity associated with decreased reversibility is obvious, but nevertheless the 450-mV difference between the peak potentials of the two species provides good resolution (as might be expected since the HMV response gives well-separated waves anyway). It might be expected that 3 or 4 electroactive species could be measured over a 1-V working potential range, depending on the separation of their peak potentials and the nature of their redox reactions (*i.e.*, reversibility and number of electrons).

One of the most important applications of solid electrodes is as sensitive sensors for monitoring flowing streams, usually by constant-potential amperometry, resulting in high sensitivity and poor selectivity (unless a chromatographic separation is used). When the substances present must be identified it is necessary to obtain current–potential data for the flowing solutions. Flow-modulation techniques can provide reproducible voltamperograms for a low concentration of a single analyte at flow-through solid electrodes (*e.g.*, ref. 7). The improved selectivity of DHMV allows it to be applied to the analysis of mixtures of species with relatively close redox potentials, as shown in Fig. 4 for a mixture of 2.5μM NADH and 5μM ascorbic acid. Both species are irreversibly

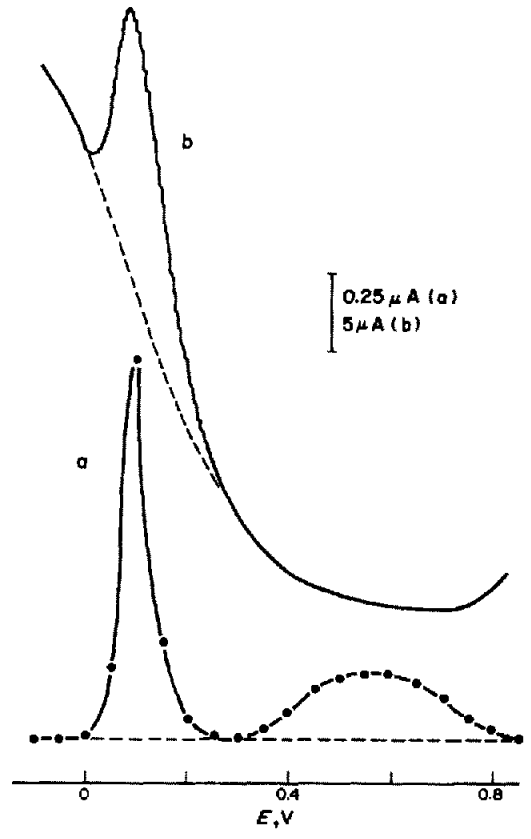

Fig. 5. Comparison of DHMV (a) and differential-pulse voltammetry (b) of 4μM dopamine and 3μM homovanillic acid in 0.1M phosphate buffer (pH 7.4). DHMV conditions as in Fig. 2. Differential-pulse conditions: amplitude 50 mV, scan-rate 5 mV/sec, rotation speed 1600 rpm. Dotted lines represent blanks.

oxidized and therefore give low sensitivity in conventional voltammetry. Because their redox potentials are relatively close the HMV voltamperogram gives strong overlap of the waves, making analysis of this mixture impossible by this method. Differential-pulse voltammetry also fails in this case. The derivative voltamperogram, however, shows two reasonably resolved peaks, about 350 mV apart and even for highly irreversible redox reactions and a peak separation of only 350 mV, DHMV provides useful qualitative and quantitative data at micromolar concentrations.

The advantages of DHMV over differential-pulse voltammetry in analysis of mixtures are clearly demonstrated in Fig. 5 [for batch analysis of a $4\mu M$ dopamine and $3\mu M$ homovanillic acid mixture by stopped-rotation modulation (a) and differential-pulse with continuous rotation (b)]. Both techniques give peaks (with similar peak potentials) for the oxidation of dopamine, but the differential-pulse peak coalesces with a high background current, due mainly to surface-controlled processes against which the technique is not effective. The DHMV dopamine peak does not suffer from this limitation, because the technique compensates for non-convective background currents. Because the oxidation of homovanillic acid is highly irreversible this reaction is not detected by the differential-pulse technique but does result in a broad (but well defined) DMHV peak. Good baseline resolution is obtained for the two DHMV peaks. Recording a differential-pulse voltamperogram takes about 4 min whereas the DHMV procedure (including data manipulation) takes about 25 min. However, at the micro- and submicromolar concentration levels, only DHMV offers the required sensitivity, the detection limits being similar to those for conventional HMV procedures, 10–50nM, depending on the species monitored and method used. The use of scanning potential-modulation procedures incorporated with on-line computerized differentiation would significantly shorten the observation time and make it more suitable for on-line work.

VALIDATION OF THE SULPHUR CONCENTRATION OF SELECTED IRON-BASE NBS STANDARD REFERENCE MATERIALS BY ISOTOPE-DILUTION SPARK-SOURCE MASS-SPECTROMETRY

R. W. BURKE, P. J. PAULSEN, E. J. MAIENTHAL
and G. M. LAMBERT

National Bureau of Standards, National Measurement Laboratory, Center for Analytical Chemistry, Washington, DC 20234, U.S.A.

(*Received* 16 *February* 1982. *Accepted* 12 *May* 1982)

Summary—An isotope-dilution spark-source mass-spectrometric procedure has been developed for the accurate determination of sulphur in iron-base alloys. Dissolution in a sealed tube is used to prevent volatilization losses and to effect isotope equilibration. Application of this technique to the re-analysis of existing NBS Standard Reference Materials yields results that are generally in good agreement with the certified values.

Sulphur is present in iron and steel as a result of impurities in the raw materials and fuels used in their production. Usually it is regarded as a detrimental element because of the potential brittleness that it imparts to the product. In special instances, however, sulphur is not removed and indeed may be intentionally added at controlled levels in order to produce a free-cutting material such as a screw stock. Whatever the kind of iron-base material produced, it is an accepted fact in the industry that its sulphur concentration must be closely controlled to achieve the desired mechanical properties.

The routine laboratory methods that are used to determine sulphur must not only be accurate but also inexpensive and rapid. The automated analytical instrumentation currently in use is capable of meeting these criteria provided an adequate range of accurate sulphur standards is available. Currently, a need exists for iron-base standards with sulphur concentrations at the 50 ppm level and above, but further needs will soon push the lower end of this range to about the 10 ppm level.

At the National Bureau of Standards (NBS), the philosophy for certification of Standard Reference Materials (SRMs) requires either that the analytical methods used are definitive, *i.e.*, free from systematic errors, or that at least two methods are used which are sufficiently different that the likelihood of their having the same kinds of bias is small. Stable isotope dilution mass spectrometry is widely used at the NBS as a definitive technique for trace element determination.[1–3] This paper describes an isotope-dilution spark-source mass-spectrometric procedure (ID–SSMS) that has been developed recently at the NBS for the accurate determination of sulphur in iron-base alloys. It was developed in response to two reports[4,5] which suggested that the certified values for sulphur in several of the currently available iron-base NBS SRMs might be high by as much as 20%. Analysis of these SRMs by this procedure has yielded results in close agreement with the certified values.

EXPERIMENTAL

Reagents

The high-purity nitric, hydrochloric and sulphuric acids used were prepared at the NBS by sub-boiling distillation.[6] Except where noted, all other chemicals were analytical-reagent grade.

Reducing solution. Hypophosphorous acid (60 ml, 50%), concentrated hydriodic acid (125 ml) and concentrated hydrochloric acid (205 ml) were mixed. This reducing mixture is the same as that recommended by Thode *et al.*[7] and subsequently used by Watanabe.[4] The high concentration of sulphur initially present in this mixture was removed by refluxing it for 1.5 hr with nitrogen continuously bubbling through it to sweep out any hydrogen sulphide produced.

Sulphur spike solution. Sulphur enriched to contain 98.5% ^{34}S was obtained from the Oak Ridge National Laboratory, Oak Ridge, Tennessee. It was dissolved by sealing it in a borosilicate tube along with 8 ml of NBS high-purity nitric acid and heating for 8 hr at 180°. The solution was transferred to a modified 200-ml standard flask and diluted with distilled water to obtain a working stock solution with a nominal sulphur concentration of 100 μg/g. The flask was modified by cutting off most of the neck and flaring the top to accept a standard-taper polyethylene stopper. This modification prevented loss of water by evaporation and thus kept the concentration of the spike solution from changing after calibration. The stopper was held firmly in place by covering it with a Teflon disc and clamping this to the neck by crimping an aluminium band round it. When not in use, this flask was kept in a closed box at 100% relative humidity.

Standard sulphur solutions. Two solutions containing known amounts of natural sulphur were prepared for calibration of the enriched ^{34}S spike solution. One was made from a weighed amount of recrystallized potassium sulphate and the other from NBS sub-boiling distilled sulphuric acid that was assayed coulometrically.

Apparatus

Dissolution. The sealed-tube dissolution procedure was similar to the one developed by Wichers *et al.*[8] The tubes used were constructed from borosilicate glass (2 mm wall thickness) and were about 25 cm long. The body of the tube was sealed at one end, had an outside diameter of 1.8 cm, was 15 cm long, and ended in a 10-cm stem having an outside diameter of 0.8 cm. The sample and reagents were added (in that order) and frozen in the tube by means of a slush of solid carbon dioxide and a 1:1 v/v mixture of chloroform and carbon tetrachloride. The tube was sealed (while still in the slush) by rotating it in an oxygen–gas flame until the open end had flowed together. Heating was continued until the internal pressure had blown the end into a smooth rounded shape. The tube was placed in a steel shell and about 50 g of solid carbon dioxide were added to provide a compensating external pressure. A copper gasket was used to make a tight seal between the shell and the screw cap. The tube was then heated in an oven at 180° for 8–16 hr (usually overnight for convenience).

Isolation of sulphur. The glass apparatus used for the separation of sulphur as hydrogen sulphide and its collection as silver sulphide consisted of a 100-ml round-bottomed flask fitted with a 15-cm straight water-cooled condenser, a 25-ml midget impinger, and a 15-ml centrifuge tube. Passing through the centre and sealed in a standard taper cap placed in the top of the condenser was a 6-mm outside diameter glass tube that extended to approximately 3 mm from the bottom of the flask. The end of this tube was drawn down to 1 mm bore to facilitate smooth bubble formation. The midget impinger was connected to a side-arm attached to the cap. All non-ground joints were butted and held together with Tygon tubing.

For initial purification of a large volume of reducing solution, a scaled-up version of this apparatus was used in which a 500-ml flask and a 30-cm condenser were employed.

Measurement of isotopic ratio. The $^{32}S/^{34}S$ ratio was measured with a JEOL model 01BM-2 spark-source mass-spectrometer equipped with electronic detection and an ion-multiplier. This instrument has magnetic switching between mass peaks and the magnetic field is controlled by a Hall-probe gaussmeter. To eliminate dispersion and discrimination of different masses by magnetic fields in the electrostatic and drift regions of the flight path, magnetic shielding was installed inside the vacuum envelope between the ion-source and the entrance to the magnet. A second modification involved splitting the ion-current monitor into upper and lower halves, each having its own vibrating-reed electrometer. This modification permits the monitoring and centring of the ion-beam in the z-axis and is necessary to achieve precise measurements. This centring is dependent on both the positioning of the sample electrodes in the z-axis and their positions relative to one another along the x-axis.

Procedure

The same analytical procedure was used for all samples analysed in this study in which the sealed-tube dissolution technique was employed. Generally, three samples and a blank were processed as a group. The order of addition of the reactants, the techniques used, and the precautions taken are given in some detail below.

Spike addition and sample dissolution. A weighed amount of sulphur spike solution with a ^{34}S content approximately equal to the amount of natural sulphur expected to be present in the sample was transferred to the tube. To do this the polyethylene stopper in the flask of spike solution was replaced by a similar stopper with a hole in its bottom. An 18-gauge platinum needle with a Kel-F hub was inserted through this hole, a 10-ml polyethylene syringe with the rubber tip of its plunger covered with a thin Teflon sheet was attached to the needle and a suitable volume of spike withdrawn. The syringe was disconnected and its end sealed with a Kel-F cap. Any static charge on the syringe was removed by wiping with a damp lintless cloth. The syringe and contents were weighed on a semi-micro balance to ± 0.02 mg. An appropriate volume of spike solution was then carefully delivered from the syringe into a vertically held dissolution tube and the syringe was again capped, wiped and weighed. The spike solution was washed down to the bottom of the tube with 1 ml of distilled water added slowly from a disposable Pasteur pipette while the tube was rotated. The tube was placed in the cooling slush to freeze the contents. A sample weighing between 0.5 and 1 g was added, followed by 8 ml of the purified nitric acid and 2 ml of the hydrochloric acid. Sufficient time was allowed for the nitric acid to freeze before the hydrochloric acid was added (this was done to prevent chemical reactions that could have led to the volatilization of sulphur before the tube was sealed). The tube was then sealed, placed in the steel shell, and heated *etc.*, as described under *Dissolution*, above. After cooling, the tube was cooled in the slush, and a small hole was blown in the tip by using an oxygen–gas torch. The neck of the tube was scored and opened and the contents were transferred to a 100-ml borosilicate glass beaker. A 0.5-ml portion of 0.02*M* sodium carbonate was added to both the sample and blank solutions to provide a counter-cation to prevent loss of sulphur by volatilization as sulphuric acid. The solutions were evaporated to dryness on a hot-plate under a borosilicate glass cover. This cover was 20 cm in diameter, with a 10-cm vertical wall which tapered to a cone of height 5 cm, with a glass tube sealed through its centre. The tube was sealed at its end but had four evenly spaced holes in it just above the end, and high-purity dry nitrogen was dispersed through these holes and down over the solution to hasten evaporation. The cover rested directly on the ceramic hot-plate and the nitrogen escaped through the gaps caused by the irregularity of the surfaces. Any condensate drained to the sides, where it evaporated, thus preventing any fall-back into the beakers. The high temperature and the nitrogen flow swept the vaporized acids efficiently from the system, and condensate occurred only at the start of the evaporation, if at all. This system was adopted for the express purpose of preventing contamination by sulphur compounds in the laboratory atmosphere; before its use the laboratory atmosphere contributed 70–90% of the total blank. After the initial evaporation, the sides of the beaker were washed down with hydrochloric acid (2, 1 and 1 ml volumes in succession, with evaporation to dryness after each addition), to ensure all the nitric acid was removed.

Reduction and separation of sulphur as hydrogen sulphide. First, 25 ml of the reducing mixture were placed in the round-bottomed flask of the reflux apparatus and heated to boiling. The mixture was refluxed for 45 min, with nitrogen bubbling through it at 20–25 ml/min. This second pretreatment of the reducing solution was used to ensure that all residual sulphur was removed and also to clean out the apparatus. After the solution had cooled, the spiked sample, dissolved in 5 ml of hydrochloric acid, was added to the flask and the mixture was again refluxed for 45 min. The hydrogen sulphide generated was passed first through the midget impinger containing 10 ml of distilled water to remove hydrochloric and hydriodic acids, and then into the centrifuge tube, containing 10 ml of 0.1*M* silver nitrate. The silver sulphide precipitate formed was centrifuged and washed three times with 5-ml portions of hot distilled water. Before the last rinse, 100-mesh gold powder (99.999% pure, 50 mg) was added and the mixture was co-dispersed before final centrifugation. The supernatant liquid was removed with a disposable Pasteur-type pipette and the residue was dried at 110° for 30 min. It was then transferred to a stainless-steel vial and the silver sulphide was homogenized with the gold powder by mixing for 3 min with a stainless-steel ball on a "Wig-L-Bug"

mixer. The mixture was then pressed between two flat, polished, tungsten carbide dies under a 2000-kg load. The resulting disc was cut in half with steel cutters, stacked, and re-pressed. Multiple halvings and pressings were used to homogenize the mixture further and to form it into two electrodes each having dimensions of 2 × 5 × 0.2 mm. The electrodes were mounted in the spark-source mass-spectrometer and the system evacuated to a pressure of less than 2×10^{-7} mmHg. A mass scan was made from $m/z = 240$ to $m/z = 10$, with the ion-multiplier electronic detection system. The maximum gain was used in order to survey each sample for any element present above the 0.1-ppm level. The altered isotopic ratio of the sulphur was then measured by use of magnetic peak switching under the control of a Hall probe. The ratio of $^{32}S/^{34}S$ was measured by means of the singly-charged sulphur ions [S^+] at nominal m/z ratio of 32 and 34. Three sets of measurements, each containing 25 ratios, were collected for every sample. Each set of 25 ratios required 25–30 min of measurement time. The ratio data were stored directly in a computer as they were collected and, after each set of measurements, the sulphur concentration was calculated by using the equation:

$$\text{sulphur (ppm)} = \frac{WK}{m} \frac{(A_{sp} - B_{sp}R)}{(BR - A)}$$

where R = measured $^{32}S/^{34}S$ ratio, A_{sp} and B_{sp} = abundances of ^{32}S, ^{34}S in the spike, A and B = abundances of natural ^{32}S and ^{34}S, W = sulphur spike added (μg), m = sample weight (g), and K = ratio of atomic weight of natural sulphur to atomic weight of the spike sulphur.

RESULTS AND DISCUSSION

By use of the sealed-tube dissolution and ID-SSMS procedure, sulphur was determined in a number of NBS iron-base SRMs. The results obtained and the IDMS results reported by Watanabe[4,5] are compared with the NBS certified values in Table 1. With the exception of SRM 365, the agreement of the certified values with those obtained in the present study is significantly better than their agreement with the values reported by Watanabe. In general, his results are considerably lower than the certified values.

In an attempt to explain the discrepancy between the two sets of IDMS results, the pertinent experimental parameters in both procedures were examined for potential systematic bias. In doing so, it was noted that in the dissolution techniques employed by Watanabe, the ^{34}S spike was always added *after* the sample dissolution. Hence, if sulphur were lost during the dissolution step before the addition of and equilibration with the spike, the resulting IDMS values would be low. To check this possibility, SRMs 362 and 364 were analysed by the open-beaker dissolution procedure employed by Watanabe[4] and compared with the sealed-tube dissolution results. These SRMs were selected for this test because the discrepancy between the two sets of IDMS results was largest for these samples. The results of this study, given in Table 2, clearly show that there is a significant loss of sulphur during sample dissolution for these particular low-alloy steels. This loss is almost certainly due to volatilization of sulphur during the dissolution. In addition, the reproducibility of the open-beaker results suggests that it is a particular form of sulphur present in these

alloy steels that is lost. Although no open-beaker tests were done in which the spike was added to these samples before dissolution, the fact that the ^{34}S is added in the relatively non-volatile sulphate form suggests that these results would also have been low.

The sulphur results obtained for two other NBS iron-base SRMs by the sealed-tube ID-SSMS procedure are summarized in Table 3. The agreement between the certified value for sulphur in SRM C1288 and the value found by the proposed procedure is considered acceptable. However, the value found for SRM 342a is significantly lower than the certified value. Since this SRM was certified more than a decade ago, by use of procedures acceptable at the time by industry, this discrepancy is perhaps understandable. Because the present study indicates that the sulphur value certified for SRM 342a is too high, it would be advisable for the procedures used in the initial certification to be examined for possible bias.

Through correspondence, provision of additional samples, and by the use of the sealed-tube dissolution technique, Watanabe has confirmed that his earlier results were low.[10] His latest thermal IDMS results for the NBS SRMs listed in Table 1 are almost identical with the NBS ID-SSMS results. Two reasons have been identified for the initial low values. The principal one was the volatilization of some sulphur from the sample before equilibration with the spike sulphur. A secondary reason, proposed by Watanabe, was that additional losses could have occurred when he rinsed the chip samples before analysis. However, the SRMs issued by NBS are certified for use in the "as received" condition unless explicitly specified to the contrary on the analysis certificate. The cleaning of chip steel samples before analysis has never been recommended.

The key step in the proposed procedure for obtaining accurate sulphur values is the dissolution of the iron samples in a sealed tube. This dissolution technique enables the sulphur in the sample to equilibrate completely with the spike sulphur without possibility of loss of either by volatilization. A critical operation after the dissolution is the complete removal of nitric acid. Even traces of nitric acid will prevent complete reduction of sulphate to sulphide with the acid reducing mixture used. In experiments done to evaluate the sulphur blank, 10 μl of nitric acid proved sufficient to prevent this reduction. Following reduction, the collection of the evolved hydrogen sulphide in silver nitrate solution was preferred to the cadmium acetate solution used by Watanabe[4] because it is more efficient and also eliminates the need for subsequent conversion of cadmium sulphide into silver sulphide.

The reduction procedure used for isolating sulphur from iron samples is relatively specific and is applicable to sulphur levels of a few micrograms. Complete mass scans of the gold–silver sulphide mixtures showed major lines for only sulphur, silver and gold. Apart from a small amount of phosphorus, estimated to be less than 1% of the sulphur recovered, and trace levels of iodine and chlorine, no other elements were detected in significant quantities. The last three elements apparently originate as volatile components of the reducing solution that are not completely removed by the water scrubber.

Although no experiments were performed to measure the efficiency of the recovery of sulphur, the absolute sulphur signal obtained by processing 5 μg of ^{34}S spike indicated a high overall yield. The combination of good recovery for this amount of sulphur and the high sensitivity of the spark-source mass-spectrometer indicated a theoretical detection limit well below 0.1 μg of sulphur. However, as is the case for most common elements at levels below 1 μg, it is the blank that is the limiting factor. The total sulphur blank for all steps in the present procedure averaged 0.5 ± 0.1 μg. About 0.2 μg originated from the gold powder used.

The sealed-tube dissolution ID-SSMS procedure described in this paper is illustrative of the analytical techniques required to meet the growing need for more accurately characterized standards. The availability of steel standards with accurately determined sulphur content is especially important since almost all sulphur determinations in industry today are performed with automated analysers. These analysers clearly have the desired speed, precision, and sensitivity to meet existing needs. Their accuracy, however, is highly dependent on the quality and variety of standards available for calibration. The application of this technique for the accurate measurement of the sulphur concentration of NBS SRMs 361, 362, 363, 364 and 365 is especially important since this series of standards should be extremely useful for calibrating automated sulphur analysers to be used for accurate determination of the sulphur content of low-alloy and carbon steels. Similarly, the technique should be equally valuable in validating the sulphur concentration of SRMs 1261, 1262, 1263, 1264 and 1265, which are currently used for calibrating optical emission spectrometers.

METAL COMPLEXES OF CYCLIC TETRA-AZATETRA-ACETIC ACIDS

RITA DELGADO and J. J. R. FRAÚSTO DA SILVA
Centro de Química Estrutural, Instituto Superior Técnico, Lisbon, Portugal

(*Received* 5 *February*, 1982. *Accepted* 11 *May* 1982)

Summary—The cyclic tetra-aza complexones cDOTA ([12]ane N_4·4ac), cTRITA ([13]ane N_4·4ac) and cTETA ([14]ane N_4·4ac) have been synthesized and characterized by elemental analysis, titration, melting-point determination and NMR (and infrared) spectroscopy. The ionization constants and the stability constants of the MH_2L, MHL and ML complexes formed with alkali, alkaline-earth and some transition metals were determined at 25.0 ± 0.1° and ionic strength 0.10*M* [KNO_3 and $(CH_3)_4NNO_3$]. It was confirmed that cDOTA forms the most stable Ca^{2+} and Sr^{2+} complexes but the reported inversion of the order of stability of the complexes of these two ions with cTRITA was not confirmed. Also, the values of the stability constants determined in this work differ substantially from those previously reported for ML species. cDOTA is an interesting alternative to classical non-cyclic complexones for the complexometric determination of Ca^{2+} and Mg^{2+} but neither this ligand nor the other two offer advantages over EDTA or DCTA for the complexometric titration of transition metals.

Cyclic polyoxa and polyaza ligands which form stable complexes with a variety of metal ions are of current interest either because of their usefulness in new processes of organic synthesis or as models for the study of certain biological reactions or systems.

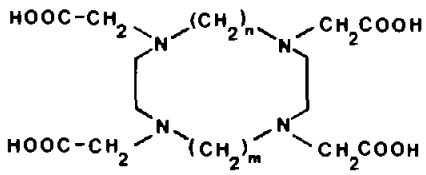
The effects of cavity size and of conformation on the spectroscopic and magnetic properties of the metal complexes, on the kinetics of complex formation and on the thermodynamic stability of the species formed have also been studied by many inorganic chemists but, so far, few analytical chemists have been concerned with such ligands as possible reagents for complexometric titrations.

Indeed, the macrocycles that have been studied are not suitable for this purpose, but derivatives of them might be of interest. For example, the polyaminocarboxylic acids derived from cyclic polyaza ligands should be relatively soluble in water, and should form quite stable complexes with metal ions.

Very few such derivatives have been reported in the literature; references have been found to a dipropionic acid derivative of a diazatetraoxa macrocycle,[1] to the tetra-acetic acid derivatives of three tetra-aza macrocycles[2] and to the tetra-acetic acid derivative of a dimethyltetra-aza macrocycle.[3]

In the first two cases, the authors were indeed concerned with the determination of stability constants of alkaline-earth and transition metal complexes; the third case, however, is a preparative and spectroscopic study of the cobalt, nickel, copper and zinc species formed with the particular ligand chosen.

The dipropionic acid derivative mentioned above[1] forms only very weak complexes and is not of special analytical interest; in contrast, the tetra-acetic acid derivatives of tetra-aza macrocycles synthesized by Stetter and Frank[2] form very stable complexes and one of them (**a**) was reported to form the most stable Ca^{2+} complex in aqueous solution known to date. For a second ligand of this group (**b**) the stability constant of the strontium complex was reported[2] to be higher than that of the calcium complex by a factor of almost 10^4, which would be a quite exceptional result for classical non-cyclic complexones, but possible, at least in principle, for derivatives of macrocycles with the correct cavity size. Stetter and Frank reported later[2a] that they were unable to confirm their unusual initial results. On the other hand, the stability constants of the complexes formed with the transition-metal ions are high but not exceptional.



a $m = 2$, $n = 2$:
1,4,7,10-tetra-azacyclododecane-*N*,*N*′,*N*″,*N*‴-tetra-acetic acid ([12]ane N_4·4ac) or cDOTA

b $m = 2$, $n = 3$:
1,4,7,10-tetra-azacyclotridecane-*N*,*N*′,*N*″,*N*‴-tetra-acetic acid ([13]ane N_4·4ac) or cTRITA

c $m = 3$, $n = 3$:
1,4,8,11-tetra-azacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetra-acetic acid ([14]ane N_4·4ac) or cTETA

These reports led us to undertake the synthesis of the ligands to allow more detailed study of the species formed in aqueous solution, the thermodynamic data for the reactions with metal ions and their suitability as reagents for complexometric titration. In the present paper we report the synthesis and analysis of the ligands, and give values for the stability constants of the MH_2L, MHL and ML species formed with various metal ions. Our values differ, sometimes quite considerably, from those reported by Stetter and Frank;[2] in particular, no inversion of the normal

order of stability of the calcium and strontium complexes of **b** was found.

The trend for the three cyclic complexones is the same as for the non-cyclic classical ones.

EXPERIMENTAL

Synthesis and characterization of the ligands

The cyclic tetra-azatetra-acetic acids were prepared by reaction of the corresponding cyclic amines with chloroacetic acid in aqueous alkaline solution. The cyclic tetramines [12]ane N_4 and [13]ane N_4 were synthesized as described in the literature;[4,5] [14]ane N_4 was obtained from a commercial source (Strem Chemicals). The method of preparation of the cyclic tetramines involved the condensation of a linear tosylated amine with a tosylated diol at 100–120°, in dry dimethylformamide as solvent. Tosylation of the amines and of the diols was done as described in the literature,[6,7] but the yield from the diols, particularly from 1,3-propanediol, was rather low (40–60%).

Hydrolysis of the tosyl groups in the cyclic tetramines was better achieved by refluxing with a mixture of glacial acetic acid with 48% hydrobromic acid (9:16 v/v) for 48–60 hr.

The condensation of the amines with chloroacetic acid offered no difficulties but the pH had to be kept below 10 and the temperature between 40 and 60°. The reaction mixtures were acidified to pH 2 with hydrochloric acid, and the products (cDOTA and cTETA) crystallized as small bright colourless needles on standing overnight in the refrigerator; the crystallization of cTRITA required the previous separation of the potassium chloride present.

All products were recrystallized from water. Both cDOTA and cTRITA crystallized with two moles of potassium chloride per mole of product and recrystallization did not change their composition. cTETA was obtained free from potassium chloride.

All intermediate and final products were characterized by elemental analysis, melting points, infrared and/or NMR spectra, and by the titration curves in the case of the tetra-acetic acids.

cDOTA (with 2 KCl): m.p. 298° (dec.); m.w. (titration) 553.5. Found: C 34.7%, H 5.4%, N 10.3%; required: C 34.70%, H 5.06%, N 10.12%. Proton NMR spectrum (solvent D_2O, reference DTSS, pD = 4.50), Fig. 1(*a*): δ 3.683 (8 H, acetate groups), δ 3.281 (16 αCH_2 ring protons).

cTRITA (with 2KCl): m.p. 242° (dec.); m.w. (titration) 567.6. Found: C 36.1%, H 5.6%, N 9.9%; required: C 35.97%, H 5.33%, N 9.87%. Proton NMR spectrum (solvent D_2O, reference DTSS, pD = 3.05), Fig. 1(*b*): δ 3.71, 3.67 (2 singlets, 8 H, acetate groups), δ 3.33 (multiplet, 16 αCH_2 ring protons), δ 2.05 (quintuplet, 2 βCH_2 ring protons).

cTETA: m.p. 313° (dec.); m.w. (titration) 432.5. Found C 49.7%, H 7.3%, N 12.9%; required C 50.00%, H 7.40%, N 13.00%. Proton NMR spectrum (solvent D_2O, reference DTSS, pD = 3.40), Fig. 1(*c*): δ 3.475 (8 H, acetate groups a), δ 3.210 (singlet, 8 αCH_2 ring protons b), δ 3.142 (triplet, 8 αCH_2 ring protons c), δ 1.924 (quintuplet, 4 βCH_2 ring protons d).

Reagents

Metal salts. Metal nitrates of analytical reagent grade were used and solutions were prepared in demineralized water and standardized by EDTA titration or gravimetry (Be).

The ionic strength was adjusted with solutions of potassium or tetramethylammonium nitrate (prepared from tetramethylammonium hydroxide and nitric acid and recrystallized twice from 80% ethanol).

Carbonate-free potassium and tetramethylammonium hydroxides. Carbonate-free solutions of these titrants were prepared according to Schwarzenbach and Biederman,[8] under purified nitrogen. The solutions (*ca.* 0.050*M*) were standardized by titration with 0.01*M* hydrochloric acid. Carbonate was tested for regularly[9] and the solutions were discarded when the concentration reached 0.5% of the hydroxide concentration.

Potentiometric titrations

The experimental set-up has been described previously;[10] a Radiometer pHM 4 measuring instrument was used together with a Radiometer G 202 B glass electrode and a K 401 saturated calomel reference. The temperature was controlled at 25.0 ± 0.1° by circulating water through the jacketed titration cell. The ionic strength was kept to 0.10*M* by use of potassium nitrate or tetramethylammonium nitrate as background salts; the ionic product of water in these media was taken as 1.68×10^{-14}.[10]

The glass electrode was calibrated in terms of $[H^+]$ by titrating solutions of hydrochloric acid and potassium hydroxide of known concentrations and correlating the mV readings with calculated values of $[H^+]$. The $[H^+]$-dependent junction potentials were found to be negligible (from Gran plots[9]) and the correlation between measured e.m.f. and calculated $[H^+]$ was strictly represented by $E = E^{0\prime} + Q \log [H^+]$ for both the acid and alkaline zones, with slightly different values of $E^{0\prime}$. In each zone the relevant value of $E^{0\prime}$ was used; in intermediate pH ranges (4.5–8.5) an average $E^{0\prime}$ value was adopted. With this procedure experimental and calculated titration curves were completely superimposable.

To obtain the titration curves of the complexones, 50.0 ml of approximately $10^{-3}M$ solutions of the ligands, 5.0 ml of demineralized water and 5.0 ml of 1.200M potassium nitrate or tetramethylammonium nitrate were titrated with 0.050M carbonate-free potassium hydroxide or tetramethylammonium hydroxide. To obtain the titration curves of the complexones in the presence of metal ions, 5.0 ml of 1.00×10^{-2} or $2.00 \times 10^{-2}M$ solutions of the metal salts were added instead of the demineralized water.

Other measurements

NMR spectra were recorded with a 100-MHz Jeol JNM 100 PTF spectrometer coupled to a Jeol 980 A computer. When deuterated chloroform or acetone was used as solvent, tetramethylsilane (TMS) was the reference compound; when deuterium oxide was the solvent, the reference compound was the sodium salt of 2,2,3,3-tetradeutero-3-(trimethylsilyl)propionic acid (DTSS).

Melting points were determined with a Reichert-Thermovar instrument provided with a microscope, and are uncorrected.

Elemental analyses were done with a Perkin-Elmer 240 Elemental Analyzer.

Calculation of the stability constants

The stability constants of the various species formed were obtained from the experimental data with the aid of the program MINIQUAD[11,12] and an IBM 360 computer. The program uses a non-linear least-squares method to optimize data and requires previous knowledge of approximate values for the constants.

Suitable approximate values for the constants were obtained by use of simpler programs based on methods of calculation previously described in other publications from our laboratory.[10] The values were improved by comparison of the experimental titration curves of the complexones in the presence of the various metal ions with calculated titration curves for values of stability constants close to the estimated values, until a satisfactory superimposition of the curves was achieved. This was done on a 2200WANG computer coupled to a 2212 plotter. The β values for the best superimposition were then refined by MINIQUAD. In the present work, the values selected were those for which the calculated relative standard deviation was less than 10%, the "fitting index" R was less than 0.003 and the confidence level was higher than 95% for 6 degrees of freedom, following the procedure of other authors.[13,14]

The standard deviations quoted refer to calculation from data obtained in one experiment; however, the logarithmic values obtained from a series of titrations performed on different occasions were differed by not more than ± 0.05 from those presented, even in the most unfavourable cases.

RESULTS AND DISCUSSION

Titration curves for the three complexones studied, alone and in the presence of several metal ions, are shown in Figs 2, 3 and 4.

As can be seen, all the ligands are tetrabasic, with two pKs of the order of 3–4 and two of the order of 10–11. The values refined by MINIQUAD are presented in Table 1 together with those determined by Stetter and Frank[2] at 20.0° and $\mu = 0.1$ (potassium chloride) and by Desreux *et al.*[15] at 25.0° and $\mu = 1.0$ (sodium chloride). Our values were determined at $25.0 \pm 0.1°$ and $\mu = 0.10$ (tetramethylammonium nitrate or potassium nitrate); both sets of results are presented to allow comparisons.

Agreement between the several sets of values is fair, taking into account the different experimental conditions in which they were determined. The major differences are found in the values of pK_4 for cDOTA and cTETA and of pK_3 for cTETA.

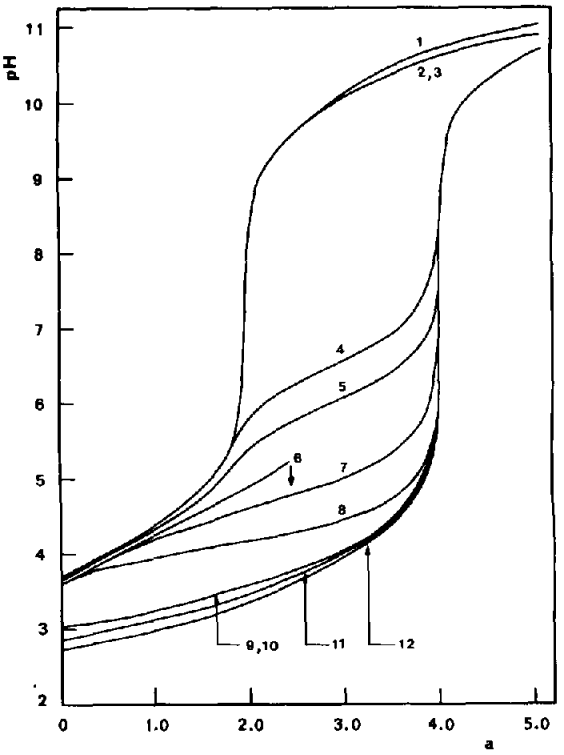

Fig. 2. Titration curves for cDOTA alone and in the presence of metal ions in 1:1 ratio. $T = 25.0 \pm 0.1°C$. $\mu = 0.1M$ [$(CH_3)_4NNO_3$]. 1—cDOTA alone, $10^{-3}M$, and with 2,3—Na^+ or Li^+; 4—Mg^{2+}; 5—Ba^{2+}; 6—Be^{2+}; 7—Sr^{2+}; 8—Ca^{2+}; 9, 10—Co^{2+} or Ni^{2+}; 11—Zn^{2+}; 12—Cu^{2+}.

The discrepancy in the case of cDOTA may be explained by the fact that we used non-complexing tetramethylammonium nitrate medium and Desreux *et al.* used 1M sodium chloride. Although they made a correction for the formation of a sodium complex this may have been insufficient. In our determinations we obtained a value for the stability constant of this sodium complex that was higher than their guessed value, and if our value is adopted, the constants of Desreux *et al.* come close to ours. The values are already close for 0.1M potassium nitrate medium (but potassium also forms a complex with cDOTA).

The discrepancy in the case of cTETA may also be explained in the same way, but now the correction made by Desreux *et al.* may be too high. We found for the sodium complex of this ligand log $K = 0.4 \pm 0.1$ (with a 100:1 molar ratio of sodium to ligand) and if this value is used instead of log $K = 1.64$, again closer agreement between their value and ours is obtained.

It seems, from the available data, that the first two protons ionize from two *trans* acetic acid moieties and the last two from protonated *trans* nitrogen atoms, but hydrogen-bonding to pairs of nitrogen atoms is not excluded.[15,16]

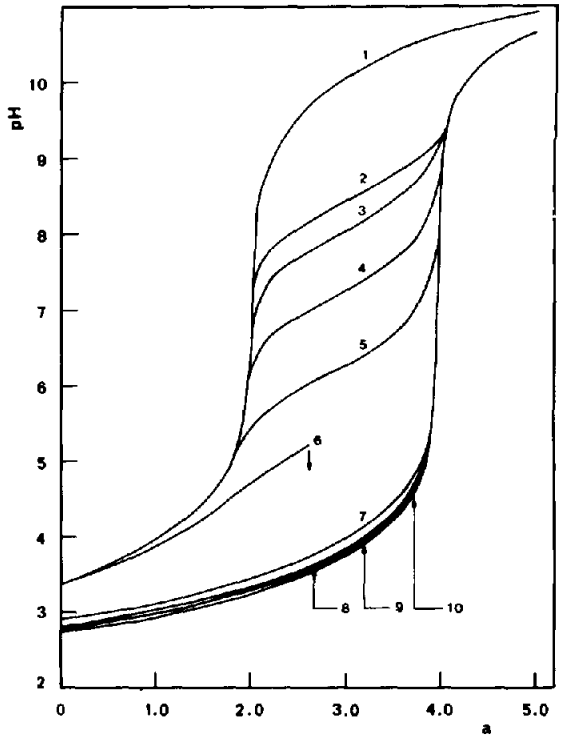

Fig. 3. Titration curves for cTRITA alone and in the presence of metal ions in 1:1 ratio. $T = 25.0 \pm 0.1$°C. $\mu = 0.1M$ (KNO_3). 1—cTRITA alone, $10^{-3}M$, and with 2—Mg^{2+}; 3—Ba^{2+}; 4—Sr^{2+}; 5—Ca^{2+}; 6 Be^{2+}; 7—Zn^{2+}; 8—Co^{2+}; 9—Ni^{2+}; 10—Cu^{2+}.

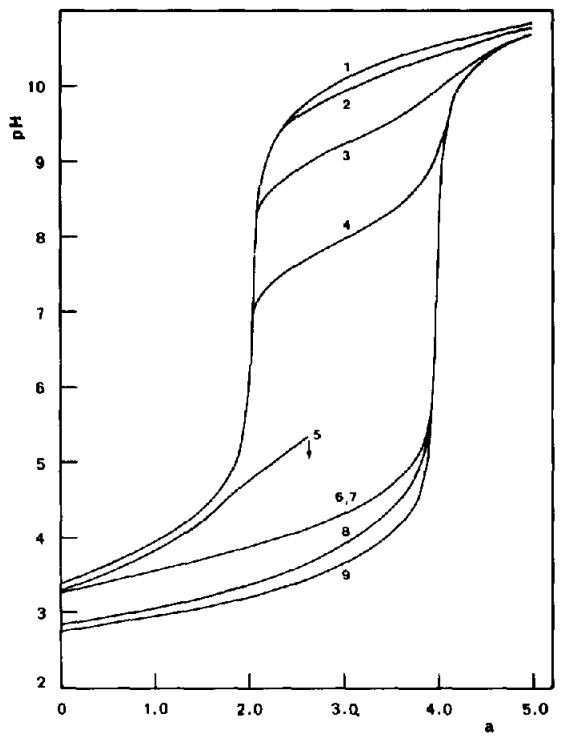

Fig. 4. Titration curves for cTETA alone and in the presence of metal ions in 1:1 ratio. $T = 25.0 \pm 0.1$ C. $\mu = 0.1M$ (KNO_3). 1—cTETA alone, $10^{-3}M$, and with 2—Ba^{2+}; 3—Sr^{2+}; 4—Ca^{2+}; 5—Be^{2+}; 6,7—Co^{2+} or Zn^{2+}; 8—Ni^{2+}; 9—Cu^{2+}.

Regarding the formation of the metal complexes, two observations immediately arise from Figs 2–4. First, the stabilities of the complexes of the alkaline-earth metals decrease as the size of the cavity of the ligands increases. Secondly, there is no inversion of the order of stability of the calcium and strontium complexes of cTRITA, contrary to the original report by Stetter and Frank,[2] and log K_{CaL} > log K_{SrL} for

these cyclic complexones, as with the classical non-cyclic ones, and as later found by Stetter and Frank.[2a]

For the transition metals the situation is not so clearly defined; from the titration curves the only conclusion which can be reached is that the cobalt and zinc complexes of cTETA are markedly less stable than those of nickel and copper, in contrast with what happens with the other two ligands.

Values for the stability constants of the various species identified in 1:1 mixtures of the metal ions and of the ligands* are given in Table 2, along with the corresponding values for some ML species.[2,15] These values confirm the qualitative observations made above but differ quite considerably from those reported by Stetter and Frank,[2] which are generally lower than ours by a factor of 10^2–10^3.

Since these authors did not consider MH_2L and MHL species, their values might be expected to be higher rather than lower, so we see no obvious reason for the difference. It should, however, be stressed that our values were found to be reproducible from titration to titration, and to vary little with differences in the nature of the ionic medium. To obtain such reproducibility required great care, particularly with the transition metals which gave rather slow reaction. Usually, the mixtures of metal and ligand were left to equilibrate for 2 hr before the titration, and in the case of Ni^{2+} and cDOTA it took 24 hr to reach stable pH values. After each addition of titrant, the reading was not taken until the pH was stable, and this took 1–3 min, sometimes more, particularly in the case of nickel and cobalt complexes. With cTRITA, the reactions were generally faster.

For the alkali-metal complexes of cDOTA and for the alkaline-earth metal complexes of all ligands the stability follows the order of the ionic potential, except for magnesium and beryllium, which behave "abnormally", as usual, because of their small radii.

Beryllium forms quite stable complexes with the three complexones and, at first sight, this seems of interest for the development of complexometric methods for this metal, but the side-reaction of beryllium with hydroxide prevents this (see below).

For the transition metals, the Irving–Williams order of stability is observed; it is interesting to note, however, that the difference in stability between the complexes of the same metals with cDOTA, cTRITA and even cTETA (in the cases of nickel and copper) is rather small, unlike the behaviour with the alkaline-earth metals and also with the complexes of the transition metals with the parent cyclic amines (judging from the few values available for copper[17]) and with the corresponding non-cyclic amines.

This seems to imply that for the alkaline-earth metals the size of the internal cavity of the ligand and its conformation are critical and that all nitrogen atoms may be involved in bonding to the metal, as postulated for the complexes of rare-earths with cDOTA.[18]

In contrast, the transition metals do not seem to coordinate to all the nitrogen atoms of the ligands. This conclusion was also reached by Häflinger and Kaden on the basis of a spectral study of the complexes formed by cobalt, nickel, copper and zinc with meso-5,12-dimethyl-1,4,8,11-tetra-azacyclotetradecane-*N*,*N*',*N*'',*N*'''-tetra-acetic acid, which is similar to cTETA. A comparison with the values of stability constants for the complexes of a few classical non-

*2:1 ratios were also used but the partial formation constants of the 2:1 complexes were too low to be calculated with precision in these conditions; however, in the case of Ni^{2+}–cTETA we obtained log $\beta_{M_2L} = 23.01 \pm 0.05$.

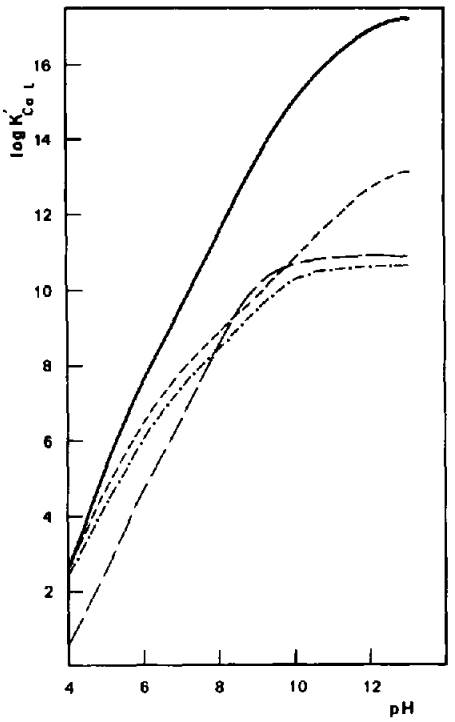

Fig. 5. Variation of the conditional stability constants (log K'_{CaL}) of the calcium complexes of cDOTA (——), *trans*-DCTA (---), EGTA (--) and EDTA (—·—) with pH.

cyclic complexones (Table 3) provides some support for this hypothesis.

Although these complexones are not directly comparable with those studied in the present work a few conclusions can be extracted from the values presented in this table.

1. Co-ordination by one strongly basic nitrogen atom (pK ~ 10), one nitrogen atom of intermediate basicity (pK ~ 6) and two carboxylate groups, as in ethylenediaminediacetic acid (EDDA), gives complexes with stability constants lower than those determined for the corresponding cDOTA complexes by a factor of about 10^6–10^{10}, but that are not too different from those determined for the cDOTA MHL complexes.

2. Co-ordination by a ligand such as EDTA, *i.e.*, EDDA plus two carboxylate groups, gives transition-metal complexes with stability constants lower by a factor of up to 10^4 than those determined for the cyclic complexones.

3. When the basicity of one of the nitrogen atoms is increased as in DCTA (pK_4 ~ 12.3), the complexes of the transition metals compare in stability with those of the cyclic complexones but the complexes of the alkaline-earth metals have stability constants that are 4–6 orders of magnitude below the values found for those of the strongest cyclic complexone, cDOTA.

Hence, it seems that for the transition metals the MHL complexes of the cyclic complexones may be like those of EDDA *i.e.*, co-ordinated to two nitrogen atoms and to two carboxylate groups. Their ML complexes require more ligand atoms to be co-ordinated and it is tempting to suggest that the two remaining carboxylate groups may be involved. In any case it is unlikely that the four nitrogen atoms can participate since then much higher stability constants would result (the log K values for the copper complexes of the cyclic amines are[17] about 25–29). The fact that the less stable complexes of the cyclic complexones form in preference to the more stable ones involving the four nitrogen atoms, as in the parent amines, may be the result of the combination of various factors (conformational, thermodynamic and kinetic) but at the present stage of our work it is not possible to advance a concrete soundly based explanation.

Our final comments refer to the possible use of the cyclic complexones, particularly cDOTA, as reagents for complexometric titrations. In Figs. 5 and 6 the logarithms of the conditional constants of the calcium and magnesium complexes of cDOTA, EDTA, EGTA and DCTA are plotted *vs.* pH. These show that cDOTA is indeed the most powerful ligand for both metal ions and that the selectivity ratio log K'_{CaL}/log K'_{MgL} is as good for cDOTA as for EGTA, at pH > 10 (and is better still for cTETA). These ligands could then be interesting alternatives for titrations of these ions.

For beryllium, the conditional constants of the complexes are too low (log K'_{BeL} < 3) even at the most favourable pH values, so none of the new ligands is suitable for beryllium determination.

For the transition metals, the cyclic complexones have no advantages over the classical non-cyclic ones such as EDTA or DCTA.

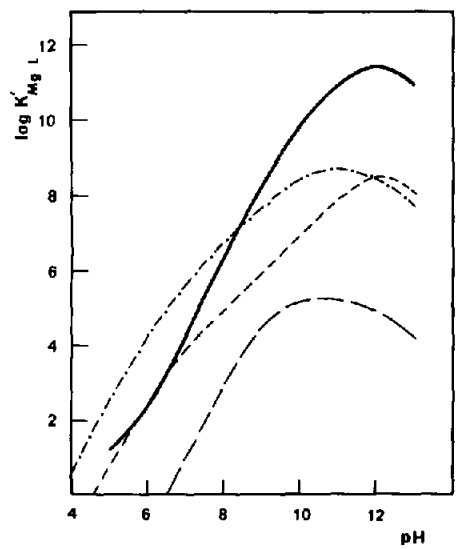

Fig. 6. Variation of the conditional stability constants (log K'_{MgL}) of the magnesium complexes of cDOTA (——), *trans*-DCTA (---), EGTA (--) and EDTA (—·—) with pH.

SELENIUM IN ENVIRONMENTAL WATERS: DETERMINATION, SPECIATION AND CONCENTRATION LEVELS

H. ROBBERECHT and R. VAN GRIEKEN
Department of Chemistry, University of Antwerp (U.I.A.), Universiteitsplein 1, B-2610 Wilrijk, Belgium

(*Received* 14 *January* 1982. *Accepted* 8 *May* 1982)

Summary—This article reviews the different methods used for the determination of selenium species in all types of environmental waters. Basic difficulties are discussed and the efficiency of the methods is explained in view of the sub-μg/l. concentration levels. Special attention is paid to preconcentration steps. Published data on speciation and concentration levels in various water samples are critically reviewed.

As the toxicological and physiological importance of selenium has become more and more evident[1–12] during the past twenty years, there has been an increasing interest in this essential element.

Deficiency of selenium results in selenium-responsive diseases in various animal species. Selenium also prevents several types of chemically induced cancer in animals.[4,5] Although its role in human health is still not fully understood and remains controversial, Shamberger[6–9] has pointed out that human cancer death rates are lower in countries where more selenium occurs in the environment and that human mortality from heart disease is also lower in the high-selenium areas. Since the initial observations that selenite prevents the injurious effects of cadmium on the testes[10] and of mercury(II) on the kidney and intestine,[11] there has been much work and speculation on the mechanisms of these antagonistic interactions, as summarized by Magos and Webb.[12]

As the difference between the essential and the toxic concentration level is rather narrow, precise knowledge of the selenium content in the environment and food products is mandatory. Hofsommer and Bielig[13] give a summary of methods for the determination of selenium in foodstuffs, the source that contributes most to the intake of selenium. Drinking water contributes only 1–6% to selenium uptake, according to Commins,[14] for typical concentrations and a water consumption of 3 l./day. Underwood,[15] however, calculated that the human intake of selenium ranges from 22 to 220 μg/day, with a mean value of 60 μg/day, in which case a daily intake of 2 litres of drinking water containing the EPA upper limit of selenium (10 μg/l.) would be responsible for a significant fraction of the total intake. Valentine *et al.*[16] screened a population in New Mexico, exposed to selenium from well waters having a selenium content ranging from 10 to as much as 3900 μg/l. Presumably these waters were contaminated by a uranium-mill tailing pond nearby. These various data stress the importance of determining selenium concentrations in all kinds of environmental waters, since these are frequently used as a source for drinking water.

All the publications discussed deal with aqueous solutions, although not all specifically refer to environmental waters. The different procedures for selenium determination in environmental water samples are critically reviewed below, with special attention to determination at the sub-μg/l. level.

Since there is much confusion about the definition of the terms "detection limit" and "sensitivity", users of the data should always check the definition applied. The preconcentration steps, mostly involving co-precipitation or complexation, are examined for interferences and basic difficulties. Since selenium is present at such a very low level, sampling and storing need special care.

Knowledge of the chemical speciation of trace metals in natural waters is essential to an understanding of the toxicity and bio-availability of these elements, so special attention is also paid to the content of the different forms of selenium in water samples. Selenium concentrations in the different types of water in various countries are compiled at the end of this article.

SAMPLING AND STORAGE

Progress in handling natural waters and analysing them for ultratrace amounts of metals has mainly been achieved by laboratory work under relatively favourable conditions. Unfortunately, samples from the sea or rivers often become heavily contaminated during sampling; this is a crucial step, the importance of which has not yet been fully realized by all investigators. Consequently many published data, some of them varying by several orders of magnitude, are associated with gross and mainly positive errors. Mart[17,18] has discussed some general and specific

contamination factors affecting the accuracy of heavy-metal analysis at the trace level, with particular reference to the determination of zinc, cadmium, lead, bismuth and copper. The pretreatment and cleaning procedures for sampling bottles and other laboratory ware, the sampling method, the filtration of the samples and their long-term storage can be adapted and taken into account in the determination of other trace elements, such as selenium. Numerous reports concerning adsorption effects in bottles have been published[19–28] but most of them result from experiments with trace elements in doubly distilled water. In analysis for selenium, not only adsorption losses but also volatility risks have to be taken into account. Shendrikar and West[29] investigated rates of selenium losses from aqueous solutions stored at different acidities (pH 7, pH 3.8 and in 0.5% v/v nitric acid) in various materials. The losses by adsorption from a 1-mg/l. selenium solution in Pyrex beakers in 15 days were 4, 1.5 and 1%, respectively. In flint-glass beakers, losses of about 5, 2.5 and 1.5%, respectively, occurred. Losses in polyethylene beakers were not greater than 8, 3 and 2%, respectively. These observations are useful but inadequate with respect to the preservation of environmental samples, for the following reasons.

(*a*) The selenium concentration of 1 mg/l. used was much higher than that found in most environmental samples, where concentrations lie at the μg/l. level.

(*b*) Only one type of water (probably distilled water) was used, whereas both pure synthetic solutions and contaminated natural waters should preferably be tested.

(*c*) The selenium oxidation was presumably Se(IV) and both Se(VI) and Se(IV) should be investigated, because both can be important in the natural environment.

(*d*) A test period of 15 days is inadequate for a major control study, which can require no less than three months from the time of preparation of samples to confirmatory analyses, packaging, shipping and final analyses by participating laboratories.

Cheam and Agemian[30] studied the stability of inorganic Se(IV) and Se(VI) species at levels of 1 and 10 μg/l. under various conditions of pH, type of water and type of container. Use of polyethylene containers and adjustment to pH 1.5 will provide optimum conditions of preservation for both distilled and natural water samples up to 125 days. Algal growth is detrimental to solution stability at natural pH values of pH 5.4–7.2, but adjustment to pH 1.5 with sulphuric acid successfully prevents this effect. Container size and temperature are also discussed. Storage of samples at 4° gives satisfactory stability but is less practicable. However, sulphuric acid interferes with some analytical methods, and if natural waters are to be tested it may be preferable to use unacidified natural water stored in polyethylene bottles at 4°. It was noted that Se(VI) is generally more stable than Se(IV) in aqueous solutions. An interlaboratory quality control study[31] used the preferred conditions of acidification of 0.02% v/v sulphuric acid and storage at room temperature in polyethylene bottles. Excellent recoveries over the selenium concentration range 0–1000 μg/l. confirmed the effectiveness of the proposed preservation method. Cutter[32] stated that acidification can be used for the preservation of water samples, but that it should not be excessive because the speciation can be changed. A sample spiked with Se(VI) and stored in 4*M* hydrochloric acid for 7 days showed 60% conversion into Se(IV). Sample storage in 1*M* hydrochloric acid preserves the Se(VI) as well as the Se(IV). Freezing the samples avoids the introduction of contaminants and, in addition, the frozen samples can be analysed for volatile compounds—the methyl species, even in airtight containers, are completely lost from liquid samples within a day.

Massée *et al.*[33] studied sorption losses for selenium, arsenic, cadmium, silver and zinc at the $10^{-7}M$ level from distilled water and artificial sea-water, during storage in containers made of borosilicate glass, high-pressure polyethylene or Teflon. The effects of pH and storage time were studied, and special attention was paid to the effect of the ratio of inner container surface area to sample volume. For Se(IV) at the 8-μg/l. level, losses were insignificant in all three container materials, irrespective of the water matrix composition. This is probably because the selenium is present as oxy-acids, which are partly dissociated, and the anions do not adhere to the container walls. Schutz and Turekian[34] observed no losses of selenium onto borosilicate glass from sea-water. Glickstein[35] used radioisotope tracers (Na_2SeO_3) to study the volatilization and surface adsorption losses of nanogram quantities of selenium in sea-water. For concentrations below ~0.02 μg/l., serious losses were observed at pH 8.1 after 40 hr. Thompson *et al.*[36] spiked acidified river water with selenium at the 50-μg/l. level. They observed losses starting after 16 days of storage at 20°. Robberecht and Van Grieken,[37] using different tracer experiments, showed that losses of both Se(VI) and Se(IV) from simulated natural waters onto Pyrex and polyethylene containers were negligible, even after prolonged storage. Elemental selenium, however, appeared to be rapidly lost on both materials. Measures and Burton[38] compared selenium values resulting from sea-water samples analysed at sea with those obtained in the laboratory. They found that samples acidified to pH 2 with hydrochloric acid and stored either in glass or linear polyethylene containers, showed no significant change in concentration of either oxidation state over a period of 4.5 months. This is in good agreement with earlier results.[30,38–40]

Reamer *et al.*[41] studied selenium adsorption in several hydride generation systems and construction materials by use of ^{75}Se as radiotracer (100 μg/l.). Polypropylene, two types of Teflon, and both silaned and unsilaned glass were evaluated. Glass and polypropylene cause the highest adsorption losses (23–32%) and silaned glass the lowest (2–8%). The adsorption decreased as a function of the number of

reductions done and adsorbed selenide was leached from the material only by 2*N* nitric acid.

The various literature data indicate that adsorption losses of selenium will depend on various factors such as element concentration, chemical form, container material, contact time, pH, salinity, suspended matter and micro-organisms. Reduction of contact time and acidification with a strong acid will generally prevent or minimize the losses. Acidification, however, can change the initial composition of the aqueous sample, but storage of the unacidified water at 4° in pre-cleaned polyethylene bottles can prevent this problem. For the study of volatile organoselenium compounds, freezing the samples is the best method of storage.

DETERMINATION PROCEDURES

Spectrophotometric analysis

This was probably the most cited technique in the past, but it was not always sensitive enough for determination of selenium in trace amounts. An excellent review of methods and reagents is given by Shendrikar.[42]

Spectrophotometry. Osburn *et al.*[43] have described a simple method for the determination of 0.1-mg/l. Se(IV) in aqueous solutions, involving oxidation of hydroxylamine hydrochloride to nitrous acid by selenious acid followed by diazotation of sulphanilamide by the resulting nitrite and subsequent coupling of the diazonium salt with *N*-(1-naphthyl)ethylenediamine dihydrochloride. Interferences from $Cu(II)$ can be removed by ion-exchange. Any Se(VI) can be reduced to Se(IV) by heating the sample with 4*M* hydrochloric acid.

Campbell and Yahaya[44] determined microgram amounts of Se(IV) by measuring the decrease in absorbance of dithizone in carbon tetrachloride at 620 nm. Of several metals tested, only copper (at the 10-μg level) and iron (at the 100-μg level) interfered. High concentrations of nitric or perchloric acid caused low results.

Pal and Das[45] determined Se(IV) in the range 0.05–100 mg/l. by measuring the yellow acetothioacetanilide complex at 400 nm. Silver, platinum, palladium and gold interfered.

Spectrophotometric methods based on catalytic reactions are generally much more sensitive than those based on stoichiometric reactions.[46] Most catalytic methods involve oxidation–reduction reactions in which the catalyst, usually a multivalent ion, changes its oxidation state.[47] Feigl and West[48] proposed a very sensitive qualitative test for selenium, based on the catalytic reduction of Methylene Blue by sodium sulphide. The reaction was later developed for the determination of low-levels of selenium.[49–52]

A similar catalytic method[50] was modified by Tzeng and Zeitlin[53] for determination of selenium as selenite in sea-water, after preconcentration by adsorption on a colloid which was then floated. They stated that their method is temperature-sensitive and that this can contribute some uncertainties to the results.

Kawashima and Tanaka[54] proposed determination of Se(IV) based on its catalytic effect on the reduction of 1,4,6,11-tetra-azonaphthalene by hypophosphorous acid and attempts have been made[55] to use this procedure for Se(IV) in sea-water. When arylhydrazines are oxidized, then coupled with aromatic compounds, they produce intensely coloured azo dyes.[56] Kawashima *et al.*[57] found that, in the presence of chlorate, Se(IV) catalyses the oxidative coupling reaction of *p*-hydrazinobenzenesulphonic acid with 1-naphthylamine to produce an intensely coloured compound, and based on it a new catalytic method for small amounts of Se(IV). Kawashima *et al.*[58] replaced 1-naphthylamine by *m*-phenylenediamine. The sensitivity and reproducibility were improved by extracting the product into organic solvents. Under optimum conditions 0.12–0.5 μg of Se(IV) in 10 ml of extract could be determined. This corresponds to a working range of 8–33 μg/l. in water. A method based on the catalytic effect of selenium on the reduction of picrate by sodium sulphide is described by Diamandis and Hadjiioannou.[59] Selenium (3–30 μg) may be determined in 15 ml of solution with an average error of about 4%. The reaction can be followed spectrophotometrically, or by potentiometric monitoring with a picrate-selective electrode. The oxidation state of selenium is not mentioned, but the method is probably only sensitive to Se(IV).

Fluorimetry. Haste[60] and Haste and Gillis[61] proposed 3,3′-diaminobenzidine (DAB) as a sensitive fluorimetric reagent for selenium, since the piazselenol formed with Se(IV) shows a strong fluorescence. It has been used for fluorimetric determinations in many materials. In water analysis, the DAB reaction has been the most popular for determination of selenium. The method is sensitive but is lengthy and pH-dependent, and the reagent solutions are generally unstable and must be prepared daily. Strong oxidizing or reducing agents must be absent, so the addition of masking reagents[62] or EDTA[62–64] is necessary. Rossum and Villarruz[63] proposed two methods for the determination of selenium in water samples. In their distillation method, they claimed to separate selenium quantitatively from other elements by distillation of the tetrabromide. In the second method they first oxidized all selenium compounds to selenate with acid permanganate, then reduced selenate to selenite with warm 4*M* hydrochloric acid. The addition of EDTA eliminated negative interference from iron(III). Engberg[65] used both methods for determination of selenium in ground and river water. Chau and Riley[66] used co-precipitation with iron(III) hydroxide at pH 4–6 to concentrate Se(IV) from sea-water. Selenium was separated from the iron and other cations by ion-exchange and determined fluorimetrically with DAB. Selenium(VI) could be determined similarly after reduction to Se(IV) by boiling with sulphur di-

oxide, but the method was insufficiently sensitive for sea-water analysis. Morette and Divin[67] used the DAB method for the determination of Se(IV) and Se(VI) in ground waters in France. Selenate was reduced to selenite by boiling with hydrobromic acid and determined by difference. More recently, Desai and Paul[68] reported on rapid and accurate methods for simultaneous determination of Se(IV) and Se(VI). Selenium(IV) is determined by spectrophotometry after sequential complexation by diethyldithiocarbamate (DDTC) and solvent extraction by chloroform in the presence of perchlorate ions. Selenium(VI), which remains in the aqueous phase, is reduced to Se(IV) by 25% hydrobromic acid and determined either spectrophotometrically with DDTC or fluorimetrically after reaction with DAB.

2,3-Diaminonaphthalene (DAN) was first introduced as a fluorimetric reagent for Se(IV) by Parker and Harvey.[69] The fluorescence intensity and extractability into organic solvents from acidic media are superior to those obtained with DAB. Rankin[64] claimed to convert inorganic selenium into Se(VI) by oxidation with hydrogen peroxide. Hydrochloric acid was then used for the reduction to Se(IV) for reaction with DAN. Nitrite, which interferes, can be removed by oxidation to nitrate, and interfering metals masked by complexation. Verlinden and Deelstra[73] applied this technique to drinking water and found a recovery of only 48% for added selenium.

Raihle[70] established a technique for the determination of elemental selenium and Se(IV). Elemental selenium is oxidized to selenious acid by a bromine–bromide redox buffer, before addition of DAN; Se(VI) is not reduced to Se(IV) under these conditions. Hiraki *et al.*[71,72] and Sugimura *et al.*[39,74,75] used this technique to study selenium speciation in sea-water. These authors preconcentrated Se(IV) either by adsorption of the DDTC complex on a macroreticular resin[39,74] or by co-precipitation on ferric hydroxide. To remove Fe(III) before the fluorimetry, they first used ion-exchange separation[71] but more recently have used extraction with a capric acid–chloroform solution.[72] The Se(VI) in the filtrate is reduced to elemental selenium by boiling with hydrazine sulphate, then concentrated by co-precipitation on sodium tellurite.[39,72,74] The precipitate is redissolved and the DAN method is applied, with a recovery of around 95%. Organic selenium compounds are separated from the sea-water by adsorption on Amberlite XAD-2 resin.[75] Up to 45% of the selenium is present in organic form. Another DAN fluorimetric procedure has been described by Nazarenko and Kislova[76,77] for the specific determination of selenites, selenates and organoselenium compounds in water with the aid of various selective reducing and oxidizing reagents (Table 1). The limit of detection is 0.01 μg/l. The relative standard deviation is 23% for 0.05–1.0 μg/l. of selenium and 5% for 50–500 μg/l. No organoselenium compounds were found in well water or tap water. This is probably due to the fact that heating the acid solution hydrolyses the organoselenium species, which therefore appear as selenite.

Table 1 summarizes the commonly used preconcentration techniques for the fluorimetric determination (with DAN) of various selenium species in all types of water.

Turbidimetry and nephelometry. Some older publications deal with the turbidimetric or nephelometric de-

Table 1. Determination of various selenium species in natural water samples by fluorimetry of the DAN–selenite complex

Preconcentration and sample treatment method	Sample volume, *l.*	Species	Detection limit, μg/*l.*	Ref.
H_2O_2 oxidation, HCl reduction	0.05	Se (total)	0.2	64
HBr/Br_2 oxidation	0.01	Se(0) + Se(IV)	—	70
Co-precipitation with $Fe(OH)_3$, redissolution, removal of Fe(III)		Se(IV)	—	71
Co-precipitation with $Fe(OH)_3$, redissolution, capric acid $CHCl_3$ extraction, removal of Fe(III)	2–3	Se(IV)	—	72
Hydrazine sulphate reduction, co-precipitation with Te, redissolution, HCl reduction	2–5	Se(VI), Se(total)	—	39, 72, 74
Complexation with DDTC	5	Se(IV)	—	39, 74
Adsorption on XAD-2 resin, elution (with CH_3OH, or NH_4OH)	—	organic Se (neutral, basic or acidic)	—	75
HNO_3 heating	0.05–0.1	Se(IV)	0.01	76, 77
$HClO_4/HNO_3$ heating	0.05–0.1	Se(IV), organic Se	0.01	76, 77
$HClO_4/HNO_3$ heating, HCl reduction	0.05–0.1	Se(total)	0.01	76, 77

termination of selenium in water.[78–80] Fogg and Wilkinson[78] described a turbidimetric procedure for use after reduction of Se(VI) to Se(IV) by distillation with hydrobromic acid and bromine, and subsequent precipitation as elemental selenium with ascorbic acid. Destruction of organic material by heating with nitric acid–perchloric acid mixture is necessary for effluent analysis. Sherrat and Conchie[79] isolated selenium from interfering substances by ion-exchange, reduced Se(VI) to Se(IV) in 6*N* hydrochloric acid, then reduced Se(IV) to elemental selenium by ascorbic acid or hydrazine sulphate.

Atomic-absorption spectrometric methods

The use of atomic-absorption spectrometry (AAS) has increased during the last two decades to cover a large fraction of selenium determinations. Very recently, Verlinden *et al.*[81] have comprehensively reviewed AAS determination of selenium in various materials, including water.

Flame AAS (FAAS). This technique in its conventional form is not sensitive enough for direct determination of selenium in environmental water; indeed, even with optimized experimental conditions, the detection limits are at best[81] around 100 μg/l.

With the "tantalum sampling boat" technique it is possible[82] to reach a limit of detection of 10 μg/l. Use of the Delves cup or an electrically heated platinum loop cannot significantly enhance the sensitivity for selenium.[83]

Various chemical preconcentration methods have been proposed, mostly involving extraction with DDTC or ammonium pyrrolidinedithiocarbamate (APDC) into methyl isobutyl ketone (MIBK), but none has been used for selenium determination in environmental water by conventional FAAS. Only Guegueniat *et al.*[85] used a double preconcentration on manganese dioxide for trace element determination in coastal waters by FAAS; it was possible to detect 0.03 μg/l. of soluble selenium in 30-l. samples.

Electrochemical preconcentration of Se(IV) by reduction and deposition of elemental selenium on a platinum spiral was used by Lund and Bye[86] for air–acetylene FAAS. The electrolysis is done in the presence of hydrazine dihydrochloride to prevent the generation of chlorine, which would oxidize Se(IV) to the non-reducible Se(VI). A detection limit of 5 μg/l. and an electrolysis efficiency of 10% are obtained for a 25-ml sample and a 5-min electrolysis time. Recently Holen *et al.*[87] reached a detection limit of 0.5 μg/l. by electrothermal heating of the filament before its introduction into an argon–hydrogen (entrained air) flame.

In recent years, there has been a growing interest in the technique of hydride generation for the determination of selenium and a few other elements in various materials.[81] The volatile selenium hydride is formed by reduction of Se(IV) with reducing agents such as Zn–$SnCl_2$–KI, $TiCl_3$–Mg or in particular, $NaBH_4$. The hydride is flushed from the solution with argon, helium or nitrogen as carrier gas. The hydride evolved is either conveyed directly into the atomization system as it is generated, or is stored in a rubber balloon, a collapsible plastic bag or a pressurized chamber before transfer to the atomizer, or it is collected in a liquid-nitrogen trap and flushed into the flame as the cold trap is warmed. Hydride generation FAAS techniques for selenium are more sensitive by three orders of magnitude than nebulization FAAS, as the detection limit can be around 0.2 μg/l.[82] An additional advantage is that selenium is separated from the matrix before atomization, thus avoiding the interferences that occur when the conventional techniques are used.

The literature on hydride-generation FAAS for environmental water analysis is summarized in Table 2.

It appears that with regard to sensitivity, the sample pretreatment step is of paramount importance. For most uncontaminated environmental waters, only the last three methods listed in Table 2 will be suitable.

Electrothermal AAS (ETAAS). The flameless technique, ETAAS, in which a small sample aliquot is electrothermally atomized in a graphite furnace, is especially suitable for direct analysis of samples as it offers a high sensitivity (50 pg of Se is the detection limit), but it is not simple, nor free from interferences or volatility losses. Treatment of the graphite furnace, or addition of various metal ions, such as nickel,[101–107] cobalt,[106,108] molybdenum,[100] lanthanum,[103] copper,[109–111] mercury,[112] chromium,[113] proved to diminish the chemical interferences in water analysis, allows use of higher ashing temperatures without losses and results in a significantly enhanced sensitivity. Vickrey and Buren[103] reported that added metal solutions counteract signal depression by interfering elements not only because they reduce the volatility of selenium, but also because they modify the graphite furnace surface, leading to more efficient atom formation. Surface treatment can replace the matrix modifier—use of metal-coated or pyrolytic graphite-coated cuvettes[103] or graphite tubes lined with tantalum foil[114] yields optimal results.

Various detection limits have been reported for determination of selenium in water samples by ETAAS without preconcentration. Table 3 summarizes some published results. Pretreatment of the water samples and some slight modifications can give enhanced sensitivity. Henn[100] developed a method for the determination of selenium (1–50 μg/l.) in waters and industrial effluents which involved mineralization with hydrogen peroxide, drying, redissolution in hydrochloric acid, preliminary purification on cation-exchange resins, and ETAAS after addition of molybdenum salts (100 mg/l.) to increase the sensitivity, raise the ashing temperature and decrease the interferences. The same technique was used by Martin *et al.*[115] for determination of selenium in fresh water, waste, sediments and muds after digestion with nitric acid–hydrogen peroxide mixture and addition of nickel

Table 2. Determination of selenium in environmental waters by hydride-generation FAAS

Pretreatment	Reducing agent	Flame type	Detection limit, μg/l	Ref.
None	$NaBH_4$	Ar/H_2	50	88
None	$NaBH_4$	N_2/H_2	5	89
HCl, H_2SO_4	$KI/SnCl_2/Zn$	Ar/H_2	2	90
Digestion with acid $KMnO_4$ solutions, reduction by HCl	$KI/SnCl_2/Zn$	N_2/H_2	2	91
None	$TiCl_3/Mg$ or $NaBH_4$*	Air/C_2H_2	1.7	92
H_2SO_4, HNO_3, $K_2S_2O_8$	$NaBH_4$	Ar/H_2	1	93
Acid digestion	$NaBH_4$	N_2/H_2	0.6	94
None	$NaBH_4$*	Ar/H_2	0.15–0.25	95
$K_2S_2O_8$/HCl	$KI/SnCl_2/Al$	Ar/H_2	0.1	96
HCl heating (1 hr)	$NaBH_4$	Tube furnace	0.02	97
Adsorption of hydrides on $HgCl_2$- or $AgNO_3$-impregnated filters, re-extraction with HNO_3, $HClO_4$	$NaBH_4$ or $KI/SnCl_2/Zn$	Ar/H_2	0.02	98
Co-precipitation with $Fe(OH)_3$, flotation with air bubbles, scavenging, redissolution in HCl	$NaBH_4$	N_2/H_2	0.02	99

*The hydrides were collected in a collapsible bag. In all other cases there was direct injection.

nitrate to prevent losses during ashing. They obtained a detection limit of 0.02 μg/l. Use of the standard-additions method was mandatory. They were not able to analyse sea-water or brines since the suppressive effect of chloride on the sensitivity was not sufficiently decreased by the additive.

Chemical preconcentration has often been combined with ETAAS. Kamada *et al.*[109,110] proposed selective extraction of Se(IV) and differential determination of Se(IV) and Se(VI) by using DDTC, APDC and dithizone in organic solvents, combined with ETAAS. The sensitivity was 0.4 μg/l. for 1% absorption, and the relative standard deviation was 3% at 0.8 μg/l. Recently Kamada and Yamamoto[110] showed that copper(II) was useful in diminishing the volatility of selenium in ETAAS, but the detection limit was only slightly improved to 0.3 μg/l. Ohta and Suzuki[111] also tried to determine selenium in various water samples in the same way, but found no species present above the 0.4 μg/l. level.

Subramanian and Meranger[116] selected optimum conditions for the quantitative extraction of selenium, arsenic and antimony from aqueous solution with APDC into MIBK, and subsequent determination by ETAAS. Nitrite (75 μg/l.) completely suppressed the extraction of all three elements. The detection limit of 0.3 μg/l. for selenium, and the fact that low levels of nitrite suppressed the signal suggests that this technique is unlikely to be useful for the analysis of polluted waters. Nève *et al.*[104] recently proposed a simple evaporation step for water samples, with nitric acid added to minimize loss of selenium. The Se(IV) is selectively reacted with 4-chloro-1,2-diaminobenzene and the reaction product is detected by ETAAS after addition of nickel as matrix modifier. Total selenium is determined similarly after hydrogen peroxide digestion. The limit of detection is 20 ng/l. There are some questions concerning the speciation, since in this procedure for selenite, heating in the presence of concentrated nitric acid may result in partial hydrolysis of any organoselenium compounds and oxidation of selenide and elemental selenium to Se(IV).

Hydride generation in combination with ETAAS is probably the most studied method for determination of selenium in environmental water, yet it is plagued by numerous interferences.[96,117–133] Meyer *et al.*[131] found that these depend very strongly on the concentration of hydrochloric acid in the sample solution. Vijan and Leung[132] utilized the capability of hydrochloric acid to form chloro-complexes with common interfering heavy metals, such as copper and nickel, to eliminate practically all their suppressive effect. Bujmovic[120] found that organic interferences could be removed by irradiation with ultraviolet light.

The applications of hydride-generation ETAAS to water analysis are included in Table 3. Many authors lead the evolved selenium hydride directly into a carbon furnace but some authors[118,125,134] prefer a low-cost quartz tube. Others[117,118,135,136] collect the hydride, stripped from the solution, in a liquid-nitrogen trap. This tube is warmed to cause instantaneous transfer of the hydride into the atomizer. Because of the lesser dilution, better sensitivity can be obtained.

Various automated hydride-generation ETAAS

Table 3. Determination of selenium in environmental waters by ETAAS

Type of water	Pretreatment	Detection limit, μg/l.	Ref.
	(a) Direct analysis		
—	none	36	137
Waste	none (tantalum-foil lined tube)	8	114
Waste	none	3.1	112
Power-plant effluent	none	0.25	138
	(b) Digestion only		
Sewage	predigestion	10	139

Lake	$NaBH_4$ reduction	0.05	122, 123
—	$NaBH_4$ reduction	0.02	121
Sea/river	$NaBH_4$ reduction cold trap concentration	0.005	135
Sea/river	cold trap concentration GC/AAS detection for $(CH_3)_2$ Se and $(CH_3)_2Se_2$	0.0007	135

techniques have been described[96,121,133] allowing 30–70 water analyses per hour. In the procedure of Pyen and Fishman,[133] organic selenium-containing compounds are first decomposed by $HCl–K_2S_2O_8$ digestion. The Se(VI) produced, along with any inorganic selenium, is reduced to Se(IV) with stannous chloride and potassium iodide, and then to selenide with sodium borohydride. The hydrogen selenide is stripped from the solution with nitrogen, and then decomposed in a tube furnace at 800° placed in the optical path of the ETAAS unit. Goulden and Brooksbank[96] used digestion with either HNO_3/H_2SO_4 or acid persulphate to break down organoselenium compounds, and found hydride-generation ETAAS, with a 0.01-μg/l. detection limit, at least two orders of magnitude more sensitive than hydride-generation FAAS.

Cutter[135] proposed a complex method for determination of selenite, selenate, dimethyl selenide and dimethyl diselenide in natural waters. Volatile methyl species of selenium are removed from the sample by a stream of helium and inorganic forms of selenium are selectively reduced to the hydride with sodium borohydride and stripped. Both the organic selenides and the H_2Se are trapped in a liquid-nitrogen trap. The methyl species are separated by gas–liquid chromatography and measured in a quartz-tube furnace. No free methyl selenides were detected in lake, rain and sea-water samples, probably because they are present at levels below the detection limit (0.7 ng/l.) or because they have disappeared during sample storage. For Se(IV) and Se(VI), the detection limit is 5 ng/l. and the time of analysis is 15 and 30 min per sample, respectively. It was not possible to analyse chlorinated drinking water since chlorine interferes with the reduction step.

Atomic-fluorescence spectrometry

The method of determination of selenium, arsenic, antimony, and tellurium by sodium borohydride reduction with subsequent atomic-fluorescence determination of the evolved hydride was studied by Thompson.[140] The hydrides were passed directly into an argon–hydrogen (entrained air) flame. The atomic fluorescence was excited by use of modulated microwave sources and detected by a dispersive measuring system. The detection limit for selenium in 15 ml of sample was 0.06 μg/l. Nakahara *et al.*[141] used a non-dispersive system to compare the zinc and sodium borohydride reduction systems. The best attainable detection limits for selenium were 0.43 ng and 0.2 ng, respectively. With the proposed method, 1-μg/l. levels of selenium can be determined accurately. The presence of several elements, including other hydride-forming elements, in 1000-fold ratio to selenium caused a negative interference, but tellurium gave a positive interference. The method was applied to the determination of selenium in waste waters in the range 0.9–26 μg/l.

Emission spectroscopy

The use of the inductively coupled plasma (ICP) as an excitation source in optical atomic emission spectroscopy (AES) for single and multielement inorganic trace analysis of pollutants is becoming widespread. The recent availability of commercial instruments has stimulated use for the determination of metals and metalloids in diverse environmental materials ranging from airborne particulates and fly-ash to industrial effluents and sewage waters. The capabilities and limitations of ICP–AES in water pollution analysis have been reviewed by Barnes.[142] Winge *et al.*[143] evaluated the accuracy, precision and detection limits for ICP–AES water analyses. Pneumatic nebulization gives a detection limit of 30 40 μg/l. Only with ultrasonic nebulization is it possible to reach a limit of detection of 1 μg/l., which is well below the EPA-recommended levels for public water supplies and irrigation water, 10 and 20 μg/l. respectively.[144,145]

Thompson *et al.*[146] developed a method for simultaneous determination of selenium, antimony, bismuth, arsenic and tellurium by generation of their gaseous hydrides and introduction of these hydrides into an ICP-source. A detection limit of 0.8 μg/l. was obtained for selenium in aqueous solutions. The presence of certain metal ions in solution resulted in low recoveries of some of the elements, especially selenium and tellurium, but this could be overcome by co-precipitation separation on lanthanum hydroxide. With 200 ml of river water it was possible to reach a detection limit of 0.05 μg/l.[147] Goulden *et al.*[148] concentrated 100 ml of water to 10 ml and were able to detect selenium at the 0.03 μg/l. level. Koyama *et al.*[149] used ICP–AES for determination of organic selenium compounds after destruction with concentrated nitric acid. The method allowed determination at the 10–100 mg/l. selenium level. The method is thus of little use, since organoselenium species occur in natural waters only in the ng/l. range.

Fricke *et al.*[150] coupled a semi-automated hydride-generation device to a microwave-induced Ar/H_2 plasma (MIP) and used a chromatographic column to separate species causing spectral interference. In this way they separated the hydrides of selenium, arsenic, tin, germanium and antimony and, with a 20-ml sample, obtained a limit of detection of 1.25 μg/l.

Belcher *et al.*[151,152] have proposed methods for the determination of selenium, based on molecular emission cavity analysis (MECA). Kouimtzis *et al.*[153] elaborated this technique for the determination of the element in water samples. Selenium is first co-precipitated with ferric hydroxide. After dissolution of the precipitate in hydrochloric acid, Se(IV) is reduced by hydroxylamine or sulphur dioxide; the elemental selenium is filtered off and determined by MECA. For a 250-ml sample the detection limit is 0.2 μg/l. It should be emphasized that the selenium must be in the selenite form before co-precipitation. If the concentration of selenium in the samples is higher than 5 μg/l. there is no need for co-precipitation. It was suggested that organic selenium compounds, if present, may first be decomposed by digestion with permanganate in hot acid solution, but Pyen and Fishman[132] found this treatment to be insufficient to destroy all organic compounds.

X-ray emission analysis

As with most other techniques, it is impossible to determine selenium directly by X-ray emission methods at the concentration levels in natural waters: indeed the detection limits are around 200 μg/l. for elements such as selenium[154] with secondary target-energy-dispersive X-ray fluorescence analysis or X-ray energy spectrometry (XES). A simple evaporation enrichment step is not very helpful: even in optimized conditions, spotting on a cellulose filter paper and drying results in a detection limit of 30 μg/l. for low-salinity samples by XES,[155] and spotting a droplet of water onto a Mylar foil and analysis by the highly sensitive proton-induced X-ray emission analysis (PIXE) yields detection limits of around 60 μg/l. for selenium.[156] More favourable sensitivities are obtained when a large volume of water, *e.g.*, 200 ml, is freeze-dried after addition of graphite and the pelletized residue is analyzed by a versatile XES-procedure in which the matrix corrections are based on the scatter peaks in the spectrum, but the detection limit of 1 μg/l. is still well above natural concentrations.[157] Greathouse and Craun[158] evaporated 30 ml of water and applied PIXE to reach a detection limit of 1 μg/l. In a screening analysis of 3834 household tap-water samples, only 10% showed selenium levels above this limit. An additional common drawback to all evaporation procedures is the volatility of selenium compounds.

Clearly, there is a need for chemical preconcentra-

tion techniques to boost the sensitivity of X-ray emission analysis sufficiently for environmental water applications, and over 100 articles have been published on ion-exchange, co-precipitation, solvent extraction, immobilization after chelation, or electrodeposition. Most lead to thin homogeneous targets which are ideal for accurate and sensitive X-ray emission analysis. In view of the multielement potential of X-ray emission methods, most of these papers deal with non-selective enrichment. By using multielement extraction with APDC into chloroform and evaporation onto filter paper, Marcie[159] was able to determine selenium down to 10 μg/l. by wavelength-dispersive X-ray fluorescence.

By co-precipitation on polyvinylpyrrolidine thionalide[160] or DDTC[161] a detection limit of a few μg/l. can be obtained. By using chelating 2,2'-diaminodiethylamine cellulose filters, Smits and Van Grieken[162,163] could collect both Se(IV) and Se(VI) from water at pH 3–6, and reach a detection limit of 0.05 μg/l. for XES-analysis, but ionic strengths above 0.001 appeared to interfere with the collection.

Specifically aiming for selenium determination in water, Pradzynski *et al.*[164] used co-precipitation with APDC in the presence of iron(III), followed by XES to determine 0.6–50 μg/l. of selenium in fresh waters, even when appreciable concentrations of transition metals were present. They stated that the relative speed and economy made the method suitable for application in environmental monitoring.

Robberecht and Van Grieken[37] reported that selenate and selenite in various environmental waters can be determined by XES after preconcentration of elemental selenium on activated carbon. Selenite is reduced to elemental selenium with ascorbic acid. Selenate plus selenite is determined after refluxing the samples with thiourea in sulphuric acid and then adsorbing the elemental form on activated carbon. Selenate is determined by difference. The limit of detection is 50 ng/l. for selenite and 60 ng/l. for total selenium. The coefficient of variation is approximately 10% for both species at the 0.5–1 μg/l. Se level. Humic material, common abundant ions and oxidizing substances do not interfere. The applicability of this method to environmental water has been clearly demonstrated.[165]

Neutron-activation analysis (NAA)

Because of its high sensitivity (10^{-8}–10^{-9} g of Se) this technique is widely used for determination of selenium, especially in biological material, but also in environmental waters. Thermal neutrons are most often used for the activation because radioactive selenium isotopes are formed in (n,γ) reactions. Only the ^{77m}Se and ^{75}Se radioisotopes are currently utilized in activation analysis. ^{77m}Se, providing the highest sensitivity thanks to a very short half-life (17.5 sec), is used only in instrumental neutron-activation analysis (INAA). ^{75}Se is used more often because its long half-life (120.4 days) allows chemical separation, but long activation times are required. The sample material is usually irradiated in a nuclear reactor with a flux of 10^{13}–10^{15} n.cm^{-2}.sec^{-1} for 7–32 days (for ^{75}Se) or several seconds (for ^{77m}Se). The activity of the irradiated samples is measured with a high-resolution Ge(Li) γ-ray detector coupled to a multichannel analyser, or sometimes with an NaI(Tl) detector.

The most important step in the NAA of water is the enrichment of selenium. Three ways of preconcentrating the element from the water have been described, namely selective extraction, non-selective extraction and freeze-drying. The irradiation can also be followed by radiochemical separation. As can be seen in Table 4, only five papers deal with irradiation of whole water samples without any pretreatment, and physical preconcentration by evaporation or freeze-drying usually does not give sufficient sensitivity for analysis of unpolluted water.

Kharkar *et al.*[177] and Schutz and Turekian[178] applied a very elaborate multielement chemical post-irradiation separation scheme for the analysis of ocean and river water in which ^{75}Se was purified by precipitation as SeS_2, distillation of Se with HBr–HCl and final precipitation with sodium bisulphite. Hashimoto and Winchester[179] performed post-irradiation separation by distillation and precipitation with hydrazine for rain and snow analysis. Jørstad and Selbu[180] used freeze-drying and irradiation, then concentrated ^{75}Se by controlled-potential electrolysis, and obtained a 0.68-μg/l. detection limit for sea-water.

Massée *et al.*[181] determined selenium in fresh water and sea-water by reduction of selenite to elemental selenium with ascorbic acid and adsorption of selenium onto activated carbon. They also determined Se(VI) after reduction to Se(IV) by refluxing with concentrated hydrochloric acid. This allowed determination of Se(IV) and Se(VI) in 40 samples daily, with a detection limit of 10 ng/l. Very recently, Orvini *et al.*[182] presented an extended speciation scheme for the determination of selenium in polluted river waters. They used filtration, charcoal adsorption, selective reduction by ascorbic acid followed by charcoal adsorption and collection on anion-exchange resin for determination of suspended and colloidal compounds, selenite and selenate, respectively. They found an important fraction of the selenium to be present in the colloidal fraction. This was probably due to the fact that at pH 6.5 organoselenium compounds and some selenite adsorb on the charcoal and are included in this fraction. Lieser *et al.*[183,184] also employed carbon adsorption either alone or in the presence of DDTC or dithizone as chelating agents, for the partial recovery of selenium from sea-water for subsequent NAA determination.

Spark-source mass-spectrometry (SSMS)

Although it has several suitable stable isotopes, selenium is not an ideal element for SSMS because of its volatility in a high-temperature spark, which results in a low relative sensitivity coefficient[185] and

Table 4. Determination of selenium in water by non-destructive neutron-activation analysis without chemical preconcentration

Experimental conditions	Type of water	Detection limit, μg/l.	Ref.
10 ml enclosed in quartz 2.6×10^{12} n.cm^{-2}.sec^{-1} (14 hr) 30 days decay time	Subsurface waters	0.7	166–168

poor precision and accuracy. Hamilton and Minski[185] freeze-dried 1 litre of water in the presence of pure carbon powder and pressed the residue into electrodes, using bismuth as an internal standard. A limit of detection of 0.05 μg/l. was obtained for selenium. Similarly Wahlgren *et al.*[187] freeze-dried 1-litre samples, ashed the residue under ozone at low temperature, spiked with yttrium as an internal standard and slurried with graphite and compressed into electrodes. They reported a detection limit of 0.1 μg/l.

Gas-liquid chromatography (GLC)

Determination of selenium by GLC is based almost exclusively on the detection of the amount of volatile piazselenol formed in the reaction of Se(IV) with an appropriate reagent. Species other than Se(IV) must first be converted into the quadrivalent form by reduction or oxidation. Piazselenols can readily be extracted from water into organic solvents for direct injection into a gas chromatograph. Piazselenols are usually detected with an electron-capture detector, which gives the highest sensitivity and selectivity for such compounds. Table 5 lists applications of GLC to environmental water, and the various reagents that have been proposed.

Nakashima and Tôei[188] proposed a GLC procedure for selenium involving electron-capture detection of 5-chloropiazselenol and 4,5-dichloropiazselenol. They reported the latter as being three times more sensitive than the former, owing to the additional electronegative group. The minimum amount of selenium detectable was about 0.04 μg as the 5-chloropiazselenol. By extracting the 4,6-dibromopiazselenol into 1 ml of toluene from 500 ml of water sample, Shimoishi and Tôei[196] were able to determine Se(IV) and total selenium in natural waters down to 0.002 μg/l. Young and Christian[194] confirmed the work of Nakashima and Tôei[188] and found the 4,5-dichloropiazselenol to give the same sensitivity as the selenium–DAN complex. However, they used DAN because of impurities encountered in commercial chlorophenylenediamine products. Measures and Burton[195] studied the speciation of dissolved selenium in estuarine waters by developing the procedures described by Shimoishi[193] and Gosink and Reynolds.[192] Total dissolved selenium was determined after photo-oxidation by ultraviolet radiation at a well-defined pH. This led to a reproducible proportionation of species between selenite and selenate. Afterwards the determination procedures were opti-

Table 5. GLC determination of various selenium species in natural waters

Pretreatment and compound extracted	Sample volume, *l.*	Species	Detection limit, *μg/l.*	Ref.
4,5-Dichloropiazselenol	—	Se(IV)	—	188
2,3-Diaminopiazselenol	0.1	Se(IV)	2	189

mized so that as little as 0.8 ng/l. of selenite in sea-water could be determined.[38] Organic selenium compounds were not tested, and the calibration curve was found to be linear only over the range 0.8–240 ng/l. The method was applied for routine determination of both Se(IV) and total dissolved selenium in sea-water.[197,198] Uchida *et al.*[40] determined various selenium species in river water and sea-water by electron-capture detection GLC after reaction with 1,2-diamino-3,5-dibromobenzene. This reagent reacts with Se(IV) to form 4,6-dibromopiazselenol which is extracted into toluene. After Se(−II) and Se(0) have been oxidized by bromine and Se(VI) has been reduced by a bromine–bromide solution to Se(IV) state, total selenium is determined by the same method. The limit of detection is 0.002 μg/l.

Talmi and Andren[189] coupled the gas-chromatographic separation to a microwave-emission spectrometric detection system for the determination of selenium in various environmental samples. By reaction with 5-nitro-*o*-phenylenediame and extraction of the piazselenol into toluene, they were able to determine selenium in water at the 0.1 μg/l. level.

HPLC

The potential of high-pressure liquid chromatography (HPLC) as a method in inorganic trace analysis has been reviewed by several authors.[199–201] Several piazselenols and selenium diethyldithiocarbamates can be separated from the reagents by reversed-phase chromatography and determined by ultraviolet detection in the nano- and picogram range. The separation of selenium from copper, nickel and lead as diethyldithiocarbamates makes possible the simultaneous determination of these elements. Schwedt and Schwarz[201] tested the method for the determination of selenium in drinking, river and waste water. They reported a limit of detection of 0.7, 0.3 and 5.0 μg/l. for the piazselenol, 5-chloropiazselenol and diethyldithiocarbamate, respectively.

Electrochemical methods

In acidic medium selenite can be reduced at a mercury electrode in two discrete steps. The reaction $Se^{4+} + Hg + 4e \rightarrow HgSe$ is irreversible. Selenium can be accumulated at an electrode surface in this way. At −0.45 V the enriched selenide layer can be stripped cathodically by the reversible process $HgSe + 2H^+ + 2e \rightleftharpoons Hg + H_2Se$. Both reactions can be used in voltammetry. Direct-current polarography of Se(IV) in acidic medium gives rise to two reduction waves at the dropping mercury electrode, but, in practice, this technique is too insensitive and it suffers from severe interference problems, especially from elements that form insoluble selenides. Alternating-current polarography, differential-pulse polarography and cathodic-stripping voltammetry have been used increasingly successfully for trace selenium determinations in recent years. Some of the relevant publications will be discussed here, although not all were specifically intended for environmental waters.

Shafiqul Alam *et al.*[202] determined Se(IV) in hydrochloric and perchloric acid solutions by a.c. polarography at a dropping mercury electrode, with detection limits around 10 μg/l. The use of a hanging mercury drop electrode and a 2–12 min selenium accumulation before cathodic stripping yielded detection limits of 0.1–2 μg/l. The most serious interference, from lead(II), can be prevented by the addition of EDTA.

Howard *et al.*[203] determined Se(IV) by differential-pulse polarography of the 4-chloro-*o*-phenylenediamine piazselenol, which gives a reduction peak at 0.11 V *vs.* SCE at pH 2.5 in formate buffer. The detection limit was 0.4 μg/l. Interferences from chromium(VI), copper(II), molybdenum(VI), nickel(II), tin(II), tellurium(IV) and vanadium(V) were overcome by treatment of the sample with a Chelex-100 resin column. The method appeared to be applicable to the analysis of fresh water and of saline solutions such as estuarine water and sea-water.

A cathodic-stripping voltammetric procedure for the determination of selenium in the range 0.2–20 μg/l. was described more than ten years ago by Henze *et al.*[204] The electrolytic preconcentration on the hanging Hg droplet was effected at −0.4 V *vs.* SCE from a supporting electrolyte containing ammonium sulphate in the presence of EDTA and copper chloride. The procedure was substantially free from interferences. Arlt and Naumann[205] added copper(II) (1 mg/l.) and stripped the intermetallic compound Cu_2Se or Cu_6Se cathodically from a hanging mercury drop electrode, with the specific aim of determining selenium in drinking water. Only sulphide at concentrations above 20 μg/l. appeared to interfere. Krapivkina *et al.*[206] studied the voltammetric behaviour of selenium at a graphite electrode and recommended cathodic or anodic stripping of intermetallic copper–selenium compounds, to obtain a detection limit of 0.06 μg/l.

Recently Henze[207] discussed the determination of selenium, arsenic and tellurium at sub-μg/l. levels. After electrolytic depositions of the elements as intermetallic compounds after addition of copper(II), the determination is done by differential-pulse cathodic-stripping voltammetry. At a selenium concentration of 1 μg/l., the standard deviation is only 2.3%. The simultaneous determination of selenium and tellurium or of selenium and arsenic is possible but inorganic compounds that may be present in natural waters, can, in practice, cause depression or even complete suppression of the peaks.

Deldime and Hartman[208] discussed the electrochemical characteristics of the differential pulse- and cathodic-stripping polarography of selenium. The addition of copper and of 2*N* hydrochloric acid as supporting electrolyte can decrease the interfering effect of certain trace metals. Denis *et al.*[209] used reduction of selenium to selenide by sodium borohydride, evolution of hydrogen selenide and its trapping in an alkaline cell, as a preseparation step before differential-pulse cathodic-stripping voltammetry. The detection limit was 1 μg/l. with a precision of approximately 5% at concentrations above 4 μg/l. Metal interferences can be removed by batch extraction with immobilized 8-hydroxyquinoline.

Nguyen *et al.*[210] used differential-pulse anodic-stripping voltammetry for the simultaneous determination of copper, lead, cadmium and zinc, and differential-pulse cathodic-stripping voltammetry at a hanging mercury drop electrode for selenium determination, specifically in rain water and snow. With special care to purify and pretreat sampling containers and laboratory ware, they were able to determine selenium down to 10 ng/l. in a 15-ml sample.

Alternative electrochemical techniques, such as amperometric titration on a rotating platinum electrode[211] and potentiometric titration with a fluoride-selective electrode[212] yield detection limits of only around 1 mg/l., and are thus definitely not sensitive enough for direct application to environmental waters.

CHEMICAL SPECIATION OF SELENIUM IN NATURAL WATERS

Knowledge of the speciation of environmentally and biomedically relevant elements, *i.e.*, their distribution in different chemical forms, is important because bio-availability and toxicity both depend critically on the chemical form. The measurement of the total concentration of a trace element provides little information about the bio-availability since different forms have different assimilability.[213] Generally, the free (hydrated) metal ion is the form most toxic to aquatic life. Strongly complexed metal, or metal associated with colloidal particles, is much less toxic.[213–219] For speciation determination at ultratrace concentration levels, very sensitive analysis is required and the whole analytical procedure must be designed to keep blanks and contamination to an absolute minimum. Also, any preliminary separation step and the analytical measurement must wherever possible avoid altering the equilibria between the various chemical species in the sample. However, in a dynamic system such as a natural water, some disruption of the chemical equilibria is inevitable, although it can be minimized by use of rapid separation procedures.[220]

The protein-bound form of selenium seems to be the most available form for animal and man, so the study of organoselenium compounds in water is very important. Nhimi and Laham[221] studied the relative toxicity of organic and inorganic selenium to newly-hatched zebra fish (*Branchydanio rerio*) and found that selenium dioxide was the most toxic of the compounds tested. Palmer and Olson[222] stated that there are only small differences in toxicity between selenate and selenite when they are added to the drinking water of rats. Earlier, Schroeder and Mitchener[223] reported severe toxicity at the 2-mg/l. level for selenite but not for selenate.

Selenium, like sulphur, exists in several oxidation states, *viz.* −2, 0, +4 and +6. The chemical diversity of these oxidation states is a major factor affecting the behaviour of the element in the environment. Gissel-Nielsen[224] presented some possible cycles for selenium in its different forms. Some of the properties are summarized here from more comprehensive presentations.[225,226] Hydrogen selenide is readily oxidized to non-toxic elemental red selenium, which is insol-

uble in aqueous systems and is generally resistant to oxidation and reduction. In water it will be adsorbed on particulate material present. Methylated selenium (dimethyl selenide or dimethyl diselenide) can be produced in water by microbial or fungal activity.[227–230] Since these compounds are poorly soluble in water, they will be lost from solution.[135,231,232] Ridley *et al.*[232] discussed the formation of dimethyl selenide by biomethylation reactions. They found the products to be volatile and slowly oxidized by molecular oxygen to stable, water-soluble species. Their presence in natural waters has yet to be demonstrated, although methods for their detection have been developed.[135,232]

Selenium(IV) exists as the weak selenious acid, H_2SeO_3, and as a number of inorganic selenites. Most selenites are less soluble than the corresponding selenates. In aqueous solution (pH range 3.5–9.0), dissolved selenites exist predominantly as the hydrogen selenite ion. Selenites have high affinity for iron, aluminium and manganese hydroxides.[233,234] Under acidic conditions, selenites are rapidly reduced to elemental selenium by mild reductants such as ascorbic acid or sulphur dioxide. Alkaline and oxidizing conditions favour the formation and stabilization of selenate. Most selenates are very soluble and do not form stable complexes. The conversion of selenate into the less soluble selenite or elemental selenium is a slow process, which is not appreciably enhanced by acid environments. In natural waters selenium exists in two common oxidation states, Se(VI) and Se(IV). Sillén[235] has suggested that most of the selenium in sea-water should be present in the thermodynamically stable sexivalent state, but in view of the oxidation–reduction potential, Chau and Riley[66] concluded that the quadrivalent state was more probable. The geochemical behaviour of selenium in aqueous systems has been mapped in pH–*E*h diagrams, such as calculated[236] by Delahay *et al.*, Tischendorf and Ungethum, and Dyachkova and Khodakovsky. Such diagrams reveal that over wide ranges of *E*h and pH, selenium is stable as H_2SeO_3, $HSeO_3^-$ and SeO_3^{2-}, all quadrivalent forms. On the other hand, the field of predominance of SeO_4^{2-} is restricted to extremely oxidizing conditions, so the existence of selenates is rather limited. If selenates exist, it could only be in hot arid climates, where waters normally have a strongly alkaline character.[236] However, selenates may have a metastable existence outside their *E*h–pH equilibrium range.[94] There are contradictory observations concerning the ratio of Se(IV) to Se(VI) in different types of waters.

Literature information on the speciation of selenium in environmental water is very confusing. The findings of Measures and Burton[195,237] indicate that Se(IV) is present in some rivers as a minor fraction of the total dissolved selenium (less than 10%). Hiraki *et al.*[238] report that Se(IV) accounts for 2–16% of the total selenium in samples from two rivers in east central Japan, whereas it comprises 75% of the dissolved selenium in the Kuji river.[239] Several investigators have found that Se(IV) forms a substantial fraction of the dissolved selenium content in some oceanic waters, particularly deep waters. Selenium(IV) was found to be uniformly distributed with depth, but Se(VI) increased to about three times the surface value. The ratio of Se(IV) to Se(VI) ranged from 1–4 for surface samples, to 0.7–1.5 for deep samples. Recently Measures and Burton[198] found that the ratio of selenite to selenate in ocean water increased from 0.1 in the surface layer to a maximum of 0.6 at 1300 m, the deep-water value being 0.55. In ocean water the similarity of depth profiles of selenium species to those of dissolved silicate and phosphate indicates that the distribution of the element is probably mainly controlled by biological processes[197] and that the oxidation phenomena are restricted to the surface-layers.[198] Shimoishi *et al.*[193,196] found the percentage of selenite in sea-water and river water to vary from 35 to 70%. Sinemus *et al.*[97] studied the influence of the oxidation state on the determination of selenium in lake water and found that the element was present only as Se(VI). Uchida *et al.*[40] determined various selenium species in river water and sea-water and concluded that the amount of Se(−II, 0) in river water was larger than that in sea-water, whereas Se(IV) in sea-water was more prevalent than in river water. Total selenium values for river water were found to vary widely, whereas those for sea-water were fairly constant, with Se(VI) dominating. Cutter's findings[135] were similar. For lake water and rain water the selenite concentration was about ten times that of selenate. The reverse was true for sea-water, where the selenate content was at least fifteen times that of selenite. Selenite concentration seemed to increase with the depth of sampling. Massée *et al.*[181] proved that selenite was the predominant species in various environmental waters, and the sexivalent form contributed about 60% of the total selenium only in drinking water. In waste water, 30–100% of the selenium was found to be in the quadrivalent form.[109] Robberecht and Van Grieken[165] stated that the type of water is important for the ratio of selenate to selenite. They found that for the quite polluted Scheldt river, its estuary and the North Sea, most of the selenium was present as selenite. In drinking water, swimming pool water, geothermal water and some waste waters, however, the element was predominantly present as selenate.

The redox state of chemical elements is controlled not only by thermodynamic equilibria but also by some other processes such as biochemical reactions, chemical treatment, surface interaction and adsorption. For this reason other characteristics of water samples are important.

Another reason for discrepancies between the various investigations lies in artefacts arising during the analysis, every step of which must be chosen very carefully. Acidification probably causes desorption and hydrolysis of adsorbed organoselenium com-

pounds from colloidal matter. In this way the easily adsorbed selenite can return to the soluble fraction. Heating in the presence of nitric acid causes partial or total oxidation of selenides and elemental selenium.[76,77,104] Sugimura *et al.*[73,74] collected selenite as the DDTC complex on Amberlite XAD-2 resin. Since this resin adsorbs all organic compounds, these authors recently changed their procedure so that all organoselenium compounds are adsorbed before the selenite complex is formed.[75] In this way, they found that up to 45% of the selenium in sea-water was present in an organic form.

In many of the methods of selenium determination, the element must be present as Se(IV), and many ways of conversion into this form have been proposed. Cutter[135] discussed several methods for reduction of Se(IV), and found heating the solution in a boiling water-bath with 4*N* hydrochloric acid the only suitable method. He found that acid concentration is important, and also that the boiling time must be controlled to avoid reduction to the metallic state. Thus, uncontrolled conversion steps may explain some of the literature discrepancies concerning selenium speciation in water. Various published reduction and oxidation methods used in selenium analysis are summarized in Tables 6 and 7. Reported selenium concentration levels in different water samples can only be compared after critical examination of the pretreatment steps. The speciation of selenium in water samples can only be elucidated if other characteristics of the water are taken into account and the different separation methods and conversion steps are shown not to disturb the speciation equilibrium.

CONCENTRATION LEVELS

Summaries of the literature values for the concentrations and major chemical forms of selenium in various types of waters are listed in Tables 8–12.

It is remarkable that most of the selenium in drinking water is present as Se(VI), probably because of chlorination in the preparation of potable water. For all types of water very little information is available concerning the organoselenium compounds.

Apparently, waters rarely contain selenium at levels

above a few μg/l. Only older publications report higher values. However, drainage water from seleniferous soils can contain high amounts of selenium. Although the WHO limit for selenium, like the EPA-proposed maximum contaminant level, is 10 μg/l.[144] and the USSR limit is 1 μg/l. as SeO_3^{2-},[262] most evidence indicates that there is greater overall potential for selenium deficiency than for toxicity at current levels of selenium intake.[261] The maximum no-observed-adverse-health-effect level for selenium in water is at least 100 μg/l. and may be as high as 500 μg/l. A concentration of 20 μg/l. just barely provides a minimum nutritional amount of selenium with a consumption of 2 l./day. The criteria for protection of fresh-water aquatic life, 9.7 μg/l. as a 24-hr average and a concentration never above 22 μg/l., and those for the protection of salt-water aquatic life,[275] 4.4 μg/l. as a 24-hr average and a concentration never above 10 μg/l., are seldom exceeded.

Acknowledgements—The work of one of us (H.R.) was supported by the Belgian Ministry of Health through the

AN IMPROVED SENSITIVE ASSAY FOR POLONIUM-210 BY USE OF A BACKGROUND-REJECTING EXTRACTIVE LIQUID-SCINTILLATION METHOD*

G. N. CASE and W. J. MCDOWELL
Chemical Technology Division, Oak Ridge National Laboratory Oak Ridge, TN 37830, U.S.A.

(*Received* 14 *December* 1981. *Accepted* 21 *April* 1982)

Summary—A procedure is described for the determination of polonium-210 in various types of materials, including ores, mill tailings, and environmental samples, by a combined solvent-extraction liquid-scintillation spectrometry method. Concentration of polonium-210 and separation from interfering elements (such as iron) are accomplished by extraction from a 7*M* phosphoric acid–0.01*M* hydrochloric acid solution with 0.20*M* trioctylphosphine oxide solution (together with a scintillator) in toluene. The polonium-210 is determined by counting the 5.3-MeV alpha-radiation with a photon/electron-rejecting alpha liquid-scintillation spectrometer. Extraction coefficients of over 1000 for polonium ensure quantitative recovery, and no other alpha-emitters in the decay chains of uranium-238, uranium-235 and thorium-232 are extracted. The results for several samples show the relative standard deviation to be ~1.2%. A lower limit of detection of 0.0038 pCi is proposed, based on a counting time of 1000 min and an easily obtainable background of 0.01 cpm for the alpha peak.

Polonium-210, the daughter of naturally occurring uranium-238, is a common alpha-emitting radionuclide found in biological and environmental materials. It is rated as a Class 1 radionuclide (very high radiotoxicity),[1] yet few methods for determining polonium-210 levels in environmental samples have been developed. Most such methods involve lengthy chemical separations, deposition onto silver disks, and counting on a surface barrier detector. They also depend on the use of polonium-208 and polonium-209 tracers to determine polonium-210 recovery and counting efficiency.[2,3]

Early methods for determination of polonium-210 used stannous chloride to co-precipitate polonium with tellurium or selenium, followed by deposition of the polonium on silver disks from ~0.5*M* hydrochloric acid, and counting with a gas-flow proportional counter.[4,5] Later methods[2] used pyrosulphate fusion, along with solvent extraction with trilaurylamine chloride for polonium separation, followed by deposition onto silver disks and alpha-counting on a surface barrier detector. Polonium-208 or polonium-209 tracers were used to determine recovery and counting efficiency; the precision and accuracy were reported to be within the statistical accuracy of the counting. Recent methods reported by Chou *et al.*[6] and Godoy *et al.*[3] are very similar to past procedures.

This paper describes use of a new technique, developed at Oak Ridge National Laboratory (ORNL),[7] that combines solvent extraction and alpha liquid-scintillation spectrometry[8] and is of wide applicability to alpha-assay problems. Pulse-shape discrimination electronics are used to reject beta and gamma pulses[9] and thus lower the background count to acceptable levels.

The use of liquid-scintillation methods for alpha counting has been known for some time,[10-13] and more recently the ability to obtain a useful degree of alpha-energy resolution has been demonstrated.[14,15] However, the new technique of combining solvent extraction of a nuclide into a solvent containing a scintillator and counting on a high-resolution spectrometer (in conjunction with pulse-shape discrimination electronics to reject beta and gamma pulses) is competitive with, and in some cases more desirable than, other methods. At ORNL, this concept, called photon/electron-rejecting alpha liquid-scintillation (PERALS) spectrometry, has been used extensively.[7,8,16,22] The present method for separation of polonium-210 and its assay by PERALS spectrometry was developed and used for a study of polonium distribution in uranium milling streams.[23]

EXPERIMENTAL

Reagents

The scintillator, [2-(4-biphenylyl)-6-phenylbenzoxazole] (PBBO), and the extractant, trioctylphosphine oxide (TOPO), were obtained from Eastman Organic Chemicals. Eastman scintillation-grade naphthalene and high-purity distilled-in-glass toluene from Burdick and Jackson Laboratory, Inc. were used. All other chemicals used were reagent grade.

The extractive solution was composed of 77 g of TOPO, 180 g of naphthalene, and 4.0 g of PBBO dissolved in and diluted to 1 litre with toluene.

*Research sponsored by the Division of Chemical Sciences, U.S. Department of Energy under contract W-7405-eng-26 with the Union Carbide Corporation.

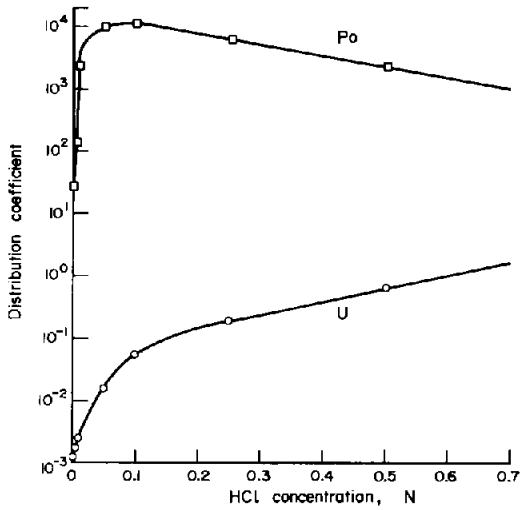

Fig. 1. Polonium and uranium extraction by 0.20*M* trioctylphosphine oxide in toluene as a function of hydrochloric acid concentration.

Equipment

The PERALS spectrometer and pulse-shape discrimination (PSD) equipment previously developed at ORNL were used to count the 5.3-MeV alpha radiation of polonium-210. The PSD equipment was an improved version (developed by D. G. Prater of ORNL Instruments and Controls Division) of that previously[9] described. The detector and associated electronics have also already been described.[24] A Teflon-lined pressure vessel was used for dissolving solid samples. A mechanical wrist-action shaker was used for equilibration in the polonium extractions.

Procedure for solids

Place approximately 0.5 g of the sample (accurately weighed) in a Teflon-lined pressure vessel, and add 2 ml each of concentrated hydrochloric, nitric, and hydrofluoric acids. Seal the vessel, and heat it in an oven at 140° for ~2 hr. Remove the vessel from the oven, let it cool for ~1 hr, and transfer the dissolved sample to a 250-ml Teflon beaker with ~5 ml of water. Add 5 ml of concentrated phosphoric acid. Using a hot-plate with a heat control, evaporate the solution to ~5 ml, rinse down the beaker with ~5 ml of water, and again evaporate to ~5 ml. The acid remaining in the sample should now mainly be phosphoric acid. Retention of hydrochloric acid will increase the extraction of uranium (see Fig. 1), but the uranium can be removed by a scrub (see below). Transfer the sample to a 30-ml separatory funnel with ~5 ml of water and add 1 ml of 0.1*M* hydrochloric acid. The solution should now be ~7.0*M* phosphoric acid–0.01*M* hydrochloric acid. Add by pipette a known volume (usually in the range 1.2–1.5 ml) of extractant solution and shake the funnel on a wrist-action shaker for at least 30 min; run off the aqueous phase and scrub the organic phase with ~5 ml of 7.4*M* phosphoric acid–0.001*M* hydrochloric acid to remove any co-extracted uranium. After the phases have separated, pipette 1.0 ml of the organic phase into a 10 × 75 mm culture tube. Deoxygenate the solution by bubbling argon, methane, propane or acetylene (presaturated with toluene) through it for ~2 min, using a disposable transfer pipette as a sparging lance. (Deoxygenation is necessary if the beta and gamma pulses are to be discriminated from alpha pulses by the electronics.) Seal the sample with a cork coated with a room-temperature vulcanizing silicone sealer, and count the polonium-210 with a beta/gamma-rejecting PERALS spectrometer. Samples are generally stable for 48 hr when sealed as described. Good pulse-shape characteristics can be restored by repeating the sparging.

Procedure for aqueous samples

Combine a measured quantity of the aqueous sample with 5 ml of concentrated phosphoric acid and 2 ml of concentrated hydrochloric acid in a 250-ml Teflon beaker. Apply the procedure given above for solid samples, starting with the evaporation step. Some aqueous samples may require or permit modified procedures; for example, analysis of a sample of ~6*M* commercial (wet-process) phosphoric acid needs only the addition of 0.1*M* hydrochloric acid and extraction *etc.*, before the scintillation counting.

RESULTS AND DISCUSSION

Sample preparation

Dissolution. It was found necessary to use mixed acids in a pressure vessel for the dissolution of solid samples. Some forms of polonium (usually the bivalent state)[2] have been reported to be volatile, causing some concern over the possibility of losing polonium in the dissolution or subsequent evaporation; however, recovery tests with known amounts of polonium showed no loss in the procedures described here. This is in agreement with earlier work by Scott and Stannard.[25]

Extraction. TOPO is an excellent extractant for polonium from hydrochloric acid media.[26] Figure 1 shows the distribution coefficients for polonium and uranium from 7.4*M* phosphoric acid, as a function of hydrochloric acid concentration. Essentially 100% of the polonium is extracted over a very wide hydrochloric acid concentration range. Although phosphoric acid has little effect on polonium extraction, the extraction of uranium and iron is suppressed by increasing phosphoric acid concentration.[26] At 0.01*M* hydrochloric acid and 7.4*M* phosphoric acid, the separation factor for polonium from uranium is about 10^6. Suppression of iron extraction by complexing with phosphate is necessary because small amounts of Fe(III) in the extractive scintillator can quench the light emission to the extent that counting of the polonium is impossible. At higher hydrochloric acid concentrations some uranium is extracted along with the polonium but can be easily removed by scrubbing as described in the procedure. Figure 2 shows the spectra obtained with and without the scrubbing step. These spectra show no evidence for the extraction of any other alpha-emitting nuclides.

The rate of extraction was found to be low, so adequate time must be allowed to ensure complete extraction. Equilibration for 1–2 min gave extraction coefficients in the range 100–200 for 1*M* hydrochloric acid–7.4*M* phosphoric acid medium. After 20–30 min equilibration, however, extraction coefficients up to 900–1000 were obtained for this system. For ~0.005–0.1*M* hydrochloric acid–7.4*M* phosphoric acid, the extraction coefficients were always $\gg 1000$ (approaching 10^4) after the same length of time. Equilibration times in this work were, therefore, always greater than 20 min to ensure quantitative polonium extraction.

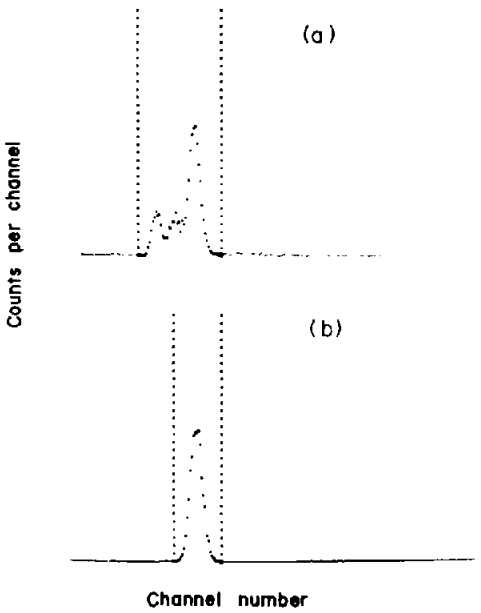

Fig. 2. Energy spectra of uranium and polonium extracted together and of polonium after scrubbing with 0.001 *M* hydrochloric acid–7.4 *M* phosphoric acid. (a) ^{238,234}U and ^{210}Po spectra when extracted together by 0.20 *M* TOPO extractive scintillator; (b) ^{210}Po spectrum after scrubbing the organic with equal volume of 0.001 *M* HCl–7.4 *M* H_3PO_4.

Counting. Figure 3 compares alpha spectra obtained with and without pulse-shape discrimination (PSD). The high-energy alpha-radiation (~8 MeV) is from polonium-214. White and Ross[26] found that bismuth is extracted by TOPO from hydrochloric acid solutions. Our work has confirmed that bismuth is extracted from the hydrochloric acid–phosphoric acid medium. However, the beta and gamma radiation from bismuth-214 and bismuth-210 is effectively rejected by the PSD electronics, leaving only the two alpha-radiation peaks for polonium-210 and polonium-214. Since the alpha energies of the two polonium isotopes are widely separated, integrating the polonium-210 peak gives an accurate determination of the counts from this isotope. No error occurs in the polonium-210 count because of production of this isotope from the decay of extracted bismuth-210 if the sample is counted within 8 hr after extraction ($t_{1/2}$ is 5 days for ^{210}Bi and 138 days for ^{210}Po).

To evaluate the accuracy and reproducibility of the method, eight portions of New Brunswick Laboratory (NBL) Standard No. 104 were assayed. This counting standard was prepared by blending a weighed quantity of pitchblende ore (NBL-analysed sample No. 6-A) with a pulverized silica sand. The uranium content, as reported from the NBL chemical analysis of the final product, is 0.0103 ± 0.004% U at the 95% confidence level. The radium to uranium ratio is 3.49×10^{-7}, in secular equilibrium with the uranium.

If the polonium-210 in the NBL standard is assumed to be in equilibrium (a reasonable assumption because of the method of sample preparation), its activity may be calculated from the uranium (or the radium) concentration. The resulting value is 76.32 dpm (polonium-210) per gram of sample. Table 1 gives results obtained for this standard by the present

Table 1. Counting results from samples of New Brunswick Laboratory (NBL) standard No. 104 (0.0103 ± 0.004% U)

Sample weight, *g*	Total counts*	Observed ^{210}Po activity, *dpm/g*
0.6104	3085	75.8
0.4863	2412	74.4
0.7230	3616	75.0
0.3865	1940	75.3
0.8210	4094	74.8
0.2946	1451	73.9
0.5002	2531	75.9
0.1965	984	75.1

*The NBL sample, after dissolution, was extracted into 1.5 ml of extractive scintillator, and 1.0 ml was then pipetted for counting. Counting time for each sample was 100 min.

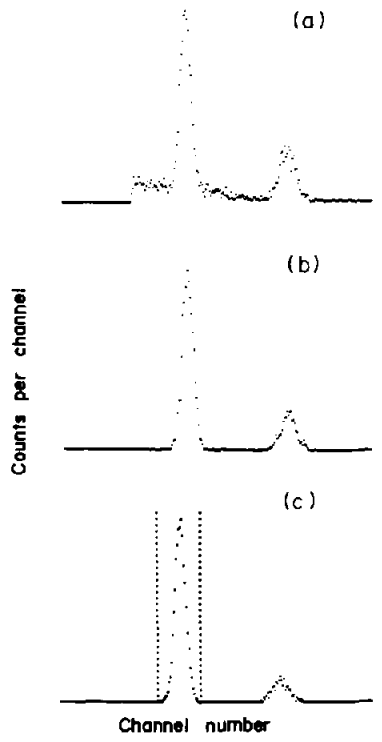

Fig. 3. Examples of polonium energy spectra. The low energy cut-off in (*a*) is caused by a low-level discriminator for the purpose of improving operation of the pulse-shape discriminator. The polonium-214 peak on the right decreases as time elapses between successive counts, because the polonium-214 ($t_{1/2}$ = 164 μsec) arises from the beta-gamma decay of the bismuth-214 ($t_{1/2}$ = 20 min) extracted. (a) ^{210,214}Po energy spectra with beta-gamma background; (b) ^{210,214}Po energy spectra with background rejected by pulse-shape discrimination; (c) ^{210,214}Po energy spectra showing integration of the ^{210}Po peak.

method. The relative standard deviation is 0.9%, and the average value is 75.0 dpm (polonium-210) per gram (>98% recovery of the calculated available polonium-210). Additional assays with another NBL standard gave similar results; eight analyses gave a relative standard deviation of 1.3% and >99% recovery of calculated available polonium-210.

The overall reproducibility of the method for uranium ore samples was examined by analysing six portions of well-mixed Kerr-McGee Ambrosia Lake ore, ranging in weight from 0.2 to 0.89 g. The calculated dpm of polonium-210 per gram showed a relative standard deviation of 1.2%.

The lower limit of detection by this counting method has been estimated previously[2] on the basis of a 1000-min counting time and a background of 0.01 cpm for the alpha peak. Backgrounds as low as this were not always obtained in this work, but were not greater than 0.03 cpm.

CONCLUSIONS

The TOPO/PERALS spectrometry method is effective in analysis for polonium-210 in ores, mill tailings, and other materials, and provides an excellent quantitative assay. Sample preparation is less complicated and requires fewer steps than previous methods, with no need to use tracers for calculating recovery and counting efficiency. Although the method was developed for assay of samples from uranium process streams, it could also be effectively used for low-level environmental samples because of the high extraction coefficients, low background, and high counting efficiency.

ORIGIN OF DOUBLE-PEAK SIGNALS FOR TRACE LEAD, BISMUTH, SILVER AND ZINC IN A MICROAMOUNT OF STEEL IN ATOMIC-ABSORPTION SPECTROMETRY WITH DIRECT ELECTROTHERMAL ATOMIZATION OF A SOLID SAMPLE IN A GRAPHITE-CUP CUVETTE

KUNIO TAKADA and KICHINOSUKE HIROKAWA
The Research Institute for Iron, Steel and Other Metals, Tohoku University, Sendai, 980, Japan

(*Received* 15 *October* 1981. *Revised* 25 *November* 1981. *Accepted* 15 *April* 1982)

Summary—Atomic-absorption signals of trace lead, bismuth, silver and zinc in steel, obtained by directly atomizing one sample particle, were found to consist of a small first peak and a large second peak. It was concluded that the first peak was caused by the analyte element existing around the grain-boundaries of the steel and near the sample surface and the second by the fraction of the analyte element existing within the crystal grains of the steel.

When a solid sample is directly atomized in atomic-absorption spectrometry, there should be no contamination and/or loss of the elements sought, and the analytical procedure should be shorter because no decomposition of the sample and preconcentration of the elements of interest will be required. Various direct methods of atomization[1–3] of solid samples have been reported, the electrothermal graphite atomizer[4–8] and induction-heated graphite atomizer[9–11] being used. When an electrothermal graphite-furnace atomizer was used, the atomic-absorption signals for trace lead in iron,[4] low-alloy steel,[4,7] stainless steel,[5,6] copper,[4] copper-base alloy[4] and nickel-base alloy[7] usually appeared as double peaks. Therefore, in this case peak-area measurements[4–7] give better accuracy and precision than peak-height measurements. However, the cause of the double peaks has not been described. We have studied this problem by direct atomization of solid samples with an electrothermal graphite-cup cuvette. We conclude that the first peak comes from lead on the sample surface and at the grain boundaries, and the second from lead within the grains. The atomization mechanism for trace bismuth, silver and zinc in iron and low-alloy steel has also been examined.

EXPERIMENTAL

Apparatus

A Hitachi 170-50 atomic-absorption spectrometer equipped with a Hitachi GA-2 electrothermal graphite-cup cuvette atomizer, a Hitachi 056 chart recorder, a Tokyo Kagaku RD-202 digital integrator and a Shimadzu LM-20 microbalance (standard deviation 5 μg) was used, with hollow-cathode lamps as light sources and deuterium-lamp correction of background absorption. Table 1 gives the parameters used for the lamps.

Samples

The samples[4,8] used were standard low-alloy steel, carbon steel and iron samples. Certified values and analytical values obtained in our institute by flame atomic-absorption spectrometry are shown in Table 2.

Procedure

A micro sample was prepared by carefully cutting a solid sample with a pair of nippers. The micro samples were irregular in shape. A single particle of sample was weighed on the microbalance, then put into a graphite-cup cuvette atomizer. The cuvette was sheathed by argon at 2.0 l./min flow-rate. It was heated directly to atomization temperature without any preheating (*i.e.*, no drying or ashing stage). The shapes and areas of the atomic-absorption signals were recorded.

RESULTS

Double peaks of the lead signal

The lead was uniformly distributed as very small particles in the steel.[4] The shapes of the absorption signals of lead at various atomization temperatures are shown in Fig. 1. They usually consisted of a small first peak and a large second peak, at atomization temperatures from 1350° to 2080°. The appearance behaviour of peaks was examined by use of various atomization procedures. When atomization was interrupted at the end of the appearance of the first peak (1st atomization), only the signal corresponding to the second peak was obtained when the atomization was resumed (2nd atomization) as shown in Fig. 2(a). When atomization was interrupted during the appearance of the second peak (2nd atomization), however, double peaks were obtained on resumption of atomization (3rd atomization) as shown in Fig. 2(b).

On the alternate repetition of the 1st and 2nd atomizations as in Fig. 2(b), the first peak and second peak (partially) were alternately obtained, as shown in Fig. 3. It was assumed from these results that lead on the sample surface or in the grain boundary region was easily atomized, and that at the same time lead inside the grains began to move to the sample surface. Therefore the following experiments were performed.

Table 1. Operating conditions of hollow-cathode lamps

Element	Type	Wavelength, *nm*	Lamp current, *mA*
Ag	Hitachi HLA-3	328.1	2.5
Bi	Westinghouse WL22932A	223.1	5.0

Pb	JSS 161-3	Low-alloy steel	0.003	0.0028
Zn	JSS 370-1	Carbon steel	—	0.0007

Micro samples were annealed in quartz boats for 23.5 hr *in vacuo* (1.3×10^{-5} Pa) at 100°, 300° or 600°, and the absorption signals for lead were recorded. As shown in Fig. 4, the higher the annealing temperature, the smaller the first peak. No first peak was detected for the sample annealed at 600°. However, when a micro sample that had been annealed for 23.5 hr *in vacuo* (1.3×10^{-5} Pa) at 800°, was cut into a few particles and each particle was directly atomized, a very small first peak was obtained.

Atomic-absorption signals of bismuth and silver

The atomic-absorption signals for bismuth and silver in carbon steel and iron are shown in Figs. 5 and 6. These also had double peaks at low atomization temperature (<1610°). At an atomization temperature of 1610°, the first peaks began to overlap with the second peaks, giving peaks with a shoulder, and these absorption signals had a single peak at higher atomization temperature (1830–2080°).

Similarly to lead in steel, when the atomization was stopped at the end of the appearance of the first peak of bismuth [1st atomization in Fig. 7(a)], the absorption signal in the next atomization [2nd atomization in Fig. 7(a)] had only a single peak (corresponding to the second peak). Moreover, when the atomization was stopped during appearance of the second peak [1st atomization in Fig. 7(b)], the absorption signal in the next atomization [2nd atomization in Fig. 7(b)] showed double peaks. For micro samples annealed for 23.5 hr *in vacuo* (1.3×10^{-5} Pa), one at 100° and one at 600°, the absorption signals for bismuth appeared as shown in Fig. 8. The first peak disappears if the sample is annealed at 600°. When individual

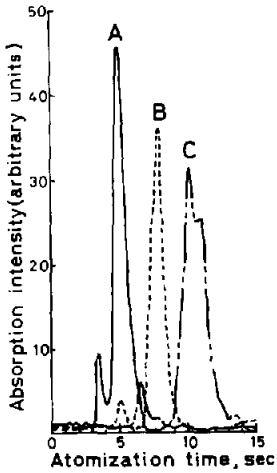

Fig. 1. Profiles of atomic-absorption signal for lead in steel at various atomization temperatures. Atomization temperature: A 1830°, B 1610°, C 1450°. Sample: JSS 160-3. Sample weight: A 70, B 60, C 78 μg.

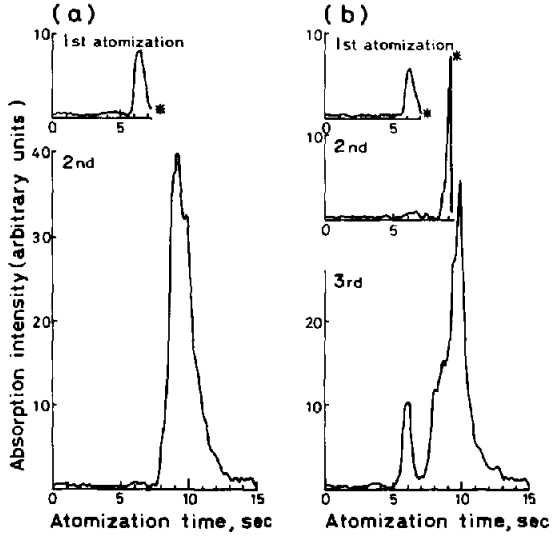

Fig. 2. Profiles of atomic-absorption signal for lead in steel by interrupted atomization. Atomization temperature: 1450°. Sample: JSS 160-3. Sample weight: (a) 120, (b) 215 μg. *Point at which atomization was stopped.

pieces cut off from a sample annealed for 23.5 hr at 1.3×10^{-5} Pa and 800° were directly atomized, the bismuth absorption signal had only a single peak (corresponding to the second peak). These phenomena were similar to those for lead in steel, and similar behaviour was observed for silver in iron.

Atomic-absorption signal of zinc

Atomic-absorption signals for zinc in carbon steel at various atomization temperatures are shown in Fig. 9. They usually consisted of a small first peak and a large second peak for atomization at 1300–2080°. The signals for micro samples annealed for 23.5 hr at

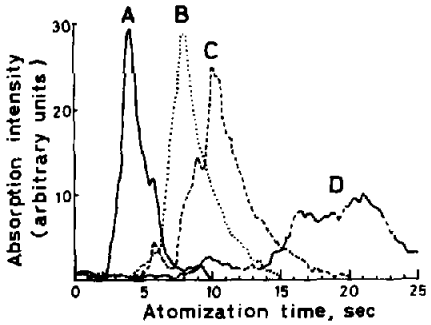

Fig. 5. Profiles of atomic-absorption signal for bismuth in steel at various atomization temperatures. Atomization temperature: A 1830°, B 1610°, C 1450°, D 1300°. Sample: JSS 370-1. Sample weight: A 387, B 500, C 457, D 367 μg.

1.3×10^{-5} Pa and 100, 300 and 600° are shown in Fig. 10. The first peak was removed by annealing at 600°. When the atomization was stopped at the end of the appearance of the first peak for zinc (1st atomization), only the absorption signal corresponding to the second peak appeared in the next atomization (2nd atomization), as shown in Fig. 11. These phenomena were similar to those for lead in steel. However, when the atomization was stopped during appearance of the second peak for zinc (2nd atomization in Fig. 11), the absorption signal in the next atomization (3rd atomization in Fig. 11) usually gave only a single peak corresponding to the second peak for zinc. Atomization of individual pieces cut off from a sample annealed for 23.5 hr at 1.3×10^{-5} Pa and 800° generally gave double peaks which were similar to those for zinc in an unannealed sample. This phenomenon was different from the behaviour of lead in steel.

DISCUSSION

Mechanism of atomization of lead

The appearance behaviour of the absorption signals can be accounted for by the following metallurgical

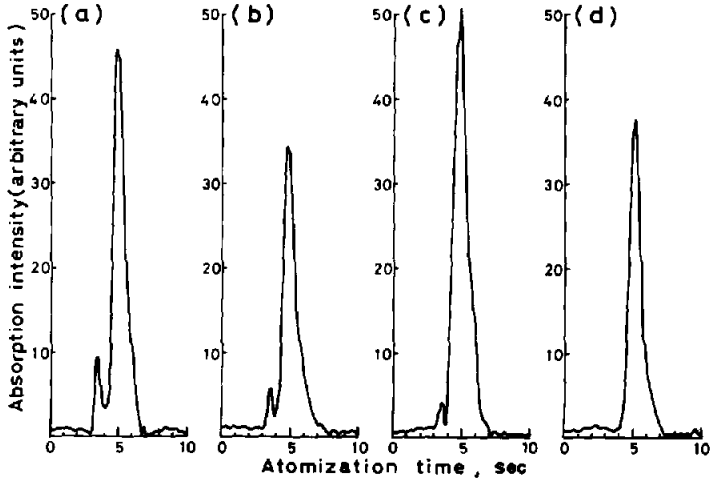

Fig. 4. Profiles of atomic-absorption signal for lead in steel after annealing for 23.5 hr at 1.3×10^{-5} Pa. Annealing conditions: (a) no annealing, (b) 100°, (c) 300°, (d) 600°. Sample: JSS 160-3. Sample weight: (a) 70, (b) 67, (c) 90, (d) 50 μg. Atomization temperature: 1830°.

considerations. The steel samples used are polycrystalline, and the phase-diagram of the lead–iron system does not show a solid solution at any concentration range. Therefore trace lead may exist as particles at the grain boundaries and in the grains. A model of a polycrystalline sample of lead–iron alloy is illustrated in Fig. 12(a). In the atomization procedure, lead near the surface of the sample and at the grain boundaries

rapidly evaporates from the sample: at the same time grain growth occurs and then lead in each grain is evaporated, as shown in (a)–(c) in Fig. 12. The surface and boundary lead (which we will call lead A) gives the first peak and the lead inside the grains (lead B) gives the second peak in the double-peak signal for lead. As indicated in Figs. 2 and 3, lead A had evaporated out of the sample by the end of appearance of the first peak [Fig. 12(a)→(b)], and then lead B gave a single peak corresponding to the second peak [Fig. 12(b)→(c)]. When the atomization was stopped during the appearance of the second peak, lead B (which migrated onto the cut surface of the sample and into the grain boundaries by diffusion during the atomization) remained there on cooling of the sample. When this sample was atomized again, the lead remaining on the sample surface and at the grain boundaries

gave the first peak and the lead still left inside the grains gave the second peak. Thus a double-peak absorption signal again appeared. It is shown in Fig. 4 that lead A evaporates more rapidly than lead B out of the sample. Lead B was not affected by annealing at below 600–800°. Because the lead B precipitates as very small particles in the grain, its diffusion temperature is higher. Therefore the area of the second peaks obtained before and after annealing does not differ (for similar sample weight). The grain size of the steel increased during the annealing. When the sample from which lead A had been removed by annealing *in vacuo* at 800° was cut up, some of lead B was exposed at and near the cutting surface. Therefore the appearance of a very small first peak after annealing and cutting was due to this lead.

As lead is a typical segregation element in steel, any segregation may affect the accuracy of lead determination by direct atomization. When the direct-atomization absorption signal consisted of a large first peak and a small second peak for lead, the lead values found were higher than those obtained by flame atomic-absorption spectrometry. For example, when the lead in two pure irons was determined, we obtained values of 0.0014 and 0.0033% by direct atomization (means of 5 determinations), but below 0.0001 and 0.0011% (means of duplicates) by flame atomic-absorption. For another pure iron, when the first peak was small and the second large, (as in Fig. 1), the values (0.0033 and 0.0034%) obtained by direct atomization agreed reasonably with that obtained by flame atomic-absorption (0.0029%), but whenever the area of the first peak was about equal to or bigger than that of the second peak, the values (0.0062, 0.0086 and 0.0049%) found by direct atomization never agreed with that from flame atomic-absorption (0.0029%). This may be explained as follows: the *sensitivity* of the

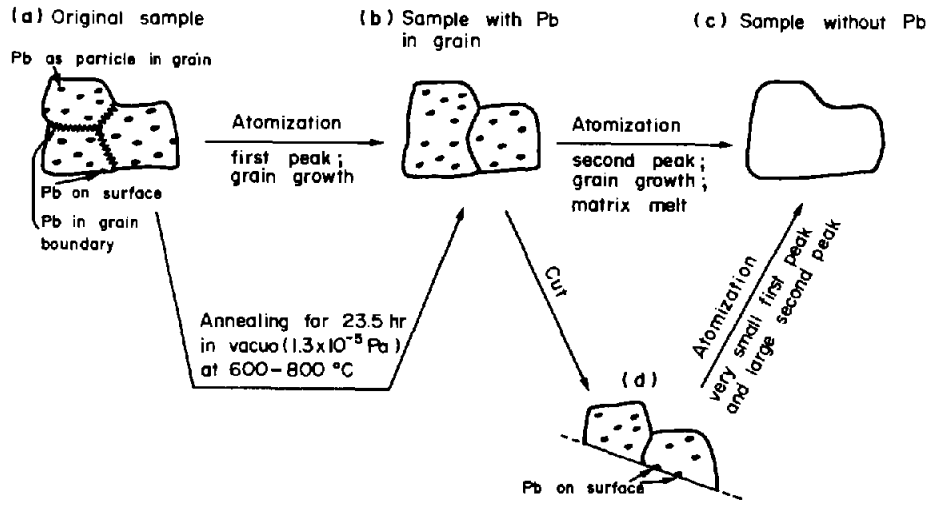

Fig. 12. Model of atomization process of lead in steel.

first peak was larger than that of the second, because lead vaporized from the sample at low atomization temperature had longer retention time (first peak) in the cuvette than the lead vaporized at high atomization temperature (second peak). Bäckman and Karlsson[5] have reported that the absorption signal area for lead in thin-flake samples (large surface area) was 20% larger than that for ball-type samples (small surface area). This may also indicate that the absorption signal of the first peak will generally have a sensitivity different from that of the second peak. Thus segregation of lead in micro samples may be detected from the shape of the double-peak signal for lead. In our experiments, the area of the first peak lead signal was usually 2–8% of the total area of the double-peak signal.

Mechanism of atomization of bismuth and silver

Neither bismuth nor silver gives a solid solution phase on the iron side of the phase system. Moreover the boiling points and vapour pressures of bismuth and silver are similar to those of lead. Therefore the various phenomena of the absorption signals for bismuth or silver were similar to those for lead and can be explained in the same way. The only differences from the behaviour of lead were the overlap of the two peaks for bismuth or silver at high atomization temperature, and the complete elimination of the first peak of bismuth or silver for individual pieces cut off from the samples annealed at 800°. The first difference might be due to the diffusion rate of bismuth or silver in the sample at the high atomization temperature being larger than that for lead, and the second might be due to differences in sensitivity.

Mechanism of atomization of zinc

Zinc does give solid solution on the iron side of the phase system, so trace zinc exists in the grain boundary and almost homogeneously in the grains. A model of a polycrystalline sample of zinc–iron alloy is illustrated in Fig. 13. In the atomization, zinc on the cut surface and in the grain boundaries (zinc A) is evap-

orated first, and the zinc within the grains (zinc B) is evaporated subsequently. If it is assumed that zinc A gives a small first peak and zinc B a large second peak in the double peaks, various phenomena in the absorption signal from zinc in steel can be explained. When only zinc A has been evaporated, because atomization has been stopped at the end of the first peak, zinc B left in the grains will give only a single peak (corresponding to the second peak) on subsequent atomization, as seen in Fig. 11. Atomization of zinc A, diffusion of zinc B and grain growth occur simultaneously. These phenomena are similar to those for lead. However, when the atomization is stopped during the appearance of the second peak, zinc B, which has arrived at the cut surface of the sample and at the grain boundaries by diffusion will not be left there during cooling of the sample, because of the high vapour pressure of zinc. Therefore, when this sample is atomized again, only zinc B left inside the grains of the sample will be atomized, and will usually give a single peak corresponding to the second peak in the double peaks. It is shown in Fig. 10 that zinc A evaporates more rapidly than zinc B, because of the higher volatilization of zinc near the sample surface. The area of the second peak obtained before and after annealing was found to be approximately equal for samples of the same weight. When the sample that had lost its zinc A by annealing was cut up, some of zinc B in the grains was exposed at the cut surface, and became zinc A. Therefore the double peaks for zinc after annealing and cutting had a shape similar to that for zinc before annealing.

CONCLUSION

As trace lead, bismuth and silver do not give solid solutions with large amounts of iron, these elements mainly exist as particles in the grains, whereas trace zinc, which does give a solid solution, is almost homogeneously distributed in the grains. Moreover, these elements will be exposed at the grain boundaries and on the sample surface when the sample is cut. When such samples are directly atomized, these fractions in the grain boundaries and near the surface give a small absorption signal, which is followed by a large absorption signal from the fraction within the grains. Thus direct atomization of these elements in steels gives double peaks in the absorption signals. In practical analysis, however, it is desirable to obtain a single peak. As shown in Fig. 14, the distance between the two peaks becomes shorter as the atomization temperature is increased. It is therefore recommended that the sample should be rapidly heated to above 2500° and then held at the appropriate temperature for the ideal absorption signal; this temperature will depend on the rate of diffusion of the trace element in solid and molten iron, retention time of the atoms, vapour pressure, carbide formation and so one. Even so, it seems to be difficult to obtain an "ideal" single peak for some elements, such as lead and zinc.

Lead in copper, copper alloys and silver gives double atomization peaks. Lead is practically insoluble in these metals and is more volatile than they are. The behaviour of lead in copper and in silver is similar to that in iron.

On the other hand, lead in Sn, Sb, Bi, Zn, Cd, Te, In and Tl gives a single atomization peak. These elements have a lower melting point or higher vapour pressure than lead, and lead dissolves in them to various extent.

THE EFFECT OF INCOMPLETE SPIKE REACTION ON THE DETERMINATION OF TRACE METALS IN A COMPLEXING MATRIX BY STANDARD ADDITIONS

A. CORSINI, C. C. WAN and S. CHIANG
Department of Chemistry, McMaster University, Hamilton, Ontario, Canada L8S 4M1

(*Received* 8 *March* 1982. *Accepted* 14 *April* 1982)

Summary—In the determination of trace metals, a preconcentration step is frequently necessary. A simple model is developed to demonstrate the magnitude of the error incurred in the application of the standard-additions method if full equilibration of the spike with a sample matrix that contains complexing species is not reached before the preconcentration is completed.

The standard-additions method (SAM) is nowadays routinely used and reference to it can be found in many textbooks on instrumental analysis, e.g., that by Skoog and West.[1] SAM is especially valuable in trace and subtrace metal determinations in conjunction with such techniques as atomic-absorption and atomic-emission spectroscopy (AAS and AES) and anodic-stripping voltammetry (ASV). The method, which is intended to compensate for any effect of the sample matrix on the response characteristics, is based on the assumption that the analyte spike added in increasing amounts to aliquots of the sample behaves identically to the sample analyte throughout the analytical procedure and is affected to the same extent by any chemical interference.[2] The blank value is determined in the absence of the analyte element in a closely matched matrix, and subtracted to yield the analytical result.

Much use has been made of SAM in the determination of trace metals in natural waters. Natural waters contain a multitude of ligands that are both natural and anthropogic in origin. Consequently, the soluble metals (*i.e.*, ions) are highly speciated in forms that include the free (hydrated) metal ion, metal complexes of various labilities, and colloidally adsorbed metal.[3,4] The determination of metals in natural waters by AAS or AES very often includes a preconcentration step to "enhance" the metal concentration. In sea-water analysis, preconcentration also permits isolation of the metals from the salt matrix. Solvent extraction and ion-exchange are the most frequently used means of preconcentration.[5–8]

In such complicated systems as natural waters, the analyte spikes may not be completely equilibrated with the sample before the preconcentration step, and, as pointed out by others,[5,9,10] the application of SAM in these circumstances can lead to an erroneous estimate of the *total* soluble analyte concentration. To date, however, the magnitude of the potential error has not been demonstrated. The purpose of this study is to show the relationship between the analyte concentration recovered (*i.e.*, the analytical result) and the degree of reaction of the spike with the matrix components. A simple model is used which takes into account the fraction of reacted spike plus original analyte transferred to the preconcentration phase.

Procedure

In the model, the sample solution is assigned a total analyte metal (M_a) concentration of 1.00 ng/ml with respect to a particular metal, which is assumed to be distributed between hydrated (*i.e.*, ionic) and complexed forms. Four aliquots of the sample solution are taken and after being spiked with known amounts of the analyte metal (M_s), contain final spike concentrations of 0.00, 1.00, 2.00 and 3.00 ng/ml. The total analyte (M_a plus M_s) is then subjected to a preconcentration procedure. It is between the time of spike addition and completion of the preconcentration step that M_s can react with matrix components. In the model, we are concerned particularly with the degree of reaction of the spike with a ligand, L, during this time interval. In a real sample, several different ligands can be present that form metal complexes of various labilities but in order to keep the model simple only a single ligand, L, is considered. For the time interval, the following degrees of spike reaction (DSR) with L are assigned: 0, 25, 50, 75 and 100%. For DSR = 0, none of M_s has yet reacted with L; for DSR = 100%, M_s has come into complete equilibrium with L (whether the equilibrium constant be high or low) and is no longer distinguishable from M_a. The following equilibrium (charges omitted) depicts this situation:

$$(M_a + M_s) + L \overset{K_1}{\rightleftharpoons} (M_aL + M_sL) \qquad (1)$$

For intermediate values of DSR, only a portion of M_s has participated in the reaction with L. Thus, for DSR = 50%, half of the M_s ions have "seen" a ligand

Table 1. Calculation of combined spike and analyte recovery for DSR = 50%, F_t = 0.50; original analyte concentration 1.00 ng/ml

Spike added, *ng/ml*	Unreacted spike recovered, *ng/ml*	Reacted spike recovered, *ng/ml*	Analyte recovered, *ng/ml*	Combined spike and analyte recovered, *ng/ml*
0	0	0	1.00 × 0.50	0.50
1.00	0.50	0.50 × 0.50	0.50	1.25
2.00	1.00	1.00 × 0.50	0.50	2.00
3.00	1.50	1.50 × 0.50	0.50	2.75

and are either bound to L (and so are indistinguishable from M_aL) or have dissociated from M_sL (so are indistinguishable from M_a). The remaining half have not been complexed to L at all and in this sense are distinguishable from M_a ions.

In the calculation of the combined amount of added spike and original analyte that is recovered in the preconcentration step, the portion of unreacted spike is differentiated from the portion of reacted spike (and from the original analyte); it is assumed that the separation method is efficient enough to achieve quantitative separation of unreacted spike. In contrast, for the portion of reacted spike and for the original analyte, the degree of separation is unknown, because it will depend on the stability constants, concentrations and rates of reaction of the species involved, as well as the temperature, pH and other reaction conditions. Therefore, in the model the total amount of added spike and original analyte that is separated at each value of DSR is calculated for a range of fractions (F_t) of *reacted* spike plus original analyte transferred in the separation step. Nine values of F_t have been chosen (from 0.001 to 0.999) so nine standard-addition plots can be constructed for each value of DSR. Table 1 shows the calculation for the construction of the line represented by DSR = 50% and F_t = 0.50. A plot of combined recovery (last column) against spike concentration added (first column) gives an SAM line that yields 0.67 ng/ml as the original concentration analyte (1.00 ng/ml actually present) when extrapolated to the x-axis. For simplicity, the instrument response is assumed to be a linear function of concentration and is plotted as combined spike and analyte concentration found and the degree of preconcentration is not included in the calculation, since its use would simply involve multiplication and eventually division by the same number (the preconcentration factor).

Table 2. Recovery (ng/ml) of original analyte (1.00 ng/ml) as a function of DSR and F_t

F_t	DSR, % 0	25	50	75	100
0.001	0.001	0.001	0.002	0.004	1.00
0.0099	0.0099	0.013	0.020	0.038	1.00
0.091	0.091	0.12	0.17	0.28	1.00
0.24	0.24	0.30	0.39	0.56	1.00
0.50	0.50	0.57	0.67	0.80	1.00
0.76	0.76	0.80	0.86	0.93	1.00
0.91	0.91	0.93	0.95	0.98	1.00
0.990	0.990	0.992	0.994	1.00	1.00
0.999	0.999	0.999	0.999	1.00	1.00

Table 2 records the analytical estimates of the original analyte concentration for various combinations of DSR and F_t. Each value is derived from calculations as shown in Table 1 and the corresponding SAM plot. It should be noted that the range of F_t values corresponds to distribution ratios ranging from 10^{-3} to 10^3 for a solvent-extraction process involving equal phase volumes; strictly speaking, however, F_t is the fraction of reacted spike and original analyte transferred to the second phase in *any* two-phase separation procedure, whether or not equilibrium exists.

DISCUSSION

Complexing species in natural waters range from simple unidentate ligands such as chloride and hydroxide to amino-acids and high molecular-weight polyfunctional molecules such as polypeptides and humic materials. Trace metals exist in these media as hydrated ions, and as labile, moderately labile, and non-labile complexes and as colloidally-bound metal (inert). Useful operational definitions of lability have been proposed in terms of the time-frame of the experimental technique and evidence shows that the proportion of metal in each form is greatly dependent on the nature of the metal.[3,4,10]

A quantity often sought in the analysis of natural waters is the *total* soluble concentration of particular trace metals. Frequently, the determination is made by graphite-furnace AAS in conjunction with SAM and a preconcentration step. The relevant equilibria can be depicted simply as

$$M_a + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M_aL \quad (K_L) \qquad (2)$$

$$M_s + L \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} M_sL \quad (K_L) \qquad (3)$$

$$M_a + R \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} M_aR \quad (K_R) \qquad (4)$$

$$M_s + R \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} M_sR \quad (K_R) \qquad (5)$$

where L denotes a natural ligand, R the separation agent (*e.g.*, a solvent-extraction reagent or an ion-

exchange resin). K_L and K_R are the relevant equilibrium constants and k_1 *etc.* represent the appropriate rate constants.

A source of concern in these determinations is the problem of whether M_s has reached complete equilibration with the complexing matrix components (L) before completion of the preconcentration. The degree of spike reaction with L will decide the accuracy of the analysis. In Table 2, the recovery of analyte metal, present originally at 1.00 ng/ml, is shown for various degrees of spike reaction with L. At each value of DSR, the recovery has been calculated as a function of the fraction of reacted spike plus original analyte transferred to the organic phase or resin (see *Procedure*). The effect of DSR is illustrated by the data for $F_t = 0.50$ and the corresponding SAM plots (Fig. 1). Note that quantitative recovery of the analyte is possible only if the spike has completely equilibrated with L (DSR = 100%). If the spike has not reacted at all with L (DSR = 0%), only 50% of the original analyte is recovered (*i.e.*, 0.5 ng/ml). Also of interest is the fact that although the accuracy is diminished as DSR is decreased, the sensitivity is increased. This arises because the calculation is made on the basis that *unreacted* spike is quantitatively transferred and that the parameter F_t applies only to *reacted* spike and original analyte. At DSR = 0% the basis of the calculation is certainly valid since this situation merely corresponds to the case in which the rate constant k_1 is so small that in the time interval between spiking and the completion of preconcentration (usually only some minutes), no M_s has entered reaction with L. At the other extreme (DSR = 100%), k_1 is large enough to allow complete equilibration in the experimental time interval and no unreacted spike exists.

Several other features in Table 2 are noteworthy. (*i*) If DSR = 100%, the analytical recovery of analyte metal will be complete, regardless of the value of F_t

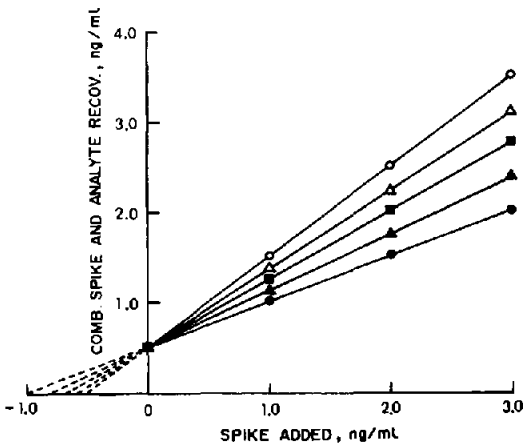

Fig. 1. Effect of DSR on analytical recovery of original metal analyte present (1.00 ng/ml), at $F_t = 0.50$. DSR = 0% (—○—); 25% (—△—); 50% (—■—); 75% (—▲—); 100% (—●—).

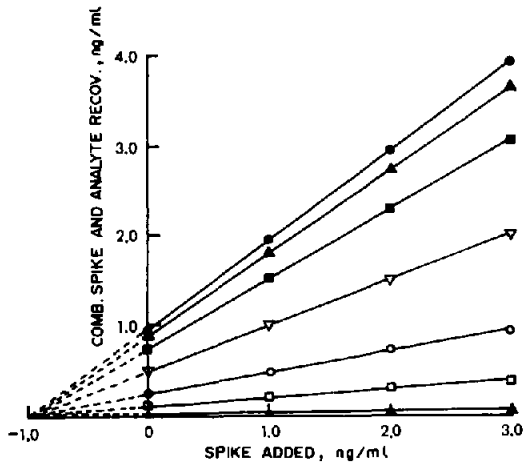

Fig. 2. Effect of F_t on analytical recovery of original metal analyte (1.00 ng/ml), at DSR = 100%. F_t = 0.99 (—●—); 0.91 (—▲—); 0.76 (—■—); 0.50 (—▽—); 0.24 (—○—); 0.091 (—□—); 0.0099 (—△—).

(last column and Fig. 2). The effect of F_t on sensitivity, however, is great and for the examples illustrated here, values of $F_t < 0.50$ are not practical. For higher concentrations of analyte and spike, lower F_t values could be tolerated. (*ii*) No matter what the value of DSR, complete recovery of the analyte metal is possible if F_t is sufficiently large (last two rows, where $F_t = 0.99$ and 0.999 corresponds to solvent-extraction distribution ratios of 10^2 and 10^3 for the matrix containing L).

It is assumed, of course, that the dissociation kinetics for M_sL (M_sL) and the formation kinetics for M_sR (M_sR) are favourable for the time interval involved. In fact, if the preconcentration reaction is sufficiently powerful to remove the analyte element quantitatively from its matrix, the application of SAM, which is a method for calibration of a chemical procedure and not merely of an instrument, is not necessary, because chemical interference from matrix components will not occur. A simple calibration graph prepared with use of the appropriate solvent would suffice. In this regard, it is interesting to observe that in a study of the preconcentration of trace elements from sea-water with silica-immobilized 8-hydroxyquinoline,[7] calibration was done by addition of a standard spike to the solution obtained *after* elution of the analyte element from the column. (*iii*) For the examples shown, the application of SAM is most practical for $F_t = 0.50$, 0.76 and 0.91. It should be stressed that quantitative separation of the spike and analyte element ($F_t \geq 0.99$) is not a prerequisite for a good analytical result. What *is* a prerequisite is knowledge that the spike has fully equilibrated with the matrix components. Very infrequently do investigators possess this knowledge. Indeed, complete recovery of the spike is not sufficient evidence that the analytical result is to be trusted, as such a recovery could simply be the result of unfavourable kinetics (*i.e.*, DSR = 0%), with no recovery of the analyte.

In summary, suitable combinations of thermodynamic and kinetic factors are required for SAM to yield reliable results. Two combinations are: (*i*) K_R sufficiently greater than K_L for F_t, if not in the range 0.99–0.999, to be large enough to be practical, and k_1, k_{-1} and k_2 ($\gg k_{-2}$) sufficiently large to allow complete spike equilibration and rapid formation of M_uR (M_sR); (*ii*) K_R large and $\gg K_L$, to give complete separation of the spike and analyte element ($F_t = 0.99$–0.999); k_1 can vary from a small value (DSR = 0%) to a high value (DSR = 100%) but M_uL (M_sL) should be labile (k_{-1} large) and M_uR (M_sR) should form quickly.

In the analysis of natural waters, investigators do not have enough knowledge of all relevant thermodynamic and kinetic parameters to be certain that complete spike equilibrium has occurred, and of the extent of separation of the analyte metal. Under these conditions, it would seem prudent to use powerful preconcentration separation methods—for example, solvent extraction systems that employ strong chelating agents which give complexes having good solubility in organic solvents, or strong chelating ion-exchange media, even more powerful than Chelex-100. Such media require considerably more development. One advantage of solvent extraction methods is the solubility of organic colloids, onto which metal ions are adsorbed.[9] If quantitative separation of spike and analyte cannot be ensured, then complete equilibration of the spike should be promoted, *e.g.*, by heating the spiked aliquot and allowing a reasonable amount of standing time before the preconcentration step. For storage of water samples, many investigators acidify the sample with nitric acid to pH 1–2. This practice is effective in minimizing adsorption of trace elements on the container walls. It would also appear to be an appropriate way to promote equilibration of the spike, in that organometallic complexes should be effectively dissociated at low pH. Thus, on adjustment of the pH for preconcentration, M_s and M_u should be indistinguishable, even if complexes reform. Finally, more drastic measures such as destruction of matrix components (*e.g.*, by ultraviolet irradiation) can be used when deemed necessary.

(*Received* 21 *January* 1982. *Accepted* 14 *April* 1982)

Summary—The possibility of applying diethylammonium diethyldithiocarbamate and butyl acetate for the extraction of copper, cadmium, lead and bismuth from molar solutions of orthophosphoric acid, and from solutions containing up to 55% pyrophosphoric acid and 20% tripolyphosphoric acid has been investigated. Some characteristics of the various diethylammonium diethyldithiocarbamate–butyl acetate–phosphoric acid systems are described. Suitable conditions have been found for flame atomic-absorption spectrometric determination of the ions extracted. This extraction/AAS approach has been used to determine copper, cadmium, lead and bismuth in some iron-, aluminium- and tin-containing samples dissolved in concentrated orthophosphoric acid. The same approach is used for determining 10^{-5}–10^{-6}% copper, cadmium and lead in orthophosphoric acid and in alkali-metal mono and dihydrogen phosphates.

Orthophosphoric acid and condensed phosphoric acid (CPA) are effective solvents for many inorganic substances, especially those containing iron, aluminium, chromium and silicon as matrix elements.[1–7] However, they find "somewhat limited use in analytical chemistry",[1] since the formation of various phosphate complexes and insoluble phosphates interferes in many of the subsequent steps of the analysis. In order to determine some major and especially some minor elements in phosphate media, efforts have been made to suppress the influence of the phosphate ions either by dilution[5] or by introduction of other mineral acids.[4]

In the present work an attempt is made to combine the efficiency of phosphoric acid as a solvent with a suitable method for separation of the determined elements both from the interfering phosphate ions and from the matrix element(s). Extraction of the determined elements directly from the phosphoric acid solution with diethylammonium diethyldithiocarbamate (DADDTC) and butyl acetate (BA) is found to be effective, and the procedure is applied to determination of Cu, Cd, Pb and Bi in some iron-, aluminium- and tin-containing samples.

DADDTC is a suitable reagent for extracting metal ions from highly acidic solutions.[8–13] It has the advantage of being poorly soluble in water and is therefore introduced into the extraction system as a solution in the organic solvent used. DADDTC is in this way somewhat protected against decomposition in the acidic aqueous phase. The extraction of metal ions from hydrochloric, sulphuric or nitric acid media with DADDTC in chloroform or tetrachloromethane has been studied[11,12] and the first of these solvents is widely used. In our work, flame-AAS determination of the extracted metals was envisaged and butyl acetate was therefore chosen as the solvent.

Extraction of dithiocarbamate complexes from orthophosphoric acid media has not been widely investigated.[14,15] In a previous work,[16] we showed that when phosphoric acid is heated, considerable amounts of pyrophosphoric, tripolyphosphoric and tetrapolyphosphoric acids are formed. The formation and extraction of diethyldithiocarbamate complexes in such media has not hitherto been studied. Possible interactions between the organic and aqueous phases have to be taken into account. Low stability has been reported[17–19] for some dithiocarbamate complexes extracted with basic organic solvents. Butyl acetate is also able to solvate the hydroxonium ion and thus to affect the stability and distribution of the extracted chelates.

EXPERIMENTAL

Reagents

Diethylammonium diethyldithiocarbamate. Solutions (0.01%, 0.1% and 1.0%) in n-butyl acetate or chloroform were prepared.

Cu(II), Cd(II), Pb(II) and Bi(III). Working solutions (10 μg/ml and 50 μg/ml) were prepared from Merck standard solutions.

Saturated aqueous solution of sodium bicarbonate. All

solutions were prepared with demineralized and doubly-distilled water and were tested for Cu, Cd, Pb and Bi.

The iron powder, potassium alum and stannous chloride (all Merck products) contained less than 10^{-6}% Cu, Cd, Pb or Bi.

Procedure

Fresh DADDTC solutions were prepared every third day. Preliminary experiments showed that on longer storage the concentration of the reagent decreased sufficiently to invalidate the results. The decrease is practically the same in both organic solvents tested.

The organic and aqueous phases were shaken mechanically in 100-ml reagent flasks and then transferred to separatory funnels. The aqueous phase was discarded and the organic phase filtered (medium-pore paper) into small glass test-tubes provided with stoppers. The filtration was found not to affect the results.

The distribution of the chelating agent was checked by determining the DDTC concentration in the organic phase: after the aqueous phase had been discarded, a saturated aqueous sodium bicarbonate solution containing an excess of Cu(II) was added to the separatory funnel and the concentration of the $Cu(DDTC)_2$ formed in the organic phase was determined spectrophotometrically.[20]

The metal ions were extracted with 5-ml portions of DADDTC solution in butyl acetate from 50 ml of aqueous solution containing different concentrations of phosphoric acid or mixtures of the various phosphoric acids. The composition of the mixtures was as follows: (*a*) 90% H_3PO_4 + 10% $H_4P_2O_7$; (*b*) 30% H_3PO_4 + 55% $H_4P_2O_7$ + 15% $H_5P_3O_{10}$; (*c*) 25% H_3PO_4 + 35% $H_4P_2O_7$ + 20% $H_5P_3O_{10}$ + 20% $H_6P_4O_{13}$; these solutions were prepared from 4 *M* orthophosphoric acid by heating. The procedure and the method of checking the acid contents are described in a previous paper.[16]

The concentration of the metal ions in the organic phase was determined by AAS (Pye Unicam SP 90, three-slot burner and air/propane flame) at the following wavelengths: Cu 324.8 nm, Cd 228.8 nm, Pb 217.0 nm and Bi 223.1 nm, with background correction. The calibration graphs were prepared by extraction of the metal ions from 15 ml of saturated aqueous sodium bicarbonate solution with 10 ml of 1% DADDTC solution in butyl acetate, over the concentration interval 0.1–1.0 μg/ml. Triple extraction was used to prove the quantitative recovery of Cu, Cd, Pb and Bi.

RESULTS AND DISCUSSION

Some characteristics of the extraction system

The extraction of a metal ion from acidic aqueous solutions with DADDTC is a complex and, in general, a non-equilibrium process. It may be represented as follows:

$$\begin{array}{ccccc} (\text{DADDTC})_0 & & (\text{HDDTC})_0 & & [\text{M(DDTC)}_n]_0 \\ \downarrow & & \rightleftarrows & & \\ (\text{DADDTC})_{aq} & \xrightarrow{H^+} & (\text{HDDTC})_{aq} & \rightleftharpoons & [\text{M(DDTC)}_n]_{aq} \\ & & \downarrow & & \\ & & (C_2H_5)_2NH_2^+ + CS_2 & & \end{array}$$

The following facts deserve special attention. The DADDTC is introduced into the extraction system as a solution in the organic solvent and decomposes rapidly (within a few seconds) into diethyldithiocarbamic acid (HDDTC) and diethylamine when the phases are shaken together. Thus, HDDTC is the chelating agent under these conditions.[21] At pH <4 over 99% of the HDDTC should be in the organic phase.[22] In acidic aqueous solutions HDDTC decomposes rapidly into carbon disulphide and protonated diethylamine. The apparent rate constant is pH-dependent at pH > 2 but constant at pH < 2.[23,24] A half-life of about 7 sec has been calculated for decomposition of HDDC in mineral acid solutions at 20°.[21] The diethyldithiocarbamate complexes are formed in the aqueous phase.

The properties of the organic solvent must also be taken into account, since (*a*) the solvent chosen determines the distribution of HDDTC and $M(DDTC)_n$ between the phases; (*b*) butyl acetate and water are partly mutually soluble; (*c*) being a basic solvent, butyl acetate solvates hydroxonium ions and in this way extracts mineral acids from the aqueous phase. These interactions may cause decomposition of the reagent and the complexes in the organic phase, or at least may change those characteristics of the two phases which determine the distribution of the species between the phases.

Because of the complex character of this extraction system, in this work only some overall effects due to the interactions mentioned were examined. The results were used to optimize the extraction conditions for Cu, Cd, Pb and Bi.

As a first step, the distribution of HDDTC was checked. Some information can be obtained from the fact that decomposition of HDDTC in the aqueous phase causes gradual decrease in its concentration in the organic phase when the phases are contacted. In the case of the 1*M* $HCl/CHCl_3$–HDDTC and 1*M* HCl/CCl_4–HDDTC systems it has been shown[21] that the ratio of the time needed for a 50% decrease of the HDDTC concentration in the organic phase ($\tau_{50\%}$) to the half-life of HDDTC in the aqueous phase ($\tau_{\frac{1}{2}}$) is approximately equal to the distribution constant. We studied this relation for the systems 4*M* H_3PO_4/BA–HDDTC, 4*M* $H_3PO_4/CHCl_3$–HDDTC and 1*M* $HCl/CHCl_3$–HDDTC, where BA stands for butyl acetate. The results were expressed as described by Bode and Neumann[21] (Fig. 1). The following values were found for the ratio if $\tau_{\frac{1}{2}}$ is taken as 7 sec: for 4*M* H_3PO_4/BA–HDDTC 34, for 4*M* $H_3PO_4/CHCl_3$–HDDTC and 1*M* $HCl/CHCl_3$–HDDTC 2570 (*cf.*[21] 2700 for 1*M* $HCl/CHCl_3$–HDDTC). No influence of the nature of the mineral acid was noted in the case of chloroform as solvent, but in the case of BA it was found that $\tau_{50\%}$ depends on the acid used, the order being $H_3PO_4 > H_2SO_4 > HCl$. The extractability of these acids with basic organic solvents increases in the same order.[25,26]

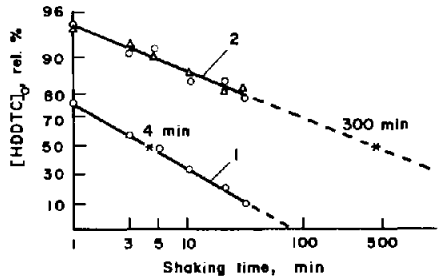

Fig. 1. The HDDTC concentration in the organic phase in relation to the shaking time; 1 butyl acetate; 2—chloroform: ○—4*M* H_3PO_4; △—1*M* HCl; $V_{org} = V_{aq} = 20$ ml.

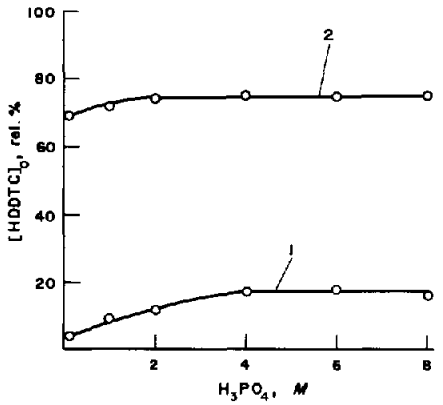

Fig. 2. The HDDTC concentration in the organic phase in relation to the H_3PO_4 concentration in the aqueous phase; $V_{org} = 5$ ml; $V_{aq} = 50$ ml; shaking time 10 min; 1—butyl acetate; 2—chloroform.

The influence of the phosphoric acid concentration (Fig. 2) and of the degree of condensation of the acid (Table 1) on the HDDTC distribution was also investigated. The acidity was always in the range where the HDDTC decomposition rate can be considered constant. Thus changes in the HDDTC concentration in the organic phase as a function of type of acid used could be considered as due solely to variations in the HDDTC distribution. As can be seen, the HDDTC concentration in the organic phase increases with increasing phosphoric acid concentration (up to 4*M*) in the aqueous phase and also with the degree of the phosphoric acid condensation. No significant difference between the two organic solvents was noted. In practice this means that the poor extraction of metal ions from phosphoric acid solutions may be due not only to the formation of phosphate complexes but also to the lower HDDTC concentrations in the aqueous phase.

We assume that there is a slight salting-out effect when the concentration of the highly hydrated phosphoric acids increases.

Stability of the extracted complexes with time

Irreproducible AAS signals were obtained for Cu, Cd, Pb and Bi extracted from solutions with acidity higher than 1*M* phosphoric acid. The values varied with the time needed for the phases to separate and with the interval of time between the extraction and the AAS determination. Rapid discard of the aqueous phase did not lead to significantly better results. Gradual decomposition of the extracted DDTC complexes caused by acidic aqueous phase finely dispersed in the organic phase was assumed to be the possible reason. Washing the organic phase with water, or better with saturated sodium bicarbonate solution, was found to be very effective for preventing this. Washing with bicarbonate solution does not appreciably change the extraction recovery of the metal ions.

When treated in this manner and stored in the cold and the dark, the extracts were stable for at least 20 days.

The shaking time

The extraction does not reach equilibrium, because the HDDTC decomposes rapidly in the aqueous phase. Thus the shaking time is critical in obtaining quantitative results. The relation between the recovery and the shaking time for Cu, Cd, Pb and Bi was investigated. It was found that shaking for no longer than 5–7 min is optimal for the simultaneous extraction of the four elements from 4*M* phosphoric acid with 1% DADDTC solution in butyl acetate. Longer shaking decreases the recovery of Cd and Pb.

Extraction of Cu, Cd, Pb and Bi from phosphoric acid

The extraction of each element was studied at different phosphoric acid concentrations and in the presence of polyphosphoric acids. Three DADDTC concentrations were used (Table 2). Cu, Cd, Pb and Bi are extracted simultaneously with 1% DADDTC in BA from solutions with concentrations of up to 4*M*

Table 1. Concentration of HDDTC in the organic phase in relation to the degree of condensation of H_3PO_4 in the aqueous phase; $V_{org} = 5$ ml, $V_{aq} = 50$ ml; shaking time 10 min

H_3PO_4, 50% $H_4P_2O_7$, 20% $H_5P_3O_{10}$ and 4M alkali-metal mono or dihydrogen phosphate. BA is not a suitable solvent when the aqueous phase contains tetrapolyphosphoric acid, because a stable emulsion is formed.

Extraction of Cu, Cd, Pb and Bi from phosphoric acid solutions containing Fe, Al and Sn as matrix elements

Potassium alum, stannous chloride and iron powder were used as matrices for testing the extraction of Cu, Cd, Pb and Bi from a complex metal-ion–phosphate matrix. Model solutions were prepared by dissolving the matrix substance in concentrated phosphoric acid with heating. Cu, Cd, Pb and Bi, 10 μg each, were added prior to heating. No influence of the matrix on the extraction or the AAS determination was found in the presence of up to 300 mg of Al or Sn. The extraction of Cd and Pb was completely suppressed in the presence of 2 mg of iron, but masking of iron with 50% ammonium fluoride solution was found to be effective in this case. A 2–4% ammonium fluoride solution was found to be effective for preliminary stripping of the organic phase to remove the matrix element from the aqueous phase finely dispersed in the organic phase (prior to the stripping with bicarbonate). Without this preliminary stripping there will be considerable extraction of iron, accompanied by interference in the AAS determinations,[27] and in the case of aluminium and tin as matrix elements there will be extensive hydrolysis accompanied by losses of the determine elements. It was found experimentally that stripping with ammonium fluoride did not adversely affect the extraction.

Applications

The general scheme is as follows. The sample is dissolved in concentrated phosphoric acid or in a mixture of concentrated phosphoric acid and 1–1.5 ml of concentrated nitric, sulphuric and hydrochloric acid in fused silica beakers. The solution thus obtained is diluted to 50 ml (final phosphoric acid concentration ~4M) with demineralized and doubly-distilled water. Cu, Cd, Pb and Bi are extracted from the total volume or from a suitable fraction of it, depending on the expected Cu, Cd, Pb and Bi content. If a fraction is used, enough concentrated phosphoric acid is added to give a final concentration of 4M, and the resulting solution is diluted to 50 ml. The Cu, Cd, Pb and Bi are then extracted by shaking

for 5–7 min with 5 ml of 1% DADDTC solution in BA. The aqueous phase is discarded and the organic phase stripped by shaking for 10–20 sec with 5 ml of 2–4% ammonium fluoride solution. The aqueous phase is discarded and the organic phase again stripped, by shaking for 15–30 sec with 10 ml of saturated sodium bicarbonate solution. The aqueous phase is discarded and the organic phase filtered through a medium paper into a suitable test-tube. A blank containing all the reagents is prepared and extracted and stripped in the same way as the samples. Cu, Cd, Pb and Bi are determined in the samples and blanks by AAS. The calibration graphs covering the range 0.1–2.0 μg/ml are prepared by simultaneous extraction of the four elements from 50 ml of 0.1*M* phosphoric acid with 10 ml of 1% DADDTC solution in BA, and AAS analysis of the extract.

By this procedure the Cu, Cd, Pb and Bi content was determined in iron metal, in Cr–Ni high-alloy steel, in aluminium metal, in γ-alumina, in tin metal, in orthophosphoric acid and in alkali-metal mono and dihydrogen phosphates. The results are presented in Tables 3 and 4. Some specific details follow.

Iron metal. A 0.1–1.0 g sample is dissolved in 15 ml of concentrated phosphoric acid and a few drops of concentrated nitric acid. The time needed for complete dissolution depends on the grain size of the sample.

Cr–Ni steel. A 0.1–1.0 g sample is dissolved in a mixture of 15 ml of concentrated phosphoric acid, 1.5 ml of concentrated nitric acid, and 1.0 ml each of concentrated sulphuric and hydrochloric acids with heating at 270–280°. About 2 hr are needed for complete dissolution. Ten ml of 50% ammonium fluoride solution are needed to mask the iron in a 1.0-g sample.

Aluminium metal. Samples of 0.1–1.0 g are dissolved as for iron metal. When the vigorous reaction is over, the samples are heated for about 2–3 hr on a sand-bath.

γ-Alumina. Fifteen ml of concentrated phosphoric acid are heated at 270–280° on a sand-bath for 40 min so that polyphosphoric acids are formed. Then a sample of 0.1–2.0 g of γ-alumina is carefully added and heating continued until dissolution is complete. Before the dissolution is over, 10–15 ml of doubly-distilled water and 0.1–0.2 ml of concentrated sulphuric acid are *cautiously* added to prevent condensation of the phosphoric acid to too high a degree.

Tin metal. A sample of 0.1–1.0 g is dissolved as for Cr–Ni steel; 20–40 min are needed for complete dissolution.

Phosphoric acid and alkali-metal phosphates. A sample of 10–15 ml of concentrated phosphoric acid or 5–10 g of alkali-metal phosphate is diluted (or dissolved) with doubly-distilled water to give a total volume of 50 ml. Extraction is done as described above. Only the stripping with bicarbonate is required.

The results presented in this work show that DADDTC and BA may be successfully used to extract Cu, Cd, Pb and Bi from concentrated solutions of phosphoric acid even when the aqueous solution contains considerable amounts of pyrophosphoric and/or tripolyphosphoric acid. Rapid discard of the aqueous phase and stripping of the organic phase are required in order to obtain results with good reproducibility. We assume that this conclusion will also apply to systems employing other basic organic solvents used in AAS. We assume also that the procedure may be successfully applied when CPA is used as the solvent. In that case, phosphoric acid solutions with a composition near to that employed here can be prepared by partial hydrolysis of the CPA (when the sample has dissolved) with sulphuric acid and water.

SHORT COMMUNICATIONS

ORGANOSULPHUR BEHAVIOUR IN A GC/MS MEMBRANE INTERFACE

MICHAEL THOMPSON* and MIRIAM STANISAVLJEVIĆ†
Department of Chemistry, University of Toronto, 80 St. George Street, Toronto, Ontario M5S 1A1, Canada

(*Received* 19 *March* 1982. *Accepted* 17 *April* 1982)

Summary—The behaviour of 0.1–1.0 ng amounts of S as dimethyldisulphide, n-butanethiol and di-isopropylsulphide in a membrane gas-chromatograph/mass-spectrometer interface has been studied. Results are presented for an all-Teflon system which incorporated a membrane housing constructed from either glass or polymer.

The identification of organosulphur compounds is important in environmental, industrial, clinical and biochemical analysis. Various methods have been used to study such species present in a wide spectrum of samples, including atmospheric pollutants, petroleum spills, marine sediments, pesticide residues, flavour volatiles, mouth air and natural gas. Much of this work has been done by gas chromatography with flame photometric detection (FPD), where both loss due to adsorption and catalytic structural changes caused by components of the analytical system have been a source of concern for some time.[1] It is of note that similar difficulties have been encountered in the HPLC of metal diethyldithiocarbamates.[2,3] Interfacing transfer lines and devices that are constructed from metal and glass to connect the gas chromatograph to the mass spectrometer are expected to exhibit analogous behaviour. Recently we presented the design of a relatively inert (Teflon) connection, with a membrane separator, for the packed-column GC/MS analysis of organosulphur compounds of low molecular weight.[1] The present paper describes an appraisal of losses due to adsorption of these compounds on glass, based on comparison of the performance of a similar device constructed from glass.

EXPERIMENTAL

Equipment

The all-polymer interface consisting of transfer lines with four-port valve system, membrane housing and re-entrant tube between a Varian 2740 gas chromatograph and a modified AEI MS-902 mass spectrometer was as described previously. A glass separator similar in design to the polymer device, and fitted with a glass frit for membrane support, was used interchangeably with the polymer separator. A flame photometric detector (FPD) was used.

Procedure

The performance of the Teflon separator was assessed at various nitrogen flow-rates and interface temperatures with sequential injections of 0.1-μg amounts of standard compounds, once without connection of the mass spectrometer, and the second with the MS operating in the single-ion monitoring (SIM) mode at the m/z value of a common fragment (CH_3S^+). The yields were evaluated by peak-area subtraction of the second FPD signal from the first. The amount entering the ion source at this relatively high concentration was confirmed by a separate calibration check. By a similar procedure used at 60° and a flow-rate of 15 ml/min the test compounds (0.1, 0.5 and 1.0 ng as S) were introduced into the all-polymer system and the interface incorporating the glass separator.

RESULTS AND DISCUSSION

The yields for the 0.1-μg amounts of the standard organosulphur compounds with the all-Teflon system exhibit a decreasing trend with increase of separator temperature and diminish markedly with higher flow-rates (Table 1). These results are consistent with the expected behaviour of the silicone membrane with respect to compound solubility and diffusion, although the highest value (70%) does not match the yield of over 90% reported by other workers.[4]

The yields for dimethyldisulphide, n-butanethiol and di-isopropylsulphide obtained with the Teflon separator, together with the relative SIM signals and amount lost in the glass device, are shown in Table 2. The mass-spectral signals appear to reflect the amounts transferred by the membrane, although at the 0.1-ng level the signals were barely discernible, a reasonable result in view of the fact that the limit-of-detection of the mass spectrometer system used was approximately 0.05 ng. A complete absence of any

	1.0	52.0	1.2	0.30

*No SIM signal detected.

SIM signal was observed for the experiments conducted with the glass separator. Accordingly, we attribute the loss to surface adsorption both before and after the membrane in the analytical train. The relatively large loss of n-butanethiol at the 0.10-ng level is not surprising in the light of well-known tendency of thiols to adsorb on surfaces. Silanization of the glass separator by conventional methods improved the situation marginally but did not produce the results given by the all-polymer system.

This preliminary work confirms that adsorption losses of organosulphur species at low concentration levels are to be expected in glass interfaces and that the polymer system can be used successfully, even if only at moderate temperatures.

DETERMINATION OF TIN IN POLY(VINYL CHLORIDE) BY ATOMIC-ABSORPTION SPECTROSCOPY

JAMIL ANWAR and I. L. MARR
Chemistry Department, Aberdeen University, Old Aberdeen, Scotland

(*Received* 22 *February* 1982. *Accepted* 8 *May* 1982)

Summary—A simple procedure is described for the determination of tin in PVC by atomic-absorption spectroscopy with an air–hydrogen flame, after wet digestion of the sample with sulphuric acid and hydrogen peroxide.

Organotin compounds have been used as stabilizers in poly(vinyl chloride) for several years and are generally present to the extent of 1–2%. A significant amount of work has been done on the analysis of these stabilizers but mostly in relation to qualitative aspects[1,2] or to the determination of specific organotin compounds.[3,4] On the other hand, not much work has been published on the determination of total tin in poly(vinyl chloride).

Bergnes *et al.*[5] determined tin in PVC by titration with EDTA after dissolution in hot tetrahydrofuran and dilution with ethanol to precipitate the PVC, which was filtered off. Olivier[6] adopted a similar approach for extracting the tin into an aqueous phase but then back-extracted it into methyl isobutyl ketone (MIBK) from the aqueous solution at pH 4–5 containing ammonium pyrrolidine dithiocarbamate. The MIBK extract was then aspirated into an air–acetylene flame. Fassy and Lalet[7] determined tin in PVC at a level of 300 μg/g by ashing the sample, converting tin into its acetate and nebulizing the solution into an air–acetylene flame for atomic-absorption measurement at 224.6 nm.

In attempts to determine tin in PVC samples in this laboratory none of the above-mentioned methods gave adequately precise results. Therefore a comparatively simple procedure based on decomposition with sulphuric acid and hydrogen peroxide[8] and aspiration of the aqueous solution into an air–hydrogen flame to measure the tin absorption, has been adopted. The method is easy, rapid and sufficiently precise.

EXPERIMENTAL

Instrument

A Perkin–Elmer 305 atomic-absorption spectrophotometer was used with a 10-cm single-slot burner and readout on a chart recorder. Tin absorption was measured at 224.6 nm; an air–hydrogen flame was used.

Procedure

Weigh out 0.1 g of PVC sample and transfer it to a micro Kjeldahl tube. Add 1 ml of concentrated sulphuric acid and char by gentle heating. Complete the decomposition by heating for about 10 min with slow dropwise addition of 2 ml of 50% hydrogen peroxide. Boil the contents for another 5 min to remove all the hydrogen peroxide and water. The liquor should be colourless. Let it cool and transfer it to a 25-ml standard flask. Rinse the Kjeldahl tube and make up to volume with water. Determine the atomic absorbance as for the standards (see below).

Calibration

Prepare a 500-ppm solution of tin by dissolving 0.250 g of pure tin metal in 25 ml of concentrated hydrochloric acid and diluting accurately to 500 ml with water. Transfer an aliquot containing 0.5–2.5 mg of tin into a 100-ml standard flask followed by 3 ml of concentrated sulphuric acid and 8 ml of hydrogen peroxide. Shake to mix and make up to the mark with water. Prepare a blank by taking the same volumes of sulphuric acid and hydrogen peroxide. Nebulize the calibration solutions and samples into a fuel-rich air–hydrogen flame and measure the tin absorbance at 224.6 nm.

RESULTS AND DISCUSSION

The effects of acids and the blank

It has been shown[9] that the presence of concentrated hydrochloric acid, even up to 20% v/v, does not effect the atomic-absorption determination of tin, so the presence of less than 0.3% v/v hydrochloric acid in the calibration solutions but none in the samples was considered not to present any difficulties. Sulphuric acid does cause a slight depression in the tin absorption, however,[9] so equal amounts of this acid should be present in both calibration and sample solutions.

Sodium stannate is sometimes used as stabilizer to prevent the slow decomposition of hydrogen peroxide. Though with analytical-reagent grade hydrogen peroxide the amounts of sodium and additional tin were so minute that in practice the blank (containing a volume of hydrogen peroxide equivalent to that used for the sample) did not give any noticeable absorbance, and was unnecessary, in cases where the hydrogen peroxide does contain considerable amounts of sodium stannate, the preparation of a blank would be essential.

PVC Sample	Additive	No. of determinations	Sn,%	
			Stated	Found
A	Dioctylthiotin	3	0.152	0.146
B	Dibitylthiotin	3	0.152	0.144
C	Butyltin maleate	5	0.159	0.153

Other methods

The methods mentioned in the introduction were all tried, but none gave acceptable results, which led to the need for a new method.

A dry-ashing procedure was tried in which up to 1 g of sample was ignited at 800° in a silica crucible, but nothing was left after half an hour. In another attempt 0.5 g of sample was heated with 2 g of magnesium nitrate at 800° for half an hour. The residue was dissolved by adding hot hydrochloric acid but no trace of tin could be detected in the solution.

Extraction of tin by dissolving the PVC in an organic solvent and reprecipitating only the polymer by addition of water or ethanol was also tried. The ethanol extract was titrated with 0.001*M* EDTA, with Catechol Violet as indicator, as described by Burgnes *et al.*[5] and also the aqueous extract was aspirated into an air–hydrogen flame, but the results obtained in both cases, and given in Table 2, were poor and imprecise, which is most probably due to incomplete extraction of the tin or its adsorption on the precipitated polymer.

Another approach suggested by Olivier[6] for the determination of trace metals in polymers is based on the direct aspiration of a 2% solution of the polymer in an organic solvent into the flame. This method was also tried but in this case rapid blockage of the burner assembly was indicated by a sharp decrease in the absorption with time. A comparison of results and standard deviations obtained by the different methods is shown in Table 1.

Analysis of PVC samples

By courtesy of Messrs. Albright and Wilson three samples of PVC, each containing a different additive at around the 1–2% level, were made available: 100 mg of sample could be easily and completely decomposed with 1 ml of concentrated sulphuric acid and 2 ml of 50% hydrogen peroxide. The whole decomposition procedure took 15 min at the most.

The air–hydrogen flame was found adequately sensitive for the amounts of tin present in the samples and a linear calibration graph for tin in the range 5–20 μg/ml could easily be obtained by use of a slightly fuel-rich flame.[10] The results obtained for the analysis of PVC samples containing various organotin additives are given in Table 2. A relative standard deviation of 2% was obtained for five successive determinations of butyltin maleate in PVC.

In conclusion, with the present method tin can be determined with more satisfactory results and with very little effort, compared to other methods given in the literature.

RADIOCHEMICAL DETERMINATION OF COBALT-60 IN ENVIRONMENTAL SAMPLES*

C. D. JENNINGS
Western Oregon State College, Monmouth, OR 97361, U.S.A.
and
T. M. BEASLEY
Oregon State University, Marine Science Center, Newport, OR 97365, U.S.A.

(*Received* 20 *December* 1981. *Accepted* 13 *April* 1982)

Summary—A procedure for the radiochemical determination of ^{60}Co in low-activity samples of sediment and biological material is described. Cobalt recovery is high and decontamination from tervalent lanthanides and naturally-occurring radionuclides is complete. Cobalt is precipitated with 1-nitroso-2-naphthol, decontaminated from iron by precipitation of the iron as ferric phosphate, extracted into methyl isobutyl ketone, and finally precipitated as cobalt mercury(II) thiocyanate for yield determination and beta-counting.

Decreasing concentrations of radiocobalt (principally ^{60}Co) in the environment during the past twenty years have made its accurate measurement in natural materials increasingly difficult. Reliance on NaI(Tl) gamma-ray spectrometry, a technique that worked well when activities of radiocobalt were much higher than those of naturally-occurring gamma-emitters in the environment, is no longer of sufficient accuracy now that the isotopes of cobalt are often masked by the spectrum of natural radioactivity. Nor does the refinement of Ge(Li) detectors solve this problem: while affording much better resolution than NaI(Tl) detectors, the efficiencies of Ge(Li) for the high-energy gamma-ray transitions of ^{60}Co (1.17 and 1.33 MeV, respectively) are low and make its use for quantification of trace amounts of this radionuclide questionable. The solution lies in the radiochemical separation of cobalt from interfering stable and radioactive elements, thus allowing the ^{60}Co to be determined by low-level beta-counting techniques.

Previously published radiochemical separation procedures for cobalt radioisotopes have emphasized purification from highly radioactive fission-product or neutron-activation product matrices.[1-4] In these instances, neither high chemical yield nor separation from natural radioactivities is important. The same cannot be said, however, for the determination of low levels of radiocobalt in environmental samples.

This paper describes a simple, effective method of extracting cobalt from sediment and biological matrices in a form suitable for the ^{60}Co beta-emissions to be counted. The advantages of the separation scheme described are (1) cobalt is isolated from a wide range of elements existing in natural samples, by precipitation with 1-nitroso-2-naphthol; (2) the difficult isolation of cobalt from iron is accomplished by precipitation of ferric phosphate; (3) it is the first procedure to confirm decontamination from residual fallout and naturally-occurring radionuclides present in environmental materials today.

It should be mentioned that nuclear power plants produce more ^{57}Co and ^{58}Co than ^{60}Co. In the radiocobalt analysis of samples collected from such locales, the purified cobalt fraction should be counted on a gamma-ray spectrometer to determine the isotopic composition of the sample.

EXPERIMENTAL

Reagents

Use reagent grade chemicals unless otherwise specified, and use doubly distilled water in the preparation of all solutions and in steps requiring water washes.

Ammonium mercury(II) thiocyanate. Dissolve 316.8 g of mercury(II) thiocyanate, in 250 ml of 1*M* ammonium chloride.

Cobalt carrier and yield monitor (Co 10 mg/ml). Dissolve 4.04 g of cobalt chloride hexahydrate in water and dilute to volume in a 100-ml standard flask. The solution can be standardized by precipitating the cobalt in a 1-ml aliquot with sodium hydroxide, centrifuging the precipitate and then washing it with water, transferring it with ethanol to a 2.5-cm stainless-steel planchet and drying it under a heat lamp. The weight of cobalt hydroxide obtained is reproducible.

1-Nitroso-2-naphthol solution. Dissolve 10 g of 1-nitroso-2-naphthol in 100 ml of glacial acetic acid.

Trisodium phosphate solution. Dissolve 23.05 g of trisodium phosphate (12-hydrate), in 1 litre of water.

Procedures

Sediment dissolution. Weigh 10 g of sediment into a 250-ml plastic beaker, add 1 ml of cobalt yield monitor, 50 ml of 8*M* nitric acid, 50 ml of concentrated hydrofluoric

*Supported by the U.S. Department of Energy under contract DE-AT06-76EV70030.

acid and evaporate to dryness under a heat lamp. Add about 100 ml of 6*M* hydrochloric acid and evaporate to dryness again. Transfer the residue to a glass beaker with 6*M* hydrochloric acid; add 100 ml of 6*M* hydrochloric acid to the plastic beaker along with 1 g of boric acid, warm under a heat lamp until the boric acid is dissolved, and then transfer to the glass beaker. Evaporate on a hot-plate to 50 ml and then filter through S&S white-band filter paper. Put the filter back into the glass beaker, add 10 ml of concentrated nitric acid and 10 ml of concentrated perchloric acid, boil till fumes of perchloric acid appear and filter through a glass fibre filter, combining this filtrate with the previous one. Retain the filtrate for cobalt determination.

Total dissolution is preferred to leaching, because Duursma *et al.*[5] have shown that the longer clay sediments are in contact with a solution containing radioactive cobalt, the greater is the fraction that is not extracted by weak leaching agents. Moreover, 6*M* hydrochloric acid has been found to remove only 75–85% of the ^{55}Fe and 65% of the stable iron from Columbia River sediments,[6] and cobalt would be expected to behave similarly.

Dissolution of biological material. Place a known weight of dried biological sample in a beaker, add 1 ml of cobalt yield monitor, slowly bring the temperature up to 450° in a muffle furnace, and ash the sample for 24 hr or until a light grey ash forms. Cool the sample, dissolve the residue in 100 ml of 6*M* hydrochloric acid, then reduce the volume to 50 ml on a hot-plate. Filter through S&S white-band filter paper, and continue as described above for sediments, from the same stage in the procedure.

Cobalt determination. Dilute the filtrate from the dissolution procedure until its acid concentration is 1*M*. Add approximately 2 g of hydroxylamine hydrochloride. Bring almost to the boil, add 7 ml of the 10% 1-nitroso-2-naphthol solution and boil for 2 min. Filter off on S&S white-band filter paper, wash several times with water and discard the filtrate. Place the filter and precipitate in a 250-ml beaker, add 10 ml each of concentrated nitric and perchloric acids and heat to fumes of perchloric acid to destroy the precipitate. Transfer to a 50-ml centrifuge tube, dilute to 20 ml and precipitate cobaltous hydroxide with sodium hydroxide. Centrifuge, discard the supernatant solution and wash the precipitate with water. Dissolve the precipitate in a minimum of concentrated hydrochloric acid with heating in a water-bath (80°). Dilute to about 20 ml with water. For each 20 mg of iron present, add 5 ml of 0.1*M* trisodium phosphate. Adjust to approximately pH 5–6 with ammonia solution, then to pH 3–3.5 by adding 1 ml of glacial acetic acid. Heat in a boiling water-bath to coagulate the precipitate of ferric phosphate. Filter off on S&S white-band paper, collecting the filtrate in a clean 50-ml centrifuge tube, and wash the precipitate three times with hot, dilute (2.5% v/v) acetic acid. Discard the precipitate. Precipitate cobaltous hydroxide from the combined filtrate and washings with sodium hydroxide, centrifuge and wash the precipitate with water. Dissolve the precipitate in a minimum of concentrated hydrochloric acid (2 or 3 drops) with heating in a hot water-bath, dilute to 10 ml with water and add 2 ml of concentrated ammonia solution. Filter into a 125-ml separatory funnel. Discard the filter. Add 2 ml of glacial acetic acid, 20 ml of 25% ammonium thiocyanate solution and 20 ml of methyl isobutyl ketone (MIBK) to the separatory funnel and shake it for 5 min. Allow the phases to separate and discard the aqueous phase. Add 20 ml of 25% ammonium thiocyanate solution and shake for 1 min. After phase separation, discard the aqueous phase. Repeat this washing step. Strip the cobalt by shaking with two 5-ml portions of water for 30 sec each time. Combine these two aqueous extracts in a clean 50-ml glass centrifuge tube. Add 3 drops of concentrated hydrochloric acid. Heat nearly to boiling and add 2 ml of 1*M* ammonium mercuric thiocyanate. Cool in an ice-bath and stir vigorously with a glass rod until precipitation of the blue cobalt mercuric thiocyanate is complete. Centrifuge, and discard the supernatant solution. Wash the precipitate with cold water, then with cold ethanol, discarding the washings. Add 1 ml of ethanol, shake to obtain a suspension of the precipitate and transfer this with a Pasteur pipette to a weighed 2.5-cm stainless-steel planchet. Rinse the centrifuge tube with 250 μl of ethanol and add this immediately to the planchet to ensure an even coating with the precipitate. Dry under a heat lamp and weigh as $Co[Hg(SCN)_4]$ (11.98% cobalt). Count on a low-background beta-counter, making appropriate corrections for chemical yield, self-absorption and efficiency.

RESULTS AND DISCUSSION

A radiochemical procedure for cobalt can be in error if it fails to separate the cobalt from major stable element interferences or if it is not sufficiently specific and contaminating radionuclides are isolated along with the cobalt. Part of the procedure described here has been shown to decontaminate cobalt from reactor fission products and activation products in samples cooled for only 5–24 hr,[1] but no consideration was given to separation of cobalt from environmental samples or its isolation from natural radionuclides. Present-day environmental materials, such as Columbia River sediments, are much more likely to be contaminated by transuranic radionuclides (Pu and Am), and long-lived fission and neutron-activation products such as ^{137}Cs, ^{55}Fe and tervalent lanthanides, especially radionuclides of Eu. This is evident in the work of Robertson *et al.*[7] and from the radionuclides certified by the National Bureau of Standards (NBS) for certain of their standard reference materials discussed below.

As shown in Table 1, the extraction by MIBK is completely selective for separation from tervalent ^{152}Eu; the slightly higher count-rate for ^{152}Eu in the aqueous phase after the MIBK extraction is due to the slight decrease in volume of the aqueous phase. The efficiency of decontamination from naturally-occurring radionuclides was confirmed by extracting cobalt from deep-sea sediments which measurements of ^{239,240}Pu activity had previously shown to be below the depth of man-made radioactivity. Replicate analyses produced count-rates indistinguishable from the background. The completeness of decontamination of cobalt from naturally-occurring radionuclides is further supported by the fact that our results on the Columbia River sediment standard reference material supplied by the NBS (Table 2) are in excellent agreement with the certified value. This material also contains substantial amounts of ^{228}Th, ^{230}Th and ^{232}Th in radioactive equilibrium with their daughter products, as well as ^{137}Cs, ^{152}Eu and ^{55}Fe. A 10-g sample was used for the sediment analysis because the amount available is often limited, but the procedure should be applicable to samples of up to 50 g.

The procedure is applicable to the analysis of both sediments and biological materials (Table 2), attesting

to its utility in the analysis of environmental materials. When the procedure was traced with ^{60}Co, 92 ± 2% of the cobalt was found to be carried through the extraction with MIBK, and the recovery of $Co[Hg(SCN)_4]$ was 95 ± 5%, giving an overall chemical recovery of 86 ± 5%. With care and familiarity, the entire procedure should easily provide cobalt recoveries of at least 75%.

Some notes from our testing of this procedure may be helpful in circumventing problems that occur if this analysis is attempted in series with other radiochemical separations. First, cobalt is not collected effectively by either calcium oxalate or calcium sulphate from dilute acid solutions. Secondly, a substantial but variable proportion of the cobalt is co-precipitated when hydrous ferric oxide is precipitated with ammonia as suggested by Marsh and Maeck.[1] To separate cobalt from iron we used Young and Hall's[9] procedure precipitating ferric phosphate, which we found co-precipitated only 3% of the cobalt.

Finally, the precipitate of $Co[Hg(SCN)_4]$ will not form easily unless the volume is kept low and 3–4 mg of cobalt are present in the sample. If a plastic centrifuge tube is used for this step, a substantial amount of the precipitate adheres to the walls and cannot be recovered. In our experiments, 55 ± 7% of the cobalt was recovered in plastic tubes and 95 ± 5% in glass tubes.

ANNOTATIONS

ON THE ACID DECOMPOSITION OF HUMAN BLOOD AND PLASMA FOR THE DETERMINATION OF SELENIUM

M. VERLINDEN*
Department of Pharmaceutical Sciences, University of Antwerp (U.I.A.) Universiteitsplein 1, B-2610 Wilrijk, Belgium

(*Received* 19 *January* 1982. *Accepted* 20 *May* 1982)

Summary—A systematic investigation has been made of various methods for decomposition of blood and plasma for determination of selenium, and various sources of error have been identified. The method recommended is graded destruction by heating with nitric acid and perchloric acid, to a final temperature of 210°.

Because of the increasing interest in selenium as an essential trace element for human physiology, classical methods for its determination have given way to more sensitive techniques such as fluorimetry[1] and hydride-generation atomic-absorption spectrometry[2] which are capable of determining ng amounts of the element. Most methods require dissolution of the sample, and in the case of the two techniques just mentioned, selenium must be present as selenium(IV). As with any analytical procedure, the sample preparation must not introduce appreciable errors. With selenium, two opposing phenomena are involved. Many selenium compounds are volatile and can be lost during an ill-controlled destruction procedure. It seems less well recognized that very acid-resistant organoselenium compounds such as selenomethionine, selenocysteine and the trimethylselenonium ion are often not fully decomposed, hence causing low results. Loss of volatile molecules such as H_2Se, Se_2Cl_2, $SeCl_4$, $SeOCl_2$ and $SeO_2.2HCl$ can be avoided[3] by inhibiting their formation in the first place and by keeping the temperature and the rate of decomposition under control. Moreover, decomposition in a closed vessel prevents loss of volatile products at elevated temperatures. Selenomethionine, a normal metabolite in plants, is easily incorporated into mammalian proteins.[4] Selenocysteine is synthesized from H_2Se and selenite[5] and has been proved to be the active centre of the enzyme glutathione-peroxidase, which represents about 10% of the selenium in human blood.[6] Evidence was presented by Burck[4] suggesting that trimethylselenonium ions are normal excretory products in human urine. It is therefore necessary to focus attention on problems associated with the decomposition of such compounds. In this paper the wet acid digestion of biological materials, especially of human blood and plasma, will be discussed and the accuracy of selenium determinations in these matrices by hydride-generation AAS (HGAAS) established.

HISTORICAL OUTLINE

Of the methods available, digestion with acid in an open system is undoubtedly the most popular, because of its large oxidative capacity and ability to give stringent control of each digestion stage. When a sufficiently high oxidation potential is maintained throughout, temperatures up to 200–250° can be applied without significant loss of selenite or selenate.[7]

Wet digestion with nitric acid under elevated pressure, in a closed PTFE vessel, has been applied less frequently. Its correct use prevents loss of volatile compounds, but the capacity is small (approximately 0.5 g of dry organic material for a 125-ml vessel), and its use is time-consuming. Table 1 surveys procedures (published in 1959–1980) for destruction of biological materials before determination of selenium. Columns B, C and D reflect the evolution that took place.

A predigestion period was included and the oxidative power increased stepwise by adding the acids consecutively instead of all at once. This served two major purposes: to prevent formation of volatile selenium compounds whilst giving drastic but controlled conditions for the breakdown of resistant organoselenium compounds. The rate and extent of destruction are mainly governed by the rate of temperature increase and the highest temperature reached. Appreciable uncertainty as to completion of the digestion arises from the fact that the final temperature is often described only qualitatively, *e.g.*, "the temperature at which copious white fumes are evolved...", or "the temperature at which the liquid briskly boils...". This should (but may not) be 200–210° when nitric/per-

chloric acid mixtures are used, and around 250–300° when sulphuric acid is present.

The AOAC gradually refined the methods it recommended. In 1968 Hoffman *et al.*[23] proposed the addition of nitric, perchloric and sulphuric acids to the dry sample. Watkinson's method[1] (the basis for most of the digestion procedures developed over the past 20 years) was modified by Olson[10] who introduced a predigestion stage involving solubilization of the organic matter and mild oxidation of easily hydrolysed compounds at low temperature (20–80°). The initial reaction is vigorous, with foaming and evolution of dense brown nitrogen dioxide fumes. When this reaction has subsided slight heating results in complete solubilization of all suspended matter and the real destruction can commence. As the temperature is increased, nitric acid condenses in the lower neck of the digestion flask.[23] Perchloric acid is added and heating continued until all organic materials are mineralized (near the boiling point of perchloric acid). A new reaction is seen to ensue, from the evolution of residual nitric acid; the digest rapidly turns from pale green to colourless and clear. Dense white vapours of perchloric acid are evolved, and the temperature rises to approximately 200°.[20]

Hall and Gupta[20] used a procedure in which the rate of destruction was not closely monitored, and attributed loss of selenium (up to 60%) to use of high temperatures, prolonged digestion, or both. However, it seems more logical to attribute these losses to charring during the second stage of the decomposition. Charring occurs when the acid-to-sample ratio is too low or water is withdrawn from the sample too suddenly. It yields carbon particles with reducing properties, thus converting inorganic selenium into the gaseous hydride.[1,8,32] It is often seen when sulphuric acid is added to the digest too early,[8,12,27] or the temperature is increased too fast, so that the nitric acid is driven off before solubilization is complete. It follows that predigestion should proceed smoothly if the temperature is slowly increased[13,27] with sufficient nitric acid present.[9,27] At the end of the predigestion the volume may be reduced as this shortens the total digestion time.[9] Losses due to charring are largely determined by the nature of the sample.[27] Olson demonstrated that the degree of decomposition is mainly dependent upon the length of the perchloric acid stage. His paper dealt directly with the problem of very resistant selenium compounds. He initially modified Watkinson's method by increasing the heating time to 15 min beyond the appearance of perchloric acid fumes[10] and later extended this to 30

min, to ensure the complete mineralization of $(CH_3)_3Se^+$.[13]

Both nitric and perchloric acid interfere severely in the fluorimetric determination of selenium[12,13] and to a lesser extent in the HGAAS determination.[2] Therefore the procedure finally adopted by the AOAC includes the use of a perchloric/sulphuric acid mixture at a late stage to enable nitric acid to be boiled off.[27] In a later modification sulphuric acid was added to the digest after all the organic material had already been destroyed, so that the incidence of charring could be reduced.[32] Repeated heating and cooling of the digest after the addition of small amounts of water, hydrogen peroxide, ammonium oxalate or hydroxylamine hydrochloride can be used to drive off residual traces of nitric acid.[10,17,23,26,27,30,32] During digestion with perchloric acid, selenite is easily oxidized to selenate.[1,9,26] Reduction back to selenium(IV) can be achieved in sulphuric acid medium by addition of hydrogen peroxide and heating.[9] When a nitric/perchloric acid digestion is used the reduction can be done with 4*M* hydrochloric acid.[1]

EXPERIMENTAL

Digestion apparatus

Twenty destructions were conducted concurrently, by using a temperature- and time-controlled heated aluminium block in which Pyrex tubes (diameter 42 mm, height 30 cm, usable volume 250 ml) were inserted to a depth of 6 cm. The tubes were surrounded by a shield to protect them against temperature fluctuations caused by air draughts. The system is commercially available (Tecator Digestor 20). Glass air-condensers were made and fitted to the tubes; to ensure effective reflux of acid vapours they needed to be at least 30 cm long. Selenium(IV) was reduced to selenite by heating with 4*M* hydrochlorie acid for 5 min at 100°.

For comparison some destructions were done in pressure vessels (Perkin-Elmer, Autoklav III; maximum temperature 160°, maximum pressure 145 atm) in which a 125-ml PTFE vessel fitted with a magnetic rod and a PTFE lid is accommodated by a steel mantle heated by an electrical hot plate (IKA-Combimag RCT).

Reagents and glassware

Reagents were of analytical grade. Quartz and polypropylene 25-ml standard flasks were used for aqueous standards and samples. Acid-soaked and rinsed polyethylene flasks were used for storage of digested materials at −18°.

Biological materials

Freeze-dried standard (reference) materials were stored in a desiccator and before use were dried as recommended by the manufacturer.

Blood was obtained by venepuncture with evacuated tubes (Vacutainer, Becton-Dickinson), with Li-heparin as anticoagulant. Blood was aspirated into the air-free tube, thus minimizing the risk of contamination. Plasma samples were obtained by centrifuging blood at 1100 *g* for 10 min. The supernatant plasma was transferred to polystyrene disposable tubes by means of a polyethylene syringe. Transfer of red blood cells was carefully avoided; haemolysed plasma samples were discarded. Pipetting was done with Eppendorf micropipettes provided with an n-heptane-treated polyethylene tip.

Assessment of selenium concentration

Selenium concentrations were determined by HGAAS, using optimized parameters as published elsewhere.[2] The generation medium was 0.5*M* sulphuric acid. A Perkin–Elmer 372 atomic-absorption spectrometer and MHS-1 hydride generation system were used. The method of standard additions was used throughout.

Destruction procedures

Two open wet-digestion procedures were tested; they differed in the final temperature achieved.

Procedure I. On the basis of some literature data[10,15,16,18] the following procedure was established. Accurately weigh dry material or pipette blood (or plasma) into a digestion tube. Add a few glass beads to prevent bumping. Add 20 ml of concentrated nitric acid for 2–5 g of organic material (50 ml for samples weighing between 10 and 15 g). As pointed out by Ihnat and Miller,[32] the sample size is mainly determined by the water and fat, starch or sugar content. In general, 2 ml of blood or plasma are digested.

Fit the air-condensers and place the tubes in the aluminium block. Increase the temperature to 75° during approximately 15 min. Let the mixture stand overnight at 75°, and another 6 hr at 125°. Remove the condensers and reduce the volume to 3–5 ml by heating at 125°. Add 2.0 ml of concentrated perchloric acid (72%). Keep the block temperature at 125° until the liquid volume is approximately 2 ml. Allow to cool. Add 1 ml of concentrated hydrochloric acid and heat for 5 min in a boiling water-bath. The solution should generally be clear and citron-yellow. Transfer quantitatively to a 25-ml standard flask and dilute to volume. When only 1-ml blood (or plasma) samples are available, solution should not be made up to more than 10.0 ml if the blood selenium concentration is expected to be only moderate.

A total digestion run (18 samples and 2 blanks) takes between 22 and 30 hr.

Procedure II. As will be shown, the most reliable destruction of blood was achieved with the following procedure, which combines several aspects of procedures described by others.[8–10,12–14,18,20]

The predigestion is performed as in procedure I. When the volume has been reduced to 3–5 ml at 125°, 5.0 ml of perchloric acid (72%) are added, the condensers are replaced and the temperature of the heating block is gradually increased to 210°. This usually takes 30 min. The digest is held at this temperature for 30 min. Initially brown nitrogen dioxide vapours appear in the condensers, their colour gradually becoming lighter. Nitric acid is driven off, suddenly yielding a clear and colourless solution, and the perchloric acid refluxes in the upper part of the condensers. The condensers are then removed and the digest is kept at 210°, without vigorous boiling, until the volume is reduced to about 2 ml. This is completed in less than half an hour. Selenate is then reduced to selenite as in procedure I. The digest is then transferred to a 25.0-ml standard flask and diluted to volume. The whole procedure takes between 15 and 23 hr.

In both procedures the predigestion period may be shortened to as little as 4 hr without appreciable loss of selenium.

Destruction in a Teflon bomb

A maximum of 0.5 g of dry material or 2 ml of blood (or plasma) is introduced into the vessel and 4.0 or 5.0 ml of concentrated nitric acid (according to the nature and amount of the sample) are added. A Teflon-coated magnetic-stirrer rod is introduced. The vessel is closed and placed in the steel mantle, then heated for 60 min, with magnetic stirring, the temperature at the Teflon wall being maintained at 120°. The entire bomb is then allowed to cool to room temperature, before the lid is removed. Residual

nitrogen dioxide vapours are driven off by magnetic stirring for 10 min. The contents are transferred to a 25-ml standard flask and diluted to volume. The Teflon vessel is then boiled in nitric acid and rinsed with water, to remove any stains left after the decomposition (tests of the nitric acid after this procedure have not shown any residual selenium). A blank is then prepared by applying the full treatment to the same volume of nitric acid as used for the decomposition, in the same Teflon vessel.

RESULTS AND DISCUSSION

The accuracy of a procedure refers to the overall error, and is largely determined by the systematic error or bias of the method.[34] In HGAAS, this bias, which is not due to random error of measurement, may arise in the sample preparation as well as in the final measurement. Aqueous standards that have been subjected to a given digestion procedure yield data on the recovery of selenium from the digestion matrix but the results may not reflect the complex situation which arises when selenium is present in an organic matrix.

As demonstrated by Nève *et al.*[26] and by Doll and Armbrecht[34] chemical constituents remaining after a nitric acid digestion of an organic sample such as serum may cause severe loss of both native and added selenium. Binding effects of the matrix on selenium and interference effects of the matrix on the method are generally evaluated by analysing a standard material similar in composition to test material.[34]

Table 2 gives the results obtained for several standard materials. Unfortunately the freeze-dried animal blood standard, IAEA A-2, cannot be considered a true standard reference material (SRM), as demonstrated by the large confidence interval of the recommended value for the selenium concentration. It is therefore a less suitable material for discriminating between procedures I and II; both seemed to recover all the native selenium. Appreciable losses were observed when blood was mineralized in a pressure bomb. The pressure often became too high, causing the safety valve to open, and volatile selenium compounds may thus have been lost. Such losses seemed to be more of a problem than incomplete destruction did. However, incomplete destruction (at 125°) seems to be responsible for the low concentration of selenium found in NBS bovine liver.

As no reliable SRM was available, the results for a large number of different blood samples treated by procedures I and II were compared. As it was impractical to withdraw sufficiently large blood samples from each donor for repeated analysis by both procedures, samples were analysed once by each procedure.

As the degree of biological variation is the same for both sets of results, the difference in variance between the two groups of results reflects the difference in repeatability of the destruction methods. Results for selenium in blood (170 donors) and plasma (17 donors) are given in Table 3. The mean selenium

levels in plasma did not differ significantly (two-sided t-test, $P > 0.05$), but procedure II gave an average blood-selenium concentration about 20% higher than that obtained procedure I. This difference was highly significant ($t = 12.26$, paired observations with unequal variances,[35] $P < 0.000025$, one-sided test). The variances were slightly different, but only at the 2.5% significance level; hence the repeatability of both procedures was considered very similar. All destructions were performed on fresh samples.

In recovery experiments, several selenium species were added to pooled blood samples, at the beginning of the digestion. Aqueous standards were treated in the same way. Average recoveries are given in Table 4.

Selenite was recovered quantitatively from either water or blood by the low-temperature procedure, but only 65% of the selenomethionine-selenium. When this selenomethionine digest was subjected to a second destruction in an pressure bomb, the recovery rose to 83%, indicating incomplete destruction at 125°. The high-temperature procedure gave practically complete recovery of selenite from water and blood, and of selenomethionine from water, but only 85% recovery of selenomethionine from blood. Selenocystine was recovered to a varying extent by procedure I. It is clear that blood and plasma give matrix effects. Possibly acid-resistant organic selenium compounds prevail in the erythrocytes of whole blood, which might explain the different behaviour of blood and plasma toward acid mineralization. The need for drastic decomposition was stressed by Nève *et al.*,[26] who attributed low recoveries in decompositions with nitric acid at 140–150° to matrix effects.

Recently Robberecht *et al.*[36] studied possible losses of biologically incorporated selenium during destruction by both procedures described here. Radioactive ^{75}Se was incorporated physiologically into various organs of rats. The ratio of the radioactivity before and after destruction was measured. In both cases this ratio was almost 1 for the various organs, whereas for blood 95% of the selenium was recovered.[36]

These results support our finding that the low recoveries for blood-selenium by procedure I are a consequence of incomplete decomposition and that this loss of Se(IV) is considerably more serious than volatilization losses.

Further studies were undertaken to evaluate the accuracy and the overall reproducibility of the hydride generation technique for the determination of selenium. Binding and other matrix effects could account for part of the method bias. Youden[37] has described a method to distinguish "constant bias" from "constant % bias". Increasing sizes of sample are analysed and the expected and measured concentrations of the analyte are compared. If the measurements are unbiased, the slope of the regression line should be unity. When the determinand concentration is unknown, as in our case, the quantity recovered may be expected to be directly proportional to the sample size, in the absence of bias. Selenium concentrations were therefore determined in one 0.5-ml, two 1.0-ml, two 2.0-ml, one 3.0-ml, one 5.0-ml and one 6.0-ml portions of

pooled blood samples, by destruction procedure I. The regression data, with and without bias, were calculated and are given in Table 5, the reference values for the "unbiased" selenium concentrations being taken successively as the concentrations found in the 0.5, 2.0 and 6.0 ml samples.

According to Youden, for 8 experimental points, the sum of the squares of the "biased" deviations must be less than 55.6% of the corresponding "unbiased" sum to indicate significant ($P < 0.05$) deviation of the experimental data from the unbiased line.[37]

From the figures in Table 5 it appears that there is no bias due to matrix effects that cannot be compensated for by the method of standard additions, whether a 0.5-ml or a 6.0-ml sample is used for estimation of the selenium concentration. The last column gives the results obtained when 202 ng/ml (the concentration found by procedure II) is taken as the "true" concentration, and these show a constant % bias from the unbiased line. This is likely to indicate that procedure I has a constant efficiency, lower than that of procedure II, for recovery of selenium as Se(IV) from blood. Efficient compensation of matrix effects by the standard-additions method was also shown by determining selenium in 10 blood and 3 plasma samples by both HGAAS and fluorimetry.[38] Each sample was decomposed by procedure II, as nitrous compounds that persist after procedure I severely interfere with the fluorimetric determination.[38] The results all belonged to the same distribution of values, as demonstrated by a paired *t*-test[35] ($P > 0.05$).

The precision and overall reproducibility of the combined destruction–HGAAS technique have been established in several ways. The liberation of selenium as H_2Se from a digest and the measurement of its absorbance at 196.0 nm are fairly precise,[39] the relative standard deviation (s_r) being below 2%, and hardly influenced by the nature of the sample. However, the condition of the atomization tube plays a major role, as discussed elsewhere.[40] The repeatability of the destruction procedures was established by analysis of pooled human blood. It was poor for destruction in the bomb ($s_r = 20\%$, $n = 8$), whereas s_r values between 8 and 11% are common for both wet procedures. Plasma may be mineralized somewhat more precisely ($s_r = 5\%$, $n = 8$). Blood samples digested in several batches did not exhibit significantly different results.

A modest interlaboratory study was undertaken to evaluate the overall reproducibility of the HGAAS technique. Blood and plasma from 3 male and 3 female donors was pooled and freeze-dried for 18 hr at 0.02 mbar pressure. The moisture content of the fresh blood was 77% w/w, and of plasma 91%. Samples were distributed to two other laboratories for determination of selenium by HGAAS.

Laboratory 3 used a destruction procedure very similar to our procedure II. Investigators in laboratory 2 used mineralization in stream of oxygen. Table 6 shows the results. From these data it is seen that differences encountered when procedures I and II are applied to fresh blood (Table 3), disappear when the procedures are applied to freeze-dried blood. When the water content was taken into account the results corresponded to those obtained for fresh blood by procedure II. It seems unlikely that the different behaviour of fresh and freeze-dried blood is merely due to chance. The plasma samples gave excellent overall reproducibility.

Our own results for blood selenium did not differ statistically from those found in laboratory 3. For procedure I the results from the three laboratories did not differ significantly, but procedure II produced a

value different from that obtained in laboratory 2 (at the 5% significance level, but not at the 2.5% level). It is concluded that the overall reproducibility is very satisfactory for analysis of freeze-dried blood and plasma.

The overall reproducibility of HGAAS after mineralization of fresh blood by procedure II was tested on 40 different blood samples. After venepuncture the blood samples were divided into two parts, one of which was analysed as soon as possible, and the other frozen and transported in dry ice to laboratory 3, where it was analysed. We found an average selenium concentration of 121 ng/ml in whole blood, with a standard deviation of 13 ng/ml. The corresponding values from laboratory 3 were 121 and 19 ng/ml. Although the individual results diverged in a few instances, the overall agreement (based on pairing of observations with unequal variances[35]) was excellent ($t = 0$). Our own results gave a slightly better standard error of the mean (2.1 ng/ml, against 3 ng/ml from laboratory 3).

CONCLUSION

It has been shown that blood and plasma (especially blood) require harsb conditions for the liberation of their selenium content. Graded severity of destruction with nitric–perchloric acid mixture, with a final stage at 210°, is recommended. The accuracy and reproducibility of this method (combined with determination by hydride-generation atomic-absorption spectrometry) are satisfactory. Digestion at a lower temperature may lead to erroneous results, especially in the case of whole blood. It is emphasized that the stability of some organic selenium compounds may present a greater threat to the accuracy than does their volatility.

Acknowledgements—The author is indebted to the National Fund for Scientific Research (Belgium), for a grant which financed this investigation to a large extent. She wishes to express her gratitude to Dr. M. van Sprundel (U.I.A., Department of Medicine) for his invaluable help during the final stages of this study. In addition, she extends her thanks to Prof. G. Tölg and Dr. A. Meyer (Max-Planck-Institut für Metallforschung, Stuttgart, G.F.R.) and to Dr. G. S. Fell (Royal Infirmary, University of Glasgow, Scotland) for offering the opportunities for interlaboratory comparisons. The Department of Pharmaceutical Sciences, U.I.A., especially Prof. H. Deelstra, is thanked for providing technical facilities.

THE ELECTROLYTIC TEST FOR DETECTION OF ARSENIC ALONE AND IN THE PRESENCE OF OTHER METALS

ROBIN J. SPRING
Gramerci, Colville Road, High Wycombe, Bucks, England

(*Received* 27 *August* 1981. *Revised* 28 *April* 1982. *Accepted* 11 *May* 1982)

Summary—A historical account is given of the development of the electrolytic generation of arsine in the Marsh test, showing how it was early realized that a step in an analytical procedure could be advantageously replaced by a more efficient one. It also shows that well-designed apparatus never really becomes outmoded.

The detection of toxins in the dead, especially in criminal cases, posed analytical problems in the 19th century. The same prohlems arose in the detection of toxins in adulterated food. In the preface to his book *On Poisons in Relation to Medical Jurisprudence*,[1] Taylor stated "There are many poisons which cannot at present be detected by chemical analysis, there are numerous circumstances which occur to prevent their detection in the food, the vomited matters, or the contents of the viscera in the dead." The Marsh test (1836), the Berzelius adaptation of this (1837) and the Reinsch test (1838) were available, but they only detected arsenic and antimony, and were quantitative only if applied with the utmost care. Their reliability often depended on the skill of the operator. Thus, according to Henry's diary for 1837,[2] Faraday insisted on the necessity for much practice before expressing an opinion about suspected arsenic poisoning, thought the Marsh test needed a skilled operator, and that, without proper precautions, the whole of the metal might escape without being caught. Henry also noted that Daniell considered the Marsh test a good one, but that arsenic-free tin was difficult to obtain, and a reagent blank was therefore necessary. Long before these tests were developed, however, Cruikshank, by observing the ease with which copper was deposited electrolytically, was the first to suggest electricity as a possible analytical tool for the detection of metals. By 1812, Fischer had detected arsenic electrolytically by the "galvoplastic" method, wherein the substance was precipitated on the cathode of the cell.[3] Fischer also first recognized the displacement of one metal from solution by another in what is now called the electrochemical series.[4] In 1840, Cozzi detected metals in animal fluids. In 1850 de Claubeny detected poisonous metals by electrolytic deposition on platinum, followed by dissolution and analysis by the standard methods. He considered his method totally reliable, especially for the detection of copper in bread. In 1857, Otto's *Lehrbuch de Chemie* gave a delicate test for manganese and lead by electrolysis and in the same year Despretz described the electrochemical decomposition of certain salts. Copper and lead acetates gave lead dioxide at the anode and copper at the cathode. Manganese gave no deposit on the cathode, but a black dioxide film on the anode. Potassium antimonyl tartrate gave a crystalline deposit of antimony at the cathode and a yellowish-red coating, supposed to be anhydrous antimonic acid, at the anode. Bismuth nitrate gave a reddish-brown deposit on the anode. Despretz thought his antimony, lead and manganese results were new, and that the separation of copper from lead was virtually complete.[5] In 1861, in a paper on the application of electrolysis to the detection of the poisonous metals in the presence of organic matter,[6] Bloxam stated "Every analyst is only too well aware of the difficulties which beset the detection of the poisonous metals in mixtures containing organic matters, such as the contents of the stomach, the solids and fluids of the body, and the articles of food." This may have been inspired by Todd's letter to "The Times" in 1859, following the conviction of Dr. Smethurst for murdering his mistress, Isabella Bankes, which stated: "I trust this very important case will not be lost on toxicologists ... and that it will induce analytical chemists to review carefully all the processes hitherto in use for the purpose of detecting mineral and other poisons with a view to clear up every possible source of fallacy."[7]

In his revision of Bowman's *Practical Handbook of Medical Chemistry* (4th Ed., 1862), Bloxam described his electrolytic test for arsenic,[8] listing the objections to the Marsh test, such as the presence of arsenic in commercial sulphuric acid, and of arsenic and antimony in zinc, the frothing of the reaction mixture despite the addition of alcohol, and the impossibility of further analysis of the mixture because of the large excess of zinc sulphate. He then stated: "The detection of the poisonous metals by the decomposing action of the galvanic current is, I think, free from these objections, and so minute quantities of the poisonous metals may be detected by this method, that it

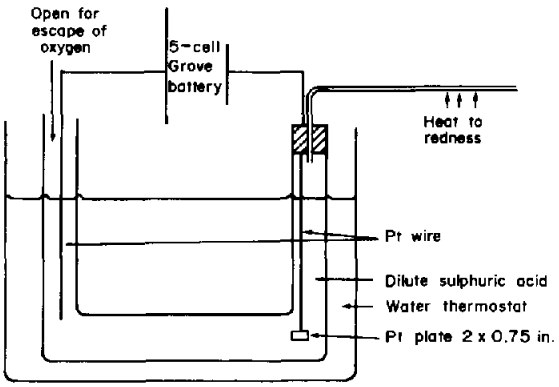

Fig. 1.

may safely be relied upon in most cases of chemico-legal investigations."[6] Bloxam's first apparatus for the analysis is shown in Fig. 1.

First the U-tube was charged with 1 fl. oz of sulphuric acid (1 + 4) and the emission tube was heated to redness for 15 min before introduction of the specimen, to verify that no arsenic was present in the acid. Then portions of arsenious acid solution containing 0.076, 0.0076 and 0.00076 grn of arsenic were successively introduced. In all cases good mirrors were obtained. Bloxam then pulped 1 oz of lean meat, $1\frac{1}{2}$ oz of milk and $\frac{1}{2}$ oz of white of egg in a mortar, mixed all this with 5 fl. oz of hydrochloric acid (1 + 4), digested the mixture on the water-bath for 15 min, filtered, and evaporated the filtrate to $3\frac{1}{4}$ fl. oz of dark brown viscid liquid. To this he added 0.1 grn of arsenious oxide and placed a quarter of the whole in the decomposition tube. He obtained an arsenic mirror for this and smaller quantities of arsenious oxide, down to 0.01 grn.[6]

One problem Bloxam had to overcome was that the arsenious sulphide often present in such mixtures was insoluble in hydrochloric acid, and he wondered whether heating with potassium chlorate and hydrochloric acid would lead to a positive result. He showed that it was necessary to reduce the resulting arsenic(V) back to arsenic(III) with sulphurous acid if a mirror was to be obtained from small quantities (0.05 grn). A mixture similar to that just mentioned gave a good arsenic mirror. He also showed that arsenic could be detected in beer (added to the mixture). He was still not satisfied, however, since not all the arsenic was detected. Using two cells, separated with a parchment membrane, to prevent the chlorine evolved at the anode from passing to the cathode and converting the liberated arsine into arsenic(III) chloride, he was able to show that this was the source of the discrepancy, and with this apparatus he could detect 0.0001 grn of arsenious oxide in a mixture of foods.[6] His apparatus at this stage was as shown in Fig. 2.

The advantages of this method were the ability to detect arsenic by use of platinum, a metal not contaminated with it, the same sulphuric acid could be used throughout and tested for any length of time before the introduction of the specimen, the experiment could be interrupted at any time by breaking the circuit, and both the clearest and the foulest mixtures could be analysed equally well, leaving a residue that could be further analysed for other metals. However, Bloxam concludes: "On considering the detection of the other poisonous metals in this way, it is obvious that lead must be altogether excepted on account of its insoluble sulphate. Silver must also be omitted, where hydrochloric acid is the solvent; and baryta, of course, would not be expected to answer. The remaining important poisonous metals, antimony, copper, mercury, bismuth and zinc, were therefore tried, bismuth being included on account of the medicinal use of its compounds."[6]

Bloxam was very interested in the determination of antimony at the cathode. To the food mixture used for the detection of arsenic he added 0.01 grn of tartar emetic (*i.e.*, 0.036 grn of Sb) and analysed as for arsenic. The antimony deposited on the cathode was dissolved in ammonium polysulphide solution and the solution was evaporated on a watch-glass till an orange stain (indicating antimony) appeared. On the strength of his results Bloxam compiled a scheme of analysis for the poisonous metals antimony, mercury, copper and bismuth but forgot to state specifically that arsenic was also detectable. If mercury interfered with the arsenic determination, the liquid from the decomposition cell or a fresh portion of the original hydrochloric acid solution should be distilled to separate mercury from arsenic. Later, Bloxam showed how the interference of mercury could be avoided and how the error caused by the evolution of stibine might be obviated.[9] He also improved his apparatus yet again by using broad strips of platinum foil instead of wire for the electrodes, and adding the sample to the cathode compartment through a thistle funnel.

To prevent the evolution of stibine, he boiled the sample with hydrochloric acid and potassium chlorate, evaporated the solution to low bulk, saturated it with hydrogen sulphide and placed it in the decompo-

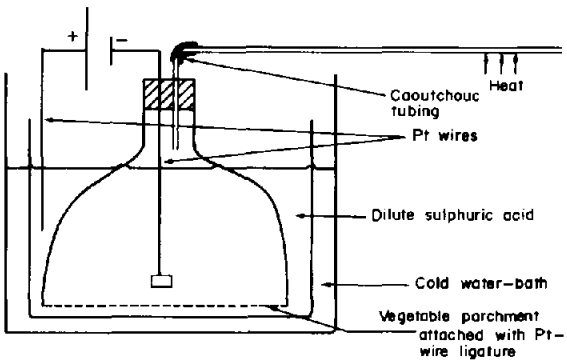

Fig. 2.

sition cell; deposits of arsenic and arsenious sulphide were formed in the heated tube. The dark precipitate collected after the experiment was identified as Sb_2S_3. Bloxam showed that, with 1 grn of mercuric chloride and 0.01 grn of arsenious oxide (or 0.25 and 0.0025 grn respectively) mixed with white of egg, bread, milk and beer, there was no difficulty in detecting the arsenic. The addition of hydrogen sulphide to the electrolytic cell yielded a crust of arsenic, whereas without it only mercury was deposited on the cathode. Similar results were obtained with remains which had putrified for about a year. Bloxam was particularly concerned about the purity of his reagents (with good reason) since he was unable to obtain hydrochloric acid pure enough for large quantities to be used without contributing a detectable blank. The sulphuric acid available was also impure, and he later published a paper on the production of pure sulphuric acid for the purpose.[10] He also feared that the potassium chlorate and hydrogen sulphide used were impure. He recommended the reaction:

$$Sb_2S_3 + 6HCl = 2SbCl_3 + 3H_2S$$

for the production of the hydrogen sulphide, but did not suggest how to obtain pure potassium chlorate.

Underlying the tests for the poisonous metals there clearly run organic (medical) and inorganic (mineral) criteria of applicability. Not only the poisonous metals, however, were to come under investigation by electrolytic methods. As the science of electrochemistry developed, its range was extended to estimation of many more substances. This progress is well outlined by Smith.[11]

Bloxam's work in this direction was seminal. His papers of 1861 and 1862 were the efforts of an analyst attempting to achieve workable detection techniques for arsenic, originally in connection with death by arsenic poisoning. He also saw the use to which his test might be put in inorganic mineral analysis.

The medical analyst, seeing (as Bloxam saw) difficulties in the application of the test to large quantities of viscera, might well have been deterred from pursuing its application. For example, the Joint Committee of the Society of Public Analysts and the Society of Chemical Industry was still recommending the standard Marsh–Berzelius test for arsenic in 1909.[12] By this time, the hydrochloric and sulphuric acids were pure enough for the purpose, if subjected to special further purification. The zinc used was also specially purified, the standard arsenic mirrors were made with 4, 6, 8 and 10 μg of arsenious acid, and the test still involved visual comparison.[12]

In inorganic analysis, however, continued interest in the electrolytic arsenic test was predictable, and Thorpe[13] and Hefti[14] used it in mineral analysis.[13] The typical electrolytic apparatus used for this purpose in the present century,[13] apart from the use of a mercury cathode, is very reminiscent of Bloxam's 1862 apparatus.

The early researches of Bloxam into arsenic detection are thus seen to be both an important link in electrolytical analysis and illustrative of the zeal of an analyst to apply new methods to the problems of toxicology, as well as providing a period piece of instructive electrochemistry.

SYSTEME D'ANALYSE ET D'ACQUISITION DE DONNEES CINETIQUES PILOTE PAR MICROPROCESSEUR

J. C. FONTAINE, P. LEVOIR et J. J. MEYER
Institut de Topologie et de Dynamique des Systèmes, Université Paris VII, associé au C.N.R.S., 1, rue Guy de la Brosse, 75005 Paris, France

(*Reçu le* 25 *avril* 1982. *Accepté le* 16 *juin* 1982)

Résumé—Cet article décrit un système interactif et économique d'analyse et d'acquisition de données cinétiques basé sur un microprocesseur 6809. La détermination de constantes de vitesse du second ordre nécessite le calcul préliminaire d'un paramètre du système chimique étudié. La valeur de ce paramètre, calculée et affichée par notre appareillage, permet le contrôle de la validité des conditions expérimentales. Les données cinétiques retenues sont finalement enregistrées sur cartouche magnétique en vue d'un traitement ultérieur sur mini-ordinateur.

On peut accéder à des constantes de vitesse élevées du second ordre par une méthode stationnaire en diminuant la concentration des réactifs et en ralentissant ainsi la vitesse de réaction. Dans ces conditions (TFCR EXSEL: Très Faible Concentration en Réactif Excès de Sel),[1] pour les constantes de vitesse les plus élevées accessibles (10^8 l.mole^{-1}.sec^{-1}), le temps de demi-réaction est de l'ordre de la seconde. Cependant plus la concentration des réactifs est faible plus la mesure sélective précise du courant faradique devient difficile. Par la mise au point d'un potentiostat à réaction positive et à circuit détecteur de courant à haute sensibilité, nous avons réussi à détecter spécifiquement le courant faradique parmi tous les courants parasites présents.[2]

Or le dépouillement manuel de la courbe cinétique traduisant la vitesse de disparition d'une espèce électroactive par l'enregistrement en fonction du temps de son courant limite de diffusion (Fig. 1) est une opération longue et peu précise. Le résultat obtenu peut en plus être fonction des choix de l'opérateur. En outre il est très difficile d'estimer rapidement *a priori* si les conditions expérimentales (état du solvant, agitation) sont adéquates pour obtenir des mesures valables.

Pour dépasser ces limitations nous avons conçu un système à microprocesseur (Fig. 2) adapté à nos conditions expérimentales et permettant:

—un contrôle rapide de la validité de ces conditions expérimentales;
—une amélioration de la précision des mesures par la mise en oeuvre d'un ensemble matériel et logiciel adapté à nos besoins;
—une amélioration de la reproductibilité des résultats par un traitement informatique ultérieur des données cinétiques enregistrées sur cartouche magnétique.

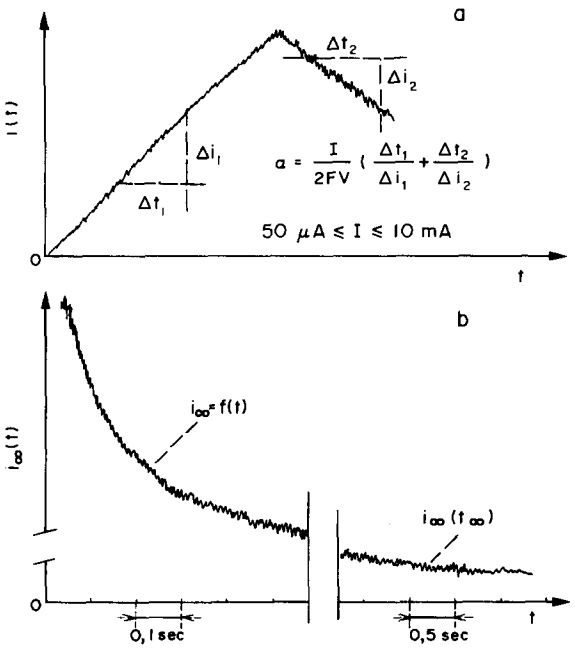

Fig. 1(*a*) Electrolyse et détermination de α: F = 1 Faraday (96500 C); V = volume de la cellule; I = courant d'électrolyse. (*b*) Courbe cinétique.

Contraintes expérimentales

La mesure précise du courant faradique $i(t)$ (Fig. 1) auquel correspond une variation globale de tension de quelques mV doit répondre à différentes exigences:

—pour ne pas diminuer la précision de l'enregistrement de $i_\infty(t)$, il faut que le traitement analogique introduise une erreur de l'ordre de 0,1% maximum, ce qui correspond à une résolution de 10 bits;
—vu le mode de calcul de la constante de vitesse k (à partir de la pente p de $\log([i_\infty(t)]/[i_\infty(t) - i_\infty(t_\infty)])$, il faut que $i_\infty(t) - i_\infty(t_\infty)$ soit connu avec la meilleure précision possible;
—à cause du bruit (dû en partie à l'agitation) superposé à $i_\infty(t_\infty)$, il est nécessaire d'accroître la réso-

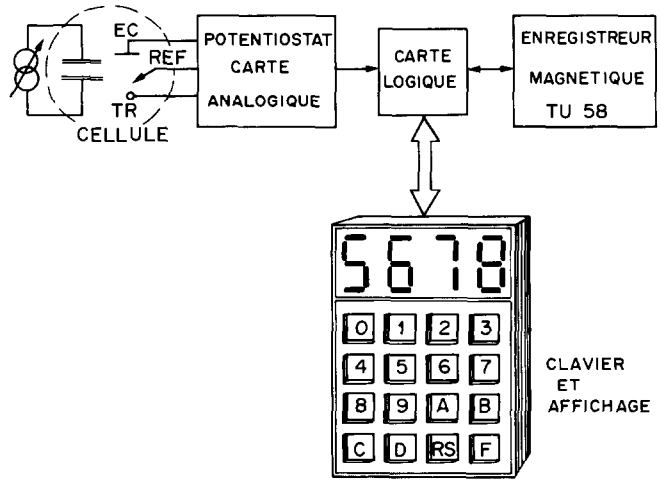

Fig. 2. Schéma descriptif de l'appareillage.

lution de cette mesure en vue d'un moyennage ou lissage ultérieur.

PARTIE EXPERIMENTALE

Description des circuits analogiques

Pour réduire au minimum les erreurs (statique, dynamique et de réjection) nous avons choisi (Fig. 3):

—un amplificateur d'instrumentation type AD522[3] stable et précis à faible niveau, peu bruyant entre 0 et 10 Hz, avec une erreur de non-linéarité de gain très nettement inférieure à 0,1% sur toutes les gammes (G = 1, 2, 5, 10, 20 et 50 dans notre cas) et avec un RRMC élevé indispensable à la réjection de la tension parasite de 50 Hz superposée au signal et provenant de la haute impédance de l'électrode de référence;

—un convertisseur tension–fréquence type AD537K[4] associé à un compteur programmable; il intègre le signal pendant le temps de conversion choisi et possède ainsi, pour des temps de conversion multiples entiers de la période du secteur, une réjection théoriquement infinie pour le 50 Hz et ses harmoniques. En fait, pour une fréquence du secteur variant entre 49,5 et 50,5 Hz, la réjection reste[5] au minimum de 37 db qui ajoutés aux 75 db de l'amplificateur d'instrumentation (gain = 1) donne au minimum 112 db de réjection du secteur;

—un photocoupleur qui transmet le signal de sortie du convertisseur tension-fréquence vers l'unité logique qui de ce fait peut être éloignée du dispositif expérimental sans risques de perturbation. De plus ce dispositif assure de la façon la plus efficace possible la séparation entre la masse analogique et la masse numérique.

Microprocesseur et circuits périphériques

L'acquisition des données en provenance du convertisseur tension–fréquence, leur prétraitement (calcul de α), leur enregistrement sur cartouche magnétique et la gestion de l'ensemble du système sont confiés à un microprocesseur MC6809.[6] A ce microprocesseur nous avons associé un certain nombre de circuits (Fig. 4) dont les caractéristiques et la fonction sont décrites ci-après:

—un circuit "mémoire" EPROM effaçable par U.V., de capacité 2K × 8 bits, type 2716[7] contenant l'ensemble logiciel;

—4 circuits "mémoire" RAM statiques type 2114[8] de capacité globale 2K × 8 bits, 512 octets permettant le stockage temporaire des données cinétiques, 512 autres octets étant réservés à la gestion de l'enregistrement magnétique;

—un PTM 6840[9,10] dont les 3 compteurs sont utilisés de la manière suivante:

(*a*) le compteur 1 compte les impulsions en provenance du convertisseur tension–fréquence après synchronisation sur l'horloge du microprocesseur à l'aide d'une bascule type D,

(*b*) le compteur 2 programmé en mode monostable établit les temps de porte pour le compteur 1 et, par conséquent, la résolution de la mesure,

(*c*) le compteur 3 détermine la cadence d'échantillonnage et déclenche une interruption de programme (ligne $\overline{\text{FIRQ}}$) pour chaque point acquis;

—un UART 6850[10] auquel sont associés un générateur de bauds et des circuits convertisseurs de niveau (standard RS232C); ces circuits assurent une liaison type série avec l'enregistreur magnétique à cartouche TU 58;[11] seize vitesses de transmission standard sont sélectionnables au moyen de commutateurs DIL (50 à 19200 bauds), différents formats pouvant être choisis par programme; on peut donc facilement envisager l'utilisation d'autres types de périphériques (ordinateur hôte, disquette, etc...);

—un PIA 6821[10] dont un port est utilisé pour l'interfaçage du clavier; une pression sur l'une quelconque des touches du clavier déclenche une interruption de programme (ligne $\overline{\text{IRQ}}$) dont la priorité est inférieure à celle générée par le PTM: une perturbation accidentelle de la mesure est ainsi exclue.

Clavier et affichage (Fig. 5)

Afin de permettre le contrôle interactif du déroulement de l'expérience, nous avons adjoint au système un clavier et un afficheur gérés tous les deux par le microprocesseur. Ceux-ci ont été placés dans un boitier séparé style calculatrice de poche (Fig. 2) pour des raisons ergonomiques.

Clavier. Il s'agit d'un clavier matriciel à 16 touches dont les fonctions sont définies par programme. Ce clavier est encodé par un circuit intégré CMOS encodeur de clavier type 74C922.[12]

Afficheur. L'afficheur comporte 4 indicateurs "7 segments + point" à diodes électro-luminescentes pilotés par un circuit intégré CMOS type 74C911.[12]

Logiciel

L'ensemble logiciel de 2K octets comporte un moniteur permettant (Fig. 6):

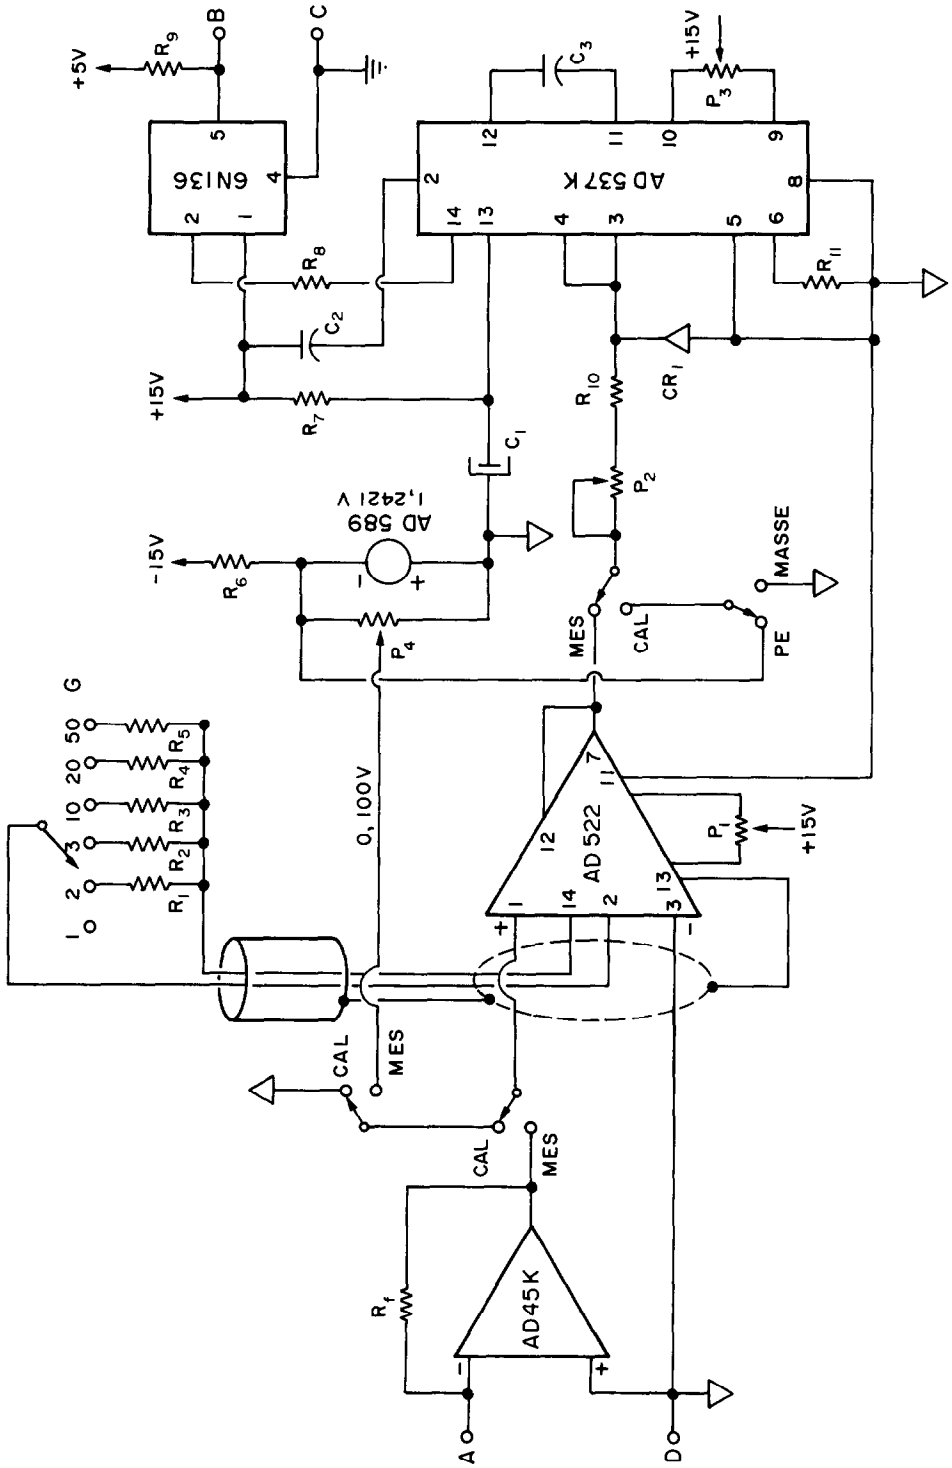

Fig. 3. Carte analogique $R_1 = 200000\ \Omega$; $R_2 = 50000{,}0\ \Omega$; $R_3 = 22222{,}2\ \Omega$; $R_4 = 10526{,}3\ \Omega$; $R_5 = 4081{,}63\ \Omega$; $R_6 = 2{,}7$ kΩ; $R_7 = 100\ \Omega$; $R_8 = 820\ \Omega$; $R_9 = 2{,}4$ kΩ; $R_{10} = 820\ \Omega$; $R_{11} = 8{,}3$ kΩ; $P_1 = 10$ kΩ (20 tours); $P_2 = 200\ \Omega$; $P_3 = 20$ kΩ; $P_4 = 10$ kΩ; $C_1 = 2\ \mu$F; $C_2 = 10$ nF; $C_3 = 680$ pF (NPO céramique); $CR_1 = HP\ 5082 - 2811$ Diode Schottky.

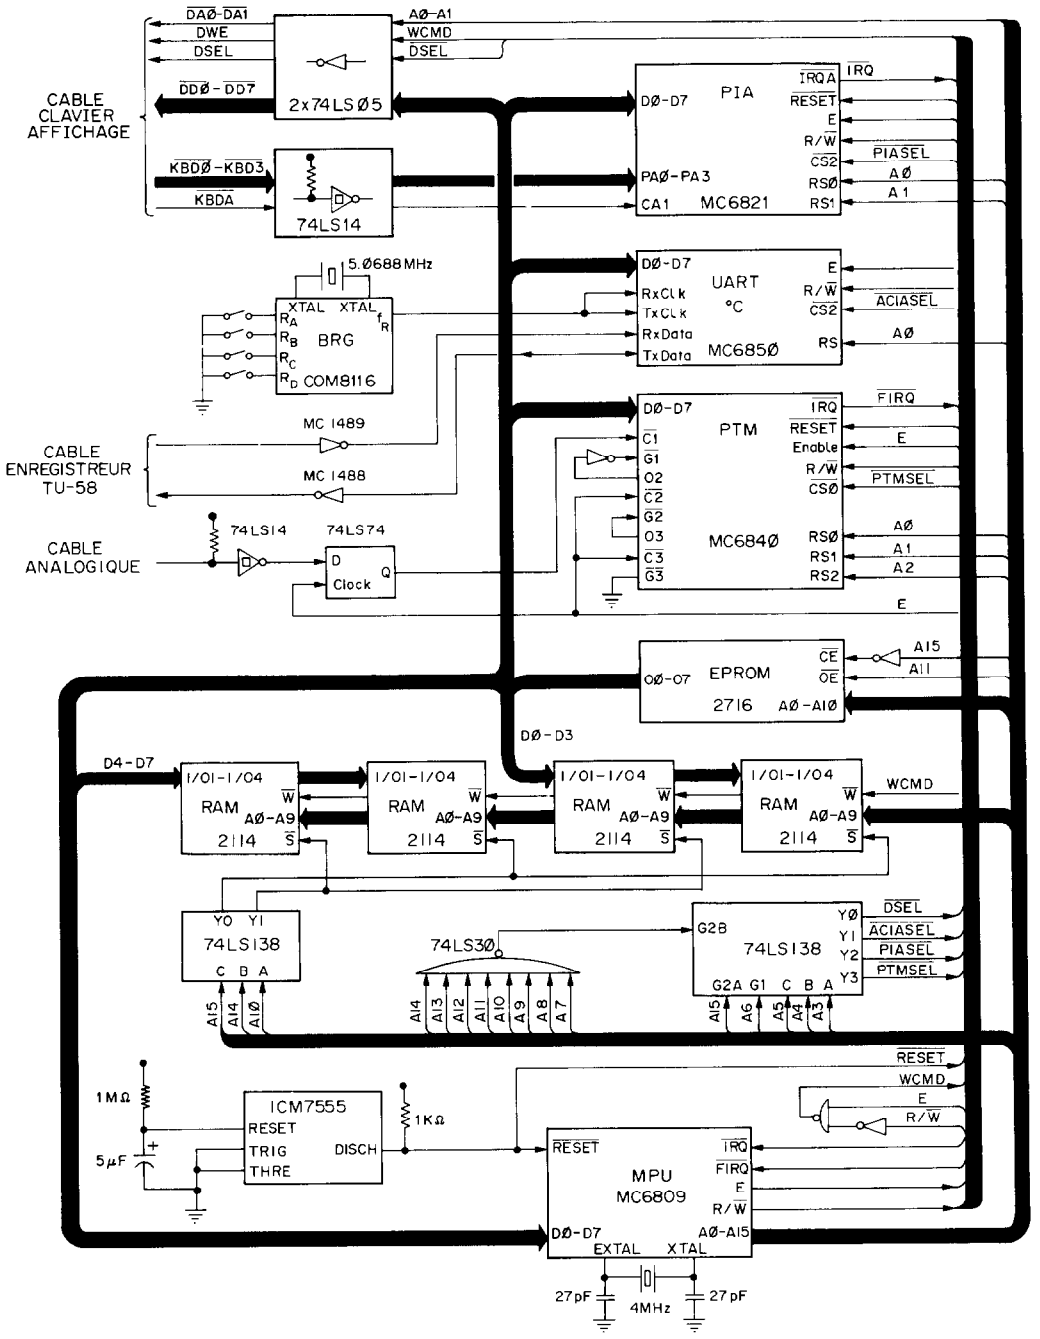

Fig. 4. Carte logique.

—d'initialiser et de tester le système à sa mise sous tension;

—de gérer les différents périphériques;

—d'interpréter les différentes commandes (acquisition, calcul de α, enregistrement).

Programme moniteur et de gestion des périphériques (Fig. 6). Les différents programmes associés aux périphériques (clavier, afficheur, cartouches) permettent à l'opérateur d'une manière interactive.

—d'entrer par le clavier en mode interruptible les commandes suivantes:

(*a*) C0: calcul de α par la méthode des pentes,
(*b*) C1: acquisition d'un signal,
(*c*) C2: enregistrement des données,

—de contrôler par affichage (résultats, messages, erreurs) le bon déroulement de la commande en exécution;

—d'enregistrer en fin de cinétique les valeurs de $i_\infty(t)$, $i_\infty(t_\infty)$, ainsi qu'un certain nombre de paramètres (gains,

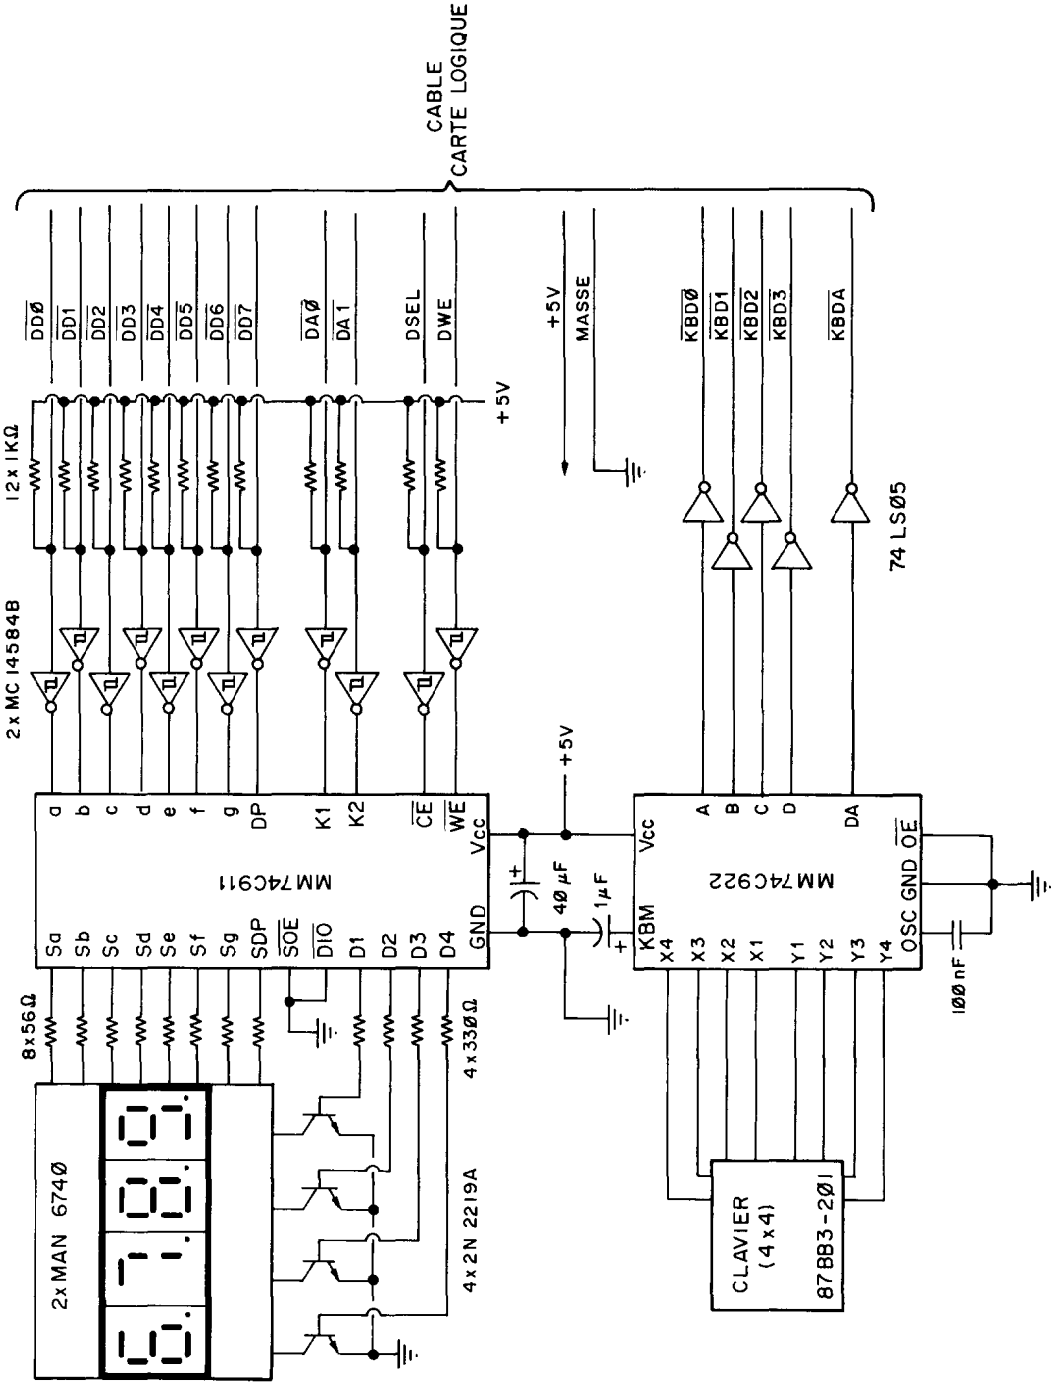

Fig. 5. Clavier et affichage.

pas d'échantillonage) sur cartouche magnétique dans un fichier de 512 octets.

La structure de fichier choisie est compatible avec le format de fichier du système d'exploitation RT 11[13] en vue d'un traitement plus élaboré sur ordinateur PDP 11/10.

Module d'acquisition. Ce module gère l'acquisition, soit du signal cinétique $i_\infty(t)$ (128 points de 16 bits), soit de $i_\infty(t)$ et $i_\infty(t_\infty)$ (64 points supplémentaires de 16 bits).

Le programme demande à l'opérateur d'entrer un pas d'échantilonnage de 0,1 sec pour les cinétiques rapides ou 0,5 sec pour les cinétiques plus lentes auquel correspond respectivement un temps de porte de 20 ou 40 msec; les registres du PTM sont alors initialisés en fonction de ce choix. Par pression sur la touche F du clavier l'opérateur déclenche le processus d'acquisition.

Module de prétraitement des données (Fig. 7). Ce module, appelé par la commande C0, détermine la valeur de la constante α qui, d'une part, permet de contrôler la validité des conditions expérimentales avant la cinétique et, d'autre part, entre dans le calcul de la constante de vitesse.[14]

L'opérateur, après avoir entré à l'aide du clavier les valeurs du gain, du pas d'échantillonnage et du courant d'électrolyse, commande l'acquisition de deux signaux linéaires successifs (128 points par signal) dont le module calcule les pentes, ces dernières permettant la détermination de α (Fig. 1a). Cette valeur est calculée en virgule fixe sur 32 bits puis affichée en vue d'interprétation.

PERFORMANCES DU SYSTEME

A partir des spécifications garanties par le constructeur et pour un temps de porte de 20 msec, l'erreur de mesure maximale calculée est de 0,12% à 25° et de l'ordre de 0,25% pour une variation de température de 30°. Des mesures effectuées sur des périodes de 10 hr et pour des variations de température de l'ordre de 15° montrent que l'erreur globale reste inférieure à 0,1% même pour des courants faradiques très faibles (quelques mV à l'entrée de l'amplificateur d'instrumentation).

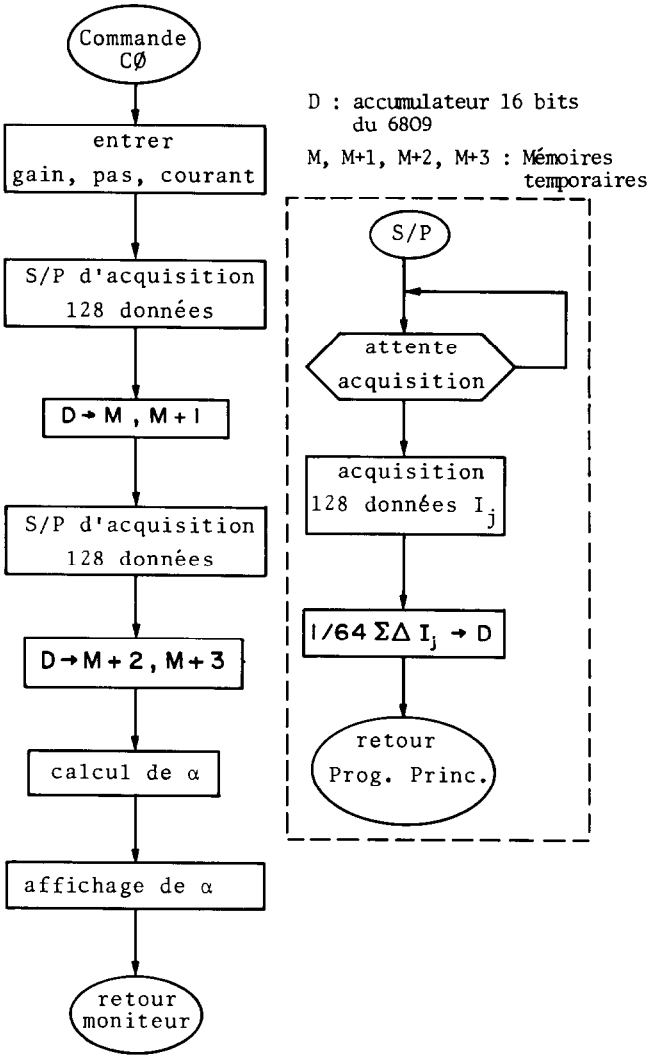

Fig. 7. Organigramme du calcul de α (Commande C0).

CONCLUSION

La structure modulaire du système (matériel et logiciel) et sa très grande souplesse d'emploi devraient, moyennant quelques adaptations (conversion de niveau, programme), permettre son application à d'autres techniques cinétiques et spectroscopiques (écoulement bloqué, spectroscopie de masse, UV, IR, *etc.*).

La liaison série RS 232C en sortie permet d'envisager d'autres dispositifs de stockage temporaire (disques souples) ou de traitement sur le site par liaison à un ordinateur hôte.

Remerciement—Nous tenons à exprimer notre vive gratitude au Professeur J. E. Dubois pour l'intérêt qu'il a porté à ce travail et pour l'aide précieuse qu'il nous a apportée.

Summary—This paper describes a low-cost 6809 microprocessor-based system designed for the acquisition, analysis, preprocessing and recording of electrochemical kinetic data. Determination of second-order rate constants involves a preliminary calculation of a characteristic parameter of the electrochemical system investigated, the value of which, computed and displayed by our apparatus, allows checking of the correctness of the experimental conditions. At the end of the experiment the data are recorded on a magnetic tape cartridge and can be transferred from the tape to a minicomputer for further mathematical processing.

A DUMMY CELL FOR DIFFERENTIAL-PULSE POLAROGRAPHIC ANALYSERS

H. GUTERMAN and SAM BEN-YAAKOV*
Department of Electrical Engineering, Ben-Gurion University of the Negev, Beer Sheva, Israel 84120

(*Received* 7 *September* 1981. *Revised* 11 *May* 1982. *Accepted* 14 *June* 1982)

Summary—A non-linear network is proposed for simulating the response of electrochemical cells in differential-pulse polarographic (DPP) analysis. The response of a DPP analyser connected to the dummy cell is a bell-shaped current peak (I_p) located at any desired point along the potential-scan range. Approximate model calculations of the expected I_p as a function of the dummy-cell parameters are in good agreement with measured data. It is suggested that the dummy cell could be useful in the analytical laboratory and during studies for improving DPP analysers.

Differential pulse polarography (DPP) has been shown to have great potentialities as an analytical tool for the determination of trace heavy metals[1,2] and other compounds.[3] In this voltammetric method, the electrochemical cell is subjected to a pulse-type potential-scan which produces large transient currents, thereby increasing the sensitivity of analysis. The signal-to-noise ratio is further improved by applying a differential mode of operation in which the background current preceding the potential-pulse period is subtracted from the pulse current.[4]

A typical DPP polarogram for a single oxidation–reduction reaction is a bell-shaped current peak, located at a characteristic potential E_p which is a function of $E_{\frac{1}{2}}$ of the reaction and other parameters of the experimental conditions and electrochemical reactions involved.[5] This characteristic response is not reproduced when a classical dummy cell (composed of a linear RC network[6]) is substituted for the electrochemical cell. The classical dummy cell being a linear network, its response is independent of the scan potential. Consequently, the response obtained with such a dummy cell is constant, except for the transient currents at the beginning and end of the scan. Such a cell therefore cannot be used as a means of testing the operation of polarographic analysers in the DPP mode.

The purpose of this study was to investigate the possibility of devising an electrical dummy cell that would reproduce the normal DPP response of an electrochemical cell. It was deemed necessary for the response of the polarographic analyser, when loaded by the dummy cell, to be a current peak located at any desired point on the potential-sweep range. To meet these goals, the dummy cell must reproduce the behaviour of the real electrochemical cell in at least two respects: (*a*) it should simulate the response of the cell to a pulsed potential-excitation, and (*b*), its response must be dependent on the scan potential in such a way that the maximum response (vis-à-vis DPP) is obtained at a preselected potential. The first requirement could be met by including a capacitor in the dummy cell to simulate the transient diffusion-dependent current produced in response to the pulse excitation. The second requirement calls for the inclusion of a non-linear response with respect to the voltage applied across the dummy cell. This could be accomplished with a diode network that would switch from a state of cut-off to a state of conductance at a given potential.

THE DUMMY CELL

The design of the proposed dummy cell follows the concept outlined above. It was found that the design could be simplified by allowing a connection to the electronics earth (ground) besides the normal connection to the terminals for the working, reference and auxiliary electrodes. The consequence of using this approach is that the response of the dummy cell will depend not only on the potential difference between the working electrode (WE) and reference electrode (REF) but also on the potential of these electrodes with respect to the ground potential of the system. Since these voltages are dependent on the electronic design of each particular polarographic analyser, it is not possible to offer a universal dummy cell that will be suitable for operation with any polarograph. However, once the concept of operation of the proposed dummy cell is comprehended, it is relatively simple to modify the design of the cell so that it can be used in conjunction with polarographic analysers of different designs. The particular dummy-cell design given here is directly compatible with potentiostats in which the WE is at ground, (or virtual ground) potential.[4,7–9] The polarographic analyser used in this study is of this design. It includes a three-electrode potentiostat, an amplifier, and analogue gates to generate the exci-

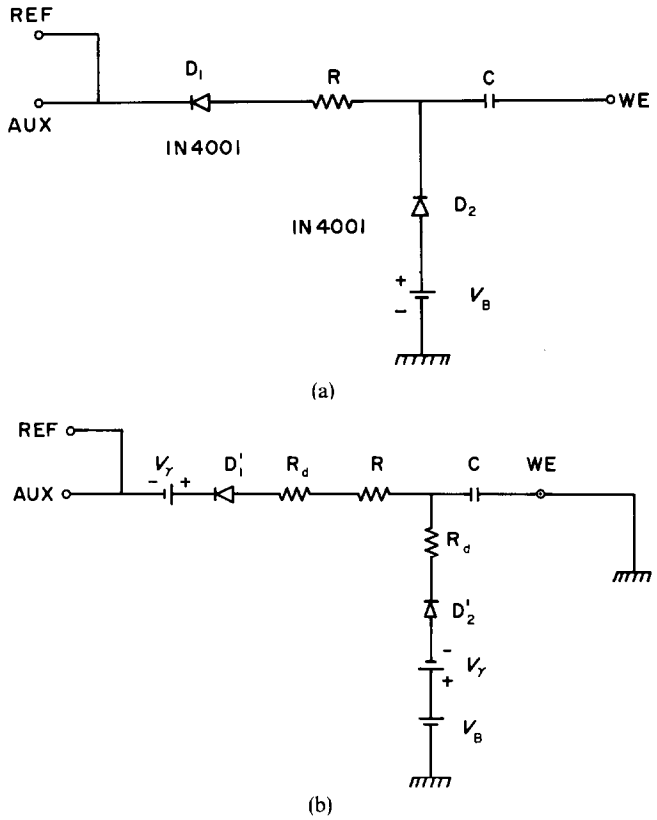

Fig. 1. Proposed dummy cell (*a*) and equivalent linear circuit used in model calculations (*b*) (for meaning of V_γ, see Appendix).

tation potentials and process the current response in differential mode. The design is similar to the one described by Vassos[4] except that the potential scan is not a linear ramp on which the pulses are superimposed, but rather a staircase waveform as described earlier.[5,8,10]

The dummy cell (Fig. 1a) comprises a resistor (R, resistance R), a capacitor (C, capacitance C), two diodes (D_1, D_2), and a bucking-off voltage source that could be a battery, a floating power supply or a grounded power supply (V_B). The diodes form a switch that blocks the passage of the excitation pulses to the RC network (and to the WE) when V_B is negative with respect to V_{REF} (referred to ground and the WE). Current pulses will be fed to the WE when V_B is sufficiently positive with respect to the REF electrode for D_1 to be conducting. Thus with ideal diodes conduction should occur only at the voltage of V_B, but because of the exponential nature of real diode conduction curves at emf below 0.6 V, the conduction window is broadened, giving the peak shape displayed by a DPP polarogram.

No attempt has been made to conduct an accurate mathematical analysis of the response of the proposed dummy cell to the pulsed-potential excitation used. Such an analysis, which must take into account the non-linearity and non-ideality of the practical diodes used, could be done by standard numerical-analysis methods. Such a treatment was deemed superfluous, in view of the fact that the response could be easily measured, but because in practical applications it would be desirable to have a rough estimate of the peak current (I_p), and peak-current potential (E_p), we present in the Appendix an approximate derivation of these parameters. In most cases, however, determination of the components of the dummy cell by trial and error will probably be preferred.

EXPERIMENTAL

Instruments and cells

The dummy cell was tested in conjunction with a Ben-Gurion University Model E1204 polarographic analyser[8,10] to which a Rekondenki Model BW-11 x–y plotter was connected. A standard power supply was used as the buck-off voltage source (V_B). The dummy cell was constructed from standard electronic components.

DPP procedure

All measurements were made with $E_{pulse} = 50$ mV, $E_{step} = 10$ mV, $t = 640$ msec.[8,10] The potential scan was started at $V_{REF} = 1400$ mV and terminated at $V_{REF} = 200$ mV. V_B was set to 1500 mV.

RESULTS AND DISCUSSION

The response of the polarographic analyser, when loaded by the proposed dummy cell and operated in the DPP mode, was a bell-shaped current peak with an amplitude dependent on the series resistance

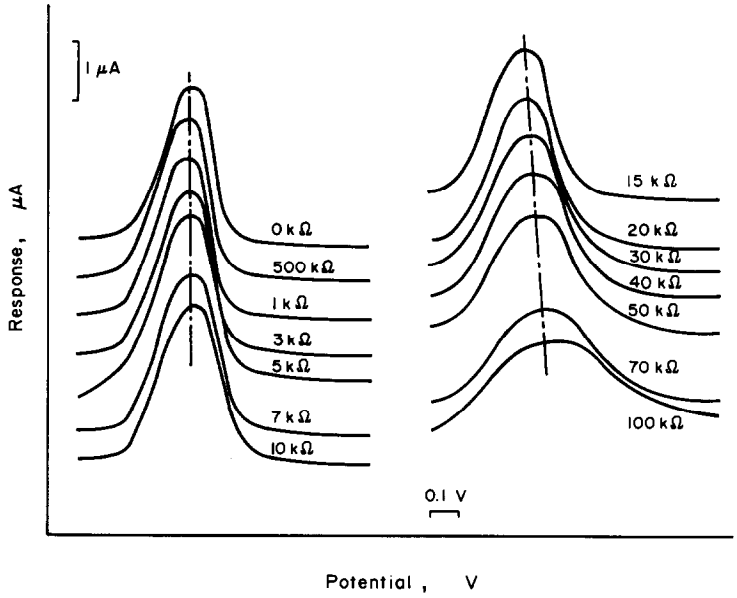

Fig. 2. DPP current response obtained with proposed dummy cell, for various resistors, R; V_B = 1500 mV. Peaks are located at about V_{REF} = 800 mV.

(Fig. 2). When V_B (Fig. 1) was 1.5 V, the current peak was obtained at E_p = 0.8 V as expected (see Appendix). The normalized peak current (Fig. 3) was found to be dependent only on τ and E_{pulse}, as predicted from the derivation given in the Appendix. However, the functional relationship between I_P/C and τ_R (= CR) did not follow exactly the predicted values obtained from the approximate analysis given in the Appendix. This is attributed to the fact that the approximate derivation does not allow for variations of R_d along the V–I curve for the diodes. Nonetheless, the values predicted by the linear model were close to the measured ones when R_d is between 6 and 10 kΩ, which was the actual range of R_d.

Besides determining the current peak-height, the charging time-constant also had a marked effect on the shape of the I_P curve (Fig. 2). The width at half-height ($\Delta E_{\frac{1}{2}}$) increased as a function of τ_R (Fig. 4), ranging from about 200 mV for $\tau_R = 0$ to about 550 mV for τ_R = 250 msec. It should be noted, however, that long time-constants are inconsistent with the approximate analysis given in the Appendix, which assumes that the response for each pulse is independent of that for the preceding pulse. By the

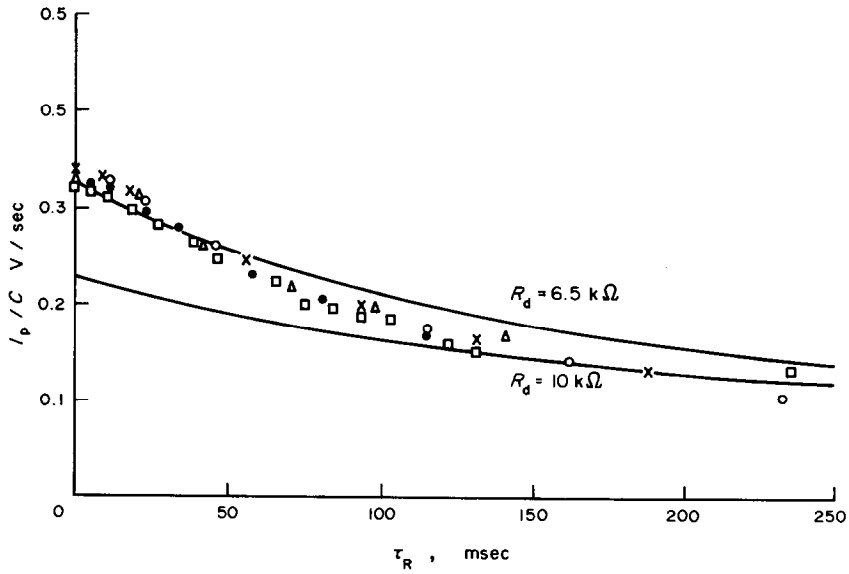

Fig. 3. Calculated and measured peak response (I_P/C) as a function of charging time-constant, $\tau_R = RC$. Solid line: model calculation; □ 9.4 μF; ○ 23.2 μF; ● 11.6 μF; △ 14.1 μF; × 18.8 μF.

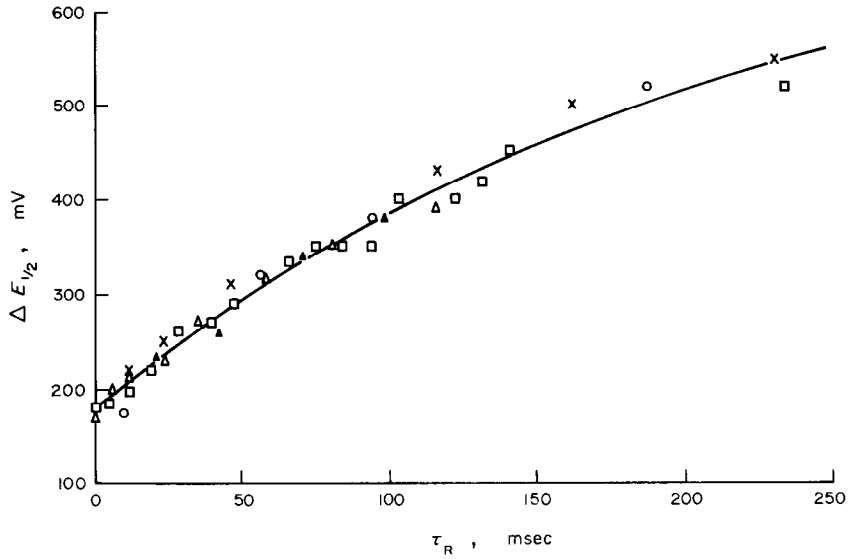

Fig. 4. Current-peak width at half-height ($\Delta E_{\frac{1}{2}}$), as a function of charging time-constant $\tau_R = RC$. □ 9.4 μF; △ 11.6 μF; ○ 18.8 μF; × 23.2 μF. Solid line is a least-squares fit of the data to an exponential curve.

least-squares fitting technique, the $\Delta E_{\frac{1}{2}}$ *vs.* τ_R function was approximated by an exponential function of the form:

$$\Delta E_{\frac{1}{2}} = V_{off} + V_{max}[1 - \exp(a\tau)] \qquad (1)$$

The best fit (Fig. 4) was obtained for $V_{off} = 178.9$ mV; $V_{max} = 557.1$ mV; $a = -4.608$ sec^{-1}.

This relationship is presumably a result of the exponential nature of the characteristic *V–I* curves of the diodes.[11,12] No attempt was made to derive an analytical expression for $\Delta E_{\frac{1}{2}}$.

A general comparison cannot be made between the DPP response obtained with an electrochemical cell and the one obtained with the proposed dummy cell, because the electrochemical response is a function of the particular experimental conditions used.[1,13] Comparison between the I_P obtained with the dummy cell and the I_P range found in an ASV analysis conducted with the same analyser and a glassy-carbon electrode,[10] showed that an I_P range of a few μA corresponds to a heavy metal concentration range of few ng/ml for a 30-sec deposition time. The $\Delta E_{\frac{1}{2}}$ previously obtained with an electrochemical cell[10] was about 70 mV, whereas the range 200–500 mV was obtained in this study. However, these comparisons are superficial since the DPP response is extremely sensitive to the particular experimental conditions used.

A closer examination of the processes which determine the response of the electrochemical cell and the dummy cell reveals that the mathematical relationships are of different nature. The time-dependence of the diffusion-controlled current in response to a potential step is proportional to $1/\sqrt{t}$,[14,15] whereas the charging current of the dummy-cell capacitor is proportional to $\exp(-t/\tau)$ (see Appendix). The I_P responses could be made equal for any given experimental conditions, but the equality may break down if any of the experimental parameters, say E_{step}, E_{pulse} or the excitation-pulse forms, is changed.

Notwithstanding the different processes which control the response of the real cell and the proposed dummy cell, the latter can be extremely useful in particular experimental situations. A typical problem which arises during a set of DPP measurements is to locate the source of trouble when malfunction occurs. An important step in a systematic procedure for pinpointing the reason for an analytical difficulty is to determine whether the source of the trouble is the analyser or the electrochemical cell. This could be easily accomplished by using the proposed dummy cell for testing the analyser response independently of the electrochemical cell. Since the analyser response when connected to a dummy cell is predetermined, any deviation from normal operation, such as a change in amplifier gain, incorrect scan-potential or waveform, or a malfunction of the differential processor, will cause a change in the standard response. The proposed dummy cell can also be applied in instrumentation studies aimed at improving the sensitivity or noise-rejection capability of DPP analysers.[8,16] In such studies it is imperative to obtain a reproducible response during many measurements that may extend over a long period of time. Under these conditions, the real electrochemical cell may prove to be inconvenient, owing to problems associated with the long-term stability and reliability of reference and working electrodes. Hence, in such situations, the application of the proposed dummy cell could be beneficial. However, since the response of the proposed dummy cell is only a first approximation to that of the electrochemical cell, care should be taken to examine the

extent to which the dummy cell is capable of simulating the real cell in any given experimental conditions.

APPENDIX

Approximate analysis of the dummy cell

The analysis is done on an equivalent circuit (Fig. 1b) which is based on a linear, piecewise approximation of the dummy cell network.[13,14] The peak current will be obtained when the two diodes just about reach the edge of conductance; *i.e.*, when

$$V_{REF} \cong V_B - 2V_\gamma \qquad (A.1)$$

where V_γ is the break-point of the *V–I* characteristic curves for the diodes.

The *V–I* characteristic curves of the IN4001 diodes used here show a voltage break at approximately 350 mV and a dynamic resistance range of 5–10 kΩ. It should be noted that this break-point at low current levels is at a much lower voltage than the 0.6 V break-point usually assumed for silicon diodes. This fact is well known[11,12] and is attributed to different conduction mechanisms in the silicon *p–n* junction.

The *V–I* characteristic curve of a diode and resistor in series, which represents the case in hand, seems to justify the linear piecewise equivalent circuit used in the approximate analysis.

The potential pulse, superimposed on this V_{REF} (equation A.1) will drive D_1 into conduction and will charge C through R. This charging current is amplified by the input circuit of the polarograph and processed by the analyser to produce the output response. It is assumed that the base-line current, which is subtracted from the pulse response, is zero, since the diodes were at the edge of conductance until the pulse appeared.

Since *C*, which simulates the diffusion process, is large, the voltage fluctuation across it will be relatively small, *i.e.*, it is assumed that C does not charge appreciably during the pulse period. Hence, D_2 will remain at the edge of conduction during the pulse period. An approximate value for I_P—or more accurately, the upper limit of I_P—can thus be derived by calculating the charging current of C through $(R + R_d)$ assuming that the current through D_2 is zero, and that the response to the preceding pulse excitation has already subsided.

The charging current will thus be:

$$I_C = \left(\frac{E_{step} + E_{pulse}}{R + R_d}\right)\exp\left(-\frac{t}{\tau}\right) \qquad (A.2)$$

where E_{step} = step height, E_{pulse} = pulse height, $\tau = (R + R_d)C$.

The response output of the polarograph is obtained by integrating the input current over one cycle of the power-line frequency:

$$I_C = \frac{E_{step} + E_{pulse}}{R + R_d}\int_{t_1}^{t_1+\Delta}\exp\left(-\frac{t}{\tau}\right)dt \qquad (A.3)$$

where t_1 = initial integration delay (20 msec), $\Delta = 1/f$ = period of power-line frequency (50 Hz in our case). Hence:

$$\frac{I_P}{C} = (E_{pulse} + E_{step})\left[\exp\left(-\frac{t_1}{\tau}\right) - \exp\left(-\frac{t_1+\Delta}{\tau}\right)\right] \qquad (A.4)$$

which predicts that the normalized peak current (with respect to *C*) will be dependent only on E_{pulse} and τ, given that t_1 and τ are fixed for a given polarographic analyser.[8]

FLOW-INJECTION ANALYSIS OF OXIDIZABLE SPECIES WITH REVERSE-PULSE AMPEROMETRIC DETECTION

JOSEPH WANG* and HOWARD D. DEWALD
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 10 *May* 1982. *Accepted* 12 *June* 1982)

Summary—The technique of reverse-pulse amperometry is applied for the detection of oxidizable organic species at a solid-electrode flow detector. Exploiting the reverse-pulse amperometric waveform gives better sensitivity than d.c. amperometric detection. Species (*e.g.*, phenols) giving responses that are poorly separated from background are easily monitored. Reducible species can be monitored without deaeration of the solution. The effects of flow-rate, waiting time between pulses, precision, and linearity of response are reported. At a flow-rate of 1.0 ml/min injection rates of 180 samples per hour and detection limits of a few tenths of a nanogram are obtainable.

Continuous analysis in flowing streams with solid-electrode flow detectors has gained increased attention in recent years.[1,2] Most solid-electrode detectors utilized in liquid chromatography (LC) or flow-injection analysis (FIA) employ d.c. amperometric detection. Recently, several pulsed-potential waveforms have been applied to LC and FIA detection, mainly in conjunction with cathodic reactions at the dropping mercury electrode. These include differential-pulse detection,[3] square-wave detection,[4] and reverse-pulse amperometric detection of amalgam-soluble metals.[5] Applications of reverse-pulse amperometry (RPA) to the flow analysis of oxidizable organic species at a solid-electrode detector have not yet been described.

This study characterizes the analytical utility of RPA in a flow-cell with a carbon electrode, as applied to redox reactions in which the (oxidizable) reactant and the (reducible) product coexist in solution. This approach is a variant of normal pulse voltammetry; it is based on the application of an unsymmetrical square-wave potential with a long application of a positive initial potential E_i, followed by a short pulse at a more negative final potential E_f. Oxidizable species are measured by monitoring the reduction (at the end of the more negative pulse) of the oxidation product from the initial potential (in the plateau region):

$$A \xrightarrow{E_i} B \xrightarrow{E_f} A$$

The current sampled at this point is proportional to the concentration of the species in the flowing stream. The generation/detection capability of RPA yields, at a single electrode, advantages similar to those reported recently for dual-electrode detectors.[6,7] Different aspects of electrochemical detection can be improved with the RPA detection mode: sensitivity, detection of species with high redox potentials, and detection of reducible species without interference from dissolved oxygen. The equipment is simple (a modern polarographic analyser with the normal pulse mode and a potential-hold capability) and available in most laboratories.

*Author for correspondence.

EXPERIMENTAL

Apparatus

The electrochemical "wall-jet" detector has been described in detail previously.[8] The working electrode was a planar glassy-carbon disk (0.25 cm diameter) with a solution stream directed onto it from a solution inlet nozzle (0.34 mm diameter). The distance between the nozzle tip and the surface of the glassy carbon was 0.025 cm. An Ag/AgCl reference electrode was placed in the cell downstream from the working electrode.

The carrier and sample solutions were stored in two Nalgene beakers, with similar hydraulic heads to provide equal flow-rates. These reservoirs were connected, through two Teflon tubes (1.0 mm bore, 0.05 mm wall), to a three-way Teflon stopcock located 12 cm from the detector. The stopcock and the cell were connected by 1.0-mm bore Teflon tubing. All measurements were made with a Princeton Applied Research Model 174 Polarographic Analyzer. Detection peaks were recorded on a Houston Omniscribe strip-chart recorder.

Reagents

The chemicals and reagents used have been described in detail previously,[9] except as noted. Stock solutions of NADH, chlorpromazine, phenol and benzoquinone were prepared each day. Aliquots of the stock solution were added to the phosphate buffer supporting electrolyte to give the desired concentration.

Procedure

The potential limits (E_i and E_f) for the RPA were set with the PULSE mode of the polarographic analyser, in a similar way to that described by Maizota and Johnson.[5] E_i and E_f were chosen to be in the limiting current regions for the forward and reverse reactions, respectively. The flow-

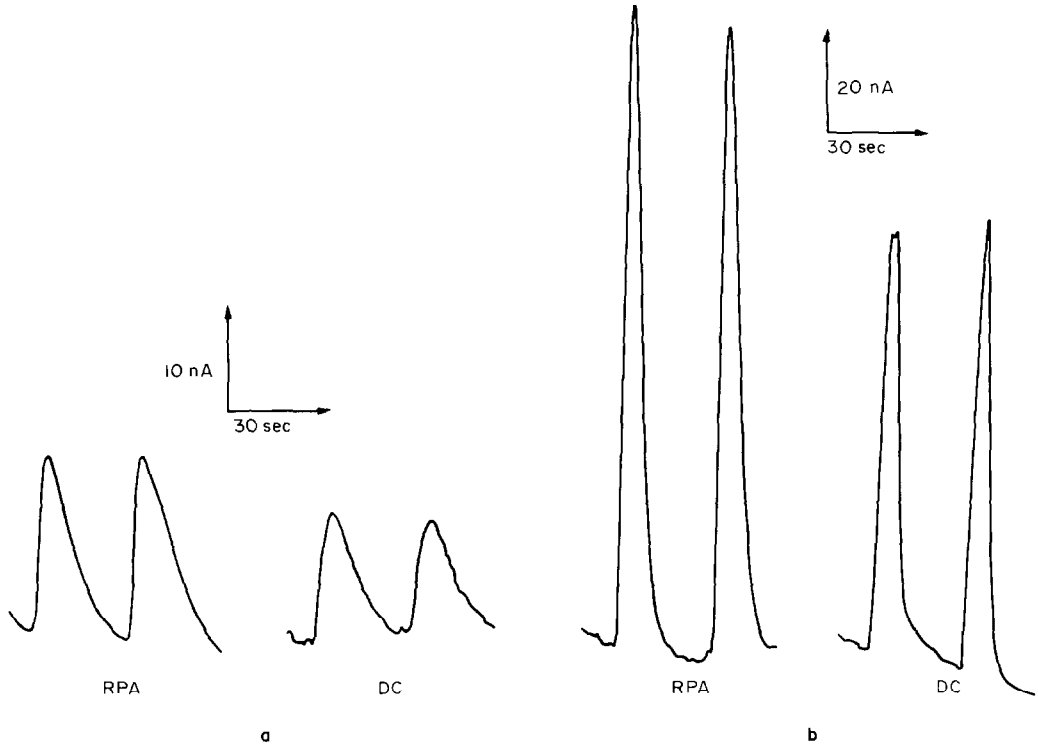

Fig. 1. Typical peaks for detection of 10μM ferrocyanide (a) and NADH (b) by FIA and RPA and d.c. detection modes. Conditions: flow-rate, 1.0 ml/min; Sample flow, 5 sec; carrier flow (0.1M phosphate buffer), 25 sec; sample size, 83 μl; pulse repetition time, 0.5 sec; low-pass filter, 1 sec; potentials, (a) RPA with $E_i = +1.0$ V, $E_f = -0.3$ V; d.c. at +1.0 V; (b) RPA, $E_i = +0.9$ V, $E_f = +0.2$ V; d.c. at +0.9 V.

injection measurements were performed with the three-way valve by alternating periodically, for fixed times, between the carrier solution (the supporting electrolyte) and the sample solution. Details are given in the following section.

RESULTS AND DISCUSSION

Figure 1 compares RPA detection peaks with those obtained in conventional d.c. amperometric detection for injections of 10μM solutions of ferrocyanide (a) and NADH (b). The advantage of the RPA detection mode is evidenced by its higher (by ~50%) peak currents. A surprising aspect of the RPA detection is that compounds (*e.g.*, NADH, ascorbic acid) which appear chemically irreversible with "slower" potential-scan techniques (such as cyclic voltammetry), have a significant RPA response because of the different time scale. (Initially, we intended to exploit the expected discrimination against compounds with irreversible redox reactions for improving the selectivity in flow-analysis of mixtures containing "reversible" and "irreversible" compounds.) A similar observation was reported recently for d.c. measurement at a dual-electrode detector with a short spacer between the upstream and downstream electrodes.[7]

For comparison of the results obtained by RPA with those for d.c. detection, the relative signal, expressed as RPA-peak current/d.c. peak current (i_{RPA}/i_{dc}) may be used. The value of i_{dc} is given by the equation for the limiting current at the "wall-jet" detector [ref. 10 equation (10)], and the RPA response can be described on the basis of the mixed hydrodynamic–Cottrell behaviour of pulse voltammetry at convective solid electrodes.[11] At low convection rates and short pulse-widths the RPA current will obey the Cottrell equation (and will be independent of convection transport); at higher convection rates, the convection transport will control the current. This behaviour is indicated by the data of Fig. 2a. The relative insensitivity of the RPA response to the flow-rate (below 1.0 ml/min) would be advantageous for making measurements in flowing systems with poorly controlled flow-rates. The mixed hydrodynamic–Cottrell RPA response assumes that the oxidation product is stable and is not adsorbed on the electrode. Therefore, RPA may be used as a tool for confirming the identity of an analyte which gives a product (at E_i) that is subject to chemical reaction or adsorption at the electrode (with the i_{RPA}/i_{dc} value as the criterion in a similar way to the collection efficiency in ring–disk or other dual electrode experiments). Table 1 gives the i_{RPA}/i_{dc} values for several compounds. Though for most compounds a 50% increase in sensitivity is observed ($i_{RPA}/i_{dc} \sim 1.5$), for chlorpromazine (a compound known to interact with a carbon surface[12]) there is a 20% decrease ($i_{RPA}/i_{dc} = 0.79$).

The effect of the waiting time between pulses (pulse repetition time) on the RPA response is shown in

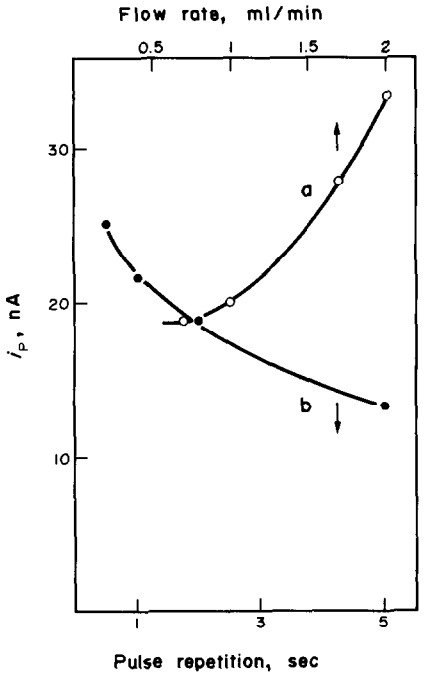

Fig. 2. Dependence of the FIA/RPA peak currents on the volume flow-rate (a) and the waiting time between pulses (b). Conditions: (a) 10μM ferrocyanide; sample flow, 5 sec; carrier flow (0.1M phosphate buffer) 25 sec; $E_i = +1.0$ V; $E_f = 0.3$ V; low-pass filter, 1 sec; (b) 5 μM benzoquinone; sample flow, 5 sec; carrier flow (0.1M phosphate buffer) 20 sec; flow-rate, 1.0 ml/min; $E_i = -0.8$ V; $E_f = +0.6$ V; low-pass filter, 1 sec.

Fig. 2b. The four repetition times available with the PAR 174 analyser were examined. As the waiting time increases, from 0.5 to 5 sec, the FIA/RPA peak current decreases by more than 50%. This is because as the waiting time increases, the frequency of sampling the current decreases, *i.e.*, fewer points are sampled during the passage of the short peak-shaped sample-plug profile through the detector (a peak-shaped response was obtained at the different times employed). Different effects on the peak current are expected if larger volumes are injected or if the product formed at E_i is not stable. From the data found, a repetition time of 0.5 sec was selected.

The main application of RPA detection is not to measurement of easily-oxidized analytes. Amperometric d.c. detection of compounds which react at high potentials (> 1.0 V), where background processes (water or mobile-phase oxidation) occur, suffers from detector drift, increased background and noise levels, and the need for high current gain.[6,7,13] These compounds may be better detected by using the generation/detection capability of RPA, *i.e.*, by detecting the oxidation product at lower potentials. A reverse-pulse procedure was exploited in a similar way to deal with the interfering hydrogen-evolution reaction, in batch analysis at the dropping mercury electrode.[14] Among the important compounds that are oxidized at potentials near that for solvent decomposition is phenol, the oxidation of which reaches a current plateau at potentials higher than +1.2 V (*vs.* Ag/AgCl electrode).[15] Problems associated with d.c. amperometric detection of phenolic compounds have been reported.[15,16] Figure 3a illustrates the RPA detection peaks for successive injections of 2.6μM phenol in phosphate buffer solution (corresponding to 20 ng in the injection volume used). The sampling rate is 180/hr. Well-defined and reproducible peaks are observed. A detection limit near 50nM (0.4 ng) is expected (signal/noise = 2).

Two separate experiments were performed to estimate the precision of the results. For a series of 10 repeated injections of a 25μM ferrocyanide solution, the average value of the peak current was 0.364 μA (with a range of 0.354–0.370 μA), and the relative

Table 1. Values of i_{RPA}/i_{dc} for several compounds*

Compound	E_i, V	E_f, V	i_{RPA}/i_{dc}
Ferrocyanide	+0.9	0.0	1.55
Chlorpromazine	+0.9	0.0	0.79
NADH	+0.9	+0.2	1.46
Phenol	+1.4	−0.1	1.54
Benzoquinone	−0.8	+0.6	1.41

*Concentration, 10 μM. FIA conditions and instrumental parameters as for Fig. 1. The d.c. measurements were made at potential E_i.

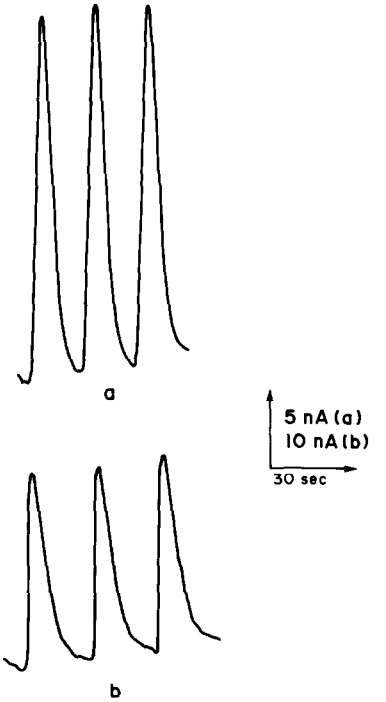

Fig. 3. Detection peaks in flow-injection analysis of a 2.6μM phenol solution (a) and a 5μM benzoquinone solution (b). Conditions: flow-rate, 1.0 ml/min; repetition time, 0.5 sec; low-pass filter, 1 sec; sample flow, 5 sec; carrier flow (0.1M phosphate buffer), 15 sec (a); 20 sec (b); potentials, $E_i = +1.4$ V, $E_f = +0.6$ V (a).

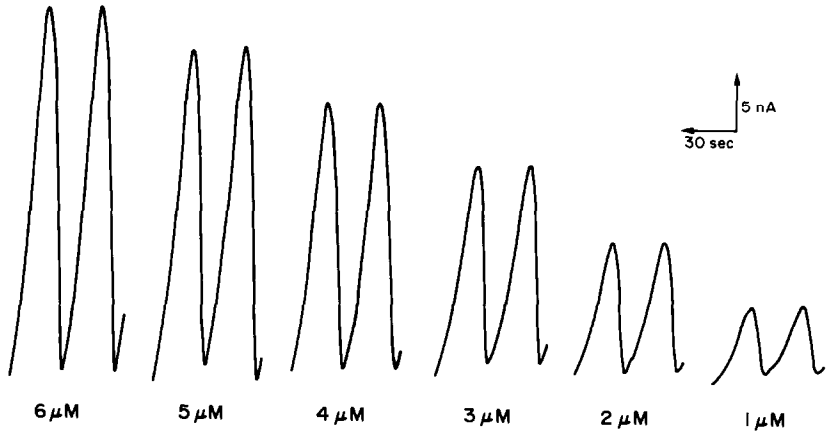

Fig. 4. Reverse-pulse amperometric detection for injections of 1, 2, 3, 4, 5 and 6 μM chlorpromazine solutions. Flow conditions, repetition time and filter, as for Fig. 1. $E_i = +0.9$ V, $E_f = 0.0$ V.

standard deviation was 1.3% (conditions as in Fig. 1a, except that the carrier flowed for 10 sec). A series of 8 repeated injections of an 11μM phenol solution yielded an average value for the peak current of 139 nA (range 134–142 nA), and a relative standard deviation of 1.0% (conditions as in Fig. 3a, except that the carrier flowed for 25 sec).

Another benefit of RPA detection is that low concentrations of reducible species can be monitored without interference from dissolved oxygen. The classical d.c. amperometric detection of reducible species usually requires the removal of oxygen from the test solution. MacCrehan and Durst[6] employed serial dual-electrode detection for eliminating oxygen interferences. In RPA detection, a similar advantage is obtained with a single electrode. Species are reduced at E_i (where reduction of oxygen occurs), and the species generated are oxidized and measured at E_f (which is insufficient to oxidize the hydrogen peroxide produced in the reduction of oxygen). This advantage of RPA detection was demonstrated[5] for detection of amalgam-forming metal ions by use of a dropping mercury electrode. We have exploited this capability for detecting reducible organic species at a solid electrode. Typical peaks for 5μM benzoquinone obtained by FIA and RPA are shown in Fig. 3b. A defined anodic response is obtainable through the oxidation, at $E_f = +0.6$ V, of the hydroquinone generated (by reduction) at $E_i = -0.8$ V.

To demonstrate the utility of RPA for measurements of low concentrations of organic compounds, FIA current–time data were recorded (Fig. 4) for chlorpromazine in the 1–6μM concentration range (corresponding to 29–174 ng for the 83-μl injection). Well-defined peaks and low noise level are observed. The estimated detection limit (signal/noise = 2) is 57 nM, which corresponds to 1.6 ng for the sample volume injected. The data of Fig. 4 yielded a linear calibration plot, the slope of which corresponds to a sensitivity of 5.9 nA.l.μmole^{-1} (correlation coefficient 0.995, intercept −0.2 nA). The tailing of the peak and the longer (25 sec) wash time needed in the chlorpromazine experiment may indicate that for compounds like chlorpromazine,[12] that interact with the carbon surface the RPA involves a slow "stripping" of the analyte from the surface.

In view of the results presented here, RPA flow-detection of electroactive species may be considered as a rival approach to d.c. amperometric detection. The low detection limit is a result of combining a sensitive detection mode with an effective "wall-jet" detector. The improved sensitivity, and detection of compounds with extreme redox potentials or of reducible species without the need for deaeration, indicate great promise and applicability for flow-through detectors.

DETERMINATION OF tert-BUTYLHYDROQUINONE IN EDIBLE OILS BY DIFFERENTIAL-PULSE POLAROGRAPHY

N. THUNYAUDOM TONMANEE and V. S. ARCHER*
Department of Chemistry, The University of Wyoming, Laramie, WY 82071, U.S.A.

(*Received* 8 *April* 1982. *Accepted* 9 *June* 1982)

Summary—A differential-pulse polarographic method for the determination of tert-butylhydroquinone (TBHQ) in vegetable oils has been developed and tested with a variety of oil samples. No prior extraction or other separation of TBHQ from the sample matrix is required. An oil sample is dissolved in a 1:5 v/v toluene/ethanol mixed solvent containing an acetate buffer, and polarograms are obtained directly for this solution. Recovery studies indicate that this method is suitable for routine determination of TBHQ at the concentrations normally used in edible oils.

Various phenolic antioxidants are commonly added to cooking oils and other food products to increase their stability. Among the most commonly used of these antioxidants are butylated hydroxytoluene (BHT), butylated hydroxyanisole (BHA) and propyl gallate (PG). One of the newest food-grade antioxidants to be approved for use in certain classes of food is tert-butylhydroquinone (TBHQ). Regulations issued by the U.S. Food and Drug Administration permit the use of TBHQ by itself, or combinations of TBHQ with BHA and/or BHT, in food products at a maximum antioxidant concentration of 0.02% w/w of the fat or oil in the food.[1] TBHQ can also be used in animal and poultry fats at a maximum concentration of 0.01%.[1]

TBHQ has been determined at low concentrations in fats, oils and other food products by means of a colour reaction with dimethylamine.[2] A gas chromatographic method for TBHQ has been described in another publication.[3] These procedures necessarily require prior extraction of the TBHQ from the food product.

Most antioxidants can be anodically oxidized at suitable electrodes in appropriate solvent systems. The electrochemical behaviour of a number of phenolic antioxidants has been reported,[4–7] with correlation of polarographic half-wave potentials with structure and/or antioxidation efficiency.

The anodic oxidation reactions of 2-substituted hydroquinones in aqueous perchloric acid solutions have been studied by cyclic voltammetry and controlled-potential coulometry.[8] With a methyl group in the 2-position, a simple 2-electron oxidation of the hydroquinone to the quinone occurs. A similar 2-electron oxidation of TBHQ to the corresponding quinone (TBQ) would be expected under normal voltammetric conditions:

$$TBHQ \rightarrow TBQ + 2H^+ + 2e^-$$

The polarographic behaviour of a series of alkylated hydroquinones, including TBHQ, was studied by Ryba *et al.*[7] They determined the half-wave potentials ($E_{1/2}$) for a number of these compounds in 50% v/v aqueous ethanol buffered with acetate. The $E_{1/2}$ values for anodic oxidation of TBHQ exhibited a pH-dependence consistent with a simple 2-electron oxidation reaction. The $E_{1/2}$ value for TBHQ at 25° was 0.067 V *vs.* SCE in a supporting electrolyte consisting of 0.10*M* sodium acetate/0.10*M* acetic acid in 50% v/v aqueous ethanol.

Luckadoo[9] developed a method for determination of TBHQ in safflower oil by d.c. polarography. This procedure involved extraction of the oil sample with methanol and polarographic determination of TBHQ after addition of a small volume of aqueous acetate buffer. The average recovery for TBHQ was 98%.

The previously cited methods for determination of TBHQ all involve a separation step prior to analysis. McBride and Evans[10] reported a method for rapid voltammetric determination of tocopherols, BHA and PG in oils and fats that does not require a prior separation. This linear-sweep voltammetric procedure allows determination of BHA and PG at concentrations above 0.001%. The differential-pulse polarographic method reported here also allows the direct determination of TBHQ in common types of vegetable oil without prior separation.

EXPERIMENTAL

Reagents

Antioxidants. The following food-grade antioxidants were obtained from Eastman Chemical Products. Inc.: Tenox® TBHQ, Tenox® 22 (20% BHA, 6% TBHQ, 4%

*Author for correspondence.

anhydrous citric acid, 70% propylene glycol), Tenox® 26 (10% BHA, 10% BHT, 6% anhydrous citric acid, 28% corn oil, 6% TBHQ, 28% glyceryl mono-oleate, 12% propylene glycol), Tenox® 20 (20% TBHQ, 10% anhydrous citric acid, 70% propylene glycol) and Tenox® 20A (20% TBHQ, 3% anhydrous citric acid, 32% glyceryl mono-oleate, 15% propylene glycol, 30% corn oil).

Cooking oils. Several brands of cooking oil containing no preservatives were purchased in local supermarkets: A (pure soybean oil), B (partially hydrogenated soybean oil), C (partially hydrogenated soybean oil with polyglycerides), D (partially hydrogenated soybean oil with polyglycerides), E (partially hydrogenated soybean oil, polyglycerides, artificial colour and flavouring), F (sunflower and soybean oils), G (sunflower oil), H (safflower oil), I (corn oil with isopropyl citrate), J (peanut oil).

An additional oil which contained TBHQ as a preservative was also purchased locally: K (sunflower oil with TBHQ and citric acid).

Solvents and other reagents. Absolute ethanol (U.S.P.) was obtained from U.S. Industrial Chemicals Co. All other chemicals used were reagent grade.

Apparatus

All polarograms were obtained with a Princeton Applied Research (PAR) Model 174A Polarographic Analyzer equipped with a PAR 174/70 drop-timer. The current–potential curves were recorded on an MFE Model 815 x–y recorder.

A three-electrode cell system including a Metrohm EA874 cell top and Metrohm EA875-20 cell bottom was used for all experiments. A saturated calomel electrode (SCE) with a porous Vycor® junction and a separate salt bridge with porous Vycor® junction was used as the reference electrode. The auxiliary electrode was a platinum foil of about 8 cm^2 area. The dropping mercury electrode (DME) had a flow-rate of 1.71 ± 0.03 mg/sec. This flow-rate was checked weekly.

TBHQ standard solutions. A stock solution of TBHQ was prepared by weighing 0.1662 g into a 10-ml standard flask, and dissolving and diluting it to volume with absolute ethanol. A $1.00 \times 10^{-3}M$ TBHQ standard solution was prepared by 100-fold dilution of the stock solution with absolute ethanol. Fresh solutions were prepared daily.

Preparation of TBHQ solutions in oils. The following approximate amounts of TBHQ were weighed accurately into 150-ml beakers: 0.005, 0.01 and 0.02 g. The selected oil was added carefully to bring the individual weights to about 100 g and the mixtures were weighed accurately. The samples were dissolved in the oil by stirring for about 3 hr at room temperature, with an argon atmosphere maintained over the sample. The oil samples were subsequently stored in polyethylene bottles.

Solutions of TBHQ in one of the oils were also prepared by using the Tenox® 20, 20A, 26 and 22 antioxidant preparations in such quantities as to give final antioxidant concentrations that corresponded to the levels allowed by U.S. FDA regulations.

Procedures

For investigation of the polarographic behaviour of solutions of TBHQ in various solvent/supporting electrolyte systems, all working solutions were prepared from stock solutions of the supporting electrolyte by adding increments of the TBHQ standard solutions. The solvent systems used were 50% ethanol, absolute ethanol and 1:5 v/v toluene/absolute ethanol. Various acetic acid (HOAc)/sodium acetate (NaOAc) buffer systems were used as the supporting electrolytes.

Differential-pulse polarography. Differential-pulse polarograms were obtained with solutions that had been purged with argon (saturated with the appropriate solvent) for at least 15 min immediately before the initial scan. The solutions were blanketed with argon during each scan and purged briefly with argon after each increment of TBHQ standard was added, before the next scan. The scans were all made at 2 mV/sec scan-rate, 25 mV modulation amplitude and 0.50 sec drop-time.

Procedure for determination of TBHQ in oil samples. A 1.00-ml aliquot of the oil sample was weighed accurately into the cell bottom. A 25.00-ml aliquot of buffer solution ($0.050M$ NaOAc/$1.0 \times 10^{-4}M$ HOAc in 1:5 toluene/absolute ethanol) was added, and argon was bubbled through the mixture for about 15 min to dissolve the sample and purge the solution. A differential-pulse polarogram was obtained over the range from −0.30 to 0.10 V *vs.* SCE, with the instrumental parameters already listed. Four standard additions of $1.00 \times 10^{-3}M$ TBHQ were made, each followed by a differential pulse polarographic scan. The peak currents were measured by the three base-line methods discussed in the following section.

RESULTS, DISCUSSION AND CONCLUSIONS

Initial investigation of the polarographic behaviour of TBHQ

A well-defined anodic differential-pulse polarogram was obtained for TBHQ with a TBHQ supporting electrolyte of $0.10M$ NaOAc/$0.10M$ HOAc in 50% v/v aqueous ethanol. The peak potential (E_p) was 0.065 V *vs.* SCE, which is very close to the $E_{1/2}$ value reported by Ryba *et al.*[7] for the same medium. Plots of peak current *vs.* TBHQ concentration were found to be linear in the range from 1.00×10^{-6} to $8.00 \times 10^{-5}M$.

The electrochemical behaviour of TBHQ was next studied with a supporting electrolyte of $0.10M$ NaOAc/$0.10M$ HOAc in absolute ethanol. The differential-pulse polarograms showed very well-defined peaks at TBHQ concentrations down to $1.0 \times 10^{-6}M$. The peak potential in this solvent/supporting electrolyte system shifted to −0.035 V *vs.* SCE. Plots of peak current *vs.* TBHQ concentration were linear over the same concentration range as for the aqueous ethanol system, but the sensitivity was much greater, the slope of the least-squares line being about 58% greater for the pure solvent than for the mixed solvent system. There was also less background noise.

Obviously, TBHQ could be determined in a number of food products by this method if a suitable extraction procedure were used to separate the TBHQ from the sample matrix. However, it was desired to develop a method for direct determination of TBHQ in cooking oils, without a separation step. Since the cooking oils were essentially insoluble in ethanol, a series of polarographic experiments was performed with toluene/absolute ethanol mixed solvent systems. Higher proportions of toluene adversely affected the anodic oxidation of TBHQ at the DME; however, it was found that 1:5 v/v toluene/ethanol would dissolve an adequate amount of common cooking oils and that the polarographic behaviour of TBHQ was quite satisfactory in this solvent system, though the peak current was smaller and the sensitivity somewhat lower than for the absolute ethanol system.

Differential-pulse polarograms were obtained for a solution containing 1.00 ml of a soybean oil (C) dissolved in 25.0 ml of 0.10*M* NaOAc/0.10*M* HOAc in 1:5 v/v toluene/ethanol. Standard additions of TBHQ were made to the solution and differential-pulse polarograms recorded for the concentration range 1.00–8.00 × 10^{-5}*M*. This procedure was repeated using another soybean oil (B) and a safflower oil (H). The peak potential (E_p) of TBHQ was about +0.010 V *vs.* SCE in these solutions, but there was an interfering substance (or substances) present in these oils which had a peak potential between 0.028 and 0.042 V *vs.* SCE. All the vegetable oils used in this study exhibited an oxidation peak in the range 0.02–0.05 V *vs.* SCE. By decreasing the concentration of HOAc in the supporting electrolyte, it was possible to shift the anodic differential-pulse polarographic peak of TBHQ to potentials sufficiently negative for the other peak not to interfere to so great an extent.

Differential-pulse polarograms were obtained for solutions containing 1.00 ml of a sunflower oil sample (K) dissolved in 25.0 ml of various acetate buffers in 1:5 v/v toluene/ethanol. (Oil K contained TBHQ as a preservative.) The peak potential of the TBHQ was found to be about −0.05 V *vs.* SCE with a 0.10*M* NaOAc/1.0 × 10^{-4}*M* HOAc supporting electrolyte or about −0.04 V with a 0.050*M* NaOAc/1.0 × 10^{-4}*M* HOAc supporting electrolyte. The peak at about 0.03 V *vs.* SCE was not shifted by the change in pH and was only a minor source of interference in the less acidic buffer systems. The supporting electrolyte used in all subsequent polarographic work was the 0.050*M* NaOAc/1.00 × 10^{-4}*M* HOAc buffer, because it was difficult to dissolve enough NaOAc in the solvent system to give 0.10*M* solutions.

Methods of quantitation

Because all the oils used in this study contained a substance (or substances) which gave an anodic peak at between 0.02 and 0.05 V *vs.* SCE, the TBHQ peak was always superimposed on the rising portion of this peak. This made it necessary to devise empirical methods for estimating the base-line current in order to measure the peak current for TBHQ. Obviously, a blank can be used to determine a base-line if a sample of the oil being analysed, and not containing TBHQ, is available for reference. This was the case for the recovery studies reported here, but would not be the case for most practical oil analyses. Therefore in addition to use of a blank for base-line determination, two empirical base-line methods were devised and tested. Figure 1 illustrates the three methods used for base-line determination and subsequent measurement of peak currents in the recovery studies: curve 1 illustrates the "blank" method, curve 2 the "tangent" method and curve 3 the "extrapolation" method.

The TBHQ in each oil sample was determined by the standard-additions method.

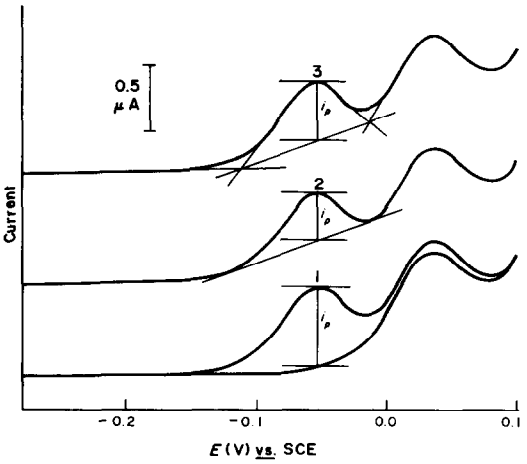

Fig. 1. Three methods for estimation of base-line current and measurement of peak current of TBHQ in cooking oils: 1, "blank" base-line method; 2, "tangent" base-line method; 3, "extrapolation" base-line method.

Recovery studies

Recovery studies were performed on ten brands of vegetable oil, which were obtained locally. None of these oils contained TBHQ. Solutions containing about 0.005, 0.01 and 0.02% TBHQ in each oil were prepared accurately. The TBHQ in each sample was determined as already described. In most cases, peak height was measured by use of all three base-line methods. Ten replicate determinations were done on the three samples of oil D, and triplicate determinations on the other oil samples. The results are reported in Table 1.

The "tangent" method invariably gave low results, as would be expected, especially for the samples containing 0.005 or 0.01% TBHQ. The recoveries by the "blank" method were generally satisfactory, but in some cases (oils E, A and G) the results were excessively high. Under normal circumstances, this method could not be used for "real" samples because samples of the "pure" oil would not be available for reference.

The "extrapolation" method gave good recoveries for all three concentrations of TBHQ in most of the oils used in this study. The only really poor results obtained with this method were for TBHQ at the 0.005% level in the sunflower oil (G) and the corn oil (I). Therefore, this should be the method of choice.

The best indication of the inherent precision of the method is given by the results obtained for oil D. The relative standard deviation for the "extrapolation" method is below 1% at all three concentrations in this case. The recoveries are also quite satisfactory.

It should be noted that the peak potentials for TBHQ are somewhat dependent on which oil is used. In addition, the peaks are shifted to more positive potentials at higher concentrations of TBHQ. This shift is due to the hydrogen ion that is produced in the electrode reaction and the relatively low buffer capacity of the supporting electrolyte. The lower

*A more complete description of the oils is given in the reagents section.

instantaneous pH at the electrode surface in these cases causes a slight positive shift in the potential at which TBHQ may be oxidized. The peak potentials (E_p) reported in Table 1 are for oils which contain about 0.005% TBHQ. The uncertainty is about ±5 mV in each case. With the exception of the corn oil (I), all the peak potentials are within about 10 mV of −0.050 V *vs.* SCE.

The TBHQ peaks obtained for the corn oil (I) were extremely broad and poorly resolved, but the results obtained at the two higher concentrations of TBHQ were quite satisfactory. The peaks obtained for TBHQ in the other nine oil samples were all well resolved. Figure 2 shows typical differential-pulse polarograms obtained for TBHQ in one of them (oil D). The steep base-line due to the interfering peak at about 0.036 V *vs.* SCE made it necessary to use either the "blank" or the "extrapolation" method for the oil samples containing 0.005% TBHQ in order to achieve adequate recoveries.

Recovery studies were also performed on several commercial antioxidant preparations marketed by Eastman Chemical Products, Inc. for direct addition to cooking oils and other food products, *viz.* Tenox® 22, 26, 20 and 20A (the compositions of which were given in the reagents section). Appropriate amounts were added to oil D and the TBHQ determined as in the other recovery studies. The polarograms were of the same form as those obtained by direct addition of TBHQ to the oil (see Fig. 2). Five replicate determinations were done on each sample. The results are

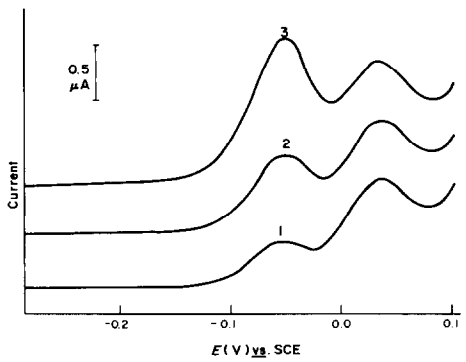

Fig. 2. Differential-pulse polarograms of TBHQ recovery studies in soybean oil D: 1, 0.00532% TBHQ added; 2, 0.0106% TBHQ added; 3, 0.0200% TBHQ added.

Table 2. TBHQ recovery from soybean oil D plus antioxidant preparations

Antioxidant preparation	TBHQ added, %	No. of replicates	Mean recovery, % ($\pm\sigma$) "Blank" base-line method	"Tangent" base-line method	"Extrapolation" base-line method
Tenox® 22	0.00456	5	99.9 (±0.5)	76.0 (±0.3)	96.6 (±0.5)
Tenox® 26	0.00465	5	99.9 (±0.7)	75.7 (±0.6)	93 (±2)
Tenox® 20	0.0200	5	101 (±2)	94.5 (±0.7)	100.1 (±0.6)
Tenox® 20A	0.0200	5	103 (±2)	93 (±1)	99 (±1)

reported in Table 2. The recoveries obtained by either the "blank" or the "extrapolation" method were satisfactory. Obviously, none of the other components of the preparations interfered. Both BHA and BHT can be electrochemically oxidized but only at electrode potentials more positive than the working range of a DME.

One sunflower oil sample (K) which contained TBHQ as a preservative was obtained locally. The TBHQ was determined in this sample by the procedure given. The amount of TBHQ found in this sample by the "extrapolation" method was 0.0088%. Since U.S. FDA regulations allow adding TBHQ to vegetable oils in amounts not greater than 0.02%, this result would seem to be reasonable.

The differential pulse polarographic method described in this paper should be useful as an alternative method for determination of TBHQ in cooking oil samples. The accuracy and precision should be adequate for most routine analyses of this type of sample. One of the principle advantages of this technique is that no prior separation of TBHQ is required: the oil sample (1 ml) is weighed directly into a polarographic cell, a known volume of solvent/supporting electrolyte mixture is added and a polarogram is run. Quantitation is straightforward by the "extrapolation" method in conjunction with standard additions.

Acknowledgement—The TBHQ and the Tenox® antioxidant preparations were provided by the Health and Nutrition Division of Eastman Chemical Products, Inc., Kingsport, Tennessee 37662.

POTENTIOMETRIC DETERMINATION OF CERTAIN α-AMINOHYDROXY COMPOUNDS BY USING AN AMMONIA GAS-SENSING ELECTRODE

D. P. NIKOLELIS, C. E. EFSTATHIOU and T. P. HADJIIOANNOU
Laboratory of Analytical Chemistry, University of Athens, 104 Solonos St., Athens 144, Greece

(*Received* 14 *April* 1982. *Accepted* 7 *June* 1982)

Summary—A simple method is described for the determination of certain α-aminohydroxy compounds, based on the potentiometric measurement of ammonia released after oxidation with an excess of periodate. Ammonia is measured directly in the reaction mixture, with an ammonia gas-sensing electrode. Ethanolamine, diethanolamine, triethanolamine, serine, threonine, and glucosamine (0.3–6 μmole) can be determined with average errors of about 1–2%.

The ammonia gas-sensing electrode has been used extensively for the direct potentiometric determination of ammonia in a variety of matrices of clinical or environmental importance.[1] It has also been used for the construction of bioselective sensors, such as enzyme electrodes, by taking advantage of the fact that ammonia is a product of biodegradation of many nitrogen-containing organic compounds.[2] Ammonia is also obtained from the chemical degradation (*e.g.*, hydrolysis) of many organic compounds, thus making possible their potentiometric determination.

In a previous paper we described a simple method for assaying nicotinamide in multivitamin preparations by potentiometric measurement of ammonia released after alkaline hydrolysis of the sample.[3] In this paper we describe a simple procedure for the determination of various α-aminohydroxy compounds, based on the determination of ammonia released after oxidation with an excess of periodate.

It is known that periodate cleaves the carbon–carbon bond of α-aminohydroxy compounds smoothly.[4] The general reaction scheme for the three α-amino alcohols, ethanolamine, diethanolamine and triethanolamine, is

$$(HOCH_2CH_2)_nNH_{3-n} + nIO_4^- \rightarrow 2nHCHO + NH_3 + nIO_3^- \quad (n = 1\text{–}3).$$

The optimum conditions (pH, temperature and reaction period) for completion of these reactions have been reported[5] and various analytical schemes have been developed. Titrimetric methods are based on the iodometric determination of either the excess of periodate or the iodate produced, after masking of the excess of periodate with molybdate.[6] Other schemes are based on the spectrophotometric measurement of the formaldehyde produced.[7] These methods offer high accuracy and sensitivity but they lack selectivity when other compounds reacting with periodate, such as vicinal glycols, polyhydroxy compounds and carbohydrates are present. The titrimetric determination of the ammonia released is not subject to these interferences but it involves tedious and time-consuming separation steps (*e.g.*, by microdiffusion[8]).

With the ammonia gas-sensing electrode, ammonia can be determined directly in the reaction mixture. No separation steps are necessary and the sensitivity of the analysis is greatly improved. To evaluate the method, it was applied to the determination of three ethanolamines, the α-hydroxyamino-acids serine and threonine, and the amino-sugar glucosamine. Microamounts of these compounds in the range 0.3–6 μmole were determined with average errors of about 1–2%.

EXPERIMENTAL

Apparatus

An Orion Model 95-10 ammonia gas-sensing electrode was used, and the potential measurements were made with an Orion Model 801 digital pH/mV meter. All measurements were made at 25°C ± 0.1° in a 10-ml cell equipped with a magnetic stirrer.

When not in use, the electrode was kept in 0.05*M* ammonium chloride.[9]

Reagents

Analytical-grade materials and demineralized, distilled water were used throughout.

*Sodium metaperiodate, 0.100*M. Dissolve 21.4 g of reagent in water and dilute to 1 litre. Store in an amber bottle.

*Potassium carbonate, 1.00*M *solution.*

*Sodium bicarbonate, 0.20*M *solution.*

*Potassium hydroxide, 2.00*M *solution.*

α-Aminohydroxy compounds. Prepare 0.0200*M* stock solutions of serine, threonine and glucosamine hydrochloride by dissolving the appropriate amount of each compound in water. Prepare 0.0200*M* stock solutions of ethanolamines by diluting 1*M* solutions, which have been titrated potentiometrically with standard 1.000*M* hydrochloric acid solution. Prepare fresh standard solutions, $1.00 \times 10^{-4}M$, $2.50 \times 10^{-4}M$, $7.50 \times 10^{-4}M$ and $2.00 \times 10^{-3}M$, as needed, by appropriate dilution of the stock solutions.

Procedures

Monoethanolamine, diethanolamine, serine and threonine. Pipette 4.00 ml of a 1:1 mixture of 0.100*M* sodium metaperiodate and 1.00*M* potassium carbonate (this mixture is stable for at least one day at room temperature) and 3.00 ml of the standard or unknown α-aminohydroxy compound solution into the measurement cell. Start the stirrer and read the potential when it has stabilized to within ±0.1 mV (in about 3–4 min). Find the unknown concentration from a calibration graph of potential *vs.* log [α-aminohydroxy compound].

Triethanolamine. Incubate the reaction mixture (prepared as before) in a 10-ml vial fitted with a well-fitting stopper, for 60 min, in a water-bath at 60°, cool to room temperature, transfer the contents of the vial into the measurement cell and measure as for monoethanolamine *etc.*

Glucosamine. Pipette 3.00 ml of a 2:1 mixture of 0.100*M* sodium metaperiodate and 0.20*M* sodium bicarbobonate (this mixture is stable for at least 15 min at room temperature, but then disodium paraperiodate, $Na_2H_3IO_6$, starts to precipitate) and 3.00 ml of the standard or unknown glucosamine solution into a 10-ml vial with a well-fitting stopper. Shake the vial and immerse it in a water-bath at 60° for 60 min. Cool the vial to room temperature, pipette 1.00 ml of 2.00*M* potassium hydroxide into it, mix, and transfer the contents into the measurement cell. Measure as above.

RESULTS AND DISCUSSION

Completion of the reactions

Figure 1 shows recordings of the potential of the ammonia gas-sensing electrode during the course of the reaction of α-aminohydroxy compounds with periodate in alkaline (carbonate) solution. Since gas-sensing electrodes are slow-response concentration transducers, for comparison of speed of response an increase of ammonia concentration by addition of ammonium chloride has been included. The latter was added in an amount equivalent to that of the α-aminohydroxy compound.

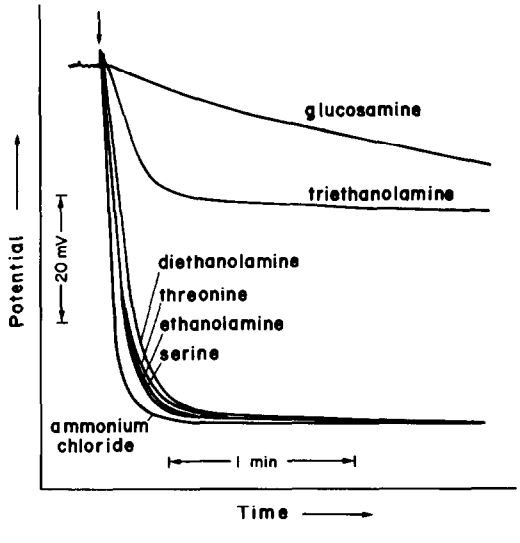

Fig. 1. Records of the potential of the ammonia gas-sensing electrode during the reaction of periodate with α-aminohydroxy compounds. In a mixture of 4.00 ml of composite 0.0500*M* periodate–0.500*M* carbonate solution and 3.00 ml of $6.67 \times 10^{-5}M$ ammonium chloride, 100 μl of 0.0200*M* solution of the relevant α-aminohydroxy compound are injected. Ammonium chloride is also injected for comparison. ↓: α-aminohydroxy compound (or ammonium chloride) solution injection. Concentrations at the start of the reaction: $NaIO_4$, 0.0282*M*; K_2CO_3, 0.282*M*; NH_4Cl, $2.82 \times 10^{-5}M$ (added in all cases to keep the initial potential stable); α-aminohydroxy compound (or NH_4Cl), $2.82 \times 10^{-4}M$. Temperature: 25°C.

It has been reported that the ammonia electrode responds to lower organic amines.[1] It can be seen from Fig. 1 that there is no direct response of the electrode to α-aminohydroxy compounds. This is probably because the hydroxyl groups make these compounds more hydrophilic and therefore less able to diffuse through the hydrophobic membrane of the ammonia gas-sensing electrode.

Ethanolamine, diethanolamine, serine and threonine react quantitatively and almost instantaneously with periodate, and weakly alkaline (bicarbonate) media have been recommended[4,6] for making the reaction quantitative. However, the reactions also proceed quickly in more alkaline (carbonate) solutions, and then practically all the ammonia released is in molecular form and thus is measured quantitatively with the ammonia gas-sensing electrode.

On the other hand, triethanolamine and glucosamine react very slowly and incompletely. In fact, under all conditions tested (*e.g.*, bicarbonate solutions, phosphate buffers of pH 7–9, carbonate and borate buffers of pH 9–10, use of Mn^{2+} as catalyst plus nitrilotriacetic acid as activator,[10] at temperatures from 25° to 75°) the ammonia released never exceeded 90% of the theoretical amount. These findings contradict those of other workers[6] who claim complete oxidation, at least for triethanolamine. It is possible that the reaction is stoichiometric with regard to the periodate consumed or iodate produced per molecule of triethanolamine but that some of the ammonia condenses with the formaldehyde formed as one of the reaction products. Attempts to release ammonia quantitatively by addition of glycine as a scavenger for formaldehyde failed, because glycine is oxidized by periodate at elevated temperature and releases large amounts of ammonia. Plots of the percentage of ammonia released from triethanolamine and glucosamine *vs.* reaction period, under a variety of conditions, are shown in Fig. 2. The ammonia released from triethanolamine and glucosamine was 80 and 88% of the theoretical amount, respectively, when the reaction with periodate took place in alkaline (carbonate) and weakly alkaline (bicarbonate) solutions respectively, at 60° for 60 min.

Analytical results

The potential of the ammonia gas-sensing electrode was found to be linearly dependent on the logarithm of the concentration of the α-aminohydroxy compound, according to the general equation.

$$E = \text{constant} - S\log[\alpha\text{-aminohydroxy compound}]$$

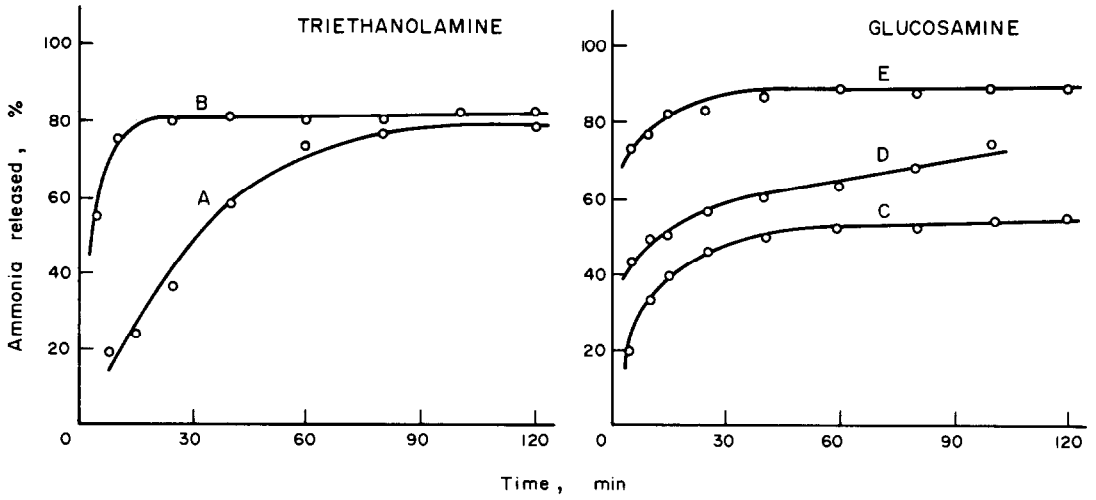

Fig. 2. Rate of release of ammonia for triethanolamine and glucosamine. Initial concentrations and temperatures: A–$NaIO_4$, 0.0286M; K_2CO_3 0.286M; triethanolamine, 3.21 × $10^{-4}M$; 25°C. B—as in A but at 60°C. C—$NaIO_4$, 0.0286M; K_2CO_3, 0.286M; glucosamine, 3.21 × $10^{-4}M$; 25°C. D—same as C but at 60°C. E—$NaIO_4$, 0.0333M; $NaHCO_3$, 0.0333M; glucosamine, 3.75 × $10^{-4}M$; 60°C.

for the concentration range 1 × 10^{-4}–2 × $10^{-3}M$. The working range can be extended to higher concentrations provided that enough periodate is added to oxidize the compound to be determined plus any other oxidizable compound. Working curves for ethanolamine, diethanolamine and α-hydroxyamino-acids, obtained by plotting potential *vs.* log[α-aminohydroxy compound], practically coincide with a working curve obtained with standard solutions of ammonium chloride. Therefore, for these compounds the

*At these interference levels it took about 10 min to obtain a steady potential indication.

†At this interference level the potential was not stabilized even after 10 min, drifting continuously toward smaller values (smaller error).

working curve can be based on standard ammonium chloride solutions. The working curves for triethanolamine and glucosamine were shifted slightly toward more positive potentials because of the incomplete release of ammonia.

Table 1 gives typical analytical results for the determination of six α-aminohydroxy compounds, together with the regression equations of the corresponding working curves. The relative standard deviation for $5 \times 10^{-4}M$ ethanolamine was 2.0% ($n = 12$).

Interferences

Positive analytical errors are to be expected in the presence of free ammonia or ammonium salts, or compounds releasing ammonia under the conditions of the measurement, such as amides or nitriles. Such interferences can be overcome by running blanks from which periodate is omitted.

Negative analytical errors are to be expected in the presence of compounds that react with ammonia, such as aldehydes. Negative analytical errors are also to be expected in the presence of compounds that consume periodate, such as vicinal glycols, polyhydroxy compounds and carbohydrates. Such interferences can be minimized by using as much periodate as possible. Again the problem is only partially solved because aldehydes released from the cleavage of these compounds may react with some of the ammonia. The interference, expressed in terms of analytical error, caused by such compounds in the analysis of various α-aminohydroxy compounds at various concentration ratios is shown in Table 2.

It can be seen from Table 2 that α-aminohydroxy compounds which are oxidized at 25° by periodate in alkaline (carbonate) solution can be determined even in the presence of a hundredfold excess of propylene glycol and glycerol, because these interferents react very slowly with periodate in alkaline solutions. On the other hand, glucose reacts quickly with periodate, reducing its oxidative capacity. Formaldehyde masks ammonia only when it is present in large excess. Determination of triethanolamine and glucosamine results in more intense interference because of the higher temperature used for their determinations.

At high interferent concentrations, it was noticed that the ammonia was released only slowly for the easily oxidized compounds, probably owing to the reduced availability of periodate because of the equilibrium existing between the free anion and its complex compound with the polyhydroxy compound, favoured by the alkaline pH.[4]

CONCLUSIONS

The proposed method for the determination of α-aminohydroxy compounds is simple, fast, sensitive and selective enough for many possible applications. The accuracy attained is similar to that of other direct potentiometric measurements. This method comple-

ments other methods for the determination of α-aminohydroxy compounds and broadens the spectrum of possible applications of the ammonia gas-sensing electrode. A possible use for the method would be the determination of total serine and threonine in the hydrolysis products of peptides and proteins, and of ethanolamines in petroleum plant effluents and cutting fluids. The possibility of the determination of glucosamine in serum glycoproteins is under consideration.

SPECTROPHOTOMETRIC DETERMINATION OF SOME PHENOLS WITH SODIUM METAPERIODATE AND AMINOPHENOLS

C. S. PRAKASA SASTRY, K. EKAMBARESWARA RAO and U. V. PRASAD
Department of Chemistry, Andhra University, Waltair 530003, India

(*Received* 6 *November* 1981. *Revised* 26 *April* 1982. *Accepted* 7 *June* 1982)

Summary—New spectrophotometric methods have been developed for the assay of some phenols by use of two pairs of reagents, *m*-aminophenol and periodate (for catechol, catecholamines, eugenol and guaiacol) and metol and periodate (for pyrogallol, gallic acid, propyl gallate, phloroglucinol and butylated hydroxyanisole). The methods are simple, sensitive, reproducible, accurate within ±1.0%, and applicable to the assay of antioxidants (gallic acid, propyl gallate and butylated hydroxyanisole) in oils and fats, catecholamines in dosage forms, and eugenol in clove oil.

It has long been known that phenols are readily oxidized. The products are mostly complicated mixtures of dimeric, polymeric, and quinonoid compounds.[1–3] Several spectrophotometric and colorimetric methods for assay of phenols are cited in the literature.[4–23] Recently kinetic determination of phenols by a fixed-time method using sodium metaperiodate as oxidant has been reported.[24] We have now developed simple, rapid, sensitive and accurate spectrophotometric determinations of some phenols at the microgram level, with sodium metaperiodate in the presence of aminophenol. They are based on our observations that catechol (reagent: $NaIO_4$ and aniline or *m*-aminophenol), catecholamines, eugenol and guaiacol (reagent: $NaIO_4$ and *m*-aminophenol), pyrogallol, gallic acid and propyl gallate (reagent: $NaIO_4$ and metol or *p*-aminophenol) and phloroglucinol and butylated hydroxyanisole (reagent: $NaIO_4$ and metol) develop characteristic colours (λ_{max} shown in Table 1) and that the intensity of colour is directly proportional to the amount of phenol. These methods have wide applicability in purity assays of antioxidants (gallic acid, propyl gallate and butylated hydroxyanisole) and sympathomimetics (catecholamines), and also for estimation of these antioxidants in oils and fats, catecholamines in dosage forms and eugenol in clove oil.

A: *m*-Aminophenol; B: *p*-aminophenol; C: aniline; D: metol (*p*-*N*-methylaminophenol sulphate).
*Used in suggested procedure.
†Range for maximum absorbance and stability.

EXPERIMENTAL

Reagents

All solutions were prepared in doubly distilled water. The solutions (0.2%) of aminophenols or aniline in pH 3.0 buffer were always freshly prepared. The sodium metaperiodate solution was 0.01*M*. Buffer solutions of glycine and hydrochloric acid (pH 1.0–2.1) and of potassium hydrogen phthalate and hydrochloric acid (pH 2.2–3.7) were prepared according to Lurie.[25]

All the phenols used were of commercially available general-reagent or C.P. grade. Their stock solutions were prepared in distilled water, the compounds insoluble in water being dissolved initially in the minimum volume of alcohol or pH 3.0 buffer solution. Working solutions were prepared by appropriate dilution of the stock solutions. All other reagents were of analytical grade.

General procedures

To a 25 ml standard flask, add, in the following order, 15 ml of buffer solution, aminophenol solution (*m*-, *p*- or *p*-*N*-methyl), sodium metaperiodate solution and 1–4 ml of the phenol solution, and dilute to the mark. Measure the absorbance at λ_{max} after maximum colour development, against a reagent blank prepared under similar conditions. Prepare a calibration graph in the same way. The buffer pH, the volume of perrodate solution, and the other experimental conditions needed are shown in Table 1.

Procedure for propyl gallate or gallic acid in oils and fats

Dissolve 10 g of oil or fat in 50 ml of carbon tetrachloride and extract with four 20-ml portions of 50% aqueous alcohol. Neutralize the combined alcoholic extracts with calcium carbonate (1 g) then dilute with water to 100 ml in a standard flask and filter through a dry paper. Use the filtrate for propyl gallate or gallic acid determination by the procedure above.

For the determination of butylated hydroxyanisole in oils or simultaneous determination of butylated hydroxyanisole and propyl gallate if both are present, separate the antioxidant(s) by the procedure suggested by Schwien and Conroy,[26] and apply the general procedure.

Procedures for dosage forms of catecholamines

Use pH 3.0 buffer to bring the catecholamine present in the dosage form (tablet, powder or injection) into the working range (100 μg/ml) and apply the general procedure.

Procedure for adrenaline in biological fluids

Take a 1-ml sample of urine or blood and precipitate the protein with trichloroacetic acid (0.5 ml of 5% solution). To the clear centrifugate, add a few drops of sodium hydroxide solution to adjust the pH to 3.0. Then apply the general procedure to determine the adrenaline.

Procedure for eugenol in clove oil

Dissolve the clove oil in methanol and dilute to bring the eugenol concentration into the working range (100 μg/ml), and apply the general procedure.

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of the reaction products show characteristic maxima (shown in Table 1), whereas the reagent mixtures used have practically no (or only low) absorption in these regions (Figs. 1–3). The time taken for maximum colour development and the stability period in each case are shown in

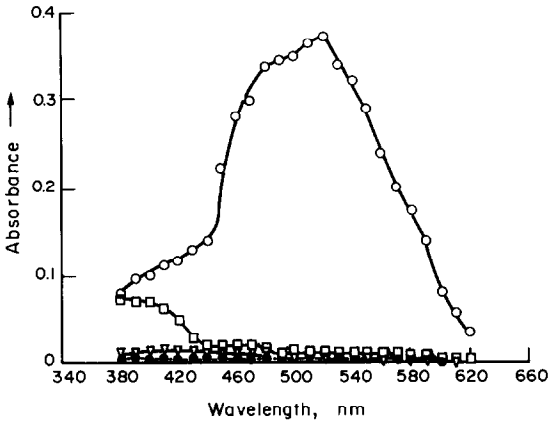

Fig. 1. Absorption spectrum of catechol–periodate–*m*-aminophenol system ○——○ catechol–IO_4^-–mAP *vs.* reagent blank; □——□ IO_4^-–catechol *vs.* IO_4^-; ◇——◇ IO_4^-–mAP *vs.* IO_4^-; ●——● mAP–catechol *vs.* mAP. $[IO_4^-] = 8.0 \times 10^{-4}M$; [mAP] = $7.3 \times 10^{-4}M$; [catechol] = $9.1 \times 10^{-5}M$.

*Mean of three readings.

Table 1. The studies show that *m*-aminophenol/periodate is the best reagent for catechol, catechol monoalkyl ethers and catecholamines, and metol/periodate for pyrogallol, gallic acid, propyl gallate, phloroglucinol and butylated hydroxyanisole.

Effect of pH and reagent concentration

The optimum conditions are presented in Table 1. Higher pH should not be used, as the phenols themselves then develop colours with periodate.

Effect of order of addition

The order of addition of the reactants has no influence on the colour development if mixing is done immediately, but any delay in adding the aminophenol to the phenol–periodate mixture or adding the phenol to the aminophenol–periodate mixture (exception: catechol) causes a considerable decrease in absorbance.

Table 3. Recovery of added antioxidants from edible oils and fats

Sample	Antioxidant added, mg	Recovery, %	
		Proposed method	Literature method
Coconut oil	PG, 10	96.4	95.7[29]
Groundnut oil	PG, 10	97.1	96.6
Sunflower oil	PG, 10	98.3	97.8
Cottonseed oil (hydrogenated)	PG, 10	95.6	95.9
Groundnut oil	GA, 10	95.5	96.1[28]
Sunflower oil	BHA, 10	96.1	96.5[29]
Sunflower oil	PG, 5*	97.2	97.5
	BHA, 5*	95.8	96.3

*Separated initially by the Schwien and Conroy method.
PG, propyl gallate; GA, gallic acid; BHA, butylated hydroxyanisole.

Effect of solvent

Investigation of other polar solvents (60% v/v solution in water) such as acetonitrile, methanol and tert.-butyl alcohol showed that aqueous medium is the best for maximum colour development. Extraction of the coloured products into organic solvents gives a spectral shift and reduces the colour intensity.

Analytical data

The Beer's law ranges and molar absorptivities are given in Table 2. The precision and accuracy were found by analysis of 10 separate samples containing known amounts of the phenol tested, and the results are summarized in Table 2. The recovery of propyl gallate, gallic acid and butylated hydroxyanisole from various oils and fats by the proposed and literature methods are shown in Table 3, and results for catecholamines in dosage forms and for eugenol in clove oil are shown in Table 4.

Interferences

Phenol and its *o*-, *m*- or *p*-monosubstituted derivatives (other than catechol and its monoalkyl ethers) do not respond to the procedure, except for *o*-aminophenol which itself produces a colour with periodate and so interferes.

In the determination of propyl gallate (250 μg), the following amounts of other substances do not interfere: antioxidants—butylated hydroxyanisole (250 μg), butylated hydroxytoluene (500 μg); phenols—phenol (750 μg), hydroquinone (500 μg), resorcinol (500 μg); other constituents in foods—ascorbic acid (1 mg), citric acid (5 mg), benzoic acid (10 mg), tryptophan (1 mg), cysteine (1 mg), glucose (10 mg), sucrose (10 mg) and sodium chloride (10 mg).

In the determination of adrenaline in dosage forms, the excipients usually present, *viz.* chlorbutol, chloro-

cresol, sodium metabisulphite, sodium chloride and tartrazine, do not interfere.

The methods proposed are very sensitive and have reasonable accuracy. If interfering substances are present in real samples, suitable separation techniques must necessarily be applied before the individual determinations are done.

Mechanism

The colour developed may be due to oxidative coupling of the phenol and aminophenol, as reported earlier for monohydric phenols, or to charge-transfer complex-formation involving electron transfer between the aminophenol (or its intermediate oxidation product) and the phenol (or its oxidation product).

MEASURING AND MAXIMIZING PRECISION IN ANALYSES BASED ON USE OF CALIBRATION GRAPHS

DOUGLAS G. MITCHELL* and JOHN S. GARDEN
Division of Laboratories and Research, New York State Department of Health, Albany, NY 12201, U.S.A.

(*Received* 16 *September* 1981. *Revised* 9 *February* 1982. *Accepted* 26 *May* 1982)

Summary—Confidence-band statistics are used as a basis for measuring and improving precision in chemical analysis. Currently used calibration procedures often result in loss of precision and are therefore replaced by weighted least-squares and multiple-curve calibration techniques. Measures of precision such as correlation coefficient, relative standard deviation, and detection limit are replaced by more meaningful parameters based on confidence-band statistics. These new techniques are incorporated into a general scheme for developing methods for routine analysis.

To yield accurate data, an analytical method must meet four basic conditions. First it must be inherently precise; without precision, accuracy is impossible, unless a large number of replicate analyses are done. Secondly, it must be free from systematic error, or at least free from unpredictable error. These two conditions are fundamental, and together define the upper limit of performance. During routine analysis based on use of calibration graphs, the actual performance will be significantly worse unless the following additional conditions are met: the calibration procedure itself must not excessively degrade the precision, and repetition of the calibration at intervals of time should give the same results (within the precision of the method) as the original calibration (*i.e.*, the calibration should be stable as a function of time).

During the development of an analytical method, the analyst will first measure performance without using a calibration graph. Thus precision will be measured by repetitive analysis of standards at a few different concentrations, the detection limit will be measured by repetitive analysis of low-concentration standards, and accuracy will be measured by repetitive analysis of standard materials. The next developmental step will be choice of calibration standards, calibration range and a method for calculating or plotting the calibration graph. The analyst should then measure the precision of the data obtained by use of the calibration graph. In practice, this step is often omitted, because of the extra work involved, lack of awareness of its effects on data quality, and lack of suitable measurement techniques.

Here we present general procedures for measuring and maximizing precision in calibration-graph analysis. Both these aspects of precision are important. Generally used measures of precision are inadequate for calibration-based data, and the calibration graph itself may be the major source of error in an analytical method (this is particularly likely at low concentrations). These procedures are based on the use of confidence bands or confidence-interval statistics to measure precision and to select calibration conditions yielding optimum precision.[1,2] These statistical techniques are not widely known. Their major advantage is that data quality can be measured in terms of all the factors affecting precision, thus providing meaningful data-quality parameters and facilitating selection of conditions which minimize the loss in precision inherent in the calibration process.

PRECISION OF CURRENTLY USED CALIBRATION PROCEDURES

The most precise calibration procedure is the two-standard method. Standards closely bracketing the sample concentration are selected, and the high standard, the sample, and the low standard are analysed in sequence. The sample concentration is calculated by linear interpolation between the two standards. Although very precise, this method is usually impractical for routine analysis because it requires at least one standard measurement for each sample analysed.

For routine analysis most analysts use calibration graphs, the precision of which is considerably lower than that of the two-standard method, for three reasons.

(*a*) Calibration data often do not fit the chosen mathematical model. Calibration graphs are almost always computed by using a least-squares best-fit procedure with an *n*th-order polynomial. Although a first-order equation is appropriate for many analyses (*e.g.*, absorption measurements at low absorbances), for many others the calibration graph is non-linear, and usually convex. For convenience a second- or

*To whom correspondence should be addressed.

higher-order model is used to calculate the curve, but it may not fit the data. In fact, the curve is often first-order at low concentrations, approximately second-order at high concentrations, but neither of these over the entire range.

(*b*) The data show non-constant variance. The least-squares best-fit procedure minimizes the sum of squares of residuals about the calibration curve. Even if the data fit the mathematical model, the least-squares procedure will yield precise results only if the data show constant variance.[2] With calibration over moderate-to-wide calibration ranges the assumption of constant variance is almost always false. For example, many atomic- and molecular-absorption procedures have constant relative standard deviations (RSDs) over absorbance ranges of about 0.1–0.7, and if the relative variance is constant, the absolute variance must increase with concentration.

A common result of incorrectly assuming constant variance is gross error at low concentrations. The analytical method usually has the largest *absolute* errors at high concentrations. The least-squares procedure minimizes these errors, often rotating the line so that it does not pass through the origin, thus causing large *relative* errors at low concentrations.

(*c*) The precision varies with position on the calibration graph. A given calibration graph shows maximum absolute precision at a concentration equal to the weighted mean concentration of the standards. Variance is greater at both higher and lower concentrations. It increases rapidly with concentration at concentrations above that of the highest standard, particularly with curves of second- and higher-order equations.

The two-standard method does not have any of these disadvantages and hence yields excellent precision. Over narrow ranges calibration graphs are linear, and the data show approximately constant variance. Each measurement is near the mean concentration of the standards.

Manual graph-plotting can also yield good precision because the analyst is not bound by a mathematical model, and non-constant variance can be intuitively compensated for. This approach, however, is time-consuming for routine analysis, and data quality will be very dependent on the skill of the analyst, and on the number of calibration points he is willing to generate.

In general, the wider the calibration range, the worse the precision obtained with conventionally computed calibration graphs. Although a wide range offers direct analysis of samples with widely differing concentrations, the precision is poorer than in analysis over a more limited range. This trade-off between data quality and cost can be minimized by using the improved computational procedures described here.

Confidence-band statistics

A confidence interval is a band either side of a measurement, which will include the "true" value of the measurement with a given significance level α. In calibration-graph analyses, confidence bands around both the sample signal and the calibration graph can be calculated. These are then combined to yield a confidence band around the predicted concentration. The combined band estimates the precision of sample analysis in terms of *all* the factors which affect precision, provided standards are subjected to the same treatment as the samples (Fig. 1). First a calibration graph, say $Y = b_0 + b_1X$ is obtained by a least-squares procedure, then a confidence band around it is computed. The area enclosed by the band will include the line for the "true" equation at, say, a 90% significance level. Confidence bands around the regression equation are usually shaped like a double concave lens, wider at high concentrations because variance increases with increasing concentration. Next, a confidence band around the sample signal Y_0 is computed. This also broadens with increasing concentration, with a resulting increase in the *absolute* precision. These bands are combined as shown in Fig. 1 to produce a confidence band around the predicted sample concentration X_0. Procedures for calculating confidence bands are given in previous papers,[1,2] and

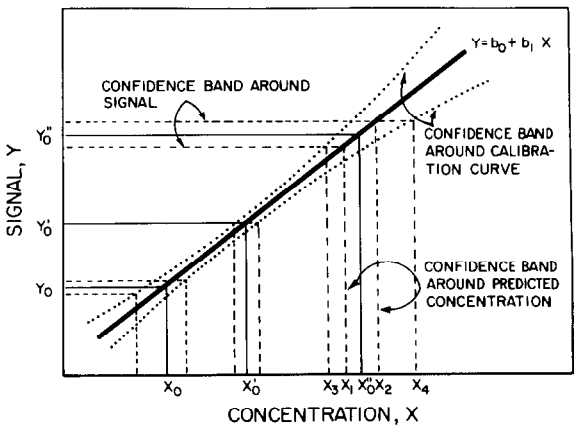

Fig. 1. First-order calibration graph showing confidence bands around the line and around predicted sample concentrations. The latter bands include variation due to (*a*) both sample signal and the curve (band around X_0), (*b*) the curve only (band around X'_0), and (*c*) the sample only (band around X''_0).

the reader is referred to these for the mathematical treatment. Qualitatively, the precision of a given calibration-graph analysis can be improved by (*a*) using an inherently more precise physicochemical measurement method, (*b*) using a more appropriate mathematical model, (*c*) selecting standards such that their weighted mean concentration is roughly equal to the sample concentration, (*d*) making more replicate sample measurements, and (*e*) increasing the number of standard measurements. (This assumes that the calibration curve is "valid" during all measurements, *i.e.*, there is no drift).

Procedures for minimizing loss of precision during calibration

To minimize the loss of precision during calibration, the range covered can be limited, but this may limit the usefulness of the method. Some loss could be avoided by improving the computational procedure by correcting the weakness of the conventional least-squares procedure. Error due to data not fitting the mathematical model could be minimized by finding a more correct model, ideally a single mathematical function to fit the data. This is difficult with non-linear graphs because the data do not usually fit a simple second-order model, and confidence-bands widen as the number of terms in the equation increases.

A simple, semi-empirical approach is to use a multiple-curve procedure.[1] Several calibration curves are computed from various combinations of contiguous standard measurements. The curve giving the narrowest confidence band around each predicted sample concentration is the most appropriate for that particular sample and is used to calculate the sample concentration. For example, if six standard concentrations are used, a low-concentration sample is often best analysed with a calibration graph based on the four standards of lowest concentration rather than all six standards. This approach may intuitively seem incorrect, since we are choosing not to use all the available data, but inclusion of measurements based on the two highest standards may result in a very poor fit to the mathematical model, outweighing the benefits of the additional information.

The effects of non-constant variance can be compensated for by weighting each standard measurement according to the variance at that concentration and then using the least-squares procedure.[2] Without weighting, the least-squares procedure is heavily influenced by variation in measurements of high-concentration standards, which have the worst (absolute) precision. The weighting factors are inversely proportional to variance at each concentration, and a knowledge of the ratio of variances at these concentrations is required for the computation. Use of a weighted least-squares procedure also allows self-consistent rejection of outlying standard measurements and outlying (replicate) sample measurements.

Suggested data-quality parameters

Since confidence-band statistics measure data quality in terms of all the factors affecting precision, they can be used to develop a set of very useful data-quality parameters. In this section, we present these parameters.

(*a*) *Calibration-curve quality.* This is usually measured with parameters such as length of linear range, correlation coefficient, and standard error of estimate. Despite the usefulness of these, their fundamental defects include not indicating whether the chosen mathematical model is adequate and not measuring precision in terms directly meaningful to the data user.

A long linear calibration range is desirable because the linear segment of the curve usually has the maximum sensitivity and because it allows use of a first-order regression equation over a wide range. However, information on length of linear range is of very limited value to the analyst because it cannot be converted into a quantitative statement of precision. The coefficient of correlation, r, between signal and standard concentration measures both precision and the adequacy of the mathematical model. It has no units and has a maximum value of 1.0. Although in analytical chemistry calibration graphs typically show r values of >0.98, this parameter is of limited value for the following reasons. (*i*) r values cannot be meaningfully compared if they are obtained from curves based on different standards (since r is a function of calibration range, it is easier to get a high r value with well-spaced standards than with standards within a narrow concentration range). (*ii*) Curve shape can change without necessarily affecting r. Anscombe[3] shows four 11-point curves for a first-order equation, each with the same r value. One curve shows points spread around a straight line; another set of data is parabolic, misfitted with a straight line; another perfectly fits a straight line but with one outlier; and the fourth shows 11 replicate measurements at the same level. (*iii*) r values do not yield quantitative comparisons of data quality, even if the same standards are used. Although a curve with an r of 0.99 is usually "better" than a curve with an r of 0.98, this is not a quantitative statement. It does not state, for example, that increasing r from 0.98 to 0.99 may improve precision by say 20% at a given concentration. (*iv*) The r value does not indicate whether the chosen mathematical model (*e.g.*, a first- or second-order equation) adequately fits the data.

The standard error of estimate (SEE) of a calibration curve is the SD of the residuals about the curve. It is not affected by the calibration range, and it has the same advantages as a correlation coefficient. However, SEE values are affected by choice of units.

To achieve a more meaningful approach to calibration-curve quality, we use the following two-step procedure. A mathematical model is chosen and the data are tested for lack of fit. If there is significant lack of fit, another model is chosen and tested. When an

appropriate mathematical model is found, calibration-curve quality is measured in terms of confidence-band widths.

The adequacy of the mathematical model can be tested in several ways. If replicate standard measurements are available, an F-test for lack of fit can be used to compare the variation between replicate standard measurements with the variation between residuals about the calibration curve. If variation about the curve is significantly greater than variation between replicate standards, the curve is inappropriate, and a better mathematical model is sought. Otherwise, the model is considered to fit the data adequately. If replicate measurements are not available, the extra-sum-of-squares test can be used to test the effect of adding an extra term to the equation (usually the square of the concentration). If the extra-sum-of-squares due to inclusion of the extra term is significant, then the extra term should be included in the equation. This latter test is inferior to the lack of fit test because it tests only the effect of adding an extra term to the equation, and does not consider the adequacy of either equation.

If a multiple-curve technique[1] is used, an appropriate regression equation for all standard measurements is not always needed, although it can be used for rejecting outlying standard measurements. First- and second-order equations would certainly be appropriate for various segments of the calibration range.

Calibration-curve quality can be measured directly in concentration terms by using confidence-band statistics. A confidence band around the calibration curve is calculated and then used to calculate the confidence band around each predicted sample concentration. Figure 1 illustrates the procedure for predicting sample concentration X'_0 from signal Y'_0 by using $Y = b_0 + b_1x$. The sample signal is assumed to be accurately measured, so as to isolate the effects of calibration-curve quality. A confidence band is calculated around the curve. Signal Y'_0, projected onto the line and bands, intersects the confidence bands, yielding the lower and upper bounds for concentration X'_0. The width of the confidence band about X'_0 will be different at each concentration. For quality-control purposes, confidence bands at a few key concentrations should be calculated for each set of calibration data and checked against a chosen quality standard.

(*b*) *Sample-data quality*. Precision of sample analysis is usually measured in terms of RSD at various sample concentrations. The RSDs are obtained by repetitively analysing samples or standards and then calculating the mean and SD. In practice, RSD values overestimate the precision obtainable from a routine method, for two reasons. The RSD data are often based on analysis of replicate fractions from sample extracts or digests rather than of independent, replicate samples. Such data estimate the precision of the measurement step rather than of the complete analysis. (*ii*) Even when independent replicate samples are analysed, the same calibration graph is usually used, thus ignoring the effects of calibration-curve quality and overestimating the precision of the method. In Fig. 1, signal Y''_0 and a confidence band around the signal are projected onto the calibration line $Y = b_0 + b_1X$ and its confidence band. The narrow band $X_2 - X_1$ around the predicted concentration is obtained when the band around the line is ignored. Use of the band yields the correct confidence band, $X_4 - X_3$.

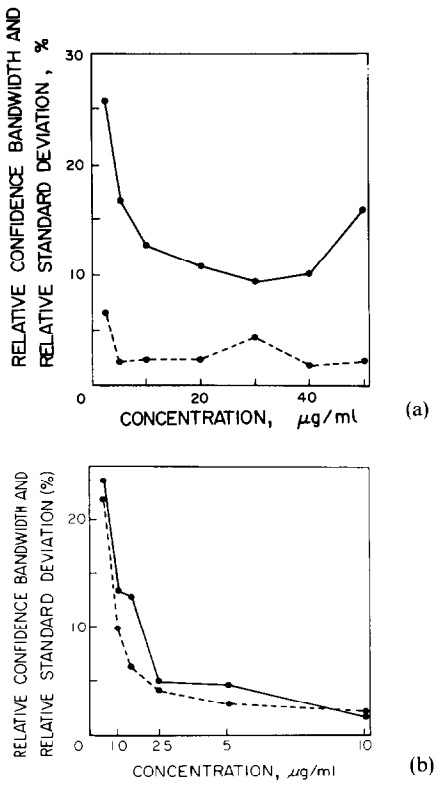

Fig. 2. Comparison of relative standard deviation and relative confidence-band widths for (*a*) determination of chloride and (*b*) determination of lead. (——) Relative confidence-band width = (upper limit—lower limit) × 100/predicted concentration; (– – –) relative standard deviation.

The net effect is that typical RSD data may overestimate precision by a factor of up to about 3. For example, Fig. 2 shows RSDs obtained by replicate sample analysis with a single calibration graph and relative confidence-band widths calculated by assuming triplicate sample measurements for the determination of chloride in water by an AutoAnalyzer procedure[4] and of lead by conventional atomic-absorption spectrometry. Over the range studied the chloride procedure yielded lower RSD values than the lead procedure, but the confidence-band widths were wider for the chloride procedure. This was because the chloride measurements did not closely fit the chosen second-order model, whereas the lead measurements more closely fitted their model.

Thus an analyst would incorrectly conclude from RSD data that the chloride procedure was more precise than the lead procedure. To avoid this disadvantage, we recommend determining confidence-band widths for measuring the precision of a given calibration-graph procedure, for intermethod comparisons, and for monitoring precision on a day-to-day basis.

(*c*) *Minimum reportable concentration.* The lower limit of the concentration range can be defined in several ways (see for example, the third paper in the series by Wilson[5–8]). It is typically some multiple of the detection limit, itself often defined as the concentration at which the RSD is 50%. For a useful discussion of detection limits, see Liteanu and Rîcă.[9] In this paper, we define the lower limit as the lowest concentration at which the analyte can be shown to be present (with a given confidence level). Then samples with predicted concentrations below this threshold level will be reported as containing less than the minimum reportable concentration. For calibration-graph analyses, the detection limit, which is really a measure of the signal:noise ratio for the method, is only one factor (though the major one) affecting whether an analyte at low levels can be shown to be present. Once again calibration parameters are important. For example, if a measurement technique yields a detection limit of 1 arbitrary unit (based on repetitive analysis without calibration), an analyte at a concentration of 2 units is more likely to be detected by use of a 0–3 unit calibration range than a 0–100 range.

Confidence-band statistics provide a useful measurement of the minimum reportable concentration. It is the concentration at which the confidence band around the predicted sample concentration just includes zero as a lower bound (with a given significance level). For example, consider a sample with a predicted concentration of 2 and a symmetrical 90% confidence band of ± 2. There is a $90 + 10/2 = 95\%$ probability that the sample has a concentration above a lower bound of zero. Thus the minimum reportable concentration is 2 at the 95% level of significance.

Choice of calibration conditions has an important effect on the minimum reportable concentration, but not on detection limits as usually defined. To illustrate this, we made a number of replicate measurements of iron in water by conventional atomic-absorption spectrometry. These yielded a detection limit, without a calibration graph, (defined as the concentration at which the RSD is 50%), of 0.015 μg/ml. The minimum reportable concentration was then calculated for four different calibration graphs, each calculated from various combinations of randomly selected data points but always using a total of 18 measurements. As expected, minimum reportable concentrations increased with increasing dynamic range (Table 1), and were always higher than the detection limit.

Note that the minimum reportable concentrations varied by a factor of 12, depending on the calibration range.

The minimum reportable concentration can be routinely calculated from calibration-graph data and will yield more realistic estimates of the concentration at which the analyte can be detected with given calibration conditions on a given day.

(*d*) *Maximum reportable concentration.* In many analytical procedures the sensitivity decreases with increasing concentration, the signal asymptotically approaching a value which is constant irrespective of further increase in concentration. The resulting nonlinearity, increased variance and loss of sensitivity at high concentrations result in less precise data than those obtained at lower concentrations. The analyst should select a cut-off or maximum reportable concentration, above which samples should be diluted and re-analysed, or analysed with use of a different calibration graph. This cut-off level is usually selected arbitrarily (*e.g.*, at the concentration of the highest standard used or at the concentration at which the deviation from linearity exceeds, say, 5%).

The maximum reportable concentration should be selected with care. If it is too low, many samples may require re-analysis. If it is too high, the precision for the more concentrated samples will be poor.

Wilson[7] suggests several criteria for selecting the upper limit of the concentration range for analyses not based on calibration graphs. For calibration-based methods, the maximum reportable concentration can be defined as the maximum concentration at which the method yields adequate precision. This can be readily determined by using confidence band statistics.

To illustrate this approach, we determined iron in water by conventional atomic-absorption spectro-

metry over the very wide dynamic range of 0.05–100 μg/ml (Table 2 and Fig. 3). Inspection of the plot shows that a first-order equation should fit the data up to a concentration of about 5 μg/ml, with a second-order equation appropriate at higher concentrations. Confidence bands around the predicted concentrations were calculated from the weighted least-squares curves of best fit. Relative confidence-band widths were obtained by two computational procedures: a single second-order curve was fitted to data over the iron-concentration range 0.05–18 μg/ml, and multiple first- and second-order curves were fitted to segments of the data. As expected, relative confidence-band widths were high at low and high concentrations, and the multiple-curve techniques yielded narrower bands than the single-curve technique (Table 2).

With 20% RSD taken as an adequate confidence-band width, the maximum analysis concentration was about 15 μg/ml with the single-curve procedure and about 22 μg/ml with the multiple-curve procedure.

Note that the multiple-curve procedure always includes a calibration standard of higher concentration than the sample. This is contrary to much present practice, but it suggests that an imprecise measurement of a higher concentration standard is better than no measurement at all.

METHOD DEVELOPMENT WITH CONFIDENCE-BAND STATISTICS

Analytical method development involves a number of steps, such as choice of sample preparation and measurement techniques, studies of systematic error, precision and potential interferents. The confidence-band statistics and precision parameters described above can make a useful contribution. To illustrate this, we present below diagramatically (and in Fig. 4) a general procedure for developing a calibration-graph analytical method. Steps benefiting from confidence-band statistics are discussed in some detail. Others are included for completeness and are only briefly discussed. We use, as an example, data for the determination of iron in potable water.

1. *Select sample preparation and measurement techniques*

The inherent precision and accuracy of these techniques will be the major factor in determining overall data quality. They should be carefully chosen on the basis of published or otherwise known performance data, plus practical factors such as degree of technical difficulty, availability of instrumentation and trained

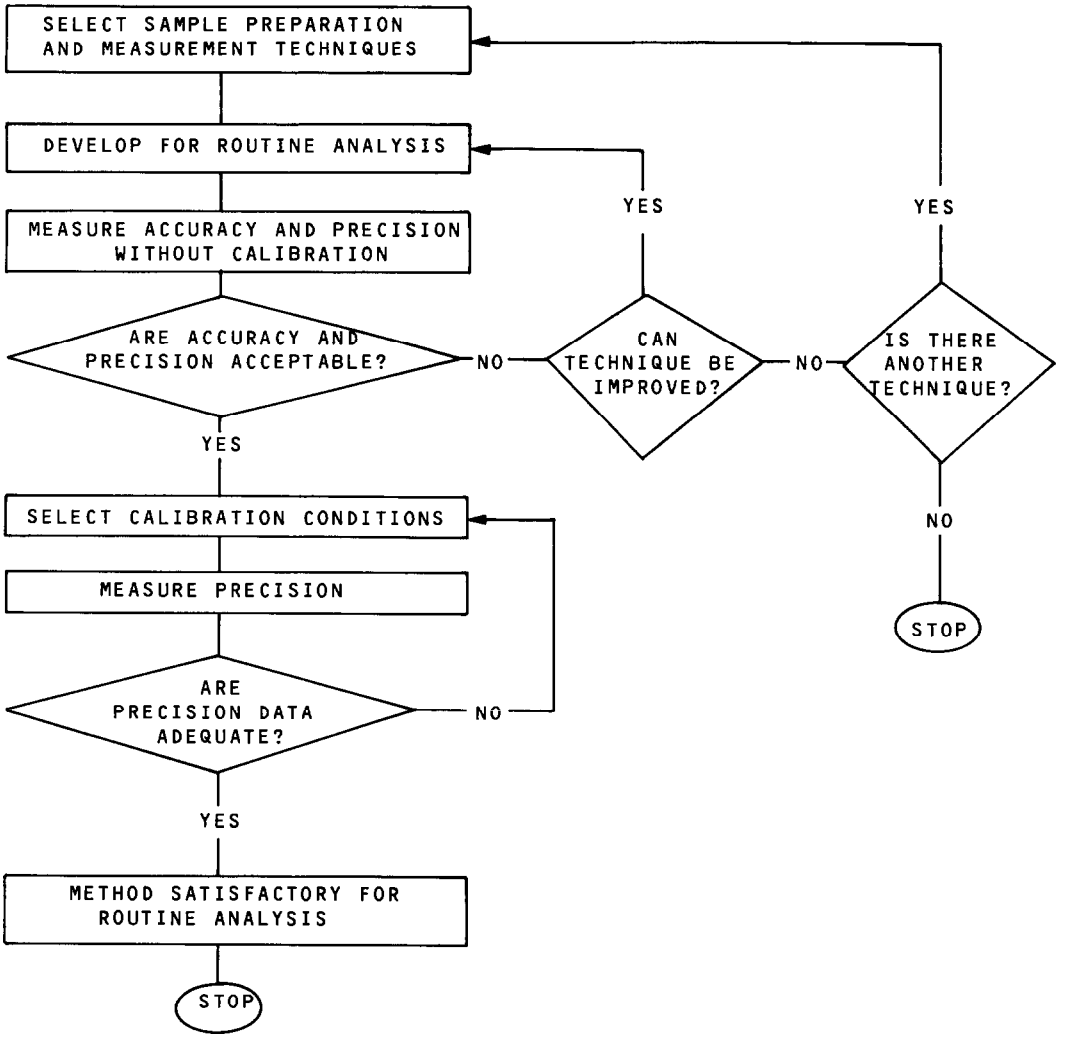

Fig. 4. Method-development procedure for calibration-based analyses.

staff, and cost. In our example, we chose an atomic-absorption procedure using an air–acetylene flame.

2. *Develop method for routine analysis*

The proposed procedure should be carefully "debugged", with error-prone steps (such as critical pH-adjustments) eliminated, simplified or automated.

3. *Measure accuracy and precision without calibration*

These two quality-parameters define the upper limit of performance. The proposed method should be studied in considerable detail. Wilson[5–8] gives excellent guidelines for this step. The studies should also generate sufficient data for calculation of standard deviations at the concentration of each proposed calibration standard (this is required for calculating a weighted least-squares curve of best fit[2]). The stability (freedom from drift) of the proposed method should also be determined. If unstable, it may be improved, for example, by improving temperature control or the instrumentation. Alternatively, drift can be compensated for by frequent calibration. If overall performance is still inadequate, the analyst can consider improving the technique or changing to an alternative technique.

4. *Select calibration conditions*

These can be chosen to meet analytical requirements. Thus, if accuracy at low concentrations is required, the analyst should choose low concentration standards or the multiple-curve technique. If there is a key concentration, such as an action level, the analyst can choose standards with a weighted mean concentration equal to the key value. If a wide determination range is required, the concentration of the highest standard can be at the top of the linear range (or higher with the multiple-curve technique).

In our example we chose an iron-concentration range of 0–2.0 μg/ml, the upper end being the maximum iron level found in at least 99% of samples analysed. The standards ranged from 0.50 to 2.5 μg/ml, with the graph linear over the entire range. The

Calibration data: the curve is first-order, by lack-of-fit test, with no outliers, the equation being signal = 10.8 + 409.2 × concentration; correlation coefficient $r = 0.99887$.

weighted mean concentration of the standards was 0.3 μg/ml, the maximum allowable level of iron in potable water in New York State.

5. Measure precision of the proposed method

This should include measurement of relative confidence-band widths at several concentrations and of the maximum and minimum reportable concentrations. In our example, a FORTRAN program REGRES (available from the authors) was used to calculate calibration-graph statistics (Table 3). The program calculated a first-order line of best fit and then tested it for lack of fit (no significant lack of fit was found). It also printed out the calibration equation, the correlation coefficient and detailed calibration data (Table 3).

6. Are precision data adequate?

Precision at several key concentrations was measured by analysing appropriate standards. Data for standards containing iron at the 0.1, 0.3 and 1.0 μg/ml levels are listed in Table 4. The predicted concentrations and relative confidence-band widths for both the multiple-curve and the single-curve procedures and the calibration range for the continguous standards chosen by the multiple-curve technique are listed.

For this analysis, use of the multiple-curve technique did not greatly improve precision (there would have been a much larger improvement if the graph had been non-linear). At the key 0.3 μg/ml level, the multiple-curve technique yielded a relative confidence-band width of 13.9% A sample with a predicted concentration of 0.3 × (100 − 13.9/100) = 0.26 μg/ml or less, does not give a signal exceeding that of the standard at the 95% level of significance (assuming no systematic error).

Thus, the confidence-band width at the key 0.3 μg/ml level should be quite adequate for this application. If it were not, the analyst could consider replicate sample analysis, analysing more standards, or changing the method. For example, triplicate sample analysis would reduce the band width to 9.5% ($13.9/\sqrt{3}$) and raise the cut-off value from 0.26 to 0.27 μg/ml.

7. Method satisfactory for routine analysis

If the precision is adequate, the analyst can, with a reasonable degree of confidence, introduce the method into routine use. It is necessary to document the method, add quality-control procedures and continually monitor analytical performance to ensure that the method continues to work satisfactorily. Large changes in confidence-band widths and errors in control-standard concentrations indicate problems, such as poor instrument response and inaccurate or

Table 4. Control standard data

Mean signal		Predicted concn., *μg/ml*		Confidence-band width, %		Calibration range, *μg/ml*

unstable standards. Other sources of error, such as changes in sample matrix, changes in sampling techniques, and unstable samples, may require more detective work to identify.

DISCUSSION

Confidence-band statistics provide a useful tool for studying and monitoring analytical methods and often give considerable insight into method performance. For example, the fact that confidence bands are usually much wider than RSDs often explains the lower-than-expected precision found in interlaboratory comparisons. Also, minimum reportable concentrations are usually greater by a factor of 3–10 than detection limits reported in the literature and are a much more realistic estimate of the levels at which the analyte can be shown to be present.

In our view, confidence-band data-quality parameters should always be used in calibration-based routine analysis instead of such parameters as RSD, detection limit and correlation coefficient, which are poor measures of the data quality to be expected from a routine procedure. In some cases confidence-band statistics yield information not readily obtainable with other techniques. For example, suppose measurements are to be made over a concentration range of 1–100. If the graph is linear up to a concentration of 120, 120 would be a better highest standard than 100. However, if the curve is non-linear above a concentration of 100, the 120 standard might degrade the fit to the mathematical model sufficiently to negate the benefits of the higher-level measurement. The decision can be based on confidence-band data. As another example, an analyst in our laboratory was determining nitrate in drinking water and used two calibration graphs covering different but overlapping ranges. The results were interpreted by use of both curves. For sample concentrations in the overlapping range, the analyst assumed that the data from the more sensitive calibration graph would be the most precise, and reported the results obtained from this graph. Comparison of confidence-band data showed that this assumption was incorrect.

SPECTROPHOTOMETRIC DETERMINATION OF METHYLPHENOBARBITONE BY USE OF ORTHOGONAL POLYNOMIALS

ABDEL-AZIZ M. WAHBI,* SAIED BELAL,† HASSAN ABDINE and MONA BEDAIR
Faculty of Pharmacy, University of Alexandria, Pharmaceutical Analytical Chemistry Department, Alexandra, Egypt

(*Received* 6 *May* 1981. *Revised* 19 *October* 1981. *Accepted* 19 *May* 1982)

Summary—A direct spectrophotometric method for the determination of methylphenobarbitone in presence of degradation products is presented. The method is based on use of the combined polynomial method. The coefficient of the combined polynomial P_w, calculated over the wavelength range 228–272 nm at 4-nm intervals, is unaffected by the presence of any degradation products and is linearly related to the methylphenobarbitone concentration with a relative standard deviation of 0.4%. The mean recovery is 99.1 ± 0.8%. The method can also be used for assessing the stability of methylphenobarbitone.

Methylphenobarbitone, a member of the barbiturate group, can be determined by several methods including potentiometric titration,[1,2] photometric titration in non-aqueous solvents,[3] other acid–base titrations,[4] complexometric,[5,6] argentimetric,[7] mercurimetric,[8] amperometric,[9–11] coulometric[12] and conductometric titration methods.[13] Colorimetric,[14,15] spectrophotometric[16–18] and spectrofluorimetric[19,20] methods have also been reported. An official method for methylphenobarbitone and phenobarbitone[21] is based on titration with silver nitrate in sodium carbonate solution.[7,22,23]

The present work is concerned with applying the combined polynomial method[24] (a modification of Glenn's method[25] of orthogonal functions) to the determination of methylphenobarbitone in presence of its degradation products. The method has been successfully applied to the determination of thiamine hydrochloride in the presence of its degradation products.[26]

Being an *N*-substituted barbiturate, methylphenobarbitone is unstable in alkaline solutions. Stainier *et al.*[27] reported that the time taken for disappearance of the absorption peak in 1*M* sodium hydroxide is 1 hr. The spectrum of the product from alkaline degradation of methylphenobarbitone has an inflection at about 246 nm, which interferes in determination of the parent compound by means of its absorbance maximum at 246 nm (Fig. 1). The degradation products spectrum has an inflection at about 246 nm.

APPLICATION OF THE COMBINED POLYNOMIAL METHOD

According to the general rules,[25,28–31] the quadratic, P_2, and cubic, P_3, polynomials have been chosen for construction of the required combined polynomial, P_w. The quadratic polynomial makes the major contribution to the absorption curve of methylphenobarbitone and therefore its coefficient p_2 should give a precise estimate of the concentration. Accordingly, p_2 and p_3 (the polynomial coefficients) were calculated from the absorption spectra of methylphenobarbitone (0.002% solution) and its degradation products (equivalent in concentration to 0.002% methylphenobarbitone) in pH-10 buffer, by using 12-point orthogonal polynomials at 2- and 4-nm intervals. The signs and values of the integers a and b were varied until $p_w(Z)$ was negligible in comparison with $\alpha_w c_X$ (see previous work[26] for details). This was achieved by calculating the ratio $p_w(Z)/p(X)$, which gives the relative error in the determination of methylphenobarbitone (X), caused by the presence of the degradation products (Z). It was found that for $p_w = 4p_2 - 3p_3$ calculated over the wavelength range 228–272 nm at 4-nm intervals, with 12-point orthogonal polynomials, $p_w(Z) = +0.0149 \times 10^{-3}$ and $p_w(X) = -15.95 \times 10^{-3}$, so the expected error, $100\, p_w(Z)/p_w(X) = -0.09\%$. Accordingly, the p_w-convoluted curves for the analyte (X) and the irrelevant absorption were plotted (Fig. 1). The finally chosen set of wavelengths (for the integers $a = 4$, $b = -3$) was found to occur on a slope in the p_w-convoluted curve of methylphenobarbitone. This means that the calculated p_w will be affected by any shifts in the spectrophotometer wavelength scale which may occur during measurement. For that reason, an experiment was designed to estimate the

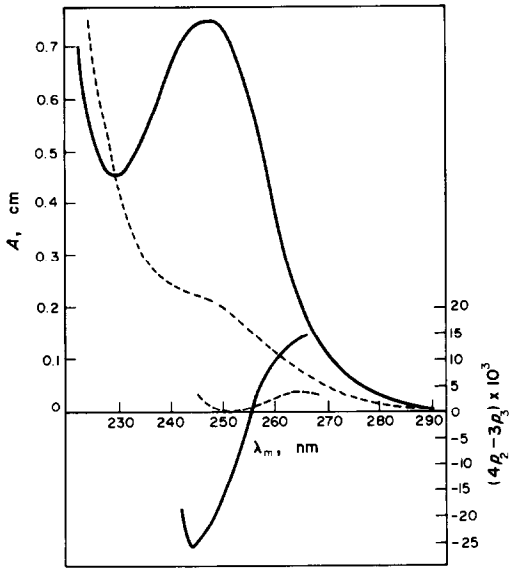

Fig. 1. Absorption curves of 0.022% methylphenobarbitone (——) and its degradation products (---) in pH-10 buffer, and the corresponding ($4p_2$-$3p_3$) convoluted curves derived therefrom, by use of 12-point orthogonal polynomials (4-nm intervals).

effect of a $\pm$0.5-nm shift in the wavelength scale, on the calculated p_w for methylphenobarbitone. A methylphenobarbitone solution buffered at pH 10 was measured at three sets of wavelengths centred at 249.5, 250 and 250.5 mm, with measurements at 4-nm intervals. Then $p_w = (4p_2 - 3p_3)$ was calculated for each set of 12 absorbances. The results are shown in Table 1. To minimize such effects, a standard and a sample should be measured side by side in a constant-temperature laboratory.

Once the wavelength range and intervals, and the values of a and b have been chosen, the combined polynomial can be constructed as shown in Table 2. The value of p_w can be obtained directly by dividing $\Sigma A_i P_{wi}$ by D, where A_i is the absorbance at the ith wavelength, and P_{wi} and D are defined in Table 2.

Linearity of P_w with respect to concentration

Seven solutions of methylphenobarbitone covering a concentration range of 0.5–3.5 mg per 100 ml of buffer solution (pH 10) were prepared by accurate dilution of a stock solution of methylphenobarbitone. The absorbance (in 1-cm cells) of each solution was then measured at 4-nm intervals from 228 to 272 nm inclusive, against the buffer solution. The coefficient p_w of the combined polynomial, P_w, was then calculated for each set of twelve absorbances. Graphs of $p_w = (4p_2 - 3p_3)$ and A_{max} against concentration were plotted and showed reasonable linearity (correlation coefficients 0.9999 and 0.9997 respectively). Linear equations were calculated by regression analysis; they were

$$10^3 p_w = 0.0273 - 7.2902c$$

$$A_{248} = -0.006 + 0.3473c$$

where c is the concentration in mg per 100 ml.

Reproducibility of p_w

Separate determinations of p_w were made for different concentrations of methylphenobarbitone in pH-10 buffer solution, and p_w (for a 1% solution in a 1-cm cell) was calculated for each solution. The results had a relative standard deviation of 0.4%, indicating reasonable reproducibility.

EXPERIMENTAL

Determination of methylphenobarbitone by the combined polynomial method

Weigh accurately about 40.0 mg of methylphenobarbitone and transfer it to a 100-ml standard flask with 10 ml of ethanol. Warm to dissolve and make up to volume with pH-10 buffer solution. Pipette 5 ml into a 100-ml standard flask and dilute to volume with pH-10 buffer solution. Measure the absorbance of this solution at 4-nm intervals over the wavelength range 228–272 nm, against a corresponding blank.

Prepare and treat a standard reference solution similarly.

Preparation of alkali-induced degradation products of methylphenobarbitone

Weigh accurately about 40.0 mg of methylphenobarbitone, transfer it to a 100-ml standard flask with 10 ml of 1*M* sodium hydroxide and leave to stand for 2 hr. Add 10 ml of 1*M* hydrochloric acid, then dilute to volume with pH-10 buffer. Pipette 5 ml of this solution into a 100-ml standard flask and dilute to volume with pH-10 buffer. Measure the absorbance of this solution at 4-nm intervals over the wavelength range 228–272 nm against a blank.

RESULTS AND DISCUSSION

Six mixtures of methylphenobarbitone and its degradation products, in pH-10 buffer, were prepared, and assayed by the combined polynomial method. The results obtained are shown in Table 3. The mean recovery was found to be 99.1 ± 0.8%

Errors in the method can be attributed to (*i*) wavelength setting errors, (*ii*) non-zero coefficients that may have been contributed by the added degradation products to the assay coefficient, (*iii*), overall shifts in the wavelength calibration, which could affect coefficients sited on slopes in the corresponding p_w-convoluted curve (Fig. 1).

Several trials have been made of the application of the single polynomial method for the determination of methylphenobarbitone in presence of its degradation products, by use of P_2 from the twelve-point orthogonal polynomials for measurements at 2- and 4-nm intervals, but without success. For example, the mean recovery was found to be 95.5 ± 1.5% from use of p_2 calculated over the same set of wavelengths (228–272 nm at 4-nm intervals, Table 4). The poor results obtained by using p_2 alone were due to the contribution to p_2 from the degradation products, which was cancelled by the method using $4p_2 - 3p_3$.

For comparison, recoveries were calculated from the maximum absorbances and were unacceptably high (Table 3). The error in each result decreased with increase in the concentration of methylphenobarbitone relative to the concentration of the degradation products (the latter being kept constant in the mixtures).

The modified Vierordt method[32] was applied to the determination of methylphenobarbitone (λ_1 = 228 nm, λ_2 = 248 nm) in the same six mixtures. The mean recovery was found to be 102.6 ± 1.4%.

However, the presence of a linear irrelevant absorption, such as may originate from differences between batches of the samples and the "reference" standard of methylphenobarbitone, will certainly lead to erroneous results in the modified Vierordt method. On the other hand the results obtained by using the combined polynomial method will not be affected by interferences contributing to coefficients other than those involved in p_w. In other words, the calculation of $(4p_2 - 3p_3)$ will correct for constant, linear, quartic, quintic, *etc.* components of an irrelevant absorption. In support of this argument, Table 3 shows a systematic error in the recovery experiments when the modified Vierordt method was used, the recovery decreasing systematically from 104.8 to 100.9%. This systematic error could originate by chance from contamination of either the reference solutions of methylphenobarbitone or the prepared mixtures. However, this systematic error does not appear in the results obtained by using p_w. Moreover, it also does not appear in the results obtained by using p_2, although the latter gives poor results. This example illustrates the superiority of the combined polynomial method to the modified Vierordt method.

Table 3. Spectrophotometric determination of methylphenobarbitone in presence of the degradation products, by different methods

Expt.	Added,* mg	Recovery, %			
		A_{248}	p_2	p_w $(4p_2 - 3p_3)$	Modified Vierordt

s.d.		5.6	1.5	0.8	1.5

*Each contains degradation product corresponding to 0.50 mg methylphenobarbitone.

Degradation of methylphenobarbitone

The recovery experiments reported in Table 3 are not enough to prove the specificity of the method. There may be different intermediate products which, of course, will not be revealed by these recovery experiments. A 0.05% solution of methylphenobarbitone in 0.1*M* sodium hydroxide was therefore prepared and kept at room temperature in the dark, and 5-ml portions of this solution were diluted to 100 ml with pH-10 buffer solution at zero time and then at hourly intervals. The absorbances were measured at 4-nm intervals in the range 228–272 nm. The 0.1*M* sodium hydroxide medium was used to accelerate the rate of decomposition of methylphenobarbitone. The coefficient p_w was calculated from each set of twelve absorbances and the concentration of methylphenobarbitone was computed. The plot of log c% against time (data in Table 4) gave a straight line with a slope of $-0.02031\ hr^{-1}$ and a correlation coefficient of 0.9976. It may therefore be concluded that the proposed method based on calculating $(4p_2 - 3p_3)$ is specific for the intact molecule, and not affected by the degradation products.

To test the specificity of the official method of analysis for the intact molecule of methylphenobarbitone, a 2% solution of the drug in 0.1*M* sodium hydroxide was assayed at hourly intervals by the argentimetric method after neutralization with a precalculated volume of 0.1*M* nitric acid and addition of 25 ml of a 4% solution of anhydrous sodium carbonate. The volume of silver nitrate solution consumed did not vary with time and so did not reveal the degradation of methylphenobarbitone. This indicates that the official method of analysis is not specific for the intact molecule of methylphenobarbitone, which is shown by the polynomial method to undergo cleavage in 0.1*M* sodium hydroxide medium. In this respect, the proposed method is considered superior to the official method in determining methylphenobarbitone in presence of degradation products.

Table 4. Decrease of concentration of methylphenobarbitone with time, calculated from $(4p_2 - 3p_3)$

SHORT COMMUNICATIONS

N-PHENYL-*N'*-ACETYLTHIOUREA—A SPECIFIC REAGENT FOR PHOTOMETRIC DETERMINATION OF RUTHENIUM

S. C. SHOME and P. K. HALDAR
Department of Chemistry, Presidency College, Calcutta 700073, India

(*Received* 16 *April* 1981. *Revised* 20 *April* 1982. *Accepted* 14 *June* 1982)

Summary—*N*-Phenyl-*N'*-acetylthiourea is recommended as a specific chelating agent for the spectrophotometric determination of ruthenium. The blue complex formed in 5–8*M* hydrochloroic acid is not extractable into common organic solvents but is soluble in 30% ethanol solution. The colour is stable for up to 48 hr and Beer's law is obeyed at 650 nm over the metal concentration range 2–18 μg/ml. The molar absorptivity is 4.7×10^3 l.mole^{-1}.cm^{-1}.

Beamish and Van Loon[1] have critically reviewed the use of organic thio-ligands in the photometric determination of ruthenium, but these reagents generally lack selectivity. Many of the more recent reagents are also deficient in this respect,[2–8] but *o*-hydroxythiobenzhydrazide[9] and *N,N*-diphenylthiourea[10] have good selectivity. We now introduce *N*-phenyl-*N'*-acetylthiourea (PhAT) as a chelating agent that is specific for the spectrophotometric determination of ruthenium in the sense that it does not give a colour reaction with any other metal ion in acid medium.

EXPERIMENTAL

Reagents

Ruthenium(III) chloride monohydrate was dissolved in dilute hydrochloric acid, and the solution was standardized by hydrolytic precipitation and diluted as required. Solutions of other ions were prepared by dissolving the corresponding salts in distilled water or dilute hydrochloric acid. All reagents used were of analytical or general reagent quality.

Preparation and properties of N-*phenyl*-N'-*acetylthiourea*

The reagent was prepared by the general procedure described by Charonaut and le Perdriel.[11] Ammonium thiocyanate (0.1 mole) was dissolved in acetone and 0.1 mole of acetyl chloride was added slowly with constant shaking. The mixture was refluxed for 15 min on a hot water-bath, cooled and filtered. A solution of 0.1 mole of aniline in acetone was added slowly to the filtrate with constant shaking. The mixture was refluxed for 10 min on a hot water-bath, then most of the acetone was removed by distillation. The residue was added slowly to crushed ice with constant stirring. The crude solid reagent was filtered off and recrystallized from aqueous ethanol. The pure compound melts at 174°. It is appreciably soluble in water and highly soluble in ethanol and most of the common organic solvents. It is stable towards heat, light, air, acids and alkalis, but attacked by strong oxidants. A 0.01*M* ethanolic solution of PhAT was used throughout.

Procedure

A measured volume of ruthenium(III) chloride solution was placed in a 25-ml Erlenmeyer flask and its acidity adjusted to between 5 and 8*M* hydrochloric acid. Then 3–4 ml of 0.01*M* ethanolic PhAT solution were added and the mixture was stirred well and warmed for 10 min on a hot water-bath, then cooled. The contents of the flask were transferred quantitatively to a 25-ml standard flask and made up with concentrated hydrochloric acid and ethanol so that the final solution was about 6*M* in the acid and contained about 30% ethanol. The absorbance was measured at 650 nm against a reagent blank prepared under identical conditions.

RESULTS AND DISCUSSION

Spectral characteristics of the complex

The complex exhibits maximum absorption at 620 nm and the reagent has no absorption at wavelengths longer than 550 nm when measured against distilled water. The absorbance is constant for up to 48 hr. The ruthenium concentration range for conformity to Beer's law at 650 nm is 2–18 μg/ml, and the optimal range[12] is 4–15 μg/ml. The molar absorptivity at 650 nm is 4.7×10^3 l.mole^{-1}.cm^{-1}.

The optimal final acidity is 5–8*M* hydrochloric acid. The complex is appreciably soluble in water, highly soluble in ethanol and incompletely extracted by the common organic solvents. The minimal molar-ratio of reagent to ruthenium for complete colour development is 16. Both ruthenium(III) and ruthenium(IV) give the same colour reaction with PhAT, so presumably the reagent reduces Ru(IV).

Table 1. Effect of diverse ions in the spectrophotometric determination of 190 μg of ruthenium

Foreign ion	Amount added,* mg	Foreign ion	Amount added,* mg
Fe^{3+}	1.5	Cd^{2+}	1.5
Co^{2+}	1.5	Hg^{2+}	1.5
Ni^{2+}	1.5	Pb^{2+}	2.0
Cr^{3+}	2.0	UO_2^{2+}	5.0

W(VI)	2.5	Th^{4+}	5.0
Mo(VI)	1.0	Au^{3+}	2.0
Cu^{2+}	2.0	Rh^{3+}	1.8
Zn^{2+}	2.0	Pd^{2+}	2.0
Ga^{3+}	1.5	Os(VIII)†	2.0
In^{3+}	1.5	Ir^{3+}	2.0
Tl^{3+}	2.5	Pt^{4+}	2.0

*Causes an error less than ±2%.
†Os (VIII) is reduced to Os (VI) in alcoholic medium.

The coefficient of variation of the measurements is 0.5%.

Effect of other ions

The organic reagent produced no colour with any of the ions tested. Hence, no masking agent was required in the determination of ruthenium. The tolerance limits for the ions tested are shown in Table 1. Ruthenium can be determined with PhAT in the presence of appreciable amounts of foreign ions commonly associated with it.

Specific and sensitive methods for the spectrophotometric determination of ruthenium are of importance because the metal occurs only as a minor constituent in its sources. Though thiourea and substituted thioureas offer sensitive colour reactions with reuthenium, the advantage of *N*-phenyl-*N'*-acetylthiourea lies in its selectivity and the simplicity of the procedure.

DETERMINATION OF THORIUM AND SCANDIUM BY INDIRECT CHRONOPOTENTIOMETRIC STRIPPING ANALYSIS

J. ADAM
Analytical Laboratory, Institute of Geological Sciences, Charles University, Albertov 6, Prague 2, Czechoslovakia

(*Received* 26 *October* 1981. *Revised* 28 *February* 1982. *Accepted* 14 *June* 1982)

Summary—A highly sensitive chronopotentiometric determination of thorium or of scandium is described. It is based on the substitution of thorium or scandium for lead (or zinc) in the lead–EDTA complex, and measurement of the liberated lead by deposition on a mercury film electrode, followed by a chemical oxidation stripping process during which the potential of the mercury electrode is monitored. Thorium has been determined at concentrations in the range 10^{-5}–$10^{-7}M$ by use of deposition times from 1 min to 1 hr.

Potentiometric stripping analysis was introduced by Jagner and Graneli.[1] The method, which is related to anodic stripping voltammetry, is based on two steps: in the first the metal ions in solution are concentrated by electrolysis onto a mercury film electrode from a solution containing also mercury(II). At the completion of this step the potentiostat is disconnected from the electrochemical cell. In the second step the potential of the electrode is recorded as a function of time as the metal in the mercury film is oxidized, either by the excess of mercury(II) or by the dissolved oxygen in the solution, and thus stripped back into the solution.

This approach has been used[2–4] for the determination of ions forming amalgams and being reversibly reduced and oxidized at the mercury electrode, including copper, zinc, lead, cadmium, bismuth and thallium. We have extended the study to cover the determination of metals which do not form amalgams, such as thorium, scandium and the rare earths, by making use of a substitution reaction between the EDTA complex of lead, or of zinc, and those metals having EDTA complexes with formation constants at least four orders of magnitude greater than those for lead and zinc:

$$PbY^{2-}(ZnY^{2-}) + Me^{2+} \rightarrow MeY^{2-} + Pb^{2+}(Zn^{2+})$$

The relevant log K values are: PbY 18, ZnY 16.5, ThY 23.2, ScY 23.1, InY 25. Free lead and zinc can readily be determined by potentiometric stripping analysis. Note that the thermodynamic formation constants can be used, as the side-reaction coefficient for protonation of the EDTA will affect all the constants equally, at a given pH.

EXPERIMENTAL

Reagents

All solutions ($10^{-3}M$) of the metals were prepared from their *p.a.* chlorides or nitrates dissolved in doubly distilled water. Hydrochloric acid ($0.5M$ and $0.1M$) and acetate buffer solutions ($0.1M$, various pH values) were prepared from reagent-grade chemicals diluted with doubly-distilled water.

Apparatus

Potentiometric stripping measurements were made with an REC 80 Servograph with the REA 120 scanning unit and TTA 80 titration assembly, and pH values were measured on a model PHM 64 meter, all from Radiometer, Copenhagen. Micropipettes with capacities from 5 to 500 μl (Bie & Bentsen, Denmark) were used for measuring out the metal solutions.

Electrodes

Radiometer electrodes were used: a P 1312 platinum counter-electrode, a K 4040 saturated calomel electrode and an F 3500 glassy-carbon electrode. The surface of the glassy-carbon electrode was polished for 1–2 min with 3-μm diamond paste, then rinsed with acetone. When not in use, the electrode was stored in ethanol.

The following procedure is recommended for precoating the surface of the glassy-carbon electrode: immerse the electrode in $0.1M$ hydrochloric acid containing 25 mg of mercury(II) per litre and plate the mercury at -0.5 V *vs.* SCE for 2 min, then strip it off again. Repeat this cycle, plating at -0.7 V, then -0.8 V and finally at -0.9 V. Wash the electrode with distilled water and use for the measurements. This preparation procedure should be repeated every two days.

Procedure

To 10 ml of $5 \times 10^{-3}M$ lead–EDTA solution add 5 ml of pH-3.17 buffer and then the sample containing thorium or scandium: for the calibration take from 0.1 to 0.9 ml of $5 \times 10^{-3}M$ thorium or scandium solution. Boil for 5 min under an infrared lamp, then cool to room temperature and add air-saturated buffer solution to make up to 25 ml. There is then enough dissolved oxygen to oxidize the metal back into solution quantitatively in the stripping process. Transfer the solution to the cell and electrolyse for 12 min at -0.8 V *vs.* SCE (or at -1.3 V for zinc), then disconnect the potentiostat and record the potential as a function of time (a suitable chart speed is 1 mm/sec). The time taken to complete the stripping process is proportional to the initial concentration of thorium (or of scandium): completion is indicated by the potential moving rapidly to less negative

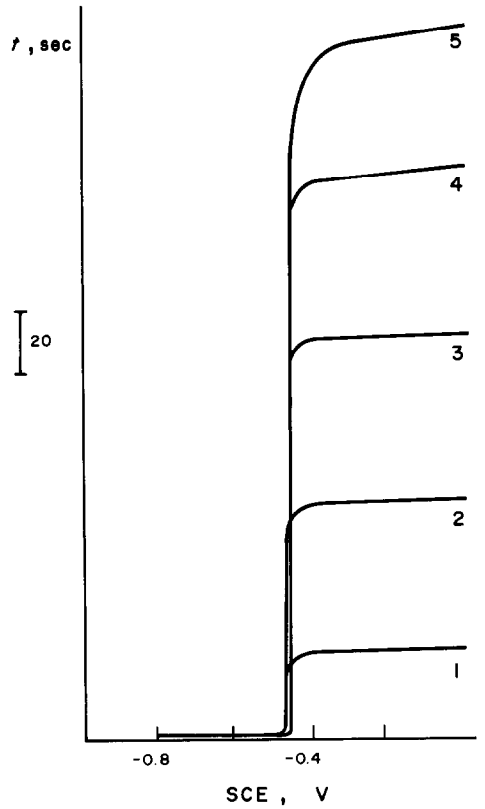

Fig. 1. Set of stripping chronopotentiometric curves calibration graph for thorium or scandium in acetate buffer at pH 3. Electrolysis for 1 min at −0.8 V. Curves 1–5: 2, 6, 10, 14, 18 × $10^{-5}M$ Th or Sc.

values. Figure 1 shows a typical set of curves obtained with the lead–EDTA complex. Similar results are obtained when the zinc–EDTA complex is used.

RESULTS AND DISCUSSION

Thorium and scandium can displace lead or zinc from their respective EDTA complexes in weakly acidic solution, but to speed up the reaction it is preferable to heat the solution to boiling for a few minutes. The best results are obtained by working in the pH range 2.7–4.4. At higher pH the products of hydrolysis of the thorium aquo-ions are adsorbed on to the mercury electrode, and at lower pH the substitution reaction is too slow.

The determination of thorium suffers interferences from traces of complexones such as EDTA, DCTA *etc.*, and from sulphate, which precipitates lead and complexes thorium. Other cations with log K_{MY} values close to 23 [in the range 20–29, including Sn(II), Cr(III), Sc, In and Zr] interfere as they react similarly to thorium with the lead and zinc complexes, though the rates of reaction are sometimes different.

The determination of scandium, which has a log K_{MY} value of 23.1, is similar to that of thorium, and so are the interferences. The optimum pH range is 2.6–3.0, limited by slowness of reaction and by hydrolysis at low and high pH values respectively, as with thorium. The variation of stripping time with pH in the initial chemical steps is shown in Fig. 1.

The limit of detection depends on the electrolysis time, but the determination of thorium or of scandium is feasible in the concentration range from $10^{-5}M$ (1 min electrolysis) to $10^{-7}M$ (1 hr electrolysis) when dissolved aerial oxygen is used as the oxidizing agent. The concentration of thorium or scandium can be found from a calibration graph, but is better obtained by using the standard-addition method as it is difficult to keep a constant ionic strength in all samples and standards, and this factor does have a significant effect on the measured stripping times. Table 1 includes some results for determinations of thorium in the presence of a number of other metals. Thorium, scandium and indium would be measured as their sum.

Acknowledgement—The author wishes to thank Radiometer of Copenhagen for the loan of the apparatus, and Professor J. Růžička of the Technical University, Lyngby, for providing facilities for carrying out these experiments.

COMPLEXOMETRIC DETERMINATION OF MERCURY(II) BY USE OF 4-AMINO-5-MERCAPTO-3-PROPYL-1,2,4-TRIAZOLE AS REPLACING REAGENT

H. R. A. GADIYAR, R. V. GADAG and M. R. GAJENDRAGAD*
Department of Chemistry, Karnataka Regional Engineering College, Surathkal, (D.K.), P.O. Srinivasnagar-574157, Karnataka, India

(*Received* 21 *September* 1981. *Revised* 25 *March* 1982. *Accepted* 3 *June* 1982)

Summary—A simple, rapid, and selective complexometric method is proposed for the determination of mercury(II). Mercury(II) is first complexed with excess of EDTA and the surplus EDTA is back-titrated (pH 5–6) with zinc sulphate solution, with Xylenol Orange as indicator. 4-Amino-5-mercapto-3-propyl-1,2,4-triazole is then added to displace EDTA from the Hg–EDTA complex and the released EDTA is titrated with zinc sulphate solution. Reproducible and accurate results are obtained in the range 1–40 mg of mercury, with a relative error of approximately 0.4%.

Mercury(II) is normally not determined by direct EDTA titration, particularly in presence of other ions.[1] Usually the mercury(II) and other metal ions are first complexed with EDTA and the Hg–EDTA complex is then selectively decomposed by replacing reagents[1–3] and the EDTA released is titrated. However, many of these methods suffer severe interference from copper(II), some require heating for demasking the Hg–EDTA complex, and others require cooling to avoid the copper interference. A satisfactory method for use in presence of copper was described by Ueno, however.[4] The method now reported uses 4-amino-5-mercapto-3-propyl-1,2,4-triazole (HPAMT) as a selective demasking agent for the Hg–EDTA complex at pH 5–6. Copper(II) does not interfere and the decomposition takes less than 5 min even at room temperature.

EXPERIMENTAL

Reagents

HPAMT. Synthesized as reported in the literature[5] (found: C 38.2%, H 6.2%, N 35.6%, S 20.3%; $C_5H_{10}N_4S$ requires C 37.95%, H 6.37%, N 35.41%, S 20.26%; m.p. 104°), and used as a 0.025*M* solution in acetone.

Mercuric chloride solution. Prepared from analytical-grade material and standardized by the ethylenediamine method.[6]

Zinc sulphate solution. Standardized by the quinaldinate method.

EDTA solution, 0.025M.

Xylenol Orange indicator solution, 0.5%.

Procedure

An acidic solution of the sample, containing 1–40 mg of Hg(II), was mixed with excess (about 5 ml) of EDTA and adjusted to pH 5–6 with hexamine. The excess of EDTA was back-titrated with zinc sulphate solution (Xylenol Orange as indicator). At least 100% excess of HPAMT (calculated on the basis of a 2:1 reaction ratio of HPAMT to Hg) was added and the mixture allowed to stand for 5 min. The EDTA released was then titrated with zinc solution. The second titration gave the amount of Hg(II) present.

*To whom correspondence should be addressed.

RESULTS AND DISCUSSION

The fact that HPAMT displaces EDTA quantitatively (at pH 5–6) from the Hg–EDTA complex indicates that the $Hg(HPAMT)_2$ complex is more stable than the Hg–EDTA complex. The release is quantitative at room temperature. Further, unlike many sulphur ligands, HPAMT forms a highly soluble $Hg(HPAMT)_2$ complex, and the absence of a precipitate in the reaction mixture assists accurate determination of the end-point. At least 100% excess of the reagent is required for complete release of the EDTA, but a larger excess has no adverse effect. Zinc sulphate was found to be ideal as the titrant as it gives a sharp end-point and does not react with HPAMT. Equally good results are obtainable with lead nitrate as titrant, in the absence of a large amount of chloride or sulphate in solution.

Table 1. Determination of 24.89 mg of mercury in a mixture of metal ions

Metal ions	Quantity added, *mg*	Mercury found, *mg*
Pb(II) + Cd(II)	200 each	24.7_8
Cd(II) + Zn(II)	200 each	24.8_9
Cu(II) + Co(II)	70 + 100	24.9_9
Cu(II) + Pb(II) + Cd(II)	70 + 200 + 200	24.8_9

Mercury in the range 5–40 mg was determined with a relative error not exceeding 0.4% and an overall standard deviation of 0.07 mg. The effect of diverse metal ions on the determination of 25 mg of Hg^{2+} was studied and the tolerance limits found were 200 mg of Cd^{2+}, Pb^{2+} or Au^{3+}, 100 mg of Co^{2+}, 70 mg of Cu^{2+}, 50 mg of Ni^{2+} and 25 mg of Mn^{2+}, either singly or in combination. It is important to note that Cu^{2+} can be tolerated in up to threefold ratio without masking or cooling to below room temperature.

Some results for synthetic mixtures are given in Table 1. However, no satisfactory results were obtained in the presence of Bi^{3+}, As(III), Sb(III), Al^{3+}, Fe^{2+} and Fe^{3+}, as the end-point in these cases was not sharp.

DETERMINATION OF PHOSPHORUS AND TUNGSTEN IN HETEROPOLY ACIDS BY EDTA-TITRATION

HIROMU HAYASHI* and J. B. MOFFAT†
Guelph-Waterloo Centre for Graduate Work in Chemistry and Department of Chemistry, University of Waterloo, Waterloo, Ontario, Canada

(*Received* 2 *February* 1982. *Accepted* 14 *June* 1982)

Summary—Previous methods for the titrimetric determination of phosphorus and tungsten with EDTA are found to be unsatisfactory for heteropoly acids. Successful modifications of the procedures are described.

The application of heteropoly acids and their salts in catalytic processes has received increased attention in recent years.[1,2] Tungsto- and molybdophosphates decompose in alkaline media to form simple tungstate or molybdate ions and hydrogen phosphate,[1,3] which finds use in a popular method[4] for the titrimetric determination of phosphorus after precipitation as ammonium 12-molybdophosphate.[3]

$$[PMo_{12}O_{40}]^{3-} + 23OH^- \rightarrow 12MoO_4^{2-} + HPO_4^{2-} + 11H_2O \quad (1)$$

$$[P_2W_{18}O_{62}]^{6-} + 34OH^- \rightarrow 18WO_4^{2-} + 2HPO_4^{2-} + 16H_2O \quad (2)$$

However, calcination of the hydrated 12-tungstophosphoric acid at high temperatures results in decomposition of the heteropoly structure with some loss of the matrix oxide by sublimation.[2] The stoichiometry given above no longer applies to the catalyst thus obtained and it is necessary to analyse separately for both phosphorus and tungsten.

EDTA methods have been reported for the determination of phosphorus in uranium ores, concentrates and liquors, by precipitation as ammonium molybdophosphate and titration with EDTA.[5] Phosphates, metaphosphates, pyrophosphates, and tripolyphosphates have also been determined by precipitation as magnesium ammonium phosphate followed by EDTA titration.[6] Further discussion of EDTA techniques for the determination of phosphorus can be found in the literature.[4,7] The determination of tungsten by precipitation as lead tungstate and subsequent EDTA titration was suggested some years ago[8] and has been applied to tungsten–iron and tungsten–molybdenum alloys[9] and to tungsten oxides.[10]

Though these methods have been satisfactorily used for analysing a variety of relatively simple compounds of phosphorus and tungsten, attempts to apply them to tungstophosphates have produced less than satisfactory results. We report here some modifications of earlier procedures that make them satisfactory for analysis of 12-tungstophosphoric acid and dimeric 9-tungstophosphoric acid by EDTA titration.

EXPERIMENTAL

Samples

Analytical-reagent grade 12-tungstophosphoric acid, authentic simple tungstates and phosphates were obtained from BDH Chemicals. The 12-acid was shown to be the 24-hydrate by thermogravimetry.[2] The dimeric 9-tungstophosphoric acid was prepared from the A-form of the ammonium salt.[11]

Reagents

Stock solutions of 0.01*M* magnesium chloride and 1*M* ammonia/1*M* ammonium chloride buffer. Eriochrome Black T, 1% solution in 10% ammonia solution,[12] prepared fresh every month. Stock solutions of 0.02*M* lead nitrate and of acetate buffer[10] (50 g of sodium acetate and 12 ml of glacial acetic acid diluted to 1000 ml). Aqueous 1% Xylenol Orange solution.

Procedures

Phosphorus. Add 5 ml of 1*M* sodium hydroxide to an aliquot of heteropoly acid solution (containing ~50 μmole of phosphorus) and dissolve the resultant precipitate by gentle boiling. Neutralize with 5 ml of 1*M* hydrochloric acid, then add 20 ml of ammonia/ammonium chloride buffer and 10 ml of 0.01*M* magnesium chloride. Titrate the surplus magnesium with 0.01*M* EDTA (Eriochrome Black T indicator) after leaving sealed overnight.

Tungsten. To an aliquot of heteropoly acid solution (*ca.* 100 μmole of tungsten), add 1.6 ml of 1*M* sodium hydroxide and 20 ml of water. Boil gently to dissolve the sample and dilute with water to about 450 ml. Quickly add 20 ml of acetate buffer to make the pH 5.0, and then 10 ml of 0.02*M* lead nitrate. Boil for 15 min, cool, and filter off the white precipitate. Titrate the surplus lead in the filtrate with 0.01*M* EDTA (Xylenol Orange indicator). Correct the tungsten value for phosphate as discussed in the text.

RESULTS AND DISCUSSION

Table 1 shows the results of alkalimetric titrations of tungstophosphoric acids and their calcined

products, in which a known amount of heteropoly acid (*ca.* 100 μmole of phosphorus) was dissolved in 20 ml of 0.25*M* sodium hydroxide and the excess of alkali was titrated with 0.25*M* hydrochloric acid (phenolphthalein as indicator).[3] The uncalcined 12-tungstophosphoric acid was the 24-hydrate, calcination of which at 400° gave the anhydrous acid and at 525° resulted in decomposition. This thermal behaviour was confirmed by thermogravimetric analysis and powder X-ray diffraction.[2] The calcined products and the dimeric 9-acid required complete hydrolysis by gentle boiling in alkali before the titration. This simple technique seemed suitable for routine analysis of the stoichiometric heteropoly acid.

The EDTA determination of phosphorus[6] is based on the complete precipitation of phosphate as ammonium magnesium phosphate ($NH_4MgPO_4 \cdot 6H_2O$) with a known (and excessive) amount of magnesium chloride at pH 10.5 in ammonia/ammonium chloride medium. Fine crystals are deposited on the walls of the container within 5–10 min and titration after 30 min gives fairly good results for simple phosphates (Table 2), but not for the heteropoly acids. The modified procedure described above gives results in good agreement with the expected values for the uncalcined tungstophosphoric acids (Table 2). Evidence for some loss of phosphorus on calcination appears in these results though it is not shown by those obtained by alkalimetry (Table 1).

The modifications are simple, but essential both for complete decomposition of the heteropoly acid and quantitative precipitation of $NH_4MgPO_4 \cdot 6H_2O$.

Tungsten(VI) forms a white precipitate of lead tungstate with lead ions.[13] Titration[10] of the remaining lead with EDTA at pH 5 gives excellent results for a simple tungstate and an isopolytungstate (Table 3). The complete decomposition of the isopoly salt into simple tungstate by gentle boiling in alkaline medium is again important. However, the values obtained for tungsten in heteropoly acids were about 15% too high. The discrepancy was suspected to arise from the precipitation of lead phosphate, which is only slightly soluble in water,[14] along with the lead tungstate. Precipitates were obtained from both Na_2HPO_4 and Na_3PO_4 with lead in acetate buffer. EDTA titration of the excess of lead in the filtrate confirmed the precipitation of $Pb_3(PO_4)_2$. Since 1 mmole of phosphate will react with 1.5 mmole of lead (which in turn will

ELUTION AND SPECTROPHOTOMETRIC DETERMINATION OF GOLD AFTER ITS SEPARATION FROM NON-VOLATILE PLATINUM METALS BY COLUMN EXTRACTION CHROMATOGRAPHY

A. FLIEGER and S. PRZESZLAKOWSKI
Department of Inorganic and Analytical Chemistry, Medical School, 20–081 Lublin, Poland

(*Received* 8 *January* 1982. *Accepted* 10 *June* 1982)

Summary—Mixtures of gold(III) and iridium(IV) were separated by column extraction chromatography on silica treated with a tri-n-octylamine (TOA) salt. A mixture 2.25*M* in hydrochloric acid and 5*M* in nitric acid was used for elution of iridium. Gold was eluted together with the TOA salt by acetone, and after evaporation of the acetone, the TOA chloroaurate was dissolved in chloroform, converted into TOA bromoaurate and determined spectrophotometrically at 395 nm ($\epsilon = 3.4 \times 10^3$ l.mole^{-1}.cm^{-1}). Beer's law was obeyed over the concentration range 5–67 ppm of gold. The method was found suitable for determination of gold after its separation from other metals by extraction chromatography on supports treated with liquid anion-exchangers.

The determination of gold after its separation from other metals by chromatography on solid anion-exchange resins requires combustion of the resin, owing to irreversible retention of this metal.[1,2] A simple and rapid method of analysis for non-volatile platinum metals, based on their column chromatographic separation on silica treated with a tri-n-octylamine (TOA) salt and elution with mixtures of hydrochloric and nitric acid, has been described,[3] but it was found that gold(III) was very strongly retained and could not be eluted even by a mixture of concentrated hydrochloric and nitric acids. Preliminary experiments in our laboratory indicated that although the gold could be eluted from the column together with the TOA salt and remaining aqueous solution with acetone, and subsequently determined spectrophotometrically with Rodamine B,[4] this procedure was inconvenient since the presence of TOA interfered, and mineralization of the amine salt with a mixture of concentrated nitric acid, sulphuric acid and hydrogen peroxide required refluxing at a temperature of 220–230° for 4 hr.[5]

Many spectrophotometric methods for gold are based on ion-pair formation between halide complexes of gold and basic dyes.[6,7] A selective and precise extraction–spectrophotometric method utilizing the bromoaurate complex with tri-n-octylphosphine oxide was proposed by Holbrook and Rein.[8] Since gold had been reported to form coloured spots on paper treated with tri-n-octylamine hydrobromide,[9,10] it was thought that formation of an ion-pair composed of bromoaurate and tri-n-octylammonium ions could be utilized for extraction–spectrophotometric determination of gold after elution of chloroaurate from TOA-coated silica with acetone.

EXPERIMENTAL

Reagents

Pure tri-n-octylamine (Fluka) was further purified by vacuum distillation, the fraction boiling at 190–200°/5–10 mmHg being collected. Reagent grade chloroform was also distilled before use.

Standard gold solution was prepared by dissolving 46.5 mg of $HAuCl_4.4H_2O$ (pure, POCh, Poland) in 1*M* hydrochloric acid.

Iridium(IV) solution was prepared in the manner described previously.[3]

All other reagents were of analytical grade.

Procedure

Glass tubes (10 × 300 mm) were used, packed with purified silica gel coated with TOA salt. The sorbent (10 g) was slurried with 50 ml of the first eluent (2.25*M* HCl + 5*M* HNO_3), poured into the column and covered with a cellulose filter paper. The column length was 190 mm, the volume of organic phase 1.4 ml and the hold-up volume 8 ml. The volume of organic phase was determined by eluting the TOA salt together with the remaining aqueous phase from the column with 35 ml of acetone; the solvent was then evaporated and the volume of TOA was measured in a narrow calibrated test-tube.

After the column had been washed with 8 ml of the first eluent, 2 or 3 ml of a synthetic mixture containing 176 μg of iridium and 890 or 445 μg of gold was introduced into it. Elution under hydrostatic pressure (head 250 mm) was used for the separation. Iridium was eluted with 40 ml of the first eluent (and was found in a 15-ml fraction of the eluate). The column was then washed with 12 ml of 3*M* hydrochloric acid and gold was eluted together with the organic stationary phase and aqueous solution with 35 ml of acetone. The acetone was then evaporated on a water-bath and the bright yellow residue (TOA chloroaurate and excess of TOA salt) with remaining aqueous solution was treated with 40 ml of chloroform and transferred into a separatory funnel, which was then thoroughly shaken. When the phases had separated, the organic (lower) phase was run into a 50-ml standard flask and the aqueous phase

was washed with 5 ml of chloroform, the washings also being added to the flask. The combined extracts were diluted to the mark with chloroform and mixed. Then 5 ml of the chloroform phase were pipetted into a small separatory funnel and 5 ml of 1.8*M* aqueous hydrobromic acid (containing 4×10^{-4}% bromine) and 10 drops of concentrated phosphoric acid were added. The mixture was then shaken for 1 min, and after separation of the phases, the lower (organic) phase was dried by addition of a small amount of anhydrous sodium sulphate. The absorbance of the organic phase was then measured in a 1-cm cell at 395 nm against a reagent blank similarly prepared (the concentration of TOA salt in the reagent blank was 0.06*M*). A calibration graph was prepared with standard TOA bromoaurate solutions made as follows. A 0.12*M* solution of TOA in chloroform was shaken with an equal volume of the first eluent (2.25*M* HCl + 5*M* HNO_3), and after separation of the phases, the lower phase was filtered through a cellulose filter. More dilute solutions of the TOA salt were obtained by dilution of this 0.12*M* TOA salt solution with chloroform. A 5-ml volume of this organic solution was then introduced into a small separatory funnel and 5 ml of 1.8*M* hydrobromic acid (containing 4×10^{-4}% bromine) 10 drops of concentrated phosphoric acid and 0.1–1 ml of standard gold solution were added. The mixture was shaken for 1 min and then treated as described for samples.

The procedure for column preparation and chromatographic separation has already been described.[3]

RESULTS AND DISCUSSION

Since gold(III) can be very easily separated from other noble metals by column extraction chromatography, owing to the very strong retention of gold in the system TOA salt–(HCl + HNO_3), a simple method for elution of gold and its determination was sought. Attention was paid to the spectrophotometric method based on the bromoaurate complex with tri-n-octylphosphine oxide, which was found to be very selective for gold, only iridium(IV) and tin(II) interfering (at low concentrations).[8] Since it was found that gold and the tri-n-octylamine salt can be easily eluted from the column with acetone, and bromoaurate should form a coloured ion-pair with the tri-n-octylammonium cation, we decided to modify the method proposed by Holbrook and Rein[8] for the determination of gold in the eluate from the column. It was also supposed that chloroaurate tri-n-octylammonium ion-association complex should be convertible into the bromoaurate complex by treatment with a sufficient excess of hydrobromic acid owing to the higher stability of the bromide complexes of gold[11] and the higher affinity of bromide for alkylammonium cations.[12,13]

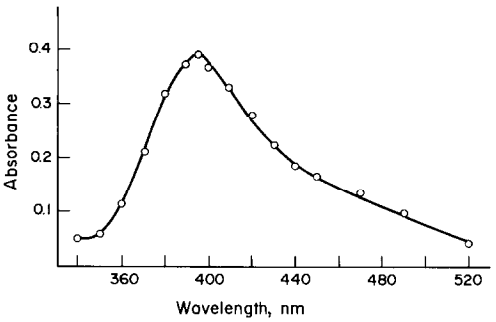

Fig. 1. Spectrum of bromoaurate–TOA complex in chloroform, measured *vs.* reagent blank. TOA concentration 0.06*M*; gold concentration 22.5 ppm.

Preliminary experiments indicated that gold(III) is not extracted by chloroform from hydrobromic acid media, but the organic phase becomes yellow after addition of a small amount of tri-n-octylamine. In further experiments, a small amount of bromine was added to the hydrobromic acid solutions to prevent the reduction of gold, and phosphoric acid was added to the aqueous solution (before the extraction) as masking agent for iron(III) if traces of this metal were present in the aqueous solution.

The absorption spectrum of the TOA–bromoaurate complex in chloroform (Fig. 1) is analogous to the spectrum of the TOPO-bromoaurate complex reported by Holbrook and Rein,[8] but the molar absorptivity is a bit lower (3.4×10^3 l.mole^{-1}.cm^{-1} at 395 nm). The absorbance of the organic phase is stable for 20 min and then slowly decreases.

The absorbance depends somewhat on the TOA salt concentration in the range 0.03–0.12*M* (see Table 1); since 40 ml of chloroform were used for the dissolution of the TOA–chloroaurate complex and the excess of TOA salt after their elution from the column, and the concentration of TOA salt was then 0.06*M*, a tri-n-octylamine hydrobromide solution of this concentration in chloroform was used as the blank for gold determination. It should be remarked that the absorbance of the organic phase was the

Table 1. Influence of tri-n-octylamine salt concentration in chloroform on absorbance of the bromide complex of gold (18 ppm); the organic phase was shaken with 1.8*M* hydrobromic acid containing 4×10^{-4}% bromine

same whether the gold was extracted from hydrobromic acid medium or the TOA–chloroaurate complex in chloroform was shaken with 1.8*M* hydrobromic acid. Beer's law is obeyed over the gold concentration range 5–67 ppm.

The results of gold determination after its separation from iridium(IV) by column extraction chromatography on silica treated with TOA salt and eluted with mixture of hydrochloric acid and nitric acid (2.25*M* HCl + 5*M* HNO_3) are given in Table 2.

In our opinion, the proposed method can be utilized not only for the determination of non-volatile noble metals after their separation by column extraction chromatography, but also for determination of gold in other materials containing larger amounts of this metal (owing to the relatively low sensitivity of the method) in the absence of metals which form coloured anionic bromide complexes extractable by TOA. Furthermore, extraction chromatography with the system TOA HCl–HNO_3 is more convenient than use of anion-exchange resins for the separation and determination of non-volatile noble metals, owing to the easier elution of platinum(IV) and iridium(IV) and the simple and rapid method for determination of gold (which is very strongly retained in both anion-exchange chromatographic systems).

It should be noted that gold(III) and the TOA salt can probably be eluted from the column with methyl isobutyl ketone, like gold bound with tributyl phosphate,[14] and subsequently determined in the organic solution by AAS, in a modification of the method described by Groenewald.[15]

The sensitivity of the method described here could be increased by using a smaller volume of chloroform (*e.g.*, 10 ml) for the extraction, but a blank made in the same way would have to be used as reference solution because of the effect of the higher TOA hydrobromide concentration.

ANALYSIS OF SOME SYNTHETIC CO-POLYMERS FROM THEIR TITRATION CURVES IN NON-AQUEOUS MEDIA

S. K. CHATTERJEE,* R. L. PANDITH and L. S. PACHAURI
Department of Chemistry, University of Delhi, Delhi 110007, India

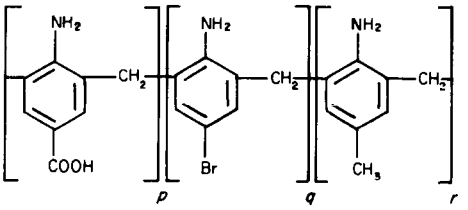
(*Received* 8 *April* 1982. *Accepted* 9 *June* 1982)

Summary—Electrometric titration in non-aqueous solvents is used for the analysis of some synthetic co-polymers with acidic and basic functional groups. The composition of the co-polymers can be deduced from the determination of these groups. The enhanced acidic/basic character of some of the functional groups in the co-polymer chain is interpreted in terms of intramolecular hydrogen bonding, and the inductive effect of the substituents. The nature of the titration curves is explained in terms of ion-association and homoconjugation.

In recent years, electrometric titration in non-aqueous solvents has been widely used for determination of organic acids and bases, alone or in mixtures.[1,2] However, there is little reference in the literature to use of these techniques for analysis of synthetic polymers. Preliminary investigations in this laboratory on some phenolic co-polymers revealed that electrometric titration in non-aqueous solvents may provide an elegant method for analysis of the acidic/basic functional groups, composition, and structural features of the co-polymers.[3–5] These observations encouraged us to extend this approach to the study of some basic co-polymers having various types of functional groups. For the present study, three substituted aromatic amines, *p*-bromoaniline (PBrA), *p*-toluidine (PT) and *p*-aminobenzoic acid (PAB), were co-polymerized with stoichiometric quantities of formaldehyde in the presence of acid catalyst to obtain the random co-polymer (**I**). In order to obtain co-polymers of various compositions, the feed was altered appropriately. These co-polymers are interesting in view of the fact that each monomeric unit in the chain has an $-NH_2$ group, and in addition some of the units have –COOH and Br as substituents. The composition of the co-polymers can be deduced from the determination of the $-NH_2$, –COOH, and Br groups present in the monomeric units. An attempt has been made in this paper to correlate characteristic features of the titration curves of the co-polymers with intramolecular hydrogen bonding, homoconjugation, and ion-association in a medium of low dielectric constant.

EXPERIMENTAL

Random co-polymer (**I**) was prepared by refluxing stoichiometric quantities of PBrA, PT and PAB and HCHO in the presence of 2 ml of concentrated hydrochloric acid as catalyst, for $2\frac{1}{2}$ hr at 130°.



I

The reaction mixture was poured into ice-cold water to precipitate the co-polymer. The product was washed several times with cold distilled water to free it from catalyst.

Three samples of the random co-polymer (**I**) were prepared by using the following feed compositions.

Sample 1: 0.1*M* PBrA + 0.1*M* PT + 0.8*M* PAB + 1.0*M* HCHO
Sample 2: 0.2*M* PBrA + 0.2*M* PT + 0.6*M* PAB + 1.0*M* HCHO
Sample 3: 0.33*M* PBrA + 0.33*M* PT + 0.33*M* PAB + 1.0*M* HCHO

The yield was 95–98% for sample 1 and 75–80% for samples 2 and 3. The halogen content of the samples was determined by treating the co-polymer with sodium metal[6] and filtering off the resultant sodium bromide.

A Radiometer pH-meter (pH M 26 C) with glass (G 202 B) and calomel (K 401) electrodes was used for pH titrations, and a Leeds and Northrup conductance bridge (4959) for conductometric titrations. The details of the titration have been described elsewhere.[3] For acidic functional groups, pyridine was used as the titration medium and sodium methoxide and tetramethylammonium hydroxide (TMAH) in methanol were used as titrants. Basic functional groups were titrated with perchloric acid in glacial acetic acid medium. The co-polymer concentration used was about 1.5 g/l. The titration curves were reproducible within ±2–3%.

RESULTS AND DISCUSSION

Figure 1 shows the potentiometric and conductometric titration curves of sample 1 in pyridine and

*Author for correspondence.

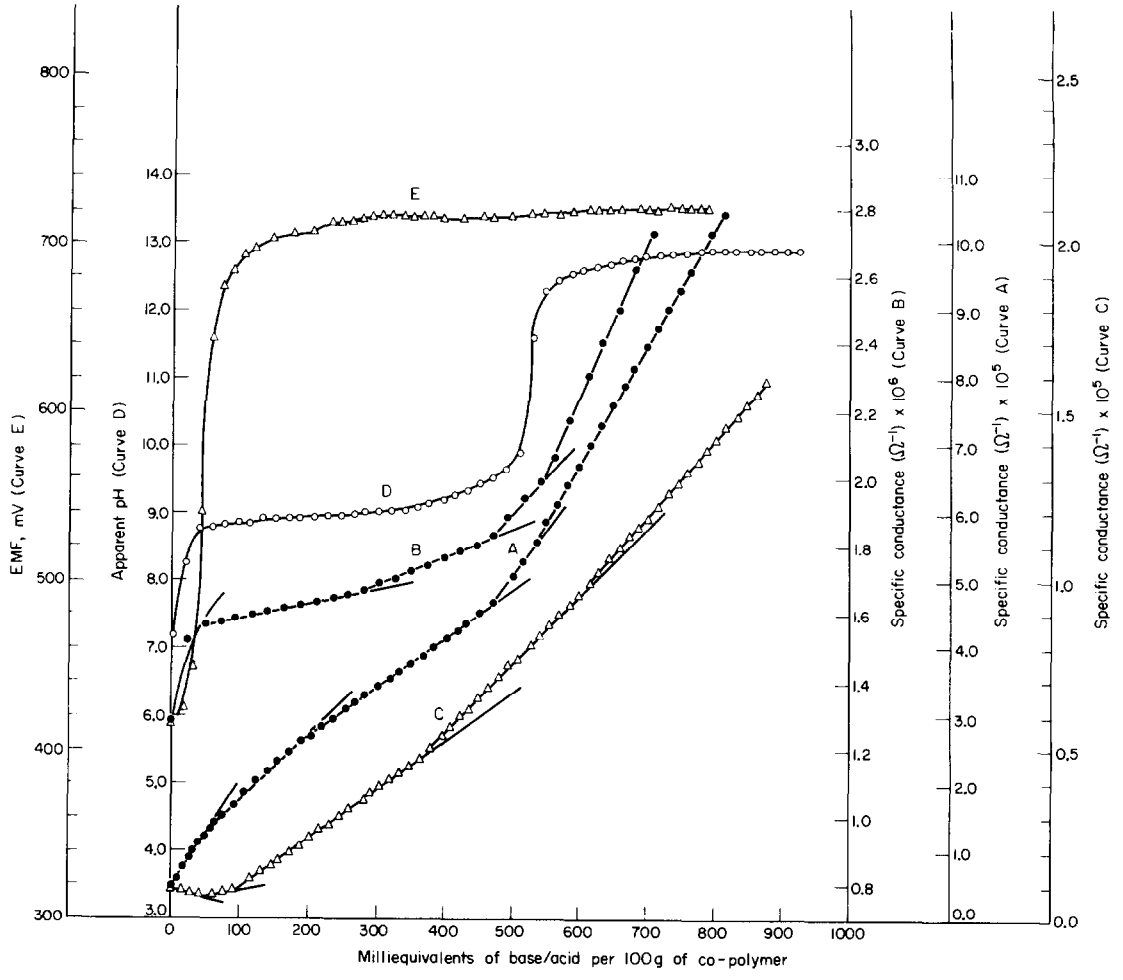


Fig. 1. Titration curves for sample 1. Conductometric curves: (A) in pyridine with TMAH, (B) in pyridine with sodium methoxide, (C) in glacial acetic acid with perchloric acid. Potentiometric curves: (D) in pyridine with sodium methoxide, (E) in glacial acetic acid with perchloric acid.

glacial acetic acid media. Those for samples 2 and 3 were similar to those for sample 1. The conductometric curves for titration with sodium methoxide (*cf.* curve B) showed a distinct final break, which coincided with the very sharp inflection on the potentiometric curve (*cf.* curve D). The titration with TMAH (*cf.* curve A) also had a final break which tallied (within experimental error) with the breaks on the other titration curves. This break obviously indicates the total amount of acidic functional groups (*e.g.*, –COOH) portion titrated. Similarly, the final break in the conductometric titration curves in glacial acetic acid medium (*cf.* curve C) indicates the complete neutralization of $-NH_2$ groups. The percentage of halogen found will give the relative proportion of PBrA units ($-C_6H_2 \cdot NH_2 \cdot CH_2 \cdot Br-$) in the co-polymer chains. The composition of the co-polymer can thus be deduced in terms of the three monomeric units PBrA ($-C_6H_2 \cdot NH_2 \cdot CH_2 \cdot Br-$), PT ($-C_6H_2 \cdot NH_2 \cdot CH_2 \cdot CH_3-$), and PAB ($-C_6H_2 \cdot NH_2 \cdot CH_2 \cdot COOH-$). Table 1 gives the results for the three samples.

The presence of additional breaks in the conductometric curves, before that for the complete neutralization of the functional groups, obviously indicates that some of the COOH and NH_2 groups in the co-polymer chain have stronger acidic (or basic) character compared to others in the same molecule. The hyperacidity of some of the OH-groups in phenolic polymers has been interpreted by several authors in terms of intramolecular hydrogen-bond formation between neighbouring OH-groups.[3–5,7] The presence of intramolecular hydrogen-bonding in such compounds has also been shown from infrared[8] and conformational studies.[9] The infrared spectra of all the co-polymers studied indicated absorptions in the ranges 3450–3600 and 3070–3350 cm^{-1}, showing the probable presence of O–H—O and N–H—N intramolecular hydrogen-bonding.

The basicity of NH_2-groups in the co-polymer chain is expected to be influenced by the inductive effect of the *para*-substituents present in the monomeric units. For instance, the conductometric curve for the co-polymers in glacial acetic acid medium (*cf.* curve C)

Table 1.

*Expressed as mole ratios.
†On the basis of halogen and COOH-group estimations.

showed first a fall in conductivity and then a region of constant conductance. There was invariably a sharp inflection in the potentiometric curve (*cf.* curve E), coinciding with the fall or constant stage of conductance. Incidentally, this portion of the titration curve also almost coincides with the relative proportion of PT in the co-polymer chain. This behaviour is expected in view of the fact that the pK values of the three monomeric units are in the order PT (pK = 5.07) > PBrA (pK = 3.97) > PAB (pK = 2.32).

This obviously shows that the inductive effect of the CH_3-group makes the $-NH_2$-groups of *p*-toluidine (PT) stronger than the NH_2-groups in the other two monomeric units. This is well reflected in the titration curves.

The difference in the nature of the conductometric curves with sodium methoxide and TMAH as titrants (*cf.* curves B and A) can be attributed to ion-association. It is expected that the smaller titrant cation (Na^+) will associate with the acid anion more strongly than the larger one [$(CH_3)_4N^+$] in a medium of low dielectric constant. The indication (on the conductometric curve) is probably due to the formation and different degrees of dissociation of acid–anion, or base–cation complexes in a medium of low dielectric constant. Such homoconjugation has been referred to by Kolthoff and co-workers in the case of weak acids in non-aqueous solvents.[10–12]

Another important aspect of this study is the general ability to account for the actual composition of the co-polymers on the basis of reactivity of the monomeric units used in the co-polymerization reaction. The rate of addition of monomeric units in the co-polymer chain will depend on factors such as (*i*) resonance stabilization of monomeric units, (*ii*) polarization of monomers, owing to the electron-attracting or electron-donating nature of the substituents, and (*iii*) the directive influence of the substituents. On the basis of these factors, the reactivity of the three monomeric units should be in the order PAB > PBrA > PT. This trend is in fact reflected in the actual composition of the products (Table 1).

In conclusion, it can be said that electrometric titration techniques in non-aqueous media may provide an elegant and simple method for estimating acidic and basic functional groups, and deducing the composition of polymers. Structural features, such as intramolecular hydrogen-bonding in polymers are well reflected in the titration curves.

ANALYTICAL DATA

STRUCTURAL INVESTIGATION OF A NEW ORGANIC ANTISEPTIC: TAUROLIDINE

A SPECTROSCOPIC STUDY OF ITS STABILITY AND EQUILIBRIA IN VARIOUS SOLVENTS

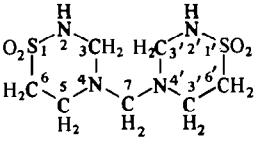
F. ERB,* N. FEBVAY and M. IMBENOTTE

Laboratoires de Toxicologie et de Physique, Faculté de Pharmacie, Rue du Professeur Laguesse, 59045 Lille, France

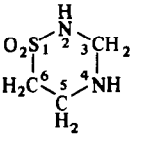
(*Received* 22 *December* 1981. *Accepted* 7 *June* 1982)

Summary—^1H and ^{13}C NMR investigations of aqueous solutions of Taurolidine and Tauroflex have been made to determine their stability. This study revealed two successive equilibria, leading particularly to Taurultam-methylol (in 15% proportion) from a 0.5% Taurolidine solution. The methylol derivative is supposed to be the component active against bacteria and their endotoxins.

Taurolidine (1) is the international common name of a new chemotherapeutic molecule with bactericidal and anti-endotoxin properties:[1–4] bis-(1,1-dioxoperhydro-1,2,4-thiadiazinyl-4)methane.



(1)



(2)

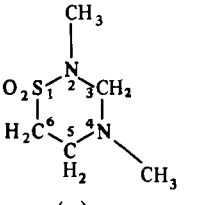
Its activity and that of Taurultam (2) [1,1-dioxoperhydro-1,2,4-thiadiazine] (DPT) should be due to the liberation of active methylol groups in aqueous solution and *in vivo*. Specialized forms (Tauroflex) are administered locally but mainly intraperitoneally and intravenously in digestive surgery.

The aim of this study was to contribute to the investigation of the different chemical species found in Taurolidine solutions, in order to better define its pharmacodynamic model. This paper describes ^1H and ^{13}C NMR, and infrared studies of Taurultam, Taurolidine solutions and Tauroflex.

EXPERIMENTAL

Reagents

Taurinamide, Taurolidine, Taurultam, Tauroflex [2% aqueous solution of Taurolidine, containing 5% poly(vinylpyrrolidone-17)] and 2,4-dimethyltaurultam (3), called compound 2012 in some publications, were a gift from Geistlich Sons Ltd., Wolhusen, Switzerland. All other reagents were obtained from commercial sources (DMSO-d_6, D_2O, TMS and $KHSO_3$ from Merck).



(3)

Apparatus

^1H and ^{13}C NMR studies were performed on Jeol C 60 HL and on Bruker WP 80 spectrometers respectively. All the chemical shifts were referred to TMS.

Infrared spectra were recorded with a Nicolet 7199 IR spectrometer. The software developed for the Nicolet 1180 computer was used for data-treatment, and particularly the subtraction of solvent spectra.

Polarographic measurements were obtained with a Tacussel PRG 5 polarograph, with 0.6*M* lithium hydroxide as supporting electrolyte.

RESULTS AND DISCUSSION

NMR study

The ^1H NMR study of a DMSO-d_6 solution of Taurolidine, illustrated in Fig. 1a, reveals all its protons and confirms its stability, mentioned in a recent publication.[5] Before investigation of the aqueous Tauroflex solution, we recorded the ^1H NMR spectra for Tauroflex solutions in mixtures of DMSO-d_6 and D_2O and of D_2O and H_2O. We used the integrated signal for the methylene bridge between the thiadiazine rings as an indication of the degree of hydrolysis; the integrated intensity was measured with an average error of 2%, taking into account the potential

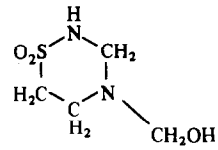
interference from the adjacent high-field protons on C_5 and C_6. In pure D_2O at equilibrium there is no more than 10% of Taurolidine, and (by extrapolation) in pure H_2O no more than 2%: Fig. 2, based on ten observations for various proportions of each solvent, shows the extent of hydrolysis.

From the solution in 17:83 v/v D_2O–DMSO-d_6 mixture a signal at 4.45 ppm (Fig. 1b) was obtained which could be due to the methylene protons of an alcohol group, indicating the possible presence of Taurultam-methylol (4).



(4)

Moreover, Fig. 1c shows a signal at 4.80 ppm arising[6] from $CH_2(OH)_2$. This assignment is made on the basis of the thorough study by Maslovich *et al.*[6] of

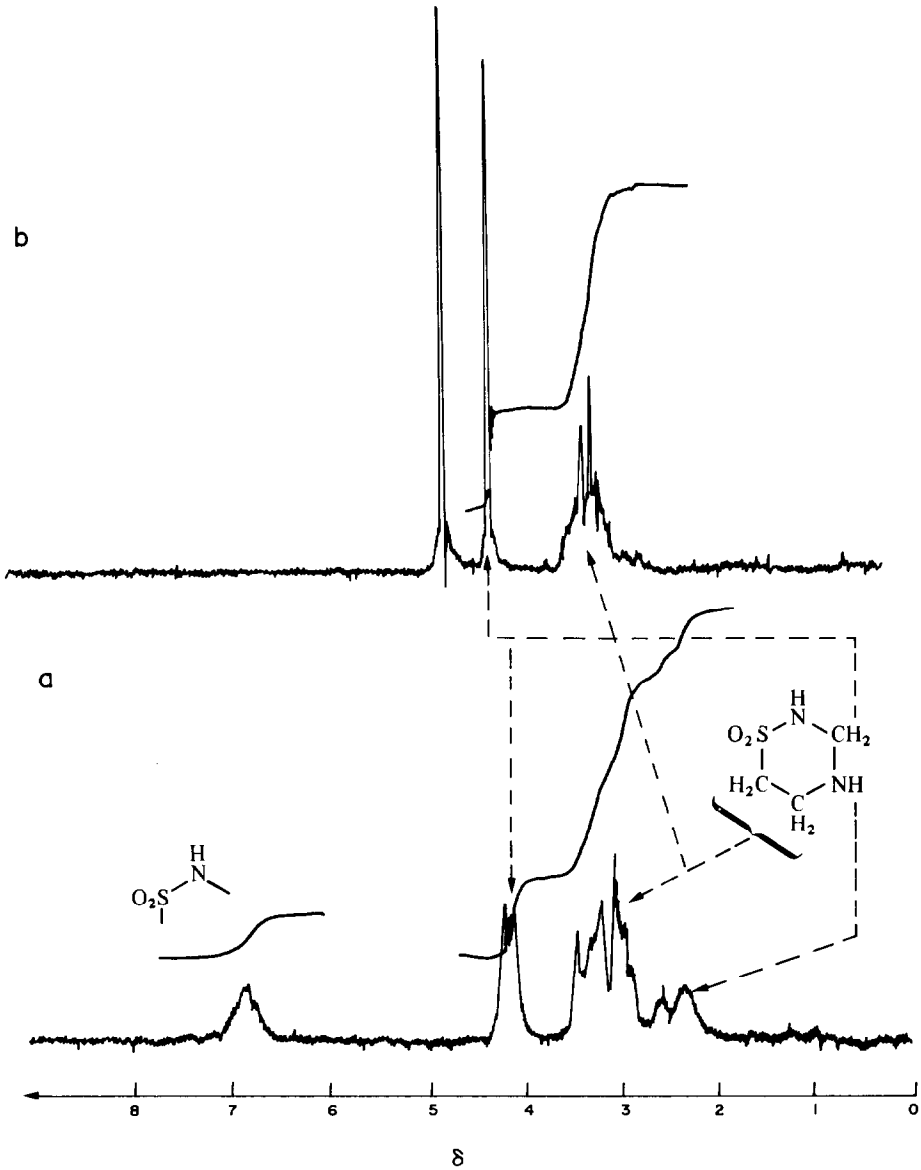


Fig. 3. ^{1}HNMR Spectra of Taurultam in (a) DMSO-d_6; (b) D_2O.

Table 1. Assignments in Tauroflex ^{13}C NMR spectrum

δ (*vs.* TMS), *ppm*	Assignment
19 large	P.V.P.
31 large	P.V.P.
36 large	P.V.P.

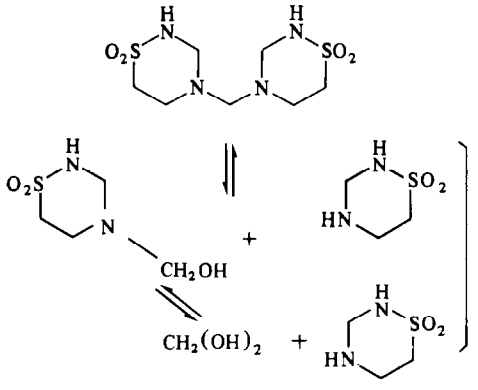
177 large	P.V.P.

*P.V.P. = poly(vinylpyrrolidone).

the ^1H and ^{13}C NMR of formaldehyde in aqueous solutions. These two observations allow us to suppose that hydrolysis of Taurolidine proceeds in two steps, each of them leading to Taurultam.

A previous study of this compound (Fig. 3) had shown that chemical shifts relative to the protons on C_5 and C_6 are similar for Taurultam and Taurolidine, but that the methylene protons on C_3 resonate slightly more upfield for Taurultam than for Taurolidine. This difference causes dissymmetry in the signal observed at 4.3 ppm in the NMR spectra of aqueous solutions of Taurolidine (Fig. 1d).

The stability of the spectra with respect to time permits us to affirm the stability of Taurultam in all the solutions concerned. The different species at equilibrium in 0.5% solutions in D_2O could be determined and are shown below.



In order to confirm these proportions, particularly that of $CH_2(OH)_2$, a polarographic study was made of Taurolidine solutions with different additions: first $KHSO_3$ to detect which portion of the polarographic wave was due to formaldehyde, then known amounts of formaldehyde solution. The result confirms the low amounts previously observed.[11]

To support our hypothesis about the presence of Taurultam-methylol in aqueous solutions of Taurolidine, we recorded the ^{13}C NMR spectra of Tauroflex. The signals were assigned (Table 1) after subtraction of the poly(vinylpyrrolidone) spectrum and preliminary study of compound 2012 for which the ^{13}C NMR chemical shifts are 35.34 (C on N_4), 40.38 (C_5), 44.76 (C_3), 52.25 (C_6) and 74.13 ppm/TMS (C on N_2).

The signal at 78.25 ppm has been assigned to a methylol group on N_4 by means of Roberts's correlation relation[7] applied to C on N_4 of compound 2012 (calculated value 78.64 ppm). This relation is very useful in structural analysis; it gives the ^{13}C NMR chemical shift of a methylol derivative from its methyl analogue:

$$\delta\,(CH_2OH) = \delta\,(CH_3) + 43.3\ \text{ppm}$$

This result confirms the ^1H NMR investigation.

For the signal at 122.44 ppm, the application of the same relation to C on N_2 of compound 2012 gives 117.43 ppm. It is hence possible that a second substitution occurs on N_2 of Taurolidine.

Infrared study

The infrared spectrum of a drop of Tauroflex between two AgBr plates is reproduced in Fig. 4, after subtraction of the absorption bands due to water. To assign the observed bands correctly, it was necessary to record the spectra of Taurinamide, Taurultam and Taurolidine powders in KBr pellets.[8]

The proposed assignments were made by means of the group frequency concept (especially with the aid of the tables of Tipson and Parker[9]) and are given in Table 2. It must be said that in the literature only one reference[10] deals with an infrared and Raman study of Taurine.

In Table 2, the characteristic wavenumbers of thiadiazine rings can be recognized, for instance the symmetrical valence vibration of the sulphur–oxygen bond, showing two components (1180 and 1160 cm^{-1}), which indicates that at least two kinds of compound with thiadiazine rings are present. It may be noted that a polarographic study of Tauroflex indicated the presence of a very low proportion of formaldehyde, which was confirmed by Knight *et al.*[11] by GLC. They found there was less than 0.004% free formaldehyde and that poly(vinylpyrrolidone) stabilizes aqueous solutions of Taurolidine by reducing the formaldehyde content.

These results indicate that infrared spectroscopy and especially NMR spectroscopy are suitable for studying the stability of Taurolidine in various solvents. These non-destructive methods provide a very good example of application of analysis to the solution of a difficult structural problem.

CONCLUSION

This investigation on aqueous solutions allows identification of the different species in equilibrium

and more accurately confirms the presence of methylol derivatives which are the basis of the pharmacologists' hypothesis about the antibacterial activity of Taurolin. A further publication will deal with the analytical aspects, including determination of the metabolites, an important step in better defining the biological applications of this new organic antiseptic.

Summary—The assumptions made in choosing the conditions for coulometric determination of plutonium are critically examined, and the chemical features making the determination possible are elucidated.

The efforts expended on the controlled-potential coulometric determination of plutonium have made it a method of choice for plutonium analyses. Factors such as electrode cleanliness and room temperature have all been considered in detail, and the success of this method has led to the belief that it is both well-understood and non-empirical.[1] The purpose of this note is to suggest that this confidence is premature, and that something remains to be studied before the method can be described in this way.

A popular adaptation of the controlled-potential technique begins with a solution in which the plutonium is apparently all in the tervalent state. By this it is implied that at the start of the electrolysis the oxidation number (N) of the plutonium is as close to 3.00 as possible, or that the initial value of N (which is close to 3.00) is accurately enough known. A current is then caused to flow through the working electrode, oxidizing the plutonium from the tervalent to the quadrivalent state:

$$Pu^{3+} = Pu^{4+} + e^- \quad (1)$$

The potential to be applied to the working electrode (*vs.* the reference electrode) is calculated by means of the Nernst equation:

$$E = E^0 + 0.05916 \log \frac{[Pu^{4+}]}{[Pu^{3+}]} \quad (2)$$

with the ratio $[Pu^{4+}]/[Pu^{3+}]$ typically set at some high value such as 999.[2] When the current has dropped to the "background" level, the number of coulombs passed through the cell is translated into a measure of the plutonium in the titration vessel. Sometimes "correction factors" to allow for incomplete electrolysis are found by manipulating equation (2).[1] In any case, it is tacitly assumed that the value of N is close to 4.00 at the end of the determination.

Although never explicitly stated, an assumption underlying the coulometric determination is that it is possible, by experimental manipulations, to produce an integral change in the plutonium oxidation number; in the present case, this change is ± 1 depending upon the direction of equation (1). Curiously, no-one seems to have calculated the plutonium oxidation numbers at the beginning and end of typical determinations to test this assumption. As the oxidation number of the plutonium in solution at equilibrium is easily calculated from the values of the solution acidity and potential, it is informative to examine these numbers.[3,4] For example, at a potential of 1.137 V (recommended by Shults[2] for the coulometric determination), plutonium *at equilibrium* in 1 *M* perchloric acid should have an oxidation number of about 5.998, and consist almost entirely of plutonium(VI). However, plutonium(VI) is not reported as present in the electrolysed solutions; what is reported is a solution containing more than 99% plutonium(IV). It follows that by the end of the electrolysis (taken as corresponding to the current falling to the background level) the solution has not come to thermodynamic equilibrium.

Equilibrium is established in the plutonium system in acid medium by the generation of tervalent, quinquevalent, and sexivalent plutonium,[5]

$$2Pu^{4+} + 2H_2O = Pu^{3+} + PuO_2^+ + 4H^+ \quad (3)$$

$$Pu^{4+} + PuO_2^+ = Pu^{3+} + PuO_2^{2+} \quad (4)$$

and the first step is rate-determining. The drift toward equilibrium establishes two reversible couples in the solution: Pu^{4+}/Pu^{3+} and PuO_2^{2+}/PuO_2^+. If the Nernst equation is to be applicable to the first of these couples under the conditions of the determination, then it should be applicable to the second couple under the same conditions. But the influence

*Mound Facility is operated by Monsanto Research Corporation for the U.S. Department of Energy under Contract No. DE-AC04-76-DP00053.

of the second couple on the potential of the electrode or upon the determination has always been ignored, and there is no evidence that application of the Nernst equation to the PuO_2^{2+}/PuO_2^{+} couple leads to the very same potential obtained by application of this equation to the Pu^{4+}/Pu^{3+} couple.

When a reaction between an oxidizing agent and a reducing agent [equation (4)] takes place at the surface of a conductor, the potential of the conductor lies between the equilibrium potential of the system which is oxidized and that of the system which is reduced.[6] In other words, the potential impressed at the electrode in the plutonium system amounts to a "mixed potential" maintained at the electrode surface by mixing unknown contributions from both reversible couples in the plutonium system. This "mixed potential" bears no simple relationship (such as that given by the Nernst equation) to the concentrations or activities of the reacting species.[7] Thus, mathematical analyses based upon applications of the Nernst equation to electrodes in non-equilibrium systems cannot be considered complete, for such potentials have an inherent tendency to drift.[8]

As the Nernst equation applies only when the net current through an electrode is zero and the electrode is at equilibrium,[9] conventional descriptions of the coulometric method solely in terms of equilibrium concepts are not satisfactory. It is therefore appropriate to reconsider the determination with a view to (1) exploiting the departure from equilibrium and (2) adapting the system to give near equilibrium conditions.

(1) A significant improvement in the performance of the controlled-potential method is realized if the analysis time is curtailed,[1] but it does not seem to be appreciated that this better performance is a logical consequence of operating under conditions far removed from equilibrium. The disproportionation reaction is not fast; if it were fast, the analysis as we know it today would not be possible. Because reaction (3) is slow, rapid electrolysis results in a much higher exchange-current density for the Pu^{4+}/Pu^{3+} couple than for the PuO_2^{2+}/PuO_2^{+} couple. In this non-equilibrium circumstance, the Nernst equation is a reasonable *approximation* to the true state of affairs.[9] Rapid electrolysis also minimizes the amount of Pu^{3+} and PuO_2^{+} internally generated by disproportionation. These latter species begin to appear as soon as substantial proportions of plutonium(IV) are generated by electrolysis;[5] both are electroactive and therefore additional sources of error which can be minimized by rapid electrolysis.

(2) A second improvement involves adding complexing agents to the plutonium solution, such as sulphuric or nitric acid, or phosphate.[10] Such reagents stabilize plutonium(IV) by forming complexes with it that are considerably more stable than those formed with other plutonium species. (That is, the α-coefficient for the side reactions of tetravalent plutonium is increased more than the α-coefficients for the other plutonium oxidation states.[11]) The effect of this is to decrease the formal (conditional) potential of the Pu(IV)/Pu(III) couple and increase that of the Pu(VI)/Pu(IV) and Pu(V)/Pu(IV) couples. Thus the solution at the end of the electrolysis will contain a very high proportion of Pu(IV), close to the proportion that would exist if the Pu^{4+}/Pu^{3+} equilibrium were the only one possible. The oxidation number of the plutonium will therefore be close to 4.00 at this time. Because the solution composition is effectively restricted to only these two lower oxidation states during the determination, the problem of mixed potentials never arises.[9] Likewise, the tendency to internal generation of other electroactive species is minimized, as can be verified by computation of the maximum (equilibrium) values of these species for selected values of N between 3.00 and 4.00.[12] These are good reasons for rapid electrolysis in sulphuric acid medium being preferred for the coulometric determination.

A discussion of non-equilibrium effects on plutonium determinations can be found elsewhere.[13]

IODOMETRIC STANDARDIZATION AND BIAMPEROMETRIC DETERMINATION OF IRIDIUM(IV)

JAIM LICHTIG
Instituto de Química, Universidade de S. Paulo, Caixa Postal 20780, S. Paulo, Brasil

(*Received* 21 *December* 1981. *Accepted* 12 *May* 1982)

Summary—Ir(IV) in the concentration range 0.4–0.8 g/l. can be easily determined iodometrically with 0.01*M* thiosulphate (starch as indicator). The relative standard deviation is 0.2–0.3%. When other coloured ions are present, biamperometric detection is recommended.

At present, solutions of a number of the platinum metals, including iridium, are standardized by methods, mostly gravimetric,[1] which are slow and tedious. Hexachloroiridate(IV) reacts quantitatively with iodide, resulting in an equivalent amount of iodine, according to the equation:

$$2IrCl_6^{2-} + 2I^- \rightleftharpoons 2IrCl_6^{3-} + I_2$$

The liberated iodine can be titrated with thiosulphate. This method, with starch as indicator,[2] has not found wide use because of difficulty with the end-point colour change from blue (starch–iodine) to pale yellowish-green ($IrCl_6^{3-}$). To overcome this difficulty, Woo and Yost[3] added a small amount of benzene to extract the iodine and titrated until the upper layer turned colourless. Other workers, however, do not agree that this modification furnishes correct results.[4,5] A potentiometric titration, with a platinum indicator electrode, was reported by Pshenitsyn and Ginzburg to give good results.[6] The aim of the present work was to re-examine the method.

EXPERIMENTAL

Reagents

A stock iridium(IV) solution (1.6 g/l.) was prepared by dissolving pure $(NH_4)_2IrCl_6$ (Johnson and Matthey) in 0.5*M* hydrochloric acid, and standardized gravimetrically with formic acid.[7] Sodium thiosulphate solution was prepared with freshly distilled water and standardized with sodium iodate. It was diluted immediately before use, to give a 0.01*M* working solution.

Procedures

Visual end-point. To 10.00 ml of a solution containing between 8 and 16 mg of iridium(IV) add 0.5 g of potassium iodide, whilst stirring. Then add 10 ml of distilled water and titrate with 0.01*M* thiosulphate added dropwise from a semimicro burette. When the colour changes from brown to yellow, add 2 drops of freshly prepared 1% aqueous starch solution and continue titration until the colour clearly changes from blue to pale yellowish-green.

Biamperometric detection. To 5.00 ml of solution containing between 1.5 and 7.5 mg of iridium(IV), add 0.5 g of potassium iodide and dilute to 30 ml with distilled water. Insert two platinum foils (0.2 cm^2 in area) and apply a potential difference of 30 mV between them. With continuous stirring, add fresh 0.01*M* thiosulphate from a semimicroburette until the current reaches zero ("dead-stop" end-point).

RESULTS AND DISCUSSION

Interferences

Iron(III) interferes but can be easily masked with fluoride; Ru(IV) interferes by reaction with the iodide; Os(IV), Os(III) and Ru(III) do not react with iodide and can be present when the biamperometric detection is used, but interfere in the visual end-point method because they are coloured. Ru(IV), Ru(III), Os(IV) and Os(III) can be previously eliminated by perchloric acid oxidation.[8]

Au(III) reacts with iodide but can be previously extracted as its chloro-complex into diethyl ether.[9] Pd(II) interferes owing to the reaction of thiosulphate with its iodo-complex, but can be eliminated by precipitation with dimethylglyoxime in acidic solution.[10]

Coloured ions such as Rh(III), Co(II) and Ni(II) do not interfere in the biamperometric determination, but can interfere in the visual method. The common ions sulphate, phosphate, perchlorate and nitrate do not interfere.

Visual end-point

This procedure was tested with 30 samples at the 0.8-g/l. Ir(IV) level and 30 samples at the 0.4-g/l. Ir(IV) level. The relative standard deviations were 0.17 and 0.26%, respectively.

The results were compared with those obtained by the formic acid gravimetric method[7] applied to three 100-ml samples, which gave relative standard deviations of 0.2 and 0.25% for the 0.8 and 0.4-g/l. solutions, respectively.

Biamperometric end-point

Thirty solutions containing 1.5 mg of Ir(IV) each and another 30 containing 7.5 mg of Ir(IV) each were titrated. Besides Ir(IV) each sample contained 1.0 g of each of Co(II), Ni(II), Rh(III), Ru(III) and Os(IV), 20 mg of Fe(III), 10 mg of Au(III) and 20 mg of Ru(IV).

The Fe(III) was masked with 1.0 ml of 1.0*M* sodium fluoride and Au(III) and Ru(IV) were eliminated beforehand as already mentioned. The relative standard deviations were 0.35 and 0.23%, respectively.

CONCLUSIONS

No difficulty was experienced in the visual end-point method, which can easily be used for the standardization of Ir(IV) solutions, and is rapid and accurate. It is much easier than the gravimetric method and does not need more than a few ml of solution. To avoid interference by coloured ions it is advisable to use biamperometric detection, which also shows good accuracy, is rapid and easy to perform, and can be used for routine determination of Ir(IV).

ENVIRONMENTAL SPECIMEN BANKING: A CHALLENGE IN TRACE ANALYSIS

M. STOEPPLER, H. W. DÜRBECK and H. W. NÜRNBERG
Institute of Applied Physical Chemistry, Chemistry Department, Nuclear Research Centre, Jülich (KFA), P.O. Box 1913, D-5170 Jülich, F.R.G.

(*Received* 30 *March* 1982. *Accepted* 15 *June* 1982)

Summary—The need for environmental specimen collection and storage ("specimen banking") is demonstrated. A survey of the banking concept, storage techniques and storage conditions for 14 selected human and environmental materials in the Federal Republic of Germany is given. This is followed by a description of the banking and analytical facilities of the Specimen Bank in Jülich, and of the sampling and sample preparation performed for marine macroalgae and several terrestrial specimens (carp, mussels, rain worms, beetles and poplar leaves), the rather new approach to the production and extensive application of appropriate control materials, and the methodology used for the determination of toxic metals, metalloids (Hg, Pb, Cd, Ni and As), anabolic steroids and polyaromatic hydrocarbons. Finally the results of the first analytical series and of particular stability studies as a part of long-term investigations are presented and future work is outlined.

Monitoring programmes on the world-wide spread of anthropogenic chemicals in the whole environment, including man himself, are increasingly recognized as of paramount importance as a basis for governmental actions to protect man, animals and plants against harmful organic and inorganic compounds.

At present, however, the number of chemicals and their metabolites entering the environment is of the order of 60000 and growing each year, so a systematic and all-encompassing determination of their ecotoxic behaviour and of discernible effects is practically impossible. Thus, it is no surprise that analytical progress and new toxicological findings are rather frequently concerned with the separation, identification and determination of those organic or inorganic compounds which are recognized to be particularly hazardous. Such observations immediately pose the question of whether these compounds have been spread quite recently, longer ago, or continuously over a certain time span, into the whole environment or just a part of it. A reliable answer could be obtained by retrospective analyses of stored materials.

This question, however, may only be answered successfully if we have available relevant specimens from the past, which have been carefully selected from important regions or environmental compartments analytically characterized at the time of sampling, and stored without deterioration. The information obtained from analysis of such "fossilized" materials would surely facilitate the making of decisions if, for instance, governmental and/or legal regulations should become necessary, since the data could form the basis for prognosis of at least the near future. Thus, from the point of view of environmental surveillance and protection it is highly desirable to investigate the feasibility of a meaningful long-term storage of carefully selected human and environmental materials. Possibilities for the realization of such storage in appropriate repositories ("specimen banks") have been amply discussed by experts from several countries within the last decade.[1,2] In the United States of America, in France and Japan as well as in the Federal Republic of Germany, such plans have recently been realized. After a preliminary period of informative meetings, the U.S. and German governments decided to face this challenge jointly through feasibility studies on national specimen banks.

In both countries, during the introductory phase, analytical investigations together with a few storage experiments were performed.[3–5] Subsequently, the world's first pilot specimen banks became operational. The bank in the United States, operated by the National Bureau of Standards (NBS), under the project leadership of the Environmental Protection Agency (EPA), was inaugurated in November 1979.[6] The German programme, designed and co-ordinated by the Umweltbundesamt (UBA) Berlin, differs from the U.S. approach. It is organized as a co-operative task shared by eleven independent research groups.[7] A central storage bank has been established in Jülich for the long-term storage of all specimens selected, together with organizational and analytical facilities. The institute at Jülich and the other groups also contribute to the project by sampling and/or analysis. The research groups in Ahrensburg, Berlin, Kiel and Münster are operating satellite (*i.e.*, comparative storage) banks for a few selected materials (see Table 1), and a data bank is located in Münster. The biggest satellite bank in Münster started operation in mid-1980, and the central bank in Jülich was inaugurated in May 1981. However, storage of a few materials had already begun early in 1980 and storage techniques had been studied before the bank building was finished.

‡Parallel storage in the satellite bank in Kiel.

This paper intends first to explain the philosophy of the pilot phase in the Federal Republic of Germany. This is followed by a description of the central bank and the associated analytical facilities in Jülich, and a summary of experimental work performed so far in our institute on sampling, sample preparation, portioning and packaging of a few materials, as well as the production of control materials. Moreover, examples (illustrated by results) are given of the efforts to provide very precise analytical determinations, together with preliminary results of stability investigations.

Philosophy of the pilot specimen bank programme

An environmental specimen bank should provide, at acceptable cost, facilities for the long-term storage ($\geqslant$50 years) of carefully selected human and environmental materials. Such a bank should make possible a meaningful retrospective analysis for numerous organic and inorganic compounds regarded to be of toxicological and/or environmental significance. Further, the bank should also provide homogeneous and well characterized materials for the continuous improvement and checking of analytical methods used in environmental surveillance.[8,9]

The German approach now being realized has three main items.

I. Selection of human and environmental materials which can be regarded mainly as accumulators or indicators for organic and/or inorganic pollutants. These materials should be representative of man and the most important environmental fields (terrestrial, aquatic and marine). In selection of these materials, done during the planning phase, it is considered that they should be quite different chemically and structurally. This also allows the evaluation and testing of comprehensive analytical methods as a sound basis for further real-time analysis (see Table 1).

Since comparative and long-term analytical studies have to be performed during the pilot phase, the stored materials should be either homogeneous materials or else be homogenized as far as possible to achieve uniformity. Examples of homogenization procedures will be given below.

II. Selection of optimal storage conditions within the general banking concept, *i.e.*, a comprehensive approach ranging from storage facilities to containers and vessels. For the human materials and sewage sludge it was decided to use and compare two temperature levels, −80° with compressor cooling, performed at the satellite banks in Ahrensburg and Münster, and $\leqslant -145°$with liquid-nitrogen vapour cooling, performed at the central bank at Jülich.

It was also decided to use for the storage vessels two different materials resistant to very low temperatures: glass bottles of different sizes (from 22 up to 500 ml) made from Duran glass with plastic screw-caps sealed with either aluminium or indium foil (for samples to be analysed for organic pollutants), and polypropylene bottles with screw-caps made of the same material (for samples to be analysed for toxic metals). The 22-ml bottles are used for sample volumes from 5 to 15 ml, and samples smaller than 2 ml are capsuled in 3-ml minivials which are in turn inserted into 22-ml bottles.

The programme should further also contribute to a possible improvement of storage vessels with the goal of finding, if feasible, a standardized material useful for both organics and metals, and additionally to develop economical and completely sealed vessels for long-term storage.

III. Repeated analysis of the compounds selected (see Table 2) over about 2–3 years to investigate whether during this time span and under the given conditions any loss, contamination, metabolization or transformation occurs. This aim first of all required a decision on the number of total samples and of the sample portions needed for each analytical series as well as on the amount needed for each individual sample. This individual amount can be different for different materials and depends on the concentration level of the compound to be determined, the method of determination, and the homogeneity of the material.

These conditions were evaluated during the preliminary analytical investigations performed in the participating laboratories. The analytical task requires extremely precise and reliable analytical methods. This was and still is one of the crucial points of the whole banking programme, since the duration of the project, owing to the considerable cost, is short compared with the calculated total storage time of $\geqslant$50 years for samples in a specimen bank. Doubtless studies of this kind will have to be continued within

Table 2. Pollutants to be determined in the materials selected for the pilot specimen bank

Toxic Metals and Organometallic Compounds
Mandatory substances: Hg, methyl-Hg, Cd and Pb
Further desirable metals and metalloids: As, Ni, Cr, Cu, Se, *etc.*
Organic Pollutants
Halogenated hydrocarbons and polychlorinated biphenyls (PCB)
Polycyclic aromatic hydrocarbons (PAH)
Aromatic amines
Phenolic compounds
Hormones and anabolic steroids
Pesticides and insecticides
Other Organic Compounds
(regarded as most suitable as model compounds for stability investigations)
Ascorbic acid
Unsaturated fatty acids

future national specimen bank programmes. The problems with the methods and the performance attained are discussed in some detail in what follows, with respect to the role of our institute within the project.

Banking and analytical facilities

The Institute of Applied Physical Chemistry of KFA Jülich contributes to the pilot environmental bank programme the facilities of the central bank, the storage and general transport organization (logistics), sampling, sample preparation and various analytical facilities. The last are located in either newly constructed or well equipped laboratories with modern instrumentation.

The central bank building[7] was constructed in 1980–1981 and has a total space of 230 m^3. The storage and working part, accessible by a dust-sluice, on average provides a dust level that is less than 10% of that of a regular laboratory, by introduction of prefiltered air, according to VDI 2038, class 5.[10] Additionally, in each of the storage compartments and laboratories laminar air-flow hoods (US Fed. Stand. class 100, *i.e.*, VDI 2083, class 3) have been installed. Four storage compartments offer considerable storage volumes: 20.4 m^3 at liquid-nitrogen vapour temperatures, ranging from $\leqslant -145°$ at the top to $-190°$ at the bottom of the 18 storage containers in three of the compartments and 1.7 m^3 at $-80°$ and 1 m^3 at temperatures from $+4°$ to $-10°$ in the fourth. Containers of the first type are loaded with about 5000 samples of all the materials shown in Table 1. The last two types are used for comparative storage, intermediate storage and storage of control materials. There are also two laboratories for the determination of mercury, arsenic and PAH, and a smaller room for sample preparation with an atmosphere on average approaching clean-room (VDI 2083, class 3) conditions. The complete floor plan of the bank building is depicted in Fig. 1.

For specimen sampling and transport two vans and occasionally the institute's mobile laboratory[11] are used. The latter is equipped with a class 100 laminar air-flow hood. The vans carry samples at liquid-nitrogen vapour temperature to the satellite banks and the co-operating laboratories. Further analytical facilities for organic and inorganic compounds, also equipped with clean working places, are located inside the main institute building as well as in the radiochemical part situated in another complex of the Chemistry Department of KFA. A schematic flow chart for the interaction of all these sections is given in Fig. 2.

EXPERIMENTAL

Sampling and sample preparation

The institute performed the sampling, homogenization, portioning and packaging for the marine macroalgae (*Fucus vesiculosus*) and contributed to the homogenization, portioning and packaging of the carp (*Cyprinus carpio*), mussels (*Dreissena polymorpha*) rain-worms (*Lumbricus*

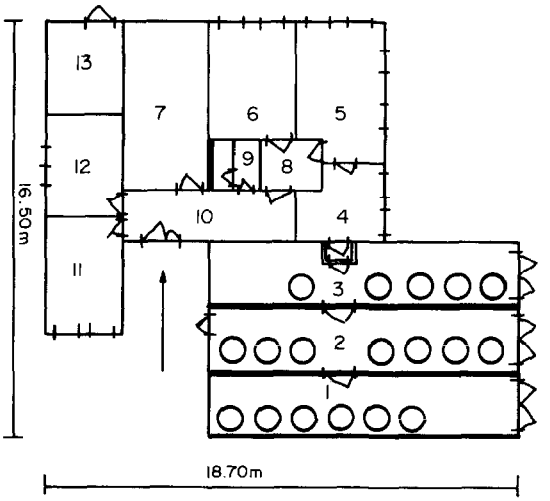

Fig. 1. Floor plan of the pilot specimen bank building. 1–3, Compartments for liquid-nitrogen vapour-phase storage (compartment 1 contains six 1.4-m^3 containers, compartments 2 and 3 contain twelve 1.0-m^3 containers); 4, sample preparation room; 5 and 6, analytical laboratories; 7, compartment for compressor cooling; 8, dust sluice; 9, lavatory; 10, vestibule with control panels for all technical functions; 11 and 12, offices (logistics); 13, technical maintenance room.

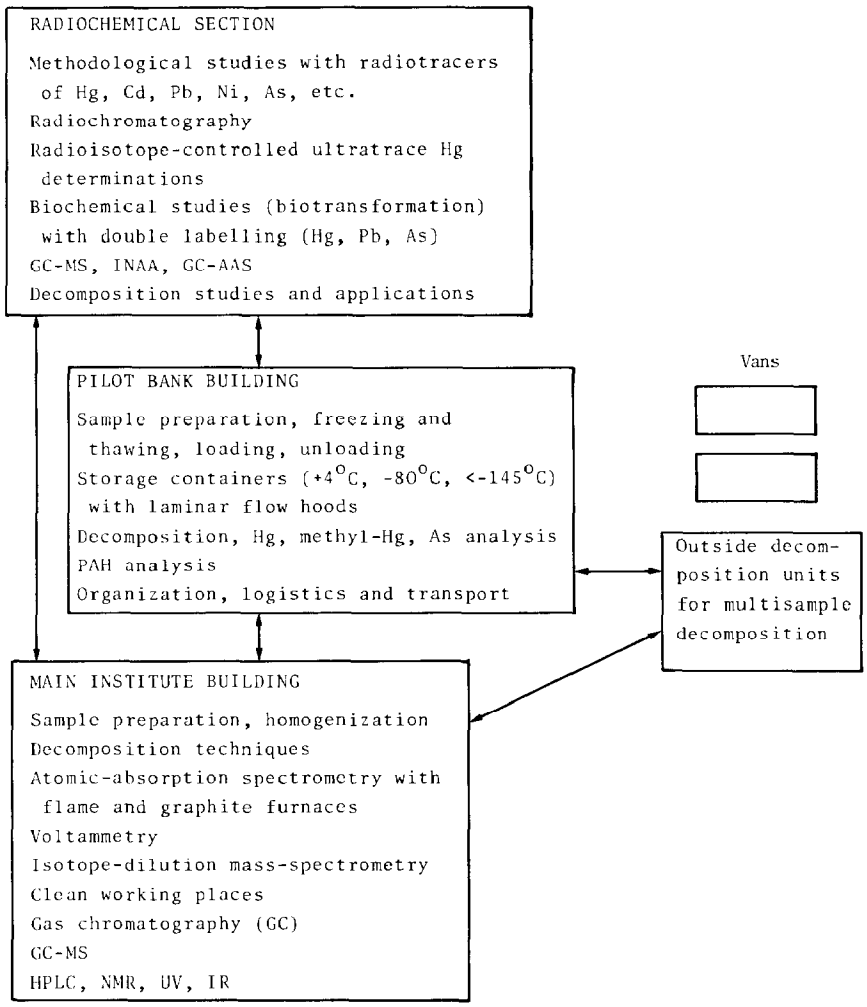

Fig. 2. Flow-chart of the pilot specimen bank and the connected analytical facilities.

rubellus), beetles (*Carabus auratus*) and Lombardy poplar (*Populus nigra italica*) under as clean conditions as possible.

Fucus vesiculosus was sampled in March 1981 at Strande, on the Baltic coast close to Kiel, with the aid of the mobile laboratory and a van.[12] The algae were first collected by hand from the shallow water (precleaned polyethylene gloves being worn), and were placed either in stainless-steel containers filled with sea-water (for the subsequent determination of organic compounds) or in polyolefin containers (for metals). Adhering material (small worms, crabs, beetles, *etc.*) was then separated by shaking and by use of stainless-steel, nickel or plastic forceps and spatulas. The samples were brought by van from the beach to the mobile laboratory, situated at a nearby field laboratory of the Institute of Marine Research, Kiel. Here, the samples were dealt with in the laminar-flow hood, being rinsed three times with clear sea-water freshly taken from the sampling site. Adhering water was removed by centrifugation with a stainless-steel salad centrifuge. The material to be reserved for organic analysis was passed three times through a mincer (stainless steel and aluminium alloy), carefully mixed and put (in ~50-g lots) into carefully precleaned 100-ml Schott Duran GL 45 bottles, weighed, sealed with aluminium foil, and immediately deep-frozen in liquid-nitrogen vapour containers.

The portions for metal determinations were first passed twice through the mincer after the preparation of material for organic analyses, then deep-frozen (with liquid nitrogen) in appropriate portions and milled in zirconium dioxide ball mills which before use were carefully cleaned with warm dilute nitric acid and checked for contamination. The whole was then thawed, carefully mixed and placed (in 1- or 2-g portions) in the minivials, which were then enclosed in the 22-ml bottles and immediately deep-frozen, as described above, in a liquid-nitrogen vapour atmosphere.

These tasks could be performed very rapidly. Thus, the time span from homogenization to packaging was only a few hours if amounts up to 5 kg had to be prepared, there was sufficient manpower to proceed without delay, and the sampling staff were experienced. Analytically significant deterioration in that time is not to be expected, even if rather sensitive organic compounds have to be investigated. Also, the unavoidable contamination from the mincer is minimized under the conditions chosen, as could be proved by comparison of, for example, nickel values for directly taken and processed materials [which yielded identical values within the analytical error limits (2*s*)].

Fillet of carp (*Cyprinus carpio*) for subsequent determination of metals and arsenic was freshly dissected at a clean-bench with special quartz knives, already approved for trace metal determinations in marine biota,[12] and 1–2 g portions were transferred into polyethylene minivials, weighed, and immediately deep-frozen as described for *Fucus vesiculosus*. This was done in co-operation with the

Table 3. Control materials made from surplus banking or other appropriate materials

Material	Characterized or to be characterized for	Portion (dry weight), g	Total amount produced, g
Pig liver I	Pb, Cd, Hg, As	2	180
Fresh whole blood I	Hg, Pb, Cd	5 (wet weight)	500
Fish fillet I (low Hg content)	Hg, As, Cd	5	720
Brown algae I	Pb, Cd, Cu, Ni, Zn, Cr, Hg	5	130
Brown algae II	Pb, Cd, Hg, As	5	1600
Soil ("Parabraunerde") I	Pb, Cd, Hg, As	10	2100
Soil ("Parabraunerde") II	Pb, Cd, Hg, As, Ni	5	1050
Grass II (*Lolium multiflorum*)	Pb, Cd, Hg, As, Ni	3.5	84
Mussels II (*Dreissena polymorpha*)	Pb, Cd, Hg, Cu, Cr, Ni	5	55
Poplar leaves I	Pb, Cd, Hg, Cu, Ni, Cr, As	5	265
Poplar leaves II	Pb, Cd, Hg, Ni, As	5	445

Remarks. Series I made from appropriate materials, series II made from surplus bank materials. Analytical methods used for the characterization: flame, graphite-furnace, cold-vapour/hydride AAS, DPASV and IDMS (Pb and Cd). Whole blood stored at $-80°C$ or $\leqslant -145°$

participating group from Ulm University (Prof. Ballschmiter and co-workers).

In another collaboration with the group from Saarbrücken University (Prof. Müller and co-workers) the homogenization, weighing and packaging of deep-frozen terrestrial and aquatic indicators or accumulators was performed. For that purpose the clean-room of the bank building was used and the species *Dreissena polymorpha* (mussel), *Lumbricus rubellus* (rain-worm), *Carabus auratus* (beetle) and leaves from *Populus nigra italica* Lombardy poplar) were processed in a manner similar to that described for *Fucus vesiculosus*. The samples were stored immediately after deep-freezing.

Production of control materials

Besides the current use of appropriate Standard Reference Materials from NBS (Bovine Liver, Orchard Leaves, Tomato Leaves, Spinach) and of materials from other sources (IAEA, BCR and EURATOM Ispra)[14] recently lyophilysed whole-blood control materials with assigned values have been made available and used successfully for determinations of cadmium, lead and mercury.[15,16] Since these materials could only be used for general calibration purposes, other materials which were completely identical with the specimen bank specimens were needed. Such materials have been produced from surplus banking materials under carefully controlled conditions. The results of characterization determinations, performed during 1981, whenever possible by physically different methods, show, at least for lead, cadmium and nickel, that the values are in excellent agreement with those found for the corresponding fresh materials. Some results for mercury, however, at the low ng/g level seem to indicate that at present a certain contamination from the laboratory environment cannot be completely ruled out. This is currently under thorough investigation. These materials (see Table 3) were freshly homogenized as described for the materials for the bank, freeze-dried, finely ground in agate or zirconium dioxide ball mills, sieved (200 μm sieves) if necessary, and subsequently bottled and stored at $-80°$ or $+4°$. The total amounts and the number of portions prepared, except when there was not enough available, were sufficient for the continuous quality-control and data evaluation during the pilot phase of the project, as described in the section on inorganic analysis.

General analytical aspects

From the philosophy of the programme it is obvious that for the pilot phase the most important challenges are the detection limits and the precision, which at present are more important than extreme accuracy. Good detection limits are a prerequisite for the scrupulous control of contamination and for reliable analysis at the low ng/g level. Good precision is essential if meaningful information is to be obtained about the effects of long-term storage of the samples.

Inorganic analysis

Since our institute is the only one participating that performs characterization determinations and long-term analytical studies for the relevant metals, metalloids and organometallic compounds in all the stored materials, these will be discussed in some detail. For most of the materials and elements the first or even the second analytical series has now been finished. Suitable routine methods have been selected and tested for the mandatory elements lead, cadmium and mercury, and in part also for nickel, manganese and arsenic, together with independent methods for checking the accuracy. The main aim was to attain an average day-to-day precision, for at least the mandatory elements, of $\leqslant 5\%$ (with a final goal of $\leqslant 3\%$), which corresponds to a confidence interval of less than 10% at $p = 0.05$. Otherwise no sound conclusions can be drawn concerning the homogeneity of samples, sources of contamination, and possible losses or decomposition of, for example, organometallic compounds.

Reagents, contamination precautions. Usually, all reagents have to be chosen so that blanks are as low as possible. This is achieved by the use of "ultrapure" reagents (*e.g.*, Merck Suprapur®) and, if necessary, by special purification procedures such as sub-boiling distillation of acids, which is of particular importance in determination of mercury (which has to be done in laboratories which are apart from any dealing with electrochemistry).

All tubes, dishes *etc.*, as well as the storage vessels for banking and control materials, have to be carefully cleaned either with warm dilute acids or, which from our experience is more promising, in a way which simulates the subsequent analytical step. An example is the cleaning of Teflon digestion vessels for decomposition under pressure, which can be done by running a "blank" decomposition with materials having very low trace-element levels

Table 4. Results of the first analytical series (performed from July to November 1981) for Pb, Cd, As and Hg in materials of the pilot specimen bank: the data for Pb, Cd and Hg are obtained from an average of 6 subsamples; analysis on different days with at least 2 × 6 determinations (firings) from each subsample

Material	Lead		Cadmium		Arsenic		Mercury	
	μg/g	C.V., %	μg/g	C.V., %	μg/g	C.V., %	ng/g	C.V., %
Whole blood	0.075	10	0.0007	7	0.001	—	1.60*	3
Adipose tissue	<0.005	—	≤0.010	—	n.d.	—	0.8	—

Dreissena polymorpha (mussels)	0.33	13	0.470	6.7	1.20	4.7	12.2	7
Fucus vesiculosus (brown algae)	0.720*	5.6	0.260	4*	8.80	10	11†	20
Average C.V., % (blood not incl.)		4.7		3.5		5.3		4.2 (*Fucus* not incl.)

*In these materials and for these elements a second series has already been performed and a mean value found which agrees with the first series within the indicated C.V.

†From the data obtained it appears that *carabus auratus* is very well homogenized, at least for Pb, Cd and As.

‡Three series have already been analysed for Hg in *fucus vesiculosus* and the conclusion is that this material is not homogeneous for Hg. Thus, no sound conclusions on the behaviour of Hg in this material can be expected.

§Owing to the fact that levels of Pb, Cd and Hg in cow milk are extremely low, other elements for long-term control are sought. Mn and Cu would be better suited for that purpose but this has still to be investigated.

("cleaning decomposition") as described elsewhere.[14,17,18] The laboratory ware cleaned in this manner has to be stored in air-tight vessels, in sealed plastic bags or at a clean-bench if not to be used immediately. Additionally, all vessels used for analyte processing and storage have to be checked for contamination before use, and discarded or cleaned again if any blank above the acceptable level is detected. In wet digestions for subsequent cold-vapour (mercury) or solvent extraction–GFAAS analysis, blanks were determined for each individual digestion vessel before and after sample digestion and determination.[19]

The methods selected had usually already been published and thoroughly checked[20–22] and were then modified for the matrices in question.

Mercury was determined by two different versions of the cold-vapour method: one using instrumentation constructed in our own laboratory partly from commercially available parts, and the other using a commercial instrument (Perkin–Elmer MHS-20 coupled with a Perkin–Elmer 280 AAS). The first approach is based on a previously published principle[23] using gold wool to preconcentrate the mercury but has been considerably improved to attain extremely low instrumental and analytical blanks with an absolute detection limit of ≤0.005 ng and a determination limit of ≤0.02 ng.[24] The determination follows a carefully optimized wet digestion[25] continuously monitored with ^{203}Hg. This method enables us to reach the required day-to-day precision of less then 5%, even at the low ng/g level, provided the material analysed is homogeneous. For repeated determinations on a whole-blood control material (see Table 3) over several months a coefficient of variation of 4.2% (Hg level 2.4 ng/ml) could be obtained. Further data for banking materials are summarized in Table 4 and show that the first goal can be reached for mercury as long as the materials are homogeneous.

The commercial system is useful for higher concentrations and also to check the accuracy of the home-made system. Sample preparation in this case is performed by pressurized decomposition, with improved multisample decomposition systems and optimized (*i.e.*, prolonged) temperature programmes making possible nearly quantitative decomposition. The results obtained by the two methods agree within the precision limits (≤5%) for all the materials investigated.

Lead and cadmium were routinely determined by graphite furnace or flame AAS, usually after a pressure decomposition step.[18] The instruments used were the Perkin–Elmer 410 and 4000 systems coupled with either the HGA 400 or 500 graphite furnaces, and a Perkin–Elmer 5000 with computerized flame control. To improve precision, accuracy and partly also detection power, for lead and sometimes also for cadmium, the L'vov platform technique[26,27] was used. Routinely attainable absolute detection limits in aqueous solutions were ≤0.2 pg for cadmium and about 2 pg for lead. Results were evaluated by comparison against scrupulously analysed control materials (see Table 3) thus avoiding the possibly erroneous and time-consuming evaluation by standard addition or by matrix-matched calibration graphs, and certainly improving the precision and accuracy as well. The results shown in Table 4 indicate a rather satisfactory day-to-day precision, which is mainly below 5% variation. Lead frequently poses problems in GFAAS, owing to poor sensitivity and matrix interferences. From our experience, however, it appears that these problems may be less severe with the L'vov platform, though they cannot be completely overcome.

Voltammetry theoretically offers a better limit of detection than AAS for cadmium and lead,[28–30] but in practice, the difficulty of achieving complete digestion, and the mag-

nitude of the blanks (of the order of 0.1–5 ng for a digestion vessel) frequently offset this advantage, at least for cadmium. Despite these limitations, voltammetry constitutes an inexpensive and elegant physically-independent reference method, particularly useful for the characterization of control materials and for accuracy checks during methodological investigations.[14]

For voltammetric determinations the robust and versatile PAR 174 A instrument has been used successfully in conjunction with either the hanging mercury drop (HMDE) or the rotating mercury-film electrode (RMFE) on a glassy carbon support.[14,16,17,20,22,28–30]

Another analytical approach for extremely precise and accurate lead and cadmium determinations is isotope-dilution mass-spectrometry, IDMS.[14,20,31,32] In our laboratory IDMS is performed with a modified Varian-MAT CH-5 mass spectrometer coupled with an HP 9825 A dedicated computer for spectra evaluation. The mass-spectrometric determination is performed after low-temperature ashing in a microwave-excited oxygen plasma and allows reliable cadmium and lead determinations at the 15 and 50 ng/g levels respectively.[33] The method has become indispensable for the characterization of control and banking materials. Since the method also allows very precise thallium determinations, this element was also determined in some materials.

Total arsenic has been determined in nearly all the materials to assist in their characterization. The samples were opened out by digestion with a mixture of nitric, perchloric and sulphuric acids, or by digestion under pressure, or by decomposition under pressure followed by dry-ashing with magnesium nitrate as ashing aid. These approaches are necessary to ensure complete decomposition of the very resistant high molecular-weight organo-arsenic compounds which appear in various aquatic and marine species.[34,35] The determination was performed with the MHS-20 PE 280 combination already mentioned, providing absolute detection limits of about 0.4–0.7 ng, depending on the blank level.

Nickel can be determined with good sensitivity at the low pg level with modern GFAAS instruments using graphite tubes coated with pyrolytic carbon[36,37] but also by d.c. or differential pulse voltammetry (relative detection limit about 1 pg/ml) following preconcentration by accumulation of an adsorption layer of nickel dimethylglyoximate at the HMDE.[38] Because of the toxicological and occupational health-hazard significance of nickel and its compounds, thorough characterization measurements of this element in the banking materials are in the preparatory stage; approximate levels have already been determined and range from less than 2 ng/ml in whole blood[39] to around 1–2 μg/g for algae and mussels and 100 μg/g (dry weight) for sewage sludge. Characterization measurements for other metals, such as chromium, copper and manganese are just being started.

Organic analysis (anabolic steroids, polyaromatic hydrocarbons)

From the variety of organic pollutants to be monitored in the pilot phase (*cf.*, Table 2) it is evident that such detailed analyses can only accomplished by the combined efforts of different research groups, each selected for its expertise in the identification and precise determination of a certain pollutant or pollutant group. Since a full discussion of all these activities is outside the scope of this paper, only those compounds will be discussed in detail that are actually determined in our institute:[40] steroid hormones, including synthetic analogues with a comparable chemical structure (stilbestrols), and polyaromatic hydroxy groups.

Steroids. These are determined by methods employing high-pressure liquid chromatography (HPLC), gas chromatography (GC) and glass-capillary gas chromatography/mass spectrometry (GC/MS), developed with the aim of meeting the requirements of the programme. Much effort has been spent on bringing the analytical procedure to the highest degree of reliability, accuracy and precision.[41] Moreover, by introducing selective and sensitive detection systems (multiple ion detection, voltammetric detection)[42] it has proved possible to optimize the methods for determinations in the upper pg-range with a coefficient of variation of about 10%. Details of these developments are summarized in this section.

By making maximum use of the separation efficiency offered by the chromatographic techniques, it has become possible to simplify the clean-up procedure remarkably, thus minimizing the risk of contamination, sample loss and decomposition. The following summary emphasizes crucial points of various clean-up procedures rather than repeating known techniques for steroid analysis.

For *clean-up* steroid hormones, stilbestrols and their metabolites are removed from the different matrices (liver, fat, urine) by a single-step extraction with appropriate solvents such as dichloromethane, dichloromethane/propan-2-ol, diethyl ether and methanol/water. Since these solvents are used in relatively large amounts (up to 200 ml) they should be checked for their suitability before use as they are normally contaminated with a variety of interfering compounds and require repeated distillation for purification. Phenolic compounds and fatty acids are removed from the crude extracts by extraction with 2*M* sodium hydroxide and treated separately. Without further purification, the organic extracts are then dried, concentrated and used for preparation of derivatives. For drying, however, the usual inorganic desiccants, such as anhydrous sodium sulphate or magnesium sulphate are quite unsuitable on account of their high levels of interferents. Instead, filtration through a precleaned filter paper is employed to remove adhering water droplets.[43]

For analysis by HPLC the clean-up procedure is different and even simpler.[44,45] The crude organic extracts or untreated liquid samples (urine) are preconcentrated directly on a short HPLC column which also separates steroids from interfering compounds. By a column-switching technique the fractions of interest are then transferred to the analytical column, where the necessary separations are accomplished.

For steroid-conjugates, which are normally to be expected in urine samples, a similar column-switching technique is applied, resulting in a very pure conjugate fraction which in particular is free from cleavage inhibitors. Thus, hydrolysis with β-glucuronidase may be achieved in 20 min for phenols and in 2–3 hr for aliphatic hydroxy groups, compared to at least 24 hr in previously described procedures.[46]

Derivative formation is required for GC and GC/MS determinations, since it markedly improves the resolving power of the gas chromatographic columns and the sensitivity of the detection systems. In general, the TMS-ethers or similar silyl derivatives are preferable to the TFA or HFBA derivatives which are only suitable for phenolic compounds, numerous by-products being formed from aliphatic hydrocarbons.[46]

Various *instrumental aspects* require attention. Routine analyses are usually done by chromatography (liquid or gas) with conventional detectors, and capillary GC/MS is mainly used for the elucidation of unknown structures or for identification in cases of uncertainty. However, optimal performance of all methods may only be achieved if a number of prerequisites are carefully checked:

inertness of chromatographic columns
temperature stability (for GC)
solvent stability (for HPLC)
long-term instrument stability
reproducibility in terms of retention indices or other independent parameters

For gas chromatography these requirements may conveniently be tested with long-chain fatty acids in the form of their trimethylsilyl esters or with other compounds of similar polarity and structure.[47] If need be, columns may be de-activated by treatment with Dexil 300 or Carbowax 20 M. Particular attention has to be paid to the GC/MS interface, which may be similarly tested and de-activated.[48,49] In HPLC, additional problems arise mainly from unsuitable phases (size and coating), unsuitable transfer lines and bad detector design (especially for voltammetric detectors).[50] A very important aspect in this context is the purity of the eluents used. For ultratrace analysis in the upper pg-range, even the quality of quartz-distilled water is unsatisfactory, and additional cleaning procedures are mandatory.[51]

Finally, proper choice of the stationary liquid phase is of great importance. For GC and GC/MS determinations slightly polar liquid phases such as SE 30, SE 52, SE 54, OV 1, OV 101 and DB 5 are generally used. In HPLC cyano- and phenyl-bonded columns are recommended for the androgens, while for the separation of phenols and the preconcentration of conjugates C-2, C-3 and C-8 bonded phases are more effective, generally in conjunction with gradient elution with acetonitrile/water mixtures.

Polyaromatic hydrocarbons. The programme for monitoring the stability of polyaromatic hydrocarbons in stored environmental materials started in spring 1981. For preliminary experiments the methodology of Grimmer *et al.*[52] was followed, but on the basis of our own experience we decided to use glass capillary columns (30 m with Sil 5 coating) to improve the resolution, especially for critical compounds. These experiments have now been successfully concluded and it is intended to simplify the clean-up procedure to reduce the risk of contamination and sample loss.

PRELIMINARY RESULTS AND DISCUSSION

Metals

The results presented in Table 4 for the first series of determinations of total metals show that in general the first goal, to attain on average a coefficient of variation (C.V.) of around 5%, could be reached provided the concentrations were well above the determination limits and the materials were homogeneous enough. The rather new approach to determining trace-metal contents in a particular material by using a scrupulously analysed control material of exactly the same origin appears to be a significant step forward. That is clearly demonstrated for the determination of lead and cadmium in soil and in poplar leaves where such control materials have been used for the first time. It seems now, after thorough investigation, that the more widespread use of appropriate and carefully analysed control materials will render possible faster, cheaper and much more reliable monitoring and surveillance programmes in the future.

As expected, the homogeneity also had a great influence on the results. This can be seen for the relatively homogeneous materials *carabus auratus*, soil, poplar leaves and human liver. Materials such as whole blood and milk, which would seem to be already homogeneous as received, did, however, pose problems due to extremely low trace-metal levels (milk) or to matrix difficulties (blood). Blood for the pilot programme stemmed from a rather large amount of outdated Red Cross blood reserves. The first application of our precision procedures for the determination of lead and cadmium in whole blood[53,54] initially led to unsatisfactory results for lead, but more recent work with some fresh-blood samples has proved much more successful. This has persuaded us to prepare an appropriate material from other Red Cross samples, and this is now being characterized by different methods, including Zeeman-compensation AAS measurements, which we hope will yield a significant improvement in precision and accuracy. The results in Table 4 also indicate that the homogenization step has to be improved for some materials, particularly the marine and aquatic specimens, which certainly require further improvements in contamination-free field homogenization at low temperatures and under ultraclean conditions. Since this will also be of paramount importance for the homogenization of sufficient amounts of sample for long-term investigations and for reliable real-time monitoring, this aspect will have to be carefully studied during the second phase of the pilot specimen bank programme, which will also include approaches to the determination of organometallic compounds, mainly of methylmercury, at trace and ultrace levels, based on earlier investigations.[21,25]

Organic compounds

Studies on the determination and long-term stability of steroids in stored samples have been made over the last 5 years.[56–60] The first investigations were dedicated to different freezing techniques such as deep-freezing and freeze-drying.

In principle, the latter method seems to be advantageous, because samples can be stored in normal glass containers and kept at room temperature. Moreover, transportation, shipment and distribution are simplified. However, results from a couple of experiments indicate that the freeze-drying process itself needs further intensive basic research since the chromatographic "fingerprint" of numerous reference steroids is totally changed during this pretreatment process. On the other hand it may be predicted that by application of strictly controlled low-temperature and vacuum conditions, this method can be satisfactorily developed so that even compounds as unstable as steroids will not change their chemical structure.

Repeated determinations on stored human urine samples, kept at $-80°$ for 2 years in carefully cleaned glass containers, showed nearly unchanged "fingerprints" in the steroid portions of all chromatograms obtained by different methods (HPLC, GC, GC/MS). This was the case for a variety of synthetic anabolic steroids, their metabolites and numerous other compounds, not all of which have been identified. In a couple of samples, however, the concentration of cholesterol showed a significant decrease (as much as 70% being lost). The reason for this unexpected degradation is absolutely unknown, but may be the differ-

ence in enzyme concentrations in the urine samples investigated. Hence future programmes should record the chromatographic fingerprints of all compounds extracted in the clean-up procedure regardless of their chemical structure or significance as pollutants. If deterioration with storage time or temperature becomes evident, structure elucidations may have to be performed, which may then serve as supporting aids for future storage, monitoring and determination programmes.

(*Received* 14 *January* 1982. *Accepted* 27 *April* 1982)

Summary—Trace-element levels estimated by different investigators are often disparate. It is becoming increasingly evident that sample contamination may explain some of the discrepancies. A method has been developed for the direct estimation of potential errors. This shows that extraneous additions occurring during sample collection and preparation may give rise to grossly misleading results on subsequent analysis.

For a long time it was thought that no great problems were associated with sample collection and manipulation in trace-element determinations. Thus, most researchers concentrated on developing suitable analytical procedures and on improving their sensitivity and specificity. However, as soon as the results of a number of investigators were reported, it became apparent that widely divergent values had been obtained.

The origin of these discrepancies has frequently been discussed. Many factors such as age, sex, pregnancy, dietary habits, environmental conditions and occupational exposure have been documented and shown to influence the metabolism of certain trace elements in healthy subjects.[1–7] However, the advent of biological reference materials left no doubt that some of the inconsistencies could be attributed to analytical inaccuracies.[8–14] This is best illustrated by the discordant values for chromium (<0.005–3.5 μg/g) obtained for Standard Reference Material (SRM) 1577, National Bureau of Standards (NBS) Bovine Liver.[14] Furthermore, evidence has accumulated that there is a further source of error, namely unsuspected contamination of samples during collection or manipulation. In this respect, the observations of Cotzias and his associates[15,16] are of paramount importance. In 1961, these investigators published a mean serum manganese level of 2.50 ng/ml which, 5 years later they admitted to be unreliable, as a detailed examination revealed that there had been a systematic contamination of the samples with exogenous metal in their first study. Shortly after, Davies *et al.*[17] showed that routine plasma zinc estimations were of no value unless a few simple but stringent technical rules were observed. They emphasized that zinc is a ubiquitous contaminant of glass, lead and rubber piping, and of water and many chemicals (even of the highest analytical grade). During the early stages of their study, these authors performed over 100 zinc estimations on blood samples collected with ordinary sterile glass syringes into "chemically clean" glass bottles with metal caps. Furthermore, a number of these specimens were allowed to stand for several hours. The results were considerably different from those obtained during the later stages of their study on samples collected and processed with due observance of the essential safeguards against contamination. These and similar observations gave impetus to closer examination of the problem during the subsequent decade.

To what extent sample contamination may invalidate the results of trace-element analyses is not easily established. Different, usually indirect, approaches have been proposed. Using neutron-activation analysis, we have developed a direct method of estimating the resulting errors. The procedure is described in detail elsewhere,[18,19] and so only a brief account of the experimental details is given here. The present paper is a summary of our results and a survey of the observations of other investigators.

EXPERIMENTAL

Principle

Using neutron-activated apparatus, we reproduced *in vitro* several routine sample-collecting and handling procedures, starting from the hypothesis that under the experimental conditions used, transfer from the instruments to the samples would be reflected by radioactivity in the samples. Figure 1, which depicts the superimposed gamma spectra of an irradiated rubber stopper of a Venoject® tube

TAL. 29/11(B)—B

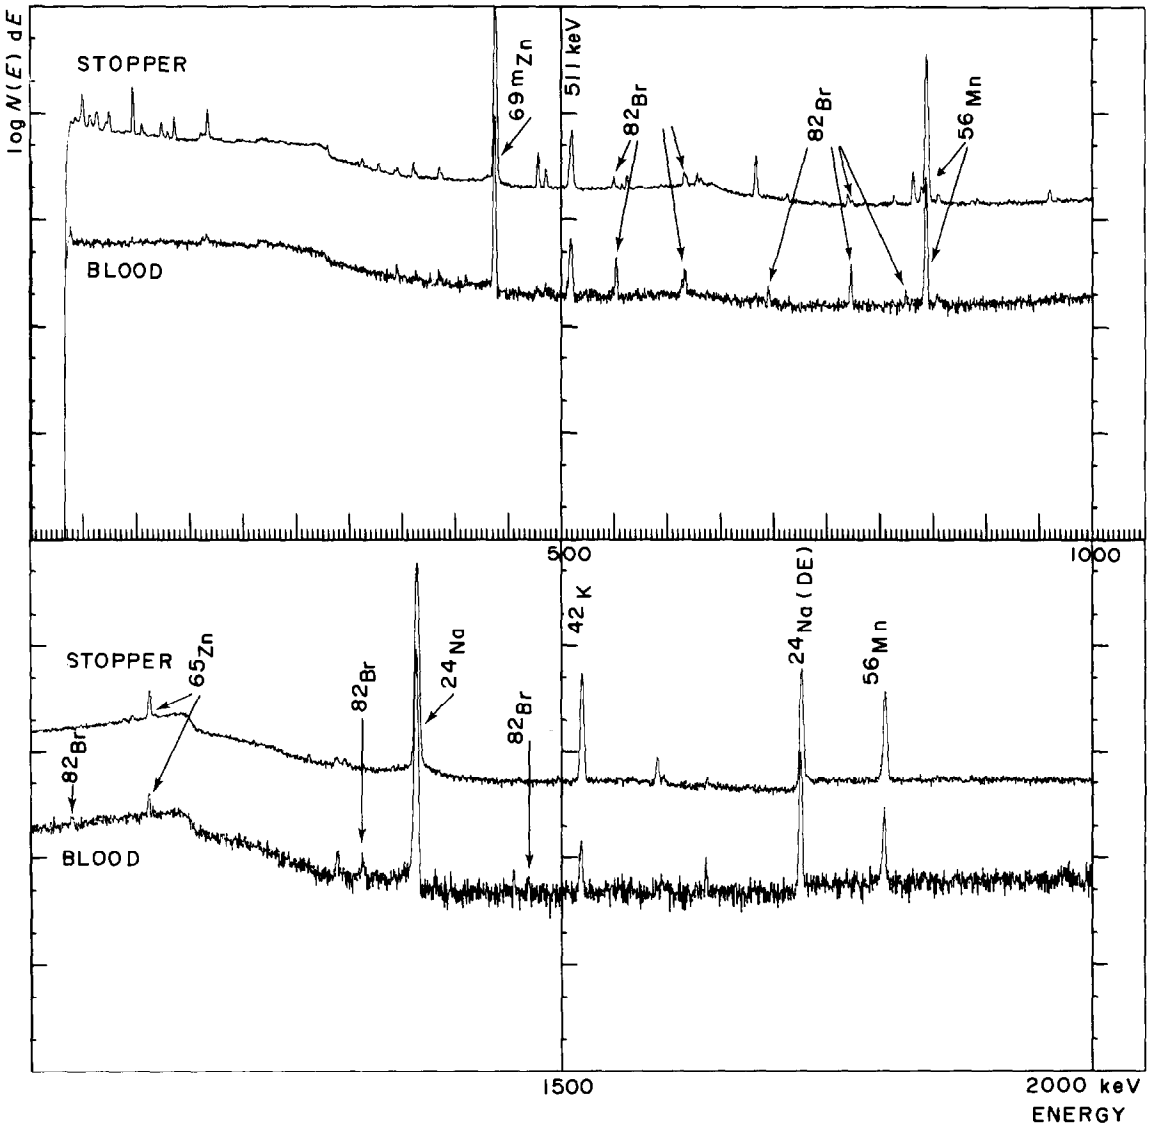

Fig. 1. Ge(Li) spectrum (waiting time 2 hr 55 min, measurement time 1 hr) showing the extraneous additions to a blood sample after contact (1 hr 30 min) with an irradiated (6 hr 25 min at 1.8×10^{12} n.cm^{-2}.sec^{-1}) rubber stopper of a Venoject® tube. The spectrum of the stopper is also shown.

(plain, silicone-coated, Terumo) and a blood sample that came into contact with it, proves that this actually occurs. It visualizes what has been observed by several workers, namely that ordinary rubber stoppers cause a marked zinc contamination.[20–27]

It is evident that the activities of the different photopeaks in such a contaminated sample may be converted into numerical values in exactly the same way as in routine neutron-activation analysis. By using various irradiation conditions and post-irradiation measurements, we succeeded in determining the extraneous additions of several elements, both qualitatively and quantitatively.

Scope

We investigated the potential additions in a number of circumstances: in blood samples collected with steel needles (sterile, disposable needle, 19Gl½, Terumo) or with polypropylene over-the-needle catheters (Intranule®, 110 16, Vygon), in blood and serum samples collected or stored in various containers (Vacutainer®, royal blue stopper, silicone-coated, brand tube with minimal trace element content, Becton-Dickinson; polyethylene containers, Kartell SpA), and in needle aspiration (Menghini needle, K. Storz, K. G.) or surgical wedge biopsies of the liver (Swann-Morton surgical blade, W. R. Swann & Co). In all these cases, the usual sampling techniques were reproduced as closely as possible in the laboratory. In order to assess additions from a steel needle or from a polypropylene catheter during venepuncture, a plastic tube was filled with normal human blood, kept at 37° and punctured with an irradiated needle or catheter. Additions from a royal blue stopper were estimated by introducing 10 ml of normal human blood into an opened Vacutainer®, which was then gently inverted 2 or 3 times every 5 min for 30 or 120 min after having been resealed with an irradiated stopper. Finally, to study additions in liver biopsies, we used the normal organ of a victim of a sudden accidental death. With irradiated Menghini needles, specimens of about 4–6 mg, comparable to small percutaneous biopsies, were obtained. Each series consisted of approximately 100 biopsies. With neutron-activated surgical blades, biopsies of about 500–750 mg were cut. In this case, each series corre-

sponded to about 10 biopsies. The intervals between the end of the irradiation, the moment of the experiment and the subsequent measurement were fixed according to the half-life of the radioisotope selected for the investigations.

Reactor irradiations

Parts of our study (estimation of manganese, copper, and in some cases zinc transfer) were performed with devices irradiated for about 6 hr at fluxes of 1.0–1.8 × 10^{12} $n.cm^{-2}.sec^{-1}$, and other parts (estimation of scandium, chromium, nickel, iron, cobalt, zinc, silver, tin, antimony and gold transfer) with devices irradiated for 5 days at a flux of approximately 10^{14} $n.cm^{-2}.sec^{-1}$. Polypropylene catheters, rubber stoppers and polyethylene containers do not resist irradiation at high neutron-fluxes, so for these we determined only manganese, copper and sometimes zinc transfer. During some of the 6-hr irradiations, standards were co-irradiated. In most cases however, flux monitors or comparators were preferred.[18,19] For details, see the publications of De Corte *et al.*[28,29]

Radioactive measurements and computation

Our experiments were performed over a period of more than 10 years so different measuring systems have been used. The specifications of those used in the initial phase of our investigations can be found in previous papers.[18,19] For the last few years we have measured our gamma spectra with a coaxial 70-cm^3 Ge(Li) detector (Philips) (energy resolution 2.0 keV for the 1332-keV photopeak of ^{60}Co; relative detection efficiency 15.6%), coupled to a 4000-channel analyser (Didac, Intertechnique). At first data reduction was performed with a PDP9, but is now done with a PDP11/45 computer (Digital Equipment Corporation) by means of a program developed by Op de Beeck and Hoste.[30]

RESULTS

Table 1 lists the transfer of scandium, chromium, manganese, iron, cobalt, nickel, copper, zinc, silver, tin, antimony and gold observed in blood samples collected with disposable steel needles. Their significance may be assessed by comparing the observed figures with the reportedly normal intrinsic concentrations in plasma or serum given in the lower half of the table. In some cases, a definitive conclusion is hard to draw because of the continuing uncertainty surrounding the plasma or serum levels of some elements in healthy adults, as pointed out in a previous publication.[47] The most important contaminations were invariably found in the first 20-ml sample. Obviously, the transfer of copper and zinc is largely negligible. The iron contamination amounts to about 15% in the first and to about 2% in subsequent 20-ml samples*. The manganese contamination in the first 20-ml sample varies from about 13% (needle No. 3) to 77% (needle No. 4) and in the third or fourth 20-ml sample from about 2% (needle No. 2, third 20-ml sample) to 10% (needle No. 1, fourth 20-ml sample). The transfers of cobalt, and more particularly of chromium and nickel, are even more important as they may equal or even exceed the intrinsic levels of these elements in human serum. The additions of scandium, silver, tin, antimony and gold are difficult to interpret for reasons already mentioned and also because we only succeeded in determining upper limits in several instances.

To avoid these serious artefacts it was decided to take blood samples with a polypropylene catheter. Table 2 summarizes the results for manganese and copper. They are expressed in the same units as in Table 1 so that they may easily be compared with the normal levels given in that table. An analysis of the data shows that errors are significantly reduced. The manganese addition of 0.025 ng/ml observed in the first sample collected with catheter No. 2 corresponds to an error of about 4%.

Figure 2 depicts the gamma spectrum of a blood sample after contact with an irradiated stopper of the Vacutainer® introduced by Becton-Dickinson for trace element studies. Table 3 summarizes the manganese, copper and zinc results. Compared with the natural levels in serum (Table 1) the amounts of copper and zinc transferred are insignificant (1–3% for copper and 1–2% for zinc). On the other hand, the amounts of manganese are important (errors of 8–51% in samples that remained in contact with the stopper for 30 min and of 11–24% in those that remained in contact for 120 min). We have no data on the potential extra additions from the tube itself. Figure 3 shows the upper right part (500–1000 keV) of Fig. 2 in more detail. It shows that whereas sodium, manganese, copper and zinc are readily taken up by the sample, gallium, lanthanum, europium and dysprosium are not (or only to a much lesser extent). We have not examined this problem further. A similar phenomenon was observed with the rubber stopper of a Venoject® tube, as shown in Fig. 1. The photopeaks in the stopper that are not reflected in the sample are from gallium, barium, lanthanum, europium, dysprosium and tungsten radioisotopes.

Table 4 enumerates the transfer of manganese and copper to serum samples stored in polyethylene containers. Though the absolute amounts of both el-

*The percentages given are based on an approximate mean "normal" level when the literature reports a range of "normal" levels.

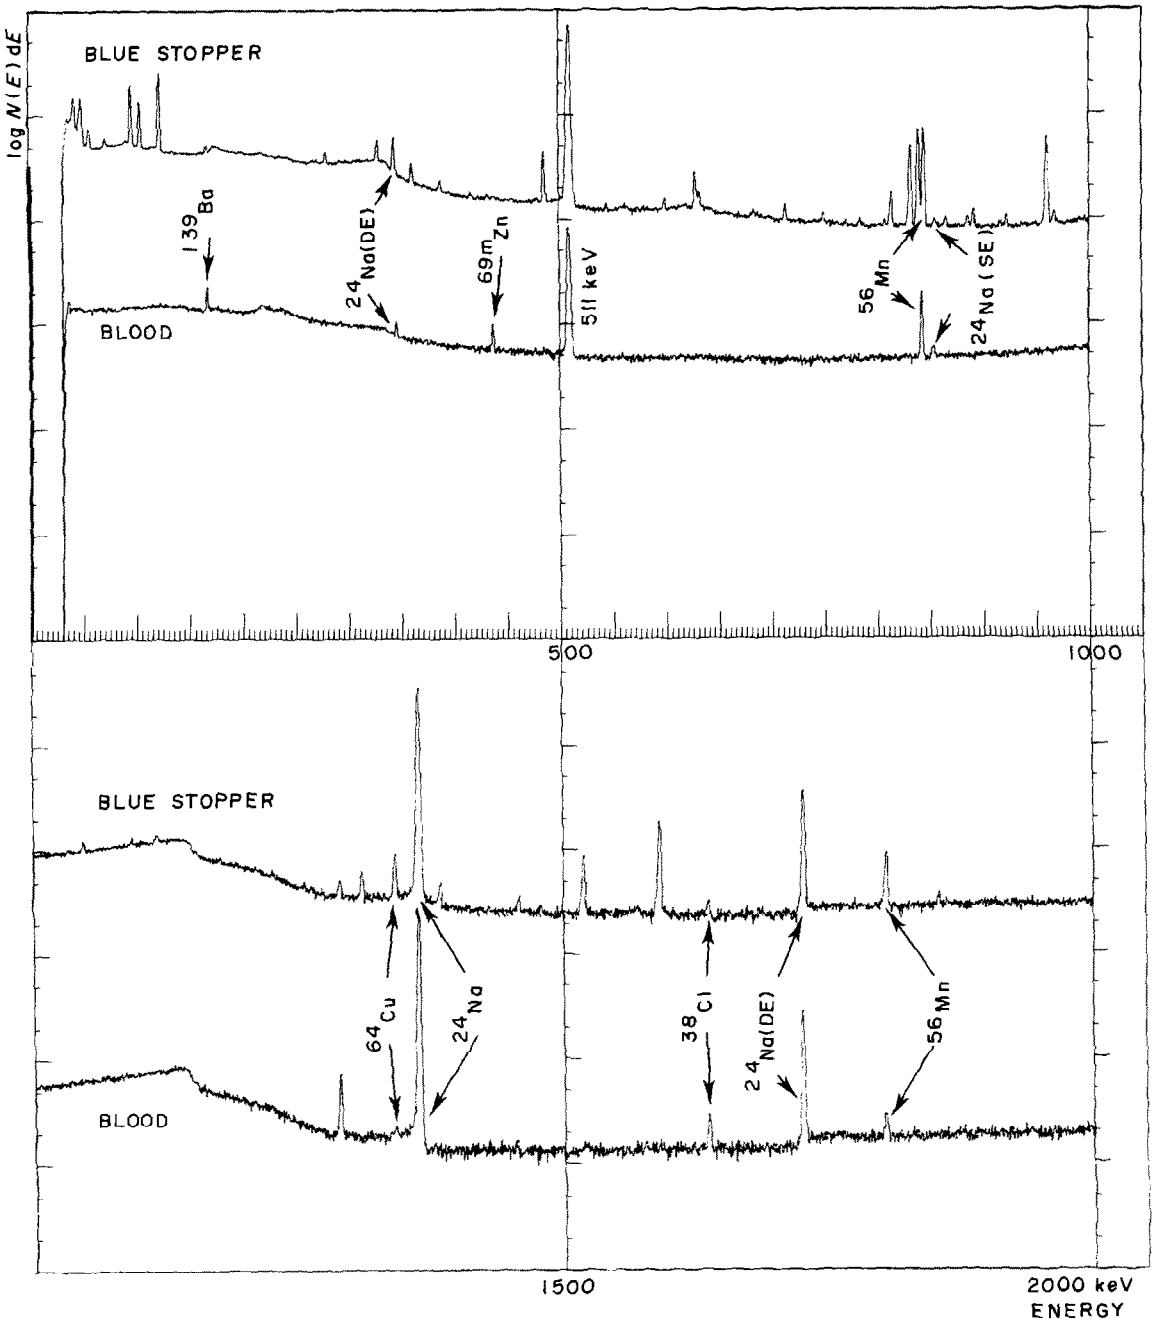

Fig. 2. Ge(Li) spectrum (waiting time 50 min, measurement time 2 hr 15 min) showing the extraneous additions to a blood sample after contact (30 min) with an irradiated (6 hr 10 min at 1.8×10^{12} n.cm^{-2}.sec^{-1}) royal blue stopper of the Vacutainer® recommended by its manufacturer for trace element studies. The spectrum of the stopper is also shown.

ements are roughly of the same order of magnitude (mean values, non-cleaned containers—manganese 0.57 ng/ml, copper 0.96 ng/ml; rinsed containers—manganese 0.084 ng/ml, copper 0.27 ng/ml), their significance is widely different. Indeed, when compared to the normal mean plasma or serum level of the element, the observed copper additions are negligible. On the contrary, the manganese additions from non-cleaned containers may equal or even exceed the normal mean natural concentration of the element. This table illustrates the vital importance of cleaning all such containers with extreme care; if only rinsing with water doubly distilled in quartz is used, errors of up to 15 or 20% for manganese may easily persist.

The values for manganese, copper and zinc listed in Table 5 give an impression of the errors to be

expected in serum samples collected and processed under suboptimal conditions. The values listed in subseries A were obtained for duplicate samples of healthy persons during the initial stage of our investigations, and those listed in subseries B after an improvement in our blood-sampling procedure (use of Spectrosil® quartz tubes and conventional polyethylene containers cleaned with meticulous care,[43–45,48,49] observance of stringent precautions against airborne contamination during sample collection and transport, sample manipulation and preparation under clean-room conditions). It is emphasized that the same radiochemical procedure was used for all analyses. It is evident that both the accuracy and precision of the manganese determinations of series A are extremely poor. The mean value is in error by about a factor of 10 (6.7 or 6.9 ng/ml *vs.* 0.63 or 0.64 ng/ml). It is interesting to note that the copper and zinc values of both series are roughly comparable. This illustrates that a sampling procedure may be adequate for analyses at the μg/ml level (serum

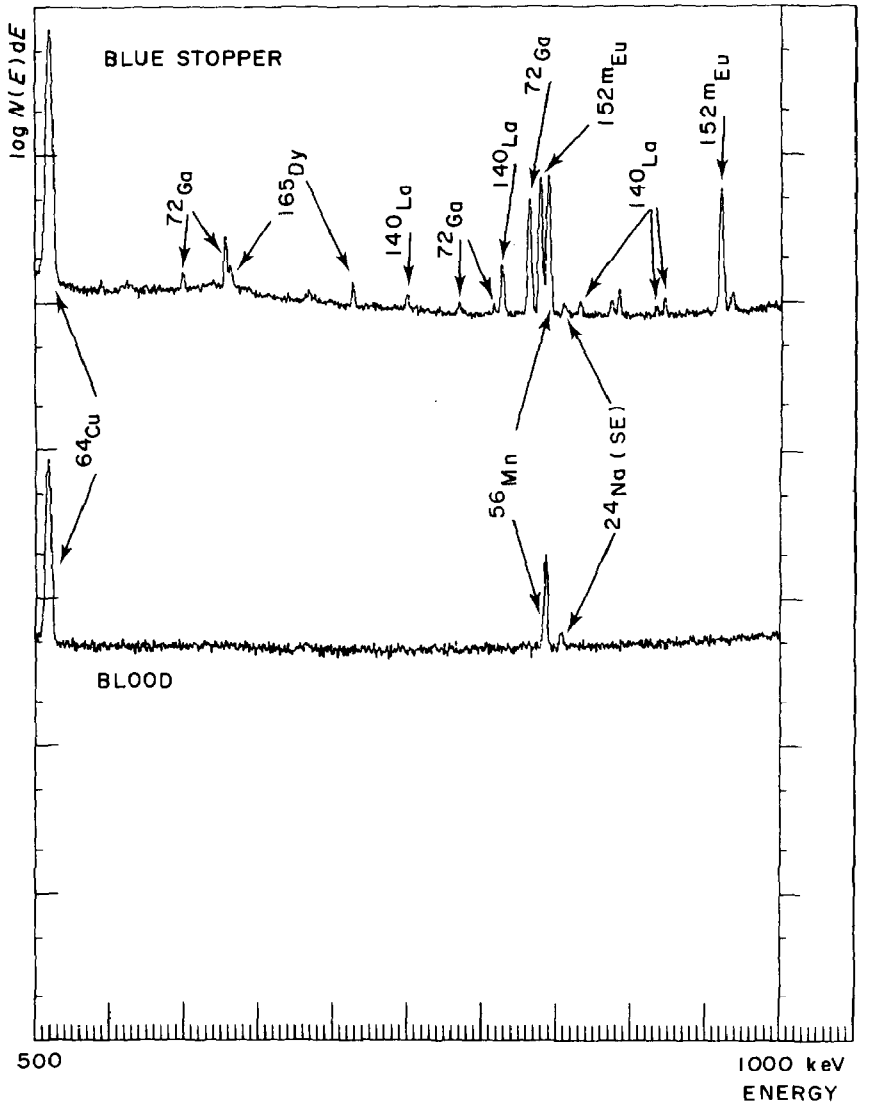

Fig. 3. Detail (500–1000 keV) of Fig. 2, showing that ^{24}Na, ^{56}Mn and ^{64}Cu appear in the sample, in contrast to ^{72}Ga, ^{140}La, ^{152m}Eu and ^{165}Dy.

copper and zinc) but inadequate for analyses at the ng/ml level (manganese).

Table 6 compares the observed contamination in needle-aspiration biopsies of the liver with published information on the intrinsic concentrations of the elements. It is obvious that the additions are again extremely important. For iron, an error of some 5 or 10% may be found; for manganese, copper and zinc, 25 or 40%. For cobalt, and particularly for chromium and nickel, they may exceed the natural levels of the elements in the sample. For the same reasons as mentioned for the additions in blood samples, for scandium, silver, tin, antimony and gold the size of the error is difficult to estimate at present, but it is evident that it is far from negligible. Thus, needle-aspiration biopsies are unsuitable for the determination of several elements in normal human liver tissue.

Table 7 surveys the additions observed in wedge biopsies of liver. As expected on theoretical grounds (surgical wedge biopsies have a much more favourable volume-to-surface ratio than percutaneous needle biopsies), the errors are considerably smaller.

*On basis of wet weight.

For manganese, iron, cobalt, copper and zinc they are practically negligible (less than 5%). The same conclusion probably holds for scandium, silver, tin and antimony. For gold, a contamination of about 10–25% is found. For chromium and nickel, the figures are even more significant. In some cases, however, some doubt remains about the normal level, thus hampering estimation of the error.

DISCUSSION

Several investigators have cautioned against the errors resulting from inadvertent sample contamination in trace-element research. Nevertheless, the real extent of the problem was slow in becoming fully recognized. One of the earliest warnings was issued by Thiers in 1957,[65] in the following terms: "unless the complete history of any sample is known with certainty, the analyst is well advised not to spend his time in analysing it." The very low serum-cobalt levels published by this investigator[42] (see Table 1) reflect his own care in sample collection and manipulation. They were largely ignored, and it was several years before they were supported by other results.[45,66–68] The precautions needed for obtaining reliable serum manganese and zinc values were outlined by Cotzias *et al.*[16] in 1966 and by Davies *et al.*[17] in 1968, but for both elements, more particularly for manganese, results obtained with apparently contaminated plasma or serum samples continued to be reported.[69–77] Heydorn and his associates[33,78] drew attention to the potential errors caused by airborne pollution in serum samples intended for manganese determinations. In recent years, several other studies have been published in which strong emphasis was laid on the importance of avoiding extraneous additions. Among these are the papers of Evenson and Patterson.[79,80] Their results suggest that most previously reported plasma-lead values are without any scientific significance because they are artificially elevated as a consequence of unsuspected contamination. Finally, Behne[81] reviewed the problems arising during sample collection and preparation. His paper includes a detailed discussion of the sources of contamination and the detection and prevention of resulting errors.

It is evident that the risk of obtaining grossly misleading figures owing to inadvertent extraneous additions is markedly higher for elements which occur at the ng/g level than for those occurring at the μg/g level and that the significance of a given addition will decrease as the concentration of an element in a matrix increases. Thus, for example, it is obvious that in Wilson's disease, primary biliary cirrhosis, or other conditions characterized by grossly increased liver-copper levels, the relative error in the result from a percutaneous needle aspiration biopsy will be lower than that when the liver-copper level is normal.

Our estimations of unwanted additions that may occur during collection and manipulation of biological samples corroborate the indirect measurements of

other researchers. Moreover, they illustrate that the resulting errors may be higher than frequently suspected, although it must be admitted that the irradiation damage to the instruments, particularly during long irradiations at high neutron-fluxes, may have increased the figures observed under our experimental conditions. There are further indications that the artefacts may be extremely important: first, although other sources of errors should not be overlooked, there are the widely divergent concentrations measured in normal human plasma or serum, varying over 2 or even 3 orders of magnitude,[47] and secondly, our own experience in determining manganese in serum (Table 5), proving that in suboptimally collected and handled samples the mean value may be increased by a factor of 10.

The risk of obtaining misleading serum zinc values because of extraneous additions from the rubber stoppers of Vacutainer® and of Venoject® tubes of various kinds has been identified by numerous investigators.[20–27,82,83] This prompted Becton-Dickinson to develop a new type of stopper for trace element studies, but our investigations show that it offers only a partial solution, as it causes considerable manganese contamination. Furthermore, its reliability in the determination of other low-level trace elements, such as vanadium, chromium, cobalt and nickel, remains to be investigated.

At a moment when sustained efforts have resulted in improving the sensitivity and specificity of analytical methods, a growing body of evidence suggests that inadequate sample collection and preparation may be the origin of errors more serious than those involved in any other step of the analytical procedure. Similar problems were encountered by researchers involved in analyses of fresh water[84,85] and lunar samples.[86,87]

Trace-element research imposes a stringent discipline on its practitioners. The analyses must be performed under rigorously controlled conditions to protect the samples from artefacts due to the containers, the reagents, or the ambient air. A detailed description of the different precautions to be observed is beyond the scope of this paper and we refer the reader to the many excellent publications on this subject.[88–104] The measures taken at the University of Ghent to preserve sample integrity are described in detail in previous publications.[43–45,48,49,105–110]

CONTAMINATION AS A LIMITING PARAMETER IN TRACE ANALYSIS

L. KOSTA
Department of Chemistry and J. Stefan Institute, University E. Kardelj, Ljubljana, Yugoslavia

(*Received* 29 *April* 1982. *Accepted* 5 *June* 1982)

Summary—The relative importance of the main parameters determining systematic errors due to contamination in trace analysis is evaluated, with respect to the laboratory environment, tools, containers and reagents. Variability in the composition and quality of materials as well as of the relevant analytical data makes the treatment of the subject only semi-quantitative but the evidence suggests that control over contamination primarily depends on good laboratory practice. Among the appproaches applicable to trace concentrations, activation analysis gives results that are least affected by contamination. In other techniques, varying blanks and the need for their control make accurate analysis at the trace level demanding in terms of time and engagement; reliable data in routine determinations at levels much below 1 mg/kg can only be expected from specialized and experienced laboratories.

Contamination in trace analysis is always understood as the increase in the measured amount or concentration of a component, resulting from its introduction at various stages of the analytical procedure, from sources other than the sample.

There is only a minor group of elements which are difficult to control in the laboratory; it includes those occurring in high concentrations in working and living environments, such as aluminium, chlorine, chromium, copper, iron, nickel, lead, sodium and zinc, and those predominating in natural dusts, including aluminium, calcium, nitrogen (ammonium and nitrate), silicon and sulphur (sulphate). Concentrations of widely spread molecular pollutants, *e.g.*, pesticides, can be reduced in the laboratory by appropriate measures to levels not detectable by current methodologies, therefore they do not need a discussion in the context of this paper.

According to present needs and interests, data on elemental concentrations at, and below, 1 mg/kg are required for biological materials, foods and environmental media. They are also highly relevant in some contemporary technologies such as telecommunications and microelectronics. In the latter, tolerances for impurities in silicon and germanium are given in terms of the number of atoms per cm^3. These range from 10^{12} to 10^{15} atoms/cm^3, equivalent to concentrations between 0.1 and 100 μg/kg.[1] Upper limits for transition elements (cobalt, chromium, iron, manganese and nickel) in raw materials and glasses used in optical waveguides are in the 10 μg/kg range.[2] Data on toxic elements in human serum, water and basic foods are given in Table 1.

In rocks and soils concentrations of common elements below 1 mg/kg are exceptional, as can be seen from data on relevant reference materials.[3,4] In metallurgy, requirements are more specific and many elements do not create contamination problems.

Techniques applicable to the lowest trace levels include atomic-absorption spectrometry, spark-source and isotope-dilution mass-spectrometry, emission spectrometry based on excitation in a plasma (ICP), voltammetric techniques, and activation analysis.[5] The last-named technique by-passes the problem of contamination and can be considered as a reference trace technique for the elements which it covers. It should be emphasized, however, that the superiority of this technique only applies to contamination and that results grossly in error because of other positive systematic effects are not uncommon. Nevertheless, it is significant that not only have more than 50% of all certified values for trace elements been obtained by activation analysis,[6] but also that most of our knowledge of their normal concentrations in biological materials is based predominantly on data obtained by this technique.

Contamination in trace analysis is comprehensively dealt with in the book by Zief and Mitchell.[7] It initiated extensive follow-up work which has made an essential contribution to our understanding of the problem. Advances in contamination control are also the subject of a recent survey by Mitchell.[8] In their book, these authors differentiate between trace and ultratrace analysis, the former encompassing levels between 1 and 100 mg/kg and the latter the range below. Only concentrations lower than 1 mg/kg require a more detailed discussion, as frequency distribution plots of interlaboratory data in this range become asymmetric and skewed towards higher values. They imply the predominance of positive systematic errors which make the assignment of correct values on purely statistical grounds uncertain.

Several independent sources, besides the sample itself, add to the final signal for a particular constituent. These are the laboratory atmosphere and working areas, tools and apparatus associated with sam-

Table 1. Concentration ranges of trace elements in human blood serum, milk, water, wheat and meat

Material	Ranges, *mg/kg*				
	100–1	1–0.1	0.1–0.01	0.01–0.001	0.001–0.0001

Data pooled from references 43–50.
Elements in concentrations exceeding 100 mg/kg not included.

pling and sample preparation, laboratory ware, and reagents. They will be discussed in sequence, mainly on the basis of recent data.

The laboratory environment

Ideally, trace analytical work depending on conventional techniques should be carried out in a high-class clean-air laboratory. According to Lievens *et al.*,[9] daily average fall-out in a laboratory is of the order of 1 $ng.cm^{-2}.day^{-1}$ for the ubiquitous elements Na, Fe, Al, one order of magnitude higher for chloride, and lower by a factor of around 10–100 for most other elements. Reported data are obviously valid only for a particular laboratory and for a given set of conditions. In the above measurements trace element levels were reduced by a factor of 10–100 in a dust-free room. Availability of clean-air facilities, however, does not in itself guarantee dust-free conditions. The placement of equipment or containers, too high exhaust velocities, room draughts, or an operator working near the fume-hood can distort laminar flow, cause turbulences and dramatically affect the performance of clean-air installations.[10,11]

Risks of contamination from laboratory construction materials and surfaces (walls, floor and ceiling) have been substantially reduced by introduction of special epoxy paints, fibreglass, disposable surface protectors, sealed plastic floors and tacky mats. The absence of metallic constituents in these materials makes it possible to adapt a conventional laboratory to trace analytical work without major investment and sophisticated equipment. Awareness and understanding of the problem are nevertheless essential for exploiting advances in technical approaches to it. Only at the lowest range of concentrations and in special operations involving exposure of the sample over a long period is the availability of an appropriate clean surface, or of one or more laminar-flow hoods providing air with less than 10^5 particles per m^3, or better, a prerequisite.

Dust and particles brought to, and released or created in the laboratory by the activities of personnel, appear a more abundant and critical source of contamination. In living quarters and in offices persistent contaminants (with regard to analytical data required at the trace level) are used in large amounts in the elemental or some other concentrated form. The list includes metallic objects made of or plated with copper, brass, lead, stainless steel and chromium. The last-named, for example, for which interlaboratory data on biological systems are particularly scanty, is used for coating the surfaces of tools and instruments, has compounds which form the basis of certain yellow and orange paints, occurs in leatherware at concentrations of up to several per cent, and is a major constituent of some cosmetics.

In the laboratory some contamination, *e.g.*, by ammonium salts, is unavoidable and in most instances is of marginal importance unless the analysis involves determination of the contaminant(s). Powdered re-

agents, however, and their concentrated solutions present a serious problem. They reflect particularities of the work in a laboratory and are frequently used in large amounts over extended periods. The experience from radiochemical laboratories shows how difficult it is to prevent spreading of powdered material or to remove the last residues from spills. Stable chemicals, in contrast to radioactive materials, cannot be traced with comparable efficiency. The risk can be greatly reduced by organizing the flow and sequence of operations so as to exclude critical phases involving concentrated chemicals from rooms and working areas reserved for trace determinations. Aspects of contamination related to the laboratory environment have been authoritatively treated by Hamilton.[12]

Sampling and sample preparation

Sampling for trace analysis is delicate in the case of certain types of compact solids, *e.g.*, metals, alloys, and rocks, which require crushing, drilling, sawing or turning. The degree of contamination obviously depends on the physical properties and chemical composition of the sample materials relative to those of the tools, and can be minimized by a proper selection of tools with respect to their composition and dimensions. Major problems are encountered in size reduction and homogenization of samples. Contamination with the constituents of the tools (blades, milling and vibrator balls, rotating parts) is unavoidable even in cases when very hard materials are used in homogenizing soft tissues or powders. Quantitative data obtained by Ure *et al.*[13] on the effect of milling techniques and materials on contamination of a liver sample, show that the levels of chromium and titanium are 20 and 3 times greater respectively when a Waring Blendor homogenizer with stainless-steel knife is used instead of an agate pestle and mortar. Replacing the stainless steel by titanium (containing 4.1 mg of Cr per kg) resulted in doubling the Ti concentration, but there was also a 50% increase in the apparent chromium level in the sample. In our own laboratory, homogenizing flour for a few minutes in a vibrator with a tungsten carbide ball was found to produce a tungsten contamination level approaching 100 ng/kg, as determined by activation analysis.

The problems encountered in collection or withdrawal of liquids (biological fluids, tap water) depend on the quality of the material used (tubing) and on the ratio between the surface area in contact with the liquid and the volume taken. From recent data by Lakomaa[14] for cerebrospinal fluid, and by Pietra *et al.*,[15] as well as from earlier results by Versieck and Speecke,[16] it follows that venepuncture needles, metallic cannulae and syringes used in blood sampling may increase the level of metals such as chromium, zinc, nickel or iron by as much as an order of magnitude. Quantitative data on the extent of metal release are not directly comparable because of variations in experimental approach, and there is evidence that neutron irradiation of materials for labelling potential contaminants enhances the release of certain constituents because of radiation damage. According to results by Vogt *et al.*,[17] contamination from the components of stainless steel in sampling blood is largely avoided by siliconing the needles; these authors claim that chromium levels between 0.1 and 0.5 mg/kg in blood serum have been found routinely.

Sampling, storage and sample preparation with special reference to biological materials have been discussed by Iyengar and Sansoni.[18,19]

Problems related to contamination in collection and storage of surface-water samples (rivers, lakes, brackish waters, open ocean) are dealt with in papers by Mart[20] and by Mart *et al.*[11] For sampling waters and liquids that can be drawn from taps, flushing has been shown to be efficient for removing accumulated corrosion products in pipes, *e.g.*, in the recent determination of nickel in the author's laboratory,[21] but this approach is not practicable when the volume withdrawn has to be kept small.

Laboratory ware

Materials used in the production of high-quality laboratory ware include polyethylene, polypropylene, Teflon, glass and silica. With appropriate treatment and handling in general they meet the standards of purity required for trace analytical work. Cleaning procedures for plastic ware used for storing water samples have been the subject of comprehensive investigations by Moody and Lindstrom[22] and very recently by Laxen and Harrison.[23] It is remarkable that among 13 methods recommended in the literature for analysis of surface waters, the latter authors found the simplest was the best suited for preliminary and routine cleaning, namely, soaking the plastic for 48 hr in dilute nitric acid, followed by thorough rinsing with purified water. Their observations can be extrapolated to cleaning plastic ware for other applications.

In all types of plastic less-expected contaminants sometimes occur as a result of particularities in the production process affecting certain batches. Salmela and Vuori[24] report the appearance of significant amounts of cadmium in solutions after cleaning Eppendorf pipette tips; presumably the source was the yellow pigment in the dye. Teflon has been found to be contaminated with stainless-steel particles embedded in the material during the manufacturing process.[25] Iron, nickel, chromium and molybdenum were leached out even after extended use. Lead was released from other products and in a certain batch of tubing used for making irradiation ampoules in the author's laboratory, mercury was found corresponding to 1 ng/cm^2; at the concentration in the sample (1 μg/kg) this could clearly give rise to an error of several hundred per cent. These examples emphasize the need for monitoring all plastic ware involved in an analysis, when very low levels of particular constituents are to be determined.

Table 2. Trace elements in laboratory ware

Material	Concentration range, *mg/kg*			
	100	10–0.1	0.1–0.01	0.01–0.001
Polyethylene and polypropylene	Na, Zn, Ca, (Al, Ti)*	K, Br, Fe, Pb, Cl, Si, Sr	Mn, Al, Sn, Se, I	Cu, Sb, Co, Hg
Poly(vinyl chloride)	Na, Sn†, Al, Ca	Br, Pb, Sn, Cd, Zn, Mg	As, Sb	—
Teflon	K, Na	Cl, Na, Al, W	Fe, Cu, Mn, Cr, Ni	Cs, Co

‡Chlorine high only in synthetic quartz.
Data compiled from references 19, 22 and 51.

Typical glasses used for manufacturing reagent bottles, beakers and flasks contain most trace elements in concentrations close to or above 1 mg/kg. On proper treatment in acid media glass usually improves, as trace constituents are leached out to leave a surface which is essentially silica. Experience with the determination of lead by dithizone illustrates that repeated applications of the reagent itself eliminate impurities from the glass surface. Blanks decrease and finally disappear after a series of samples have been treated in the same set of extraction funnels. Occasionally iron presents problems in working with glass, and Smith observed contamination by cadmium from glass ampoules used for decomposition under more severe conditions.[26] Tables 2 and 3 summarize data on impurities in materials used for making laboratory ware, and results on leaching experiments, respectively.

With silica apparatus, contamination problems are practically non-existent in the determination of most elements. Antimony appears to be a specific contaminant, but the degree to which it is leached out is measurable only by the activation technique, which possesses high sensitivity for this element.

The materials used for laboratory ware exhibit some adsorptive or exchange properties and they swell to some degree in organic solvents or reagents; this change in the fine structure of the surface makes the surface area much larger than would be expected from the dimensions of the container. It is therefore understood that flasks, reagent bottles, dishes or pipettes for handling samples and low-level reference solutions must never be used for transferring or processing stock solutions and concentrated reagents.

For protecting samples from contamination, flow-injection systems offer major advantages. Once dissolved, the sample and reagents are isolated from the laboratory environment; the only containers needed are reagent bottles and tubing, and these are continuously flushed. By injection of standards, the analytical performance is under constant control. The range of practical applications of the flow-injection technique is still rather limited, however, and the concentration levels covered are in the upper and intermediate part of the trace domain. Recently published methods for lead and cadmium with dithizone[27] and particularly the catalytic method for iodine in foods,[28] indicate the potential of this technique for routine analyses at the trace level.

Reagents and filtering media

Compared to other sources of contamination, contributions from reagents can be quantitatively measured (provided that the concentrations of impurities are known and the amount or volume added are recorded). Analysing reagents, however, adds much to the time and effort required and is only rarely justified.

An analysis normally involves the dissolution or the decomposition of the sample with either a solvent or reagent in a large excess. Residual concentrations of representative heavy metals in water (Cu, Fe, Mn, Pb, Zn) purified by various methods (including demineralization, distillation and adsorption, and combinations thereof) range from a few to a few hundred ng/kg. The differences in the data reflect the variability in materials (glass, quartz, polypropylene) and methods used, but the achievable purity appears to depend even more on parameters such as the period of storage and the degree to which a steady state has been reached in the operation of the unit. Since the concentrations of heavy metals in most commercial reagents of ultrapure quality are typically two or three orders of magnitude higher, water will not normally contribute significant amounts of any impurity if properly prepared and stored. It is perhaps worth mentioning that water purified in conventional

Table 3. Trace elements leached by nitric acid and hydrochloric acid from plastic containers after one week of contact (in ng/cm²)

Material \ Amount	6*M* HCl			9*M* HNO_3		
	10	10–1	1	10	10–1	1
Polyethylene (HP)	Na, Pb, Al	Tl, Cr, Zn	Ca, Sn, Cu, K, Mg, Ba, Ni, Cr, Cd, Sr, Se	Ca	Na, Fe, Se, Cu	Cr, Mg, Pb
(LP)	Ca	Zn, Na, Al, Fe, Cu, K, Ba	Sn, Co, Ni, Pb, Mg, Se, Cd, Sr	Na	Zn, Fe, K, Pb Ni, Sn, Sr	Mg, Ca, Cu, Se, Cr, Cd, Te, Ag, Ba
Polycarbonate	Fe, Ca, Sn, Pb	Na, Cu, Cr, Cd, Ba, Al	Mg, Te, Se, Ni, Sr	—	Al, Na, Fe, Ca, K	Cu, Zn, Ni, Se, Cr, Cd, Pb
Teflon	Fe	Cu, Zn, Cr, Al, Ba, Ca, Na, Pb, Te, K, Mg, Sn, Sr	Cd, Se, Ni	Ca, Fe	Mg, Al, Na, Zn, Pb, Ba, Cu, Ni, K, Sn	Cr, Te, Cd, Sr, Se

Elements are ranked in order of decreasing amounts introduced into the acid.
Data are compiled from reference 22. In the absence of a unified methodology, data in the literature cannot be compared, owing to variable and arbitrarily chosen parameters, (volumes, concentrations of acids, periods of contact).

Table 4. Trace elements in ultrapure acids (μg/l.) and reagents (μg/kg) at the given concentration ranges

Range	HCl	HF	HNO_3	H_2SO_4	$HClO_4$
1	Al, Si, S	B, Si, P, S	Si, S, K	Ca, Co, Cu, K, Mg, Na, (Se)	Cr, Fe, Na
1–0.1	Na, Mg, P, Ca, Fe	Na, Al, Ti, Ca, K, Fe, Cu, Zn	Al, Ti, Fe, Na, P, Mg, Ca, B, Cu, Cr	Mn, Ni, Sn, Sr, Tl	Ni, Sn, Br, K, Pb, Tl, Zn
0.1–0.01	B, Ti, V, Cu, Zn, Sn, Ba	Cr, Mn, Co, Zr, Cd, Pb	Zn, Ni, Ba, Pb, Cd		Cd, Sr
0.01	Mn, Co, Cr, Ni, Zr, Cd, Pb	Cd, Ba	Mn, Co, V	—	—

Upper limits for commercial ultrapure reagents range between 50 and 500 μg/l. for Ba, Cl and Na, and between 5 and 20 μg/l. for metals such as Cu, Fe, Mn and Pb. On extended storage, concentrations of most elements increase by a factor of up to 10 (*e.g.*, Fe). In solid reagents, *e.g.*, Na_2CO_3, KCl and NaOH, levels are slightly higher than for acids. Data compiled from references 19 and 25.

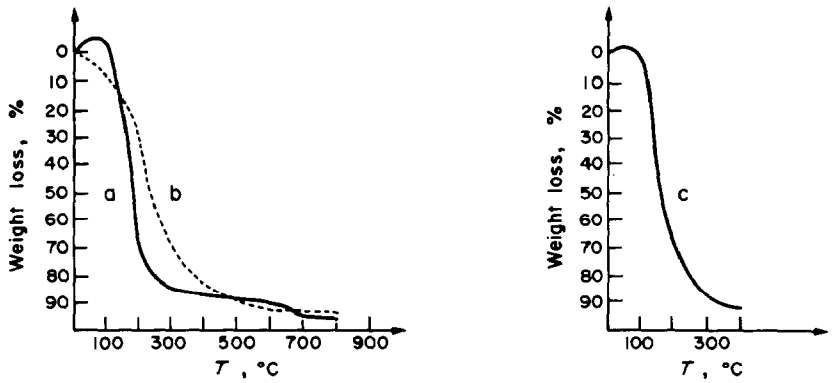

Fig. 1. Thermogravimetric curves: a,b—weight-loss of a grass sample (0.5 g) on heating in NO_2 (full line) and in air (dashed line), with temperature; c—ashing of a plant sample at constant temperature (300°C) as a function of time.

laboratories is not significantly different in quality from water produced in a clean-air area.

In total, nearly a hundred ultrapure reagents are available on the market. The extent to which concentrations of contaminants are reduced varies within wide limits and leaves much to be desired with respect to sodium, chlorine, potassium, phosphorus, silicon, sulphur, calcium and barium. Typical concentrations of copper, zinc and iron in commercial ultrapure acids, ammonia and organic solvents (which can be distilled) range between 5 and 50 μg/l. The same applies to ammonium salts and organic reagents which can be synthesized in the vapour phase or sublimed. Table 4 summarizes available data for mineral acids. Among solids, potassium chloride, and sodium carbonate and hydroxide can be purchased in comparable quality. In general, however, operations involving large amounts of solids (*e.g.*, fusion) are best avoided.

From results by Dabeka *et al.*[25] it follows that by distillation, either from quartz or polypropylene, mineral acids can be purified to a much higher degree. By use of a propylene sub-boiling still, the concentration of iron and zinc (the most persistent metals) was lowered in hydrochloric and hydrofluoric acids by a factor of 100–1000 compared to commercial acids of ultrapure grade. Considering the price of these acids it appears a sound investment to prepare some reagents, particularly mineral acids, in the laboratory.

Clean mineralization of organic samples and biological materials is feasible by ashing or by ignition in oxygen. To avoid losses a closed system is preferable; a substantial excess of gas, however, is required to prevent formation of tarry substances and deposition of carbonaceous materials. Therefore the advantage from the purity of the reagent is offset by the need for an ignition assembly with a large surface area. In our own experiments on determination of iodine and selenium by activation analysis, oxygen ignition proved very efficient,[29,30] but in determination of selenium by gas chromatography, the subsequent dissolution of the ash resulted in high blanks. On the other hand, the ignition can be done dynamically in a tube. Heng Bin Han *et al.*[31] recently reported the determination of selenium in rocks and soils at the trace levels by use of a dynamic system in a silica apparatus, as developed by Tölg.[32] Material losses to the gas stream may occur with some elements, according to experience in the author's laboratory.

A major drawback of direct ignition systems is the high temperature, at which some trace elements tend to form alloys or refractory compounds with the support material. Subsequently they do not dissolve to give a true ionic solution but remain in the form of non-reactive microaggregates and colloids. Recently, we obtained encouraging results in experiments where biological materials were heated in a slow stream of nitrogen dioxide.[33] Complete ashing was achieved in 2–3 hr at temperatures between 200 and 300°, at which the degree of dissociation of NO_2 increases from 4 to 16%.[34] The ashing effect is attributed to the oxygen formed. The diagrams in Fig. 1 show comparative thermogravimetric curves for the same material ashed in nitrogen dioxide and in air and a curve showing the rate of loss. The ignition system is shown in Fig. 2.

Ashing at low temperatures is important in techniques such as spark-source mass-spectrometry[13] since losses by volatilization are minimized or avoided, trace elements concentrated, and the risk of contamination greatly reduced, by making the electrodes directly from the solid residue.

Filtering media. In most instances the heavy metal content of filters is not negligible, but the risk of contaminating the sample by washing or leaching out the impurities is nevertheless low. Eventually, however, filters may become an integral part of the sample in the subsequent treatment or measurement. In such cases (*e.g.*, analysis of particulates, preconcentration of trace constituents on ion-exchange filter papers as in X-ray fluorescence analysis, ignition of carrier precipitates *etc.*) it is essential to know the concentrations of the relevant contaminants.

The high results obtained for selenium by gas chromatography, mentioned in the last column, were traced back to contamination from the filter paper (Schleicher & Schüll 598) used as the sample holder in the Schöniger combustion technique. Results from subsequent analyses of a set of conventional and membrane filters (Sartorius types 11106 and

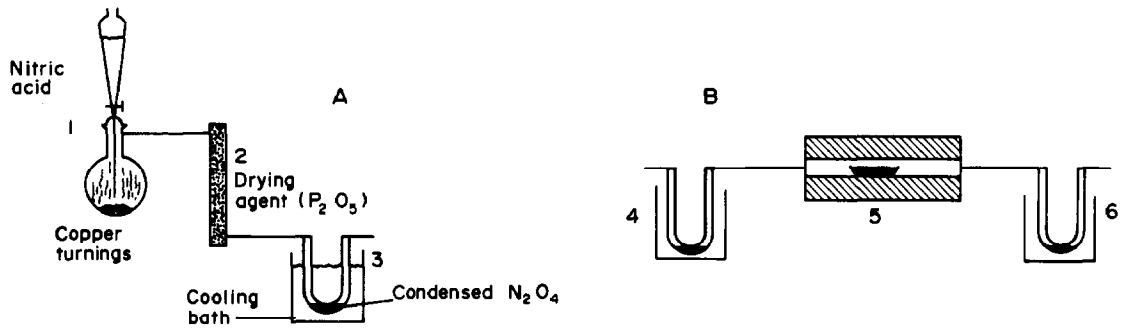

Fig. 2. A—preparation of N_2O_4 (1, reaction system; 2, drying column; 3, condensation trap). B—ignition system (4 and 6, traps; 5, ring-oven with the sample). It is noteworthy that tarry material or carbon does not form or deposit in the ignition tube or in trap 6.

11306) revealed variable concentrations of copper (0.3–3.5 ng/cm^2), manganese (0.4–20 ng/cm^2), mercury (0.1–0.6 ng/cm^2) and zinc (18–41 ng/cm^2). These levels approximately parallel those reported by other authors[35–38] for cellulose-ester and polycarbonate membrane filters. Similar figures apply for chromium, nickel and lead. Chatt and Kulathilake[35] analysed polycarbonate (Nucleopore) filters which they used for collecting microsamples of oceanic particulate matter. They determined a number of elements by photon-activation analysis. Using the same technique, Kato *et al.*[36] determined 18 elements in membrane filters based on cellulose esters (Millipore). According to their results, major contaminants such as chloride and sodium may exceed 1 μg/cm^2 levels, and calcium, potassium and magnesium occur in concentrations of several 100 ng/cm^2.

Chemically modified cellulose filters have a great tendency to attract particulate matter, owing to the static charge induced by handling. Some types have non-ionic detergents added as wetting agents. These may contain ammine salts and interfere with the determination of ammonia. Some additives absorb in the ultraviolet region and can affect results for nitrate.

Kingston and Pella[39] report preconcentration of heavy metals in sea-water on filter papers loaded with ion-exchanger before their determination by X-ray spectrometry. The absolute amounts of zinc and copper collected were around 1 μg, in which case contamination could be allowed for but the iron blanks were too variable to make the determination of iron possible.

Growing interest in determining heavy metal species associated with subcellular fractions of biological material requires data on contamination of the reagents used in gel filtration, ultrafiltration and ultracentrifugation. The amounts of reagents needed in some of these operations are large relative to the volume of the sample. Thus, the significant amounts of heavy metals found by Pietra *et al.*[15] in acrylamide gel, sephacryl and some buffers represent a major limitation.

Systems and techniques have recently been described which permit the removal of metallic contaminants from concentrated solutions of alkali-metal and transition-metal salts by use of a modified cellulose exchanger with selective chelating groups such as salicylic acid or 4-(pyridyl-2-azo)resorcinol attached. They have proved useful in lowering the contamination by elements such as copper, iron and zinc by orders of magnitude.[40–42]

In general, however, purification of solid, non-volatile reagents is still an open problem, since simple systems for removing a wide range of impurities simultaneously, without introducing other foreign material, would be needed.

Conclusions

The quality and selection of materials, and the facilities available, have considerably improved in recent years, thus minimizing contamination in analytical laboratories. With simple means and measures they make it possible to adapt conventional laboratories for trace analytical work within most of the practicable range.

Amounts of impurities introduced by reagents in the course of an analysis are measurable and constant for a given analytical procedure; other contributions are variable, but to ensure acceptable blanks, they have to be made low and constant. This is practicable only for absolute amounts of impurities of the order of a few ng, owing to limitations dictated by materials (containers, reagents, tools) in contact with the sample in the course of the analysis.

As to methods, the risk of contaminating the sample increases with their complexity. A corollary of the dependence on materials is the requirement for simple and direct methods involving only a few easily purifiable reagents and scaling down the system relative to the sample.

Contamination becomes the predominant limitation in all techniques, with the exception of activation analysis and tracer applications, at concentrations between tenths and hundredths of μg/kg, depending on the element and matrix. Compared with the performance of other multielement techniques applicable

directly (without preconcentration) to the lowest concentration range, spark-source mass-spectrometry is superior because it covers nearly all elements, and hence is currently widely used in tracing sources and levels of contamination. ICP emission spectrometry is highly sensitive, but there is a lack of data on its application to real complex samples. Atomic-absorption spectrometry, isotope-dilution mass-spectrometry and the newer voltammetric techniques have a limited coverage but proven performance in experienced laboratories. Certain developments, however, are in a less favourable direction: instead of reduction of other parameters relative to the sample size, the sample fraction measured is made smaller; to provide for loss of sensitivity, elaborate concentration procedures are sometimes introduced. They make these techniques more dependent on skill and expertise, and more prone to contamination. This is in agreement with the evidence from interlaboratory data, which suggests that in general the quality of trace analytical results has not improved in parallel with the advances in instrumentation and automation. Since contamination does not necessarily affect the precision of data, its importance has been underrated, but recently there has been a growing appreciation of the relevance of parameters other than the final measurement, including the requirement for identifying sources of blanks.

Control over contamination therefore rests more strongly on good laboratory practice and on the competence of the analyst than on facilities and instrumentation. At levels of around 1 ng or less, requirements for determining elements which are persistent contaminants necessitate an integrated analytical approach exploiting the specific potentials of individual techniques; economic factors may then become a restriction.

PURIFICATION OF ANALYTICAL REAGENTS

J. W. MITCHELL
Bell Laboratories, 600 Mountain Avenue, Murray Hill, NJ 07974, U.S.A.

(*Received* 15 *June* 1982. *Accepted* 23 *June* 1982)

Summary—Considerable progress in the purification of reagent chemicals has been made during the past decade. Improved or newly developed methods and their application for producing analytical reagents of highest purity are described. Various techniques are evaluated critically with respect to convenience and efficiency of use in the trace analysis laboratory.

In modern ultratrace analysis rigid demands are imposed on the degree of purity required for the water, acids, bases, solvents, buffers, supporting electrolytes, fluxes, oxidants and reductants, chelating agents, and other reagent chemicals used in analytical work. Some of these needs for pure reagents have been met by commercial suppliers who have recently focused their attention on this problem. Because specific attention has been given to the proper handling, containing, analysis, and storage of reagents, levels of many trace elemental impurities in commercial lots of chemicals have been reduced considerably. Even though an overall improvement in the quality of several suppliers' chemicals has been accomplished, for most ultratrace analyses the analyst must still verify that the purity of any purchased reagent is sufficient for the intended analytical application. Reagent impurities capable of interfering with the analytical measurement should be so low that they give a blank value that is less than 10% of the analyte level. Although reagents sufficiently pure for many applications are available commercially, the analytical laboratory committed to ultratrace determinations of a variety of elements must also be able to produce a wide range of pure reagent chemicals itself. For many analytical problems the level of a specific contaminant of interest can be adequately controlled only by designing a special laboratory purification method. The basic analytical reagents can now be ultrapurified on the laboratory scale with relative ease by a number of techniques either introduced or significantly improved during the past decade.

Table 1 lists some of the techniques most widely used by analysts for laboratory-scale purification of reagents. By using one of these techniques or several in combination, analytical chemists have made significant advances in recent years. Discussion of the currently used techniques is provided in this report but the copious and critical details of the execution of various procedures to attain extraordinarily high degrees of purity for processed reagents are not included. It is presumed that the trace-element analytical scientist is aware that the purification apparatus should preferably be housed in an analytical cleanroom and has assimilated a basic knowledge of contamination-control techniques for trace analysis. These issues have been discussed previously[1,2] and are also reported in other papers in this "paper symposium".

Success in ultrapurification work depends critically on analytical techniques that establish the efficiency of the purification process and provide determinations of the purity level of the processed reagent. It is vital that the level of purity attained is verified by an unequivocally reliable and preferably direct quantitative analysis, which will usually be more difficult to execute reliably than the purification procedure. Detailed discussion of the excruciatingly careful procedures required in the reliable quantitative analysis of ultrapure reagents is beyond the scope of this report and is thus omitted. Analytical methods proven to be valuable for either monitoring the efficiency of purification processes or for characterizing the final product are mentioned frequently, however, and where possible, representative data are reported.

PURIFICATION METHODS

Ion-exchange

The primary use of the ion-exchange method in the analytical laboratory continues to be the demineralization of water. For this application it is accepted universally as one of the most effective means of removing dissolved ionic species from water.

Since ultrapure water is the most abundantly used analytical reagent and its purification by ion-

Table 2. Levels (ng/ml) of Cu, Pb and Cd in water purified by different methods[3]

Element	Centrally demineralized	Demineralized and distilled in Pyrex	Doubly distilled in quartz	Distilled and Milli-Q purified
Cd	0.1–0.15	0.08–0.1	0.02–0.06	≤0.01
Pb	0.4–0.8	0.3–0.5	0.1–0.3	0.05–0.1
Cu	1.0–1.5	1.0–1.5	0.3–0.5	0.1–0.3

exchange is a perfectly straightforward application, each trace-analysis laboratory should easily have available a copious supply of this pure product. For most trace-metal analytical work demineralization of water in a mixed-bed ion-exchange column, followed by filtering and double distillation, in an all-quartz system, produces a satisfactory grade of water.[2] Prefiltering of distilled water through a charcoal cartridge followed by ion-exchange and filtering through μm pore-size Teflon filters is a suitable and more convenient alternative, since storage is obviated. In this case ion-exchange combined appropriately with prefiltering through charcoal or subsequent high-temperature pyrolysis is used to remove both trace metals and traces of organic impurities as well.

Recently Oehme and Lund[3] made comparisons of the quality of water prepared by (1) a central demineralization system, (2) distillation in a standard Pyrex still, (3) double distillation of tap water in an all-quartz still, and (4) a Milli-Q water system (Millipore Corporation). The water samples were analysed for copper, lead and cadmium by differential-pulse anodic stripping voltammetry. Their results[3] are reproduced in Table 2. Details of the analytical procedure were reported elsewhere.[4] These investigators found that centrally demineralized water and the product subsequently distilled in a normal Pyrex vessel were of comparable quality with respect to the metals tested. Double distillation of tap water in a quartz apparatus gave water that was substantially purer than the products from methods (1) and (2).

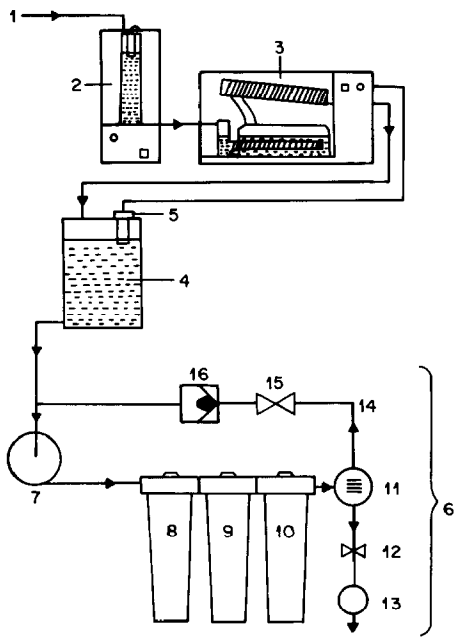

Fig. 1. Water purification system recommended by Oehme and Lund.[3] 1, Inlet for centrally demineralized water; 2, flow-controller; 3, conventional Pyrex water still; 4, polyethylene tanks as water reservoir; 5, pressure switch; 6, Millipore Milli-Q system; 7, pump; 8, activated-carbon filter cartridge; 9, 10, ion-exchange cartridges; 11, resistivity meter; 12, ball valve; 13, membrane filter; 14, recirculation path; 15, flow controller; 16, check valve.

It was stated (but not verified by analysis) that the trace organic impurity level of water produced by method (3) was also reduced. However, the relatively low production capacity of the double-distillation procedure (~2 l./hr) and interim storage of the water produced are cited as main disadvantages. The purest water with respect to the metals tested for was produced by the Milli-Q system. Oehme and Lund recommended the purification system shown schematically in Fig. 1. The feed water for the Milli-Q system was first centrally demineralized and then distilled in an ordinary still. Direct processing of centrally demineralized water through the Milli-Q system was condemned by these investigators, who experienced almost irreversible breakdown of the system, owing to suspended matter, gelatinous materials and slime from centrally demineralized water.

Mercury-cathode electrolysis

Electrolysis at the mercury cathode has been recognized for decades as being potentially extremely effective for purifying aqueous solutions of various reagents.[5] Practical use of the technique for reagent purification has increased considerably in recent years, owing to the availability of relatively inexpensive and convenient commercial apparatus optimized for treatment of several litres of reagent solutions. The ESA Model 2014P Reagent Cleaning System introduced by Environmental Sciences Associates is shown schematically in Fig. 2. The apparatus consists of a 4-litre reagent flask (usually a borosilicate glass vessel), a separate electronic console used to set the potential to values down to −1.5 V *vs.* the Ag/AgCl electrode, a reference electrode, and a counter-electrode. The nitrogen inlet passes a constant flow of inert gas through the solution to displace oxygen and

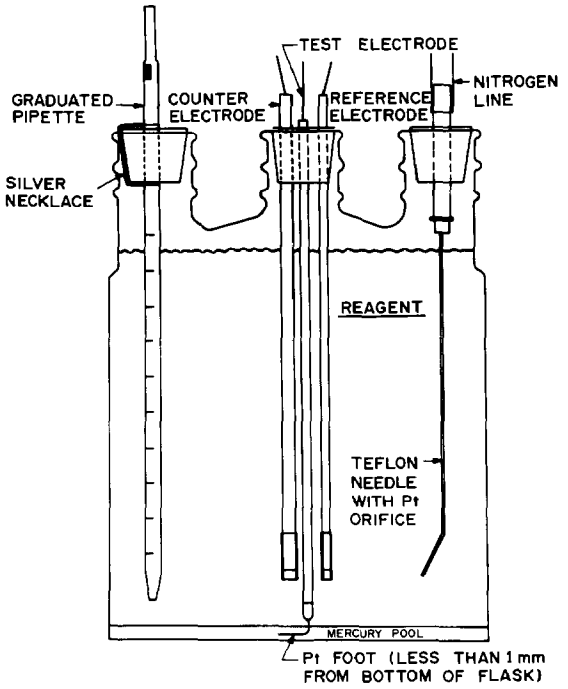

Fig. 2. Schematic diagram of mercury-cathode electrolysis apparatus.

to provide a non-contaminating method of mixing. Procedures for the use of this system and a comprehensive practical guide to reagent purification by mercury-cathode electrolysis were reported recently by Mitchell and McCrory.[6]

An improved apparatus, shown in Fig. 3, is provided by Princeton Applied Research, Princeton, New Jersey. This apparatus has the added conveniences of a levelling bulb for adjustment of the mercury volume, and stopcocks for removal of either mercury or pure reagent without opening the apparatus to the atmosphere or shutting off the applied potential. When the desired degree of purification has been obtained, the levelling bulb can be lowered so that there is no mercury in the side-arm of the solution drain. The solution can then be dispensed through the drain tube with the potentiostat still on and electrolysis maintained. In this way amalgamated impurities are prevented from being spontaneously released from the mercury pool to recontaminate the solution.

In principle, any reagent soluble in water can be purified by electrolysis at the mercury cathode, provided its component ions are not electroactive at the applied cathode potential required for reduction of the impurity ion. Electrochemical inertness at the anode potential is also required. Additionally, the reagent solution must be chemically inert with respect to reaction with mercury (including dissolution of the mercury). Solutes consisting of any combinations of the cations and anions in Table 3 can usually be purified.

Removal of electroreducible trace transition-metal cations from solutions of the salts of alkali, alkaline-earth and many rare-earth metals can be accomplished especially well. The cations listed in Table 4 can generally be effectively removed from aqueous solution by reduction to the metal and amalgamation at the mercury cathode. Electrolysis thus becomes the method of choice for the ultrapurification of various analytical buffers, fusion fluxes, masking agents, and supporting electrolytes. Sodium or potassium salts of acetic and boric acids, potassium hydrogen phthalate, mono- and dipotassium hydrogen phosphate, and the popular supporting electrolytes, sodium and potassium chloride and perchlorates can be ultrapurified. The concentrated solutions of the purified products are then used in chemical analysis procedures. The direct use of solutions eliminates the need to recover the solid product, a process plagued with problems of contamination from particulates and also from containers required for drying solids by heating.

In practice, effective electrochemical purifications can often be precluded by the chemical reactivity or excessive solubility of mercury in the reagent solution undergoing electrolysis, by simultaneous cyclic reactions of impurities at the cathode and anode, by nonformation of an amalgam, and by complexation of impurities to form difficultly reduced species.

Various techniques have been used to monitor mercury-cathode electrolysis and to establish its efficiency for removal of elemental impurities. Current–time monitoring,[5] gamma-ray spectroscopy of radioisotopes,[6] differential-pulse polarography[7] and stripping voltammetry[7] have been used to establish conditions for the purification of solutions of sodium hydroxide, sodium acetate, sodium carbonate, and components of phosphate buffer solutions.

Conditions found to be effective for impurity removal during small-scale radiotracer studies at the author's laboratory have been used on a larger scale for purification. Three litres of 1.0*M* sodium acetate solution were purified by using the apparatus shown in Fig. 2. The results reported in Table 5 demonstrate that the already reasonably pure reagents were further purified during a reasonably short electrolysis period of 40 hr. It has also been possible to prepare kg quantities of ultrapure sodium and calcium carbonates by mercury-cathode electrolysis of solutions from which these carbonates were subsequently precipitated by high-purity ammonium carbonate. More recently the mercury-cathode electrolysis of concentrated solutions of EDTA was monitored by induction-coupled plasma emission spectroscopy.[8]

To perform continuous rather than batchwise mercury-cathode purifications, Haapakka and Kankare[9] designed a flow-through cell and tested its efficiency for removing Cu, Pd, Cd and Zn from 0.1*M* sodium acetate buffer solutions. General applicability to electrolyte purification was suggested. However, the low throughput rate, 1 ml/min, of the flow-through cell offers little or no time advantage over the batchwise process, which produces up to 4 litres of purified solution within about 40 hr.

Table 3. Cations and anions purifiable by mercury-cathode electrolysis

Cations		Anions

Sub-boiling distillation

The best method available for preparing concentrated, high-purity, high-boiling acids (nitric, sulphuric, hydrochloric, perchloric) was reported in 1972. The purification is based on quiescent evaporation of the liquid by infrared heating at the surface to prevent violent boiling. This technique, described in detail by investigators at the National Bureau of Standards, is commonly referred to as sub-boiling distillation.[10] A schematic diagram of the apparatus is provided in Fig. 4. Acids of extremely high purity are produced by multiple batchwise distillation of reagent-grade acids in the vitreous silica apparatus, which is placed in a laminar-flow hood. Hydrofluoric acid has been distilled in a still fabricated from polytetrafluoroethylene and heated by electric resistance heaters sealed inside a glass tube [inserted into a Teflon (TFE) rod].[11]

The efficiency of this process for removal of dissolved trace metals results from the preclusion of the formation of fine particles of spray or droplets of the originally impure liquid, which could otherwise be swept through the apparatus and contaminate the distillate. A high-purity product is thus afforded simply by the non-violent surface evaporation of the liquid. In this way any liquid reagent is vaporized completely before transport into the condenser.

Maintaining the purity of the distilled product requires careful execution of the entire process under controlled contamination conditions. Exhaustive cleaning of Teflon (FEP) bottles for containing the purified acids and storage at $-30°$ are required in order to retard contamination during storage. Under proper conditions, acids with residual impurities at the level of only fractions of 1 ng/g have been pro-

Table 5. Purification efficiency of Hg-cathode electrolysis

Reagent	pH	Electrolysis period, *hr*	Conc. of cation in solution,* *ng/ml*

In	0.01	Ca	0.06
Cd	0.02	K	0.5
Ag	0.03	Mg	0.6
Sn	0.01	Na	1.0

duced (they were analysed by stable-isotope dilution mass spectrometry).[10] Data representative of the impurity level of various sub-boiling distilled acids are given in Table 6 for hydrochloric acid.

Isopiestic distillation

Isothermal (also called isopiestic) distillation[12,13] can produce volatile acids of medium concentration in high-purity form. Hydrochloric, hydrobromic, acetic and hydrofluoric acids can be produced. The pure acids are generated from reagent-grade material by placing an open container of concentrated reagent-grade acid adjacent to a container of pure water, within a closed system (such as a large desiccator). Acid vapours are continuously transferred into the pure water until equilibrium is obtained. This isopiestic distillation is the room-temperature version of the sub-boiling method (which it preceded) and produces a highly pure but medium strength product. Ammonia solution can also be produced, and preparation of 30% hydrofluoric acid (in 4 days), 6*M* hydrochloric acid (in 3 days) and 4.5*M* ammonia solution is routinely performed in our laboratory.

High-purity water can also be charged with pure hydrogen chloride, hydrogen bromide or hydrogen fluoride gas to prepare acids of any desired concentration. Standard apparatus constructed of polyfluorocarbon vessels has been reported for preparation of acids.[2] An essential component is a 0.45-μm Teflon filter at the outlet of the cylinder, to remove particulate matter. Preparation of hydrofluoric acid containing only 0.08 ng of lead per g has been described by Tatsumato.[14]

Low-temperature sublimation

With the exception of the lyophilization of water (freeze-drying) to obtain dry products, the potential of the sublimation technique for purifying reagents existing as liquids under ambient conditions was not recognized before the reports by Mitchell.[15] When confronted with the problem of ultrapurification of several extremely reactive, hygroscopic, corrosive, and toxic analytical reagents and research chemicals, Mitchell undertook a systematic investigation of the sublimation of liquids at temperatures and pressures below the triple point. Laboratory tests of a broad range of liquids showed that when frozen those in Tables 7 and 8 sublime easily, and in many cases as efficiently as the liquids can be distilled.

Table 7. Analytical reagents and solvents sublimable at low temperature

	M.P., °C	B.P., °C
Acetic acid (99%)	16.6	118.5
Ammonia (15%)	—	—
Benzene	5.5	80
Bromoform	8.3	149.5
Carbon tetrachloride	−23	76.8
Cyclohexane	6.5	80.7
Dioxan	11.8	101
Formic acid	8.4	110.7
Hydrazine (95%)	1.4	113.5
Hydrogen peroxide (15%)	0.5	150
Water	0	100

The primary practical advantages of low-temperature sublimation in comparison to distillation are all due to the much lower temperatures that are used. Major advantages include (1) significant reduction in problems of contamination by the container because of the greatly reduced chemical reactivity of liquids at low temperature, and (2) extraordinarily high decontamination factors for removal of dissolved ionic species from solution. Where applicable, such species can be captured on ion-exchange resins or complexed with chelating agents. The pure reagent or solvent can then be readily sublimed, leaving the impurities behind. Another practical and very important advantage is derived from the fact that any solid particulates originally present in chemically reactive or corrosive liquids remain undissolved during low-temperature sublimation, whereas they could dissolve under the conditions of distillation. A growing body of evidence has been reported from this laboratory, showing that a significant percentage of the total metallic impurity content of liquids and solids is due to impurities present in the particulate matter contaminating the reagent.[16–18]

Perhaps the most significant advantage of low-temperature sublimation is its simplicity. The apparatus shown in Fig. 5 is made of fused silica and Teflon. The reagent to be purified is frozen as a thin shell on the interior of the round-bottomed flask by rotating it in a suitable cooling bath. The flask is then attached

Table 8. Some inorganic halides sublimable at low temperatures by modified chemical vapour deposition

	M.P., °C	B.P., °C
Antimony pentachloride	2.8	79

to the remainder of the assembled apparatus, which is located in an all-plastic exhaust hood in a clean-room. The assembled vessel is then evacuated continuously with a mechanical pump which maintains an equilibrium pressure of a few mmHg. Under the continuous evacuation there is a mass-flow of vapour from the round-bottomed flask into the cylindrical vessel (submerged in a cooling bath) where the sublimed product is isolated. This self-contained reagent purification system can be easily fabricated in a modest glass-blowing shop and operated batchwise as easily as an ordinary distillation apparatus.

The efficiency of the method for the purification of hydrogen peroxide was determined experimentally by processing the 15% reagent doped with 1000 ng/ml of each of the impurities Co, Cr, Cu, Fe, Mn, and Ni.[19] X-Ray fluorescence analysis of the sublimed sample (8.5% H_2O_2), with use of a high-sensitivity co-precipitation method, showed all impurities to be below the detection limit of 0.1 μg/ml. A sample with the same carrier level of impurities (1000 ng/ml) was therefore doped with the radioisotopes, ^{51}Cr, ^{60}Co, ^{59}Fe, ^{54}Mn and ^{65}Zn and was found to contain these metals at less than 1-ng/ml level after a single sublimation. Direct analysis of another sample by neutron activation showed decontamination factors of 1100, 2700, and 320 for Mn, Co and As, respectively.

The exceptional purity and convenient processing available with this technique have been further demonstrated by treatment of aqueous hydrazine. Analytical data showing the reagent to be a high-purity and generally applicable reducing agent have been reported.[20] Analytical results obtained for analysis of several chemicals after purification by a single sublimation are reported in Table 9. This method is indeed a powerful purification tool for the trace analyst. As indicated, excellent purity is attained for hydrogen peroxide and hydrazine, two extremely useful analytical reagents for adjustment of oxidation states in trace analysis.

Purification of certain solids by sublimation under vacuum and at elevated temperature continues to be an extremely effective practical approach to the purification of various reagents. Free-flowing pure crystalline products are often generated by subliming solid chunks of reagent-grade material or a product prepurified by zone melting. The preparation of pure phosphoric acid from sublimed phosphorus pentoxide is a noteworthy analytical application. A novel low-cost procedure for the preparation of P_2O_5 in kg quantities has been reported.[21] A product was prepared which had elemental impurity levels in the ng/g range. Phosphoric acid of comparable purity was then obtained simply by dissolving the solid with a 3:1 (or higher) molar ratio of pure water.

Other techniques

Zone refining. Zone melting has not found widespread application in the trace analysis laboratory but is occasionally the method of choice for purification of selected reagents. A vertical zone melter suitable for the purification of organic and inorganic compounds melting at temperatures ranging from −10° to 300° has been designed.[22] Primary-standard benzoic acid[23] and 8-quinolinol[24] have been purified in this way. Systematic investigations of the use of zone melting to purify various metal chelates have also been conducted.[25]

Solvent extraction. Powerful broad-spectrum extractants find use in prepurification of aqueous reagent solutions for subsequent use in analysis. For example, a high-purity stock solution of dithizone in chloroform is an excellent extractant for the purification of aqueous salt solutions used as buffers or electrolytes in determination of trace elements reacting with dithizone. Reagent-grade salts of cations nonreactive with dithizone are purified by dissolution in high-purity water, filtration through 0.2-μm cellulose acetate membrane filters, and extraction two or three times in a Teflon (FEP) separatory funnel after proper adjustment of pH. After several washes of the aqueous solution with chloroform the salt solution has unusually low blanks for the elements Mn, Fe, Co, Re, Ni, Pd, Pt, Cu, Ag, Au, Zn, Ce, Hg, Ga, In, Tl, Sn, Pb, Sb, Bi, Se, Te and Pd. Aqueous solutions of alkali and alkaline-earth metal salts are especially well purified. Similarly, any reagent salts used in procedures for extractive photometry or atomic absorption can be purified first by extraction with the extractant to be used. This conventional use of extraction is a well known and often used approach to analytical purifications.[26]

Gas, liquid and column chromatography. Advances are still occurring in the design of laboratory-scale

systems for isolating compounds by gas chromatography. However, there has not been even modest use of GC for preparatory-scale purifications in analytical laboratories, owing to several factors, including economics, convenience, and low production capacity. Scaled-up HPLC methods should, however, find applications for solving complex analytical purification problems. Useful applications for removal of by-products and other interfering trace impurities from spectrophotometric reagents can be predicted.

There have been many applications of conventional column (absorption or adsorption) chromatography for purification. Two similar approaches to the removal of ultralow levels of iron from reagent salt solutions were introduced by Schilt and Lundgren[27] and by Willis and Sangster.[28] The first method removed iron(II) from aqueous reagents by complexation with a highly selective ligand sorbed onto porous polystyrene–divinylbenzene co-polymer beads (coated column method). In the second method 1,10-phenanthroline was added to the aqueous solution containing iron impurities and the mixture was then flowed over the same type of porous polymer beads (uncoated column precomplex method).

Harris and Williams[29] recently evaluated both methods quantitatively by determination of iron in solutions of hydroxylamine hydrochloride and ammonium acetate purified by both methods. They were able to optimize conditions for the superior purification method (the precomplex procedure) because of their excellent performance of extremely precise and accurate quantitative determinations of iron at the sub-ng/ml level. Their results are shown in Table 10. These investigators concluded that (1) the precomplex procedure is a highly effective purification technique, (2) it should be readily applicable for removing iron from most non-complexing neutral salts, and (3) under proper conditions the general method can be made applicable to the removal of any cation for which a highly selective ligand exists that has sufficiently significant aromatic character for it and its metal chelate to be exclusively partitioned into the column-bead phase.

Direct synthesis. Occasionally analytical reagents can be synthesized directly under conditions that generate a solution of the ultrapure reagent. Ammonium 1-pyrrolidinecarbodithioate, an important extractant for preconcentrating trace elements for determination by atomic-absorption spectroscopy, is a typical example. We have synthesized this reagent in pure form from fractionally distilled pyrrolidine, carbon disulphide, and isopiestically distilled ammonia. The free acid has a much greater solubility in chloroform than any corresponding salt. The acid can be prepared conveniently by dissolving the purified reactants in chloroform.[30] When a few gaseous or liquid starting reagents can be easily prepurified and subsequently reacted to produce a desired product, direct synthesis under conditions of controlled contamination is a viable laboratory ultrapurification method.

PURIFIED REAGENTS FOR TRACE METAL ANALYSIS

JOHN R. MOODY and ELLYN S. BEARY
U.S. National Bureau of Standards, Center for Analytical Chemistry, Inorganic Analytical Research Division, Washington DC 20234, U.S.A.

(*Received* 14 *June* 1982. *Accepted* 23 *June* 1982)

Summary—Sub-boiling distillations have become a standard tool for the reduction of the inorganic analytical blank. More than 10 years of practical experience in the production of reagent acids is reviewed and a description is given of a new laboratory especially designed to permit trouble-free operation as well as ensure the continued high quality of the reagents produced.

In the present-day real world of trace element analyses, the theoretical or even practical sensitivity limit of the instrument is very often not the limiting factor in the accuracy of an analysis. Instead, the size and variability of the analytical blank is the principal limitation. Many techniques for improving analytical accuracy are concerned with the reduction and control of this blank through all steps of the process, from choosing containers, right through to the final analytical measurement. While many of the important individual steps in attempting to control the blank have been recognized and even practised for many years, it is the purpose of this paper to review the present state-of-the-art in contamination control in trace and ultratrace analytical chemistry with particular emphasis on the production of purified reagents.

As shown by Murphy,[1] sample-contamination may be caused by the method of handling or containment, by apparatus, by the use of analytical reagents, by the environment in which the sampling or analysis is performed, and even by the presence and influence of the chemist. By its very nature, trace or ultratrace analysis may be significantly influenced by all of these sources of contamination. The specific means used to reduce the analytical blank may vary from element to element but the use of clean-air Class 100 laboratories[2] and purified reagents has become a common denominator for present day analysis. A particularly useful compilation relevant to the use of apparatus in contamination control has been published by Zief and Mitchell.[3]

In general, all other factors being equal, there is rarely a trace analytical scheme which could not be improved by the use of better analytical reagents. Commercial high-purity acids may be better than reagent-grade acids but they are not sufficiently pure for the most demanding work.[1] The method of sub-boiling (or non-ebullient) distillation has been employed at NBS for more than 11 years in the production of more than 2800 litres of purified reagent acids and solvents.[4] Despite the appearance of a number of papers on the subject, we continue to receive numerous requests for reagents, information, and practical advice each year. Although the reagents to be described are prepared on a routine basis in a number of laboratories, it is obvious that the technique has not become widespread. It is hoped that the information presented here will enable the reader to prepare these high-purity reagents.

At least for trace analysis, the subject of analytical losses is related to the problem of contamination. A frequent mechanism of analytical losses is related to the acidification of a sample to stabilize it. Improperly acidified samples may lose cations through hydrolysis or adsorption on the container walls. Some aspects of this problem have been reviewed by Maienthal and Becker.[5] Most analysts hesitate to strongly acidify samples being held in storage, because of a blank problem associated with either the acidification or the subsequent neutralization. More strongly acidified samples also require more scrupulously clean apparatus and containers because of possibly increased rates of trace-element leaching. With a supply of reagents of adequate purity, the analyst does not hesitate to take the steps necessary to ensure stability relative to adsorption losses.

Sub-boiling distillation

Conventional fractional distillation presents a number of difficulties in purifying reagent mineral acids for trace-element analysis. Usually the apparatus itself will be constructed of glass, a material that is not conducive to the attainment of low trace-metal blanks. The most important parts of the still, in this respect, include the condenser, condensate feed line and the receiver. The use of quartz in these parts helps to reduce trace-metal blanks. However, the key to lower analytical blanks does not appear to lie in seeking a greater number of theoretical plates but rather in seeking a different distillation process.

Most problems associated with the distillation process are mechanical in nature. Among these is the "creep" of liquids up the walls of the still-pot, where they may be partially entrained by vapours rising into the condenser. The boiling process itself is violent in nature, producing an aerosol of the still-pot liquid which is then entrained into the condenser. By either

means, the result is the contamination of the distillate with liquid directly from the still-pot.

One means that has been used to overcome this difficulty is isothermal distillation.[6] This process was used at NBS before the advent of sub-boiling distillation and may still be useful to many laboratories today. In principle, if containers of volatile acid and of distilled water are placed in a sealed chamber, acid vapour will be absorbed in the distilled water until an equilibrium vapour pressure is reached. The purity of the distilled water and purity of the container largely determine the quality of reagent produced.

In a more practical sense, reagents which can be produced by this method are dilute and the "distillation" rate is rather slow, being a function of the volatility of the acid. Purified hydrofluoric acid can be produced in a plastic chamber. Obviously, the use of any metal parts anywhere around the apparatus will lead to corrosion products which ultimately contaminate the acid produced.

In 1971, scientists at NBS and the Carnegie Institution became aware of a new still being produced by the French firm of Quartz et Silice*. Although initially marketed for the production of high-purity distilled water, the still became known for its ability to produce reagent acids of the highest purity. The term sub-boiling distillation was coined and the first publication was produced by 1972.[4] Since then, a number of publications have dealt with some aspect of the non-boiling principle, including the "two bottle" still by Mattinson[7] and the polypropylene still by Dabeka *et al.*[8] More recently, a Teflon analogue of the quartz sub-boiling still has become commercially available. Very similar to the original NBS design, the present version is based on the work of Tschöpel *et al.*[9]

Production and analysis of sub-boiling distilled acids

The Quartz et Silice stills have been sold in the U.S.A. under the model designations of PB-5, PB-10, and PB-15. All three stills have been used at NBS, the only significant difference between them being that of size and the resulting rate of distillation. The model PB-15 is used as our primary source of distilled water. By using a variable autotransformer it is possible to vary the distillation rates over a wide range to suit needs, or to select a distillation rate which will fill a container in a given period of time. Distilled water prepared in this manner is stored in 8-litre quartz flasks. With an input power of ~500 W it is possible to prepare about 20 litres of distilled water per day.

Normally, the rate of distillation is kept at a lower level that approximately matches the rate of consumption. The PB-15 is used solely as a redistiller to "polish" a supply of distilled (not demineralized) water which has trace-element blanks at the ng/g level or below. For this reason, it is also the only distillation process at NBS which does not run on a batch basis. After a period of trial and error, we have found that a Teflon needle valve may be used to regulate the flow of ordinary distilled water into the PB-15 still. The valve is adjusted to give an overflow from the still at 3–4 times the rate of distillation at the highest routine rate from the PB-15 still. Under these conditions, the quiescent conditions of the sub-boiling distillation process are preserved. Too great a rate of overflow causes a marked decrease in the rate of distillation since most of the heat is being conducted to the drain. In over 5 years of continuous use under these conditions, absolutely no build-up of scale or dirt has been found in the still-pot. Of course, a poorer quality of distilled water feedstock could change this observation. The still itself is supported by "Plexiglas" inside a metal-free Class 100 clean-air chamber.

Table 1 summarizes the power input and other requirements for the distillation of the common mineral acids. The power requirements are slightly different from those published by Kuehner *et al.*[4] and the distillation rates listed are also different for some reagents. Part of this difference is because the present rates are calculated for a double distillation process whereas the original values were for a single distillation.

The high-purity acids are all produced from reagent-grade acids and the distillates have essentially the same concentration as the reagent-grade acids, except for hydrochloric acid and sulphuric acid. To distil hydrochloric acid, dilution with distilled water is required to avoid the violent evolution of hydrogen chloride. In the beginning, these distillations were made with the constant boiling (6*M*) acid but experience showed that this concentration could be raised safely to 10–10.5*M*. At higher concentrations than this bubbling can be observed during the distillation, and contaminates the reagent produced.

Sulphuric acid is distilled as the concentrated reagent, but it has such an affinity for water that the

This does not imply recommendation of endorsement by the National Bureau of Standards, nor does it imply that the materials or equipment named will necessarily be the best available for the purpose.

slow permeation of water vapour through the Teflon walls of the storage container soon causes the dilution of the acid to a slight degree. In addition, both nitric acid and perchloric acid may undergo some degree of decomposition if elevated power levels are used. At the recommended power levels, the degree of decomposition is slight and no instance has been reported of an interference in trace analytical procedures.

All distillation rates are nominal and have been observed to change considerably during the year as the temperature of the tap water used for cooling the condensers varies (by about 15° from summer to winter in Washington, DC). As might be expected, the distillation rates and/or the power levels required are in accordance with the volatility of the acid being distilled. Distillation rates for hydrofluoric acid are limited by the temperature limit of the Teflon used to enclose the heating element.

It should be noted here that the original NBS Teflon still had a serious design flaw. In time, sufficient hydrogen fluoride gas diffused through the Teflon heater to attack the quartz tube used to contain the Nichrome heating element. As the quartz was dissolved, the hot metal came in contact with the Teflon, causing it to cold-flow and ultimately perforate about 3 years after it was constructed. A modified heater has been successfully used for the past 8 years. A nickel liner is inserted inside the Teflon heater tubes and then the Nichrome wire heating-element is placed inside a quartz tube to insulate it electrically from the nickel insert. An additional safety factor of lower power settings may also have been of benefit, but in any case no cold-flow has so far been observed in the heater elements.

For sulphuric acid, pieces of platinum foil have been used to reflect infrared radiation back into the still and enhance the rate of distillation. In addition the angle of the condenser relative to the liquid surface has been increased slightly to permit the more viscous sulphuric acid to flow more easily down the condenser to its tip.

A two-stage or double-distillation technique was started in 1971, became routine by 1974, and has been the only method of production since 1976. Figure 1 details this procedure. One still is modified slightly to accept a Teflon (FEP) tube which is run to the next still through a Teflon T-valve. In use, the first still is charged with reagent acid and the product is distilled into the second still. When the second still has become charged with sub-boiling acid from the first still, it is turned on and the distillate is collected in a 2-litre Teflon (FEP) bottle.

A 2.7-litre reagent-acid bottle provides sufficient acid to charge the first still and enough distillate is produced to charge the second still and yield 2 litres of doubly distilled acid. Afterwards, both stills are drained and the process is repeated. The rates of distillation in Table 1 are about 15% less than would be achieved by a single-stage distillation. All of these distillations are batch distillations.

We are frequently asked if the use of commercial high-purity acids as starting materials would result in the production of higher purity acid. The two-stage distillation permits a direct answer to this question since the results of this distillation process are not discernibly better than the single-distillation results reported in 1971.[4] Thus, the use of better starting materials will not alone guarantee better results. The double-distillation process was adopted as a means of guaranteeing that no accidental contamination of the starting material (because of deteriorating laboratory conditions) or human error could affect the quality of the distilled acids. This approach appears to be valid since in the entire 11 years of production not a single instance of trace-element contamination has been discovered. For some elements, such as lead, the double-distillation process is believed to be of some benefit. In theory, the factors limiting the quality of the dis-

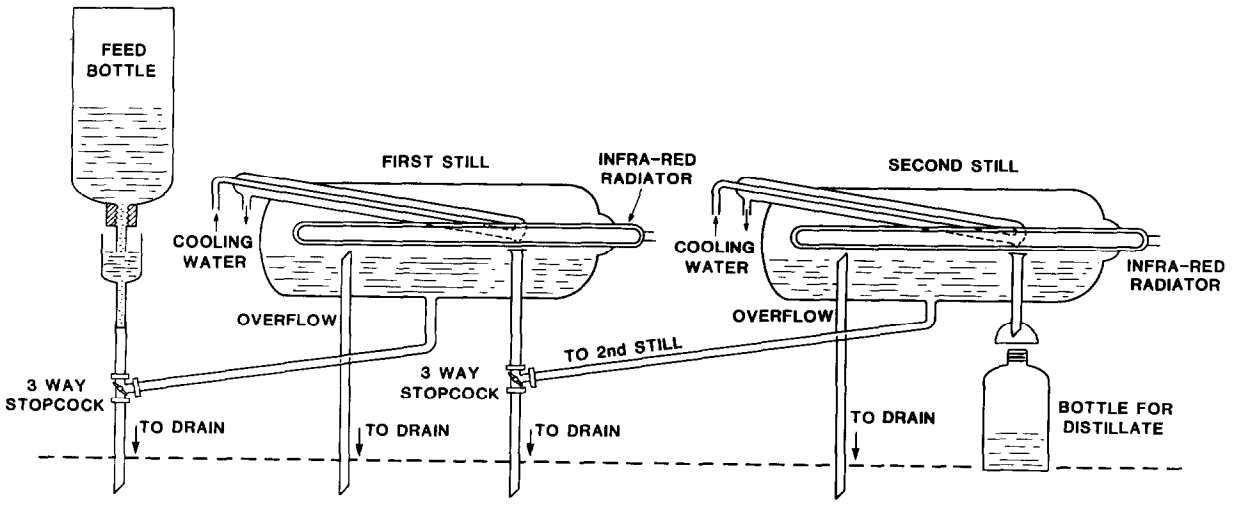

Fig. 1. Schematic diagram of apparatus for double sub-boiling distillation.

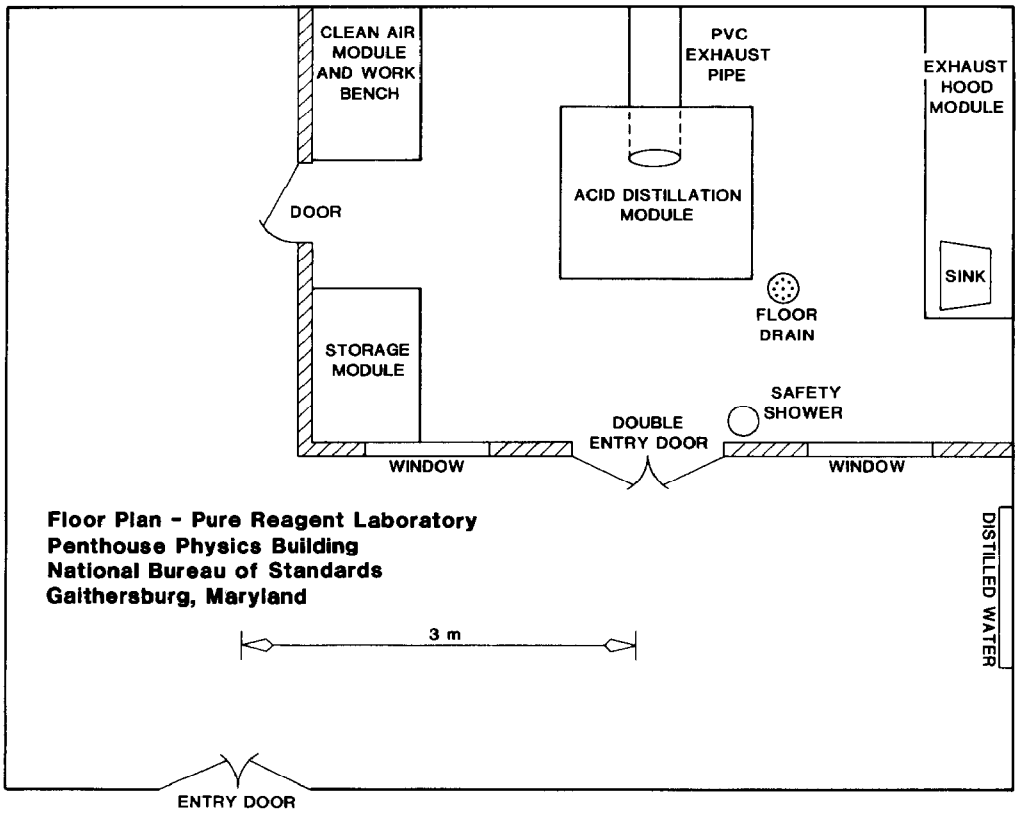

Fig. 2. Floor-plan of pure-reagent laboratory.

tilled reagents should be the purity of the quartz condenser and the Teflon storage container, and the volatility of some inorganic compounds.

Nearly all our stills have benefited from many years of leaching by acids and many of our Teflon containers have had the same continuous leaching by high-purity acids. There has even been a significant improvement in the past few years in the apparent quality of the commercial Teflon (FEP) bottle, as judged by the reduced number of inclusions observed within the bottle walls. Despite all this and the double-distillation process, no general improvement in the quality of the purified acids has been found. As described by Kuehner *et al.*,[4] the method of analysis for trace metals continues to be isotope-dilution spark-source mass-spectrometry (ID–SSMS). Some 18–23 elements are determined simultaneously, this number being limited only by the number of separated isotopes available. The results of the double-distillation process shown in Table 2 require some explanation relative to the method of analysis.

Isotope-dilution analysis is generally considered to be one of the most accurate methods available for the concentration levels concerned. For the analysis of these high-purity materials, a fixed amount of 0.1 μg of every separated isotope of interest is added to 100 ml or more (for higher purity materials) of the sample. The mixture of sample and the spike isotopes is evaporated to a single drop under Class 100 conditions. This drop is transferred to gold electrodes or mixed with gold powder to form a suitable electrode for use in SSMS. For many elements, no detectable

Na	0.8	0.7	1.2	4.0	6
Total	6.0	2.7	9.0	14.4	20.6

amounts of natural (non-spike) isotopes are found. In such a case, the ratio of noise level of the baseline (electrical detection) or the fog level of the photoplate (photographic detection) and the measured intensity of the separated isotope is used to calculate a concentration.

Such results are called upper limit numbers, which is to say that the true trace-impurity levels are less than the number reported. Discrepancies between the results shown in Table 2 and those reported by Kuehner *et al.*[4] are quite likely, for this reason. When necessary, the exact concentrations of a number of elements such as Pb, Cd, Ag, U, have been determined and found to be as low as a few pg/g (10^{-12}g/g). Even then, many of these results may be distorted by the evaporation blank, which is not easily evaluated. Rather than make possibly exaggerated claims for a given lot, we give the results reported in Table 2 as conservative averages of 10 years of determinations. Routine analytical blank determinations for our analytical work provide an excellent means of constantly monitoring the high-purity reagents between the periodic ID–SSMS analyses.

Preparation of clean bottles, and reagent storage

Relatively little has changed in the past 11 years in this regard, although some experimental work by Moody and Lindstrom[9] has shown that the cleaning methods used are adequate. Many who undertake the production of their own reagents fail to take into account the time and the extent of cleaning necessary to produce the requisite clean Teflon (FEP) (fluorinated ethylene–propylene) bottles. A similar effort is necessary to ensure quality control throughout the cycle of reagent production, storage, and use. For example, we currently have almost 850 Teflon (FEP) bottles in circulation, used solely for high-purity acids.

New bottles are rinsed with alcohol or acetone followed by distilled water to remove surface grease and dirt. They are then immersed in glass vats in boiling hydrochloric acid (1 + 1) for about 2 weeks. Next they are transferred to glass vats filled with nitric acid (1 + 1) and boiled for about 2 weeks. After this preliminary cleaning, the bottles are filled with high-purity distilled water and placed in a metal-free storage cabinet. This preliminary filling with distilled water leaches nitric acid from the Teflon and is presumed to perform some slight leaching of trace metals as well. The distilled water is changed once or twice over a period of several months. The bottles are then emptied, numbered serially by scratching the outside, and filled with the desired reagent. For quality-control purposes, the bottle is dedicated to that one reagent. Reagents are always poured from the 2-litre Teflon (FEP) bottles used to catch the distillate into one of a large number of clean bottles used for the storage of reagents. Transfers are then made from these stock bottles to the new bottles or to other bottles being returned for refill. This process guards against the accidental spread of contamination from a dirty bottle to other clean bottles of purified reagent and promotes the rotation of stock.

After the initial filling with purified acid, the bottle is placed in storage for one or more months to leach additional trace metals from the container wall. Afterwards the acid is discarded or redistilled and the bottle is refilled with freshly distilled acid. This process is repeated a total of three times before a bottle is considered to be clean enough for use. The complexity and the length of time involved in the complete process are somewhat arbitrary, but less than in some laboratories. In any event, the process does assist in the rotation of stock.

All the stills are run all day for more than 350 days per year. The constant demand for acid to be used for bottle cleaning assists in the rotation of stock and the maintenance of a fresh supply. Since our distillation capacity is greater than 1000 litres per year and our actual consumption is only ~250 litres per year, there is a temptation to distil only on demand, which would increase the age of the stock considerably. Although there is no direct evidence indicating that blank levels do increase with age, it seems prudent to avoid unnecessarily long storage times for any purified reagent. Moody and Lindstrom[10] obtained some data which would tend to support the likelihood of continued leaching. Ideally, any purified reagent should be consumed as quickly as possible.

Because our laboratory serves about 50 scientists at NBS and at least an equal number in other laboratories, it is not always possible to predict the rate of usage. We have compromised by keeping a modest stock which is easily maintained in fresh condition and which provides a buffer against temporarily high rates of usage. Fortunately, all this is consistent with keeping an adequate supply of clean Teflon bottles available for reagents or other analytical purposes. Complete records are kept of the history of usage of each bottle, to enable any potential source of contamination to be traced.

Laboratory and other refinements

During the past 11 years, we have prepared distilled acids in several NBS laboratories, and, as might be expected from the quantity of production, not without considerable difficulty. Nearly all problems have been associated with corrosion of metals within the laboratory, and a considerable effort was required to continue production without contaminating the reagents produced. The need for a specialized laboratory was clearly recognized by the mid-70s. Construction began in 1980 with completion in 1981. The new laboratory has been successfully operated for more than a year, so some useful comparative information can be given.

In the earliest days of acid production at NBS, metal clamps covered with Teflon tape backed by aluminium foil were used to support the stills, in combination with a similarly coated ring stand. This arrangement proved to be very unsatisfactory because

the metal soon corroded, requiring replacement in just a few weeks. Similar problems were observed for the clamps supporting the constant-level feed and reagent bottle. More recently, boxes were fabricated from "Plexiglas" to support the constant-level device and reagent bottle as well as to confine the fumes from them. These devices were serviceable but were difficult to adjust to compensate for changes in reagent-bottle sizes and hence the resulting liquid level within the still. In addition, the Plexiglas gradually darkened and deteriorated after prolonged exposure to perchloric acid.

These problems had to be overcome in the design of the new laboratory. The problem of adjusting the liquid levels within the stills was solved by using large poly(vinyl chloride) (PVC) bolts to adjust the height of a pair of bakelite brackets which were fabricated to support the stills. The thick bakelite does not appear to be adversely affected by years of exposure to fumes, does not produce particles, and tolerates (with some relatively inconsequential charring) the high temperatures required to distil sulphuric acid. Plexiglas and other thermoplastics may be used if the operating temperatures are kept below the softening points. The new arrangement permits the adjustment both of elevation and side-to-side as well as front-to-rear inclination of the stills. The maximum rate of distillation is achieved when the liquid level within the still is kept as close to the infrared heaters as possible.

Acid spills from the feed bottles, stills, and collector bottles were a major problem. In any operation of this type, it should be assumed that such spills are always possible. Because of human error, breakage, or electrical failures caused by corrosion, many spills occurred overnight and were not discovered for many hours. This caused further damage by contact with both liquid and fumes from the acids. A means had to be found to control or even prevent spills for the sake of both safety and equipment reliability.

The flooring in the new laboratory is a seamless resilient type chosen especially for its resistance to acid contact. A PVC material manufactured in the United Kingdom for clean-rooms would have been a better choice but it was prohibitively expensive. At the walls the covering rises 10 cm from the floor to contain spills and there are even raised coved entrance thresholds. The only penetrations through the floor are a floor drain and a glass pipe servicing a sink drain. The walls are made of concrete block sealed with epoxy paint, both for resistance to acids and to prevent particulation. A safety shower and a rubber garden hose for the rapid dilution and disposal of a major spill in the laboratory complete the safety equipment.

Other features of the laboratory are borrowed from experience with clean-laboratory design. A suspended ceiling with supports made of polyurethane-coated aluminium and panels made of plastic-laminated wood products is used. Light fixtures are made of aluminium painted with polyurethane paint. All furniture and storage cabinets are made of plastic-laminated wook products. All parts which might contact liquid, including the distillation module and a 2.5-m fume hood, are made of white PVC. A final precaution included the installation of all electrical equipment outside the laboratory, with vinyl-covered low-voltage wiring to power the stills and the hot plates for bottle cleaning.

Ventilation requirements

The original NBS acid laboratory had an air-exhaust capacity of $\sim 60\ m^3$/min, which gradually decreased to considerably lower values. This figure has proved to be grossly inadequate for the scope of work described here. After 9 years of experience in dealing with painted and coated metal surfaces in the presence of recirculating acid fumes, ample proof was obtained that no recirculation of air could be permitted and no metal surfaces could be adequately protected against prolonged exposure to acid fumes. Stainless steel exposed to acid fumes will corrode and produce particles within days. Even the air-filtration equipment, which was well protected, had a half-life of about 3 months when exposed to uncontrolled acid fumes in the laboratory.

Two basic principles were employed in the design of air-handling equipment for the new laboratory. First, the entire exhaust–air system was made of PVC for assured corrosion-resistance and long life. Commercial versions of PVC fans are available both in the United States and Europe. Commercial ductwork available in the United States is designed to be solvent-welded. Similar materials available in Europe are of at least equal quality and use flanges and Teflon gaskets to join sections together. Some of the solvent-welded joints have already proved to be leaky. In all other respects the system has been service-free and has performed as expected.

The second principle involved the means and balance of introduction of air into the laboratory. Three modular units each capable of supplying up to $75\ m^3$/min of Class 100 filtered air were integrated into the ceiling of the laboratory. The total exhaust capacity of the laboratory was fixed at $150\ m^3$/min by virtue of the fan-belt drives. The modular clean-air unit has adjustable solid-state speed controls. Two of the units were placed over the distillation module to create a Class 100 vertical air-flow area measuring 1.5×1.8 m. The total air-flow was adjusted to $\sim 80\ m^3$/min to give the distillation modules a slightly positive pressure with respect to the laboratory. All the modules were constructed of polyurethane-painted aluminium and had high-efficiency particulate (HEPA) filters with plywood frames and metal-free design. Thus, from the supply of air at the HEPA surface until the air is exhausted through the roof of the building there is no metal whatever in the system. The overpressure of Class 100 air ensures that no contamination can be introduced into the distillation module

when the doors to the distillation module are opened to service the stills.

A third clean-air module was used to form a vertical-flow clean-air bench for packaging. The air from this bench, plus the slight amount of leakage from the distillation module, serves as the supply air for a 2.5-m PVC exhaust hood. The air-flow from the third clean-air module was adjusted until the entire laboratory was at slightly negative pressure with respect to its surroundings. Although this causes the leakage of dirty air into the laboratory, it does positively prevent the leakage of acid fumes from the laboratory (which would recreate the same old problems). Thus, it is this balance of the air-flows which ensures that the lifetime of electrical equipment will be normal and that corrosion outside the laboratory will be minimal. In a large laboratory with very expensive equipment, this latter assurance is perhaps even more important than all other considerations.

To summarize, all the air entering the laboratory, except for small amounts of deliberate leakage, is filtered through HEPA filters. All of this air makes a single pass through the laboratory and is then totally exhausted. Linear air-velocities within the acid-distillation module are about 25 m/min and the flow is reasonably laminar, which assists in the prompt removal of fumes from this module. Overall, these characteristics have effectively reduced free fume levels in the laboratory to very low values, which ensures the safety of the chemists and the operational life of the equipment both inside and outside the laboratory.

Production of other reagents

Over the years a combination of need and curiosity has led us to attempt the sub-boiling distillation of a number of other reagents. Usually these reagents were characterized for only one or two trace elements. Thus, no general claim can be made for the total impurity level. However, since the distillation did improve the analytical blanks for the elements examined, it seems reasonable to expect a similar improvement for other elements as well.

The single-stage sub-boiling process has been used to purify the following reagents at NBS: acetic acid, hydrobromic acid, ethanol, methanol, isopropyl alcohol, benzene, pyridine, acetone, methyl isobutyl ketone, and small amounts of a few other solvents. It should be remembered that many organometallic compounds are reasonably volatile and thus the sub-boiling process may be considerably less advantageous than for mineral acids. Because all these materials are reasonably volatile, power inputs of about 100 W are more than adequate to produce distillation rates of 1–2 litres per day.

The so-called "two bottle" still described by Mattinson[7] could easily be called a poor man's sub-boiling still. The process involved is the same but the rates of distillation are much lower. Because the bottles are closed, a Class 100 clean-air environment is not necessary, although it would be helpful to have such an environment in which to open the "still". Fume production is also much less, but Teflon does "breathe", so the "stills" should be kept in a fume exhaust hood. Since the quality of the reagent produced is comparable with that from the sub-boiling still, only the slow rate of distillation has prevented a more general use of the device at NBS.

Occasionally such a small-scale need does arise; for example, we have attempted the preparation of fuming sulphuric and fuming nitric acid for more rapid wet digestions. By charging the receiver bottle with sub-boiling distilled acid and the still-pot bottle with reagent grade fuming acid, an equilibrium between the two is reached in a few days. By changing the charge of fuming reagent acid several times it is possible to obtain purified fuming acid with approximately 75% of the free SO_3 or NO_2 content of the reagent grade fuming acid.

However, there were several problems with the apparatus in this application. First, the Teflon walls of the bottles are so permeable to water vapour that the consequent dilution of the reagent is more than is tolerated for the intended use. In addition, both fuming reagents seemed to attack the Teflon slightly, since the residues left by evaporation were viscous and black, and considerable amounts of organic material were observed during the mass-spectrometric analysis of these acids. If this idea were to be pursued further, a quartz two-bottle still would be a logical choice.

High-quality ammonia solution is produced by passing filtered ammonia gas into a Teflon bottle of distilled water chilled in ice. If a 1-litre Teflon bottle is filled with about 600 ml of distilled water, it will be nearly full when the water is saturated with ammonia. When this material is combined with sub-boiling distilled acetic acid, solutions of acetate buffers of very low trace-metal content may be prepared. Reagents of this type are valuable in the use of Chelex resins as reported by Kingston *et al.*[11]

Summary and conclusions

This paper has addressed a particular aspect of the problem of analytical contamination. Contamination control for the reduction of analytical blanks has been recognized by a diverse group of authors over a number of years and the publications of Mitchell[3,12] and Murphy[1] exemplify this trend. Whereas Mitchell's contribution to this symposium reviews many methods of purification, this paper concentrates on the details necessary for a single method. We do not mean to suggest that sub-boiling distillation is a panacea for all analytical problems. However, the use of high-purity reagent acids is almost certainly universal among trace-element laboratories. No laboratory operating today can claim to be in the forefront if it does not either produce or have access to these reagents. It was for this reason that it was believed that an update of the paper by Keuhner *et al.*[4] would be

useful. We hope that sufficient practical detail has been given to enable any laboratory to duplicate our work without suffering through a learning experience.

CAUSES AND ELIMINATION OF SYSTEMATIC ERRORS IN THE DETERMINATION OF IRON AND COBALT IN AQUEOUS SOLUTIONS IN THE ng/ml AND pg/ml RANGE

K. GRETZINGER, L. KOTZ, P. TSCHÖPEL and G. TÖLG

Max-Planck-Institute for Metal Research, Institute of Materials Science, Laboratory for High-Purity Materials, Katharinenstraße 17, D-7070 Schwäbisch Gmünd, F.R.G.

(*Received* 14 *January* 1982. *Accepted* 24 *March* 1982)

Summary—The determination of very low levels of elements, in the ng/g and pg/g range, is very closely linked with different systematic errors causing considerable discrepancies in the analytical results for real samples. Main sources of these errors are blanks as well as losses of elements and compounds by volatilization and adsorption. In this paper, systematic errors arising from contamination of the sample solution by the vessels and the dust content of the air are demonstrated for determination of iron and cobalt at pg/ml and ng/ml levels in pure aqueous solutions by AAS with electrothermal atomization. Effective cleaning procedures are described for different vessel materials such as PTFE, quartz and glass. Blanks due to airborne dust can be substantially reduced by working on clean-benches in clean-rooms.

In the determination of extremely low absolute amounts of elements or element concentrations in the ng/ml and pg/ml range, *e.g.*, in high-purity materials, biological tissues and fluids, environmentally relevant samples or even in pure aqueous solutions, various systematic errors generally arise, such as blanks caused by contamination of the sample solution, mainly by the vessel itself, the reagents and airborne dust, or losses of trace elements by volatilization or by adsorption on the surface of the vessel.[1–6] With decreasing concentration of the element to be determined, the systematic error can prevail to such an extent that the analytical results become incorrect by orders of magnitude, as can clearly be seen from interlaboratory comparative control studies.[3,5] In addition, we have to take into account the ubiquity of the elements in question, and the anthropurgic contamination of the environment by technological and scientific activity.

Our knowledge of the sources of systematic errors and their effective elimination[7–10] is by no means sufficient, and there is an almost total lack of systematic investigation in this field. Some hints to the problems are hidden in the analytical literature, but are difficult to find.

In addition we have to learn that we are not allowed to transfer the knowledge gathered by solving one analytical task to another analytical problem or to other elements. Generalization is strictly prohibited in extreme trace analysis. Therefore, the analyst is faced with the troublesome, difficult and laborious job of gathering information piece by piece and using observations and experience in order to form a mosaic that reflects the situation clearly.

Though it is impossible to give here a fully comprehensive report on systematic errors, we should at least try to give an introduction to this field in connection with the so-called "multi-stage combined procedures" consisting of decomposition, separation, preconcentration and determination steps. These sophisticated procedures, which can easily be calibrated with aqueous standard solutions, are often used if there is a lack of suitable standard reference materials covering the extreme trace range.

The most important sources of systematic errors[4,6] inherent in these procedures are:

(1) incorrect sampling and sample storage;
(2) contamination by vessels, reagents and airborne dust;
(3) adsorption and desorption effects at the surface of the vessel;
(4) volatilization of elements, *e.g.*, mercury, arsenic, selenium, cadmium, and compounds such as oxides, halides, hydrides;
(5) matrix effects during excitation of the analytical signals for the determination;
(6) signal interferences by the background and signals from other compounds;
(7) errors in calibration from use of incorrect standards, unstable standard solutions and blanks.

Systematic errors are by no means easy to recognize and to reduce, when standard reference materials are not available. Interlaboratory comparisons, independent procedures with different techniques, testing of the procedure with radio-tracers, and use of absolute analytical procedures which need not be calibrated are helpful approaches.

As the most important systematic error is due to contamination, this paper is mainly concerned with this broad field.

Contamination

Contamination is mainly due to the reagents, the vessels and dust in the air. The possibilities for purifying solid reagents are very limited because laborious and sophisticated procedures are required, and the levels of only a few elements are decreased, while those of others might well be increased. Besides gases, only the acids commonly used in the laboratory can be easily purified to give very low blanks (in the range below 1 ng/ml), sub-boiling point distillation being used for the purpose.[11–14] In order to avoid blanks from the vessels we must use only very pure materials such as quartz, glassy carbon,[15] PTFE or polypropylene, and must avoid glass, a very impure material with a few main components and a lot of elements as impurities in the μg/g range. In addition, the surfaces of the vessels have to be cleaned very carefully by special techniques such as steaming[12,13] or leaching in very pure acids for some hours.[16–20] Rinsing with acids or water is not sufficient,[12,13] as will also be shown in this paper.

Blanks from airborne dust are restricted to a very low level by the use of clean-benches and clean-rooms[12,13,21–23] in which the air is filtered through a high-efficiency particulate-filter, reducing the dust level by 3–4 orders of magnitude compared with the air of a normal laboratory.

In continuation of an earlier investigation on zinc and magnesium[12,13] with respect to blanks from vessels, reagents and dust, element losses due to adsorption, and contamination of the sample solution during storage or simple working steps, *e.g.*, pipetting, filtration or evaporation, an examination of iron and cobalt, two elements with different levels of ubiquity, is described here. This work especially aims at the examination of the cleaning procedures for vessels made of different materials such as borosilicate glass, quartz and polytetrafluoroethylene (PTFE). Sources of errors and their elimination, simple working steps such as the filling and emptying of flasks by different techniques, as well as contamination during storage, are also investigated.

EXPERIMENTAL

Instrumentation

Perkin–Elmer model 430 double-beam atomic-absorption spectrometer, with HGA 76 graphite furnace and HGA 76B control unit, AS-1 automatic sampler (10 and 20 μl) and Perkin–Elmer 56 recorder, hollow-cathode lamps for Fe (Oriel, Darmstadt) and Co (Dr. Kern and Sprenger GmbH, Göttingen), and Perkin–Elmer graphite tubes, coated with pyrolytic graphite in our own laboratory. (For instrument settings see Table 1.) The vessels (see Fig. 1) for the automatic sampler had a volume of 2 ml and were made of borosilicate glass, quartz and PTFE in our own workshops. Isostatically pressed PTFE vessels were made by the Venus Kunststoff GmbH, Heidenheim, FRG. Each vessel was provided with a PTFE cover (see Fig. 1).

All experiments—if not stated otherwise—were done in clean-rooms on vertical-flow clean-benches with exhaust[12,13] or on a small horizontal-flow clean-bench (SLEE, London, U.K.). The sample vessels were handled with a pair of tweezers with special half-round grips made of PVC. The vessels were stored within a dust-proof "Plexiglas" box, fitted into holes in a PVC plate, and transported from the clean-room to the AAS room in a desiccator.

Standard solutions were dispensed from automatic micropipettes (Eppendorf Varipetten, Eppendorf Gerätebau, Hamburg, FRG). The solutions were homogenized (20–30 sec) by a small stirrer (type CuV-O-Stir, model 338, Hellma, Mühlheim, FRG) provided with a quartz rod (length 38 mm, diameter 3 mm) which was rinsed with doubly distilled water before and after use, and stored in a

quartz tube in a clean bench to avoid contamination. All preparation and handling was done on a clean bench unless mentioned otherwise.

Cleaning

All laboratory ware such as beakers, vessels, flasks, bottles, pipettes, stirrers *etc.* was cleaned by means of a special steaming apparatus,[12,13] shown in Fig. 2. In a 1–2 litre round-bottomed flask (6) acid (nitric or hydrochloric) or water is heated to boiling. The vessels to be cleaned are hung open end downwards on top of the quartz tubes (3) through which the vapour passes, thus washing the inner surfaces continuously, with fresh acid vapour for 4–6 hr and subsequently with water vapour for 1–2 hr. By this process the surfaces are not only cleaned very effectively but in addition are preconditioned in such a manner that the adsorption of traces of elements is substantially inhibited.

In some cases an ultrasonic cleaner (type TT3, 35-kHz, Bandelin Electronic K.G., Berlin, FRG) was used for cleaning purposes.

Table 2. Blanks

Detection limit	0.1	0.3

Reagents

Standard solutions, 2 mg/ml. Prepared in 500-ml quartz flasks from Titrisol solutions, (Merck, Darmstadt) and stored in polyethylene bottles.

Stock solutions, 1 and 0.01 μg/ml. Prepared daily by dilution of the standard solutions, in 20-ml quartz flasks.

Hydrochloric and nitric acids (subb.). Purified by sub-boiling point distillation[11–14] (quartz sub-boiling still, Heraeus Quarzschmelze GmbH, Hanau); for specification of the purity see Table 2.[12]

Doubly distilled water. Prepared by means of a quartz double still, type BD15, with quartz storage bottle (10 litre), (Westdeutsche Quarzschmelze, Geesthacht).

All vessels were cleaned by steaming.

RESULTS

Calibration curves for iron and cobalt

The sample solutions were prepared directly from the stock solution by dilution in the sample vessels with water and 10*M* hydrochloric acid (subb.) respectively. For each concentration a separate quartz beaker (2 ml), cleaned by steaming and then rinsing 3 times with doubly distilled water, was used. All measurements were done by AAS with electrothermal atomization and signal recording, and evaluation of the peak height of the signal relative to the mean value of the background.

The calibration graphs were linear in the range between 0.1 and 25 ng/ml. The reproducibility of the calibration graphs over a period of 4 months is given in Table 3, in the form of the slopes.

Table 3. Reproducibility of the AAS-calibration curves over a period of 4 months

*Expansion

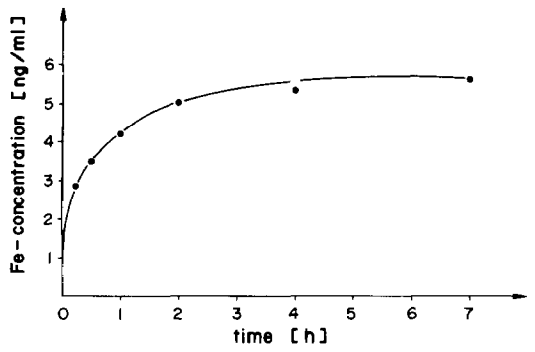

Fig. 3. Contamination of 150 ml of 2*M* HCl with Fe by 20 pipette tips.

Contamination by the pipette tips

To get an indication of the blanks arising from the tips of the automatic micropipettes[12] during dispensing of solutions, 20 tips (1000 µl) were stored for several hours in 150 ml of 2*M* hydrochloric acid (subb.). Figure 3 shows the increasing Fe content of the liquid. Within 3 hr the concentration was as high as 5 ng/ml, so each tip gave up to 37.5 ng of iron to the solution. Though during pipetting the solution does not come into contact with the whole surface of the tip, nevertheless the tips should be cleaned before use by immersion in 2*M* hydrochloric acid (prepared from the 10*M* "sub-boiling" acid) for two 24-hr periods) then rinsing with doubly distilled water and doubly distilled acetone and drying.

Contamination by vessels

In spite of very careful and punctilious cleaning of the vessels, further contamination of the sample solutions cannot be avoided during the analytical procedure or during storage for several days.

The concentration of the blank depends on various parameters such as the element itself, the kind of vessel material, its purity, the pretreatment and the cleaning procedure. The following cleaning techniques were therefore investigated for Duran glass, quartz and PTFE:

(*a*) steaming with concentrated nitric acid, hydrochloric acid or water, in the apparatus described elsewhere[12,13] (see Fig. 2);
(*b*) leaching in 150 ml of 2*M* nitric acid (subb.) or hydrochloric acid (subb.) in a 250-ml conical flask (Duran glass), previously steamed with nitric acid and water;
(*c*) ultrasonic treatment in a bath of 2*M* hydrochloric acid (subb.) and 0.1*M* EDTA. For this purpose the vessels were immersed in 100 ml of the cleaning solution contained in a conical flask which was dipped into the water-filled ultrasonic bath for 5–10 min.

After the cleaning the vessels were rinsed with doubly distilled water, closed with a PTFE cover and transported in a desiccator into the clean-room. Here the vessels were again rinsed, filled with 2 ml of 1*M* hydrochloric acid (subb.) from a quartz pipette and covered. Before measurement the solution was homogenized by stirring for 20–30 sec. During storage of up to 3 days the vessels were allowed to stand in a "Plexiglas" box in the clean-room.

Figures 3–6 show the results of the experiments for iron. Even the first measurement after about 90 min shows the appearance of considerable Fe blanks, whereas for Co no measurable contamination occurred even after 8 days' storage.

For Duran glass and quartz vessels the most effective cleaning was achieved by steaming with nitric or hydrochloric acid for 4 hr. Longer steaming times had no additional effect.

The PTFE vessels show totally different behaviour, depending on the method of producing the PTFE and the vessels (*e.g.*, extruded rod from which the vessels are machined on a lathe, or isostatic pressing of the vessel directly from PTFE powder). After tooling on a lathe all the surfaces appear very uneven and fissured when examined under a microscope. On treatment with hot acids at 120° the roughness increases.[3] The sample solution can then penetrate the pores of the material and hence can dissolve impurity particles in the bulk.[25–29] Therefore steaming is not necessarily the optimal cleaning procedure.

Storage of the PTFE-vessel in 5*M* hydrochloric acid (subb.) at 20° for 24 hr had a better effect as regards Fe. The surface of the material was scarcely attacked by this treatment. Figure 5 again shows that the amount of the blanks extracted by the sample solution from the PTFE may differ considerably from batch to batch of PTFE made by a given manufacturer or between the products of different makers. In some of the extruded PTFE, dirt particles can clearly be observed with the naked eye.

The isostatically pressed vessels have a much smoother surface than the extruded PTFE (lathe-made) containers and can be cleaned very effectively by steaming with nitric or hydrochloric acid (see Fig. 6).

In the ultrasonic cleaning method differences again appeared between the extruded PTFE vessels and the isostatically pressed ones (Fig. 4).

Filling and emptying of calibrated flasks[12,13]

Unused 100-ml flasks of different materials and of different pretreatment were used. Flasks made of Duran glass or quartz, provided with a ground-in stopper, were steamed with nitric acid and water, and flasks made of polypropylene (PP) with PP stoppers were stored in 5*M* hydrochloric acid (subb.) for 24 hr and then rinsed three times with doubly distilled water.

On a clean bench all flasks were rinsed again with doubly distilled water, filled with Fe or Co solution (10 ng/ml) and stoppered. They were then stored for up to 12 days. After vigorous shaking of the flasks 2-ml samples were taken by different techniques after

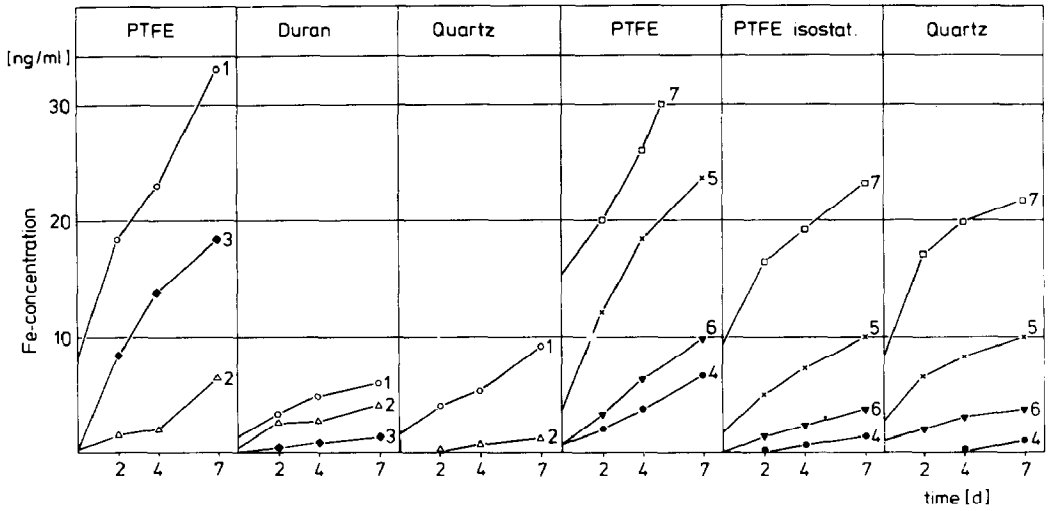

Fig. 4 Contamination of 2 ml of 1*M* HCl with Fe by vessels, cleaned by different techniques (with no. 3 and quartz vessels, no contamination was detected). 1. Rinsed with 10*M* HCl (subb.) and doubly distilled H_2O. 2. Stored in 5*M* HCl (subb.) for 24 hr, rinsed with doubly distilled H_2O. 3. Steamed with HNO_3 for 4 hr, rinsed with doubly distilled, H_2O. 4. Stored in 5*M* HCl (subb.) for 24 hr, rinsed with doubly distilled H_2O. 5. Stored in 0.1*M* EDTA for 24 hr, rinsed with doubly distilled H_2O. 6. Treated in an ultrasonic cleaner with 5*M* HCl (subb.), rinsed with doubly distilled H_2O. 7. Treated in an ultrasonic cleaner with 0.1*M* EDTA rinsed with doubly distilled H_2O.

2 hr, 4, 8 and 12 days. The solutions were homogenized in a small quartz beaker with a quartz stirrer before measurement. For each sampling technique and each solution a separate unused flask was used.

Figure 7 shows occurrence of a considerable contamination of up to several ng/ml.[18,30–32] In addition to the blanks (gains) there are probably losses of iron by adsorption on the surface of the vessels, as is also to be seen in Fig. 7 by the steep decline of the curves. With Co only negligible deviations from the theoretical value were established, probably because of the low concentration and ubiquity of this element. Similar contaminations are also shown in Tables 4 and 5 for the blank concentrations of Fe and Co in different acids and ammonia solutions that have been stored for periods of up to several months.

Contamination by airborne dust

Dust in the air also causes considerable blanks, depending on the element. To investigate the parameters influencing the iron and cobalt blanks, carefully cleaned quartz beakers (volume 20 ml, cross-section 16 cm^2) were filled with 10 ml of 1*M* hydrochloric acid (subb.) and left uncovered in different

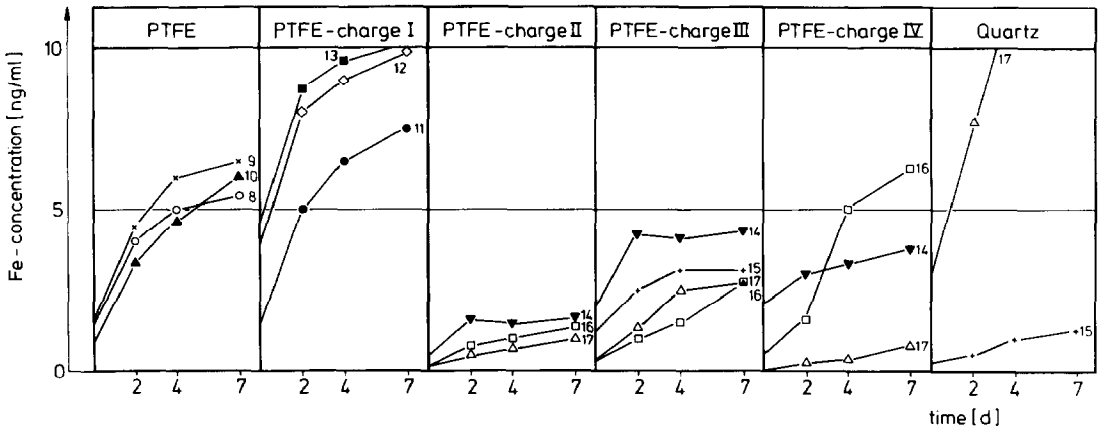

Fig. 5. Contamination of 2 ml of 1*M* HCl with Fe by vessels cleaned by different techniques (with nos. 13, 15 and 16 and vessels of PTFE charge II and IV, and with nos. 8–14 and 16 and quartz vessels, no contamination was detected). 8. Steamed with HNO_3 for 4 hr and H_2O for 1 hr. 9. Steamed with HNO_3 for 6 hr and H_2O for 1 hr. 10. Steamed with HNO_3 for 6 hr and H_2O for 1 hr. 11. Stored in 5*M* HCl (subb.), rinsed with H_2O. 16. Steamed with HNO_3 for 5 hr and H_2O for 1 hr. 17. Stored in 5*M* HNO_3 (subb.), rinsed with doubly distilled H_2O.

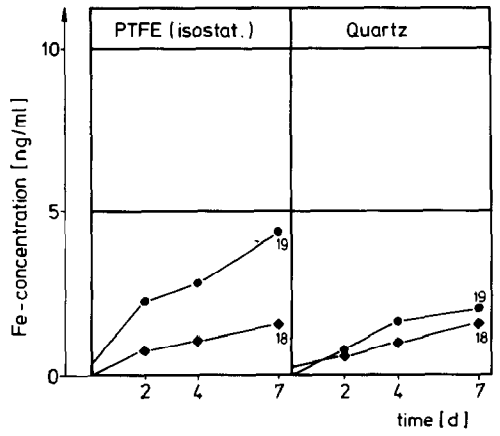

Fig. 6. Contamination of 2 ml of 1*M* HCl with Fe by vessels of isostatic PTFE and quartz (for both materials, after steaming with HNO_3 or HCl, no Fe was detected). 18. Stored in 5*M* HCl (subb.) for 24 hr, rinsed with H_2O. 19. Stored in 5*M* HNO_3 for 24 hr, rinsed with H_2O.

laboratories and on a clean-bench for 6 hr. Figure 8 shows as an example the contamination of the solution in the AAS laboratory on different days.

The dust content of the air is not constant but is influenced by several factors,[12,13] *e.g.*, the condition and history of the laboratory, the kind of air supply and ventilation, the number of persons in the laboratory, and the kind of their activity. The weather also plays an important role. If it is raining the air is generally purer than when it is dry, as is shown by Fig. 8.

For Co no real blanks could be measured, whereas the amount of Fe collected in the 10 ml of acid over a period of 6 hr was up to more than 30 ng. With respect to the surface area exposed, the uptake rate for Fe was up to 2.5 ng/cm^2.

To exclude falsification of the results by blanks from the vessels themselves, identical experiments were made simultaneously on a clean-bench, but no measurable Fe and Co blanks were found.

DISCUSSION

The aim of this contribution is to show the real limits of extreme trace analysis with modern techniques and instruments, by means of the two elements iron and cobalt, which have very different levels of ubiquity. To be able to work in the ng/ml and pg/ml range several conditions have to be fulfilled.

(1) All materials used for apparatus and tools must be as pure and inert as possible. Laboratory ware of, for example, quartz, PTFE, PP, must be cleaned very carefully, for the most part by steaming.

(2) Reagents have to be used in the purest form; acids and most other liquids have to be purified by sub-boiling point distillation.[23] Reagents that can be purified only to a limited degree or by lengthy and sophisticated procedures (and this holds for most solid salts) have to be avoided.

(3) Contamination from the air has to be substantially excluded by use of clean-benches and clean-rooms.

(4) Most important is exact knowledge of the sources of error as well as very careful and accurate work, with special attention paid to all the small but decisive manipulations during the work, which are generally taken no notice of.

Whereas for zinc and magnesium steaming of the vessels with nitric and hydrochloric acid for 4–6 hr and then with water for 1 hr is the optimal cleaning procedure irrespective of the materials used,[12,13] with iron there is a difference in the behaviour of vessels of quartz, Duran glass, isostatically pressed PTFE and extruded PTFE.

For quartz, Duran glass and isostatically pressed PTFE containers, steaming with nitric or hydrochloric acid is the best procedure (see Figs. 4 and 5). Soaking the vessels in acids or EDTA solution for 24 hr or treatment in an ultrasonic bath results in unequivocally poorer cleaning.

All PTFE vessels were contaminated with iron whereas no Co blanks could be detected. Impurities

in the bulk of the material and the surface were lower for isostatically pressed PTFE. For vessels made of extruded PTFE a bath in 5*M* hydrochloric acid (subb.) for 24 hr was the best cleaning procedure. Storage in 5*M* nitric acid (subb.) was less effective whereas EDTA gave bad results (see Figs. 4 and 5). Ultrasonic treatment during this soaking process reduces the cleaning time necessary to 10–20 min. PTFE vessels made of extruded material and steamed with hydrochloric acid, nitric acid and water give distinctly higher contamination of pure solutions than untreated containers do. The longer the steaming time the higher the blanks (see Fig. 5).

Figures 4 and 6 show very clearly that vessels manufactured by isostatic pressing of PTFE powder under controlled purity conditions possess much better properties than those made of extruded PTFE. Unfortunately, laboratory ware of this kind is not readily available commercially and can only be obtained by close co-operation between the manufacturer and the analytical laboratory.

As the PTFE powder itself is very pure, owing to the production process, additional protection of the pressing tools, the PTFE powder and the working area against dust, by use of a clean-bench during the critical phase of the production process, should result in apparatus and containers comparable to quartz with respect to purity and contamination. This is es-

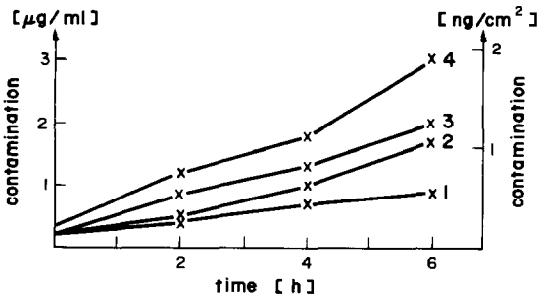

Fig. 8. Contamination of 10 ml of 1*M* HCl (subb.) with Fe by airborne dust in AAS laboratory on different days. 1 and 2, rainy weather; 3 and 4, dry weather. No contamination was detected when a clean-bench was used.

pecially important, since nowadays PTFE products increasingly contain impurities, which occur in different colours and forms such as clouds or sharply bordered inclusions, which can be very clearly seen under a microscope.

As seen in Fig. 8, remarkable amounts of impurities are brought into the sample solution from the air, especially iron. But here, too, generally valid statements are not possible because of the large number of parameters both inside and outside the laboratory that influence the dust content of the air and the composition of the dust particles. The lower the concentration of the element to be determined, the more severe will be the interferences to be expected. Blanks from airborne dust can very easily be avoided by using clean-benches, but because contamination of the sample solution by the vessel is much higher than that by the dust, the use of the expensive and sophisticated clean-room technique is only reasonable if the necessary attention also is paid to careful cleaning of all the containers and instruments.

Another part of our investigations was the sampling of solutions from calibrated flasks made of different materials, by different techniques such as pouring the solution out of the flask, and pipetting by micropipettes (PE-tips) or by quartz pipettes.

Contamination by Co is negligible (<1 ng/ml), but iron blanks (especially with Duran glass and quartz flasks with ground joints) are particularly high, and independent of the sampling technique. With PP-flasks, where the surface of the joint area is smooth, iron blanks occurred only when the solution was poured out of the flasks.

Only a small amount of our experience with very small amounts of elements and low concentrations can be dealt with in this paper, and many phenomena are still unexplored or even undiscovered. Once again, however, it becomes very clearly manifest that, in spite of both very careful working and protective measures, contamination of the sample can by no means be totally avoided. The limitations of modern trace analysis are really set by this.

GAINS OR LOSSES OF ULTRATRACE ELEMENTS IN POLYETHYLENE CONTAINERS

K. HEYDORN and E. DAMSGAARD
Isotope Division, Risø National Laboratory, DK 4000, Roskilde, Denmark

(*Received* 30 *March* 1982. *Accepted* 7 *June* 1982)

Summary—The extent of elimination of losses and reduction of blank values in ultratrace elemental analysis can only be ascertained by comprehensive investigations for each element separately. Different, and partially conflicting precautions are found to be needed in the determination of manganese, copper, selenium, and mercury by neutron-activation analysis when polyethylene irradiation containers are used.

Many problems in elemental analysis are associated with the level of concentration to be determined, and it is therefore expedient to classify the elements according to their content in a sample.[1,2]

Major and minor elements: 0.01–100%
Trace elements: 0.01–100 mg/kg
Ultratrace elements: <0.01 mg/kg

In the determination of major or minor elements the problem of the blank value can usually be disregarded, and in trace analysis it is normally easy to keep the blank value small relative to the content in the sample. In ultratrace analysis, however, the blank value is quite often comparable with the total amount present in the sample, and any uncertainty in the blank is directly reflected in the analytical result.

According to their uncertainty we may distinguish three types of blank:[3]

(*a*) known blanks for which *correction* is *possible* with complete confidence and often without significant loss of precision;

(*b*) estimated blanks, which depend on supplementary information on the particular sample analysed; correction is more uncertain, but a *maximum error* can usually be given; and

(*c*) unknown blanks, for which *no correction* can be applied even when potential sources of blank errors are known; the only solution to this problem is to reduce the individual blank contributions so that they are insignificant.

Different analytical methods have different blank problems, but one is common to all, namely the influence of the container holding the sample. In neutron-activation analysis almost all other blank problems have been eliminated, and this method is therefore particularly amenable to the study of container blank problems.

Neutron-activation analysis is the most sensitive analytical method available for more than 30 trace and ultratrace elements, while it is virtually insensitive to carbon, oxygen, and hydrogen. Polymers, particularly polyethylene, are therefore widely used as a container material for many different types of samples during irradiation in neutron-activation analysis, and some of the blank problems associated with the use of polyethylene in ultratrace analysis deserve consideration.

MATERIALS AND METHODS

In many respects polyethylene is an excellent material for trace element analysis. Its mechanical properties are satisfactory at normal temperatures, and it is very resistant to mineral acid and alkalis, as well as to many solvents. No significant adsorption or leaching takes place in most dilute aqueous solutions, which may therefore be stored without detectable changes for a considerable length of time.[4] Polyethylene is more resistant to radiation than most other polymers and as a container it is available in a variety of sizes and types. The pure form is polymerized at high pressure, without a catalyst, and this low-density form of polyethylene is a preferred material for irradiation containers in neutron-activation analysis.

One such container,* with a useful volume of approximately 1.2 ml and a weight of 1.1 g, has been widely used in the determination of trace elements by neutron-activation analysis; it therefore seemed logical to make a further study of its applicability as an irradiation container for ultratrace analysis.

The trace element levels in these polyvials were determined by instrumental neutron-activation analysis of a number of containers from different batches delivered at different times over a period of several years. Considerable variation was found for most elements, and mean values were not constant from batch to batch; only the order of magnitude is therefore given for the results presented in Table 1.

*The 0.4-dram polyvial, manufactured by Ron McIntosh, Santa Monica, California, USA.

Table 1. Trace elements in 0.4-dram polyvials (type I) determined by instrumental neutron-activation analysis

Elements in order of concentration	Total quantity,* μg
Fe	1–10
Cl, Na, K, Al, Zn	0.1–1
Cu, Cd, Cr, Br, Mn	0.01–0.1
Sb, W, Co, As, Au	0.001–0.01
Se, V, La, Ag, Sc	<0.001

*Weight of container 1.1 g.

In determination of all the major and most of the minor elements in a 1-g sample, the contribution from the polyethylene container under consideration can be ignored. Many trace elements may be determined without significant loss of precision and accuracy by counting the irradiated container with and without the sample. In this way an accurate correction is made for the individual blank value.

Trace element concentrations comparable with those of the irradiation container are more difficult to correct for the influence of the container. The uncertainty in the determination of the container blank now has a direct influence on the precision of the analysis and may be decisive for the attainable detection limit. Transfer of the sample to an unirradiated container before counting, particularly when combined with a radiochemical separation, will reduce the detection limit considerably.

This may, however, introduce both positive and negative blank values from interactions between the sample and container; the true blank value is affected in one direction by leaching of trace elements from the polyethylene and in the other by adsorption of trace elements from the sample. An estimate of the maximum blank errors is made by analysing samples stored in the container for different periods of time, supplemented by analysis of redistilled water blanks.

Leaching of the container with strong mineral acids before irradiation removes trace elements from the surface: Mitchell[5] found no release of the elements manganese, copper, *etc.* from polyethylene after treatment with 50% nitric acid. Robertson[6] recommended soaking in 8*M* reagent-grade nitric acid for several days followed by rinsing with doubly-distilled water, and Karin *et al.*[7] found a 3-day leach optimal for removal of trace elements, with no difference between use of concentrated and 8*M* nitric acid.

When treated in this way the polyethylene container does not interact significantly with most samples, and removing the sample from the container does not introduce any container blank with respect to trace elements.

Under the influence of radiation, however, some elements form volatile compounds which may be lost during transfer from the irradiation container to the counting vial. This applies to the halogens[8] and to mercury,[9] but may also be expected for selenium, arsenic, *etc.* Wherever possible these elements should be determined by counting the irradiated sample before transfer, and then the container blank afterwards. Although mercury is not found in the container before irradiation, some is often found in the container blank after transfer of an irradiated sample containing this element.[3]

In ultratrace analysis correction for the blank from the container is usually impossible, and perhaps the best way to eliminate the problem is to irradiate the sample without contact with the container. This requires irradiation of samples from which the surface layers can be removed before measurement; in the case of liquids, the temperature must be kept below the freezing point until irradiation is completed and the surface layers subsequently melted away.

This method is often impracticable, however, and the alternative is to evaluate the actual positive and negative blank errors for each element of interest under real conditions. Some experiments have, therefore, been carried out for the elements copper, manganese, mercury and selenium.

EXPERIMENTAL

Irradiation containers

I. Standard 0.4-dram polyvials from Ron McIntosh, Santa Monica, California, (*a*) cleaned by rinsing with redistilled water only, (*b*) leached with 8*M* nitric acid for 3 days, or (*c*) soaked in 3% hydrogen peroxide overnight.

II. Special 1.5-ml polyvials, courtesy of Dr. Nic Spronk, Vrije Universiteit, Amsterdam.

III. New 5-ml polyethylene ampoules from Atomic Industrial Co., Tokyo.

All containers were cleaned with redistilled water immediately before use. After filling, they were sealed by radiant heat and leak-tested by immersion in ethylene glycol and evacuation according to ANS/N 542.[10]

Reagents

Redistilled water, conductivity <4 μS.

Dimethyl selenide, Alfa Inorganics, Beverly, Massachusetts.

Radioactive tracers

Mercury metal, labelled with ^{203}Hg, 60 MBq/g.

Mercury(II) nitrate, 5 mg/l. in 0.1*M* nitric acid, labelled with ^{203}Hg, 60 MBq/l.

Determination of container blank

Correction for redistilled-water blanks was made by analysing duplicate samples of freshly redistilled water, taken from the same bottle at the same time and transferred to polyethylene irradiation containers in a clean-room. One container was treated according to the planned investigation, the other was cooled by immersion in a mixture of ethanol and solid carbon dioxide, so that the water was frozen immediately on contact with the container wall. Both samples were irradiated with thermal neutrons at a flux of approximately 7×10^{12} n.cm^{-2}.sec^{-1} for 1 hr. The container with frozen sample in it was surrounded by solid carbon dioxide during the entire irradiation, and afterwards the frozen sample was removed from the container so that the surface layer could be allowed to melt away. The solid core of ice that had not been in contact with the container wall was analysed and used to give the blank values for the redistilled water used in the experiment.

Analytical method

Copper, manganese and selenium were determined by neutron-activation analysis with radiochemical separation.[11] All counting of radioactive indicators was done with 3 × 3 in. NaI(Tl) scintillation detectors.

Container permeability

Standard 0.4-dram polyvials were exposed to ^{203}Hg-labelled mercury vapour in a desiccator containing 10 mg of mercury at room temperature and pressure. The ^{203}Hg activity was measured after different exposure times, to find the rate of diffusion of mercury into the polyethylene. All results were normalized to 1 ml of ^{203}Hg standard aqueous solution in a sealed Pyrex glass container with the same dimensions as the polyvials.

Standard 0.4-dram polyvials containing approximately 1 ml of ^{203}Hg-labelled mercuric nitrate solution were kept on an open bench in the laboratory under normal room ventilation and temperature. Measurements were made exactly as above to determine losses of mercury as a function of time.

A new 5-ml polyethylene ampoule (type III) containing an approximately 100-ppm aqueous solution of dimethyl selenide was stored at −20°. The total selenium content was determined after different lengths of time by instrumental neutron-activation analysis with ^{77m}Se ($t_{1/2}$ = 17.4 sec) as indicator;[12] with a total analysis time of less than 90 sec, the sample remained in the frozen condition for the duration of the experiments.

RESULTS

Adsorption and desorption

As shown in Table 1, selenium and mercury were not found in the standard polyethylene containers used for irradiation, whereas manganese and coppper were present at trace levels. Container blanks were therefore determined for these two elements after cleaning by the three different methods, and the mean values and standard deviations based on results for 10–15 different containers are shown in Table 2.

Up to 10% of the manganese present could be released to the water during irradiation, and the variability of this blank, *a*, exceeds the normal level of manganese in human serum.[13] Treatment with nitric acid, *b*, reduced the total manganese present by about 25%, in good agreement with the investigations of Karin;[7] at the same time the maximum release of manganese to the water dropped by a factor of more than two. The variability in the amount released is, however, still comparable with the total level to be determined. Hydrogen peroxide was found to be just as effective as nitric acid for reducing the blank value, *c*, and much better for reducing its variability.

A significant positive correlation was found between the total amount of manganese in the polyvial and the quantity released to the redistilled water blank, and a search was made for polyethylene vials with lower manganese content.

Containers of type II, with only about half as much manganese, were tested in the same manner, and the mean and standard deviation for manganese in redistilled water blanks from 10 containers are given in Table 3. Only about 1% of the manganese was released during irradiation of this type of container, and no correlation with total manganese was observed. The contribution from the container still exceeds the concentrations usually found in the redistilled water, and the variability severely limits the precision.

Unlike the other two, containers of type III could not be analysed for manganese by instrumental neutron-activation analysis: the total content was therefore determined by radiochemical separation[12] only after the redistilled water blanks had been measured in 10 containers. In this case the mean value and standard deviation of the redistilled water blank are almost indistinguishable from the concentrations found in the redistilled water alone; both adsorption and desorption can, therefore, be disregarded at the 0.01-ng/ml level for this container.

It is obvious from these results that the total manganese content of the irradiation container is not a useful guide to the selection of containers for ultra-trace analysis.

The results for coppper given in Table 2 contrast sharply with those for manganese. No reduction in copper content is brought about by leaching with nitric acid; on the contrary, the release of copper into the water is increased by an order of magnitude. Hydrogen peroxide has a similar, but less pronounced effect, and the lowest blank value is obtained when only redistilled water is used for cleaning the container. In fact, the redistilled water blank is not significantly greater than the concentration of copper found in the redistilled water alone, so neither nett adsorption or desorption takes place at the 0.4-ng/ml level in water.

Gains and losses

The absence of selenium and mercury from the irradiation container does not rule out the presence of a blank value for these elements.

Table 2. Blank values for 0.4-dram polyethylene irradiation containers (type I) with 1.1 ml of redistilled water

		Irradiation container blank, *ng*		Redistilled water blank, *ng/ml*	
Cleaning	Method	Mn	Cu	Mn	Cu
H_2O	*a*	24 ± 7	91 ± 41	1.1 ± 0.7	3.4 ± 0.4
HNO_3	*b*	18 ± 5	101 ± 15	0.4 ± 0.4	33 ± 9
H_2O_2	*c*	22 ± 8	105 ± 49	0.5 ± 0.1	10 ± 4

Table 3. Manganese blank values for different polyethylene irradiation containers

Irradiation container Type	Origin	Mn blank, *ng*	Redistilled water blank Volume, *ml*	Manganese, *ng/ml*
I	California	22 ± 8	1.1	0.5 ± 0.1
II	Amsterdam	14 ± 3	1.1	0.15 ± 0.05
III	Tokyo	19 ± 11	4.5	0.02 ± 0.01

An empty, closed polyvial (type I) absorbs up to approximately 300 ng of mercury when exposed to mercury vapour at room temperature. Initial permeation proceeds as shown in Fig. 1 with a diffusivity of approximately 1 μm^2/sec whereas desorption takes place much more rapidly, as shown in Fig. 2.

The coefficient of diffusion is thus concentration-dependent, perhaps in direct proportion to the amount of mercury present in the polyethylene. Equilibrium with the environment is reached within approximately one week, and the content of mercury in the polyvial then responds rapidly to temperature change or other causes of change in the partial vapour pressure.

This dynamic equilibrium, however, applies only to an empty container, where the mercury partial pressure is the same inside and outside. If the sample in the container may react with the mercury no such equilibrium is reached.

Mercury may be removed by oxidation with nitric acid, and Fig. 3 shows the uptake of mercury during exposure to ^{203}Hg mercury vapour at room temperature, as a function of time for various media. Samples A and B both contain 1 ml of 10*M* nitric acid with 5 and 1 μg of non-radioactive mercury(II), respectively; C and D contain 1 ml of 0.1*M* nitric acid with the same amounts of mercury.

The higher uptake by A and C relative to B and D shows that mercury(II) participates in the oxidation process:

$$Hg^{2+} + Hg \rightarrow Hg_2^{2+} + 12 \text{ kJ/mole} \quad (1)$$

The higher uptake by A and B relative to C and D is caused by the subsequent oxidation of mercury(I) to mercury(II) by the more concentrated nitric acid. This gives rise to an exponential increase in the mercury content, according to reaction (1), but even after an uptake of more than 80 μg of mercury by A the original ratio of approximately 5 between the total contents in A and B is preserved.

In the dilute nitric acid no oxidation takes place, and in C and D the uptake of mercury according to reaction (1) is limited by the amount of mercury(II) present from the beginning. However, the limiting uptake in C was only between 1 and 2 μg of mercury, which means that some mercury(II) has been reduced by other processes.

This is confirmed by Fig. 4 which shows the loss of mercury from a ^{203}Hg-labelled 0.1*M* nitric acid solution of mercury(II) (5 μg/ml), freshly dispensed and sealed in a polyvial. No loss is observed during the first 2–3 weeks, but then more than 3 μg is lost over a period of 7–8 weeks. Similar losses are observed for higher concentrations of mercury and nitric acid. Reduction of mercury(II) to mercury must therefore be caused by the polyethylene container.

Losses of selenium have been observed from solutions containing dimethyl selenide,[12] which is produced in organisms during the metabolism of selenium. In order to reduce these losses, samples of

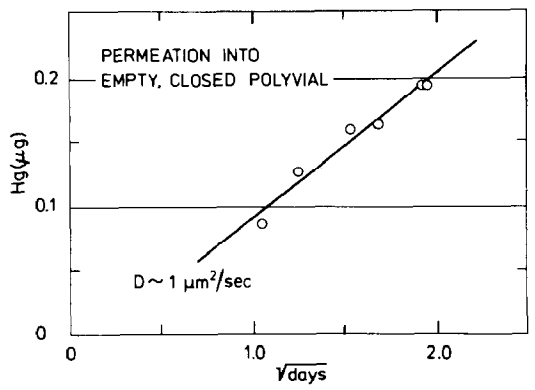

Fig. 1. Diffusion of mercury into a 0.4-dram polyethylene container (type I) exposed to mercury vapour at room temperature.

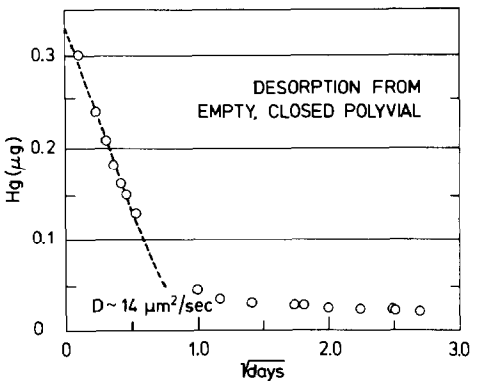

Fig. 2. Diffusion of mercury out of a 0.4-dram polyethylene container (type I) saturated with mercury at room temperature.

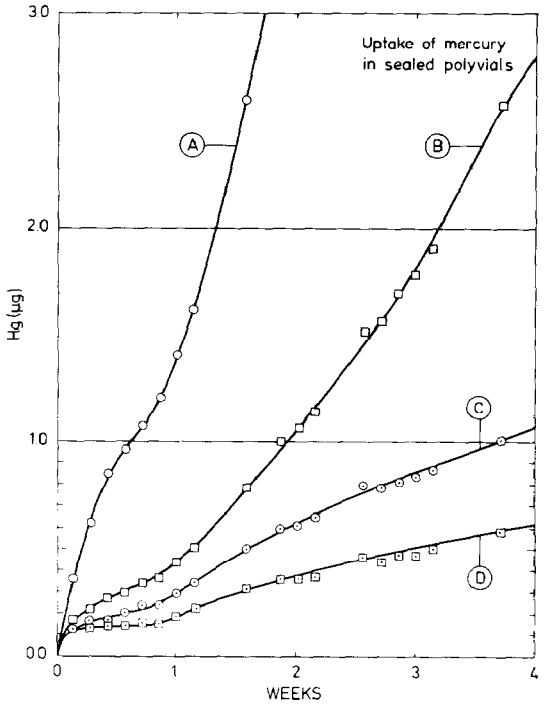

Fig. 3. Uptake of mercury in 0.4-dram polyethylene containers (type I) exposed to mercury vapour at room temperature, initially filled with solutions of mercury(II) nitrate in nitric acid. A, 5 µg Hg in 10*M* HNO_3; B, 1 µg Hg in 10*M* HNO_3; C, 5 µg Hg in 0.1*M* HNO_3; D, 1 µg Hg in 0.1*M* HNO_3.

serum are stored at −20°, and Fig. 5 shows the losses observed over a period of almost 3 months for a polyethylene container of type III. The initial losses are approximately 5 µg of selenium per day.

DISCUSSION

The release of manganese and copper from a polyethylene irradiation container to a sample has been investigated by several authors.[7,14,15] In contrast to the present study the container was irradiated empty, and inactive sample material was added only after completion of neutron activation.

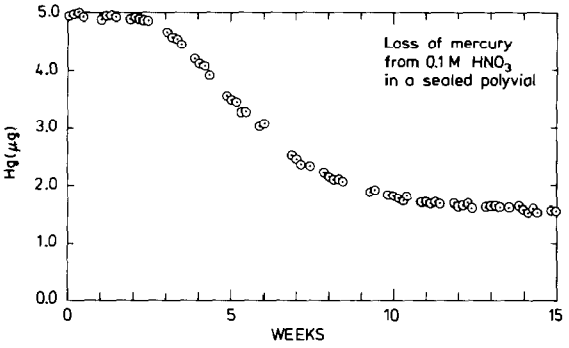

Fig. 4. Loss of mercury from a 0.4-dram polyethylene container (type I) initially filled with 5 µg of Hg as mercury(II) nitrate in 0.1*M* nitric acid.

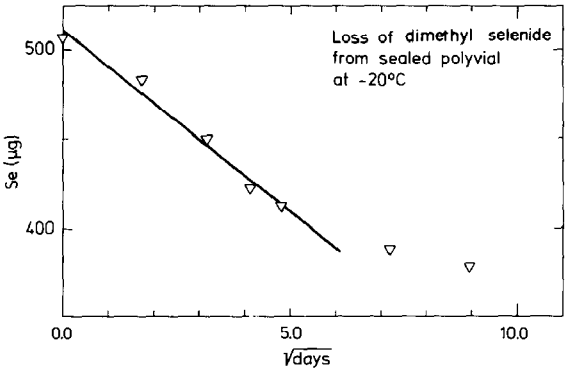

Fig. 5. Loss of selenium at −20° from a polyethylene container (type III) initially filled with approximately 5 ml of aqueous dimethyl selenide solution.

Brune[14] observed an average release of 0.07 ng of Mn and 6 ng of Cu per cm^2 of polyethylene which has been leached with nitric acid before irradiation. This is in remarkably good agreement with the results in Table 2(b) for the containers of type I, which have an inner surface area of about 5 cm^2 in contact with the water. Karin *et al.*[7] found that much higher amounts could be leached, but did not perform any leaching before irradiation. In both cases the contents of manganese and copper in the containers were higher than in those used in the present investigation.

Versieck[15] determined the actual blank value for the two elements by shaking the irradiated polyvial with lyophilized serum. In this way only a minor fraction of the leachable manganese and copper is transferred to the sample.

All investigations indicate that the manganese and copper are released from the inner surface of the container; it is therefore surprising that complete elimination of such blank contributions cannot be achieved by thorough cleaning before irradiation.

The effects of irradiation include the Szilard–Chalmers effect, or nuclear recoil, which may liberate activated nuclides from chemical bonds. However, calculations by Brune[14] clearly show that this effect could explain only a small fraction of the quantities released. Other chemical effects of radiation include the formation of hydrogen peroxide in aqueous media, which may be responsible for the dissolution of some manganese in the form of MnO_2. This and other chemical effects of reactor irradiation depend strongly on the composition of the sample being irradiated and therefore make a blank correction impossible.

Under the optimum conditions determined separately for copper and manganese, no release could be detected by using redistilled water as a sample and therefore no blank correction should be made for levels exceeding 0.01 and 0.4 ng/ml respectively.

Loss of mercury from solutions in polyethylene containers was originally attributed to adsorption[16] or volatilization,[17] and should be prevented by the

addition of mineral acid, often in combination with oxidants.[18–23] The addition of sulphide, cysteine,[24] thiocyanate[25] or certain sulphur-containing organic compounds[26] has been found to reduce or prevent losses. Mahan and Mahan[27] noted, in agreement with Fig. 4, that losses began to accelerate by the second day and recommended that analysis be done on the day the sample was collected.

Bothner and Robertson[28] found gains of mercury in acidified sea-water stored in polyethylene containers, and Cragin[29] reported uptakes of up to 200 ng per day in an oxidizing pure-water sample in a 1-litre polyethylene bottle stored in a Class 100 clean-air cabinet.

Similar effects may be responsible for the poor agreement observed in an intercalibration of mercury in sea-water.[30] While most biological samples do not sustain losses of mercury,[26] they do pick up mercury from the air, even through a sealed polyethylene envelope.[31]

Increased losses of mercury after neutron activation in polyethylene containers were reported by Bate[9] for a 1.5*M* nitric acid solution, but McFarland[32] and Larson and Tandeski[33] found no losses during irradiation of solutions containing more concentrated nitric acid or oxidizing agents. Guinn[34] proposed that radiolysis of the water causes reduction to elementary mercury, which then diffuses through the polyethylene. This mechanism was confirmed later[35] by irradiating sealed polyvials of type I containing ^{203}Hg-labeled mercury(II) nitrate solutions, with a linear accelerator. Precipitation of metallic mercury was here observed at doses as low as a few kGy.

At temperatures of $-20°$ neither gains[29] nor losses of mercury[26] have been detected, and this is probably the best method of circumventing the diffusion of mercury during storage. However, irradiation in a nuclear reactor is seldom possible at low temperatures, and transfer to quartz containers is advisable.

Diffusion of selenium through polyethylene from solutions of dimethyl selenide is so rapid at room temperature that trace analysis is virtually impossible. Storage at low temperature is therefore imperative, but in contrast to mercury the losses continue at a significant rate. Only by analysis on the day of collection can reliable results be expected.

CONCLUSION

The reduction to insignificance of gains and losses associated with the use of polyethylene containers in ultratrace analysis cannot be achieved by adherence to any standard procedure. Large systematic errors can be avoided only by carefully evaluating for each element all possible sources of positive or negative contributions to a blank value.

(*Received* 14 *January* 1982. *Accepted* 30 *April* 1982)

Summary—Two common procedures for wet destruction of biological materials for subsequent determination of selenium have been investigated. Rat organs and biological fluids were endogenously labelled with ^{75}Se to monitor losses during the procedures. Addition of nitric and perchloric acids with gradual heating up to 210° seemed to be the best method: at this temperature the labelled selenium was still recovered quantitatively, and the destruction was fast and efficient.

Since the discovery that selenium is essential to human health, the need for information about the concentration of this element in human tissues has become more urgent. For the determination of trace elements in biological samples a pretreatment is needed which will destroy all organic matter but retain the element of interest. As some selenium species are known to be volatile at higher temperatures, it is necessary to investigate possible losses at every step of the determination procedure.

For the drying step, Behne and Matamba[1] found no differences were caused in the selenium concentrations in blood serum by drying at 90°. Fourie and Peisach[2–4] studied the loss of selenium metabolically incorporated in zoological specimens and found no significant losses caused by drying at up to 105°. Iyengar *et al.*[5] studied the retention of radioactive selenium incorporated into biological tissues when different drying procedures were used and proved that, with heating at up to 120°, the loss was less than 5%. This evidence indicates that the drying of biological material is not a critical step.

For the decomposition step, Hall and Gupta[6] found selenium losses from 10% up to 60% during wet ashing with nitric and perchloric acids at temperatures from 150° up to 200°. We therefore first tested a digestion procedure with 110° as the highest temperature. A predigestion step at a lower temperature was included in this procedure, as suggested by Olson,[7] with the aim of hydrolysing easily oxidizable biological material. The temperature was then gradually increased in the presence of a sufficient amount of nitric acid to prevent charring of the organic material and consequent evolution of H_2Se from the digestion mixture.[8–11] Olson[7] stated that since some organoselenium compounds can resist acid attack by perchloric acid up to 200°, the destruction has to proceed at above this temperature for at least 15 min. After recovery experiments with the $(CH_3)_3Se^+$ ion, Olson *et al.*[10] extended the heating period to 30 min. Hall and Gupta[6] warned against using temperatures above 230°. Therefore in the second digestion procedure tested, the final temperature was set at 210°. In a recent recommendation for the determination of selenium in biological materials[12] sulphuric acid is added, but only after complete oxidation of the biological matrix, since it is especially useful for driving off the remaining nitric and perchloric acids, both of which interfere in the recommended fluorimetric determination procedure. However, since sulphuric acid enhances the risk of charring the biological matrix,[11,13,14] it was not added in the two digestion procedures used in this study.

All the published studies on the recovery of selenium during wet destruction have made use of spikes, sometimes containing radioactive tracers, which were added to the samples on the assumption that the matrix selenium and the spike, mostly added in the inorganic form, would behave similarly during the matrix decomposition.[13,15,16] This approach is questionable, however, since the concentration ranges of the trace elements in biological tissues vary over several orders of magnitude and especially since it has not been confirmed that the inorganic form and the organically bound selenium behave in the same way in the decomposition procedures.

A better appraisal is obtained by the analysis of standard reference materials, which have been analysed for selenium by a non-destructive technique, and which resemble the various types of biological samples as closely as possible. In another approach, possible losses can be studied during digestion of tissues in which radioactive selenium has been biologically incorporated.[17]

In the present investigation the radioactive ^{75}Se isotope was injected intraperitoneally into rats in

order to incorporate this element into the body tissues during normal metabolic functioning and to study the recovery of the selenium in its naturally occurring form, when the two different wet digestion procedures were applied.

EXPERIMENTAL

Reagents and apparatus

All reagents were of analytical grade. In all experiments ^{75}Se ($t_{1/2}$ = 120 days; E_γ = 265 keV) was used. Sodium selenite with initial specific activity 5.9 μCi per μg of Se, and sodium selenate with initial specific activity 6.3 μCi per μg of Se, were obtained from the Radiochemical Centre, Amersham, England. The various organs and biological fluids were decomposed in a 20-position Tecator automatic digestion apparatus (Höganäs, Sweden), including a No. 1005 heating unit and a No. 1008 control unit. The total height of the digestion tubes and specially constructed condensers was 55 cm. In the first set of experiments, the gamma-emitting nuclide was counted on a Ge(Li) detector with a 4096-channel analyser. In the second experiment a Berthold automatic gamma sample-changer unit LB MAG 312 (Wildbad, Germany) was used for quantitatively analysing the radioactivity. The detector consists of a 3 × 3 in. NaI(Tl) well-type scintillation crystal with a well diameter of 22 mm and is rather insensitive to small variations in counting geometry.

Procedure

Two adult Wistar rats with average body weight of 250 g were injected intraperitoneally with 4 μg of selenate (25 μCi) and 4.25 μg of selenite (25 μCi). After injection the rats were placed in metabolism cages for collection of urine and faeces. Standard food was supplied and they received water *ad libitum*. Every 24 hr, urine and faeces were collected and after 9 days the animals were killed. Samples of whole blood, brain, heart, kidney, liver and spleen were removed. The initial radioactivities of ^{75}Se were measured in all samples. The biological tissues were taken for destruction and the residual activity in the empty vials was checked. The digestion procedure was based on the comprehensive literature evaluation of Verlinden.[18] Concentrated nitric acid (5 ml per g of sample) was added to react with the organs overnight at room temperature; subsequently the solution was heated at 70° for 23 hr and then at 100° for 20 hr. The condensers were then removed, the volume was reduced to a few ml and 2 ml of perchloric acid were added. The mixtures were heated for 1 hr at 107° with the condensers replaced. After cooling and addition of 1 ml of concentrated hydrochloric acid the mixture was heated for 5 min at 100° to reduce all selenium to the quadrivalent state, so that it could be determined by common analytical procedures. The radioactivity of the solutions obtained after the destruction of organic matter was measured with the same geometry in the Ge(Li) detector.

In a second experiment the rats were kept alive for 30 days after injection of 33 μg of ^{75}Se (80 μCi). Half of the selenium was added as selenite, the other half as selenate. This higher amount of selenium is still only one thirtieth of the reported minimum lethal dose of selenate or selenite injected into rats,[19,20] so it is improbable that the metabolic incorporation was occurring under pathological conditions. The rats were killed, and the initial radioactivity was measured in the whole blood, brain, heart, kidney, liver, lung, muscle, spleen and thyroid. Urine and faeces were collected during the 30 days and were also included in this tracer experiment. The digestion scheme finally adopted, following recommendations in the literature,[6,7,9,10,13,14,18,21] involved addition of concentrated nitric acid (10 ml per g of sample) to the organs and predigestion overnight at room temperature; heating at 75° for 24 hr and then at 120° for 6 hr until the solution volume was reduced to 4 ml; addition of 5 ml of perchloric acid (70%) and heating (up to 215°) for 30 min; cooling and reduction of selenium to the quadrivalent state by heating for 5 min with concentrated hydrochloric acid. A standard solution containing 0.66 μg of ^{75}Se (0.34 μg of selenium as selenite and 0.32 μg as selenate) was also taken through the entire decomposition procedure. The radioactivities before and after destruction were measured in the NaI(Tl) detector.

RESULTS AND DISCUSSION

Table 1 summarizes the results for the retention of the radioactive isotope after decomposition at the lower temperature ($\leqslant$110°) of heart, liver, spleen, kidneys, brain, blood, urine and faeces of the two rats following 9 days of metabolic incorporation. For the biological fluids, the recovery is nearly complete and the reproducibility satisfactory. For some of the tissues the results are apparently too high and the reproducibility is somewhat poor. This is due to some uncertainties in the counting geometry, that could not be avoided during the counting of the whole organs and faeces because, in view of the low subtoxic quantities of selenium used, the gamma-activities were low, necessitating measurement close to the Ge(Li) detector. Still, it seems that, in the low-temperature decomposition process, the selenium is retained virtually quantitatively in the final solution. However, some lipid material remained and the faeces were not completely destroyed in this procedure. Verlinden[18] also found low selenium concentrations for blood and serum by AAS after this decomposition step.

In the second experiment, the incorporation of a higher amount of selenium took place over a longer period, and muscle and lungs were also investigated because selenium is known to affect muscle dys-

trophy, and selenium accumulation in the lungs has been reported.[22,23] The samples were also measured with a well-type NaI(Tl) detector that is less sensitive to geometry effects. Before measurement of the initial radioactivity on the Ge(Li) detector, the organs and fluids were allowed to stand for 24 hr in 10–20 ml of concentrated nitric acid, so that a more comparable geometry was obtained before and after the digestion. Table 2 summarizes the results for the recovery of incorporated ^{75}Se after the extended wet destruction with nitric and perchloric acids, and with heating to 210°.

The highest specific activities were found in kidney, liver, spleen and blood, while brain showed the lowest activity. These findings agree quite well with the literature data on the distribution of subtoxic amounts of ^{75}Se in the tissues of rats.[24] Liver and kidney seem to be the target organs in exposure of rats to selenium,[23,25] whereas in man the lungs appear to accumulate the selenium.[22,23] Harr *et al.*[25] stated that the liver-to-kidney selenium ratio is dependent on the level of selenium supply, so after addition of higher doses, higher liver-to-kidney ratios are found. This could be explained by the fact that the conversion of selenite into volatile selenium compounds takes place largely in the liver,[26] and that these can be exhaled by the rats.[27] Another way of eliminating high amounts of selenium is in the urine, in which the trimethylselenonium ion is the major metabolite excreted:[28–31] hence, the kidneys will also show higher selenium concentrations.

From Table 2 it can be concluded that even at the high decomposition temperature of 210° the recovery of ^{75}Se is almost complete for the different organs. The clear solutions obtained after digestion also point to a complete destruction of fatty materials. Hence this method seems excellent for determination of selenium in biological samples. Only thyroid and some urine samples showed a somewhat lower recovery. No explanation can yet be offered for the lower recovery from thyroid tissue. For urine, losses of selenium after wet or dry ashing are widely reported in the literature. Schwarz[32] recommended a closed system for accurate analysis, since serious losses of the element, as much as 75–84%, were observed during open wet digestion. In a dry ashing method for urine, Roquebert and Truhaut[33] found serious losses. Probably incomplete digestion of the volatile selenonium ion is the major reason for these losses. Geahchan and Chambon,[31] however, found no difference in selenium recovery when they compared destruction of urine in a closed system (Teflon Parr bomb), with an open digestion method (using a nitric–perchloric acid mixture) similar to the procedures presented above.

CONCLUSION

Selenium-75 was injected intraperitoneally to incorporate the element into the various organs of rats in a natural physiological form. The highest specific activity was found in kidney, liver, spleen and blood, while brain accumulated the least activity.

Heating with nitric–perchloric acid mixture up to 210° appeared to be a most convenient method for decomposing the different organs and biological fluids: the matrix was completely destroyed, and no significant losses of the incorporated selenium could be observed (except for thyroid and some urine samples). The decomposition procedure is rather complex and long, but can easily be performed in an automatic digestion apparatus. The resulting solutions can be used for selenium determination by, for example, hydride-generation atomic-absorption spectrometry[18] or energy-dispersive X-ray fluorescence analysis after selective reduction and preconcentration on activated charcoal.[34]

(*Received* 14 *January* 1982. *Accepted* 21 *February* 1982)

Summary—A comprehensive review is given of how neutron-activation analysis for trace elements in biological matrices can be jeopardized by radiation damage, by the impurities present in the packing material or by nuclear interferences of major elements. Systematic errors during the counting process and the quantitative interpretation of the γ-ray spectra should not be disregarded.

The difficulties of obtaining a biological sample which remains unchanged during sampling, sample treatment and storage are many and various.[1] If the original trace element content remains representative of the material to be analysed, reactor neutron-activation analysis (RNAA) is an ideal technique. It possesses an alleged freedom from blank corrections and is a multi-element method, often a purely instrumental one. Using RNAA, most chemical treatments can be postponed till after irradiation, so that the hazard of contamination prior to irradiation can be controlled. However, biological samples undergo minute or pronounced radiation damage which may affect some particular trace element determinations. A further drawback, innate to RNAA, arises from the impurities present in the materials of construction of the irradiation vials. In addition, some matrix components or major elements occurring in biological material can give rise to nuclear interferences, putting the exact determination of certain trace elements into jeopardy. The analyst should also be aware of those different systematic errors which are proper to activation analysis.[2] A crucial point is the correct measurement of the radiation.

This paper reviews the main difficulties liable to occur in the RNAA of biological materials.

PRINCIPLE OF REACTOR NEUTRON-ACTIVATION ANALYSIS (RNAA)

RNAA consists of neutron bombardment of a given material, followed by measurement of the induced radioactivity. The most usual type of activation is done with thermal or epithermal neutrons in a nuclear reactor, according to the reaction ${}^{A}_{Z}X(n,\gamma)^{A+1}_{Z}X$. The total number of radioactive atoms $^*N$ of a particular nuclide is given by equation (1):

$$^*N = \phi_{th} \cdot \sigma_{th}\left(1 + \frac{\phi_{epi} I_0}{\phi_{th}\sigma_{th}}\right)\frac{N \cdot S}{\lambda} \qquad (1)$$

where σ_{th} is the cross-section for the (n,γ) reaction with thermal neutrons (unit barn $= 10^{-24}$ cm^2), I_0 the activation resonance integral (unit barn), ϕ_{th} the thermal neutron flux (n.cm^{-2}.sec^{-1}), ϕ_{epi} the epithermal neutron flux (n.cm^{-2}.sec^{-1}), N the number of atoms of a certain nuclide ($= 6 \times 10^{23} P\theta g/A$), ($P$ = per cent of the element in the compound; θ = isotopic abundance of the target nuclide; g = weight of the compound; A = atomic weight of the element), λ, the disintegration constant ($= 0.693/t_{\frac{1}{2}}$; $t_{\frac{1}{2}}$ = half-life of the radioactive isotope), and s ($= 1 - e^{-\lambda t}$) is the saturation factor (t = irradiation time).

The amount of the element is experimentally deduced from the ratio of the radioactivity of the particular isotope in the sample to that of a standard, irradiated simultaneously, *i.e.*,

$$\frac{\text{weight of element in sample}}{\text{weight of element in standard}} = \frac{\text{radioactivity of isotope in sample}}{\text{radioactivity of isotope in standard}}.$$

The standard can be successfully replaced by a multi-comparator.[3] It is assumed that all the parameters (θ, σ, ϕ, t, counting efficiency) remain identical for the unknown and the standard and that the radionuclide is not formed from another nuclide in the sample (*i.e.*, no nuclear interference).

*Senior research associate of the National Fund for Scientific Research (Belgium).

Neutron-activation analysis combined with high-resolution γ-spectrometry is an excellent multi-element method. Radiochemical separations may be necessary, depending on the element and the matrix. The possibilities of RNAA for the elemental analysis of biological materials have been outlined by Guinn and Hoste[4] and by Erdtmann and Nürnberg.[5]

EFFECT OF THE IRRADIATION PROCESS ON BIOLOGICAL SAMPLES

As a consequence of the Szilard–Chalmers process, recoil energy up to several MeV is transmitted to the newly formed nucleus. The result is a change in the chemical bond as well as in the position of the nucleus in the matrix. High gamma dose-rates lead to a rise in temperature and to radiolysis of organic compounds and of water. This in turn may result in the loss of some elements by volatilization or diffusion. The sample gradually decomposes and is eventually completely charred. It is evident that in these circumstances only irradiation in sealed containers (usually made of quartz) can ensure a quantitative recovery of the trace elements. As there is a continuous build-up of internal pressure, there comes a point when the ampoule will burst. This is the case, for example, when 100 mg of lyophilized serum is irradiated for 12 days at 10^{14} n.cm^{-2}.sec^{-1}. The explosion hazard can be avoided by dry-ashing the sample in the quartz vial at up to 450° before the irradiation, but this is only applicable to the determination of non-volatile elements. For safety reasons, the irradiated ampoules should never be opened unless they have been thoroughly cooled in liquid nitrogen.

One of the earlier analytical applications of the Szilard–Chalmers process was developed by Comar and Le Poec[6] for the determination of iodine in biological fluids. It is based on the observation that during irradiation most of the linkages between the proteins and activated iodine are broken, so all the radioactive iodine can be fixed quantitatively on an anion-exchange resin. The same radiation effect also governs standard iodide solutions. Only a strongly alkaline medium appears reliable, as the free ^{128}I-atoms are then trapped. Neutral or acid media cannot prevent the loss of iodine by either adsorption onto the container wall or by volatilization. This phenomenon may also give rise to serious cross-contamination.

The most difficult element to determine accurately is mercury. It is common knowledge that mercury solutions contained in sealed polyethylene containers may undergo significant losses. To a limited extent this also applies to mercury in powders. Although this phenomenon occurs in unirradiated polyethylene vials at room temperature, several authors have mentioned an additional effect that is proportional to the irradiation dose.[7–10] In all cases these losses can be prevented by sealing the samples and the standards in quartz ampoules.

RNAA of biological material should therefore never be described as a non-destructuve method. There is always some radiation damage, although sometimes only to such a very minor degree that a purely instrumental procedure remains feasible.

BLANK VALUES CAUSED BY THE IRRADIATION PROCESS

A very small number of atoms of various impurities present in the irradiation vials become radioactive during neutron bombardment and are liable to be ejected from their original sites.[11] However perfectly the surface of the vials has been cleaned, radioactive isotopes of the impurities may end up in the sample as a result of this recoil effect. However, only determinations at the nano- and subnanogram levels are at risk, as the quartz and organic polymers used should be of the highest purity available. This particular kind of contamination hazard becomes more obvious when the samples have to be washed out of the containers after the irradiation. Although originally representative, the samples will yield erroneous values because of the addition of extraneous radioactive atoms.

Typical trace element concentrations in various container materials are given in the literature.[12–18] Every known container material contains detectable trace element impurities. Therefore any application of instrumental RNAA to ultratrace elements irradiated in quartz or plastic vials is open to doubt. This statement is supported by comparison of the figures given in Table 1, for the concentration of some impurities present in quartz and polyethylene, with those for normal human serum.

Several reports have appeared on the effect of such impurities.[15–17,22,31,32] Moody and Lindstrom[15] studied the amounts of impurities leached from various plastic containers by different solvents, as well as the quantities of Na, Al, K, Co, Zn, Br, Sb, La, W and Au removable from plastics after short and long irradiation times. Only minor amounts of trace elements were found to be leached out by the acids, implying that they are distributed throughout the matrix.

The interference of an impurity present in polyethylene can be exemplified by the results obtained for iodine in the IAEA V-5 wheat flour,[31] after radiochemical separation of ^{128}I. The mean value of 2.2 ± 0.4 ng/g was obtained only after switching from polyethylene to high-purity quartz vials. Analyses of the wheat flour irradiated in polyethylene yielded values up to 10 ng/g. The results appeared to be affected by the 20 ng of iodine present in the container, some of which formed part of the induced ^{128}I activity measured. The poor reproducibility of the results is typical of this kind of contamination.

Another example shows the extent to which the trace analysis of lyophilized urine is affected by impurities in the polyethylene container material.[32] Measurements of the γ-activity showed the presence of ^{110m}Ag, ^{198}Au, ^{82}Br, ^{51}Cr, ^{59}Fe, $^{122+124}$Sb, ^{46}Sc

Table 1. Comparison of the concentrations of trace elements in serum with those of impurities present in quartz and conventional polyethylene

	Serum		Quartz		Polyethylene	
Element	*ng/ml*	Reference	*ng/g*	Reference	*ng/g*	Reference

and ^{65}Zn. The highly hygroscopic and electrostatic nature of lyophilized urine necessitates a thorough rinse-out of the container and this enhances the contamination hazards. A blank value has to be taken into account for Cr and Mn (concentrations in urine 1 and 0.1 ng/ml respectively), but appears negligible for Zn (up to 0.5 μg/ml).

High-purity quartz also yields some relatively important blank values. Part of this is the result of long irradiations at high neutron fluxes (*e.g.*, 1–12 days at 10^{13} or 10^{14} n.cm^{-2}.sec^{-1}). A further part of the blank is created when the tip of the quartz ampoule is sealed by heating in a flame at 1500–1900°, as described by Mazière *et al.*[17] The impurities volatilized from the silica are deposited on the walls of the tube, and whereas those condensed on the exterior of the tube are eliminated during the cleaning of the ampoule after irradiation, the impurities condensed on the interior are only dissolved once the ampoule is opened. As the ashed or lyophilized biological material undergoes serious radiation damage, it must always be dissolved with hot, strong acids, and this procedure inevitably enhances the blank value.

Versieck *et al.*[22] investigated the Cr and Co radioactivity leached out of "Spectrosil" quartz ampoules opened by snap cutting. The corresponding concentration represented about 30% of the mean value found by RNAA for these elements in serum. The apparent mean contaminations per ml of serum were estimated as 0.0478 ng of Cr (range 0.0262–0.074 ng) and 0.0267 ng of Co (range 0.0167–0.0338). Heraeus "Suprasil" yielded lower blank values, 0.020 and 0.0075 ng/ml of serum for Cr and Co respectively.

Mazière *et al.*[17] studied the possible influence of the "wet ashing" blank on the constituents present in 100 μl of serum. A 1-g fused quartz ampoule ("Quartex") was irradiated for 1 day at 2.5×10^{14} n.cm^{-2}.sec^{-1} and the amounts of the elements leached out with a mixture of nitric acid and hydrogen peroxide were compared with those expected in 100 μl of serum. Of the 39 elements investigated, only Ba, Br, K, Na, P, Rb, Se and Sr gave blank values that could be neglected (<5%). Since then it has become common practice to use quartz of a much higher purity than that experimented on by Mazière *et al.* The list of elements giving negligible blanks can now be extended. Nevertheless, contamination with Cr, Co and Sb, caused by wet-ashing of biological samples irradiated in quartz, constitutes a real problem for ultratrace element determinations in difficult matrices such as serum.[33]

Tjioe *et al.*[34] evaluated the highly variable blank values from irradiated quartz vials, by crushing the irradiated containers in a pneumatic press and processing the sample together with the quartz splinters. The blank values were investigated for vials, made of either "Vitrosil" or "Spectrosil" quartz. The comparison of their blank values with the expected values[33] per 100 mg of lyophilized or ashed serum, points to unacceptable interferences for As, Cd, Co, Cr, Fe, Mo and Sb, but none for Br, Cu, Hg, Se and Zn.

Bereznai *et al.*[16] have also reported wet-ashing

values for 0.5 g of Heraeus "Suprasil" ampoules, amounting to 5×10^{-5} ng of Sc, 5×10^{-4} ng of Cr, $1\text{–}4 \times 10^{-2}$ ng of Co, 9×10^{-3} ng of Sb and 0.2 ng of Zn per vial.

It is evident from the various data cited that the purer quartz materials are liable to influence only the results for ultratrace levels of certain elements in specific biological matrices. In all cases requiring the subtraction of a blank, however, the accuracy is lower, because the blanks, even under similar experimental conditions, cover wide ranges.

NUCLEAR INTERFERENCES

Systematic errors, including those due to different fluxes in samples and standards, interfering nuclear reactions and self-shielding, have been discussed by De Soete *et al.*[2] It is beyond the scope of this paper to review all these aspects, which are intrinsic to the correct application of activation analysis. It may be useful, however, to draw attention to one of these errors associated with activation, *viz.* nuclear reactions jeopardizing ultratrace element determinations in biological matrices.

The principle of the RNAA method given here assumes that the radioisotope can only be formed through an (n, γ) reaction. The reactor neutron spectrum also contains fast neutrons, which can give rise to threshold reactions of the type (n, p), (n, α) and (n, 2n). Thus,

thermal neutrons yield

$$^{A}_{Z}X(n, \gamma)^{A+1}_{Z}X$$

and fast neutrons yield

$$^{A+1}_{Z+1}Y(n, p)^{A+1}_{Z}X$$

$$^{A+4}_{Z+2}Z(n, \alpha)^{A+1}_{Z}X$$

$$^{A+2}_{Z}X(n, 2n)^{A+1}_{Z}X$$

Hence the degree of interference depends mainly on the flux ratio $\phi_{thermal}/\phi_{fast}$, and the cross-sections and concentrations of neighbouring elements in the periodic table. The cross-sections of these threshold reactions appear to be a few orders of magnitude smaller than those for (n, γ) activation. Therefore this interference only becomes measurable when the concentration of the interfering element exceeds that of the element to be determined by several orders of magnitude.

The organic matrix of the biological material (as far as C, H, N, O are concerned) causes none of these interferences, but some major elements such as P might do so. The interference is expressed as an apparent concentration *i.e.*, the concentration of the analyte element yielding the same radioactivity through its (n, γ) reaction as that given by the threshold reaction of the interfering element.

$\bar{\sigma}_f$ = cross-section for fast neutron capture.

A limited list of possible interferences in determination of trace elements in biological material is given in Table 2. The apparent concentrations can be estimated from the nuclear characteristics of the isotopes,[35] the matrix composition and the thermal:fast neutron ratio, but the exact amount has to be determined experimentally, as there is a large spread in the published cross-sections for threshold reactions.[36]

Three practical examples of this limitation are now described in more detail, for Al in serum and Mn and Cr in red blood cells.

The amount of P in serum is about 132 μg/ml. The interference reaction $^{31}P(n, \alpha)^{28}Al$ ($\bar{\sigma}_f$ = 1.9 mb)* in a thermal:fast flux ratio of 6.4 produces an apparent Al concentration of about 180 ng/ml, completely masking the 4 ng/ml actually present.[19] It is improbable that a neutron flux could be found, so well thermalized that this interference could be eliminated.

Red blood cells contain about 1025 μg of Fe per g. The interference reaction $^{56}Fe(n, p)^{56}Mn$ ($\bar{\sigma}_f$ = 1.07 mb) in a thermal:fast flux ratio of 6.4 produces an apparent Mn concentration of about 11 ng/g, seriously masking the 15 ng/g actually present. Irradiation in a well thermalized position reduces this interference. The Cr determination based on the $^{50}Cr(n, \gamma)^{51}Cr$ reaction becomes unreliable in the presence of large amounts of Fe, because of the

Table 2. Nuclear interferences by fast neutron threshold reactions

Element	Thermal neutron activation reaction	Interfering reaction
Al	$^{27}Al(n, \gamma)^{28}Al$	$^{28}Si(n, p)^{28}Al$ $^{31}P(n, \alpha)^{28}Al$
Co	$^{59}Co(n, \gamma)^{60}Co$	$^{60}Ni(n, p)^{60}Co$ $^{63}Cu(n, \alpha)^{60}Co$
Cr	$^{50}Cr(n, \gamma)^{51}Cr$	$^{54}Fe(n, \alpha)^{51}Cr$
Cu	$^{63}Cu(n, \gamma)^{64}Cu$	$^{64}Zn(n, p)^{64}Cu$
K	$^{41}K(n, \gamma)^{42}K$	$^{42}Ca(n, p)^{42}K$
Mg	$^{26}Mg(n, \gamma)^{27}Mg$	$^{27}Al(n, p)^{27}Mg$ $^{30}Si(n, \alpha)^{27}Mg$
Mn	$^{55}Mn(n, \gamma)^{56}Mn$	$^{55}Fe(n, p)^{56}Mn$ $^{59}Co(n, \alpha)^{56}Mn$
Na	$^{23}Na(n, \gamma)^{24}Na$	$^{24}Mg(n, p)^{24}Na$ $^{27}Al(n, \alpha)^{24}Na$
Ni	$^{64}Ni(n, \gamma)^{65}Ni$	$^{65}Cu(n, p)^{65}Ni$ $^{68}Zn(n, \alpha)^{65}Ni$
P	$^{31}P(n, \gamma)^{32}P$	$^{32}S(n, p)^{32}P$ $^{35}Cl(n, \alpha)^{32}P$
Se	$^{80}Se(n, \gamma)^{81m}Se$	$^{81}Br(n, p)^{81m}Se$
Si	$^{30}Si(n, \gamma)^{31}Si$	$^{31}P(n, p)^{31}Si$ $^{34}S(n, \alpha)^{31}Si$

reaction $^{54}Fe(n, \alpha)^{51}Cr$. Such might be the case for the analysis of red blood cells for Cr. The Fe present already yields an apparent Cr value of 11 ng/g ($\bar{\sigma}_f = 0.74$ mb, $\phi_{th}/\phi_f = 6.4$), which is of the same order of magnitude as the actual Cr content.

Another group of nuclear interferences is due to second-order nuclear reactions, through chains of the type

$$^{A}_{Z}X(n, \gamma)^{A+1}_{Z}X \xrightarrow{\beta\text{-decay}} {}^{A+1}_{Z+1}Y(n, \gamma)^{A+2}_{Z+1}Y.$$

The possible impact of this type of nuclear reaction can be assessed from a compilation by Op de Beeck.[37] The minor contribution of such an interference can be exemplified by the second-order interference of Fe in the determination of Co in red blood cells. The nuclear reaction

$$^{58}Fe(n, \gamma)^{59}Fe \xrightarrow{\beta\text{-decay}} {}^{59}Co(n, \gamma)^{60}Co$$

on 1025 μg of Fe per g of red blood cells, irradiated for 10.7 days at 5×10^{12} n.cm^{-2}.sec^{-1} would yield an apparent Co content of 5.2×10^{-4} ng/g. This is negligible in comparison with the 0.11–0.22 ng/g reportedly present.[38]

A good rule to go by is to precede any new analysis by an investigation of the different possible nuclear interferences for each element in its particular matrix. Such a short preliminary study could prevent many an erroneous analysis result.

MEASUREMENT OF THE RADIATION

Nearly all the radioactivity measurements for RNAA are based on γ-detection (and a few on β-detection), as this allows the simultaneous determination of several isotopes. This necessitates the use of a high-resolution Ge(Li) γ-ray detector coupled to a 4000-channel analyser. Important sources of systematic errors reside in the counting process and the quantitative interpretation of the γ-spectra. Crucial points are geometry factors, γ-attenuation, losses due to dead-time, pulse pile-up phenomena, spectral interferences and peak area calculations (particularly prone to errors when the peak-to-background ratio becomes small). These problems have been thoroughly investigated by Hertogen[39] and Baedecker.[40]

The neutron activation of biological material generally yields major γ-radioactivities of ^{24}Na ($t_{\frac{1}{2}}$ 15.02 hr), ^{38}Cl ($t_{\frac{1}{2}}$ 37.2 min), ^{42}K ($t_{\frac{1}{2}}$ 12.36 hr), ^{80}Br ($t_{\frac{1}{2}}$ 17.7 min), ^{82}Br ($t_{\frac{1}{2}}$ 35.3 hr) and an important bremsstrahlung of ^{32}P (pure β-emitter, $t_{\frac{1}{2}}$ 14.28 days). These high-energy dominant activities limit the sensitivity of the method of many trace elements with comparable or shorter-lived radioisotopes. The solution is a radiochemical separation of the element of interest. Such a procedure is necessary to improve the accuracy of low radioactivity measurements of long-lived isotopes hardly discernible from the Compton scattering of higher-energy γ-rays or from bremsstrahlung. This applies, for example, to the measurement of ^{51}Cr activities in irradiated normal serum. Only a radiochemical separation of Cr (by distillation as CrO_2Cl_2) enables accurate measurement to be made of the 320-keV photopeak, free from the background Compton continua of ^{59}Fe, ^{60}Co, ^{65}Zn, ^{86}Rb, ^{134}Cs and from the ^{32}P bremsstrahlung.

CONCLUSION

RNAA is a very sensitive technique for many trace and ultratrace elements in biological materials.[4] The accuracy of the analytical results depends upon an appreciation of the basis of the activation process. Such a scrutiny may reveal errors associated with activation (flux inhomogeneities, self-shielding, interfering reactions), as well as losses due to high radiation doses and blanks originating from the activated container material. The last-named phenomenon should not be underestimated in ultratrace determinations requiring long irradiations at high neutron fluxes. A considerable amount of trace-element analysis in biological material has become purely instrumental. Radiochemical separations, however, constitute the major part of the analytical procedure and make possible many ultratrace element determinations by separating the radioisotope of interest from an overwhelming or interfering matrix activity.

The detection of the radioisotopes is commonly performed by γ-ray spectrometry with Ge–Li detectors, followed by computer evaluation of the γ-ray spectra. The main sources of systematic errors may reside in the counting process and in the quantitative interpretation of the γ-ray spectra.

MINIMIZATION OF ACCURACY RISKS IN VOLTAMMETRIC ULTRATRACE DETERMINATION OF HEAVY METALS IN NATURAL WATERS

LÉON MART
Institute of Applied Physical Chemistry, Chemistry Department, Nuclear Research Centre (KFA), D-5170 Jülich, F.R.G.

(*Received* 14 *January* 1982. *Accepted* 14 *April* 1982)

Summary—This paper describes precautions aimed at reducing the magnitude of blanks during sampling, sample pretreatment and voltammetric determination of tracemetals, including cadmium, lead, copper, mercury, nickel and cobalt. The general approach of working in controlled clean areas and performing all manipulations outside them within closed systems is described. The voltammetric determination has been adapted to clean-bench working.

As a consequence of the ecotoxicological impact of certain heavy metals,[1,2] even at trace levels in natural waters, their determination has become an important subject of environmental trace analytical chemistry.[3–6] It is also of key significance for fundamental studies in chemical oceanography and limnology of trace metals. This is reflected in the considerable number of publications dealing with methods for the determination of trace-metal levels in the environment. Confusion about these trace levels, mainly in natural waters, was only resolved in the mid-seventies, when it turned out[7–11] that trace-metal levels are really several orders of magnitude lower than had been presumed and found before. Before these recent careful and reliable investigations, only a few analysts had taken into consideration problems arising from contamination in field work[12] and in laboratories.[13–15] Progress in electronics has considerably enhanced the determination capability, while development of high-capacity filtration units has simplified upgrading of the laboratory atmosphere. Consequently sources of error can now be clearly defined and minimized.

This paper summarizes the ultimate factors limiting accuracy, consisting mainly of blanks from inadequate sampling methods or airborne contamination. Figure 1 demonstrates that from the preparation of the sampling bottles and the sampler to the determination itself, risks of contamination by dust from the environment can be of very different magnitudes. Some manipulations can be performed in controlled dust-free areas but others have to take place in extremely contaminated surroundings. The only way of keeping the samples unaltered by uncontrollable blanks will be by working in quasi-closed compartments, as will be described later. It is assumed that the determination method applied is voltammetry. However, the general precautions for avoiding risk of contamination and other sources of error during sampling, sample pretreatment and sample handling remain relevant when other methods of determination are used.

CONTROLLED ATMOSPHERE

The laboratory

Generally an existing laboratory has to be converted into a clean-room. This has usually to be achieved with a minimum of alterations and at reasonable cost. The high cost of a class 100 laminar-flow room, according to US Fed. Stand. 209, and the extreme precautions for maintaining this standard during operation, can be avoided in a pragmatic manner by adopting a less stringent approach:[13] the laboratory is flushed with a non-laminar flow of filtered air, and within this "clean" area, several laminar-flow boxes, class 100, provide dust-free conditions for all critical manipulations. Further precautions are required, such as elimination of corroding metal components and unnecessary instrumentation, and also covering walls and ceilings with a non-shedding paint.

The effectiveness of upgrading the ambient laboratory air with respect to the dust level was checked by monitoring dust particles with a particle-counting device, the Partoscope R (Kratel KG, Stuttgart, Germany). Measurements in ordinary laboratories without these provisions generally yielded around 2×10^5 particles (with a diameter of $>0.5\ \mu m$) per cubic foot (28 litres). This corresponds to about 6 μg of dust per cubic foot. Background levels (per cubic foot) during the night ranged up to 1×10^5 particles with a diameter above 0.5 μm and a few particles larger than 5 μm. Unrestricted coming and going, and in particular smoking, increased the particle numbers to levels that could no longer be counted correctly by the Partoscope as they were beyond the limit of the measurement range (2×10^5). In the dust-controlled labora-

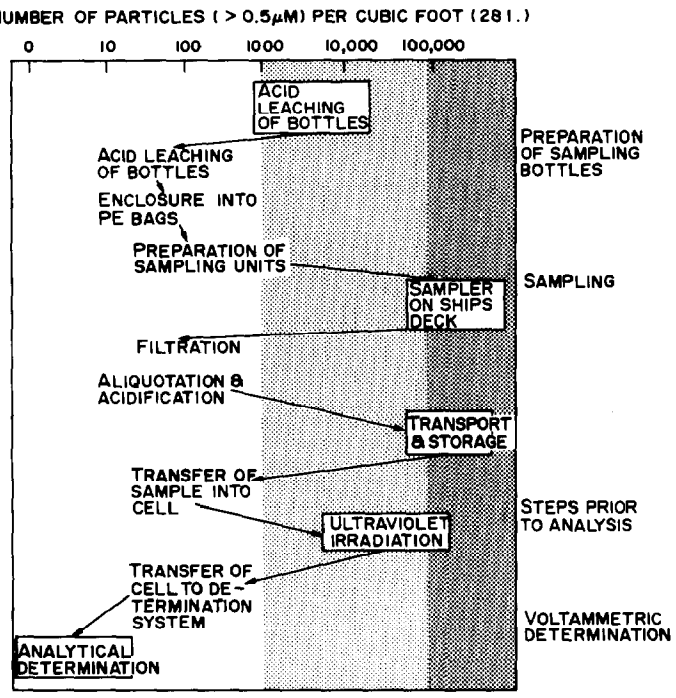

Fig. 1. Risks by dust contamination during preparative steps, sampling and determination. Principle of working either in clean areas or in closed systems.

tory, however, the particle count decreased to about 800 particles (diameter 0.5–5 μm) per cubic foot while no particles above 5 μm in diameter were present. The level generally becomes higher by a factor of about 10 if two staff members are working in the dust-controlled laboratory. At the laminar-flow clean bench the level is normally below 10 particles (0.5–5 μm) per cubic foot and can increase to 100–200 particles per cubic foot during manipulations, but only for a few seconds.

Of course, such low levels of dust can only be maintained if the staff wear protective clean-room overalls and arm sheets, together with polyethylene gloves for manipulations at the clean bench. Normal clothing increases the dust particle numbers considerably.

The laboratory in field missions

Reduction of blanks, a persistent problem in trace metal analysis, is far more difficult during field work, *e.g.*, during sampling missions on a research vessel. Laboratory air on board is severely polluted with trace metals such as lead, nickel and zinc. It is well known from numerous observations that during a journey there will frequently be work on paint-scrubbing and maintenance with lead-based anticorrosion paints. This of course creates serious problems of heavy contamination of ambient air with lead. One of the best ways of arranging to work in a clean area is to instal a clean-room container. This approach is limited only by the cost of installation and of transport to the port of departure of the research vessel. Once again, alterations to an existing laboratory may have to be restricted. Creation of a controlled atmosphere will involve reducing airborne contaminants in the form of dust and soot. The normal fresh air supply should, if possible, be cut off. Dirt particles introduced by shoes can be captured with a sticky floor covering[16] such as the plastic mats made by Dycem Ltd., Bristol (the Dycem Control Screen). A transportable clean-bench with horizontal laminar air-flow corresponding to US Fed. Stand. 209 (K. Bleymehl, Reinraumtechnik, Jülich, Germany) provides a clean working area of about 1 × 0.6 m at a height of 0.8 m. Horizontal air-flow is preferable for clean working with deep-sea sampling units. In mobile laboratories in vans for field missions on land, the installation of a clean-bench again creates satisfactory working conditions for ultratrace determination of heavy metals.[17]

EXPERIMENTAL REQUIREMENTS

Ultrapure water

High-purity water can be supplied from the reagent-grade ion-exchange unit Milli-Q (Millipore, Bedford, Mass., U.S.A.).[15] Demineralized water from a central supply is used for feeding a further ion-exchange cartridge. This water, with a conductivity of about 0.2 μS/cm is used for feeding the Milli-Q system. Water from this system yields the following low blanks: Cd < 0.1 ng/kg, Pb < 2.0 ng/kg, Cu < 10.0 ng/kg.

The lead blank can be further lowered by using the adsorption capacity of polyethylene surfaces for lead uptake from the demineralized water prepared as described above. For this purpose, water from the Milli-Q system is stored for some days in polyethyl-

ene bottles that have been leached in acid media for several days, as described later.

This system can easily be used on board a ship. The separate ion-exchange cartridge can also be fed with tap water, but this, of course, will reduce its capacity to about 500 litres.

Reagents

Hydrochloric, nitric and sulphuric acids are commercially available in high purity, *e.g.*, Suprapur® (Merck, Darmstadt). Usually the trace-metal levels are lower by a factor of 10 than those indicated on the label. In the acidification of samples to pH 2–3 (50 μl of concentrated acid added per 50 ml), the lead level in water samples is increased by 0.3 ng/kg. This blank need only be taken into consideration in deep-sea water analyses.

Reagents used in the determination of nickel and cobalt,[15] such as ammonium chloride and ammonia (both Suprapur®, Merck), and dimethylglyoxime (reagent grade) give a constant nickel blank of 4 ng/kg. Hydrogen peroxide (Suprapur®, Merck), is added as oxidant only to estuarine or polluted coastal waters[19] with higher trace-metal levels, and gives a blank of about 5 ng/kg when 200 μl are added to a 50 ml sample. Standard solutions (Titrisol, Merck) give no measurable blanks.

Cleaning of laboratory ware and sampling bottles

For sampling and storage, bottles and flasks from high-pressure (low density) polyethylene should be used in most cases. They are subjected to the following treatment: first, the bottles are carefully degreased with detergent in a washing machine, then pollutant trace metals, from the manufacture or incorporated into the raw material, are leached by soaking the bottles in an acid bath at medium temperature (60°) (Fig. 2). The acid bath has to be changed several times, finally to ultrapure water acidified to pH 2 with pure acids, *e.g.*, Suprapur® hydrochloric acid. The last manipulation, leaching in a very pure acid bath, has to be done at a clean-bench, to avoid contamination by dust particles. The sampling bottles and flasks thus prepared are filled with acidified ultrapure water (pH 2), wrapped inside two clean polyethylene bags and stored until required. Details of cleaning procedures have been described elsewhere.[16] The method of heating a large number of sampling bottles under contamination-controlled conditions is depicted in Fig. 2. Laboratory ware for mercury determinations has to be cleaned in separate containers which have not previously been loaded with laboratory ware or cells that have been used in work with mercury electrodes.

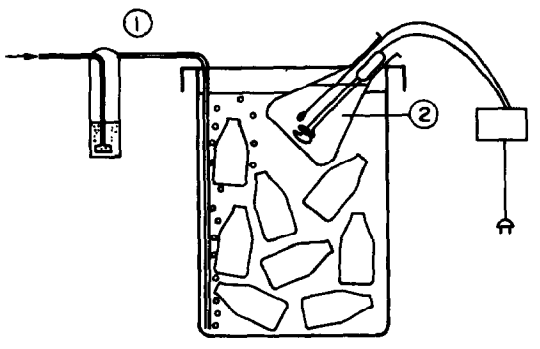

Fig. 2. Acid leaching of large quantities of bottles.[16] 1, Bubbling nitrogen avoids build-up of temperature gradients; 2, water-bath with temperature-controlled immersion heater (60–70°). (Reproduced by permission of the copyright holders, Springer-Verlag.)

Cleaning methods have recently been systematically investigated.[20]

Storage of samples

A steady state of non-leaching or non-adsorption will never be reached by cleaning or treating a surface, a fact that must be taken into account when samples have to be stored.[16,21] Keeping acidified solutions in (pH 2) polyethylene bottles at normal room temperature will increase the lead content by about 1 ng/kg per 2 weeks, because of leaching from the container walls. This effect, which mainly affects the lead blank, can be avoided by reducing the storage temperature. The best method of sample storage is deep-freezing to about −20°, which eliminates leaching of trace metals from the container walls and also losses by adsorption.

Adsorption of some trace metals, such as lead, occurs mainly in samples stored at neutral pH values. This adsorbed lead can be redissolved by acidification to pH 2. In general, samples such as sea-water, with large amounts of alkali and alkaline earth metal ions competing for adsorption sites, are less affected by losses through adsorption than are fresh water samples.

In all kinds of samples mercury is very sensitive to adsorption onto polyethylene. Thus subsamples for the determination of mercury have to be stored in glass or quartz bottles at low temperatures (4°) in a refrigerator. Of course, subsampling for mercury should be done as soon as possible, in order to avoid longer contact of the water with the plastic parts of a sampler.[22]

Collection of water samples

Surface water from rivers, lakes and the sea. Collection of pure surface water directly from a large ship is practically impossible, although it has been attempted again and again. The only safe way is to use a small rubber boat to leave the heavily contaminated area around the ship, and to collect water (in a clean bottle) at the bow of the boat whilst rowing upwind.[23] The same principle can be used on smaller ships (10–20 m length) by using a telescopic bar 3.5 m long. By means of this extension a sampling bottle can be dipped under the surface of the water while the ship proceeds at low speed.[23] Of course, precleaned polyethylene gloves are required for all manipulations with the sampling bottle.

Deep-sea water. In the last year it has turned out

that conventional deep-sea sampling methods using commercially available samplers clamped to the hydrowire may introduce large amounts of trace-metal contamination, especially of lead. Once again the determination of lead is particularly seriously affected, as it seems to be the only trace metal of interest present at extremely low levels in deep-sea waters, *e.g.*, about 1–10 ng/kg.[24–26] A recent investigation[27] has shown that no commercially available sampler for collecting water samples will give a lead blank below 10 ng/kg, thus making these samples suitable only for requirements less stringent than deep-sea sampling. Contamination problems with other trace metals are somewhat less severe than those with lead.

Contamination from the outer parts of the sampler or from the hydrowire can be avoided by using dynamic sampling, *e.g.*, collecting water with the sampler continually being lowered into virgin water during sampling. This was first achieved with the CIT sampler (California Institute of Technology).[27] Dynamic sampling, together with sophisticated precautions against contamination, has been used by us in the development of a deep-sea sampler automatically collecting three samples at different depths.[28] All manipulations such as preparation of the sampling units, that can be inserted into a main frame, and draining of samples into ultraclean bottles, are carried out within the dust-free area of a transportable clean-bench. When handled on the deck of the ship, the sampling units are hermetically sealed and thus protected from airborne contamination. Details of the sequence of operations during sampling have been published elsewhere.[25,28] A new approach to the collection of bottom-water samples at 1 m above the sea floor has been described elsewhere.[29]

Rain and snow. Rain and snow are sampled by automatic devices.[30] A humidity sensor controls the motor-activated lid of the sampler which consists of a large polyethylene funnel with a 0.45 μm filter at the bottom. The rain or snow collected is stored in a polyethylene bottle. When the rain stops the lid over the funnel closes automatically thus avoiding contamination by airborne dust during dry periods.

To our knowledge, there does not yet exist a reliable way of sampling rain or snow from a large ship during oceanic cruises. The surroundings on board ship are extremely contaminated and almost everywhere the air flow is turbulent, impeding dust-free sampling for any period longer than a few minutes. These findings have been confirmed recently by a short investigation on sampling of snow from an icebreaker in the Arctic Sea.[25] Uncontaminated snow could only be collected on ice floes upwind and at a distance from the ship.

Filtration of water samples

Apart from dealing with rain, as indicated before, filtration should only be used for turbid coastal waters, in order to distinguish so-called "dissolved" trace metals from those adsorbed on or incorporated into particulate matter. This fractionation is achieved by filtration through a membrane filter (0.45-μm pore size), according to a common convention in aquatic chemistry.

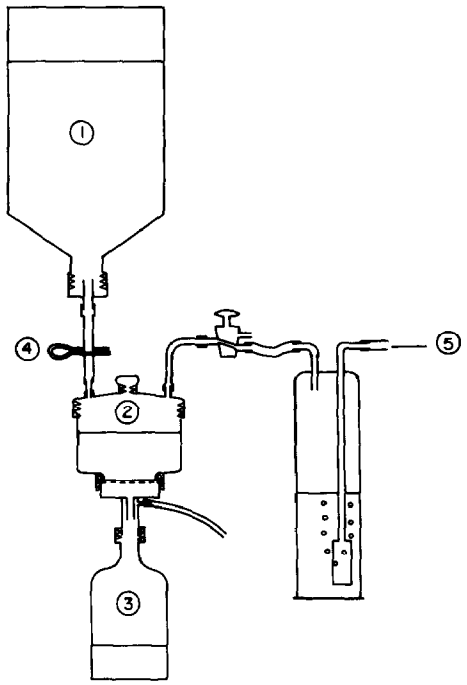

Fig. 3. Filtration unit.[16] 1, Freshly collected sample; 2, filtration unit; 3, polyethylene bottle for collection of filtered sample; 4, pinch clamp; 5, nitrogen-inlet for build-up of pressure. (Reproduced by permission of the copyright holders, Springer-Verlag.)

Membrane filters must be carefully precleaned in acid baths, to avoid leaching of trace metals during filtration. Filtration should be performed in the clean bench area, in order to avoid blanks from airborne contamination during change of filter. The filtration unit (Sartorius, SM 16511) is virtually a closed system, activated by nitrogen pressure (Fig. 3). Details of the sequence of operations during filtration have been published elsewhere.[16]

Ultraviolet irradiation

Ultraviolet irradiation, which is, apart from acidification, the only preliminary preparative step in the voltammetric determinations, may be required for degradation of organic substances binding trace metals as inert complex species. Analysis of samples from estuaries, rivers or waste waters might be significantly affected by the binding capacity of such dissolved organic substances. Irradiation requires ultraviolet lamps which often have corroding connections and soldering. The risk of contaminating samples during irradiation is thus quite significant. Samples for the determination of cadmium, lead, copper, nickel and cobalt have to be irradiated in a quasi-closed system, as depicted in Fig. 4. At a clean-bench, a subsample in a Teflon measuring cell is covered with a quartz beaker. A water-bath separates the cell and

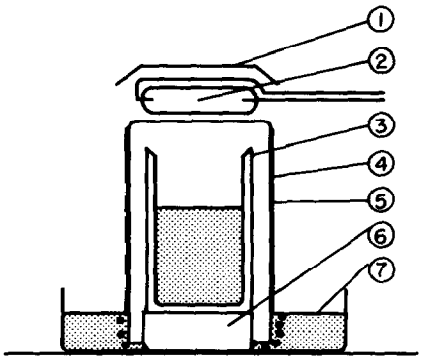

Fig. 4. Device for ultraviolet irradiation.[19] 1, Reflector; 2, ultraviolet lamp; 3, Teflon voltammetric cell filled with sample; 4, quartz beaker; 5, aluminium foil, the area of which determines the temperature under the beaker; 6, distance block; 7, glass dish with water for separating the cell from the outer atmosphere. (Reproduced by permission of the copyright holders, Springer-Verlag.)

the sample from the outer highly polluted atmosphere during irradiation.[19] After this operation, the outside of the apparatus is rinsed and the device is then opened at the clean-bench. The irradiated sample, that has boiled down to about half or one third of its original volume, can be diluted with ultrapure water, or measured out directly if it is desired to use this preconcentration factor of about 3.

For a more rapid oxidative photolytic decomposition, 200 μl of hydrogen peroxide (Suprapur®, Merck) are added to 50 ml of sample from estuaries, rivers and waste waters.[31] Heating samples to above 70° by ultraviolet irradiation must be avoided for determination of mercury: such samples are treated in closed quartz ampoules, cooled by a fan.[32]

Decomposition of particulate matter

Particulate matter collected on filters can be decomposed with particularly low contamination risks by low-temperature ashing (International Plasma Corp., Heyward, CA., U.S.A., Model 4005 B 448 AN). A prerequisite for low blanks is once again use of a controlled (essentially dust-free) atmosphere and clean combustion dishes made from quartz. Trace-metal losses seem to be negligible, as the ashing temperature is below 150°. After decomposition (3 hr) the residues are dissolved with 50 μl of pure acid and made up to 20 or 50 ml, depending on the working electrode used, *i.e.*, the hanging mercury drop or the thin mercury film on a glassy-carbon support.

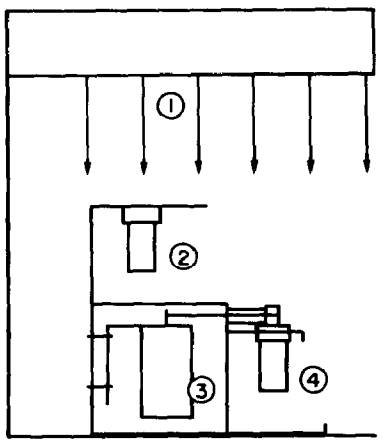

Fig. 5. Rotating electrode designed for clean-bench working. 1, Laminar clean-air flow; 2, cell for preliminary outgassing with nitrogen; 3, motor and electrical connections, completely separated from clean-air area; 4, voltammetric cell for determination.

Voltammetric determinations

The most sensitive electrochemical determination of cadmium, lead, copper, bismuth, and zinc involves preconcentration by deposition into a mercury film plated *in situ* on the glassy-carbon support of a rotating electrode.[8,19] Mention will be made here only of differential-pulse anodic-stripping voltammetry (DPASV), used for the ultratrace determination of the metals mentioned and the preferred technique for trace levels below 1 μg/kg.

We use two different sets of electrodes, one with a set of 8 electrolytic cells for work in our home laboratory[19] and a set with 2 electrodes for work during field missions.[25] Contamination that may arise with commercially available electrodes is avoided by careful design. Driving motors and electric connections are enclosed in a separate housing (Fig. 5). The cell and the electrodes, described elsewhere,[19] as well as manipulations such as changing cells in the laminar flow of the clean-bench, give rise to no measurable blanks (*i.e.*, below 0.1 ng/kg).

The determination of nickel and cobalt after interfacial preconcentration by adsorption of their dimethylglyoxime complexes at a hanging mercury drop[18] is not seriously affected by the reagent blank of 5 ng/kg for nickel. Care must be taken not to use Vycor tips (Corning Glass Corp.) to separate reference electrodes from sample solutions. Substantial amounts of nickel and cobalt may be leached from this kind of porous glass and severely contaminate the sample.

The determination of mercury at a rotating gold electrode[32] should be done in a separate laboratory. Experience over the years has shown that electrochemical laboratories usually have measurable levels of mercury vapour in the air, normally below the maximum tolerable levels for human health, but nevertheless critical for the determination of the element at ultratrace levels.

CONCLUSION

When all the precautions discussed in this article are taken, both high precision and extremely low limits of detection can be attained in the voltammetric determination of cadmium, lead, copper, mercury, nickel and cobalt (see Fig. 6). The accuracy is also good, as far as can be seen from a comparison of measurements on some sea-water samples. Table 1 summarizes the results of a first test organized by

ROLE OF RADIOTRACERS IN THE DEVELOPMENT OF TRACE ELEMENT ANALYSIS

V. KRIVAN
Sektion Analytik und Höchstreinigung der Universität Ulm, Oberer Eselsberg
D7900 Ulm/Donau, F.D.R.

(*Received* 14 *January* 1982. *Accepted* 6 *March* 1982)

Summary—This article discusses the contribution of the tracer technique to the present state of development of trace element analysis. It reviews the use of radiotracers for testing the individual steps of the analytical process, especially with regard to the sources of systematic error. The major subjects considered are: sampling, storage and pretreatment of samples, sample decomposition, separation and preconcentration, and the measurement stage.

For the determination of trace elements in various matrices, an impressive number of powerful methods based on various physical principles is at the disposal of the analyst. These analytical techniques can be classified into two groups: (1) direct instrumental or single-stage techniques, and (2) multistage or combined techniques.

The direct techniques, which include optical emission spectrometry with spark or arc sources, X-ray spectrometry, spark-source mass-spectrometry and activation analysis, are in many instances the optimum choice. In general, however, the combined techniques can be taken as models for the methodology of trace element analysis. A typical analytical process consists then of the following steps: sampling, sample preparation, decomposition, separation (preconcentration), and measurement. Each of these steps can be a source of systematic error. Thus, the principal problem in any combined procedure is to convey the very small amounts (from pg to μg) of the determined elements through all steps of the procedure, from sampling to detection, without introducing systematic errors, such as contamination or loss.

Radioactive tracers have proved to be an excellent means for examining the individual steps of the analytical process and revealing the concomitant sources of systematic error. To a considerable extent the progress achieved in trace element analysis is the result of studies using the radiotracer technique. In most cases it is probably the best approach, and some problems cannot be solved by other means. However, it should be emphasized that the radiotracer technique cannot itself provide the solution to all aspects of accurate analysis, but rather should be considered as one of the necessary tools for achieving this end. For instance, it can only make a limited contribution to the solution of such problems as calibration and standardization. A clean working atmosphere, high-purity reagents, and standard reference materials are also principal requirements if accuracy is to be achieved.

In this paper, the unique capabilities of the radiotracer technique for studying the individual steps of trace analysis and identifying the sources of systematic error are discussed. The most important applications are surveyed, and illustrated with suitable examples.

SAMPLING AND SAMPLE HANDLING

The first and perhaps the most critical step in an analysis is sampling and sample handling. It includes taking the sample, and transporting, storing and processing it before the decomposition step or direct instrumental analysis. All these stages must be considered as possible serious sources of error.

Sample homogeneity

The fundamental requirement of sampling bulk material is that the proportion of the component of interest is, within the limits of error, the same in the sample as in the whole.[1,2] No difficulties are encountered in obtaining representative samples of liquid materials. On the other hand, sampling is an extremely difficult problem in the case of solid materials because of their considerable lack of homogeneity. Close attention must be paid to the possible segregation of components. The homogeneity has to be considered not only with regard to appearance, but also to how well the sample for analysis represents the whole. The sample homogeneity requirements can also depend on the method used for determination. Solution techniques normally utilize relatively large samples, from which homogeneous fractions are analysed, resulting in the reduction of inhomogeneity errors. However, in a number of direct techniques, such as spark-source mass-spectrometry, direct X-ray fluorescence spectrometry, optical emission spectrometry and charged-particle activation analysis, only a small volume fraction of the sample is normally involved in the excitation of element-specific signals,

and thus the homogeneity of the sample is of great importance. Inhomogeneity can become a severe problem when the sample consists of particles of different sizes and the content of the trace component in question varies with particle size, as is often the case in airborne particles, geological and industrial materials. Considerable inhomogeneities also occur in biological matrices.

The radiotracer technique has proved to be well suited for examining the course of homogenization in an arbitrary mixing process.[3,4] The system to be investigated can be labelled either by the addition of a radiotracer to the component of interest, or by radioactivation. The material is then sampled at various stages of homogenization, *e.g.*, at various intervals of time, and the radioactivity of the samples (normalized to sample weight) are related to the relevant parameter, usually time. The closer together the specific activities of the samples, the greater the degree of homogeneity (f_H) of the material. We can express f_H quantitatively by means of the coefficient of variation V:

$$f_H = (1 - V)100\% \quad (1)$$

and

$$V = \sqrt{\frac{\Sigma(a_i - \bar{a})^2}{(n-1)\bar{a}^2}} \quad (2)$$

where a_i is the relative specific activity of sample i, and $\bar{a}$ the average relative activity of the n samples (taken after different homogenization periods).

The inhomogeneity problem is very serious in the analysis of compact solids such as metals or semiconductors.[5,6] In the case of metals in particular, the usual treatment for preparation of a homogeneous sample, *i.e.*, crushing, grinding and mixing, is not feasible. In many instances, a homogeneous sample can only be prepared by dissolution.

Radiotracers and autoradiography have been widely applied to homogeneity studies on solids and have contributed greatly to study of the distribution of trace admixtures in materials. Significant progress in the evaluation of two-dimensional distributions has been achieved by colour autoradiography[7] based on the relationship between radioactivity and colour shade.

Inhomogeneous distribution is evidently caused by limited solubility or lack of solubility of the trace components in the matrix, as the insoluble elements tend to form agglomerates. However, even soluble elements can be distributed inhomogeneously because of segregation during the crystallization process, whereby the elements may accumulate at the phase boundary or inside the grain, as was demonstrated by segregation of labelled copper and tungsten in an Fe–C alloy.[8] It is also possible that the concentration changes from the grain boundary to the interior were the result of heat treatment, as observed for bismuth distribution in copper grains.[9] An impressive example of an extremely inhomogeneous distribution of a trace impurity in the matrix is shown in Fig. 1. It can be seen that the tantalum (labelled as ^{182g}Ta by activation), the main impurity, is concentrated in an inclusion located approximately in the middle of the niobium disc. As a consequence of this inhomogeneity large errors can occur in bulk analysis if the sample is not excited uniformly over the whole volume when a direct instrumental technique is used, or if only a small-volume sample is taken for dissolution.

In addition to metals, semiconductors have been extensively investigated by autoradiography with regard to distribution of impurities and doping elements.[10] Radioactive tracers have also been used for studying some aspects of sampling and processing of geological materials.[11]

Contamination problems

The tracer technique offers a valuable tool for examining difficult contamination problems. For example, in the determination of essential or toxic elements in biological fluids and tissues at the ng/g level, contamination-free sampling, sample-handling and storage prior to analysis, are essential for accuracy, if activation analysis, which is a blank-free method, is applied.

In contrast to compact solids, the surface contamination introduced into these samples during sampling and storage cannot be removed by etching. These contaminations can easily exceed the actual contents by several orders of magnitude. This explains the continuous decrease in the "normal values" of several essential elements during recent years, *e.g.* for cobalt and chromium in serum and plasma, from about 10 ng/ml some years ago down to 0.1 ng/ml today.[12,13] Even if the composition of the surgical and container materials used is known, it is very difficult to establish the extent of this contamination.

The tracer technique has contributed to present knowledge of these contamination problems. The surgical instruments have been labelled *in situ* by neutron-activation and then used for *in vitro* experiments simulating medical practice, and the contamination introduced has been measured by means of its radioactivity.[14–16] The results for Co and Cr, expressed as "apparent concentrations", are given in Table 1. It can be seen that this particular type of needle cannot be used if these two elements are to be determined.

The extent of the iodine contamination of biological material in neutron-activation analysis done with irradiation containers made from polyethylene has been tested,[16] and that from containers made from high-purity quartz has been examined for 37 elements[17,18] by irradiating the cleaned quartz capsules, simulating a wet-ashing with a mixture of nitric acid and hydrogen peroxide and counting the activity of the corresponding radionuclides. In the case of Au, Cd, Co, Cr, Mn, Sc, the wet-ashing blank is either at

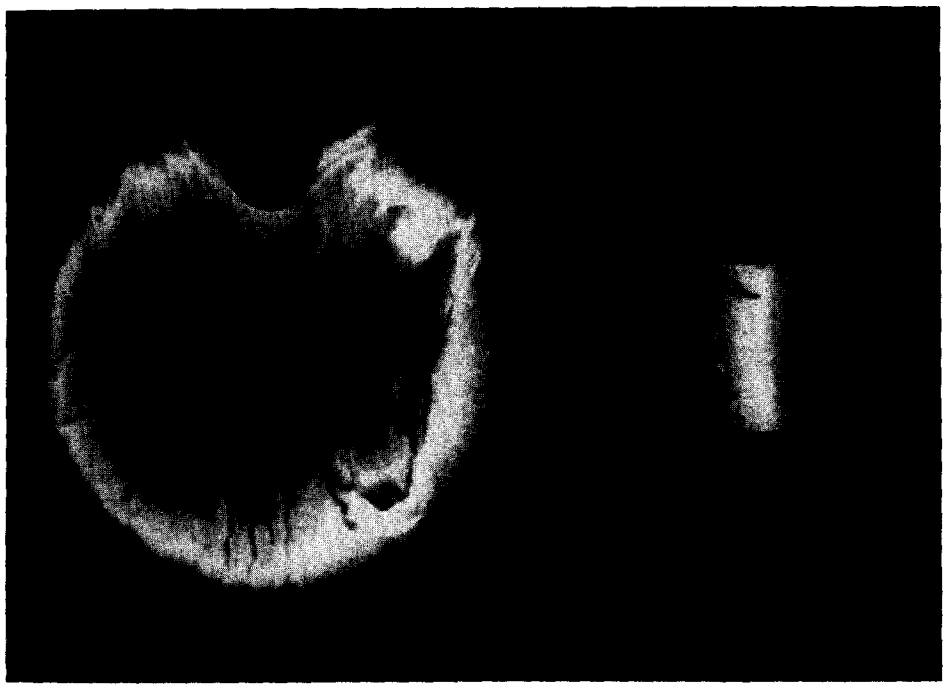

Fig. 1. Distribution of tantalum in a niobium disc, (2.5 cm diameter) determined by *in situ* labelling and autoradiography.[7] (By permission of the copyright holders.)

Table 1. "Apparent concentrations" in serum, caused by contamination introduced in taking successive 20-ml blood samples with disposable needles[16] (reproduced by permission of the copyright holders)

Element	Normal range, *ng/ml*	Sample	Apparent concentration, *ng/ml*
Co	0.1–0.3	1	0.9
		2	0.2
		3	0.1
		4	0.2
Cr	0.2–0.7	1	85
		2	12
		3	10
		4	15

the same level as the mass of these elements present in 100 μl of serum, or up to one order of magnitude higher. Thus, these contaminations can be a considerable source of error. However, if a surface layer about 20 μm thick is removed by etching before the ampoule is sealed, the wet-ashing blank can be significantly reduced.

In analysing solids of extremely high purity by activation analysis, special attention must be paid to the removal of any surface contamination which has occurred during sample preparation and irradiation. In some cases, surface decontamination can itself create problems.[19] In the determination of very low contents of chromium and iron in pure niobium by proton-activation analysis,[20] the removal of the appropriate indicator radionuclides from the surface in the post-irradiation etching was checked by the tracer technique. The sample surface was deliberately contaminated with metallic and ionic chromium and iron, and the radiotracers were produced *in situ* by irradiation with protons under the same conditions as used in irradiation for analysis. As can be seen from Fig. 2, complete removal of contaminants is achieved by the etching procedure used; the total maximum matrix loss was found to be 0.08 mg/cm^2 (corresponding to a thickness of 3×10^{-4} mm) and could therefore be neglected.

Adsorption losses

Storage of liquid samples and standards may be one of the most important sources of error in an analytical procedure, but the danger of these errors is all too often underestimated or even totally neglected. Radioactive tracers undoubtedly provide the best technique for investigation of losses of trace elements by adsorption. The adsorption losses can be determined either by counting the solution before and after the adsorption, and calculating the amount adsorbed by difference, or by directly counting the radioactivity of the solid adsorbent. Although a large amount of experimental information has been accumulated on the adsorption of inorganic species on glass, quartz, plastics and other materials[21,22] satisfactory systematic evaluation has not been possible, as the exact nature of the adsorption phenomena is in many cases not clear. Consequently, most elements do not behave predictably under all circumstances. The conclusion is that adsorption of trace elements is a very complex process. It can be affected by many factors, of which the most significant are the kind of material and its pretreatment, the nature of the ion, the pH-value, the presence of other electrolytes, the temperature and the time. The best understanding of the mechanism and course of adsorption has been obtained for glass as the adsorbent. One important type of adsorption of cations is ion-exchange with the groups ≡SiOH or ≡SiOMe (Me = alkali or alkaline-earth metal). An interesting characteristic of this adsorption is the possibility of reducing it by acidifying the solution, so that the metal cations are replaced by protons. Anion-exchange, *e.g.*, of anionic metal complexes, can also take place on glass. In this case, an increase in hyd-

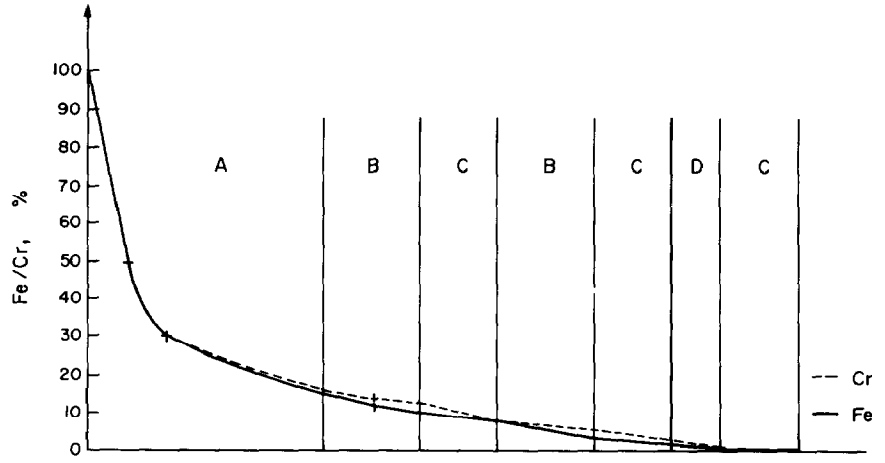

Fig. 2. Percentage removal of the indicator radionuclides ^{52}Mn and ^{56}Co produced from surface contamination of a niobium matrix with Cr and Fe during the etching procedure.[20] A—3 hr in 10*M* HCl at 65°; B—1 min in HF/HNO_3/H_2O (9:1:10); C—1 hr in 10*M* HCl at 65°; D—30 sec in HF/HNO_3/H_2O (9:1:10). Fig. 3. Decrease of cadmium concentration in water at pH 10 during storage in a soft glass container, determined by using ^{109}Cd as radiotracer.[23] [Cd], ng/ml: 1, 200; 2, 100; 3, 25; 4, carrier-free ^{109}Cd. (Reproduced from *Anal. Chem.*, 1974, **46**, 771, with permission. Copyright the American Chemical Society).

roxide-ion concentration will reduce the adsorption. However, products of metal ion hydrolysis and colloidal particles can also be involved in adsorption.[22]

From the example shown in Fig. 3, it can be seen that the adsorption losses of cadmium on glass can reach considerable levels within a few hours and depend on the cadmium concentration; the lower the concentration the larger the relative loss.[23] The adsorption properties of various materials (glass, quartz, plastics, Teflon) have been investigated with ^{110m}Ag and ^{111}Ag as tracers.[24,25] None of the materials tested was found suitable for long storage of liquids containing traces of silver. However, the adsorption can be made negligible (<1%) by addition of sodium thiosulphate.

Several tracer studies have been devoted to investigation of losses of trace mercury from solution. By use of ^{197}Hg as tracer, severe adsorption losses on polyethylene were observed for both ionic mercury (up to 74% within 48 hr) and organomercury (up to 30% within 48 hr) for unacidified samples.[26] The results of another study,[27] with ^{203}Hg, showed that evaporation can also contribute to losses of inorganic mercury from stored aqueous solutions. On storage of a solution containing 2 ng of Hg per ml in 0.5*N* nitric acid in PTFE, about 25% of the mercury is lost in 10 hr by volatilization, whereas the losses are significantly lower from hydrofluoric acid solution (~4%). Losses are negligible from both solutions if potassium iodide or potassium cyanide is added. The utilization of ^{203}Hg as tracer in a recent study on the behaviour of mercury chloride and methylmercury chloride in inland water and sea-waters[28] revealed that the loss of mercury observed upon storage of unacidified sea-water samples in polyethylene bottles was due to both adsorption and to diffusion of metallic mercury through the container wall. For the chemical speciation of mercury compounds, time and the nature of the storage were found to be of paramount importance. For example, in three days' storage in brown glass bottles, 47% of $^{203}HgCl_2$ added to sea-water became reduced to mercury, but complete reduction with tin(II) chloride could not be achieved. Large adsorption losses have also been observed for many other elements, *e.g.*, gold up to 100% on polyethylene,[29] barium up to 70% on glass,[30] and cobalt up to 95% on glass.[31]

In analysing water samples, it is important to differentiate between the trace contents in solution and in the suspended matter. For this purpose, the samples may be filtered through a 0.45-μm membrane filter. Thus, when radiotracers (^{115}Cd, ^{60}Co, ^{59}Fe, ^{197}Hg, ^{99}Mo, ^{212}Pb, ^{65}Zn) were added to a filtered sea-water sample and the solution was repeatedly filtered through a fresh membrane filter, serious adsorption losses on the filter were found for iron (up to 33%),

Table 2. Losses of trace elements occurring during oven drying, freeze drying and dry ashing, determined by the radiotracer technique (after Sansoni and Iyengar[32])

Process	Element	Matrix	Temperature, °C [Pressure, *mm Hg*]	Time, *hr*	Loss observed, %
Freeze drying	Hg	Human urine	[0.05]	48	2
		Blood	[0.05]	24	9
		Water	[0.01–0.05]	48–72	39
	Se	Human urine	[0.05]	48	3
Oven drying	Hg	Human urine	105	24	15
		Rat brain	120	24	5–16
	I	Rat blood	120	24	7
		Rat kidney	120	24	15
	Pb	Oyster	100	48	17
	Se	Human urine	105	24	30–50
Dry ashing	As	Rat blood	450	16	86
	Co	Molluscs	450	?	26
	Cr	Rat liver	500	16	6
		Rat blood	700	16	51
	Na	Human rib	600	16	10
	Sr	Rat blood	450	16	16

lead (up to 11%) and mercury (up to 19%). The losses depended on both the volume filtered and the concentration of the trace elements.[26] In this way, it was shown that it is a mistake to apply filtration in the determination of mercury in water unless the adsorption is prevented by lowering the pH of the solution.

Volatilization losses during drying and ashing

Before instrumental measurements or decomposition, biological and environmental samples are often dried. This can be done by simple drying in air (not recommended), in an oven, or by freeze drying. It has been revealed with the aid of radiotracers that surprisingly large losses of several elements can occur not only during oven drying at temperatures between 70 and 120° but also during freeze drying.[32] Table 2 gives examples of losses occurring during the sample pretreatments discussed above.

A serious reduction in accuracy may result from losses during evaporation of solutions, often an essential step in analytical procedures. The tracer technique is the routine method for investigating such losses.

SAMPLE DECOMPOSITION

One step in which severe losses can obviously be expected is the decomposition of the sample. Dry ashing in a muffle furnace (at temperatures between 400 and 500°) is still often used for the decomposition of organic material, because of its simplicity and suitability for dealing with large samples and large numbers of samples. However, numerous radiotracer studies indicate that severe losses of several elements may occur during this ashing procedure, even of those elements for which no loss would normally be expected. In addition, the extent of the volatilization loss depends on the nature of the biological material. Some examples of significant losses detected by the tracer technique are included in Table 2. Because of the danger of volatilization losses, dry ashing and wet decomposition in open systems should be avoided unless such losses have been checked for the given element and matrix. On the other hand, with the help of radiotracers, decomposition procedures using closed systems have been developed which avoid losses even for the more volatile elements. For example, good recoveries of mercury and selenium are achieved in the decomposition of biological materials with nitric acid under pressure in a Teflon tube,[33] or with oxygen activated in a microwave discharge,[34] as can be seen from Table 3.

Valuable results were obtained in an investigation (by the tracer technique)[35] of the behaviour of trace platinum elements during chemical dissolution of aluminium and nickel matrices. Aluminium and nickel samples doped with Ru, Os and Ir were labelled *in situ* by irradiation with reactor neutrons. The labelled samples were dissolved, and by means of chemical separations, were tested to determine whether the doped trace constituents had dissolved. The results showed that sample decomposition can have a decisive effect. The three trace elements were not dissolved during decomposition of the aluminium matrix, either in acid or alkaline solution. Even after further treatment, iridium could not be completely dissolved, and then separated quantitatively, but in the case of osmium and ruthenium this was possible by oxidation followed by distillation. On the other hand, Os, Ru and Ir were dissolved during the decomposition of the nickel matrix in nitric acid. These results are similar to those obtained when attempting to determine iridium and other elements in niobium,[36] when low yields and poor reproducibility were a serious problem. These results are of great importance. If a matrix is to be decomposed for the purpose of trace impurity determination, it is necessary to know the chemical state of the trace constituents of interest after the decomposition of the samples.

Table 3. Recovery of some volatile elements in decomposition of samples in closed systems (after Tölg and co-workers[33,34])

Decomposition	Element/ radioisotope	Amount applied, *ng*	Recovery, %
Wet, with HNO_3 under pressure	Be/^{7}Be	5–100	97.5
	Se/^{75}Se	1–10	98.5
	I/^{131}I	5–100	97.5
	Hg/^{203}Hg	3–80	98
Dry, with activated oxygen	Se/^{75}Se	31–250	98.5*
	Zn/^{65}Zn	60	100†
	Hg/^{203}Hg	0.5–60	91§

*Dissolved in 0.1*M* HNO_3.

SEPARATION AND PRECONCENTRATION PROCEDURES

Analytical procedures performed without chemical separations can only be successful when the signals due to the elements to be determined are not interfered with by other elements or the matrix, or when adequate corrections can be made for any interference. In many instances, it is necessary either to remove the major components or to separate the element(s) of interest from the sample. Sometime preconcentration is also required. The tracer technique is well suited for the rapid and accurate evaluation of the distribution of the elements of interest in a separation process. In fact, most of the separation data for trace elements have been obtained by using radiotracers. These data include the distribution coefficient, capacity factor, separation factor, separation efficiency and recovery factor. Radiotracers have been used extensively in all types of separation research, such as separation by phase change (volatilization, precipitation, electro-deposition, liquid-extraction,

ion-exchange, adsorption chromatography) and separation by difference in mobility (paper chromatography and electrophoresis). Some examples are given below. By means of radioactive tracers it was shown that selenium (as matrix) can be removed practically completely (>99.999%) by distillation as the tetrabromide, while the impurities Na, K, Sc, Cr, Fe, Co, Cu, Zn, Ga, Ag, Cd, La, Ta and Au remain (with good recoveries) in the residue.[37] On the other hand, trace selenium may be separated from biological materials, rocks and soils directly in the decomposition (by combustion in oxygen) under dynamic conditions in a special apparatus.[38] While concomitant elements forming relatively non-volatile oxides remain in the ash on the sample holder, selenium dioxide can be volatilized and then condensed on a cold-finger. It may then be dissolved with hydrochloric or nitric acid, by boiling under reflux. The recovery determined by using ^{75}Se as radiotracer was found to be 97%, regardless of the matrix.

Sixty-three radiotracers were used for labelling in an extensive study of the retention of ions from different acid media on columns of eleven ionic precipitates.[39] The results of about 2000 adsorption experiments enabled many new separations of great practical significance to be realized. For example, sodium and tantalum can be separated quantitatively on hydrated antimony pentoxide from 58 other cations in 12*M* hydrochloric acid medium. From 14*M* nitric acid, quantitative retention of Na, Ge, As, Se, Nb, Mo, Ag, Ta and Pa may be achieved.

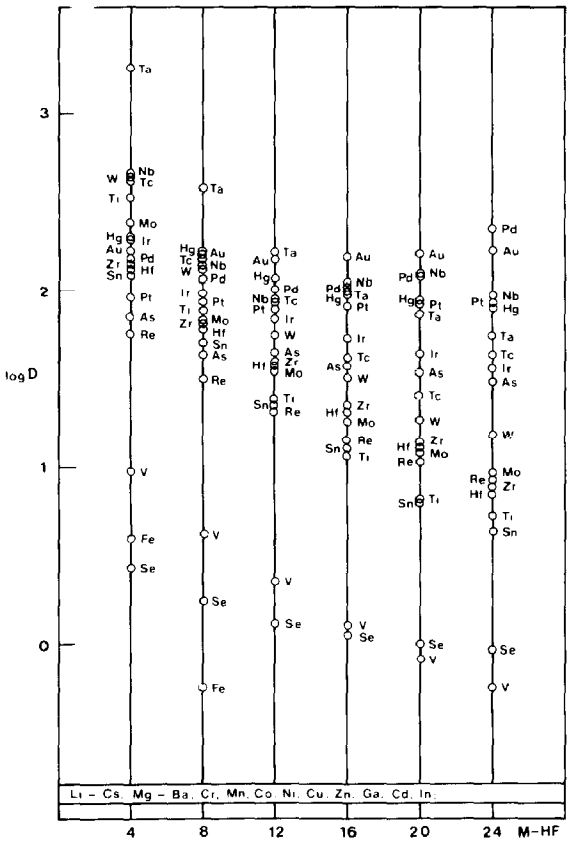

Fig. 4. Distribution coefficients for Dowex 1 × 8 resin and HF solutions, determined by the radiotracer technique (excluding Li and Mg).[41] (Reproduced from *Anal. Chem.*, 1981, **53**, 1719, with permission. Copyright by the American Chemical Society).

The radioisotopes ^{59}Fe, ^{60}Co, ^{65}Zn and ^{207}Bi have been used to study the deposition of the corresponding elements on a graphite cathode. After separation the deposited elements can be determined by AAS or optical emission spectroscopy.[40] Amounts of a few ng at the <10 ng/ml level could be separated on the graphite tube with yields above 98%.

The radiotracer method has also been used to study the adsorption of 31 elements on Dowex 1 × 8 from hydrofluoric acid and hydrofluoric acid/nitric acid media under static conditions.[41] These media are suitable for the decomposition of refractory metals, glasses and geological samples. The adsorption of the elements from hydrofluoric acid solution is illustrated in Fig. 4. The results obtained for hydrofluoric acid/nitric acid systems show that with increasing nitric acid concentration there is a continuous decrease in the *D* value for all elements tested. These distribution data allow useful separation procedures to be worked out; for example, in the determination of Zr, Mo, Hf and W in niobium and tantalum by X-ray fluorescence spectrometry.[42] One of the main steps of this procedure is, in addition to the separation of the niobium or tantalum matrix by extraction with diantipyrylmethane, the preconcentration of Zr, Mo, Hf and W on a strongly basic anion-exchange paper from hydrofluoric acid solution, followed by measurement with a wavelength-dispersive X-ray fluorescence spectrometer, with limits of detection below 0.3 ppm for all four elements.

Radioactive indicators have also been widely used in other separation techniques and their application reviewed.[21,43]

DETERMINATION

The tracer technique offers unique possibilities for clarifying what actually happens to the elements of interest during the determination stage. This knowledge often reveals sources of systematic error and facilitates optimization of the determination. The potential of the tracer technique for this purpose is exemplified by the determination of mercury by flameless atomic-absorption spectrometry.

Flameless AAS should be a suitable technique for the determination of trace mercury but its application has been limited because of significant losses of mercury occurring in the preatomization treatment in the graphite tube, *i.e.*, in the drying and pyrolysis steps. Investigations using ^{203}Hg as radiotracers have contributed to the understanding of these processes.[44] From the results given in Table 4 it can be seen that from certain media 40–90% of the trace mercury can be lost during drying at 70° whereas non-detectable

Table 4. Mercury losses during drying* (Reproduced from *Anal. Chem.*, 1982, **54**, 579 by permission. Copyright the American Chemical Society)

Solution	Mercury loss, %
2% HNO_3	77.7 ± 4.7
2% H_2SO_4	86.7 ± 4.3
2% H_2O_2	42.7 ± 3.1
2% HCl	49.3 ± 5.1
2% HNO_3 + 2% H_2O_2	48.7 ± 4.0
2% H_2SO_4 + 2% H_2O_2	44.3 ± 5.7
2% HCl + 2% H_2O_2	not detectable
2% HCl + 2% H_2O_2 + 2% HNO_3	not detectable

*In a pyrolytically coated tube at 70°, Hg 0.3 μg/ml, ramp-time 20 sec, hold-time 50 sec.

losses occur from others at temperatures up to 250°. Similar stabilization effects have been achieved by formation of mercury sulphide with hydrogen sulphide in the graphite tube before drying. A technique for the determination of mercury in biological material based on these stabilization effects has been worked out. It involves decomposition with nitric acid in a pressure bomb, adjustment of the solution with hydrochloric acid/hydrogen peroxide mixture and analysis by flameless AAS. Similar investigations on other elements are in progress in our laboratory.

Radioactive tracers have been used for investigation of a number of basic problems in atomic-emission spectrometry. For instance, the thermochemical behaviour of various elements in graphite electrodes on d.c. arc excitation was studied by the tracer technique.[45,46] Experiments with ^{59}Fe and ^{110m}Ag for measurements of the evaporation rate and the activity distribution in the electrodes led to a better understanding of the transport mechanism in the arc. With the aid of these measurements it was possible to demonstrate the influence of the cathode shape and the form of the gas discharge chamber on the evaporation of the components. On the basis of the tracer studies, two rotating plasmas within the graphite tube were applied, and this improved the detection limits.

With the help of radiotracers (^{59}Fe, ^{60}Co, ^{95}Zr and ^{45}Ca) the processes taking place in rotating disc electrodes and their influence on spectrochemical analysis in solution have been investigated.[47] Owing to the chromatographic effect, there is variation in the depth of penetration by the four elements.

The results suggest that the spectral parameters of the rotating disc electrodes depend not only on the physical properties (density, porosity, grain size, electrical and thermal conductivity) but also on the chemical properties.

CONCLUSION

In this review, an attempt has been made to show the versatility of the radiotracer technique as a tool for the investigation of all aspects of trace element analysis, especially with reference to gains and losses of determined.

THE ORIGIN OF SYSTEMATIC ERRORS IN BACKGROUND MEASUREMENTS IN ZEEMAN ATOMIC-ABSORPTION SPECTROMETRY

H. MASSMANN
Institut für Spektrochemie und angewandte Spektroskopie, D-4600 Dortmund 1, F.D.R.

(*Received* 3 *April* 1982. *Accepted* 2 *May* 1982)

Summary—The problem of background measurement in Zeeman atomic-absorption spectrometry is discussed. The background measurement may be more or less faulty if the background is caused by line-rich electron excitation spectra of molecules. Molecules also such as OH, NO, NO_2 and SO_2 show a Zeeman effect. Therefore, the background measured in two different polarization planes or measured with and without a magnetic field present may differ. The danger of systematic errors in background measurement is less if the background is caused by polyatomic molecules. Rotational structure is less marked or not at all observable.

One of the most significant and difficult problems in atomic-absorption spectrometry is to measure the true background. Correct background measurement is especially important if the addition method of calibration has to be applied, *e.g.*, if the matrix material of the analytical sample cannot be obtained completely free from determinand, in which the calibration graph has to be extrapolated to zero net absorbance. However, in order to do that, the background absorbance caused by radiation scattering and atomic or molecular absorption by the matrix material must be found. This cannot be done by merely pushing the knob marked 'automatic zero".

The problem of background measurement is mainly to determine the spectral background underlying the very narrow resonance line, and cannot be resolved by the monochromator. The normal method of background measurement or background compensation with a continuum source of radiation is correct only when the background is a spectral continuum, *e.g.*, when it is caused by radiation scattering or photodissociation of molecules. The background measurement may be more or less faulty if the background is due to line-rich electronic excitation spectra of molecules. The actual background is entirely dependent upon whether or not a rotational line of the molecular spectrum coincides with the atomic-absorption line.[1] It is very difficult to deduce this from measurements obtained with the commercial atomic-absorption instruments normally used.

In the course of the past years, the most important step forward in atomic-absorption spectrometry was the application of the Zeeman effect to the quasi-simultaneous measurement of atomic and background absorption. Nowadays, three types of commercial instruments are already available which use different Zeeman techniques. However, we do not know how these techniques compare in respect to accuracy of background measurement and how they compare with commonly used techniques of background measurement with a continuum source of radiation.

SYSTEMATIC ERRORS OF BACKGROUND MEASUREMENT WITH A CONTINUUM SOURCE OF RADIATION

The best "guinea-pig" to show the origin of systematic errors due to structured background is the OH-band in the wavelength region near the bismuth resonance line at 306.8 nm. Figure 1 shows the absorption spectrum of an acetylene–air flame in the region of the bismuth line (lower spectrum). The spectrum has been recorded with a continuum source of radiation in combination with a high-resolution instrument. The practical resolution is approximately $R = \lambda/\Delta\lambda = 2.5 \times 10^5$. The absorption scale is in arbitrary units, because the transmission T_p of the photoplate has been recorded.

The upper spectrum shows the profile of the bismuth line recorded with the same resolution. As a result of nuclear-moment splitting, the bismuth line has two components. The wavelength difference between them is approximately 0.01 nm. It can be seen that two rotational lines coincide almost exactly with the bismuth components. Therefore, the actual background under the bismuth components is very high. This cannot be deduced from background measurements with low-resolution atomic-absorption spectrometers. If a deuterium lamp is used and measurements are made with a spectral bandwidth (halfwidth of the transmission profile of the monochromator as indicated in Fig. 1) of, for example, $\Delta\lambda = 0.5$ nm, we measure only an arbitrary mean value, at large wavelength intervals. This value is far too low in comparison with the actual background

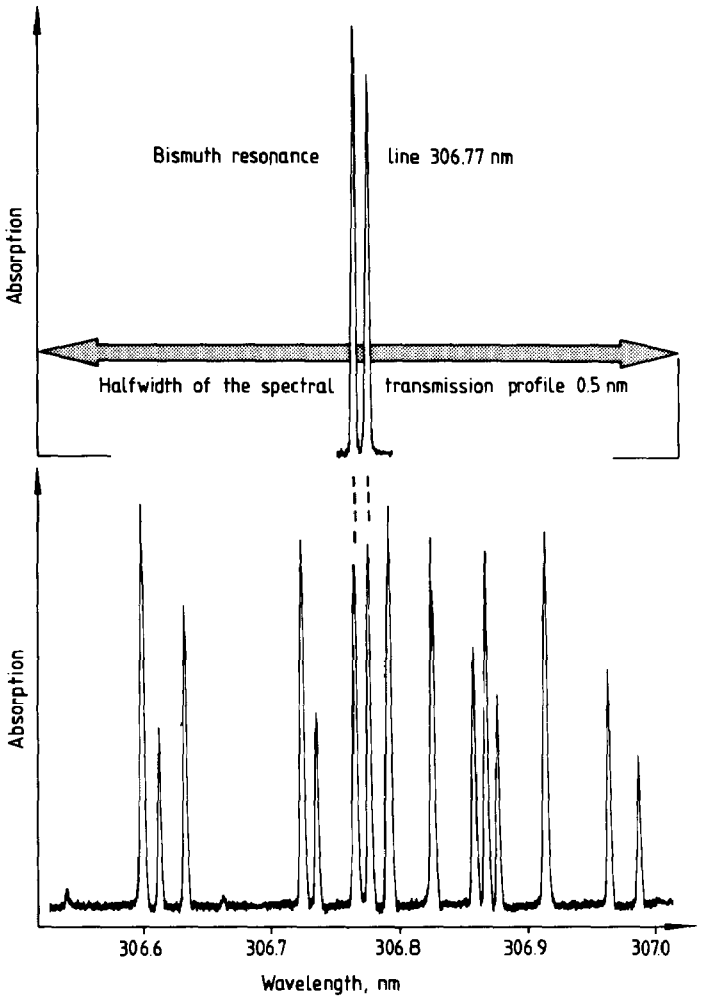

Fig. 1. Absorption spectrum of the OH-radical in an acetylene–air flame (lower spectrum) and of the 306.77-nm Bi line (upper spectrum). Absorption scale in arbitrary units. The two components of the Bi line coincide nearly exactly with two rotational lines of OH.

absorbance. This can easily be demonstrated by measuring the actual background absorbance, using a bismuth hollow-cathode lamp. Figure 2 shows the absorbance signals of an acetylene–air flame. The absorbance has been measured at 306.8 nm with a bismuth hollow-cathode lamp as source. The base-line (zero absorbance) was recorded without the flame.

It would be expected that with background compensation no change in absorbance would occur after ignition of the flame. However, the "compensated" absorbance signal of the stoichiometric flame (10-cm slot burner) is about 0.18 absorbance units, the absorbance signals of a reducing flame being lower and those of an oxidizing flame higher.

If we compare the absorbance signals of the stoichiometric flame with and without background compensation we can see only a small difference. That means that in this case background compensation is highly ineffective.

In fact, this is an extreme example. The 306.8-nm bismuth line is not suitable for determination of bismuth by flame atomic-absorption spectrometry. It may be the preferred line in furnace atomic-absorption spectrometry, where OH-interferences do not generally occur. The sensitivity of the 223.1-nm line is somewhat higher, but background interferences at 306.8 nm are much lower in general.

However, a warning must be given at this point that background measurement is not all that easy to perform. Generally, it can be stated that the measurement may be faulty in all cases, if the atomic absorption is measured in a wavelength region where molecules of the matrix cause a structured background.

The most frequently observed background interferences caused in flames as well as in furnaces by structured absorption of molecules are those of the pyrolysis products of SO_4^{2-}, NO_3^- and PO_4^{3-}. Diatomic molecules such as SO, NO and PO show very sharp rotational structure in the ultraviolet wavelength region.[1] Otherwise, for large molecules the density of the energy states is generally so high that under the conditions of atomic-absorption spectrometry (atmos-

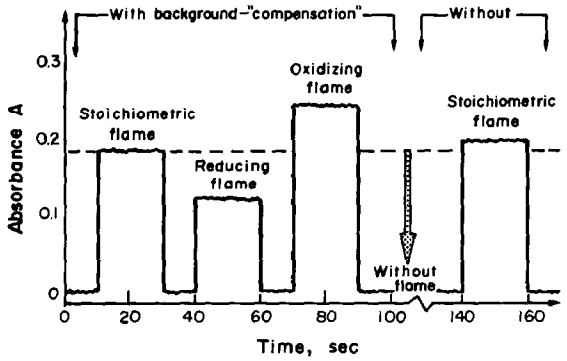

Fig. 2. Absorbance signals of an acetylene–air flame measured at 306.8 nm with and without "background compensation". The primary source was a bismuth hollow-cathode lamp. The base-line (zero absorbance) was recorded without the flame.

pheric pressure, temperature 2000–3000 K) rotational structure cannot be observed.[2] Even in this case, however, the vibrational band-edges may be very sharp. Therefore—but rarely—at some wavelengths, correct background measurement with a continuum source of radiation may be dubious.

ZEEMAN TECHNIQUES FOR QUASI-SIMULTANEOUS MEASUREMENT OF ATOMIC AND BACKGROUND ABSORPTION

The application of the Zeeman effect in atomic-absorption spectrometry for the correction of the spectral background was proposed as early as 1969.[3] Since then, many papers have appeared. Different techniques of Zeeman atomic-absorption have been applied. Yasuda *et al.* published an excellent review in 1980.[4]

Figure 3 shows the principle of some Zeeman techniques for quasi-simultaneous measurement of atomic

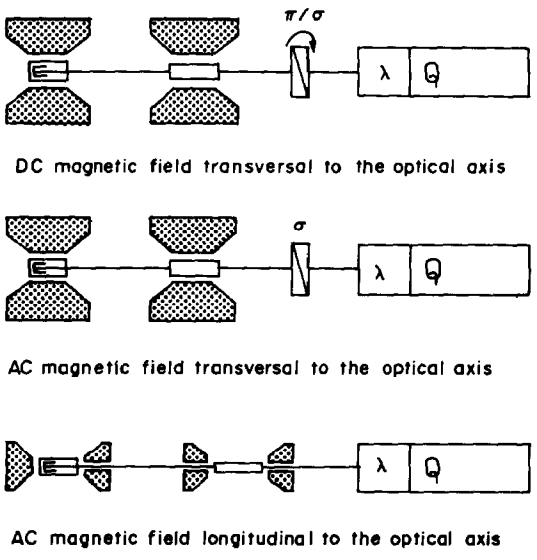

Fig. 3. Zeeman techniques for quasi-simultaneous measurement of atomic and background absorption.

and background absorption. The magnetic field can be applied either to the primary source or to the absorption cell. It may be either a constant field or a periodically modulated field. The direction of the field lines may be either transversal or longitudinal to the optical axis. Depending on which technique is used, the figures of merit such as sensitivity, precision, accuracy of background measurement *etc.*, may be widely different. In this paper, only three techniques will be discussed, those which are already realized in commercial atomic-absorption instruments.[5] In addition, these techniques are discusssed in respect to one figure of merit only: the accuracy of background measurement. These techniques are as follows.

1. Constant magnetic field transversal to the optical axis. Field applied to the absorption cell. Measurement of atomic and background absorption in two different polarization planes. (Hitachi, Ltd., Tokyo, Japan.)

2. Constant magnetic field transversal to the optical axis. Field applied to the primary source of radiation. Measurement of atomic and background absorption in two different polarization planes. (Erdmann & Grün, Wetzlar, Germany.)

3. Modulated magnetic field transversal to the optical axis. Field applied to the absorption cell. Measurement of atomic and background absorption with and without the magnetic field. (Perkin-Elmer Corporation, Norwalk, U.S.A.)

With technique 2, the background is measured on both sides of the analytical line, but—unlike measurements with a continuum source—at definitive wavelengths in close proximity to the line. In special cases, this may be a decisive advantage.

With techniques 1 and 3, the background is measured at exactly the wavelength of the analytical line. This is the dream of the spectroscopist, namely, to measure the background "under " the line, but even if this could be realized, we could not be sure that the background measured in two polarization planes or measured with and without the magnetic field would be the same. We know that molecules show the Zeeman effect, too.[6]

In molecular spectroscopy, the Zeeman effect is a powerful diagnostic tool, *e.g.*, in spin–rotation analysis. The Zeeman effect of di- and tri-atomic molecules has been extensively studied: OH,[7] NO_2,[8,9] NO,[10] SO_2,[11,12] SH,[7] NH_3, H_2O, OCS,[13] ClO_2.[14]

In order to study the influence of Zeeman splitting of sharp rotational lines of diatomic molecules in atomic-absorption spectrometry, the "guinea-pig" 306.8-nm bismuth line was used again for demonstration purposes. The magnetic field was applied to an acetylene–air flame transversal to the optical axis. Figure 4 shows the relative absorbance of the OH rotational lines at the wavelength of the 306.8-nm bismuth line as a function of the magnetic flux density.

The primary source of radiation was a bismuth hollow-cathode lamp. The measurements were made in a

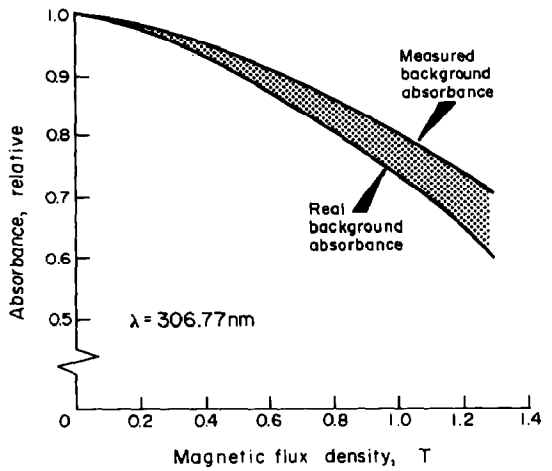

Fig. 4. Measured and real background absorbance in an acetylene–air flame at 306.77 nm as a function of the magnetic flux density (magnetic field transversal to the optical axis).

polarization plane parallel to the field lines (real background absorbance) and perpendicular to the field lines (measured background absorbance). As seen from Fig. 4, with increasing flux density, both absorbance signals decrease, but in a different way. The difference between the measured background absorbance and the real background absorbance gradually increases. At a magnetic flux density of 1 Tesla, we observe a value of the measured background exceeding 10% even at that early stage. From this experiment it can be deduced that the Zeeman technique 1 causes systematic errors in background measurement if coinciding rotational lines of molecules show Zeeman splitting.

In addition, this experiment allows predictions about the accuracy of background measurements with the Zeeman technique 3.

If background absorbance without the magnetic field is compared with the measured background absorbance at a flux density of 1 Tesla, a systematic deviation of as much as 20% can be observed in this case. This deviation is negative and has an absolute value twice as great as that with the field applied. From this experiment, it can again be deduced that the Zeeman technique must cause serious errors in background measurement if coinciding rotational lines of molecules show Zeeman splitting. Figure 5 shows the systematic deviations between the measured and the real background in an acetylene–air flame at 306.8 nm as a function of the magnetic flux density. The background absorption was measured with a constant magnetic field transversal to the optical axis (technique 1) and a periodically modulated magnetic field (technique 3). This is an example of systematic errors caused by structured background absorption due to the sharp rotational lines of diatomic molecules.

The danger of systematic errors due to structured background is much less if the background is caused by polyatomic molecules. Rotational structure is less marked or even not observable. An example of the absorption spectrum of a polyatomic molecule is shown in Fig. 6. Iron in xylol was to be determined by graphite furnace AAS. The spectrum in the neighbourhood of the 271.9-nm iron line was recorded photographically. An HGA 74 graphite furnace was used at a temperature of 2600° and a xenon-flash lamp was the primary source of radiation. The spectral resolution of $R = 10^5$ is sufficiently high for the real physical background structure of xylol at this temperature (and pressure) to be seen—but not the physical profiles of the atomic resonance lines of iron.[15] The latter cannot be fully resolved with a practical spectral resolution of only 10^5.

The edge of the vibrational band of xylol at 272.2 nm is very sharp. Background measurements in the

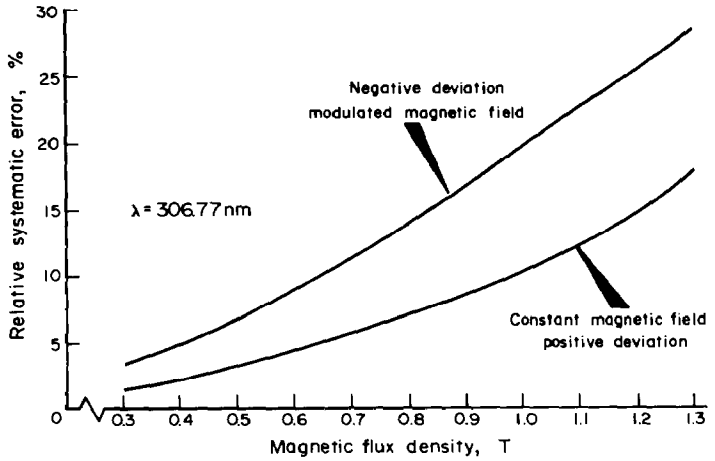

Fig. 5. Systematic errors of background measurement (relative to the height of background absorbance in an acetylene–air flame at 306.77 nm) observed with technique 1 (constant transversal magnetic field) and technique 3 (modulated transversal magnetic field), as a function of the magnetic flux density.

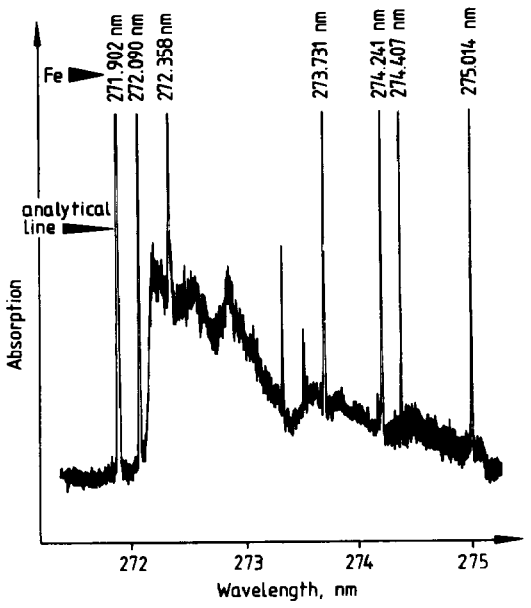

Fig. 6. Atomic-absorption spectrum of iron and molecular-absorption spectrum of xylol recorded photographically with a spectral resolution of approximately $R = 10^5$ (graphite furnace HGA 74, temperature 2600°).

neighbourhood of such edges may be problematic. The distance between the iron line at 271.9 nm and the band-edge at 272.2 nm is only about 0.3 nm. Background measurements with a deuterium lamp cannot give correct results. On the other hand, the distance between the analytical line and the band-edge is great enough to allow correct background measurements by the three Zeeman techniques mentioned. No systematic deviations between the measured and the real background could be observed.

CONCLUSION

Background measurement by Zeeman techniques in atomic-absorption spectrometry may cause serious systematic errors if the spectral background is due to sharp rotational lines of molecules.

MEASUREMENTS OF ORGANIC LEAD IN AIR—A REVIEW

W. R. A. De Jonghe and F. C. Adams
Department of Chemistry, University of Antwerp (U.I.A.), B-2610 Wilrijk, Belgium

(*Received* 8 *June* 1982. *Accepted* 13 *July* 1982)

Summary—Mounting concern over the presence and the role of organic lead compounds in the environment and living systems has resulted in the development of selective and sensitive measuring techniques. In the last decade considerable efforts have been devoted to the collection of data on the levels of the pollutant in environmental air. The procedures used and the chemical and instrumental problems associated with them, as well as the most important analytical results, are reviewed.

Organic lead compounds have been used since 1923 as additives to petrol as a convenient and economic way of increasing the octane rating of fuels for use in high-compression internal combustion engines. Commercially, five tetra-alkyl-lead (TAL) compounds containing methyl and/or ethyl groups are of importance: tetramethyl-lead (TML), trimethylethyl-lead (TMEL), dimethyldiethyl-lead (DMDEL), methyltriethyl-lead (MTEL) and tetraethyl-lead (TEL). They are all clear, colourless liquids with a fairly high vapour pressure and a fruity smell, rather insoluble in water, and very soluble in most organic solvents. Because of the thermal instability of these substances and the additional inclusion of ethylene dichloride and dibromide as scavengers in leaded fuels most of the lead exhausted is in the form of halide salts attached to small particles. Pollution by organic lead has therefore for a long time been regarded as a secondary problem compared to pollution by inorganic lead. However, as a result of spillage of leaded petrol, evaporative losses from the fuel tank and carburettor, and emission in the exhaust gases through incomplete combustion, considerable quantities of gaseous TAL appear to be emitted into the atmosphere. This knowledge, added to the hypothesis of the existence of a large-scale natural source of TML in the sea,[1] has caused in the past few years an increased concern about the organic lead levels in ambient air. In a recent review by Grandjean and Nielsen,[2] the ecologic implications were strongly emphasized.

Although the fate of TAL compounds in the environment is as yet only little understood, Röderer[3] and De Jonghe *et al.*[4] independently suggested the existence of a (bio)geochemical cycle for lead which includes TAL. Figure 1 constitutes a summary of these so far still hypothetical main pathways. Convincing evidence[5–9] indicates that TAL compounds in the environment are converted eventually into inorganic lead through tri- and dialkyl-lead salts (TriAL and DiAL). These solid compounds are very soluble in water, and therefore should be expected to undergo both dry and wet precipitation processes in the atmosphere. Hence, they enter the aquasphere, where they are subject to further decomposition reactions. Most probably the lead compounds can be taken up by aquatic organisms and can become accumulated through the food chain.[10–16] A small part of the bioaccumulated lead is withdrawn from the aquatic system, and can be ingested by humans. The remaining lead pool gradually deposits with excreta, dead organisms, or as particulate-bound lead.

Although there is *in vitro* evidence for the biological[17–22] and chemical[23–27] alkylation of lead salts to form TAL, it still remains obscure whether such mechanisms exist in natural environments. Dissolution of any TAL produced would be low, but may be increased by turbulence and emulsification. Evaporation of TAL from either solutions or emulsions is facilitated by turbulence and vertical water movements. These steps would be largely irreversible because of the hydrophobic nature of TAL. In view of the apparent lability of all alkyl-lead compounds it is questionable, however, whether these (bio)alkylation processes may indeed create significant amounts of organolead and thus increase the anthropurgic contribution to natural environments. Nevertheless, the conclusion must be drawn that all organisms in TAL-polluted biotopes could come into contact not only with TAL, but also with the highly toxic TriAL and the other derivatives.. This has to be taken into account when evaluating the potential toxic hazards arising for humans, from a TAL-polluted biotope.

It is therefore of considerable importance to be able not only to detect small amounts of organic lead but also to identify the specific types of compounds, as the environmental impact depends strongly on the state of chemical combination. Even within a certain class of organolead compounds (TAL, TriAL or DiAL) there are appreciable differences in environmental behaviour and toxic potential. TEL, for instance, appears to be significantly more toxic than TML, and the same is true for the corresponding TriAL dealkylation products.[12,28–33] In living systems the conversion of TAL into TriAL appears to be essential for the toxic effects to arise.[8,28] Thus, analytical methods capable of distinguishing between inorganic lead and

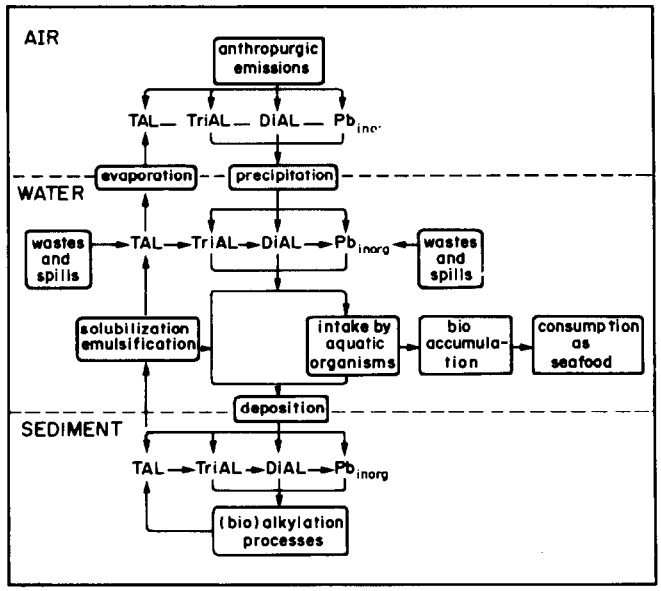

Fig. 1. Simplified (bio)geochemical cycle for TAL compounds in the environment. The actual pathways are likely to be more complex in view of disproportionation reactions[81] possibly occurring at different stages of the cycle, and the equilibria that may exist between organic lead in the particulate matter and in the gas phase.[35,36,78]

the different forms of organic lead are of special interest in environmental toxicology.

In most of the procedures commonly used for the determination of traces of organic lead in the atmosphere, separation of organic from inorganic lead is based on filtration. The particulate matter, containing most if not all of the inorganic lead, is assumed to remain quantitatively on the filter while the organic lead vapours pass on for concentration and subsequent analysis of the non-filterable lead.

In what follows we have made a distinction between the different organolead compounds: TAL, which can be supposed to be present in the gas phase only, and TriAL and DiAL compounds which may be present partly in the gas phase and partly in the particulates. Three different analytical methodologies can be distinguished: (*i*) methods that provide information on the total organolead content of the non-filterable fraction of the air-particulate system (these procedures are collected under the general heading "total organolead"), (*ii*) procedures that are based on the determination of the volatile lead compounds, termed "volatile organolead", and (*iii*) speciation methods for individual TAL compounds. The distinctions, especially between (*i*) and (*ii*) are not clear cut. Usually it is not clearly stated to which category the results of a particular method belong. A number of methods suffer from lack of specificity for organic lead, and at present the reported concentrations are probably too high, because of inclusion of inorganic lead that escapes trapping by the prefilter. Discrepancies could also be expected between the results obtained with short-term sampling procedures and those obtained with extended sampling techniques, in view of the marked diurnal fluctuations in concentration.[34] A direct comparison of the results obtained with different analytical procedures is therefore not straightforward. Finally, it should be emphasized that nearly all methodologies that have so far been developed for measuring airborne alkyl-lead pay attention exclusively to the non-filterable species, though there are indications that a fraction of the organic lead present in the atmosphere may be associated with the particulate matter.[35–38] This fraction probably contains the degradation products TriAL and DiAL, and not TAL itself.[39,40] The term "total" organolead should hence be used with caution when referring to results based only on the non-filterable fraction.

The aim of this review is to present an updated and extended version of the 1977 survey by Harrison and Perry.[41] The various analytical procedures that have been used for measuring the organic fraction of the non-filterable lead content of the air are critically described. A list of the reported concentrations is included.

Total organolead methods

With the exception of one procedure,[42] in which the air to be sampled is supplied directly from the atmosphere to the burner of an atomic-absorption spectrometer, in all methods a collection step (which is also a concentration step) and a determination step can be distinguished.

One of the approaches for collecting organic lead from air consists of the conversion of the volatile TAL compounds into non-volatile lead salts through a

series of reactions with iodine: $PbR_4 \rightarrow PbR_3^+ \rightarrow PbR_2^{2+} \rightarrow Pb^{2+}$. The reaction between TEL and iodine proceeds rapidly enough to allow quantitative collection of TEL by passing the air under test through an aqueous iodine solution.[43–46] The other TAL species react less readily, however, and thus more severe conditions are required for the collection of all five TAL compounds.

The first method with practical applicability was described by Snyder and Henderson.[47] Organic lead vapours were removed from the atmosphere by passage over iodine crystals, and were measured colorimetrically after a dithizone extraction. Although not very sensitive, the method was adopted a few years later by de Treville *et al.*[48] to evaluate the hazard in occupational exposure to TML, and by Cholak[49] to study the organic lead pollution of the air in Cincinnati, U.S.A. Using the same principle for collection, Walker[50] developed a more sophisticated procedure in which a transparent tube filled with iodine crystals was combined with a photo-optical sensor. The presence of alkyl-lead in the atmosphere could be detected by means of the yellow coating of lead iodide on the inner surface of the tube. Moreover, by connecting the photocell into an appropriate circuit, an alarm could be triggered by a predetermined amount of yellow coating. As no information was reported with regard to the sensitivity, it is difficult to ascertain the value of the latter procedure in environmental research.

In general, the use of solid iodine has a number of disadvantages. The main ones are the difficulty in avoiding channelling of the air through the tube, which results in incomplete collection, the variability of the blank values from one adsorption tube to another, and the risk of volatilization of iodine from the collecting tube during sampling. According to Linch *et al.*[51] a solution of iodine in methanol is as efficient as solid iodine for collecting TAL from the air. It is clear, however, that owing to the volatility of the solvent, monitoring with this technique is restricted to limited periods of time. For the same reason the use of a solution of iodine in carbon tetrachloride, as proposed by Nagasawa and Funakubo,[52] has little practical significance.

Moss and Browett[53] used a solution of iodine monochloride in hydrochloric acid for the collection; the TAL compounds were quantitatively converted into the corresponding dialkyl-lead salts without any further reaction to give inorganic lead. The subsequent analysis then involved extracting the collected lead at high pH as dialkyl-lead dithizonate into chloroform/carbon tetrachloride and matching the colour with a standard disc. With sampling periods of 8 hr or more, organic lead concentrations down to 10 $\mu g/m^3$ could be measured. Purdue *et al.*[54] used the same collecting agent but performed the measurement by atomic-absorption spectrometry (AAS) after extracting the dialkyl-lead with ammonium pyrrolidinedithiocarbamate (APDC) into methyl isobutyl ketone (MIBK). For a 24-hr sampling period, the minimum detectable quantity was about 0.2 $\mu g/m^3$. A similar AAS procedure was adopted by Colwill and Hickman,[55] but these authors extracted the dialkyl-lead with dithizone rather than with APDC and used considerably longer sampling periods of several days. The iodine monochloride method was also adopted by Cope *et al.*[56] and by the U.S. Environmental Protection Agency[57] for estimating the TAL emission from alkyl-lead manufacturing plants. In the latter case, the AAS analysis was performed directly on the absorbing solution without any prior treatment.

At this point it should be emphasized that the methods described so far are, strictly speaking, not specific for organic lead. They all rely on filtration for its discrimination from inorganic lead. Most commonly, the lead particulates are removed from the air stream by a membrane filter of pore size around 0.4 μm, positioned before the collection system for the organic lead. A significant proportion of the particulate atmospheric lead may escape collection by such filters[58,59] and can hence cause serious interference in the measurement of organic lead. An additional complication, encountered with any non-specific method, is that because of the widespread dispersion of lead, blank values tend to be relatively high.

Hancock and Slater[60] were able to eliminate these problems by an elegant modification of the iodine monochloride method. After sampling, the organic lead was extracted into carbon tetrachloride with dithizone, any inorganic lead being kept in the aqueous phase by masking with EDTA. The organic lead was then stripped from the carbon tetrachloride extract with nitric acid/hydrogen peroxide solution, the lead concentration in which was then determined by graphite-furnace AAS. The procedure of Hancock and Slater is sensitive and also specific for organic lead compounds, with a very low and easily repeatable blank value. For a 1-hr sampling period the limit of detection is 0.04 $\mu g/m^3$. The method has been successfully adopted and applied by several other workers,[61–64] giving detection limits ranging between 8 and 0.25 ng/m^3 for sampling periods from 6 to 48 hr.

Organic lead compounds may also be collected quantitatively by adsorption on activated carbon. In the method developed by Snyder,[65] a large volume of air (100–200 m^3) is drawn through a bed of activated carbon. After sampling, the carbon is digested in nitric acid/perchloric acid to remove the adsorbed lead. The extracted lead is then measured colorimetrically with dithizone. Owing to a significant blank level of lead in the carbon, very lengthy sampling periods of up to 2 weeks are necessary in order to obtain meaningful results. Despite this drawback and the problem of non-specificity, a similar method was adopted by Cope *et al.*[56] and by the American Society for Testing and Materials.[66] The use of AAS for the analysis, as suggested by Jacobs,[67] should allow greater sensitivities.

In the initial development of the sampling method, Snyder[65] found an irreversible adsorption of TML on

the carbon, but Lizetskaya *et al.*[68] have since reported that the adsorbed TEL can be quantitatively eluted with ethanol. As extraction of inorganic lead can be avoided in this way, lower blanks are obtained and a more sensitive measurement is possible: sampling for 6–7 hr is sufficient to allow the detection of TEL down to concentrations of 5 ng/m^3. Experiments performed by Zemskov and Stepanov[69] have indicated, however, that during prolonged sampling a considerable fraction of the adsorbed TEL can be mineralized, owing to the interaction with oxygen. The use of activated carbon for the collection of organic lead has also been described by other workers[70,71] but in their procedures the lead was determined by direct X-ray fluorescence spectrometric analysis of the graphite. Rabinowitz *et al.*[72] similarly employed an activated charcoal scrubber for the collection of vapour-phase lead, without specifying the method of measurement.

A very convenient way of determining the organic lead content in air by means of activated carbon sampling was recently reported by Birnie and Noden.[73] These authors found that the alkyl-lead compounds were retained quantitatively on a iodized glass-fibre carbon filter. Treatment of the commercially available glass-fibre carbon filters with a methanolic iodine solution was necessary to maintain a satisfactory collection efficiency under humid sampling conditions. Earlier, Carboni and De Lindemann[71] had noticed that impregnation with iodine improved the adsorption characteristics of the activated carbon. After sampling, the lead collected is extracted from the filter with a nitric acid/bromine mixture, after which the analysis can be completed by flameless AAS.[73] According to the authors the method appears to be especially suitable for personal monitoring, though with a detection limit of 4 μg/m^3 for a sampling period of 1 hr, application to ambient air samples does not seem plausible.

Methods for volatile organolead

The results obtained by any of the methods for total organolead may be inaccurate as a measure for tetra-alkyl-lead compounds, owing to the possible presence of other organic lead compounds in the atmosphere, *e.g.*, the breakdown products TriAL and DiAL. If present, these may be expected to exist in both the vapour phase and the particulate matter of small diameter. Since the collection of these less volatile organolead species by filters is therefore unlikely to be quantitative, the concentration data are probably too low to represent "total" organic lead but also too high to represent only TAL.

A number of techniques capable of measuring "volatile" organic lead have been developed, however. A rather simple and yet very sensitive procedure of this kind was reported by Harrison *et al.*[74,75] The gaseous lead alkyls were efficiently trapped from the air by means of a short adsorption tube filled with GC-column packing material and cooled in liquid nitrogen. Subsequent heating of the tube followed by nitrogen elution allowed desorption of the volatile compounds, which were then passed into the combustion air stream of an atomic-absorption spectrometer, set up for lead measurement. Although the question has not been examined systematically, it appears improbable that lead compounds other than organic lead, if collected, would be eluted in a similar way during this procedure. Hence the method can be considered as specific for volatile organic lead. According to the authors a sampling period of 30 min is sufficient for the determination of concentrations down to 3 ng/m^3. This method has been developed further by Rohbock *et al.*[76–78] To remove water vapour that might block the adsorption tube, these authors first pass the air through a cold trap at -78°. The airborne lead alkyls are then collected on GC-column packing material at liquid-air temperature. For the subsequent AAS-analysis, the compounds are thermally desorbed and flushed by argon carrier-gas into the graphite furnace of an electrothermal atomization unit. Interference by other substances is eliminated by deuterium background correction. The cold trap makes it possible to raise the sampling volume to about 200 litres of air, so a detection limit of 1 ng/m^3 can be obtained with a sampling period of about 2 hr. In addition, as the sub-μm lead particles that pass the filter act as nuclei for freezing the water vapour and are deposited in ice particles, analysis of the water retained in the trap furnishes a direct measure of the inorganic lead passing through the filter.

It was claimed that the cold-trap was completely by-passed by the lead alkyls in this procedure, but experiments by De Jonghe *et al.*[79,80] indicated that at a temperature of -78° a fraction of the less volatile TAL species TEL and MTEL was retained. Moreover, according to these authors, in general, removal of water by a cold-trap is only quantitative at temperatures so low that some TAL will also be retained, which is not surprising in view of the rather similar vapour pressure.[81] These authors preferred, therefore, to trap both the water and the lead alkyls in the same tube by using a temperature of -130°.[79] This required the use of a more loosely packed material than GC-supports, *e.g.*, 4-mm diameter glass beads, to avoid rapid clogging of the pores by deposition of ice. Such a collection system was applied in the procedure described by Jiang *et al.*[82] After sampling, the cold-trap was warmed up slowly to volatilize the accumulated lead alkyls, which were subsequently collected in a nitric acid/hydrogen peroxide mixture. By a simple additional treatment it thus became possible to perform the graphite-furnace AAS determination of airborne volatile organolead with aqueous solutions of lead nitrate. The detection limit for a 1-hr sampling was quoted as 0.04 μg/m^3.

This problem of water condensation was also successfully circumvented by Coker,[83] who used polymer beads for the collection, at room temperature. Volumes of at least 10 litres of air could be taken without breakthrough losses, allowing sampling

periods of up to 8 hr. The analysis was completed by direct thermal desorption of the trapped compounds into the burner of an atomic-absorption spectrometer. As the absolute detection limit of the method is 10–20 ng of lead, application of this method is restricted to highly polluted environments.

Species-specific TAL methods

The species-specific measurement of airborne TAL compounds implies the use of chromatographic separation techniques. Owing to the favourable vapour pressures,[81] gas–liquid chromatography has invariably been considered to give a suitable separation. Cantuti and Cartoni[84] described a procedure for the direct collection of TEL from polluted air and its GC-determination at ppm levels by electron-capture detection. The air to be analysed was passed through a sampling trap consisting of a short tube packed with normal gas chromatographic support and liquid phase. When enough air had been passed through to saturate this trap, there was equilibrium between the concentrations in the gas phase and the liquid phase. The collected compounds were introduced into the gas chromatograph column by flash heating the sample tube to about 130° in a small electric furnace positioned immediately above the injection port. The method was successfully employed for the measurement of the pollution level in the air around a factory where TEL was produced. It was later modified and improved by Tausch[85] to allow its application to the analysis of city air. In this way detection limits of about 0.05 and 0.5 $\mu g/m^3$ were obtained for the determination of TEL and TML. Gas chromatography with electron-capture detection was also used in the procedure of Corrin and Menne.[86,87] Sampling was accomplished in this case with hexane bubblers at −78°. The hexane solutions were concentrated under vacuum at −78° to approximately 2% of the original volume before injection into the gas chromatograph. As environmental samples often contain a variety of organic compounds with high electron affinity[88,89] these methods presumably lack the specificity required for detecting ultratrace quantities of TAL.

The widespread acceptance of gas chromatography as the analytical method for separating atmospheric alkyl-lead substances follows from the work of Laveskog,[90,91] who applied the technique to a detailed study of the TML and TEL concentration levels in street air. To ensure complete collection of the organic lead, instead of using equilibration between the compounds in the air and those adsorbed on the GC packing material, this author kept the adsorption tube at about −80° during sampling. It may be mentioned here that most other cryogenic trapping techniques for TAL are direct descendants of Laveskog's original system. The analysis involved desorption by heating, and transport of the desorbed compounds with an inert gas into a gas-chromatograph/mass-spectrometer combination (GC/MS). TML and TEL were detected in sequence at $m/e = 237$ [$(CH_3)_2{}^{207}Pb$ or $C_2H_5{}^{208}Pb$]. A limit of detection of 10 pg could be achieved, which for a 1-litre sample corresponded to 0.01 $\mu g/m^3$ for an individual compound in air and was attainable in about 15 min. This sensitivity is extremely high and is unlikely to be attainable with all GC/MS instruments.[41]

The use of a low to medium resolution mass spectrometer, as used by Laveskog together with gas chromatographic separation, is also unlikely to give total freedom from the mass-spectral interferences that can arise from organic materials in the atmosphere and from substances bleeding from the GC column.[41,92] However, the same method was adopted later by Allvin and Berg.[93] Nielsen *et al.*[94] recently reported a refined version of the technique. These authors collected the TAL compounds at ambient temperature on co-polymers of ethylvinyl- and divinylbenzene. After sampling was completed, the analytes were thermally desorbed and collected at −80° on a small adsorption tube containing GC column packing material to concentrate the sample in a small volume before its introduction into the GC/MS. Use of the isotope-dilution technique, accomplished by adding known amounts of deuterated TML and TEL in advance to the sampling tubes, made it possible to correct for decomposition during sampling and/or the analytical procedure. Recovery studies with standards revealed a significant loss of TEL during sampling, possibly as a result of reaction with ozone. TML, on the contrary, was recovered quantitatively and could be determined down to concentrations as low as 20 pg/m^3, with a sampling period of 24 hr. It can be mentioned that a preliminary study by Perry *et al.*[95] has indicated that the adsorption tubes used in cryogenic trapping can equally well be used for direct analysis for TAL by mass spectrometry, without prior GC-separation.

Chau *et al.*[96] used collection on cooled GC-column packing material, followed by determination of all five TAL compounds by GC/AAS. The adsorption tubes were connected to a 4-way valve between the carrier-gas inlet and the column injection-port, so that the sample could be swept into the GC column by the carrier gas. The GC was interfaced by stainless-steel tubing to the burner-nebulizer, so that conventional flame AAS could be used. Consequently, the measurement was highly specific: only lead-containing components in the GC effluent were detected. Moreover, if the AA recorder was started simultaneously with the sample introduction, the retention time could be used for identifying the different species. The method was primarily developed for the study of the biological conversion of lead compounds into TML in aquatic systems. The low analytical sensitivity (the detection limit for an individual species is about 0.08 μg) combined with a very slow air-sampling flow-rate (130–150 ml/min) makes this procedure unsuitable for the analysis of environmental air. In a later modification,[97–99] the authors were able to improve the sensitivity by three orders of magnitude by using an elec-

trically heated silica furnace in the AAS unit. In this case, the burning of hydrogen, introduced at the centre of the furnace, was claimed to improve the atomization efficiency.

Several authors[100–102] have pointed out that graphite-furnace AAS (GFAAS) has excellent performance characteristics when used as a metal-specific detection system for TAL compounds separated by gas chromatography. Radziuk *et al.*[92] applied this approach to the analysis of air samples, in combination with a collection system similar to the one described by Chau *et al.*[96–99] An empty glass tube at $-15°$ was incorporated in the sampling train to condense the moisture. The GC/GFAAS interface was achieved by passing the effluent from the GC-column through an electrically heated, Teflon-lined, aluminium transfer tube to a tantalum connecting piece, friction-fitted into the injection port of the graphite furnace. The silica windows were removed from the furnace assembly to allow optimal gas flow. During the analysis, the graphite furnace was continuously heated at 1500° for 20 min. The system described permits the determination of individual TAL compounds down to concentrations of 0.5 ng/m^3, with a sampling period of about 18 hr. Interfering absorbance signals may be observed, however, as a result of decomposition of the TAL compounds in the hot part(s) of the transfer tube, giving rise to deposition and remobilization of lead during subsequent runs (memory effect).

These problems were not encountered with the GC/GFAAS apparatus employed by Robinson and coworkers,[103–105] because the column effluent was conducted by means of a heated stainless-steel transfer line to the bottom of a specially designed "hollow-T" carbon atomizer. Effects resulting from the decomposition of TAL were avoided, as no part of the interface was exposed to extreme temperatures. The sensitivity was very good: for TML a detection limit of 0.04 ng was reported.[103] Alkyl-lead compounds from the atmosphere were collected on Tenax-packed glass columns at liquid-nitrogen temperature, allowing volumes of about 1 m^3 of air to be sampled. Despite these favourable conditions, the authors were usually not able to detect any organic lead.[104–106] They claimed that this was probably due to the gaseous fraction of atmospheric lead being predominantly inorganic in nature (instead of organic) and hence not determinable by GC/GFAAS.[105–108] In our view this assumption contradicts the results obtained by a number of other authors (see Tables 1–3) and we believe that their failure to detect organic lead is attributable to losses of collected TAL before the GC/AAS analysis, and is associated with the explosive evaporation of the accumulated gases from the adsorption tube, as may occur on removal from the liquid nitrogen.[79]

GC/GFAAS also provided the basis for the procedure reported by De Jonghe *et al.*,[40,79] who interfaced conventional GC and AAS units by introducing the GC-column effluent into the graphite furnace through the inner gas-flow entrances, thus avoiding any drastic modifications to either of the instruments. The flow of GC carrier-gas followed the same pattern as the normal gas flow (which it replaced) inside the graphite tube;[102] deuterium-lamp background correction was sufficient to correct for interfering absorbance signals. By an appropriate choice of the instrumental parameters, the GC/GFAAS analysis time could be reduced to about 6 min. The gaseous alkyl-lead compounds were collected from the air by cryogenic trapping on glass beads at $-130°$. The collected TAL species were then thermally desorbed from the trap and transferred to a short adsorption tube filled with GC packing material, to allow rapid injection into the GC/GFAAS apparatus. In general, air samples were taken for a period of 1 hr, corresponding to a volume of 360 litres; under these conditions the lowest detectable concentration was about 0.2 ng/m^3. Despite the speed of the sampling and the analytical procedure the application of the technique was quite critical and cumbersome.

Reamer *et al.*[109,110] developed a method using a gas chromatograph/microwave plasma detector (GC/MWPD) for the analysis. The TAL species were collected from the air in a cold-trap containing GC packing material at $-80°$ and were then removed from the sorbent by a freeze-drying technique. The volatile alkyl-lead compounds were concentrated in an organic solvent before separation and determination. For the background correction, a technique based on wavelength modulation was applied. With 2-hr sampling periods, the detection limit for an individual TAL compound was about 0.5 ng/m^3. The lengthy period necessary for the analysis (more than 12 hr) makes this method rather impractical for pollution-control measurements. Moreover, the GC/MWPD combination is instrumentally complex and not routinely available in analytical laboratories.

Air concentration levels

Tables 1–3 summarize the main analytical results from surveys performed with the different methods described. Usually the concentration found for organic lead is expressed as a fraction of the total lead concentration, as this figure is less dependent than the absolute level on the total lead use at a particular location and the sampling site topography and meteorology.[41] However, the total composition of atmospheric lead is not yet definitively known: to date, reliable data are available only for filter-collected particulate lead and gaseous lead alkyls in ambient air. The variable proportions of gaseous inorganic lead[105–108] and non-filterable particulate lead in Aitken particles,[111] as well as the organic lead present in the particulate matter, have not yet been sufficiently investigated. As total lead is thus more or less a fictitious quantity, it is better to use the ratio of non-filterable organic to filtered particulate lead.[112]

It appears from Tables 1–3 that a direct comparison of the alkyl-lead data so far available is still

*Each sample period is made up of sequential 10–15 min samples; individual samples show much wider ranges of concentrations.
N.R. = not reported.

rather problematic. Mean concentrations in ambient air range from 2 ng/m^3 at a rural site to up to 2000 ng/m^3 in a parking garage, whilst individual measurements at specific sites cover a wide range. Owing to the diurnal fluctuations, there is a far greater variability in the concentrations measured over short(er) averaging periods. Factors affecting roadside concentrations include the traffic density and the driving mode: cold engines running on the choke, cruising vehicles with warm engines, idling vehicles, *etc.*, apparently differ in emission factor. For instance, individual 20-min kerbside samples alongside a set of traffic lights during a period when cold vehicles (with choke-running) were leaving a factory, ranged up to 2500 ng/m^3, well above the typical kerbside values of about 100 ng/m^3 when the traffic is free-flowing.[60] Concentrations further depend on the proximity to the vehicular emissions. Measurements by Birch *et al.*[62] in a central London street showed a 30–35% decrease in the TAL concentrations found, when the sampling height was increased from 5 m to 14 m above the street, with a similar decline for particulate lead. For evaporative emission sources, the meteorological conditions should also have a profound influence on the levels measured. Similarly, the concentration and type of alkyl-lead compounds in the petrol used in the area of investigation is crucially important.

The data suggest an average alkyl-lead concentration in urban air of about 100 ng/m^3, typically representing 5–10% of the particulate lead level. The main part of the investigations carried out in the U.S. and Canada shows that the proportion of organic to particulate lead is of the order of 1:100–1:20. Since the legislation on emission control systems in cars is more stringent in the U.S.A. than in other countries of the Western World, the level of organic lead is probably 5–15% of the particulate lead content in the urban air in the latter countries. Tables 1–3 further indicate that in an urban environment a background organic lead level of 10–20 ng/m^3 is present. It is air with this composition that will be convected to rural sites and there give rise, after dilution and physicochemical transformations, to concentrations of several ng/m^3.

The question of possible methylation of inorganic lead in the environment is still unanswered. So far only Harrison and Laxen[1] have obtained indications for naturally produced organic lead in samples near the intertidal flats on the West Coast of England. When the sampled air had passed over the sea and the coastal area, organic to particulate lead ratios of up to 50% were reported. Unfortunately, the method of analysis used by these authors could not discriminate between the different alkyl-lead species, so it is impossible to verify whether such elevated ratios are accompanied by exceptionally high TML contributions. Measurements of organic lead with the species-specific technique of De Jonghe *et al.*[79] in the atmosphere at rural sites near Beijing, China,[113] were all below the detection limit of 0.1 ng/m^3, thus precluding terrestrial sources as its origin.

Another problem of present interest is the separate determination of the TAL-degradation products (TriAL and DiAL) in the atmosphere. So far, no such method has been reported. The discrepancies between the total organolead results and those obtained with species-specific TAL methods can support the idea that there are substantial quantities of TriAL and DiAL compounds in the air.[40] Nevertheless, the measurements by Nielsen *et al.*[114] appear to be the only direct evidence so far for their occurrence in natural samples. These authors found that the brain tissues of individuals residing in the lower floors of buildings in a city have a TriAL content of the order of 40 ng/g. Attempts to determine these compounds in water samples have been unsuccessful, probably because the analytical method employed[115] was not sensitive enough.

Although, in laboratory studies, individual TriAL species have allegedly been determined by gas chromatography with an element-specific detector,[116–118] the use of ion chromatography or HPLC might also be advantageous for sorting out the lower lead alkyls. Pioneering experiments of the latter kind have been done by Potter,[119] but the lack of a specific detector prohibited application. Interfacing of the HPLC system with AAS, MWPD or ICP should be a possible solution to this problem.

DETERMINATION OF SILVER IN ORES, CONCENTRATES, ZINC PROCESS SOLUTIONS, COPPER METAL AND COPPER-BASE ALLOYS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY AFTER SEPARATION BY EXTRACTION OF THE TRIBENZYLAMINE–SILVER BROMIDE COMPLEX

ELSIE M. DONALDSON

Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

(*Received* 7 *June* 1982. *Accepted* 13 *July* 1982)

Summary—A method for determining ~0.1 μg/g or more of silver in ores and concentrates and ~0.001 μg/ml or more of silver in zinc process solutions is described. Silver is separated from the matrix elements by chloroform extraction of the tribenzylamine–silver bromide ion-association complex from 0.08*M* potassium bromide–2*M* sulphuric acid and stripped with 9*M* hydrobromic acid. This solution is evaporated to dryness and organic material is destroyed with nitric and perchloric acids. Silver is determined by atomic-absorption spectrophotometry in an air–acetylene flame, at 328.1 nm, in a 10% v/v hydrochloric acid–1% v/v diethylenetriamine medium. Cadmium, bismuth and molybdenum are partly co-extracted but do not interfere. The method is also applicable to copper metal and copper-base alloys. Results obtained by this method are compared with those obtained by a fire-assay/atomic-absorption method.

A current CANMET project involves a study of the behaviour of silver in conventional and proposed zinc hydrometallurgical processes (designed to recover metallic zinc from zinc ores and concentrates) with the objective of increasing the recovery of silver in Canadian zinc plants. As part of this project, a simple, sensitive, relatively rapid and reliable atomic-absorption spectrophotometric (AAS) method was needed for the routine determination of small amounts of silver in zinc process solutions containing sulphuric acid, ferric sulphate up to ~25 g/l., zinc sulphate at ~200 g/l. and moderate amounts of various other elements. The method should also be applicable to sulphide concentrates and other processing products. Because large amounts of zinc suppress the absorbance of silver in an air–acetylene flame owing to reduction of the atomization rate, because of the high viscosity of the solution, it was considered that a suitable method would involve a reasonably selective solvent extraction–preconcentration step.

Recently, solvent extraction–AAS methods for silver have been reviewed and, from this work and studies of the literature cited, it was considered that methods based on chelation systems (phenylthiourea, ammonium pyrrolidinedithiocarbamate and other dithiocarbamates, dithizone, xanthate and 8-hydroxyquinoline)[1] including iso-octyl thioglycollate,[2] were not the most promising for the present work because of their lack of selectivity. Methods based on the extraction of silver into solvents containing tri-iso-octyl thiophosphate, triphenylphosphine and petroleum sulphides are more selective[1] but these reagents were not immediately available. Furthermore, many of these methods involve the extraction of silver from a nitric acid medium which, in the presence of chloride as a contaminant, results in incomplete extraction of the silver because of the formation of silver chloride.[1] Many recent extraction methods, with AAS and other finishes, are based on the extraction of anionic chloro-, bromo- or iodo-silver complexes as ion-association compounds from halide media into organic solvents containing high molecular-weight amines and quaternary ammonium salts such as tricaprylylmethylammonium chloride (Aliquat 336),[3,4] tricaprylylamine (Alamine 336),[4] tri-n-octylamine (TOA),[5] trialkylbenzylammonium chloride[6] and tri-n-octylmethylammonium bromide.[7] In most of these methods, and in studies of the extraction behaviour of silver with TOA,[8,9] tri-n-dodecylamine,[10] trilaurylamine,[11] tetra-alkylammonium salts[12] and various other basic extractants,[13,14] silver is extracted from dilute hydrochloric acid or from hydrochloric acid–potassium iodide media, from which zinc and usually iron are also largely co-extracted. However, the extraction curves shown in a recent study[15] of the extraction of various elements from sulphuric acid–potassium iodide media into *o*-xylene containing TOA suggested that it might be possible to separate silver from zinc and iron by extracting silver from a relatively dilute halide–sulphuric acid medium. Con-

sequently, the applicability of this type of separation was investigated in the present work. Although in most of the extraction methods mentioned above the organic extract is sprayed into the flame, an aqueous medium was chosen for this work because of the greater ease of preparation and convenience of aqueous calibration solutions for routine work.

The proposed method separates the silver from matrix elements by extraction from 0.08*M* potassium bromide–2*M* sulphuric acid into chloroform containing tribenzylamine. Silver is then stripped with 9*M* hydrobromic acid. Results obtained for ores and concentrates by this method are compared with those obtained by a fire-assay/AAS method. The applicability of the method to copper metal and copper-base alloys is shown.

EXPERIMENTAL

Apparatus

A Varian-Techtron model AA6 spectrophotometer, equipped with a 10-cm laminar-flow air–acetylene burner and a silver hollow-cathode lamp, was used under the following conditions.

Wavelength: 328.1 nm
Lamp current: 3 mA
Spectral band-pass: 0.20 nm
Height of light-path above burner: 4 mm
Acetylene flowmeter reading: 2.0 (~2.0 l./min)
Air flowmeter reading: 6.5 (~13.0 l./min)
Flame: strongly oxidizing
Aspiration rate: 2 ml/min

Reagents

Standard silver solution, 100 μg/ml. Dissolve 0.1000 g of pure silver foil in ~25 ml of 25% v/v nitric acid, add ~1 ml of 50% v/v sulphuric acid and evaporate the solution to dryness. Dissolve the salts in ~50 ml of concentrated hydrochloric acid and transfer the solution to a 1-litre standard flask containing ~350 ml each of concentrated hydrochloric acid and water. Allow the solution to cool to room temperature, then dilute to volume with water. This solution is stable for at least 2 months. Prepare a 10-μg/ml solution by diluting 10 ml of this stock solution and 36 ml of concentrated hydrochloric acid to 100 ml with water. Prepare this diluted solution fresh as required.

Diethylenetriamine. A 10% v/v solution in water.

Bromine. A 20% v/v solution in carbon tetrachloride.

Potassium bromide, 20% solution.

Tribenzylamine. A 3% solution in chloroform.

Sulphuric acid, 50% v/v.

Sulphuric acid 5% v/v. Store in a plastic squeeze-type wash-bottle.

Hydrobromic acid, 50% v/v. Store in a plastic squeeze-type wash-bottle.

Ammonia, 25% v/v solution. Add 50 ml of concentrated ammonia solution to 150 ml of water. Store in a plastic squeeze-type wash-bottle.

Ethyl acetate. Analytical reagent-grade.

Procedures

Calibration solutions. Add 10 ml of 10% diethylenetriamine solution to each of eleven 100-ml standard flasks; then, from a burette, add to the first five flasks 2, 4, 6, 8 and 10 ml, respectively, of 10-μg/ml standard silver solution. To the next five flasks, add 1.5, 2, 2.5, 3 and 4 ml, respectively, of 100-μg/ml standard solution. The last flask contains the zero calibration solution. Add sufficient concentrated hydrochloric acid to each flask for the final solution to be 10% v/v hydrochloric acid, then dilute each solution to volume with water.

Ores and concentrates. Transfer up to 1 g of powdered sample, containing up to ~500 μg of silver and not more than ~350 mg of lead, to a 250-ml Teflon beaker, cover and add 5 ml of 20% bromine solution in carbon tetrachloride (Note 1) and 15 ml of concentrated nitric acid. Mix and allow the solution to stand for ~15 min, then heat gently to remove the bromine and carbon tetrachloride. Add 30 ml of 50% sulphuric acid, heat until the evolution of oxides of nitrogen ceases, then remove the cover and wash down the sides of the beaker with water. Add 5 ml of concentrated hydrofluoric acid and carefully evaporate the solution until copious fumes of sulphur trioxide are evolved. Cool, wash down the sides of the beaker with water (Note 2) and evaporate the solution to fumes of sulphur trioxide again to ensure the complete removal of hydrofluoric and nitric acids. Cool, add ~40 ml of water and heat to dissolve the salts. Cool the solution and, if necessary, filter it (Whatman 11-cm No. 40 paper) into a 125-ml separatory funnel marked at 100 ml. Wash the beaker and the paper once each with water, then wash the beaker twice with ~5-ml portions of 25% ammonia solution (Note 3). Wash the paper and residue three times with ~5-ml portions of 25% ammonia solution followed by ~10 ml of 5% sulphuric acid, then discard the paper. Dilute the solution to ~95 ml with water.

Add 5 ml of 20% potassium bromide solution and 20 ml of 3% tribenzylamine solution (Note 4) to the resulting solution, stopper the funnel and shake it for 2 min. Allow several min for the layers to settle, then drain the chloroform phase into a 60-ml separatory funnel. Extract the aqueous phase twice more by shaking for 2 min and 1 min, respectively, with 5-ml portions of tribenzylamine solution. Wash the stem of the funnel with 1 ml of methanol after the last extraction step (Note 5). Add 15 ml of concentrated hydrobromic acid (Note 6) to the combined extracts, stopper, and shake for 3 min (Note 7). Add 5 ml of ethyl acetate, shake gently for ~5 sec and allow the layers to separate. Drain the lower aqueous phase into a 100-ml beaker and wash the stem of the funnel with 50% hydrobromic acid. Wash the chloroform phase twice (Note 8), by shaking it for ~1 min and ~30 sec, respectively, with 5-ml portions of concentrated hydrobromic acid and add the washings to the beaker. Wash the stem of the funnel with 50% hydrobromic acid each time. Cover the beaker, heat the resulting solution to remove methanol and residual chloroform, then remove the cover and evaporate the solution to dryness. Cover, add 5 ml of concentrated nitric acid and 2 ml of concentrated perchloric acid and heat until fumes of perchloric acid are evolved. Remove the cover and evaporate the solution to dryness. Depending on the expected silver content, add sufficient concentrated hydrochloric acid and 10% diethylenetriamine solution for 1 ml of each to be present for each 10 ml of final solution (Note 9). Transfer the solution to a standard flask of appropriate size (10–200 ml) and dilute to volume with water.

Measure the absorbance at 328.1 nm when this solution is aspirated into a strongly oxidizing air–acetylene flame (Note 10). Calculate the silver content (in μg) from the sample absorbance and those obtained concurrently for calibration solutions that bracket the sample concentration.

Zinc process solutions. Transfer up to 75 ml (Note 11) of the solution, containing up to ~500 μg of silver, to a 125-ml separatory funnel marked at 100 ml and add sufficient concentrated or 50% sulphuric acid for the final concentration to be ~2*M*. Dilute the solution to ~95 ml with water and allow it to cool to room temperature. Add 5 ml of 20% potassium bromide solution and 20 ml of 3% tribenzylamine solution and proceed with the extraction and subsequent determination of silver as described above.

Copper metal and copper-base alloys. Transfer up to 1 g of sample, containing up to ~500 μg of silver and not more than ~350 mg of lead, to a 400-ml beaker. Cover the

beaker, add 15 ml of concentrated nitric acid, heat gently until the sample is decomposed, then add 30 ml of 50% sulphuric acid and heat until the evolution of oxides of nitrogen ceases. Remove the cover, wash down the sides of the beaker with water and evaporate the solution until copious fumes of sulphur trioxide are evolved. Cool, wash down the sides of the beaker with water (Note 2) and evaporate the solution to fumes of sulphur trioxide again to ensure the complete removal of nitric acid. Cool, add ~40 ml of water, heat to dissolve the salts, then proceed with the filtration of the solution, if necessary, and the extraction and determination of silver as described above.

Notes

1. Bromine is added to oxidize sulphur and sulphides to sulphate.
2. If more than ~2 or 3 mg of antimony is present, add 5 or 10 ml of concentrated hydrobromic acid at this stage. Evaporate the solution to fumes of sulphur trioxide, then wash down the sides of the beaker with water and repeat the evaporation step.
3. Washing with ammonia solution is necessary to dissolve any silver chloride produced by contamination of the solution with chloride, any silver bromide resulting from the decomposition step or from the volatilization step described in Note 2, and any silver retained by lead sulphate. The beaker should be washed with ammonia solution even if the filtration step is unnecessary. To prevent the neutralization of too much sulphuric acid, the total volume of ammonia solution used should not exceed ~25–30 ml.
4. In the first extraction step, it is recommended that potassium bromide solution should be added to only two solutions at a time, followed by the extraction—within ~5 min—of the tribenzylamine–silver bromide complex. The extraction may be incomplete if the solution is allowed to stand for too long after the addition of the bromide solution. The second and third extraction steps can be applied to a series of solutions.
5. Methanol dissolves any dried tribenzylamine–silver bromide complex remaining in the stem of the funnel, but not more than ~1 ml should be used or the organic and aqueous phases may become miscible.
6. It is recommended that yellow hydrobromic acid containing bromine should be used, because it is easier to see the interface between the aqueous and organic phases.
7. A wrist-action shaker can be used, with elongated pear-shaped separatory funnels, if a heavy rubber band is stretched around the stopper and stopcock to hold the stopper in tight to prevent leakage.
8. Some tribenzylamine may separate in the chloroform phase during the washing steps but this does not interfere with the separation of silver.
9. For final sample solution volumes of 10, 25, 50, 100 and 200 ml, add 1, 2.5, 5, 10 and 20 ml, respectively, of each solution. If the residue contains molybdenum, indicated by blue salts, add the diethylenetriamine solution first and, if necessary, warm the solution to dissolve the salts.
10. Scale expansion (~3–5-fold) is recommended for the determination of ≤ 1 μg of silver per ml.
11. Up to ~100 ml of the solution can be taken if the required volume of concentrated or 50% sulphuric acid is added and the solution is evaporated to ~75 ml and then transferred to the separatory funnel (Note 3).

RESULTS AND DISCUSSION

Calibration solutions

Calibration solutions for silver determination by AAS often contain ~30–50% by volume of concentrated hydrochloric acid to keep the silver in solution. This also avoids the error resulting from contamination with chloride, which can occur in nitric acid media. However, considerably less hydrochloric acid can be employed if a soluble amine such as diethylenetriamine (DTA) is used to complex the silver.[16] This helps to reduce burner corrosion. Although DTA can also be used in conjunction with hydrobromic acid, hydrochloric acid was used for convenience in this work because concentration of the final hydrobromic acid solution by evaporation, and destruction of the excess of tribenzylamine, are usually necessary before the AAS determination. Calibration solutions containing 10% and 1% by volume of concentrated hydrochloric acid and DTA, respectively, and ≤ 1 μg of silver per ml are stable for at least 2 weeks. Solutions of higher concentration must be prepared fresh every 4 or 5 days because the absorbance slowly decreases on standing.

Separation of silver by tribenzylamine-chloroform extraction

Recently, Spivakov *et al.*[15] investigated the effects of sulphuric acid and potassium iodide concentration on the extraction of silver, zinc, iron and various other elements into *o*-xylene containing TOA. Their extraction curves suggested that it might be possible to separate silver from zinc by extracting silver from $<0.2M$ potassium iodide–sulphuric acid. They also reported that iron(III) is not extracted from up to at least $2.5M$ sulphuric acid–$1M$ potassium iodide solutions. In preliminary tests, tribenzylamine (TBA) and chloroform were chosen as extractant and diluent because of their ready availability and the high density of the mixture. Silver was added in the form of a dilute sulphuric acid solution, the extracts were evaporated to dryness, and the residues were treated with hydrogen peroxide, nitric and perchloric acids, followed by evaporation of the solution to dryness to destroy TBA. The results showed that up to 500 μg of silver can be completely extracted, in a triple extraction, into chloroform containing 1.5% TBA, from 100 ml of $0.05M$ potassium iodide–$2M$ sulphuric acid and separated from 20 g of zinc sulphate and 2.5 g of ferric sulphate. In these tests, ~1 g of ascorbic acid was added to reduce iron(III) and prevent its reaction with iodide. However, this approach was ultimately abandoned because of the difficulty of destroying large amounts of TBA and because silver could not be readily stripped from the chloroform phase. It could not be stripped with concentrated hydrochloric acid, and the use of concentrated nitric acid resulted in the formation of silver iodide in the separatory funnel. Furthermore, tests showed that small amounts of copper interfered with the extraction of silver because of the formation of insoluble cuprous iodide.

Tests involving the extraction of the silver chloro- and bromo- ion-association complexes from sodium chloride–sulphuric acid and potassium bromide–sulphuric acid media, respectively, showed that although both complexes can be readily stripped from the extracts with the corresponding halide acids, it is more convenient to strip the bromo-complex. In the

chloride system, not all the silver is stripped in one step, which means that because of the greater density of the chloroform phase the use of two separatory funnels is required for complete back-extraction of silver. Conversely, in the bromide system, the stripping step can be performed in one funnel because the density of concentrated hydrobromic acid is almost the same as or slightly greater than that of the chloroform extract. However, the addition of a solvent of low density such as ethyl acetate is required to further decrease the density of the organic phase and aid in phase separation. On the basis of these findings, the extraction of silver from a potassium bromide–sulphuric acid medium was investigated in this work.

Preliminary tests with pure silver solutions showed that up to at least 500 μg can be quantitatively extracted, in three extractions, from 100 ml of $\sim$0.2–5M sulphuric acid/$\sim$0.02–0.08M potassium bromide by shaking with $\geq$3% TBA in chloroform, as described in the procedure. The extraction of silver at this level is incomplete if less than 20 ml of TBA solution or less than a 2-min shaking period is used in the first extraction step. Extraction at higher acid concentrations was not tested because of the slowness of phase separation. The optimum sulphuric acid concentration is $\sim$0.2–2.5M. At higher acidities, TBA may precipitate in the second and third extracts but this does not interfere with either the extraction or the back-extraction of silver. Silver is not extracted in the absence of sulphuric acid. The optimum TBA concentration is $\sim$3%. Extraction is incomplete at concentrations of $\sim$2% or less and, at $>$3%, too much TBA precipitates in the chloroform phase. Concentrations of $\sim$2M sulphuric acid and 0.08M potassium bromide were chosen for subsequent work. Under these conditions, up to 500 μg of silver in $\sim$100 ml of solution can be completely separated from the amounts of zinc sulphate and ferric sulphate mentioned above. At lower potassium bromide concentrations the extraction of silver in the presence of the stated amounts of zinc and iron sulphate is incomplete.

Effect of diverse ions

Under the conditions used for the extraction of silver, bismuth—at the 25-mg level—is $\sim$84% extracted as a yellow bromo- ion-association complex into chloroform containing TBA, cadmium is $\sim$35% extracted at the 100-mg level and molybdenum(VI) is $\sim$3.5% extracted at the 200-mg level. However, at these levels, these elements will not interfere in the extraction of silver, and the amounts co-extracted will not affect its determination by AAS. More than about 25 mg of bismuth interferes in the extraction step because it forms a sticky yellow material that is relatively insoluble in chloroform and may clog the separatory funnel. A low result is obtained for silver under these conditions. The presence of molybdenum is indicated by the yellow colour of the hydrobromic acid after the stripping step and by the bluish salts obtained when the final solution is evaporated to dryness.

Up to at least 8 g of zinc, 1 g of copper(II), 700 mg of iron(III), 500 mg of nickel, 200 mg of arsenic(III), arsenic(V), chromium(III), vanadium(V), phosphorus as phosphate, manganese(II), cobalt(II), indium(III) and tin(IV), 100 mg of antimony(III), titanium(IV) and zirconium(IV), 25 mg of tellurium(IV), tellurium(VI), selenium(IV) and selenium(VI) and 10 mg of tungsten(VI) will not interfere in the determination of silver by the proposed method. Mercury(II) forms a white precipitate with TBA but up to 50 mg will not interfere. More than $\sim$25 mg of tellurium(IV) and tellurium(VI) will cause a low result for silver, and more than 10 mg of tungsten(VI) interferes by causing emulsification in the chloroform phase. Antimony(V) interferes because it hydrolyses in the solution before the extraction step. Interference from antimony(V) can be avoided by removing it by volatilization as the bromide during the sample preparation step. Arsenic, germanium, tin, selenium and mercury will also be removed under these conditions. The effects of gold, platinum and palladium, which would probably also be partly co-extracted with the silver,[4,5] were not investigated because the amounts of these elements present—relative to silver—in zinc process solutions or in a 1-g sample of ore or concentrate would not be expected to interfere in the extraction of silver or to cause error in the AAS determination.[17] Chromium(VI) would be partly extracted[18] but it would not usually be present in zinc process solutions or in the sample solution obtained after the proposed decomposition step.

Up to at least 100 mg of chloride will not interfere in the extraction of silver because silver is also extracted into chloroform as an anionic chloro-TBA ion-association complex. However, if precautions are not taken, any chloride contamination in the initial sample solution will cause a low result for silver because of the precipitation of silver chloride. This will be retained in the beaker and on the filter paper before the extraction step. This source of error can easily be eliminated by washing the beaker and the filter paper with 25% ammonia solution to dissolve the silver chloride. This washing step also eliminates error resulting from possible bromide contamination from the decomposition step and error caused by the retention of silver by lead sulphate.[19] Under these conditions, up to $\sim$350 mg of lead can be present in the sample without causing significant error in the result. Nitric acid must be absent during the extraction step.

Applications

To test the reliability of the proposed method, it was applied to a series of synthetic zinc process solutions, in which the silver, added in the form of a dilute sulphuric acid solution, was varied from 2 to 500 μg. It was also applied to Canadian Certified Reference Materials Project (CCRMP) certified refer-

Table 1. Recovery of silver from synthetic zinc process solutions

Matrix	Total Ag present, μg	Ag found, μg
2*M* sulphuric acid solution (~95 ml) containing 20 g of $ZnSO_4$ and 2.5 g of $Fe_2(SO_4)_3$	3.0_3	2.9_6

Duplicate determinations of silver in the zinc sulphate (without added silver) by the proposed method gave 1.2_0 and 0.8_6 μg.

ence ores and concentrates and to National Bureau of Standards (NBS) and British Chemical Standards (BCS) copper metal and copper-base alloys. The results of these analyses, which are the means of four or five AAS measurements, are given in Tables 1, 2 and 3. All the results shown are for individual samples. The results obtained at CANMET, during the interlaboratory certification programmes, for the CCRMP ores and concentrates by a fire-assay/AAS method[20,21] are also given in Table 2.

Precision

The precision for silver at about the 4–1100 μg/g levels was tested by analysing six samples each of three certified CCRMP ores. The results of these tests, which are the means of four or five AAS measurements, are given in Table 4. The results obtained for these ores at CANMET by a fire-assay/AAS method during the interlaboratory certification programmes are also given in Table 4.

Table 1 shows that the results obtained for the synthetic zinc process solutions agree favourably with the calculated amount of silver present. Except for PTM-1, the results obtained for the CCRMP reference ores and concentrates (Table 2) are in excellent agreement with the certified values and with those obtained at CANMET by a fire-assay/AAS method.[20,21] The results obtained for PTM-1 by the proposed method agree with those obtained at the National Institute of Metallurgy in South Africa[2] by wet-chemical AAS methods involving leaching of the sample with nitric acid and either subsequent extraction of silver into toluene containing iso-octyl thioglycollate (74.4 μg/g), or direct determination of silver

with compensation for viscosity and matrix effects (73.8 μg/g). The results obtained for the NBS and BCS copper metal and alloys (Table 3) are also in good agreement with the certified values.

Table 4 shows that the precision of the results for silver by the proposed method at about the 4–1100 μg/g levels is reasonably good. Although the relative standard deviations obtained are slightly higher than those calculated for the fire-assay/AAS results, they still compare favourably with them. However, because sample inhomogeneity can occur in ores, particularly when the noble metals are present in the native form,[22] the precision of the fire-assay/AAS results would be expected to be slightly better than that of the proposed method because of the much larger sample weight taken, *i.e.*, ~15–30 g compared with ~0.4–1 g.

In the proposed method, it may be possible to extract silver into methyl isobutyl ketone (MIBK) followed by its direct determination in the extract by AAS. Probably this would also result in an increase in sensitivity, depending on the volume of MIBK required for complete extraction. However, this approach was not investigated because of the noxious nature of MIBK and because aqueous calibration solutions are considerably easier to prepare and more convenient to use for routine work. Also more elements (*e.g.*, iron, antimony, indium and tin) would be expected to be co-extracted because of the formation of oxonium-type ion-association bromo-complexes with the MIBK.[3] The proposed method has some advantages over other methods involving the extraction of silver from hydrochloric[1,3–5] and hydrobromic acid media[7] with amines and quaternary ammonium salts, because of the wide range of sulphuric acid concentration that is applicable. The use of sulphuric acid is also advantageous for sample preparation and, unlike hydrochloric acid and probably hydrobromic acid, it is not co-extracted into chloroform containing TBA.[18] Furthermore, unlike methods based on the extraction of silver from nitric acid media with reagents such as iso-octyl thioglycollate,[2] petroleum sulphides, triphenylphosphine and tri-iso-octyl thiophosphate,[1] a relatively large amount of chloride will not interfere in the extraction step. The advantages of extracting silver from a potassium bromide–sulphuric acid medium rather than from a potassium iodide–sulphuric acid medium are that copper will not inter-

fere because it forms a soluble bromide, ascorbic acid is not required to reduce iron(III), antimony(III) is not co-extracted and, in general, fewer elements form extractable bromo-complexes than form iodo-complexes.[4]

The proposed method is suitable for silver in ores and related materials at levels as low as ~0.1 μg/g and in zinc process solutions down to the ~0.001-μg/ml level. Solutions containing ≥2 μg of silver per ml can be analysed directly by AAS, with reasonable accuracy, after tenfold dilution of the solution to reduce viscosity and matrix effects. The same amounts of concentrated hydrochloric acid and diethylenetriamine as in the calibration solutions should be added to the diluted sample solution. The method can also be used to determine microgram quantities of silver in lead chloride after treatment of a suitable sample (up to ~0.5 g) with 30 ml of 50% sulphuric acid, followed by chloride removal by double evaporation of the solution to fumes of sulphur trioxide, the sides of the beaker being washed down with water between the evaporations.

Acknowledgement—The author thanks P. E. Moloughney for permission to use his fire-assay/AAS results for silver.

(*Received* 22 *April* 1982. *Accepted* 13 *July* 1982)

Summary—Graphite-coated metal electrodes were constructed and evaluated for use in voltammetry. Aluminium, copper and platinum electrodes were sprayed with a colloidal solution of graphite particles dispersed in methyl methacrylate polymer. The polishing step was omitted for anodic stripping voltammetry with a mercury film. The resistance is about 1 Ω. Electrode areas are readily reproduced by utilizing metal supports with equal areas. Background currents are very low and useful potential ranges are extended, with −1.3 to +1.7 V *vs.* SCE being possible, depending on the electrolyte. It is possible to achieve ±0.1% precision for the peak-currents in the electrochemical oxidation of ferrocyanide. For phenol, which is strongly adsorbed, a precision of 2.5% can be achieved by polishing the electrode before each determination.

The literature on modified electrodes is becoming extensive and is growing rapidly.[1] The reason for this increasing interest is that most solid electrodes do not fulfil the requirements of good conductivity, high overpotential for hydrogen and oxygen evolution, chemical and electrochemical inertness, and low background current over the whole useful range of potential.

Among the materials most used, carbon in various forms is well suited for making electrodes for voltammetric and stripping analyses. Glassy-carbon and carbon-paste electrodes are generally employed in voltammetric experiments. Each type has its own advantages and has been used with varying degrees of success. For example, the very hard mirror-like and conductive glassy-carbon material exhibits higher background currents and lower useful potential ranges than carbon-paste electrodes,[2–6] and the latter exhibit electrochemical properties that depend on the paste used and the pasting formulation.[3,6,7]

Various modifications have been tried in attempts to build non-porous surfaces in order to diminish background currents and improve the carbon-electrode response. Pyrolytic-graphite and ordinary graphite electrodes have been modified either physically or chemically by using wax or various polymers as impregnators or binders.[8–27] The techniques generally consist of immobilizing any of a wide variety of chemical species onto conventional electrode materials, either by covalent bonding, adsorption or physical coating onto a solid electrode surface. Unfortunately, there are often practical difficulties that limit the ease with which the electrodes can be routinely prepared, utilized and renewed for subsequent use. We have recently described the modification of either a carbon-paste or glassy-carbon electrode by spraying a graphite powder on the surface to create a thin film of uniform particles, the "graphite spray electrode".[28] Though the working potential range was somewhat narrowed, the background currents were decreased.

In the present work, we describe a simple, very rapid and convenient means of making composite graphite electrodes for general voltammetric applications. The technique does not require the time-consuming impregnation procedure, but uses a colloidal solution of graphite particles dispersed in a suitable polymer for coating the planar disk surfaces of metal electrodes (platinum, copper, aluminium) with an adhering graphite-based conductive layer. The working potential-ranges are enhanced and the electrode areas are highly reproducible.

EXPERIMENTAL

Apparatus

Voltammetric measurements were made on a Brucker E 100 polarograph with a Hewlett-Packard type 7004 B recorder. Cyclic voltammetric measurements were made by use of a triangular-signal generator constructed in our

laboratory and coupled with the recorder. A three-electrode cell thermostatically controlled at 25.0 ± 0.1° was used.

The reference electrode, a saturated calomel electrode, was placed inside a salt bridge filled with the electrolyte under investigation. A platinum wire served as counter-electrode.

The working electrodes were home-made metal electrodes (see below). Deoxygenation was accomplished by passing purified nitrogen through the cell, and nitrogen was passed over the solution in the cell throughout the experiments. Stripping analyses were done by the standard-additions method, Hamilton microsyringes being used for making the additions.

Reagents and solutions

All reagents were of analytical grade (Merck). Mercury(II) nitrate solution (0.1*M*) was prepared from highly purified mercury, dissolved in nitric acid. Metal solutions more dilute than $10^{-3}M$ were prepared just before use. Water was demineralized and then distilled twice, the first time from permanganate, and stored in polyethylene bottles.

Electrode fabrication

Two procedures were investigated and gave satisfactory results. In the first (Fig. 1*a*), a collar of heat-shrinkable tubing was shrunk over the metal rod (diameter 9 mm) and the glass tube. The rod and sheath were then cut to the desired electrode length. Finally, a flat surface was obtained by manually polishing the electrode on metallographic paper (Carbinet 600, Buchler, Evanston, Illinois).

The second procedure (Fig. 1*b*) consisted of sealing the metal rod (diameter 8 mm), carefully centred, in an appropriate glass tube with epoxy resin, and then polishing the metallic disk and the glass surrounding it to a very flat surface with metallographic paper.

The modification procedure consisted of applying a graphite layer onto the polished electrode surface by means of short bursts of spray from an aerosol can of graphite solution (Acheson, Dag 40*) until the disk and the sheath (glass or heat-shrinkable tubing) appeared completely coated when inspected with a hand lens. The sheath of the electrode body was cleaned with acetone, so that only the planar surface of the electrode was coated with graphite. Between bursts of spray, the surface was heated with a hair-drier to remove any traces of organic solvent.

This procedure gives, in about 5 min, electrodes ready to use. The graphite layer is hard and tight, owing to the inherent stability and durability of the acrylic polymers. Moreover, poly(methyl methacrylate) films are extremely resistant to alkaline saponification and are relatively unaffected by acids. The total electrode assembly has a resistance of about 1 ohm, as measured with a mercury pool contact at the face of the disk.

The electrodes are ready for use in ASV measurements, but polishing is necessary in organic voltammetric analyses in order to improve the electrode response (see Fig. 4 below). This can be done by carefully polishing the graphite layer with successively finer abrasives, and finally finishing with abrasive strips of the type used for polishing ion-selective electrodes (Tacussel or Orion). The surface of an electrode prepared in this manner appears mirror-like and is sufficiently durable to permit re-use several times, with polishing before use. Poorer looking and less reproducible waves can result from breaking and chipping of the graphite layer by extensive polishing, but fortunately, respraying of the damaged surface restores the original behaviour.

Procedures

Voltammetric measurements. Cyclic and linear-scan voltammetry were applied to the oxidation of ferrocyanide dissolved in 0.5*M* potassium chloride and phenol dissolved in 0.1*M* sulphuric acid. These compounds were selected as model depolarizers, the first showing reversible behaviour on platinum, in contrast to the second, which exhibits irreversible behaviour and electrode filming or poisoning phenomena.[4,29]

Anodic stripping measurements. A concentration of $2 \times 10^{-4}M$ mercury(II) was added to all test solutions for *in situ* mercury-film deposition. The experiments were done with various media: ammonia buffer of pH 8.5, 0.1*M* tartaric acid or 0.1*M* sulphuric acid, but the simultaneous determination of Zn, Cd and Pb was done in acetate buffer, pH 4.7. The mercury film and the three metals to be determined were deposited at a potential of −1.25 V (*vs.* SCE), with magnetic stirring. At the end of the deposition period, the stirring was stopped, and after a 15-sec rest period, the metals were stripped from the mercury film by applying an anodic potential scan, in either the linear or the differential pulse mode. The scan was stopped at +0.05 V (*vs.* SCE)

*Acheson Dag 40 (Acheson Company, 1020 Brussels, Belgium) is a dispersion of colloidal graphite (30%) in poly(methyl methacrylate) dissolved in butyl acetate. The propellent gas is Freon 12.

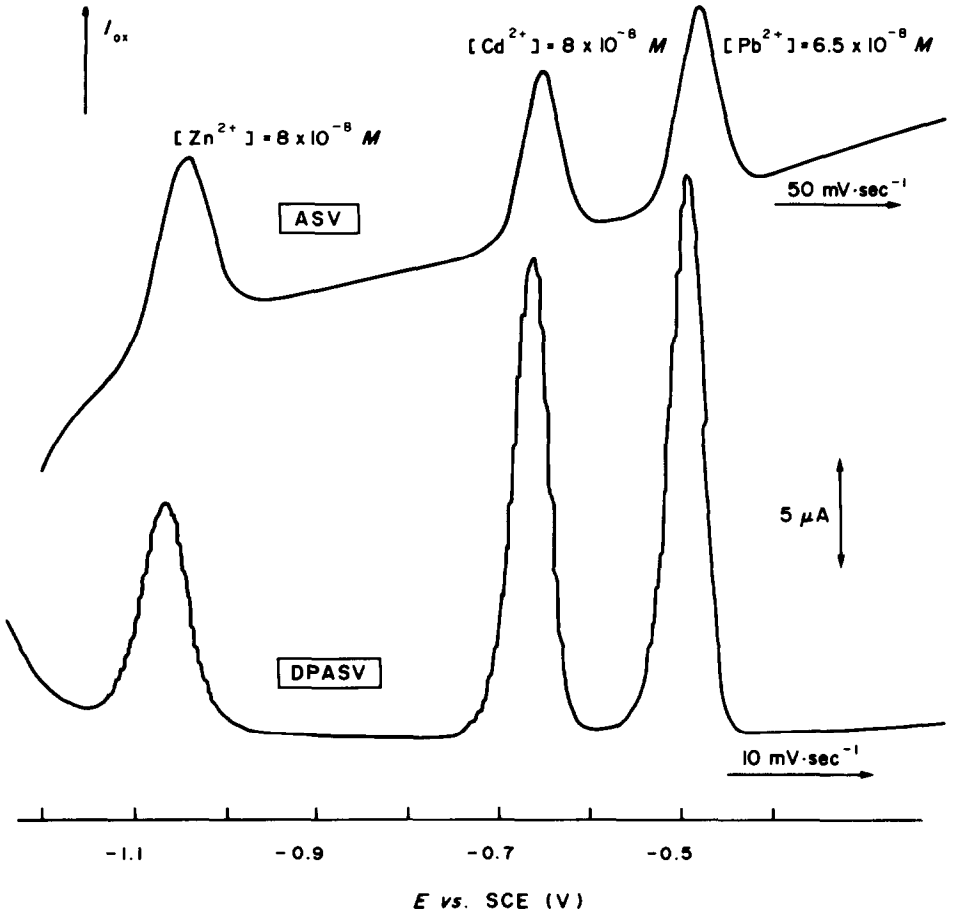

Fig. 2. Typical anodic stripping voltamperograms with the modified aluminium electrode: 5-min deposition at -1.25 V; $[Hg^{2+}] = 2 \times 10^{-4} M$; supporting electrolyte HAc/Ac$^-$ 0.1M; pH = 4.7

and this potential was maintained for 1 min before the next run was performed. In agreement with the results obtained by Florence[30] with the glassy-carbon electrode, we found that the first scan always gave lower peak-heights than the following scans and served to condition the graphite-coated electrode. The concentrations of the metals in the sample were determined by the standard-additions method, without removal of the electrode from the solution.

At the conclusion of the analyses, the graphite layer was completely removed by wiping the surface with a filter paper soaked in acetone, and the metal disk surface was then ready for respraying. Other instrumental parameters were: d.p. amplitude 40 mV; pulse repetition rate 0.5 sec; pulse duration 55 msec.

RESULTS AND DISCUSSION

Anodic stripping voltammetry

In our previous reports, we have demonstrated that it is possible to improve the surface characteristics of carbon-paste electrodes for use as thin mercury-film electrodes (TMFE) in making ASV measurements.[28,31] The technique consisted of coating the carbon-paste surface by spraying it with a graphite-based conductive solution. The resulting electrode, when electrochemically coated with mercury, exhibited good stability in various supporting electrolytes. The reproducibility of the measurements of ASV currents with freshly prepared surfaces was better than that for the simple carbon-paste electrode, but the working potential-range was decreased.

In an attempt to extend use of the spray technique to other supports than carbon, metal electrodes (Al, Cu, Pt) were investigated. The use of these conductive supports obviously requires a uniform coating and complete tightness of the graphite layer, in order to avoid any contact of the metal with the solution to be analysed. Figure 2 illustrates typical anodic stripping voltamperograms for simultaneous determination of zinc, cadmium and lead with an aluminium graphite-coated electrode. Both stripping modes employed, linear scan (LSASV) and differential pulse (DPASV), performed well, but the latter gave better sensitivity, as shown by the slopes of the base current for the supporting electrolyte at the stripping potential for lead and cadmium; viz. 10 μA/V for LSASV and 0.7 μA/V for DPASV.

The stability of the sprayed layer was confirmed by the good linearity of plots of peak currents *vs.* concentration of metal ions [for use of the standard-addition

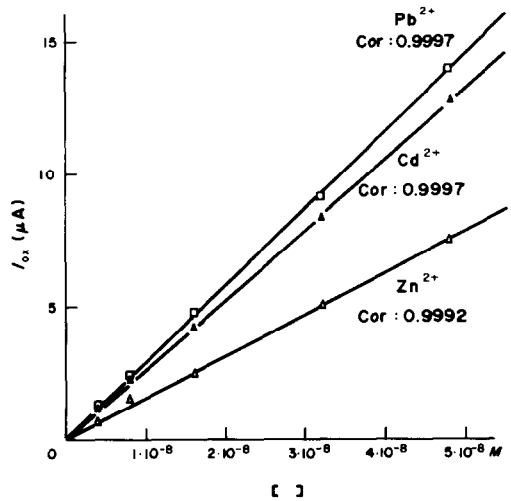

Fig. 3. Differential-pulse anodic stripping voltammetry with the modified aluminium electrode. Calibration curves for Pb, Cd and Zn; 5-min depositions at −1.25 V; $[Hg^{2+}] = 2 \times 10^{-4}M$; supporting electrolyte HAc/Ac^- 0.25M; drop time 0.5 sec; pulse amplitude 40 mV; scan-rate 10 mV/sec.

method without removal of the electrode from the solution (Fig. 3)].

With Florence's criteria,[32] the limits of detection were estimated to be $10^{-10}M$ for cadmium and lead and $4 \times 10^{-10}M$ for zinc (10-min deposition time).

In view of the cyclic voltammetric results (see below), we compared the ASV performances of polished-surface electrodes with those of unpolished sprayed-surface electrodes. As shown in Table 1, the results with both electrodes compared favourably for lead and cadmium. There is, however, a slight increase in peak-currents on the rough electrode as expected, due to the larger electrochemically active area. In contrast, peak-currents for zinc were lower on rough electrodes; this lack of sensitivity was related to the increase in peak half-width ($b_{1/2}$) and could presumably be attributed to diminution of the reversibility of the electrode process, *i.e.*, slower charge-transfer at the electrode.

The present results obtained with graphite-covered metal electrodes compare favourably with the DPASV data reported for various carbon mercury thin-film electrodes. As shown in Table 1, there is no great advantage in polishing the electrode for ASV measurements, since polishing introduces a risk of contamination. Moreover, the graphite-spray coating has the advantage of being easily renewable, ready for use, without any memory effects for several metals (mercury in particular) following removal of previous coatings, with acetone or benzene.

Cyclic and linear-scan voltammetry

The good behaviour of the modified metal electrodes in ASV has focused our interest on evaluating the electrochemical properties of the graphite coating for utilization in cyclic and organic voltammetry. The cyclic voltamperograms reported in Fig. 4 clearly show that polishing the graphite layer is necessary in order to improve the performance of the electrode. Figure 4*b* displays a typical cyclic voltamperogram of a 1mM ferrocyanide solution in 0.5M potassium chloride, obtained with a polished graphite-coated aluminium electrode. As a result of the polishing, the rate of charge-transfer is greatly improved, giving rise to a smaller ΔE_p and larger peak-currents. The peak-potential (+0.280 V *vs.* SCE) and peak-potential separation (ΔE_p 120 mV) compared favourably with the results reported for other carbon electrodes.[2,4] Over the whole range of scan-rates investigated (10–300 mV/sec) the I_a/I_c ratio was in accord with theory for a reversible system, and the peak-currents were diffusion-controlled, as shown by the linearity of plots of current *vs.* the square root of the scan-rate.

The potential-ranges available with the polished electrode were determined. The cyclic voltammetric residual currents for a typical modified aluminium electrode in common mineral acids are illustrated in Fig. 5. The background currents were very low and the useful potentials significantly extended, compared to those for other solid electrodes.

Two aspects of the reproducibility of peak-current and peak-potential measurements were investigated. First the reproducibility of a given surface was examined. This was accomplished by scanning the linear current–voltage curve for the oxidation of 1mM ferrocyanide in 0.1M potassium chloride, briefly stirring the solution, and rescanning the I–E curve. The relative standard deviation (rsd) of peak-currents for 9 replicate runs was lower than 0.1%, and the peak-potentials were almost constant. The second aspect concerned variations from surface to surface. A phe-

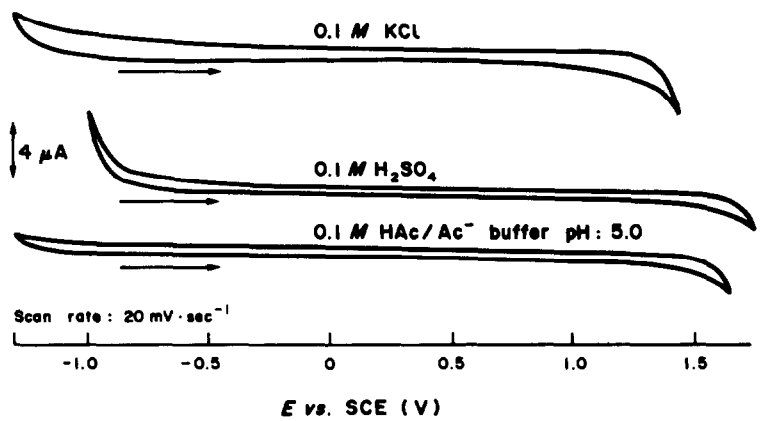

Fig. 5. Background cyclic voltamperograms for the modified aluminium electrode in several media.

nol solution was used, as it is known[4,29] to poison electrode surfaces drastically and in such cases, polishing between runs is necessary. A typical linear-scan voltamperogram is illustrated in Fig. 6. The rsd of peak-currents for 9 different surfaces was 2.5% with peak-potentials reproducible within ± 2 mV.

CONCLUSIONS

The graphite-coated metal electrode represents a new type of solid electrode, which exhibits almost ideal behaviour. It has high electrical conductivity, good mechanical strength, low residual currents, wide operating voltage range, and highly reproducible area and performance. The electrode is very rapidly prepared, easily renewable, inexpensive and machinable into various shapes. Several electrodes of equal electrochemical area and response can be readily prepared simply by machining metal supports of equal cross-sectional area and then spraying them with graphite. Copper, platinum or aluminium supports work equally well, and the less expensive metals allow construction of electrodes at very little cost. With proper coating of the supports, no metallic contamination of the solutions has been found by means of ASV. Performances reported in this work were obtained with aqueous solutions, but aqueous methanol solutions have also been successfully used in the determination of pharmaceutically interesting organic compounds. Further studies are in progress on the utilization of these electrodes in non-aqueous media.

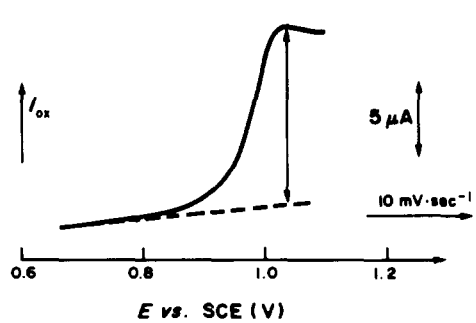

Fig. 6. Current–voltage curve from 1×10^{-4}*M* phenol in 0.1*M* sulphuric acid, at the modified aluminium electrode.

Preliminary studies have indicated that the electrode is not affected by acetonitrile, but acetone and benzene cause the polymer to dissolve or separate from the electrode.

STUDIES ON POTENTIOMETRIC STRIPPING ANALYSIS

TUEN CHI CHAU, DE YU LI and YING LIANG WU
Department of Chemistry, Jinan University, Guangzhou, China

(*Received* 26 *March* 1982. *Accepted* 13 *July* 1982)

Summary—Theoretical and experimental investigations have been made on the method of potentiometric stripping analysis. By solving Fick's second law of diffusion for the metal in the amalgam, it was found that $\tau = C_R^0 l/k[Ox]$, where τ is the elapsed time, l is the thickness of the mercury film, C_R^0 is the concentration of the metal in the amalgam, [Ox] is the concentration of the oxidant in the solution and k is a constant. Since C_R^0 is proportional to the concentration of that particular ion in the solution under given pre-electrolysis conditions, the relations given by the equation above can all be verified experimentally. The equation of the potential–time curve and the effect of complex formation on the elapsed time were also investigated and discussed. In the absence of complexation reactions in the solution and with proper control of the concentration of the oxidant, the lowest limit of detection for Pb was found to be $10^{-12}M$ for a 4-min pre-electrolysis, with dissolved oxygen as oxidant.

Potentiometric stripping analysis, recently proposed by Jagner,[1,2] is an analytical method for determining certain metal-ion concentrations in very dilute solutions. This method consists of two steps: the pre-electrolysis step and the oxidation step. In the pre-electrolysis step, metal ions are reduced at constant potential on a thin mercury film (attached to a glassy-carbon electrode) to form amalgams. This pre-electrolysis step is similar to that in anodic or chronopotentiometric stripping, but in the oxidation step, a suitable oxidant is used for stripping the amalgam instead of use of a potential sweep as in anodic stripping, or a constant current as in chronopotentiometric stripping. During the course of oxidation, the potential of the glassy-carbon electrode varies with time, and the potential–time curve is recorded. The shape of this curve is similar to those in chronopotentiometry or chronopotentiometric stripping. The potential of the electrode remains almost constant from the beginning of the oxidation of a certain metallic species in the amalgam until the amalgam is stripped of such a species. The potential then varies rapidly with time until the oxidation of the next species begins. The time of oxidation of a certain species, called the elapsed time τ for that species, can be derived from the curve and is related to the concentration of the species in the solution before pre-electrolysis.

The novelty of this method is that there is virtually no current passing through the electrode during the entire period of oxidation. Thus the problem of charging or capacitative current no longer exists. Any blank that might occur is entirely due to impurities present in the water or reagents used and these can be completely removed by experimental means. Therefore, under properly controlled experimental conditions, the sensitivity of this method could be much enhanced. In order to verify this point, we did some theoretical and experimental investigation on this method. The following is a report of this work so far. Some data have been published in Chinese scientific journals.[3,4] The cation investigated was lead.

EXPERIMENTAL

Apparatus

A model 75-3 rapid scan polarograph (Amoy, China) was used for constant-potential electrolysis. The oxidation curve was recorded with an XWX-2042 recorder (Shanghai, China). A rotating glassy-carbon electrode BDX-1 (Changtsun, China) was used as the working electrode; it had a diameter of 4.5 mm and was rotated at 2000 rpm. A spiral Ag/AgCl electrode was used as the reference electrode and a saturated potassium nitrate or chloride agar salt bridge for connection. A CY-Z oxygen meter (Shanghai, China) was used for determining oxygen in the solutions.

Reagents

All reagents used were of the general or analytical reagent grade. Any lead in these reagents was exhaustively removed by cathodic mercury-pool electrolysis at -1.8 V to give the least possible blank. The water used was first treated by reverse osmosis to remove most of the ions (except those of water, of course) and practically all of the undesirable neutral or charged particles, then passed through a cation-exchange column and a Millipore 0.45-μm filter and finally distilled in quartz before use.

All solutions were kept in plastic bottles to avoid contamination from lead. The nitrogen used for deaeration was purified by passage through vanadium(II) chloride solution.[5]

Preparation of the working electrode

A clean glassy-carbon electrode is immersed in 50 ml of 0.1M hydrochloric acid containing 25 mg of mercury(II) nitrate per litre and connected to an Ag/AgCl electrode by a saturated agar bridge, and electrolysis is performed at -0.5, -0.6, -0.7 and -0.8 V for 30 sec at each voltage and then at -0.9 V for 2 min. The total electrolysis time is 4 min. The time of electrolysis can be varied to give mercury films of different thickness. The electrode is rotated during electrolysis. The rotation is stopped when the elec-

trolysis is over and at the same time the working and reference electrodes are connected to a recorder and the film is stripped. The electrode is then rinsed with distilled water and stored in distilled water for later use.

Procedure

Measure 50 ml of a lead solution which is 0.5M in sodium nitrate, 0.05M in nitric acid and $2 \times 10^{-5}M$ in mercury(II) into an electrolysis cell. Deaerate with purified nitrogen for 60 min. After that let the stream of nitrogen pass over the surface of the solution to prevent oxygen from redissolving in the solution. Immerse a glassy-carbon electrode with a mercury film in the solution and complete the cell with an Ag/AgCl reference electrode. Electrolyse for 4 min at -1.1 V with the electrode rotating. Then stop the rotation and at the same time connect the electrodes to a recorder to trace out the potential–time curve.

RESULTS AND DISCUSSION

Theoretical considerations

Let the thickness of the mercury film be l and the co-ordinate system of the working electrode be as given in Fig. 1. The oxidation reaction proceeds at the surface of the mercury film, *i.e.*, at $x = l$. Since the Pb^{2+}/Pb couple is reversible, the rate of oxidation is controlled by the rate of diffusion of lead in the mercury film. Assuming Fick's second law to hold in the mercury film, we have

$$\partial C_R/\partial t = D_R(\partial^2 C_R/\partial x^2) \quad 0 < x < l \tag{1}$$

where D_R is the diffusion coefficient of lead in mercury, C_R is the concentration of lead in the mercury and t is the time of oxidation. We also have the following initial and boundary conditions.

Initial condition:

$$t = 0; \quad C_R = C_R^0; \quad 0 < x < l \tag{2}$$

where C_R^0 is the concentration of lead in the mercury film before oxidation begins.

Boundary conditions:

$$t > 0; \quad x = 0; \quad D_R(dC_R/dx) = 0 \tag{3}$$

$$t > 0; \quad x = l; \quad D_R(dC_R/dx) = -k[Ox] = -\beta \tag{4}$$

where k is the rate constant of the oxidation reaction and [Ox] signifies the concentration of lead in the solution. The initial condition states that the concentration of lead in the mercury film is C_R^0 after the pre-electrolysis. The first boundary condition states that the diffusion of lead is limited within the mercury film. The second boundary condition states that at $x = l$ lead is oxidized by the oxidant. If the oxidant is in large excess, [Ox] may be considered as constant, and so k[Ox] is also constant and can be represented by a constant β. Since the lead ions no longer stay within the mercury film, β is preceded by a minus sign to show that the concentration gradient is negative with respect to x.

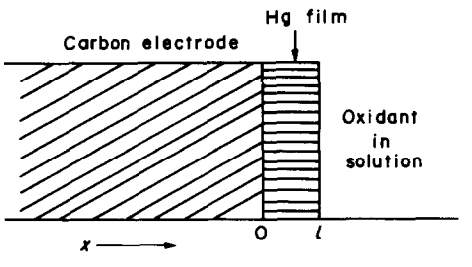

Fig. 1. The co-ordinate system of the working electrode.

We can find a solution to this problem by using the Laplace transform,[6] *i.e.*,

$$C_R = C_R^0 - \frac{\beta l}{D_R}\left\{\frac{D_R t}{l^2} + \frac{3x^2 - l^2}{6l^2} - \frac{2}{\pi^2}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^2} \times \exp(-D_R n^2\pi^2 t/l^2)\cos\frac{n\pi x}{l}\right\}. \tag{5}$$

At $x = l$, this becomes

$$C_{R(x=l)} = C_R^0 - \frac{\beta l}{D_R}\left\{\frac{D_R t}{l^2} + \frac{1}{3} - \frac{2}{\pi^2}\sum_{n=1}^{\infty}\frac{(-1)^n}{n^2} \times \exp(-D_R n^2\pi^2 t/l^2)\cos n\pi\right\}. \tag{6}$$

In our experiments, l was of the order of 10^{-5} cm and D_R of the order of 10^{-5} cm^2/sec. The maximum value of t (*i.e.*, τ) is of the order of 10^2 sec. Therefore the exponential term in equation (6) can be neglected and we have

$$C_{R(x=l)} = C_R^0 - \beta t/l - \beta l/3D_R. \tag{7}$$

At the end of the oxidation reaction, $C_{R(x=l)} = 0$ and $t = \tau$, so we have

$$\tau = lC_R^0/\beta - l^2/3D_R. \tag{8}$$

This means that under a given set of experimental conditions τ is a linear function of C_R^0. Furthermore, if C_R^0 is large enough, then

$$lC_R^0/\beta \gg l^2/3D_R,$$

and we have

$$\tau = lC_R^0/\beta = lC_R^0/k[Ox]. \tag{9}$$

The diffusion of lead ions in the solution after oxidation is given by[7]

$$C_{0(x=l)} = 2\beta(t/\pi D_0)^{1/2} \tag{10}$$

where $C_{0(x=l)}$ is the concentration of lead ion at $x = l$ and D_0 is the diffusion coefficient of lead ions in the solution.

Since the Pb^{2+}/Pb couple is reversible, the potential of the working electrode is governed by the Nernst equation, *i.e.*,

$$E = E^0 + \frac{RT}{2F}\ln\frac{C_{0(x=l)}}{C_{R(x=l)}} \tag{11}$$

where R, T, F and E^0 have their usual meaning. If $l^2/3D_R$ is negligible, substituting equations (9) and (10)

Table 1. τ values in different solutions (corrected for blanks)

$[Pb^{2+}]$, M	0.5*M* $NaNO_3$–0.05*M* HNO_3 pH = 1	0.5*M* NaCl–0.05*M* HCl pH = 1	0.5*M* NaAc–0.6*M* HNO_3 pH = 1	0.5*M* $Na_2C_4H_4O_6$–1*M* HNO_3 pH = 1

into (11) gives

$$E = E^0 + \frac{RT}{2F}\ln[2l/(\pi D_0)^{1/2}] + \frac{RT}{nF}\ln[t^{1/2}/(\tau - t)]. \quad (12)$$

This is the equation of the potential–time curve.

CORRELATION BETWEEN THEORY AND EXPERIMENT

The relation between τ and C_R^0

From equations (8) and (9), we can see that τ varies linearly with C_R^0, but it is well known that in stripping analysis, for a given set of experimental conditions, C_R^0 is directly proportional to the concentration of lead in the solution before pre-electrolysis. Therefore τ should also vary linearly with the original concentration of Pb^{2+} in solution. Table 1 gives the τ values for four sets of solutions of different composition. We can easily see that for a linear relationship holds for the chloride and nitrate systems, but for the acetate and tartrate solutions the sensitivity is too low to show the linearity clearly. The reason for the lower sensitivity will be discussed below. Figure 2 gives a typical set of stripping curves for different solutions.

Relation between τ and β

Equation (9) also shows that for constant C_R^0 and l, τ is inversely proportional to β, *i.e.*,

$$\tau \propto 1 \Big/ \sum^{n} k_n[\mathrm{Ox}]_n. \quad (13)$$

This means that the elapsed time increases with the decrease of oxidant concentration in the solution. This relation is shown in Figure 3. The presence of $2 \times 10^{-5}M$ Hg^{2+} in the solution is to maintain a large excess of oxidant.

The relationship between time of deaeration and the concentration of oxygen is given in Table 2. Figure 3 shows that τ increases linearly with deaeration time up to about 50 min. After that the increase in τ is lower and τ remains constant for deaeration times over 60 min. This can be explained by the fact that after about 50 min the removal of oxygen is more difficult and after about 60 min the concentration of oxygen remains constant despite further purging.

Relation between elapsed time and film thickness

According to equation (9), τ should be proportional to l at constant C_R^0, but since C_R^0 is itself inversely proportional to l, the net result is that τ is independent of l. Table 3 shows such a relation: τ is independent of l over a fivefold range of l values. The l values are calculated from the equation

$$l = 10^{-6}\, iwt/nFdr^2 = 2.43 \times 10^{-11}\, it/r^2 \quad (14)$$

where i = plating current (μA), w = atomic weight of mercury, t = deposition time (sec), n = number of electrons involved in reduction of Hg^{2+}, d = density of mercury (g/cm^3), r = radius of mercury film (cm).

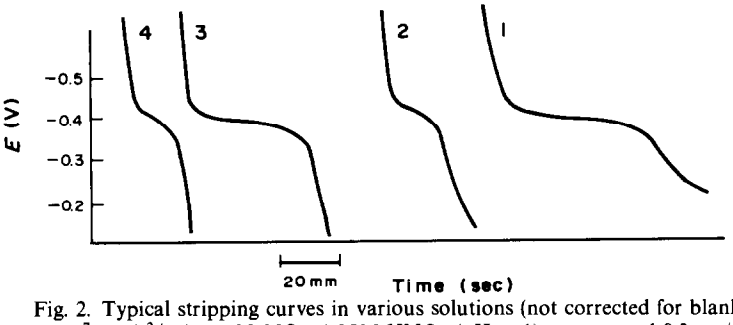

Fig. 2. Typical stripping curves in various solutions (not corrected for blanks).

4. $10^{-7}M$, Pb^{2+}, 0.5*M* $Na_2C_4H_4O_6$–1*M* HNO_3 (pH = 1) paper speed 1.5 sec/mm.

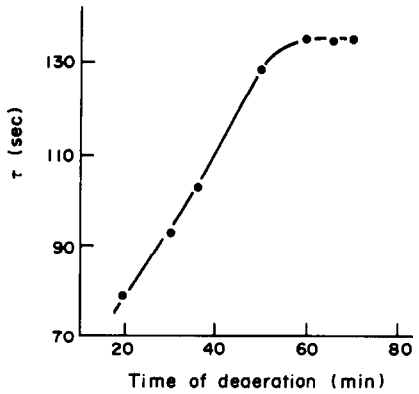

Fig. 3. Increase of τ with increasing time of deaeration. $10^{-6}M$ Pb^{2+}, 0.5*M* NaCl, 0.05*M* HCl, $2 \times 10^{-5}M$ Hg^{2+}. Pre-electrolysis time 4 min, nitrogen flow-rate 10 ml/sec.

The experimental verification of equation (12)

The simplest way of verifying equation (12) is to plot $\log[t^{1/2}/(\tau-t)]$ against E. This should give a straight line with a slope of 2.3 RT/nF (0.03 V at 25° for Pb), and this was found experimentally for nitrate and chloride solutions (slopes 0.033 and 0.030 V respectively).

In Fig. 4 we can see that the linear relationships are very well demonstrated. The slope of the line for nitrate solution is 0.033 V while that for chloride solution is 0.030 V, both are in good agreement with the theoretically predicted value.

Influence of solution composition on elapsed time and the potential–time curve

Table 1 also demonstrates the influence of solution composition on the elapsed time τ. With the same amount of lead in the solution ($[Pb^{2+}] = 10^{-6}M$) and under the same experimental conditions, the four different solutions give four different elapsed times. In our opinion, this is due to complexation reactions in the solution. In the reaction

$$Pb \rightleftharpoons Pb^{2+} + 2e^{-}.$$

Complexation decreases the concentration of lead ions, thus increasing the rate of ionization of lead and decreasing the elapsed time τ. For the solution, we

Table 2. The relationship between the time of deaeration and the partial pressure and concentration of the remaining oxygen

Time of deaeration, *min*	P_{O_2}, *mmHg*	$[O_2]$, M
10	58	1.06×10^{-4}

30	30.5	5.56×10^{-5}
40	22	4.01×10^{-5}
50	13.9	2.53×10^{-5}
60	12.5	2.28×10^{-5}

Table 3. The relation between τ and *l* for various plating times

Plating time, *min*	*l*, *cm*	τ, *sec*
4	3.0×10^{-5}	49.6
6	3.5×10^{-5}	48.7
9	6.3×10^{-5}	46.3
12	7.5×10^{-5}	48.2
15	15.0×10^{-5}	49.1

can write the side-reaction coefficient α for this complexation:

$$\alpha_{Pb(L)} = C_{Pb^{2+}}/[Pb^{2+}] = 1 + \beta_1[L] + \beta_2[L]^2 + \ldots \beta_n[L]^n \quad (15)$$

where $C_{Pb^{2+}}$ is the total lead concentration, $[Pb^{2+}]$ the free ion concentration, [L] the free ligand concentration and the β_n values the overall stability constants of the complexes. It is easy to see that as $\alpha_{Pb(L)}$ increases, $[Pb^{2+}]$ will decrease and so will the elapsed time τ.

On the other hand, in this case the E *vs.* t curve will be given by the expression

$$E = E^0 + \frac{RT}{nF}\ln\frac{C_O/\alpha_{Pb(L)(x=l)}}{C_{R(x=l)}}$$

$$= E^0 + \frac{RT}{nF}\ln[2l/(\pi D_O)^{1/2}] - \frac{RT}{nF}\ln\alpha_{Pb(L)} + \frac{RT}{nF}\ln[t^{1/2}/(\tau - t)]. \quad (16)$$

When $\ln[t^{1/2}/(\tau - t)] = 0$, we have

$$E = E^0 + \frac{RT}{nF}\ln[2l/(\pi D_O)^{1/2}] - \frac{RT}{nF}\ln\alpha_{Pb(L)}. \quad (17)$$

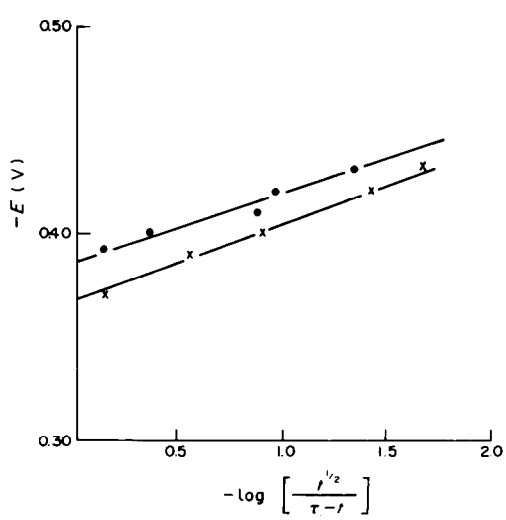

Fig. 4. The linear relationship between E and $\log[t^{1/2}/(\tau - t)]$.

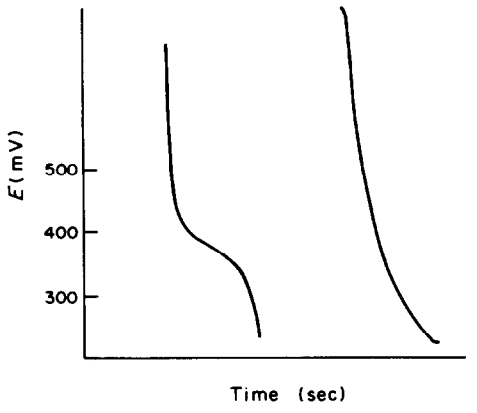

Fig. 5. The stripping curve for $10^{-12}M$ Pb, and the corresponding blank.

If we can assume that there is no complexation, as will be the case for lead and nitrate, we have $\alpha = 1$, and then

$$E_{(NO_3^-)} = E^0 + \frac{RT}{nF} \ln[2l/(\pi D_0)^{1/2}]. \quad (18)$$

When there is complexation, however, as for lead and chloride,

$$E_{(Cl^-)} = E^0 + \frac{RT}{nF} \ln[2l/(\pi D_0)^{1/2}] - \frac{RT}{nF} \ln \alpha_{Pb(Cl)}. \quad (19)$$

If we subtract equation (18) from (17) and assume that E^0 and D_0 are the same in both equations, we have, for the same l, the expression

$$E_{(NO_3^-)} - E_{(Cl^-)} = \frac{RT}{nF} \ln \alpha_{Pb(Cl)}. \quad (20)$$

The right-hand side of equation (20) is therefore equal to the difference between the intercepts on the E axis in Fig. 4, 0.02 V. From the literature[8] the value of β, for lead and chloride is $10.^{1,2}$ Since the concentration of chloride in the solution is approximately $0.5M$, $(RT/nF) \ln \alpha_{Pb(Cl)}$ can be calculated:

$$\alpha_{Pb(Cl)} \approx 10^{1.2} \times 0.5$$

$$\frac{RT}{nF} \ln \alpha_{(Cl)} \approx 0.027 \text{ V}$$

in fair agreement with the experimental value of 0.02 V, taking into consideration the difference in ionic strength and temperature.

It should be emphasized that equations (15)–(20) are valid only for rapid complexation reactions; otherwise equilibrium is not attainable in the course of the oxidation, and the equations are no longer valid.

Sensitivity

From the discussion above, it can be concluded that if there is no complexation of the analyte in the solution, the sensitivity of the method can be much enhanced by controlling the quantity of oxidant present. This is indeed the case. In a nitrate solution, if the amount of dissolved oxygen is reduced to a minimum by deaeration with nitrogen for 60 min and there are no other oxidants present, the maximum sensitivity of this method is $10^{-12}M$ for Pb. A series of 13 determinations done at different times gave an average result of 1.04 sec with a standard deviation of 0.24 sec. The stripping curve and the corresponding blank are given in Fig. 5. It should be noted that the time of pre-electrolysis in these experiments is only 4 min. The sensitivity could be further enhanced by prolonging the pre-electrolysis.

For routine analysis, deaeration for 60 min is too time-consuming. Investigations are under way to reduce the time required for the removal of oxygen, and the results will be given in later communications.

SIMULTANEOUS DETERMINATION OF ARSENIC, ANTIMONY AND TIN BY FAST-SCAN DIFFERENTIAL-PULSE POLAROGRAPHY AND ITS APPLICATION TO ALLOY STEELS

JIŘÍ LEXA

Chemical Laboratories, Central Research Institute, Škoda Works, Pilsen, Czechoslovakia

and

KAREL ŠTULÍK*

Department of Analytical Chemistry, Charles University, Albertov 2030, 128 40 Prague 2, Czechoslovakia

(*Received* 6 *April* 1982. *Accepted* 1 *July* 1982)

Summary—Arsenic, antimony and tin can be determined in the presence of one another by fast-scan differential-pulse polarography (FSDPP) on a single mercury drop in 1.5*M* hydrochloric acid. The reduction of As(III), Sb(III) and Sn(IV) to the metals is practically reversible and the reduction peaks are sufficiently separated. The lower limits of determination are 0.05, 0.005 and 0.001 μg/ml for As, Sb and Sn respectively, the calibration graphs exhibit very good linearity and the peak heights are reproducible. For application to alloy steels employed in nuclear technology, the elements to be determined must be separated from the matrix by extraction as their covalent bromides into toluene from concentrated sulphuric acid and back-extracted into the base electrolyte (1.5*M* HCl + 0.012*M* Br^- + 0.03*M* hydrazinium sulphate). The recoveries of As, Sb and Sn are 100, 95 and 92% respectively and the relative error of determination is a few per cent.

In the manufacture of alloy steels for use in nuclear technology, trace levels of arsenic, antimony and tin (and of some other elements) are of great importance. Typical values are 50–250 ppm As, 10–100 ppm Sb and 50–250 ppm Sn. Polarographic methods for determination of these elements are generally more sensitive than flame AAS, comparable with electrothermal AAS and are simpler.[1–6]

Arsenic, antimony and tin have been polarographically determined many times, on the basis of the reduction of As(III), Sb(III) and Sn(IV) in base electrolytes containing inorganic or organic acids (*e.g.*, As,[4,7] Sn,[5,8,9] Sb[10]). However, a reliable method for simultaneous determination of all three elements has not been described.

Arsenic, antimony and tin must be separated from the more complex matrices before polarographic determination. Extraction in the form of covalent halides into a non-polar solvent is especially suitable for steels, as it is very selective;[11,12] the test elements are oxidized to their highest oxidation states during the sample decomposition, but the arsenic and antimony are simultaneously reduced to the tervalent states required for polarographic determination[7] and the extraction efficiency is high, increasing from chloride to iodide.[12] This extraction has been applied to steels[13] and alloys of tin[14] and copper.[15]

In the present work we employ fast-scan differential-pulse polarography (FSDPP) recently developed[16] in Laboratorní Přístroje, Prague, using a single stationary mercury drop, which permits the polarogram to be recorded within 40 sec, with a sensitivity and resolution better than those of conventional differential-pulse polarography (DPP). The instrument polarizes the electrode with pulses of an amplitude adjustable from 12.5 to 100 mV, in either direction from the d.c. voltage ramp. The pulse duration is 100 msec and the interval between successive pulses is also 100 msec. The sampling windows before the pulse and at the end of the pulse are 20 msec wide. The scan-rate can be varied from 0.5 to 500 mV/sec. Two systems of sample-and-hold circuits can be used, one with the time constant, RC, equal to 100 msec, the other with RC = 10 msec. The static mercury-drop electrode (SMDE) has a capillary which can be closed by a needle operated by an electronic circuit, and the time of opening of the capillary, which determines the drop size, can be varied from 40 to 160 msec. The whole operation of drop-formation, potential-scan with recording, and drop-disconnection is automated.

EXPERIMENTAL

Apparatus

The FSDPP measurements were done with a PA-3 polarographic analyser, a three-electrode circuit consisting of an electronically controlled static mercury-drop electrode, a saturated calomel reference and a platinum

*Author for reprint requests.

auxiliary electrode, and a 4103 X-Y plotter (all from Laboratorní Přístroje, Czechoslovakia). The solutions were deaerated with prepurified nitrogen.

Small solution volumes were measured with Eppendorf micropipettes (FRG). The extractions were performed in 25-ml standard flasks and back-extractions in 10-ml standard flasks, fitted with polyethylene stoppers.

Reagents

All chemicals used were of *p.a.* purity from Lachema (Czechoslovakia) and Merck (FRG) and were not further purified.

A standard solution of As(III) (0.1 mg/ml) was prepared by dissolving 0.1320 g of arsenious oxide in 20 ml of 2*M* sodium hydroxide, diluting with water to about 100 ml, acidifying with 10 ml of dilute sulphuric acid (1 + 5) and diluting with water to 1000 ml. Standard solutions of Sb(III) and Sn(IV) (0.1 mg/ml) were prepared by dissolving the pure metals (99.99%) in 20 ml of hot concentrated sulphuric acid and diluting with dilute sulphuric acid to 1000 ml.

Cyclohexane, benzene, toluene and *o*-xylene (*p.a.*) were used for the extractions. The hydrochloric acid was standardized by acid–base titration.

All measurements were made at room temperature and all potentials referred to the SCE.

RESULTS AND DISCUSSION

Selection of the base electrolyte

From the literature survey, base electrolytes containing hydrochloric or oxalic acid might be suitable for simultaneous determination of the three elements. Therefore hydrochloric acid at various concentrations, its mixture with oxalic acid, oxalic acid alone and a mixture of oxalic acid with Methylene Blue were tested. The last electrolyte was selected because it was reported[5] to be advantageous for a.c. polarographic determination of tin. The FSDPP polarograms of the three elements in these base electrolytes are shown in Figs. 1 4. The Sn(IV) → Sn(II) reduction peak (which generally occurs[1] at between 0 and −0.2

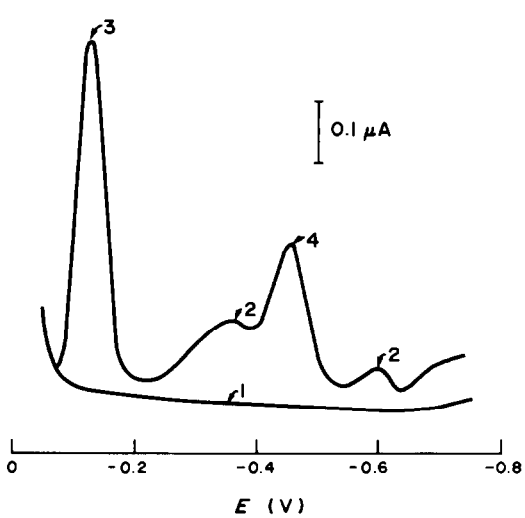

Fig. 1. The FSDPP curves for 1.5*M* HCl medium. 1—Base electrolyte, 2—As, 3—Sb, 4 Sn. c_M = 1 μg/ml, potential scan-rate = 20 mV/sec, pulse amplitude = −50 mV, RC = 10 msec.

Table 1. Tests for reversibility of the electrode reactions As(III) → As, Sb(III) → Sb and Sn(II) → Sn: c_{metal} = 1 μg/ml, potential scan-rate = 20 mV/sec, pulse amplitude = ±50 mV, RC = 10 msec; E_p^+ and I_p^+ are the peak potential and current, respectively, for the pulse in a positive direction, E_p^- and I_p^- are those for the pulse in a negative direction[17]

Test metal	Base electrolyte	$E_p^- - E_p^+$, mV	$\lvert I_p^+/I_p^- \rvert$	Electrode process
As	1.5*M* HCl	55	1.00	Reversible
Sb		45	1.03	Reversible
Sn		50	0.98	Reversible
As	1.5*M* HCl + 0.1*M* oxalic acid	40	1.43	Quasi-reversible, $\alpha < 0.5$
Sb		35	1.02	Quasi-reversible, $\alpha < 0.5$
Sn		40	0.90	Quasi-reversible, $\alpha \geqslant 0.5$
As	0.5*M* oxalic acid	45	1.05	Reversible
Sb		55	0.97	Reversible
Sn		50	0.95	Reversible
As	0.5*M* oxalic acid + Methylene Blue	65	0.91	Irreversible
Sb		65	0.83	Irreversible
Sn		55	1.05	Reversible

V) does not appear in the given potential range except for the base electrolyte containing Methylene Blue, thus only the Sn(II) → Sn reduction peak is generally recorded. In hydrochloric acid arsenic yields three peaks:[4] the first, at about −0.4 V, corresponds to the As(III) → As reduction; the second, at about −0.6 V, has the character of a polarographic maximum and disappears at arsenic concentrations below 0.3 μg/ml; the third, corresponding to the As → As^{3-} reduction, at a potential of −0.84 V, does not appear in the given potential range. The first peak is proportional to the arsenic concentration and strongly depends on the hydrochloric acid concentration, apparently as a result of changes in the distribution of the various chloride and hydroxide complexes of arsenic.[7]

Tests for reversibility were done with the peaks for Sb and Sn and the first peak for As, by the method of Birke *et al.*[17] The results are given in Table 1.

It is evident that hydrochloric acid solutions are best suited for the simultaneous determination of the three elements. In 0.5*M* oxalic acid, antimony and tin could be simultaneously determined, and tin alone could be determined in 0.5*M* oxalic acid containing Methylene Blue at the $5 \times 10^{-4}M$ level.

The effect of hydrochloric acid concentration on the peak heights and potentials is shown in Fig. 5. A graphy under these conditions are compared in Fig. 6. It can be seen that the FSDPP method is more selectivity of measurement. The results obtained by FSDPP, conventional DPP and sampled d.c. polarography under these conditions are compared in Fig. 6. It can be seen that the FSDPP method is more selective than DPP, and more sensitive for Sb and Sn, but somewhat less sensitive for As.

The parameters of the calibration regression lines are given in Table 2. The calibration graphs were obtained both for the three elements separately (calibration A) and in mixtures (calibration B). The limit of determination was taken as three times the standard deviation of the baseline signal. It can be seen that the calibration graphs exhibit very good linearity and that the limit of determination is sufficiently low for the given purpose.

The effect of bromide and iodide

In view of the possible use of bromide or iodide for extraction of the test elements, their effect on the FSDPP curves was studied. It was found that the presence of bromide in the base electrolyte at concentrations up to 0.015*M* leads to only a small shift in the peak potentials (by −20 mV for arsenic and +20 mV for antimony and tin) and to a maximum decrease in the peak height of about 10% with arsenic

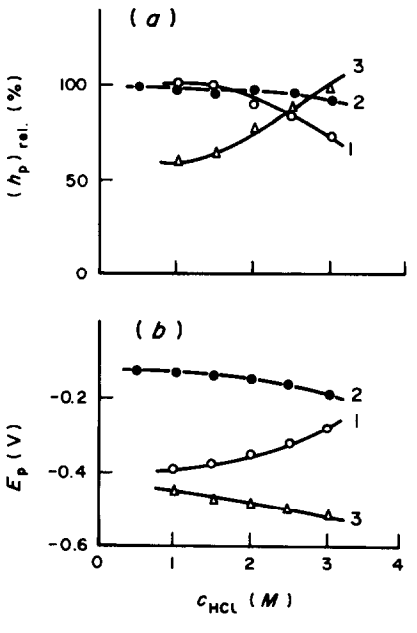

Fig. 5. The effect of HCl concentration on the height h_p (*a*) and the potential E_p (*b*) of the peaks of As (1), Sb (2) and Sn (3). $c_{As,Sn}$ = 1 μg/ml, c_{Sb} = 0.5 μg/ml, for other conditions see Fig. 1.

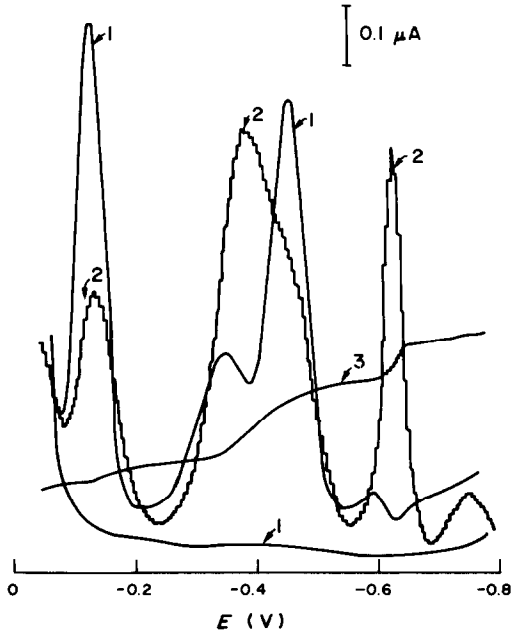

Fig. 6. Comparison of the FSDPP (1), DPP (2) and sampled d.c. polarographic (3) curves for As, Sb and Sn in 1.5*M* HCl. $c_{As,Sn}$ = 1 μg/ml, c_{Sb} = 0.5 μg/ml, potential scan-rate = 5 mV/sec, pulse amplitude = −50 mV, RC = 100 msec, drop-time with DPP and sampled d.c. = 1 sec.

and tin and about 20% with antimony. Further, it was found that the concentration of bromide extracted from sulphuric acid into toluene varied from less than 10^{-4} *M* for 6.4*M* sulphuric acid to 8.8×10^{-3} *M* for 11.7*M* acid (the bromide was back-extracted into 0.1*M* sodium hydroxide and after pH adjustment was potentiometrically titrated with 0.02*M* silver nitrate, a silver ion-selective electrode being used). As this concentration will be further decreased on back-extraction of the sample into the base electrolyte, it will not exceed 5×10^{-4} *M* and thus the addition of enough bromide to the base electrolyte to give a concentration of 0.012*M* will swamp the effect of this extracted bromide (there will be a relative change of only 4% in the bromide concentration after the extraction). The calibration graphs obtained with base electrolyte that was 0.012*M* in bromide gave a linearity as good as that in the absence of bromide, with limits of determination of 0.03, 0.03 and 0.04 μg/ml for arsenic, antimony and tin, respectively.

On the other hand, even low concentrations of iodide strongly affect the peaks of antimony and tin. Therefore, removal of iodide by precipitation with excess of silver nitrate was attempted. However, the FSDPP peaks of the three elements, especially arsenic, decreased with increasing amount of precipitate, owing to adsorption, and thus the use of iodide for the extraction was found unsuitable.

For further measurements, 1.5*M* hydrochloric acid–0.012*M* bromide base electrolyte was therefore used. In this electrolyte, the three elements were simultaneously determined at various concentrations, and it was found that the individual elements could be determined without increase in measurement error in the presence of a tenfold ratio of the other two, except that arsenic could tolerate only a fourfold ratio of tin.

Extraction of arsenic, antimony and tin bromides

Cyclohexane, benzene, toluene and *o*-xylene were tested as extractants. The elements were extracted from 8.3*M* sulphuric acid–0.21*M* sodium bromide mixture in a 25-ml standard flask with 1 ml of solvent and back-extracted into the base electrolyte in a 10-ml standard flask. The extraction time was 5 min. Under these conditions, toluene and *o*-xylene yielded the highest recoveries, about 100% for arsenic and 47% for antimony. Tin was not extracted. Toluene was therefore used in subsequent experiments.

The effect of the bromide concentration on the extraction of the elements was examined at three different concentrations of sulphuric acid. The results are shown in Fig. 7. The extraction of tin was always negligible, that of arsenic decreased above a certain concentration of bromide, whereas that of antimony increased and approached a constant value.

With further increase in the sulphuric acid concentration, extraction of all the three elements was increased, becoming practically complete from the 12*M* acid (see Fig. 8). The bromide concentration has little effect at this acid concentration. Under these con-

Table 2. Characteristics of the calibration regression lines: $c_{As,Sn}$ = 0.2–2.4 μg/ml, c_{Sb} = 0.1–0.9 μg/ml, potential scan-rate = 20 mV/sec, pulse amplitude = −50 mV, 25 nA/cm; equation: $h_p = bc_M + a$, where h_p = peak height in cm

ditions, the rate of equilibration between the phases and the number of extractions required for complete extraction were tested. The equilibrium is established within 2 min, but an extraction time of 5 min is used, to give a safety margin. The effect of the number of extractions is shown in Table 3, which shows that two suffice for complete extraction. The optimum conditions for selective and group extraction of the elements are summarized in Table 4.

Because arsenic and antimony are oxidized to the quinquevalent state in the decomposition of steel samples, but must be in the tervalent state for extraction as the bromides, we tested the extraction of As(V) and Sb(V) under the same conditions. Results identical with those for As(III) and Sb(III) were obtained, which indicates that As(V) and Sb(V) are reduced to the tervalent state during the extraction, presumably by hydrogen bromide in the aqueous phase. This would lead to the formation of a small amount of bromine, which would also be extracted. To prevent any possible interference, we decided to add $0.03M$ hydrazinium sulphate to the base electrolyte.

The calibration graphs for the three elements were then obtained after extraction under the conditions above. The parameters of the regression lines are given in Table 5, and show that the extraction does not introduce additional errors into the procedure.

Application to alloy steels

Two standards that had been analysed at various laboratories by various methods were used. The sample decomposition with a mixture of hydrochloric and nitric acid[18] was selected to suppress volatilization of the chlorides of the test elements. To prevent

precipitation of ferric sulphate, excess of nitric acid was removed chemically, by addition of formic acid. The problem of precipitation of ferric sulphate also occurs in the extraction from fairly concentrated sulphuric acid, where part of the As, Sb and Sn can be lost by adsorption on the precipitate. However, it was found that these losses are small and constant and their effect can be eliminated, if necessary, by using the standard-addition method. To suppress the possible oxidation of the test elements by bromine, hydrazinium sulphate was added both to the aqueous solution before the extraction and to the base electrolyte.

For 0.2-g samples, the calibration graphs are linear from 0.001 to 0.03% As, Sb and Sn, the detection limits being 2×10^{-4}, 3×10^{-4} and 9×10^{-4}% for As, Sb and Sn respectively.

Procedure

A 0.200-g sample is dissolved in 10 ml of a 3:1 v/v mixture of concentrated hydrochloric and nitric acids in a covered tall beaker. The dissolution can be hastened by cautious heating, but evaporation must be suppressed to prevent volatilization of the As, Sb and Sn. After the dissolution, 20 ml of 14*M* sulphuric acid are added and the mixture is carefully evaporated to the first appearance of white fumes. The beaker walls are rinsed with a small amount of water, 2 ml of formic acid are added and the evaporation is repeated. A ferric sulphate precipitate must not appear, since tin would be adsorbed on it. The hot solution is transferred to a 25-ml standard flask, and cooled with water to room temperature. Then 1.0 ml of a 1.3% solution of hydrazinium sulphate in 0.5*M* sodium bromide is added, followed by 1.00 ml of toluene. The whole is diluted with water to the mark, the flask is shaken for 5 min, the phases are allowed to separate and 0.500 ml of the organic phase is pipetted into 10.0 ml of the base electrolyte (1.5*M* HCl + 0.012*M* NaBr + 0.03*M* hydrazinium sulphate) in a 10-ml standard flask. The flask is shaken for 1 min, the organic phase is separated, and the elements are determined by FSDPP over the range of potential from −0.05 to −0.6 V.

The parameters of the calibration graphs for this procedure, obtained by analyses of synthetic standards made from pure iron (free from the test elements) are summarized in Table 6. Comparison with Table 5 indicates that losses of arsenic and antimony are small, but almost 30% of the tin is lost during the procedure. However, this is a systematic error that can be considerably suppressed by using a suitable calibration procedure or the standard-addition method. It is due to loss of tin(IV) chloride during the decomposition, and could perhaps be avoided by use of a decomposition method not needing hydrochloric acid.

The method was tested on two reference materials. The precision of the determination is summarized in Table 7. It is highest for antimony, 1.5–2.7% relative error; for arsenic and tin the values are 4.1–4.6% and 7.4–8.2% respectively. As seen from Table 8, except for one determination of arsenic, the accuracy of the method is satisfactory, and the precision is the same as or better than that of the other methods listed.

In view of the high selectivity of the extraction method (only selenium and germanium are co-extracted under the given conditions[19]) the method can be useful in analysis of a great variety of materials, from alloys to organic substances.

SYNTHESIS OF SOME NEW *o*-THIOAZO LIGANDS AND EVALUATION OF THEIR METALLOCHROMIC PROPERTIES

D. L. PRINGLE, M. T. MOHABBIS, M. H. MAHONEY, C. H. SOTAK and J. M. SULLIVAN
Chemistry Department, University of Northern Colorado, Greeley, CO 80639, U.S.A.

(*Received* 8 *February* 1982. *Accepted* 26 *June* 1982)

Summary—The synthesis of several new *o*-thioazo derivatives of *p*-cresol and 2-naphthol is reported, as well as their spectral properties, acid dissociation constants, and potential as metallochromic reagents. All the ligands form complexes with Cu^{2+} and Ni^{2+}. *o*-Mercaptoazo complexes of Fe^{3+} and Cu^{2+} with molar absorptivities of 3.83×10^4 and 3.58×10^4 l.mole^{-1}.cm^{-1}, respectively, are described.

Sulphur-containing chromogenic agents such as dithizone and the dithiocarbamates are well known to analytical chemists. Other sulphur-containing ligands such as 8-mercaptoquinoline[1] and 6-mercaptopurine[2] have been studied and have found limited use as analytical reagents. There are some sulphur-containing azo derivatives such as 1-(2-thiazolylazo)-2-naphthol[3] and 2-(2-thioazolylazo)-5-dimethylaminophenol[4] that have been explored as metallochromic reagents, but in both the sulphur is part of the heterocyclic thiazol ring. Azo dyes in which the sulphur is bonded directly to one or both of the aromatic rings have not been explored to any great extent. Burawoy *et al.*[5–7] reported on the synthesis of a number of *o*-mercaptoazo compounds and indicated that many of these formed precipitates with a variety of transition metal ions, but very little has been done on the potential of such compounds as colorimetric reagents. Koch and Pringle[8] reported the synthesis of bis-(2[(tetrahydro-2H-pyran-2-yl)thio]phenyl)diazene and its potential as a colorimetric reagent for Hg(II). This reagent, with the sulphur atoms protected by pyranyl groups, is indefinitely stable in solution, contrary to the azomercaptans reported by Burawoy, and other thiol ligands.

The purpose of this paper is to report the synthesis of the compounds shown in Table 1, evaluate their metallochromic behaviour, and compare the effects of the various sulphur-blocking groups. The blocking groups (R) were selected to provide a variety of steric effects and also, as in the case of compounds **I** and **II**, a comparison of a mercapto group with a thioether group. The acetic acid grouping was introduced into compounds **IV** and **VI** to increase the solubility and also to provide a blocking group that could enter into complex formation. A compound similar to **IV** and **VI**, 2-aminophenylthioacetic acid,[9] has been shown to act as a uni-, bi- or terdentate ligand and to complex with Cu^{2+}, Ni^{2+} and Cd^{2+}.

I and **V**, which proved to be the most difficult to synthesize, were prepared by coupling diazotized 2-benzylthioaniline with *p*-cresol or 2-naphthol and then debenzylating with anhydrous aluminium bromide. The debenzylation and final acidification were done in a nitrogen atmosphere. The other dyes were easily produced by diazotizing the appropriately

Table 1. Structures of thioazo ligands

blocked *o*-alkylthioaniline and coupling with *p*-cresol, 2-naphthol or 2-naphthol-3,6-disulphonic acid. After suitable purification and the determination of the acid dissociation constants, the ligands and their metal complexes were investigated spectrophotometrically.

EXPERIMENTAL

Syntheses

Preparation of [*2-(methylthio)phenyl*](*2-hydroxy-5-methylphenyl*)*diazene* (*II*). Diazotized *o*-methylthioaniline[10] (6.2 ml in 2 ml of concentrated sulphuric acid, with 2.3 g of sodium nitrite) was added dropwise to 4.5 g of *p*-cresol in 1800 ml of water containing 5.0 g of sodium hydroxide and 140 g of sodium carbonate. The reaction mixture was stirred continuously and maintained at 0°. The product was filtered off and recrystallized from methyl alcohol, yielding 4.5 g (43%) of orange-red needles, m.p. 103–105°. Calculated for $C_{14}H_{14}N_2SO$: C, 65.09%; H, 5.46%; N, 10.85%; S, 12.41%; found: C, 64.9%; H, 5.5%; N, 10.9%; S, 12.4%. ^{1}H NMR ($CDCl_3$): δ 2.4 (s, 3, $ArCH_3$), 7.3 (m, 7, ArH), and 12.6 (br. s, 1, OH).

Preparation of [*2-(benzylthio)phenyl*](*2-hydroxy-5-methylphenyl*)*diazene* (*III*). 2-Benzylthioaniline,[11] 2.0 g, was dissolved in 10 ml of 95% ethanol and diazotized by the addition of 5.0 ml of 4*M* hydrochloric acid containing 1.0 g of sodium nitrite, both solutions being at 0°. The diazonium salt was immediately added to a 10% sodium carbonate/10% sodium hydroxide solution containing 1.5 g of *p*-cresol and cooled to 0°. After 30 min of stirring 1.7 g (55%) of crude product were recovered by filtration. Recrystallization from ethanol gave orange-red needles, m.p. 101–102° (lit.[12] 102–103°). ^{1}H NMR ($CDCl_3$): δ 2.4 (s, 3, $ArCH_3$), 4.2 (s, 2, $ArCH_2S$), 7.3 (m, 7, Ar), and 12.4 (s, 1, OH).

Preparation of (*2-mercaptophenyl*)(*2-hydroxy-5-methylphenyl*)*diazene* (*I*). One g of **III** was placed, under nitrogen, in a double Schlenck flask and dissolved in 40 ml of deaerated anhydrous benzene. Anhydrous aluminium bromide, dissolved in 40 ml of benzene, was then added. The solution, which immediately changed from orange-red to violet, was stirred for 24 hr at room temperature. The product was collected on the glass frit in the flask and washed with 40 ml of benzene. After removal of the last traces of benzene by evacuation, 40 ml of 1*M* hydrochloric acid were added. This resulted in a yellow product which was again collected within the flask and washed twice with deaerated water. The product was dissolved in 50 ml of benzene, the solution was filtered and the benzene removed under reduced pressure. The product, a yellow powder, m.p. 121–123°, was stored under nitrogen. ^{1}H NMR ($CDCl_3$): δ 2.4 (s, 3, $ArCH_3$), 7.3 (m, 8, ArH and SH), and 12.0 (s, 1, OH).

Preparation of sodium o-aminophenylthioacetate.[9,13] Two g of sodium metal, cut into small pieces, were slowly added to 10 ml of *o*-aminothiophenol dissolved in 25 ml of absolute ethanol. Monochloroacetic acid, 8.0 g, neutralized with 4*M* sodium hydroxide, was added dropwise. After refluxing for 1 hr, the solution was cooled to room temperature and used for subsequent syntheses with no further isolation.

Preparation of [*2-(carboxymethylthio)phenyl*](*2-hydroxy-5-methylphenyl*)*diazene* (*IV*). Twenty-five ml of the *o*-aminophenylthioacetate solution were diazotized by addition to a solution of 3.2 g of sodium nitrite in 10 ml of water and 20 ml of 5*M* hydrochloric acid at 0°. The diazonium salt solution was then added to 5.0 g of *p*-cresol dissolved in 300 ml of water containing 2.0 g of sodium hydroxide and 70.0 g of sodium bicarbonate. After 30 min of stirring the solution was acidified with concentrated hydrochloric acid to pH < 2. The crude product was recrystallized from 95% ethanol, giving 5.5 g (47%) of orange needles, m.p. 146–148°. Calculated for $C_{15}H_{14}N_2SO_3$: C, 59.58%; H, 4.67%; N, 9.27%; S, 10.6%; found: C, 60.0%; H, 4.8%; N, 8.4%; S, 11.9%. ^{1}H NMR (acetone, d_6): δ 2.4 (s, 3, $ArCH_3$), 4.0 (s, 2, $SCH_2C{=}O$), 6.1 (br.s, 1, COOH), 7.4 (br.m, *ca.* 8, ArH), and 12.0 (br.s, *ca.* 1, OH); infrared (KBr) 3300–2300 (acid O—H) and 1690 (C=O) cm^{-1}.

Preparation of [*2-(carboxymethylthio)phenyl*](*2-naphthol*) *diazene* (*VI*). Twenty-five ml of diazotized *o*-aminophenylthioacetate solution, prepared as above, were added to 300 ml of an aqueous solution containing 5.76 g of 2-naphthol, 5.0 g of sodium hydroxide and 70.0 g of sodium bicarbonate, both solutions being cooled to 0° both before mixing and during the 30-min reaction time. The mixture was then acidified with concentrated hydrochloric acid to pH < 2. The dark red precipitate was isolated and recrystallized from glacial acetic acid. The yield was 6.0 g (46%) of greenish prisms which had a metallic lustre, m.p. 167–169°. Calculated for $C_{18}H_{14}N_2SO_3$: C, 63.89%; H, 4.17%; N, 8.28%; S, 9.47%; found: C, 63.6%; H, 4.3%; N, 8.1%; S, 9.6%. ^{1}H NMR (acetone, d_6): δ 4.0 (s, 2, $SCH_2C{=}O$), 5.2 (br.s, 1, COOH), 7.9 (m, 10, ArH), and 15.8 (s, 1, OH); infrared (KBr) 3400–2200 (acid O—H) and 1705 (C=O) cm^{-1}.

Preparation of (*2-mercaptophenyl*)(*2-naphthol*)-*diazene* (*V*). [2-(Benzylthio)phenyl](2-naphthol)diazene (0.5 g, prepared by diazotizing 2-aminophenylbenzylsulphide and coupling with 2-naphthol) was placed in one arm of a double Schlenk flask and dissolved in 40 ml of deaerated anhydrous benzene under an atmosphere of nitrogen. Addition of 0.60 g of freshly sublimed anhydrous aluminium bromide, dissolved in 10 ml of benzene, caused the red solution to change immediately to violet. After stirring for 24 hr at room temperature, the product was collected on the glass frit of the flask and washed with 50 ml of benzene. The benzene was removed by syringe and evacuation. The resulting solid was treated with 1*M* hydrochloric acid, collected on the frit, and washed with 50 ml of deaerated water. The product was dissolved in 50 ml of benzene, the solution was filtered, and the benzene removed under reduced pressure. The final product was a reddish-orange powder, sintering at 113–114° (lit.[14] 118°). ^{1}H NMR ($CDCl_3$): δ 3.30 (s, 1, SH), 7.2 (m, *ca.* 11, ArH) and 15.8 (br.s, 1, OH).

Preparation of [*2-(methylthio)phenyl*](*2-naphthol-3,6-disulphonic acid*)*diazene, monosodium salt* (*VII*). Diazotized 2-methylthioaniline (4.2 g dissolved in 20 ml of 1:1 ethanol–water mixture containing 4.1 g of sodium nitrite, followed by addition of 15 ml of 4*M* hydrochloric acid to the mixture, cooled to −5°) was added to 12 g of 2-naphthol-3,6-disulphonic acid, disodium salt, dissolved in 30 ml of 20% sodium hydroxide solution. The reaction temperature was kept at 0°. After 1 hr the mixture was acidified with 6*M* hydrochloric acid, cooled and filtered. The crude product was crystallized three times from 95% ethanol and finally extracted with acetone in a Soxhlet extractor. After stripping of the acetone, 4.0 g (15%) of a deep purple solid were recovered. Analysis with titanium(III) chloride showed that the product was 87% pure, on the basis of its azo content.

K_a *determinations*

The K_a value for the OH and/or SH group of each dye was determined spectrophotometrically. The absorbance of the dye, taken over a number of closely-spaced pH values, was plotted *vs.* pH; the inflection point of this curve served as the K_a value. The methods of Clark and Lubs, and of Bates and Bower, as found in Bates,[15] were used to prepare the buffered solutions. Because of solubility difficulties, many of the K_a values were determined in aqueous ethanol media. The K_a values reported are based on the apparent pH values measured in the media used, and may not agree with the K_a values measured in purely aqueous medium.

Table 2. Properties of the thioazo ligands

Ligand	λ_{max}, nm (ϵ, $l.mole^{-1}.cm^{-1}$) pH < 7	7 > pH < 12	pH > 12	pK_a values
I	425 (4.30 × 10^3)[a]	555 (4.4 × 10^3)	470 (3.30 × 10^3)	SH, ~4.5[d] OH, ?[d]
II	415 (1.00 × 10^4)[a]		485 (1.62 × 10^4)	OH, 11.75[a]
III	415 (9.50 × 10^3)[a]		485 (1.06 × 10^4)	OH, 11.15[c]
IV	409 (9.00 × 10^3)[b]		490 (9.50 × 10^3)	COOH, 5.38[a] OH, 11.25b
V	488 (1.35 × 10^4)[a]	545 (1.08 × 10^4)	455 (1.70 × 10^4)	SH, 5.64[a] OH, ~12.7[d]
VI	490 (1.90 × 10^4)[b]		460–490 (1.37 × 10^4)	COOH, 5.30[a] OH, 12.25[b]
VII	500 (1.00 × 10^3)[c]		513 (6.50 × 10^2)	SO_3H, 2.54[c] OH, 10.97[e]

[a]50% ethanol. [b]40% ethanol. [c]20% ethanol. [d]Too unstable toward air oxidation to make suitable estimates. [e]Water.

Furthermore, the K_a values reported for **V** and **VI** are most likely only approximate, as they were determined in very basic solutions with the attendant alkaline errors in the pH measurements. The K_a values for the carboxylic acid protons in compounds **III** and **IV** were determined by a pH-titration with 0.1*M* sodium hydroxide.

Mole-ratio determination

The combining ratio of dye and metal ion was determined by the standard spectrophotometric mole-ratio method. The pH used for each determination was selected by study of the pH-dependence of the absorbance for each complex.

RESULTS AND DISCUSSION

With the exception of **I** and **V**, the azo ligands were stable and could be stored indefinitely both as the solid and in solution. **I** and **V**, however, were difficult to synthesize, needing a nitrogen atmosphere, and were very unstable in solution. A chloroform solution of **I** would slowly change from yellow to green over a period of two days. A solution of **V** made up in absolute ethanol which had been purged with nitrogen showed signs of deterioration after only an hour or two.

Table 2 shows the spectral characteristics of each of the azo ligands as well as the values for their acid dissociation constants. Since compounds **I**–**VI** showed little solubility in water, the spectral data were obtained by use of ethanol–water mixtures as solvents. **VII**, however, was very soluble in water. Most of the compounds were yellow in acidic media and changed to orange or red with increasing pH. Compounds **I** and **V** showed an intermediate colour change, from yellow to violet and then to orange.

The K_a values for the OH proton fell into two categories. The phenolic protons of **I**–**IV** had pK_a values of about 11.5, whereas the naphthol protons of **V**–**VII** had values near 12.5. The NMR-shift values also showed a similar effect in that the phenolic protons had a chemical shift of approximately 12.3 ppm and the OH on the naphthol derivatives had a shift of about 15.8 ppm. The K_a values of the COOH group in **IV** and **VI** were determined potentiometrically because the dissociation was not accompanied by a spectral change, presumably because the carboxylic acid group is not conjugated to the aromatic system. The pK_a values for the SH groups are only approximate, because of the unstable nature of their solutions.

Each of the ligands was tested for complex formation with a variety of metal ions, which included Ag^+, Ba^{2+}, Bi^{3+}, Ca^{2+}, Cd^{2+}, Cu^{2+}, Fe^{3+}, Hg(I), Hg(II), Ni^{2+}, Pb^{2+} and Zn^{2+}. Table 3 summarizes the results. Copper and nickel reacted with all the ligands, though in the case of **VI**, the copper complex was only partially soluble in 50% aqueous ethanol and the copper and nickel complexes of **V** were both insoluble in water–ethanol mixtures. **VI** was unique in that it formed fluorescent precipitates with Ba^{2+}, Cd^{2+} and Mg^{2+}. Attempts to dissolve these precipitates in water, carbon tetrachloride, ethanol, methanol, cyclohexene, and acetone were all unsuccessful.

The ligands in which the sulphur was present in a thioether group (**II**, **III**, **IV**, **VI** and **VII**) all formed 1:1 complexes with copper and nickel. In an attempt to find the extent of involvement of the sulphur atom in the bonding, the oxygen analogue of **III**, [(2-benzoxy)phenyl](2-hydroxy-5-methylphenyl)diazene, and phenyl(2-hydroxy-5-methylphenyl)diazene were prepared, and their copper complexes studied. The benzoxy and phenyl diazenes both formed 3:1 complexes with copper, in contrast to the 1:1 complex of **III**. This would indicate that the sulphur atom is unquestionably involved in the bonding, most likely though strong $d\pi$–$d\pi$ interaction with the metal ion.

From an analytical point of view, **I** and **V** are perhaps the most interesting. When a chloroform solution of **I** is shaken with an aqueous solution of Cu^{2+}, Ni^{2+}, Hg(II) or Ag^+, an intensely blue complex is extracted into the chloroform layer. The molar absorptivity of the copper complex is 3.58 × 10^4 $l.mole^{-1}.cm^{-1}$. The complex obeys Beer's law up to a copper concentration of 2.5 ppm, but the plot does not pass through the origin, probably because the oxidation product of the uncomplexed ligand interferes. The exact nature of the complexes of **I** has yet to be studied, because of the lack of stability of the dye, although once the complex is formed, its colour seems to be stable indefinitely.

V proved to react with the greatest number of metal ions. A solution of **V** in absolute ethanol was added to a test solution of each of the metals listed

Table 3. Properties of thioazo complexes

Ligand	Metal(s)	Mole ratio (L:M)	pH range	Colour	λ_{max}, *nm*	ϵ, $l.mole^{-1}.cm^{-1}$
I	Cu^{2+}	—	[a]	Blue	570	3.58×10^4
	Ni^{2+}, Hg(II), Hg(I)	—	[a]	Blue	580	—
II	Cu^{2+}	1:1	5–10[b]	Pink	520	1.40×10^4
	Ni^{2+}	—	—	Pink	510	6.70×10^3
III	Cu^{2+}	1:1	7.5–11[c]	Orange	520	1.06×10^4
	Ni^{2+}	—	—	Orange	510	9.00×10^3
IV	Cu^{2+}	1:1	6–9[b]	Pink	520	1.05×10^4
	Ni^{2+}	—	—	Pink	510	9.00×10^3
	Ag^{+}[d]					
V	Fe^{3+}	2:1	4–5[c]	Rose	525	3.83×10^4
	[Ba^{2+}, Ca^{2+}][f]					
	[Ni^{2+}, Ag^{+}, Zn^{2+}, Cd^{2+}, Hg(II), Pb^{2+}, Cu^{2+}][g]					
VI	Cu^{2+}[h]	—	—	Pink	525	—
	Ni^{2+}	1:1	7	Pink	520	2.02×10^4
	[Ba^{2+}, Cd^{2+}, Mg^{2+}][i]					
VII	Cu^{2+}	2:1	9–11	Red	513	2.00×10^3
	[Fe^{3+}, Ca^{2+}][j]					

[a]Complex was extracted into $CHCl_3$ for acidic solution of the metal ion. [b]Acetate buffer. [c]Carbonate buffer. [d]Complex forms only in the presence of a large excess of Ag^{+}. [e]Perchloric acid–sodium carbonate buffer. [f]Show evidence of very weak complex formation. [g]Form chloroform soluble precipitates of various colours. [h]Only sparingly soluble. [i]Form fluorescent precipitates which are insoluble in common solvents. [j]Quenched the dye's fluorescence.

and then buffered at pH 5.6, the final ethanol–water ratio being 1:1. Under these conditions a number of transition metals gave highly coloured complexes, Ba^{2+}, Ca^{2+} and Fe^{3+} formed soluble complexes. The Fe^{3+} complex seemed the most highly coloured and stable. The molar absorptivity was 3.83×10^4 $l.mole^{-1}.cm^{-1}$, and the combining ratio was 2:1 (L:M). The complex formed very slowly, but once formed, it also decomposed very slowly. Figure 1 shows the mole-ratio data for this complex as well as the time-dependence for its formation and decomposition. As in the case of **I**, the complex of **V** is far more stable than the ligand itself.

The ligands in which the sulphur is present in a thioether group, although more stable and easier to work with, do not have exceptionally high molar absorptivities (*ca.* 10^4 $l.mole^{-1}.cm^{-1}$), nor do they show large enough bathochromic shifts to make them attractive analytically. The ligands in which the sulphur is present as a thiol group, however, have high molar absorptivities and show large bathochromic shifts when complexed. Successful attempts to stabilize thioazo ligands should prove useful in producing new chromogenic agents.

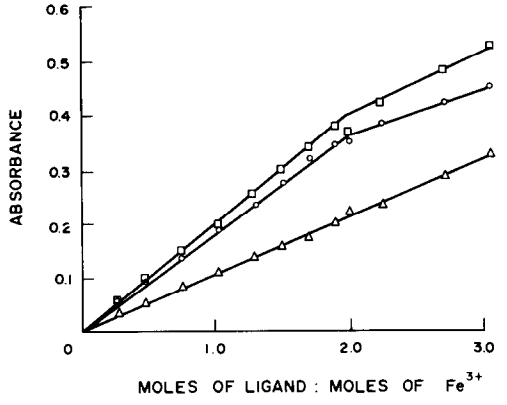

Fig. 1. Mole-ratio plot for Fe^{3+} and V, △, immediately after mixing Fe^{3+} and ligand; □, 4 hr after mixing; ○, 4 days after mixing. Final Fe^{3+} concentration, $1.00 \times 10^{-5} M$; wavelength, 525 nm.

A SURVEY OF THE INFORMATION ON CO-ORDINATION COMPOUND FEATURES WHICH CAN BE GAINED FROM ELECTROANALYTICAL METHODS*

GINO BONTEMPELLI, MILLA ANDREUZZI-SEDEA and MARIO FIORANI
Istituto di Chimica Analitica, Università di Padova, Via Marzolo 1, 35100 Padova, Italia

(*Received* 10 *February* 1982. *Accepted* 18 *June* 1982)

Summary—The information provided by modern electroanalytical techniques on co-ordination compounds is surveyed. The problem of the interaction between the electrode and intermediates or products is also briefly considered; it is pointed out that the electroanalytical approach can be successfully employed to provide new insight into chemical properties of metal complexes only when weakly interacting species are involved. The information obtainable is considered under the following headings: (*i*) mechanistic studies on metal complexes and electroanalytical evidence for their reactivity and stability; (*ii*) structural features of co-ordination compounds in solution; (*iii*) feasibility of electrochemical syntheses; and (*iv*) stability of intermediate oxidation states with reference to the nature of the ligands co-ordinated to the metal.

Recent years have seen a growing interest in the application of electroanalytical techniques for investigation of the redox properties of co-ordination compounds.[1–4] Most of the work seems to have been concerned with correlations between the electronic configuration of metal complexes and their oxidation and reduction potentials, proof of existence of a co-ordination compound under given experimental conditions and study of the equilibria in which it is involved. However, electroanalytical methods allow many other interesting pieces of information to be obtained. In the last decade, this type of investigation has received considerable impetus from wider knowledge of the more subtle criteria for interpreting the responses of dynamic electroanalytical techniques and from the greater availability of theoretical tools for quantitative treatment of the experimental data.[5,6]

The responses of the dynamic techniques are more meaningful than those of the static methods (*e.g.*, potentiometry). This is because the electrode may be used as a tool able to produce a variable but precisely known amount of reactive species in a small volume surrounding the electrode surface (by control of the current or the electrode potential) and at the same time monitor the chemical reactions in which such species are involved. Consequently, these dynamic techniques provide not only information on the electrochemical quantities typical of the redox process, but also allow investigation of the chemical reactions coupled with the charge-transfer step; moreover, since the relevant responses can be obtained within a few msec after stimulation of the electrode, they may be used for studying mechanisms involving very fast reactions, allowing detection of short-lived transient intermediates.

*This topic was the subject of a plenary lecture presented by M. F. at the XIV National Meeting of the Italian Chemical Society (Catania, September 1981).

It is because these techniques are able to provide such a wealth of information that they are among the best tools for the *in situ* characterization of co-ordination compounds; unlike other methods they do not require preliminary separation of the species of interest.

The most widely used of these techniques is cyclic voltammetry, which is unmatched in its ability to provide qualitative information with a modest expenditure of time and effort in the acquisition and interpretation of data. When quantitative kinetic data are desired, supplementary techniques such as chronoamperometry, and rotating disk, ring–disk and a.c. voltammetry are often preferred because of their greater accuracy.

The aim of this survey is not to review all the electroanalytical work on metal complexes, but to discuss the considerable insight which can be gained through electroanalytical techniques into the chemical properties of co-ordination compounds. We wish, in particular, to refute the opinion, rather common amongst inorganic chemists, that the conclusions drawn about the nature of co-ordination compounds from electroanalytical investigations are always ambiguous and speculative unless accompanied by various kinds of spectroscopic evidence. We feel that in many cases electroanalytical findings can easily give an adequate description of these species, provided the data are properly interpreted. Only when detailed information cannot be gathered by electroanalytical techniques alone (for instance, in the exhaustive description of an intermediate species), does combination with non-electroanalytical methods become advisable or profitable. It is the existence of this comparatively small area in which conclusive statements cannot be inferred by the electroanalytical approach on its own, that has led to the rapid growth of modern spectro-electrochemical methods.[7]

In any case, electroanalytical investigations, either alone or coupled with other measurements, can provide some types of chemical information which are difficult or tedious to gather otherwise.

The information obtainable will be dealt with under four headings: (*i*) mechanistic studies, (*ii*) structural features of species in solution, (*iii*) electrochemical synthesis, (*iv*) stabilization of intermediate oxidation states.

First, however, it is worthwhile considering the nature of electrode reactions with reference to degree of interaction of reactants, intermediates and products with the electrode surface. When the interactions are very strong, the species are bonded to the surface or even, as in electro-deposition and electrodissolution, are really part of the electrode. Weaker interactions cause chemical or physical adsorption of the species and hence affect the relevant responses both thermodynamically and kinetically. Only when very weak interactions are present, are the reactants, intermediates and products freely diffusing solution species, the properties of which are unaffected by the presence of the electrode.

It is only in this last case that the thermodynamic and kinetic conclusions drawn from electroanalytical data correctly describe the properties of the species under ordinary solution conditions.

Therefore, the strength of the interactions should be checked whenever information gained by the electroanalytical approach is to be used for outlining chemical, physicochemical and configurational properties of co-ordination compounds.

In this connection, it should be remarked that one of the advantages of non-aqueous solvents over water is the very rare occurrence of adsorption processes.

MECHANISTIC STUDIES

The elucidation of the mechanism of catalytic reduction of oxygen in biological and non-biological systems can be taken as a representative example of electroanalytical studies on this subject. It was achieved[8,9] by investigating the electrochemical reduction of molecular oxygen in aprotic solvents in the presence of a series of cobalt chelates which are known as oxygen-carrier model systems. The prototype chelate is *N,N'*-ethylenebis(salicylideneaminato)-cobalt(III) $[Co(salen)]^+$. Voltammetric measurements have allowed it to be ascertained that the overall process occurs through the sequence:

Oxygen reacts with the cobalt(II) complex obtained as the primary reduction product, yielding an oxygen adduct within which charge transfer occurs from the metal to the O_2 ligand. Remarkably less energy is required for the reduction of O_2 to the superoxide ion in this step than in the direct process, thanks to the formation of the cobalt–oxygen bond. Subsequently, interaction of the superoxide ion with the acceptor M^+ (transfer of activated oxygen) allows renewal of the depolarizer Co(III), completing the catalytic cycle.

Electroanalytical techniques were used for determining the extent of oxygen activation by the metal co-ordination and to gain information on the nature of the ligands which favour the process thermodynamically and kinetically.

The electroanalytical approach can also give information concerning metal-promoted organic syntheses, not only with respect to catalytic activity in a reaction mechanism but also with regard to improving the yield.

An example is the promotion of the coupling reaction of organic halides by the triphenylphosphine complex of nickel(0):[10]

$$2RX + Ni^0 \rightarrow R\text{–}R + Ni^{II}X_2 \qquad (5)$$

An appropriate combination of voltammetric, chronoamperometric and coulometric findings has shown the possibility of continuously recycling the nickel(0) complex by cathodic reduction and that the coupling product R–R is formed by the reaction scheme shown in Fig. 1.[11]

It seems worthwhile to describe this scheme in some detail to illustrate the depth of insight into charge-transfer mechanisms which can be gained by use of electroanalytical techniques.

The nickel promoter $[Ni^0L_4]$ (L = triphenylphosphine), obtained by cathodic reduction of the nickel(II) species initially present in the solution, undergoes oxidative addition of organic halides (RX) leading to σ-bonded organometallic nickel(II) derivatives having stabilities which depend on the nature of the co-ordinated organic group.

Aryl groups give thermally stable derivatives and the nickel–carbon bond can be cleaved only by a further reduction, which can occur in two cathodic steps, at different potentials (see route 2). In both steps the coupling product is formed (in the first by a

$$[Co^{III}(salen)]^+ + e^- \rightleftarrows [Co^{II}(salen)] \qquad (1)$$

$$[Co^{II}(salen)] + O_2 \rightleftarrows [Co^{II}(salen)\,O_2] \qquad (2)$$

$$[Co^{II}(salen)\,O_2] \rightarrow [Co^{III}(salen)\,O_2^-] \qquad (3)$$

$$[Co^{III}(salen)\,O_2^-] + M^+ \rightarrow \underline{[Co^{III}(salen)]^+} + MO_2 \qquad (4)$$

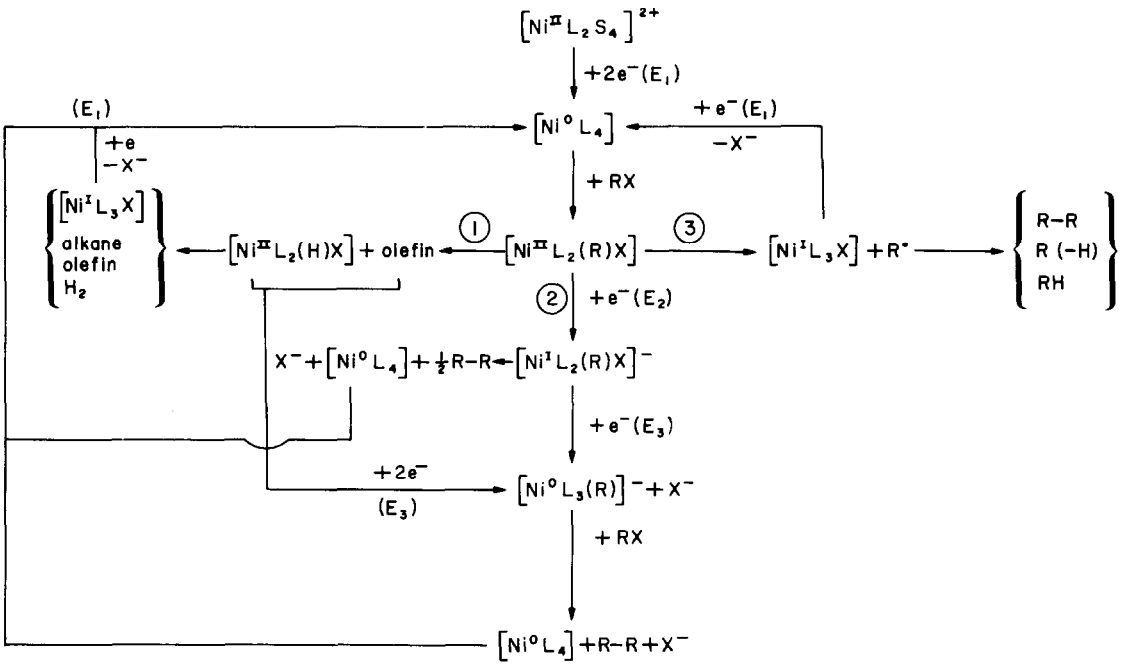

Fig. 1. Reaction scheme for the coupling of organic halides electrocatalysed by the Ni–PPh_3 system. (L = PPh_3; S = CH_3CN; X = Cl, Br or I; R = alkyl, aryl or aralkyl group). $E_1 > E_2 > E_3$.

radical dimerization, in the second by formation of an organic anion) together with the nickel(0) species which immediately reacts with the organic substrate, completing the electrocatalytic cycle.

In contrast the alkyl derivatives undergo thermal decomposition at room temperature. This decomposition involves reductive elimination of the organic moiety by two pathways, depending on whether a hydrogen atom is present or not in the β-position of the organic group. In the case of alkyl halides not bearing hydrogen atoms in the β-position, a simple homolytic fission takes place, yielding the coupling product by dimerization of the organic radicals formed and nickel(I) (see route 3). The nickel(I) is then reduced to the nickel(0) promoter at the same potential as that used for reduction of the nickel(II) initially present, again allowing cyclic regeneration of the inorganic promoter.

If, however, the organic group has a hydrogen atom in the β-position, the thermal decomposition of the organonickel intermediate occurs by a β-elimination reaction (see route 1) to give the corresponding olefin and an unstable nickel hydride which decomposes, yielding nickel(I) reducible at the working potential, again renewing the nickel(0) promoter and completing the electrocatalytic cycle.

In this last case it is also possible to obtain the coupling product by cathodic reduction at more negative potentials at which the nickel hydride intermediate can also be reduced. In this way, nickel(0) is regenerated by an electrocatalytic pathway partially overlapping with route 2. In this case it is therefore possible to pilot the process towards the generation of the desired products simply by choosing the appropriate working potential.

In connection with this subject, the basic contribution recently made by Saveant[12] to the understanding of the reaction pathways involved in an electrocatalytic process, must be acknowledged.

The next example illustrates the information which can be gained on the existence of previously unknown complexes and on the procedures for their preparation.

The cathodic reduction of nickel(II) in acetonitrile in the presence of triphenylphosphine may be considered as a reference point for this discussion. An appropriate combination of voltammetric and spectrophotometric work has established that this reduction occurs through the following reaction sequence:[13]

$$[Ni^{II}L_2S_4]^{2+} + 2e^- \xrightarrow[-4S]{+2L} [Ni^0L_4] \quad E_1 \qquad (6)$$

$$[Ni^0L_4] + [Ni^{II}L_2S_4]^{2+} \xrightarrow[-4S]{+2L} 2[Ni^{I}L_4]^{+} \qquad (7)$$

$$[Ni^{I}L_4]^{+} + e^- \rightleftharpoons [Ni^0L_4] \quad E_2 > E_1 \qquad (8)$$

L = triphenylphosphine; S = CH_3CN = solvent

Nickel(II) undergoes a direct two-electron reduction which is affected by a quite high overvoltage because of the significant molecular rearrangements accompanying such a charge-transfer step. The nickel(0) complex obtained then reacts with the depolarizer, giving nickel(I) which is reducible in turn to nickel(0) in a reversible electrode reaction at the working potential.

Consequently, the nickel(II) is not really reduced to nickel(0) in a simple two-electron electrode reaction which requires a very high activation energy, but by an autocatalytic process. In the overall electrochemical reaction the activation energy is considerably lowered thanks to the catalytic activity displayed by the nickel(0) produced in the electrode process. In other words, during the reduction, the slow Ni(II) → Ni(I) transfer at the electrode is substituted for the fast occurrence of the same redox reaction in the homogeneous solution phase.

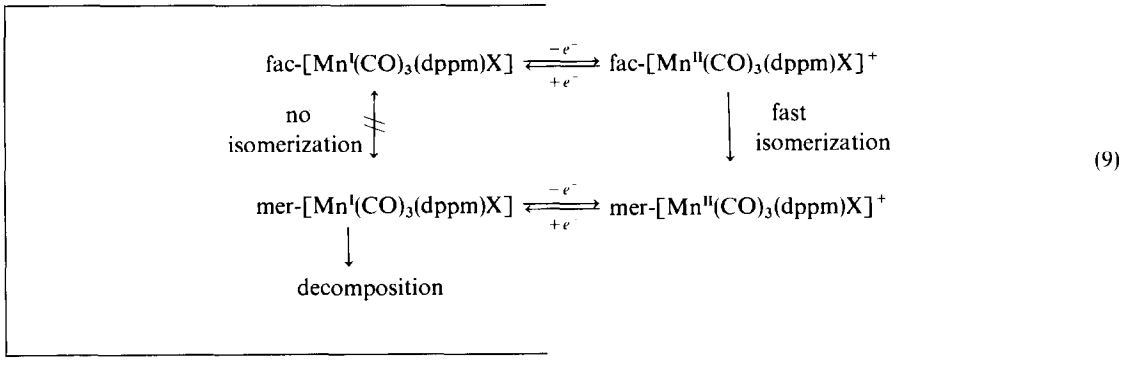
Among the findings provided by this mechanistic study, we may emphasize the discovery of the previously unknown nickel(I) complex $[NiL_4]^+$ and the useful suggestions that can be provided for its preparation. It has been found possible, in fact, to prepare this complex by reacting equimolar amounts of the corresponding nickel(0) and nickel(II) species (see step 7).

Although this statement is about 30 years old, electroanalytical methods have seldom been employed for deducing the structure of co-ordination compounds; nevertheless, the degree of reversibility is a good basis for predicting the configurational features of metal complexes in solution. In this connection, it should be emphasized that the usual methods of structure determination, which require preliminary separation of the co-ordination compound investigated, are only seemingly more direct procedures, since in many cases the geometric and/or ligand configuration may not be the same in solution and in the solid state. In recent years, however, there has been more interest in use of electroanalytical techniques for tackling this problem.

For example, consider the structural study of the octahedral manganese complexes with the metal (in both the +1 and +2 oxidation states) of the type $Mn(CO)_3(dppm)X$, where dppm = diphenylphosphinemethane and X = Cl, Br,[15] for which the two isomers shown in Fig. 2 can be envisioned.

Previous work in this field allowed characterization of only the facial isomer for Mn(I), and no information was available on the isomers formed with Mn(II).

By cyclic voltammetry of solutions of the previously characterized fac-$[Mn^I(CO)_3(dppm)X]$ complex, the charge-transfer reactions and chemical events in the following scheme could be identified.



(9)

SOLUTION STATE OF METAL COMPLEXES

Electroanalytical techniques can also be used for inferring structural properties of co-ordination compounds and to obtain valuable information concerning these species in solution, because the overvoltage of an electrochemical process reflects all changes accompanying the electron-transfer reaction, including changes in structure and in stoichiometric composition during the electrode reaction.

This connection between the degree of reversibility characterizing an electrode process and the configurational features of the redox partners involved is analogous to Libby's symmetry principle[14] which states that a reversible electrode reaction is observed when the co-ordination spheres of the oxidized and reduced forms are identical.

To account for the simplicity of the conceptual approach used to gain this information, let us consider the relevant cyclic voltammetric behaviour reported in Fig. 3.

At low temperature (−35°), a one-electron anodic peak was observed, with which only one cathodic peak was associated (full line). This redox system was found to be quite reversible, indicating that under the experimental conditions the oxidation product was the isostructural fac-Mn(II) complex, sufficiently stable not to decompose during the time-span of the voltammetric experiment at this temperature.

When the temperature was raised to 22° the cathodic peak was decreased but at the same time a new cathodic–anodic system located at less positive potentials appeared and increased with temperature (dashed line in Fig. 3). This behaviour showed that the stability of the fac-Mn(II) complex is lost at room temperature; under these conditions the charge-

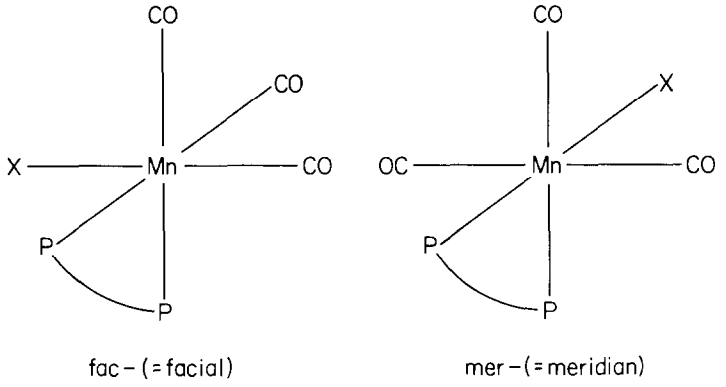


Fig. 2. Isomeric forms for the octahedral manganese complexes with the ligand set $(CO)_3$ (dppm)X.

transfer step is apparently followed by a chemical reaction (E.C. process) which has to be a fac/mer isomerization since it appears to involve no ligand-loss. The new redox system which became evident at room temperature also exhibited reversible character, suggesting the same structural features for the redox partners [mer-Mn(II) + $e^- \leftrightarrows$ mer-Mn(I)]. Finally, by controlled-potential electrolyses it was possible to confirm all these findings, as well as to check the thermal instability of the mer-Mn(I) species.

The correctness of all these conclusions was then confirmed by infrared and e.p.r. spectroscopy. A comparison between the two approaches shows that the electroanalytical method provides the desired information in a simpler and more straightforward way.

Another example is a voltammetric and chronoamperometric study of nickel halide phosphine complexes of the type $[Ni^{II}(PPh_3)_2X_2]$ (PPh_3 = triphenylphosphine; X = Cl, Br).[16]

The conclusions drawn were based not only on the degree of reversibility of the processes involved, but also on the kinetic character of the relevant responses. It was found that such nickel(II) complexes undergo the following ligand-disproportionation equilibria in polar solvents:

$$2[Ni^{II}(PPh_3)_2X_2] \rightleftarrows [Ni^{II}(PPh_3)_3X]^+ + [Ni^{II}(PPh_3)X_3]^- \quad (10)$$

$$3[Ni^{II}(PPh_3)X_3]^- \rightleftarrows [Ni^{II}(PPh_3)_3X]^+ + 2[Ni^{II}X_4]^{2-} \quad (11)$$

the first being almost completely shifted towards the right-hand side, and the second occurring quite

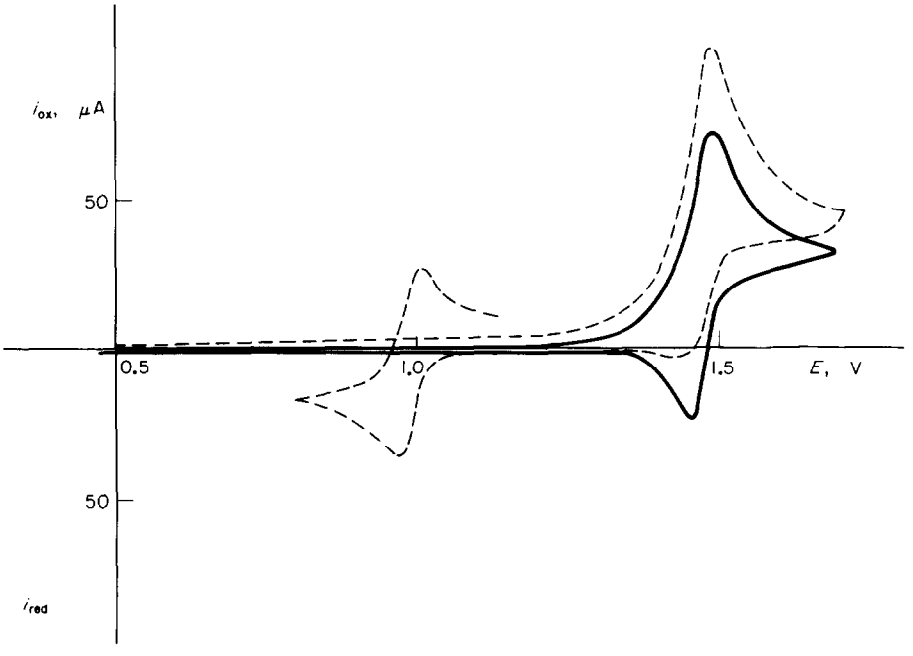

Fig. 3. Cyclic voltammetric curves recorded with a platinum microelectrode for a CH_3CN solution containing fac-$[Mn^I(CO)_3(dppm)X]$ ($2 \times 10^{-3}M$) and $[NBu_4^+][ClO_4^-]$ (0.1M); (——) at −35°C; (– – – –) at 22°C. Scan-rate: 0.5 V/sec.

slowly. Moreover, two different nickel(I) reduction products were found, in equilibrium with each other according to the equation

$$[Ni^{I}(PPh_3)_4]^+ + X^- \rightleftarrows [Ni^{I}(PPh_3)_3X] + PPh_3 \quad (12)$$

This ligand-exchange reaction was also quite slow.

Another electroanalytical investigation on nickel complexes with a series of phosphine ligands[17] by a combination of voltammetric and spectrophotometric measurements made it possible to state that four phosphine molecules could enter the co-ordination sphere of nickel(II) only if they were small; at the most two molecules of the bulkier phosphines could be co-ordinated to the nickel(II). Voltammetric work has also shown the existence of stable nickel(I) complexes with all the phosphine ligands used. The geometric configuration of these previously unreported nickel(I) complexes was inferred from the degree of reversibility of their electrode processes.

ELECTROCHEMICAL PREPARATIVE PROCEDURES

Another useful application involves the use of electroanalytical techniques to optimize the conditions for electrochemical synthesis. Such optimization requires a profound knowledge of the reaction mechanism involved, so a new electrochemical synthesis should be always preceded by a careful electroanalytical investigation.

Most electrochemical syntheses established in this way are competitive with those done by the usual chemical methods, but sometimes they are the only known preparative procedures.

It should be pointed out here that the electrochemical methods have the advantage of giving purer products than chemical methods can, because of the absence of by-products due to the use of chemical reactants. Moreover, higher selectivity can be achieved by control of parameters such as the working potential.

For example, consider the synthesis of rhodium and iridium organometallic derivatives of the type $[M^{I}(R)(CO)(PPh_3)_2]$ (M = Rh, Ir; R = alkyl, aryl; PPh_3 = triphenylphosphine).[18]

Their chemical preparation is very difficult since rather unstable (and hence hard to handle) organolithium and organomagnesium species are used as reducing agents, and a tedious purification procedure is required to separate the oxidation products of such reagents from the desired compounds.[19,20] These derivatives can be easily prepared, however, by the electrochemical route:

$$\begin{array}{l} [M^{I}(CO)(PPh_3)_2Cl] + RX \longrightarrow [M^{III}(R)(CO)(PPh_3)_2ClX] \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \Big\downarrow +2e^- \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad [M^{I}(R)(CO)(PPh_3)_2] + Cl^- + X^- \end{array} \quad (13)$$

The products are synthesized by cathodic reduction of M(III) species, which are obtained *in situ* by simple oxidative addition of the appropriate organic halide (RX) to the corresponding M(I)–chloride complex.

Alternatively, if the organic halide has poor reactivity in the oxidative addition step, the steps in scheme (13) can be transposed. That is, the oxidation state of the metal in the starting material is first lowered to −1, so that it becomes more prone to undergo oxidative addition of RX, according to the scheme:

$$\begin{array}{l} [M^{I}(CO)(PPh_3)_2Cl] + PPh_3 + 2e^- \longrightarrow [M^{-I}(CO)(PPh_3)_3]^- + Cl^- \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \Big\downarrow +RX \\ \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad [M^{I}(R)(CO)(PPh_3)_2] + X^- + PPh_3 \end{array} \quad (14)$$

When these preparative methods are used, there is no problem in recovering the products, since they are not soluble in the solvent employed (acetonitrile). Of course, a detailed electroanalytical investigation able to give complete insight into the processes involved was necessary for designing the procedures.

The synthesis of the tetrakis(triethylphosphite)cobalt(0) complex is an example of an electrochemical procedure representing the sole available preparative method.

This compound has been obtained[21] through the following sequence of anodic and cathodic processes, in the first of which a cobalt(I)–phosphite complex is generated by oxidation of metallic cobalt in the presence of the phosphite ligand:

$$\begin{array}{l} Co_{(s)} + 5P(OEt)_3 - e^- \longrightarrow (Co^{I}[P(OEt)_3]_5)^+ \\ (Co^{I}[P(OEt)_3]_5)^+ + 2e^- \longrightarrow (Co^{-I}[P(OEt)_3]_4)^- + P(OEt)_3 \\ (Co^{-I}[P(OEt)_3]_4)^- - e^- \longrightarrow (Co^{0}[P(OEt)_3]_4) \end{array} \quad (15)$$

A facile recovery of the product is again possible owing to its low solubility in the acetonitrile medium.

All the electroanalytical studies in this field indicate that electrochemical preparations can be performed by following the two basic reaction pathways summarized in the scheme:

$$M_{(s)} - ne^- \longrightarrow M^{n+} \begin{cases} \xrightarrow[-ne^-]{+mL} M^0L_m & (a) \\ \xrightarrow[+mL]{} M^nL_m^{n+} & (b) \end{cases} \quad (16)$$

The route is chosen according to the oxidation state desired for the metal in the co-ordination compound synthesized.

In both cases the metal is anodically dissolved, thus yielding the corresponding cation. In route (*a*), the cation is returned to the metallic state by cathodic reduction in the presence of the appropriate ligand. In this way the "bare" metal atoms generated at the electrode surface are trapped by the ligand before the metallic lattice has time to grow.

In route (*b*), on the contrary, the electrogenerated cation reacts directly with the ligand. Of course, if the oxidation state for the metal in the desired co-ordination compound is different from that exhibited by the electrogenerated cation, the complex first obtained can be further electrochemically oxidized or reduced.

Route (*b*) is used, for instance, in the above-mentioned synthesis of tetrakis(triethylphosphite)cobalt(0), and route (*a*) in the synthesis of the catalytically active cyclo-octatetraene nickel(0) complex.[22]

STABILITY OF "INTERMEDIATE" OXIDATION STATES

This topic is of considerable importance in co-ordination chemistry. It is known that metals in high oxidation states give stable complexes with strongly basic ligands (*i.e.*, σ-donors), and that the lowest oxidation states are stabilized by ligands able to promote back-donation of charge (π-acceptor ligands), but a considerable uncertainty exists about the behaviour of the so-called "intermediate" oxidation states.

An unstable intermediate oxidation state will undergo disproportionation reactions. On the other hand, a stable intermediate oxidation state can be formed by interaction of higher and lower oxidation states. Therefore, electroanalytical techniques appear to be valuable tools for gaining information on this aspect of co-ordination chemistry, thanks to their ability to detect such chemical reactions when they are coupled with charge-transfer steps, and to predict these reactions on the basis of the redox potentials.

In spite of this ability, however, most of the electroanalytical investigations on intermediate oxidation states appear to be concerned with determining the electronic configurations[23] (that is, the molecular orbital occupied by the electron added or removed in the charge-transfer reaction, and the relevant spin state). Very few studies dealing with the stability of an intermediate oxidation state towards disproportionation have been reported. Amongst them, however, we may mention an extensive study concerning the stability of nickel(I) complexes in the presence of substituted phosphorus ligands.[17]

The relevant findings point out that the +1 oxidation state for nickel is stabilized relative to the +2 and 0 states only when ligands with properly balanced σ-donor/π-acceptor properties are present in the co-ordination sphere of the metal. Thus, nickel(I) is fully destabilized when phosphite ligands (π-acceptor ability much higher than σ-donor) are present, whereas the existence of stable nickel(I) complexes is made possible by the presence of phosphines, which have more suitable electronic features. Moreover, on the basis of the thermodynamic data obtained, it was possible to estimate the relevant disproportionation constants as well as to account for the failure of reported attempts to prepare phosphite–nickel(I) complexes.[24]

The already mentioned electroanalytical investigations leading to the synthesis of the tetrakis(triethylphosphite)cobalt(0) complex,[21] constitute another example.

CONCLUSIONS

The investigations cited above represent only a fraction of the reported electroanalytical studies concerned with co-ordination compounds, but this survey was not intended as a complete review of the field, but only to indicate what chemical information can be obtained by such an approach.

We think that the survey has shown that many electrode reactions fall into the class of weakly interacting systems in which the electrochemically generated intermediates and/or products diffuse into solution, where they display their inherent chemical properties. Consequently, electroanalytical techniques are able to provide thermodynamic and kinetic information concerning the species participating in the reaction and in this way give new insight into chemical properties.

Finally, it should be emphasized that the growing interest in the application of these methods to chemical and physicochemical characterization of co-ordination compounds, clearly apparent in the literature, is promoting progressive extension of the range of information which they are able to provide. It is this increase in information which is making the electroanalytical approach more competitive with the usual investigation methods such as the various types of spectroscopy.

HOMOGENEOUS ENZYMATIC FLUORESCENCE IMMUNOASSAY OF SERUM IgG BY CONTINUOUS FLOW-INJECTION ANALYSIS

TIM A. KELLY* and GARY D. CHRISTIAN†
Department of Chemistry, University of Washington, Seattle, WA 98195, U.S.A.

(*Received* 5 *April* 1982. *Accepted* 15 *June* 1982)

Summary—A new technique for automated homogeneous immunoassay has been developed and applied to the determination of serum IgG. An enzyme label, horseradish peroxidase (HRP), conjugated to the antibody (anti-human IgG) was inhibited on immunochemical association. The inhibition of activity was monitored as a decrease in the laser-induced fluorescence of dichlorofluorescein, produced by the HRP-catalysed oxidation of leuco-diacetyldichlorofluorescein by hydrogen peroxide. The entire procedure was performed by flow-injection analysis at a rate of 60 samples per hour. Serum IgG concentrations from 1.4 to 25 mg/ml could be determined after a 1:700 dilution, with a within-run precision of ±9.8%.

Automation in analytical chemistry has greatly benefited from the introduction and development of flow-injection analysis (FIA),[1–5] and recent reviews[6–9] of the theory, methodology and applications of this technique have emphasised its ease of use and versatility. In addition, competitive protein-binding techniques have added a new dimension to clinical chemical analysis. The use of immunochemical reactions has resulted in significant improvements in sensitivity, speed and specificity of measurements.

Immunoassays generally involve the measurement of a label molecule chemically bound to the antigen or antibody of interest. By monitoring of the tag and its changes in location and/or properties, the extent of reaction may be quantified. Homogeneous immunoassays are emerging as preferred methods.[10] Here, binding of the label alters the properties used for monitoring, in such a way that physical separation of the bound and free fractions of the labelled reactant (which is required in heterogeneous methods) is unnecessary. As a result, homogeneous methods are generally simpler and faster than the corresponding heterogeneous immunoassays.

Many analytical techniques (*e.g.*, radiochemistry, fluorescence spectrometry, nephelometry, enzyme analysis and electrochemistry) may be used to monitor immunochemical reactions.[11] Radioactive techniques are most common and provide the most sensitive immunoassay procedures. Radioimmunoassays, however, are heterogeneous, time-consuming, expensive, and potentially hazardous. Fluorescence and enzymatic methods offer a wide variety of rapid, inexpensive, and sensitive techniques that can be either heterogeneous or homogeneous.[10,12]

In spite of recent improvements in homogeneous immunoassay techniques, many methods are still time-consuming and may require relatively large quantities of expensive reagents. The successful application of continuous-flow FIA to immunoassays would allow rapid measurements of microsamples with minimal consumption of reagents. Lim *et al.*[13] recently described the FIA determination of albumin by use of energy-transfer immunoassay[14] for fluorescence detection. It was necessary to employ a stopped-flow step in the measurements.

In this paper we introduce a new homogeneous immunoassay system that utilizes horseradish peroxidase (HRP) as the antibody label, and the first application of continuous-flow FIA for measurement of an immunochemical system. The enzyme catalyses a recently developed indicator reaction[15] in which oxidation of leuco-diacetyldichlorofluorescein (LDADCF) by hydrogen peroxide in the presence of HRP produces the highly fluorescent dichlorofluorescein (DCF). The binding of the labelled antibody to the antigen, IgG in this case, partially inhibits the enzyme activity, resulting in a decrease in the fluorescence intensity produced by the indicator reaction. A dual-channel, dual-reagent FIA system automatically performs the appropriate sequence of reactions before the detection by a laser filter fluorimeter with a sheath flow-cell.[15] Measurements are made at a rate of 60 samples per hour.

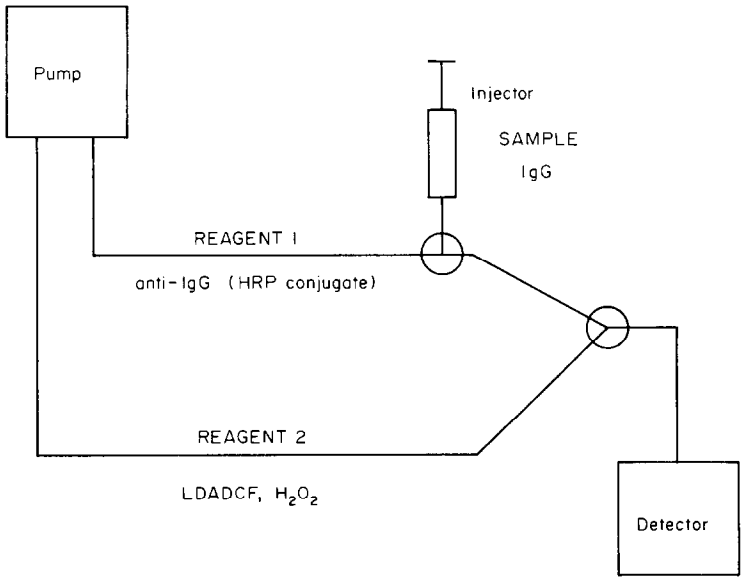

Fig. 1. Dual-reagent flow-injection analysis system.

EXPERIMENTAL

To study the binding equilibria of the antigen–antibody reaction and the activity of the conjugated enzyme, a static spectrofluorimeter (Perkin–Elmer 650–10S) was used, as described in previous studies.[15] Phosphate-buffered saline (PBS) solution (0.02*M* phosphate, 0.15*M* sodium chloride, 1% PEG-6000 and pH 7.4, boiled to prevent bacterial degradation of the proteins) was used to make all the solutions and dilutions. Successive additions of reagents or sample were made as follows, with the resultant change in fluorescence intensity monitored for each step. Step (*a*) was the addition of 2.8 ml of human IgG solution (25 μg/ml, Sigma Chem. Co. I-4506) to the cell. Next, in (*b*), various volumes of either HRP (35 IU/ml) or anti-human IgG conjugated with HRP (Miles-Yeda, Ltd. 61–130; 1:20 dilution) were added. After various periods of time (from 30 sec to 6 min), 50 μl of activated LDADCF ($10^{-5}M$) were added in step (*c*). Finally, in step (*d*), 50 μl of hydrogen peroxide ($10^{-5}M$) were added to obtain the final indicating response. Except for step (*c*), the interval between addition and subsequent fluorescence monitoring was 30 sec.

For the flow system in this study (Fig. 1), Teflon tubing (0.8 mm bore, 1.0 m long) with a 25-μl loop injector was used.[15] A dual-reagent system was incorporated. One line carried the antibody through the injector, where the antigen (standard or sample) was injected for binding to occur, before mixing in the second reagent line with the dye and hydrogen peroxide for the fluorescence indicator reaction (at a point half-way to the detector). The first reagent was a 1:250 dilution of anti-human IgG(goat) conjugated with HRP. The second reagent was $10^{-5}M$ LDADCF, activated with dilute base,[15] and hydrogen peroxide ($10^{-4}M$).

Aqueous standards were prepared with purified crystalline human IgG at appropriate concentrations. For accuracy, recovery, and comparison studies, serum samples (already analysed by radial immunodiffusion, from Calbiochem, Tri-Partigen) were diluted 700-fold with the PBS reagent before injection. By adjustment of the stream pressures to 0.36 and 0.32 atm for the streams of reagent 1 and reagent 2, respectively (reagent 2 and the sheath-stream for the detector[15] were driven by the same pressure), flow-rates of 0.50 ml/min for both reagent streams and 1.60 ml/min for the detector sheath-stream were obtained.

The fluorimeter instrumentation was used as previously described.[15] Fluorescence was excited by an argon-ion laser at 488 nm, and the emission intensity was monitored at 525 nm. The emitted light was passed through a 520-nm cut-off antifluorescent filter to remove scattered radiation.

RESULTS AND DISCUSSION

Reaction conditions

The following reaction sequence was employed:

$$\mathrm{Ag} + \mathrm{Ab\text{–}HRP} \rightleftharpoons \mathrm{Ag \cdot Ab\text{–}HRP} \quad (1)$$

$$\mathrm{LDADCF} + \mathrm{H_2O_2} \overset{\text{Ab HRP}}{\rightleftharpoons} \mathrm{DCF} + 2\mathrm{H_2O} \quad (2)$$

where Ag represents the antigen and Ab–HRP the antibody–HRP conjugate. The two reactions were evaluated initially with a static spectrofluorimeter before use in the FIA system. The particular conditions used were those generally established as optimal for immunochemical reactions,[16] and worked well for the indicator system employed. The antigen and antibody dilutions were made according to the general recommendations of the manufacturers. Enzyme activities of the free HRP solutions were adjusted to reproduce the activities quoted for the conjugated enzyme.

Response behaviour: precipitin curve

Several specific features were observed in the response behaviour. In the absence of IgG, the activities of the free and conjugated enzymes were equal. When IgG was present, binding to the antibody was found to inhibit the activity of the conjugated enzyme. The extent of inhibition varied with the concentration ratio of antigen to antibody. The inhibition served as

a means of obtaining a "precipitin curve" (Fig. 2) indicative of the binding equilibrium and stoichiometry of this immunochemical reaction. The binding observed here was association and aggregation between free antigen and antibody molecules, with no significant precipitation, because it took place in less than the 30 sec necessary to measure the reaction. The inhibition of fluorescence under these conditions makes possible the successful use of continuous-flow FIA. Longer times (up to 6 min) were found to cause little enhancement of the signals (less than 10%). The precipitin curve was obtained by subtracting the signals of HRP-conjugated antibody bound to antigen from the signal for free HRP alone. The maximum of the precipitin curve occurred at an HRP concentration of 0.56 IU/ml, corresponding to a 1250-fold dilution of the antibody, and an IgG concentration of 25 μg/ml or a 700-fold dilution of serum containing high IgG levels. These concentrations were used as a guide to the conditions for use with the flow system. They do not necessarily represent the optimal conditions for FIA, because there is greater dilution of the reagent by the sample.[15]

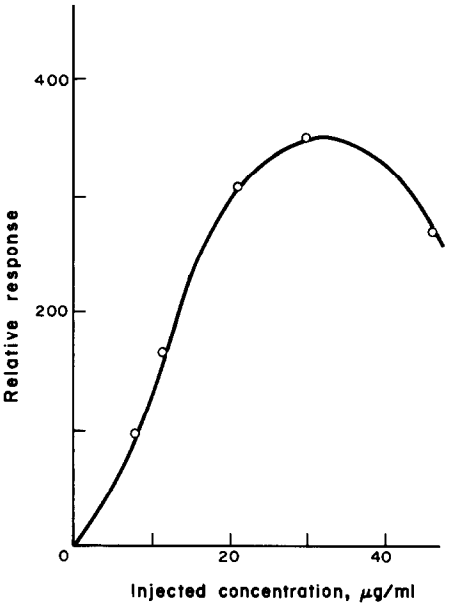

Fig. 3. Relationship of fluorescence response to concentration of IgG serum samples.

Analytical range

Since the conditions chosen for FIA correspond to the maximal inhibition of HRP activity for high IgG levels, the entire normal range of serum IgG levels (8–14 mg/ml, or 11–20 μg/ml after dilution) should fall within the region of the precipitin curve in which the antibody is in excess, and allow for straightforward quantification. Pathologically elevated IgG levels would correspond to the region of the precipitin curve where the antigen is in excess and would give rise to signals that could be misinterpreted as corresponding to an antigen level much lower than the true value, and to resolve this possible ambiguity the sample would have to be further diluted and re-analysed. A maximum response was observed at 31 μg/ml IgG (Fig. 3). Calibration was possible over the range 2–30 μg/ml. The concentrations listed correspond to those of the 1:700 diluted IgG serum samples which were injected into the flowing stream. The minimum detectable IgG concentration was 2 μg/ml ($1.25 \times 10^{-8} M$ IgG, or 50 ng in the 25-μl sample injected, corresponding to 1.4 mg/ml in the undiluted serum.

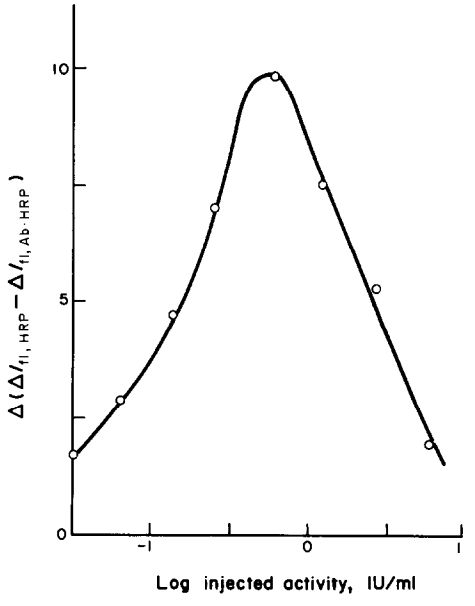

Fig. 2. Fluorescence intensity change with HRP activity. The response is the difference between the signals obtained with free HRP and with HRP conjugated to bound antibody, corresponding to a precipitin curve.

Accuracy and precision

To determine the accuracy of the assay system, recovery and comparison studies were performed. Twelve serum samples analysed by radial immunodiffusion (Tri-Partigen from Calbiochem) were analysed in triplicate, with use of a calibration curve made with aqueous standard. The average serum IgG response was 96.7% of the corresponding standard response. An average recovery of 103% from serum spiked with IgG was observed.

The flow system exhibited a within-run precision of ±9.8% for the determinations run at a rate of 60 samples per hour. The precision was adversely affected by a back-pressure developed during the sample injection. This was perhaps compounded by the viscosity of Reagent 1 being higher than that of Reagent 2, because of the presence of the PEG-6000. The PEG-6000 was necessary to minimize blank readings in the indicator reaction,[11] and this surfactant is also used to accelerate antigen–antibody complexation.[17]

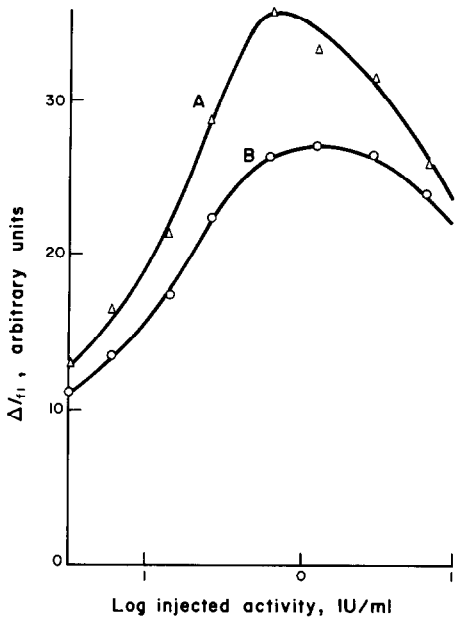

Fig. 4.

Either a by-pass stream for injection or a modified pumping system should result in significantly improved precision. Also, introduction of PEG into both streams might serve to equalize the viscosities and result in somewhat improved precision.

Time of reaction

At the pressures used, it took the sample plug 45 sec to reach the detector. Half that time was spent in the 0.5 m length of tubing before the second reagent stream was introduced. The last 0.5 m of tubing after the T-connector and before the detector gave time for the indicator reaction to take place.

Reagent consumption

Because of the rapid sequential injection of samples, reagent consumption per sample was small, about 500 μl of each reagent, amounting to a total cost of less than 8 cents per analysis. By use of the merging-zone technique,[13,18,19] this could be further reduced.

The system described here gives considerable improvement in analysis time and sensitivity, because of the choice of reaction sequence . This is apparently the first example of a non-competitive system for antigen assay, in which enzyme conjugated to the antibody is inhibited upon immunochemical reaction, opening a new area for homogeneous immunoassays.

(*Received* 21 *September* 1981)

Summary—The use of flame atomic-absorption and atomic-emission spectrometry for the determination of indium in aluminium alloys is described. Two types of flame are used: air–acetylene and nitrous oxide–acetylene. The effect of other ions, especially aluminium, has been studied, and the use of lanthanum as a releasing agent is proposed for both techniques, the amount used depending on the amount of aluminium present.

Since 1926, when Paez introduced sodium metal to obtain a finer grain in alloy castings, and the consequent creation of ALPAX, various elements have been added to aluminium to try to improve its properties for specific industrial purposes.[1] Indium is a very interesting element for the metallurgical industry, owing to its high plasticity, low melting point, relative stability and low toxicity. Its recent use in aluminium alloys, to take advantage of its lubricating action, its capacity to withstand the acids produced by the oxidation of lubricating oils, and its effect of lowering the melting point in welding and increasing the corrosion resistance of alloys, unfolds a promising future for this element in such alloys. Hence it is important to establish methods for determination of indium in these alloys, usually at the trace level. In such investigations the effect of the matrix elements, in particular aluminium, must be examined. The recentness of this exploitation of indium explains the paucity of references to its determination in aluminium alloys, and high-purity aluminium.[2]

As part of a line of research on the analysis of aluminium alloys,[3] this paper describes two methods for the determination of indium, by absorption and mination in aluminium alloys, and high-purity aluminium.[2]

*Taken in part from the Ph.D. work of A. J. Aller.

EXPERIMENTAL

Apparatus

A double-beam Pye-Unicam SP-1900 atomic-absorption spectrometer was used for both methods, with an indium hollow-cathode lamp. Table 1 lists the operating conditions.

Reagents

Standard indium solution. Dissolve 1 g of indium in 6*M* hydrochloric acid and dilute to 1 litre with distilled water.

Table 1. Operating conditions for the determination of indium by flame atomic-absorption and atomic-emission spectrometry

	Atomic absorption		Atomic emission

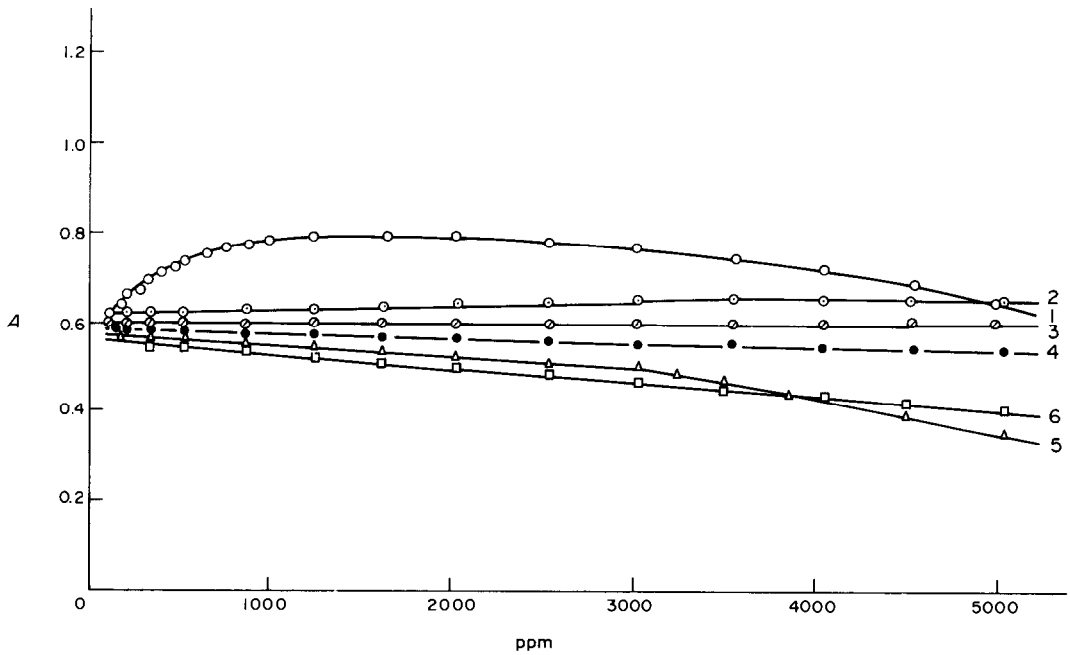

Fig. 1. Effect of various elements on the AAS signal from 5 ppm of indium, in an air–acetylene flame. 1, O——O Ca^{2+}; 2, ⊙——⊙ Bi^{3+}; 3, ⊘——⊘ Na^{+}, Sr^{2+} and La^{3+}; 4, ●——● Al^{3+}; 5, △——△ Co^{2+}, Mg^{2+}, Ni^{2+}, Fe^{3+}, Mn^{2+}, As^{3+} and Sb^{3+}; 6, □——□ V (V), W (VI), PO_4^{3-}, Cr^{3+}, Ti^{4+} and Mo (VI).

Aluminium solution. Dissolve 10 g of aluminium in 6*M* hydrochloric acid and dilute to 1 litre with distilled water.

For study of interferences, commercial 5000-ppm standard solutions for atomic-absorption spectrometry (AAS) were used.

Procedure

Dissolve the sample [large enough to give a final indium concentration of 3–5 ppm, but not less than 0.5 g (to avoid problems of inhomogeneity)] in 15 ml of 6*M* hydrochloric acid, heating slightly if necessary. Add the necessary amount of interference corrector according to the method to be used and the aluminium content expected. Dilute to 100 ml with distilled water and determine the indium content, using the conditions given in Table 1.

RESULTS AND DISCUSSION

Effect of foreign ions

Atomic-absorption spectroscopy. Solutions of composition similar to that of the sample to be studied were prepared, all with an aluminium content of 5000 ppm, and the concentrations of other ions varied from 1 to 5000 ppm, first individually and then jointly (provided that they were chemically compatible), and the difference between the indium concentration taken (1–10 ppm) and that found by AAS was investigated. Figure 1 shows the results for 5 ppm of indium.

The following effects were observed for the air–acetylene flame. Calcium gave non-linear enhancement by up to 20%, possibly by initial suppression of ionization, offset at higher concentration levels by formation of thermally stable compounds. Bismuth had a weak enhancing effect (5% at 5000 ppm) perhaps of excitation type in cases of maximum content. Sodium, strontium and lanthanum had no effect, but aluminium had a weak depressive effect (6% at 5000 ppm), probably due to formation of thermally stable compounds in the flame. There was a medium depressive effect by Co^{2+}, Mg^{2+}, Ni^{2+}, Fe^{3+}, Mn^{2+}, As^{3+} and Sb^{3+} (16% at 5000 ppm), again presumably by stable-compound formation. A strong depressive effect was given by V(V), W(VI), PO_4^{3-}, Cr^{3+}, Ti^{4+} and Mo(VI) (30% at 5000 ppm) through formation of refractory compounds.

However, these interferences were only serious for higher concentrations of the interferents, and at the usual concentration range of these elements in aluminium alloys, the effect is generally negligible (< 3%), except for that of calcium.

When several of these elements are added jointly the effect is similar, but much more difficult to predict.

In the nitrous oxide–acetylene flame the effect of all these ions is generally less marked, which seems to confirm that most of the interferences are due to formation of thermally stable indium compounds; aluminium gives about 2% depression of the signal. There is practically no influence by up to 5000 ppm of Sn^{2+}, Fe^{3+}, Cd^{2+}, Zn^{2+}, Hg^{2+}, Te(VI), Ce^{3+}, Ba^{2+}, Na^{+}, Co^{2+}, Cu^{2+}, Mg^{2+}, Bi^{3+}, Cr^{3+}, As^{3+}, Tl^{+}, Li^{+}, Mo(VI), V(V), La^{3+}, PO_4^{3-}, Ti^{4+}, Sb^{3+}, Zr^{4+}, Ca^{2+}, Pb^{2+}, Ni^{2+}, Sr^{2+}, Mn^{2+} and W(VI).

In both types of flame weaker effects are observed for low indium concentrations, and this should be taken into account for sampling.

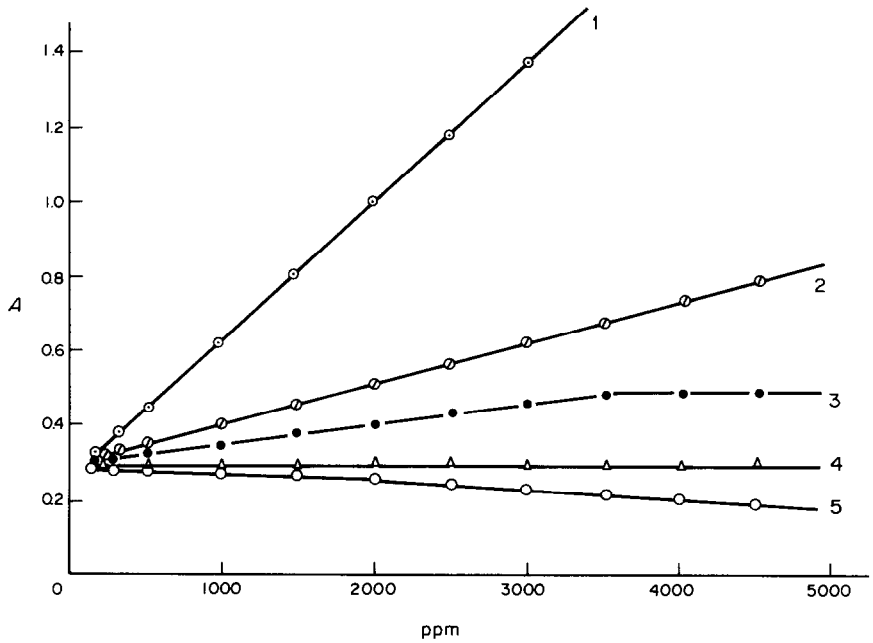

Fig. 2. Effect of various elements on the flame emission signal from 5 ppm of indium in an air–acetylene flame. 1, ⊙——⊙ W(VI), V(V), Mo(VI), La^{3+} and Ti^{4+}; 2, ∅——∅ Ce^{3+}, Sr^{2+}, Zr^{4+}, Al^{3+} and PO_4^{3-}; 3, ●——● Ca^{2+} and Na^{+}; 4, △——△ Li^{+}, Bi^{3+}, Cd^{2+}, Te^{4+}, Tl^{+}, Ni^{2+}, Fe^{3+}, Zn^{2+}, Pb^{2+} Co^{2+}, Mn^{2+}, Cr^{3+}, Cu^{2+}, As^{3+}, Sb^{3+}, Mg^{2+} and Sn^{2+} 5, O——O Hg^{2+}.

The following methods of correcting interferences were studied: the use of matrix-matched standards; the method of standard additions; the use of releasing agents. The last was found to be the easiest to use. La^{3+}, Sr^{2+} and Ca^{2+} have been used as releasing agents, and the optimum addition ratios (with respect to the aluminium present) were: Al/La = 12/1; Al/Sr = 10/1; Al/Ca = 10/1. The use of lanthanum is recommended.

Atomic-emission spectroscopy. With an air–acetylene flame and experimentation similar to that for the atomic-absorption work the results shown in Fig. 2 were obtained for 5 ppm of indium.

There was strong enhancement by W(VI), V(V), Mo(VI), La^{3+}, Ti^{4+}, Ce^{3+}, Sr^{2+}, Zr^{4+}, Al^{3+} and PO_4^{3-}, moderate enhancement by Ca^{2+} and Na^{+}, no effect by Li^{+}, Bi^{3+}, Cd^{2+}, Te(IV), Tl^{+}, Ni^{2+}, Fe^{3+}, Zn^{2+}, Pb^{2+}, Co^{2+}, Mn^{2+}, Cr^{3+}, Cu^{2+}, As^{3+}, Sb^{3+}, Mg^{2+} and Sn^{2+}, and a depressive effect by Hg^{2+}.

Again, the levels of these elements in alloy samples would be low enough for their effects to be negligible. It is very difficult to decide the reasons for the various effects, some of which are curious. For example, Na^{+} increases the readings but Li^{+} does not (both should give suppression of ionization). The enhancement observed at high interferent levels may be due to an effect of the concomitant elements on the flame background, combined with the effect of the high concentration of salts in the solution.

With the nitrous oxide–acetylene flame less marked effects are generally observed, but most of the elements cause a slight increase in the indium signal.

Interference correction was examined as before and again the use of releasing agents was considered best. The optimum ratios are Al/La = 12/1, Al/Sr = 10/1 and Al/Ca = 5/1, the use of lanthanum being recommended. We emphasize the peculiarity of the

counter-interference effect of these pairs of elements which, separately, have an enhancing effect.

Characteristics of the two methods

Table 2 summarizes the main features of both methods, showing the optimum range, detection limit and sensitivity, and a summary of the statistics for ten analyses of an aluminium alloy containing 0.030% of indium.

Application to metallurgical samples

The accuracy of the method was assessed by determination of indium in aluminium alloys (Pechiney). Table 3 shows the results obtained with both techniques, which confirm the validity of the methods.

The two techniques give very similar results, but the analytical and statistical characteristics are better for emission spectrometry. However, in the presence of large amounts of elements other than aluminium, the atomic-absorption method should be preferred.

FLUORIMETRIC DETERMINATION OF SELENIUM IN SOME MARINE MATERIALS AFTER DIGESTION WITH NITRIC AND PERCHLORIC ACIDS AND CO-PRECIPITATION OF SELENIUM WITH LANTHANUM HYDROXIDE

W. A. MAHER
Department of Physical and Inorganic Chemistry, The University of Adelaide, Box 498 G.P.O., Adelaide, South Australia, 5001

(*Received* 1 *March* 1982. *Accepted* 15 *June* 1982)

Summary—A modified spectrofluorimetric method for the determination of selenium in some marine tissues is described. Selenium is isolated from potentially interfering elements by co-precipitation, then a piazselenol is formed between selenium and 2,3-diaminonaphthalene at pH 1.0 and extracted into cyclohexane. The selenium is determined fluorometrically (λ_{ex}, 377 nm; λ_{em}, 519 nm) in the extract. The detection limit is 3.6 ng (6 times the standard deviation of the blank) and the coefficient of variation is 4% at the 10-ng level.

Of the methods available for the determination of selenium at trace levels in biological tissues, fluorimetry of the selenium–2,3-diaminonaphthalene complex is frequently used and has proved to be sensitive, precise and accurate.[1–3]. Previously reported methods, however, suffer from several limitations. Most lack simplicity of operation, as several transfers of liquid are often required. Moreover, the acidity of the sample digest is usually adjusted by the addition of ammonia solution before the formation of the piazselenol, which leads to variability in the matrix in which the complex is formed and from which it is subsequently extracted for determination.

In the procedure reported here, co-precipitation is used to isolate selenium from possible interferences and to provide, on dissolution, a constant matrix for the formation and extraction of the piazselenol. Also, all operations (sample decomposition, co-precipitation, piazselenol formation and extraction) are performed in the same centrifuge tube to reduce liquid transfers and equipment requirements.

EXPERIMENTAL

Apparatus

All fluorescence measurements were made with a Perkin–Elmer 3000 spectrofluorimeter.

Reagents

Standard selenium solutions. Stock solutions (1000 μg/ml), of selenium(IV) and selenium(VI) were prepared by dissolving analytical-reagent grade selenious acid and sodium selenate respectively in 0.01*M* hydrochloric acid. Aliquots of these solutions were diluted as required with 0.01*M* hydrochloric acid, to give working solutions in the μg/l. range. Organoselenium standards were prepared by dissolving diphenyl diselenide and *N*,*N*-dimethylselenourea in methanol. The solutions were standardized by atomic-absorption spectrometry, by comparison with standards made by dissolving the pure element in hydrochloric acid.

Lanthanum (III) solution. Prepared by dissolving 5 g of lanthanum chloride in 100 ml of distilled water.

2,3-Diaminonaphthalene (DAN) solution. Prepared by dissolving 0.1 g of DAN in 100 ml of 0.1*M* hydrochloric acid containing 0.5 g of hydroxylamine hydrochloride. This solution was purified by heating it at 50° in a water-bath for 25 min and then extracting with three 10-ml portions of cyclohexane; it was then stored at 2°, protected from light. The purified solution was stable for at least 48 hr.

EDTA-hydroxylamine solution. A masking solution was prepared by dissolving 3 g of EDTA (disodium salt) and 5 g of hydroxylamine hydrochloride in 50 ml of distilled water.

Procedure

Samples were freeze-dried and ground (to <200 μm) before analysis. A weighed sample (<0.5 g) was placed in a 30-ml Pyrex centrifuge tube, 5 ml of concentrated nitric acid were added and the mixture was allowed to stand for at least 12 hr at room temperature to ensure complete dissolution (this avoids foaming during heating). The tube was then placed in an aluminium heating block and refluxed until the evolution of brown fumes ceased. The solution was cooled, 2 ml of 72% perchloric acid were added and heating was continued for at least 30 min after the appearance of dense perchloric acid fumes. To convert selenium(VI) into selenium(IV), 1 ml of concentrated hydrochloric acid was added and the digest was heated at 70° for 30 min. Selenium was then isolated by co-precipitation).[4,5] One ml of lanthanum solution and one drop of phenolphthalein indicator were added with stirring, followed by addition of 25% ammonia solution until the solution was pink. The lanthanum precipitate (containing selenium) was separated by centrifugation, then dissolved in 5 ml of DAN solution; after addition of 0.5 ml of masking solution the tube was placed in a water-bath at 50° for 25 min. The piazselenol formed was extracted into 5 ml of cylcohexane by means of a vortex mixer (extraction time 1.5 min) and a portion of the cyclohexane layer was transferred into a 1-cm quartz cuvette. The fluorescence of the extract was

measured at 519 nm after excitation at 377 nm. Calibration graphs of fluorescence intensity *vs.* amount of selenium (0–0.1 μg and 0–1 μg) were prepared by using selenium(VI) standards carried through the entire analytical procedure.

RESULTS AND DISCUSSION

Isolation of selenium and formation of piazselenol

Only selenium(IV) will form the piazselenol.[6] Preliminary experiments also showed that selenium(VI) is not quantitatively co-precipitated with lanthanum hydroxide. Therefore any selenium(VI) initially present or produced during the digestion must be reduced to selenium(IV). The method selected was to heat the digest with hydrochloric acid. The optimum heating time was 20–30 min at 70° and the optimum hydrochloric acid concentration 6–10*M*.

To isolate selenium from other material present, co-precipitation with lanthanum hydroxide was used. Selenium was collected quantitatively only if the pH was adjusted to between 9 and 10.

Dissolution of the precipitate in the DAN and EDTA–hydroxylamine reagents resulted in a solution of pH 1.0. At this pH, the optimum conditions for formation of the piazselenol are heating for 25 min, at 50°.

Sample decomposition

The efficiency of the acid digestion for converting some organic selenium compounds into inorganic selenium was also investigated (Table 1). The recommended decomposition procedure was used, with a spike of selenium compound added to 5 ml of concentrated nitric acid and refluxed before addition of 72% perchloric acid. In both cases the recovery was greater than 97%, showing that this acid mixture should be suitable for converting the organoselenium compounds investigated, if present in marine tissues, into inorganic selenium without serious loss. The high recoveries of inorganic selenium also indicated that loss by volatilization was negligible.

Interferences

A number of ions (Ag^+, Al^{3+}, As^{3+}, Ba^{2+}, Bi^{3+}, Ca^{2+}, Co^{2+}, Cr^{3+}, Cu^{2+}, Fe^{3+}, Hg^{2+}, K^+, Mg^{2+}, Mn^{2+}, Na^+, Ni^{2+}, Pb^{2+}, Sb^{3+}, Sn^{4+}, Te^{4+}, Zn^{2+}) were tested and caused no significant interference when present in amounts of up to 1000 μg.

*Means of 4 analyses.

Accuracy, precision and detection limit

The accuracy of the method was assessed by recovery experiments and the analysis of a standard reference material (Orchard Leaves, NBS SRM 1571). As shown in Table 2, complete recovery of added selenium was obtained within experimental error for the selected marine tissues. The selenium concentration obtained by replicate analysis of the orchard leaves (76 ± 2 ng/g) was in agreement with the certified value (0.08 ± 0.01 μg/g).

The precision was estimated from 5 replicate analyses of a 10-ng Se(VI) standard carried through the entire procedure. The relative standard deviation was 4% (6 determinations).

The standard deviation of the blank (6 determinations) corresponded to 0.6 ng of selenium. The source of the blank (9 ng) was mainly the DAN reagent.

Conclusion

The procedure described allows the determination of down to 10 ng of selenium with a relative standard deviation of less than 4%. The advantage of this procedure is primarily the use of a co-precipitation step to provide a constant matrix for the formation and extraction of the piazselenol. The reduction in equipment and labour required, owing to the elimination of most liquid transfers, also makes the method particularly suitable for use in routine analyses in which selenium is to be determined in large numbers of samples.

SENSITIVE SPECTROPHOTOMETRIC DETERMINATION OF TRACES OF ZIRCONIUM WITH 2-(6-BROMO-2-BENZOTHIAZOLYLAZO)-5-DIETHYLAMINOPHENOL IN THE PRESENCE OF SODIUM LAURYL SULPHATE

CHAO-PING ZHANG
Department of Chemistry, Guizhou University, Guiyang, China

DA-YONH QI and TIAN-ZE ZHOU
Institute of Environmental Chemistry, Academia Sinica, Peking, China

(*Received* 7 *January* 1982. *Revised* 24 *May* 1982. *Accepted* 13 *July* 1982)

Summary—A simple and highly sensitive procedure for spectrophotometric determination of zirconium has been developed. At pH 4.6, zirconium reacts with 2-(6-bromo-2-benzothiazolylazo)-5-diethylaminophenol in the presence of sodium lauryl sulphate to form a red-violet complex, which has an absorption maximum at 520 nm. The molar absorptivity at 520 nm is 4.4×10^5 l.mole^{-1}.cm^{-1}. Beer's law is obeyed for 0.25–1.50 μg of zirconium in 25 ml of solution. The method has been used in the determination of zirconium in aluminium alloy and steel samples.

Arsenazo III and some azo-dyes[1] have been used as spectrophotometric reagents for determination of micro amounts of zirconium. Recently, owing to the use of surfactants,[2] the sensitivity of the determination of zirconium has been raised. It has been briefly reported that 2-(6-bromo-2-benzothiazolyazo)-5-diethylaminophenol (Br-BTAE) forms a violet-red complex with cadmium,[3] and we have now found that it can be used as a chromogenic reagent for zirconium. This paper describes the synthesis of the reagent and its use for the spectrophotometric determination of zirconium in aluminium alloy and steel samples in the presence of an anionic surfactant, sodium lauryl sulphate (NaLS).

EXPERIMENTAL

Reagents

Zirconium solution. Dissolve 1.766 g of pure zirconyl chloride octahydrate in 20 ml of hydrochloric acid (1 + 1), and dilute to 500 ml with the same concentration of acid. Standardize the solution by EDTA titration. Dilute the stock solution with 2*M* hydrochloric acid to give a 1.00-μg/ml working standard.

Br-BTAE solution, 1.00mM. Dissolve 0.0405 g of the purified 2-(6-bromo-2-benzothiazolylazo)-5-diethylaminophenol in 100 ml of *N,N*-dimethylformamide (DMF).

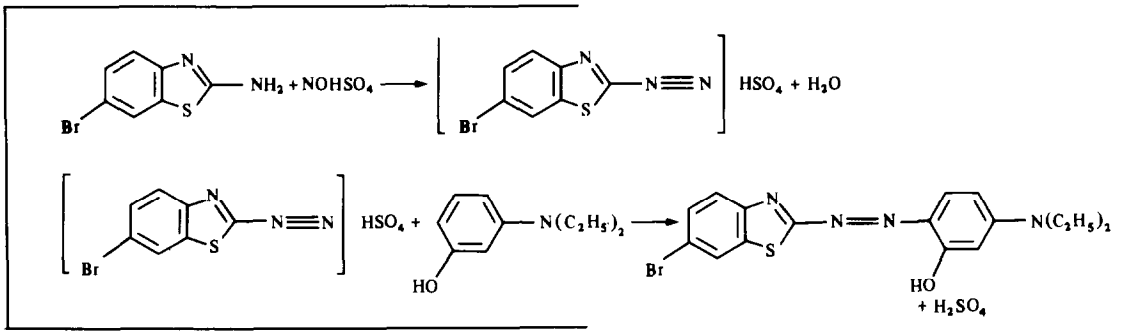
NaLS solution, 1.50%

Sodium acetate buffer (pH 4.6). Dissolve 68 g of sodium acetate trihydrate in water, add 45 ml of glacial acetic acid and dilute to 1000 ml.

Synthesis of Br-BTAE

The synthesis is based on the general procedure for synthesis of benzothiazolylazo dyes.[4] In an acidic solution, nitrosylsulphuric acid is reacted with 6-bromo-2-aminobenzothiazole to produce a diazonium salt, which is then coupled with *m*-diethylaminophenol to form the coloured azo dye.

$$2NaNO_2 + 3H_2SO_4 \rightarrow 2NOHSO_4 + Na_2SO_4 + 2H_2O$$



Sodium nitrite (2.8 g, 0.04 mole) is added portionwise with stirring and cooling to 30 ml of concentrated sulphuric acid and 16 ml of water at 20°. The pale green solution of nitrosylsulphuric acid obtained is cooled to 0–5°, and a solution of 4.6 g (0.0201 mole) of 6-bromo-2-aminobenzothiazole in 30 ml of *N,N*-dimethylformamide is added dropwise at 15–18°.

The mixture is stirred for 2 hr at 0–5°, then 1.6 g (0.016 mole) of sulphamic acid, and 10 min later, 4.6 g (0.0272

mole) of *m*-diethylaminophenol dissolved in 30 ml of *N,N*-dimethylformamide are added at 0–5°. The mixture is stirred for 1 hr at 0–5°, 120 g of sodium acetate in 200 ml of water are added, then the cooling is stopped, and the mixture is stirred for 2 hr and filtered. The product is washed with water and dried, yielding 3 g of red precipitate (36% yield).Recrystallization from *N,N*-dimethylformamide gives a material with m.p. 208.5–209.5°.

Analysis gave C 50.1%, H, 4.2%, N, 13.8%, Br, 20.1%: $C_{17}H_{17}ON_4BrS$ requires C 50.38%, H 4.23%, N, 13.82%, Br 19.71%.

Procedure

Transfer a sample containing not more than 1.5 μg of zirconium into a 50-ml beaker. Add in sequence, with swirling, 1.0 ml of 0.1*M* EDTA, 0.2 ml of Br-BTAE solution, 2.0 ml of NaLS and 1.0 ml of ethanol. Adjust to pH 4.6 with 0.1*M* sodium acetate and 0.1*M* hydrochloric acid, and then add 2.0 ml of sodium acetate buffer (pH 4.6). Transfer the solution into a 25-ml standard flask, dilute to the mark with water and mix well. Measure the absorbance at 520 nm in a 1-cm cell against a reagent blank, after 30 min. Prepare a calibration graph for the range 0.25–1.5 μg of zirconium in 25 ml of final solution.

Analysis of aluminium alloy and steel samples

Weigh a 0.1000-g sample into a 100-ml beaker and dissolve it in 10 ml of 6*M* hydrochloric acid, with heating if necessary. Filter off any residue on a small (9 cm) filter paper, and wash the residue and paper 4 or 5 times with 2*M* hydrochloric acid, collecting the filtrate and washings in a 250-ml standard flask.

Place the residue and paper in a silica crucible and dry and ignite in the usual way. Fuse the residue with a small amount of potassium pyrosulphate and cool. Add 10 ml of 6*M* hydrochloric acid and warm to dissolve. Transfer the solution to the flask containing the original filtrate. Dilute to the mark with 2*M* hydrochloric acid.

Transfer an aliquot containing not more than 1.5 μg of zirconium into a 50-ml beaker, and analyse as already described.

For samples containing a large amount of nickel, extract the nickel with α-furildioxime. For steel samples add acetylacetone to mask Fe(III).

RESULTS AND DISCUSSION

Absorption spectra

The absorption spectra of Br-BTAE and its zirconium complex at pH 4.6 in the presence of NaLS are shown in Fig. 1. The absorption maximum of the reagent lies in the range 510–540 nm and that of the zirconium complex at 520–530 nm, but the molar absorptivity of the reagent (2×10^4 l.mole^{-1}.cm^{-1}) is much smaller than that of the complex. The absorbance of the reagent blank is stable.

Effect of variables

A study of the effect of pH on the complexation of Br-BTAE with zirconium in the presence of NaLS shows that the coloured complex has constant absorbance in the pH range 1.5–5.5. However, in more acidic solution, the absorbance of the reagent blank is increased.

To decrease the effect of foreign ions, pH 4.6 is preferred. The absorbance values at pH 4.6 of 25 ml of solution containing 1.0 μg of zirconium and increasing amounts of Br-BTAE and NaLS solutions show that maximum absorbance is reached with amounts of the reagents in the ranges 0.17–1.0 and 0.7–3.0 ml respectively. To accelerate the complexation and stabilize the reagent blank, 0.5–1.5 ml of ethanol should be added. Temperature affects the time required for full colour development of the complex. In the temperature range 17–35°, the solution should be kept for 30 min for completion of colour development; the colour intensity remains virtually constant for 2 hr.

Effect of foreign ions

The following ions, when present up to the amounts (in mg) shown in brackets, do not interfere in the determination of 1.0 μg of zirconium: Na^+ (40), K^+ (20), NH_4^+ (20), Ag^+ (0.01), Ca^{2+} (5), Ba^{2+} (5), Mg^{2+} (2), Be^{2+} (1), Pb^{2+} (1), Mn^{2+} (0.1), UO_2^{2+} (0.05), Co^{2+} (0.05), Cu^{2+} (0.02), Zn^{2+} (0.02), Ni^{2+} (0.01), Cd^{2+} (0.01), Al^{3+} (1), Fe^{3+} (0.1), Bi^{3+} (0.1), Cr^{3+} (0.1), La^{3+} (0.01), Ge (IV) (0.1), Sn^{4+} (0.1), Th^{4+} (0.01), Ce^{4+} (0.025), Nb(V) (0.02), Ta(V) (0.02), V(V) (0.01), Mo(VI) (0.05), W(VI) (0.04), Cr(VI) (0.01), Cl^- (50), CH_3COOH^- (50), NO_3- (20), CNS^- (10), ClO_4^- (10), Br^- (2), I^- (1), F^- (0.09), SO_4^{2-} (20), $B_4O_7^{2-}$ (20), $P_2O_7^{2-}$ (10), SiO_3^{2-} (10), $C_2O_4^{2-}$ (10), $S_2O_3^{2-}$ (1), citrate (20), tartrate (20), S^{2-} (0.17), PO_4^{3-} (1), As(V) (0.05). The interference of Ti(IV), (0.02) and Tl(III) (0.01) can be prevented with DCTA and lactic acid respectively.

Under the experimental conditions used, hafnium behaves similarly to zirconium, but the molar absorptivity is higher.

Some transition elements such as Cu, Ni, Fe interfere in the reaction with zirconium, because they react with the reagents used. For example Ni^{2+} reacts with Br-BTAE and NaLS at pH 9.5 (molar absorptivity 2.5×10^5 l.mole^{-1}.cm^{-1}), and even at pH 4.6 nickel

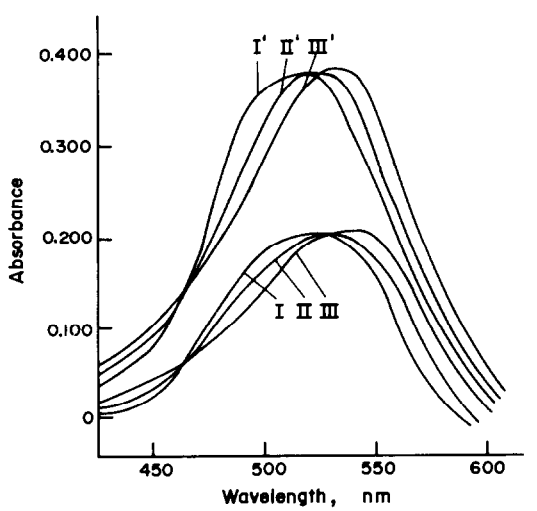


Fig. 1. Absorption spectra at different pH values (1-cm cell). Reagent *vs.* water: I—pH 2.8, II—pH 3.9, III—pH 5.1; Zr-complex *vs.* water: I'–pH 2.8, II'—pH 3.9, III'—pH 5.1.

Table 1. Determination of zirconium in aluminium alloy and steel samples

Sample	General composition, %	Zr, %	
		Present method	Spectrographic method
Aluminium alloy	Cu, 0.0073; Mg, 8.57; Mn, 0.26; Si, 0.17; Fe, 0.092; Ni, 0.093; Sb, 0.025; RE, 0.13	0.13, 0.12, 0.12, 0.11	0.12
Steel 1	Si, 0.52; Mn, 1.37; P, 0.033; S, 0.006; Nb, 0.87; Mo, 0.54; Ti, 0.095; V, 0.097; RE, 0.025	0.098, 0.099, 0.099, 0.098	0.098
Steel 2	C, 0.14; Si, 0.54; S, 0.009; Ti, 0.14; Mn, 0.87; V, 0.36; Nb, 0.034	0.20, 0.19, 0.19, 0.21	0.21
Steel 3	Ti, 0.06; Ta, 0.02; Nb, 0.02; V, 0.05; Co, 0.01; Ni, 0.01; Ce, 0.02	0.049, 0.050, 0.048, 0.052	0.050
Steel 4	Th, 0.05; Mo, 0.1; W, 0.1; Sn, 0.1	0.050, 0.051, 0.049, 0.048	0.050

still causes obvious interference. When the quantity of nickel is too high, its extraction with α-furildioxime is necessary: at pH 4.6, 5 ml of 1% α-furildioxime solution in choloroform will extract 1 mg of nickel.

The interference of Fe(III) can be eliminated with acetylacetone; 1.0 ml of 5% acetylacetone solution will mask 1 mg of Fe(III) under the conditions for determination of zirconium.

Composition of the complex

The Zr:Br-BTAE ratio has been found to be 1:2 by the continuous-variation and the mole-ratio methods, and the ratio Zr:LS 1:2 by the slope-ratio method, so the complex should be Zr (Br-BTAE)$_2$ (LS)$_2$.

Table 2. Sensitivities of methods for the spectrophotometric determination of zirconium

Methods	λ_{max} nm	ϵ, 10^5 l.mole^{-1}.cm^{-1}	Reference
TAM/Zephiramine	595	1.05	2
PADAP/antipyrine	560	1.06	5
3,5-diBr-PADAP/ antipyrine	600	1.35	5
Arsenazo III	665	1.2	6
Chlorophosphonazo III	675	2.1	7
Picramine-ε/ Ethylrhodamine B	560	3.2	8
Br-BTAE/NaLS	520	4.4	Present method

Analysis of samples

Table 1 gives results for some typical samples, showing the method is satisfactory.

Comparison with other zirconium reagents

This is one of the most sensitive reagents for zirconium. The proposed method is simple, rapid and fairly free from interference in the presence of EDTA, lactic acid, DCTA and acetylacetone, or after extraction with α-furildioxime. The sensitivities of various methods are listed in Table 2.

BIACETYL MONOXIME GLYCINIMINE AS A SELECTIVE REAGENT FOR PALLADIUM AND NICKEL

P. RIYAZUDDIN
Department of Chemistry, The New College, Madras 600 014, India

(*Received* 13 *August* 1980. *Revised* 12 *June* 1982. *Accepted* 13 *July* 1982)

Summary—Biacetyl monoxime glycinimine is proposed as a new reagent for the selective gravimetric and extractive photometric determination of Pd(II) and Ni(II). The reagent forms yellow and rose-red water-insoluble complexes with Pd (pH 0.5–5.5) and Ni (pH 5.0–11.2) respectively. The complexes can be used for direct gravimetric determination or extracted with molten naphthalene. The solidified naphthalene–complex mixture is dissolved in chloroform and measured photometrically. The effects of experimental variables and diverse ions are reported. The proposed reagent offers better selectivity than dimethylglyoxime.

Dioximes are one of the most selective groups of reagents. Dimethylglyoxime (DMG) is specific for precipitation of nickel and palladium.[1] There are many observations[2–7] indicating that DMG forms highly stable complexes with all transition metal ions from manganese to zinc, and it is well established that the nitrone form of the oxime is responsible for the complex formation.[8,9] As early as 1927, Pfeiffer *et al.*[10,11] showed that if one of the oxime groups is replaced with an imino or methylimino group, complex formation can occur in the same fashion, but only three such compounds have been reported as analytical reagents. Mashima[12,13] used *N,N'*-ethylene-(4-methoxy-1,2-benzoquinone-1-oxime-2-imine) as an extractive photometric reagent for transition metals. Mathur and Narang[14] used bis(biacetylmonoxime)-*o*-phenylenedi-imine and its ethylenedi-imine analogue as gravimetric reagents for Ni(II) and Pd(II). As a result, it was decided to investigate some imine oximes to determine their reactivity with metal ions.[15,16] This paper presents the results of a study of biacetyl monoxime glycinimine for the separation, and gravimetric and photometric determination of Pd(II) and Ni(II).

The reagent (**I**) precipitates Pd(II) quantitatively as a yellow complex at pH 0.5–5.5, and Ni(II) as a rose-red complex at pH 5.0–11.2. The complexes have composition $M(C_6N_2O_3H_9)_2$ and after drying for 2 hr at 110–120° can be weighed for determination of Pd(II) and Ni(II).

EXPERIMENTAL

Reagents

Biacetyl monoxime glycinimine was synthesized by heating equimolar solutions of biacetyl monoxime and glycine on a boiling water-bath for 3 hr. The crude sample was recrystallized from ethanol until the m.p. was constant (234–235°). Elemental analysis gave C 45.7%, N 17.6%, H 6.4%; $C_6H_{10}O_3N_2$ requires C 45.56%, N 17.71%, H 6.37%. It is a white crystalline solid, sparingly soluble in water but readily soluble in ethanol and acetone. A 0.05*M* solution was prepared in aqueous ethanol (1 + 1). A 0.02*M* palladium chloride or nitrate solution and a 0.1*M* nickel ammonium sulphate solution were prepared, and standardized with dimethylglyoxime.

Determination of Pd

A known volume of Pd(II) solution was taken in a 400-ml beaker, diluted to about 100 ml and adjusted to pH 0.5–1.5 with dilute hydrochloric or nitric acid. A threefold excess of reagent solution was added with stirring. The complex was digested on a water-bath at 50–60° for about 30 min, allowed to cool and filtered off on a porosity-4 sintered-glass crucible. The precipitate was washed with hydrochloric or nitric acid (1% v/v) followed by 10% aqueous ethanol to remove the excess of reagent, and dried at 110–120° to constant weight.

Separation and determination of Pd and Ni

Pd(II) was precipitated first at pH 1.5 and dealt with as above. The filtrate was concentrated to about 100 ml and adjusted to pH 9.0–11.0 with ammonia. A threefold excess of reagent was added with constant stirring, then the precipitate was digested for 30 min, filtered off, washed with 10% aqueous ethanol and dried at 110–120° to constant weight.

Effect of diverse ions on the gravimetric determination of Pd

Interferences were prevented by pH control. At pH 0.5–1.5, 3 g of Cl^-, Br^-, F^-, NO_3^-, SO_4^{2-}, PO_4^{3-}, CH_3COO^-, citrate, tartrate and EDTA, and 0.3 g of Pb^{2+}, Hg^{2+}, As^{3+}, Cd^{2+}, Al^{3+}, Zn^{2+}, Co^{2+}, Cu^{2+}, Ni^{2+}, Fe^{3+}, Mn^{2+}, Ba^{2+}, Sr^{2+}, Ca^{2+}, Mg^{2+}, Ag^+ (in the absence of chloride), Pt(IV), Au(III), Rh(III), Os(VIII) and Ir(III) did not interfere.

Effect of diverse ions on the gravimetric determination of Ni

Three g of Cl^-, Br^-, F^-, I^-, NO_3^-, SO_4^{2-}, PO_4^{3-}, CH_3COO^-, citrate, tartrate, NH_4^+, Ba^{2+}, Ca^{2+}, Ag^+, did not interfere. Hg^{2+}, Pb^{2+}, Cd^{2+}, Al^{3+}, Zn^{2+}, Fe^{3+}, Bi^{3+}, Cr^{3+}, Mn^{2+} were precipitated. Co^{2+}, Cu^{2+}, Fe^{2+}, and Pd^{2+} gave soluble complexes in ammoniacal medium at pH 9.0–11.0. EDTA interfered.

The interference of Fe^{3+}, Cr^{3+}, Al^{3+}, Cd^{2+}, Bi^{3+} and Zn^{2+} can be avoided by precipitating the nickel at pH

Table 1. Spectral characteristics of the Pd(II) and Ni(II) complexes

Complex	λ_{max}, nm	ϵ, $l.mole^{-1}.cm^{-1}$	Extraction pH	Validity of Beer's law, μg/ml	Optimal concn.* μg/ml	Std. devn. μg/ml
Pd(II)-BAMGI	375–380	2.1×10^3	0.5–5.5	0–90	2–9	0.009
Ni(II)-BAMGI	380–385	5.2×10^3	5.0–11.2	0–18	10–40	0.007

*For: 6.0 ppm of Ni(II) or 21.3 ppm of Pd(II); 10 determinations.

5.0–5.5 (acetate buffer) in the presence of tartrate or citrate and ammonium chloride, after removal of Pd(II), if present, at pH 0.5–1.5.

Extractive photometric determination of Pd and Ni

The complexes can be only partially extracted into chloroform, and at high concentration of the metals the complexes accumulate at the water–chloroform interface, so the technique of using molten naphthalene[17–21] was tried and proved successful.

Procedure

To the nickel or palladium sample solution, in a tightly stoppered Erlenmeyer flask, add 2.5 ml of 0.05*M* reagent and adjust to the appropriate pH. Dilute to 25–30 ml. Mix well, and warm on a water-bath at about 60°. Add 2.0 g of naphthalene and warm the mixture in a water-bath at 90° to melt the naphthalene. Shake vigorously till the naphthalene solidifies, forming microcrystals, and allow to cool to room temperature. Again warm to melt the microcrystals slowly, and let them grow to give a coarser deposit. Cool to room temperature. Collect the solid on a filter paper, wash with water, remove the surplus water with dry filter paper, and air-dry the residue. Dissolve the solid in chloroform and dilute to volume in a 10-ml standard flask. Measure the absorbance at 380 nm in a 10-mm cell against a reagent blank prepared similarly. Prepare a calibration curve by applying the procedure to suitable standards.

DISCUSSION

Experimental factors

The nickel and palladium complexes in chloroform solution give maximum absorption at 380–385 and 375–380 nm, respectively. The reagent does not absorb at these wavelengths.

The extraction is quantitative at pH 0.5–5.5 and 5.0–11.2 for palladium and nickel respectively.

The essential spectral data are given in Table 1. Digestion is not necessary but heating for up to 60 min does not affect the results. The method of continuous variations in a two-phase system[22] showed that both complexes have a metal to ligand ratio of 1:2. The absorbance remains constant for several hours.

Varying the amount of naphthalene from 0.5 to 3.0 g does not affect the extraction. The volume of chloroform required to dissolve 1.0 g of naphthalene is 2.0 ml. Tolerance levels for various ions (< 3% error) are given in Table 2.

Applications

Two mg or more of palladium or nickel can be determined gravimetrically with a precision of 0.4 and 0.5%, respectively.

The reagent is suitable for determination of palladium in hydrogenation catalysts, and dental or ornamental alloys, and readily separates it from gold, platinum, silver, copper and zinc. Synthetic solutions

Table 4. Extractive photometric determination of Pd and Ni

Samples	Nominal content, %	Found, % Present method	Found, % Polarographic method[25]
$CaCO_3$ + Pd (Merck)	5.0	4.9$_0$%	4.8$_8$
Active carbon + Pd (Merck)	10.0	9.7$_2$%	9.6$_8$
Steel BCS 335	9.47	9.6$_0$%	9.5$_6$

simulating the composition of dental alloys were analysed gravimetrically for palladium and results are given in Table 3. The photometric technique was applied for the determination of palladium in two catalysts and nickel in a standard steel. The results are summarized in Table 4.

Advantages of the reagent

There are a few drawbacks in the use of dimethylglyoxime as a selective reagent for palladium[23,24] and modified procedures have to be adopted when metals such as Pt, Rh, Ir, Au and Ni are present. The new reagent is more selective towards palladium and nickel, and does not require chemical separation of palladium from other noble metals.

ANALYTICAL DATA

STUDY OF SEMICARBAZONES AND THIOSEMICARBAZONES DERIVED FROM 1,2-NAPHTHOQUINONE, AS ACID–BASE INDICATORS: EVALUATION OF THEIR TRANSITION LIMITS THROUGH THE CHROMATICITY CO-ORDINATES

A. IZQUIERDO, E. BOSCH and V. RODRIGO
Department of Analytical Chemistry, University of Barcelona, Barcelona, Spain

(*Received* 19 *February* 1982. *Revised* 22 *April* 1982. *Accepted* 11 *July* 1982)

Summary—The use of 1,2-naphthoquinone-2-semicarbazone, 1,2-naphthoquinone-2-semicarbzone-4-sulphonic acid and 1,2-naphthoquinone-2-thiosemicarbazone-4-sulphonic acid as acid–base indicators has been studied. The sharpness of the indicator transitions has been investigated by means of photometric titrations and the colour quality specified with the aid of the CIE chromaticity system. The results show that the three substances are satisfactory as neutralization indicators.

Semicarbazones and thiosemicarbazones have not been studied previously as neutralization indicators.[1] However, both groups show a resonance structure with an acidic hydrogen atom, and if conjugated with aromatic systems that can exist in benzenoid form and quinonoid form, can have a visible-region absorption spectrum that is pH-dependent.

The study began with the 1,2-naphthoquinone-2-semicarbazone (NQS) and the good results obtained led to the comparative study of the 4-sulphonic acid derivative (NQS4S), which is more soluble in water, and finally, to study of 1,2-naphthoquinone-2-thiosemicarbazone-4-sulphonic acid (NQT4S).

The present work deals with the synthesis and spectrophotometric study of these compounds, determination of their ionization constants and their analytical applications as acid–base indicators. The colours observed during the transitions of the indicators are described in terms of the CIE chromaticity systems and with the RUCS system co-ordinates, and the complementary chromaticity co-ordinates of the transition limits are given.

EXPERIMENTAL

Apparatus

An Acta M-VII spectrophotometer and a Radiometer pH-meter (Model PHM64) with glass/calomel electrodes were used. The pH-meter was standardized with potassium hydrogen phthalate solution (pH 4.008) and Na_2HPO_4/NaH_2PO_4 solution (pH 6.865).

Chemicals

NQS. Prepared by condensing semicarbazide hydrochloride with 1,2-naphthoquinone in acidic medium. The product was recrystallized and tested for purity by TLC (Merck silica gel; butanol–acetic acid–water, 5:4:1). Required for $C_{11}H_9N_3O_2$: 61.4% C, 19.5% N and 4.2% H. Found: 61.9% C, 20.2% N and 4.6 H. $\bar{\nu}$ (KBr) 3450, 3250 and 3150 cm^{-1} (NH, NH_2), 1720, 1680 and 1634 cm^{-1} (CO). The n.m.r. spectrum agrees with the literature data.[2]

NQS4S and NQT4S. Prepared by condensing semicarbazide hydrochloride or thiosemicarbazide hydrochloride with sodium 1,2-naphthoquinone-4-sulphonate in acidic medium. The products were recrystallized and tested for purity by TLC. The first is red and the second orange in solid form. The elemental analysis of the compounds shows that both crystallize with two molecules of water (confirmed by n.m.r.).

NQS4S.$2H_2O$ requires (for $C_{11}H_9N_3O_5S.2H_2O$): 39.8% C, 12.7% N, 3.4% H and 9.7% S. Found: 39.4% C, 12.6% N, 3.3% H and 9.8% S. $\bar{\nu}$ (KBr) 3430 cm^{-1} (NH), 3075 cm^{-1} (ArH), 1700 and 1633 cm^{-1} (CO) and 1220 and 1060 cm^{-1} (SO_2) agree with Ueda *et al.*[2] NQT4S.$2H_2O$ requires (for $C_{11}H_9N_3O_4S_2.2H_2O$) 38.0% C, 12.1% N, 3.8% H and 18.5% S. Found: 37.7% C, 11.9% N, 3.5% H and 18.0% S. $\bar{\nu}$ (KBr) 3400, 3230 and 3160 cm^{-1} (thiosemicarbazone group), 3080 (ArH), 1422, 1490, 1340 and 1312 cm^{-1} (NCS) and 1185 and 1055 cm^{-1} (SO_2) agree with Ueda *et al.*,[2] Grecu and Neamtu[3,4] and Gingras *et al.*[5] The n.m.r. spectra of NQS4S and NQT4S (in DMSO with TMS as reference) agree with those in the literature[2] but both had a new peak at 3.25 ppm, corresponding to the presence of approximately two molecules of water.

Aqueous solutions ($10^{-3}M$) *of NQS, NQS4S and NQT4S. Buffer solutions*[6] *pH 2.2–11.6 and* I = *0.01.*

Analytical grade reagents and doubly-distilled water were used for the standard solutions.

Procedure

The ionization constants were determined spectrophotometrically by the Albert and Serjeant method.[7] The pH of each solution was measured, and the absorbance was recorded over the range 250–650 nm. At wavelengths longer than 650 nm the absorbance was negligible. The stability of NQS, NQS4S and NQT4S solutions with time

was determined by measurement at the absorption maximum in acidic, neutral and basic media. The colour-change pH ranges and their sharpness were evaluated by titration of 0.1 and 0.01*M* hydrochloric acid and acetic acid with 0.1 and 0.01*M* sodium hydroxide. The titrations were followed simultaneously by potentiometry and by continuous measurement of the absorbance at 494 nm for NQS; 481 nm for NQS4S and 515 nm for NQT4S (the wavelengths of maximum absorption in basic medium). The titration solution was continuously circulated between the titration vessel and the spectrophotometer cuvette by a peristaltic pump. The solutions were stirred with a stream of nitrogen. The temperature was 25 ± 1°.

The colour of the buffered indicator solutions ($10^{-5}M$) at different pH values was evaluated, generally at 0.1-pH intervals. The transmittance was measured at 10-nm intervals from 350 to 700 nm in 10- and 50-mm cuvettes (the transmission was 100% at $\lambda > 700$ nm).

RESULTS AND DISCUSSION

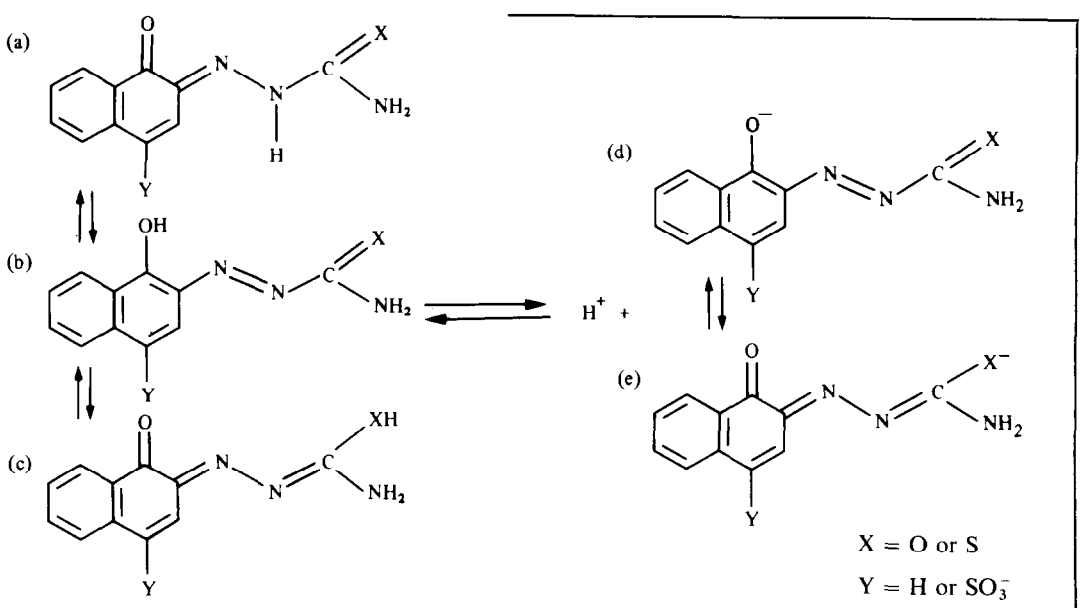
The absorption spectra of the indicators in aqueous solution at different pH values show different forms in equilibria in the pH range studied, and several isosbestic points (Table 1).

The ionization equilibria corresponding to deprotonation of the semicarbazone or thiosemicarbazone group can be complicated by the tautomeric equilibria of the neutral or monoanionic forms of the indicator in acidic medium and mono or dianionic forms in basic medium. This can probably be explained in the same way as by Gingras *et al.*[5,8] and de Castro *et al.*[9] for similar substances. The equilibria can be written as follows.

Table 1. Spectral characteristics

Substance	Medium	λ_{max}, nm	Log ε
NQS	HCl 0.1*M*	440	3.987
	and H_2O*	320	4.302
		270	4.504
	NaOH 0.1*M*	494	4.219
		304	4.052
NQS4S	HCl 0.1*M*	430	3.876
	and H_2O*	320	4.189
		272	4.372
	NaOH 0.1*M*	481	4.277
		308	4.137
		273	4.324
NQT4S	HCl 0.1*M*	455	4.932
	and H_2O*	323	4.612
		279	5.118
	NaOH 0.1*M*	515	4.630
		312	4.348

*The spectrum was the same in both media.



In all probability the main form in acid medium is (*b*), because the spectra show the "leuco" form, normally associated with benzenoid forms, and the presence of the quinonoid form (*e*) in basic medium is the cause of the colour. For NQT4S (*e*) is slowly transformed into (*d*), as demonstrated by the time stability study, since in basic medium there is a decrease in absorbance in the visible together with a displacement of the absorption maximum to shorter wavelengths and an increase in the absorbance maximum in the ultraviolet. The times needed for 10% decrease in absorbance for the indicators in acid (basic) medium were 30 days (8 hr) for NQS, 30 days (4 hr) for NQS4S and 30 hr (1 hr) for NQT4S.

Seven concordant data points were used for calculating each pK_a value (NQS 9.82 ± 0.02; NQS4S 8.94 ± 0.06 and NQT4S 8.46 ± 0.05). The pK_a value for the sulphonic group in NQS4S and NQT4S was not determined.

Table 1 shows that the neutral and anionic forms of NQS and the mono and dianionic forms of NQS4S

Table 2.

Substance	Colour-change pH-range	Acidic colour	Basic colour
NQS	9.3–10.3	Greenish-yellow	Orange
NQS4S	8.0–9.4	Yellow	Orange
NQT4S	8.1–9.0	Yellowish-orange	Red

and NQT4S exhibit different colours, which can be observed at very low indicator concentration.

The results of the photometric titrations show the good behaviour of these products as indicators for the determination of strong and moderately strong acids. Table 2 shows the limits of the colour-change pH-range for these indicators.

However, these indicators give soluble coloured complexes[2] with Cu^{2+}, Ni^{2+}, Bi^{3+}, Fe^{2+}, Fe^{3+}, Cd^{2+}, Pb^{2+}, Hg^{2+}, Co^{2+}, Zn^{2+}, Ag^{+} and Ce^{3+}, so these ions interfere and must be removed beforehand if present in the sample to be titrated.

Colour-change evaluation

The description of the colour change of indicator solutions before, during and after the colour-change pH-range is given by their chromaticity co-ordinates calculated by the weighted ordinate method ($\Delta\lambda = 10$ nm). The results are described through the x–y [CIE (1931)], u–v [CIE (1960)] and u'–v' [CIE (1976)] systems, the last two involving more uniform colour spacing. The evaluation was based on the CIE table of coefficients for standard illuminant C.[10]

U–V co-ordinates on the basis of the RUCS system of Breckenridge and Shaub[11] were also calculated because they permit comparison with the colour data for an important group of neutralization indicators, the phthaleins,[12] and some others.[13] The U–V values were calculated from the following relations

$$U = 0.075 - \frac{0.823(x + y - 1)}{x - 7.053y - 1.640}$$

$$V = \frac{3.697x - 5.077y - 1.369}{x - 7.053y - 1.640} - 0.500.$$

The results are given in Table 3, and are represented in Figs. 1 and 2. The scatter at the lower end of the curve c' in Fig. 2 is a consequence of the lower precision of measurement at high absorbance.

Table 3. Chromaticity co-ordinates for the colour change of the indicators at some pH-values in the colour-change pH-range

$$u = \frac{4x}{-2x + 12y + 3}, \quad v = \frac{6y}{-2x + 12y + 3}; \quad u' = u, \quad v' = 1.5v.$$

Table 4. Complementary chromaticity co-ordinates

Indicator	pH	Q_x	Q_y	J^*	K_λ (λ, nm)
NQS	8.400	0.146	0.117	0.087	1.035 (440)
($3.0 \times 10^{-5}M$)	12.067	0.136	0.256	0.214	0.907 (490)
NQS4S	7.695	0.145	0.064	0.120	0.899 (440)
($2.0 \times 10^{-5}M$)	10.860	0.129	0.171	0.313	0.928 (480)
NQT4S	7.452	0.154	0.150	0.394	1.119 (460)
($3.7 \times 10^{-5}M$)	10.020	0.194	0.410	0.132	1.183 (520)

*The J values refer to 10-mm path-length.

The values obtained are a function of the experimental conditions (concentration c, and path-length d). To obtain colour points before and after the colour-change pH-range, which are independent of c and d, the complementary chromaticity co-ordinates Q_x and Q_y have been calculated by the weighted ordinate method[14–16] ($\Delta\lambda = 10$ nm) on the basis of the absorbance values (Fig. 1).

The "colour concentration", J, related to the complementary stimuli, was evaluated by means of the relation $J = 2.303S_A/S_a$,[14] where S_a is a constant and S_A is calculated by the weighted ordinate method ($\Delta\lambda = 10$ nm) especially recommended by Kotrlý and Vytřas.[16] The J values also permit K_λ values for maximum absorption wavelengths to be obtained. The results are given in Table 4.

The results show that the three substances have satisfactory behaviour as neutralization indicators and that NQT4S gives the greatest sharpness. NQS and NQS4S exhibit similar sharpness to that found by King[13] for Methyl Red and Tashiro's indicator and NQT4S is comparable to some phthaleins studied by Bhuchar.[12] The criterion for sharpness was the intensity of the change in the chromaticity co-ordin-

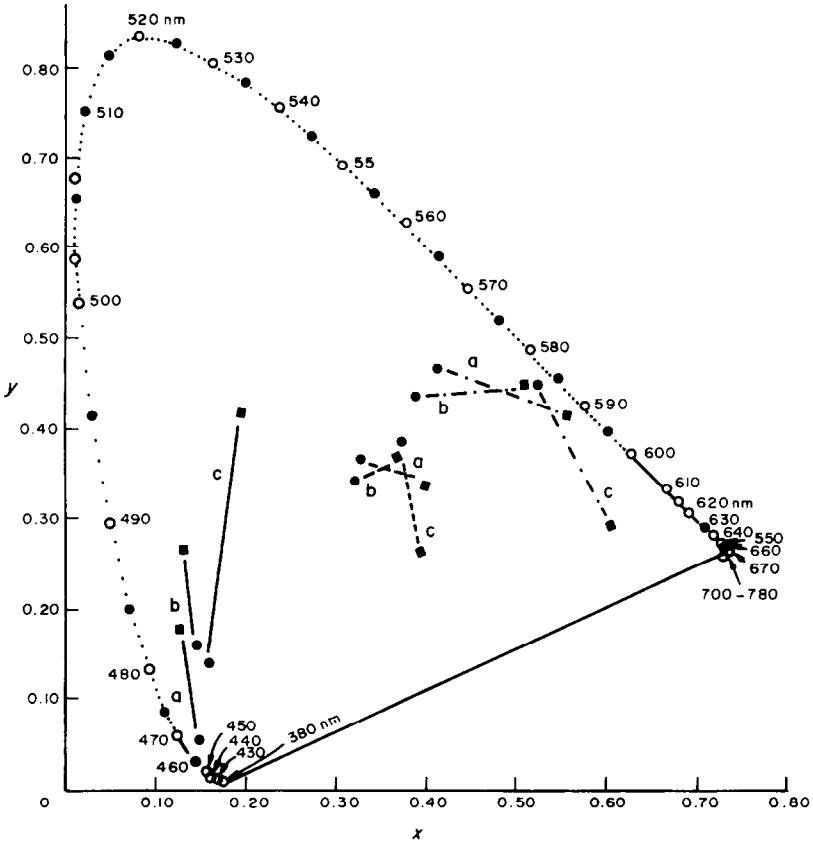

Fig. 1. Colour points in the CIE (x, y) chromaticity system, for acid–base titrations using (*a*) NQS, (*b*) NQS4S and (*c*) NQT4S as indicators. ●, Colour point of acid form of indicator; ■, colour point of basic form of indicator; - - - -, colour points ($d = 10$ mm); ·-·-·-, colour points ($d = 50$ mm); ——, complementary colour points. The co-ordinates of CIE standard source c are $x = 0.310$ and $y = 0.317$.

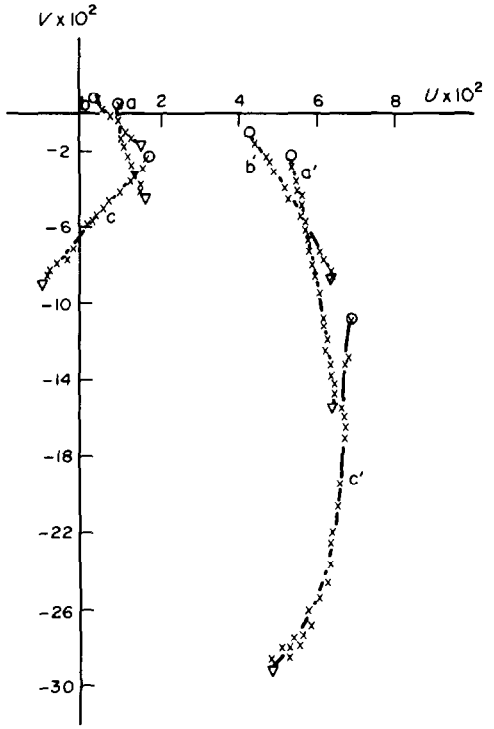

Fig. 2. The U–V co-ordinates (RUCS System) of the colour change with pH of (*a*) NQS, (*b*) NQS4S and (*c*) NQT4S (d = 10 mm) and (*a'*) NQS, (*b'*) NQS4S and (*c'*) NQT4S (d = 50 mm). ○, Colour point of acid form of indicator; ▽, colour point of basic form of indicator.

ates of the forms of the indicator at each end of the transition.

We agree with other authors that the CIE colour specification should be included among basic data on chemical acid–base indicators because they permit establishment of comparative criteria for sharpness of the colour change of indicators. Furthermore, the complementary chromaticity co-ordinates can also be used for the calculation of indices of colour quality, and for evaluation of the constants for the equilibria involved in the indicator transition.[17]

Summary—Solvent extraction of asphalt from pavement mixtures is a technique used to study the change in asphalt during service. Rheological measurements indicate that asphalts recovered from trichloroethylene or trichloroethane are markedly hardened. Compositional studies on asphaltic fractions reveal a notable decrease in saturates, naphthenes, H, N, Ni and V, and increase in polar aromatics and asphaltenes along with incorporation of Cl in all fractions. These structural changes are responsible for the hardening of the asphalt and are interpreted in terms of cyclization of saturates, aromatization of naphthenes, coupling of free radicals with neutral species to give a high content of asphaltenes, and in terms of loss of the relatively volatile Ni and V porphyrins during the extraction–recovery process.

Since it is not feasible to study *in situ* the effect of aging on asphalt during service, the practical alternative is solvent extraction of asphalt from pavement samples and its subsequent recovery. The validity of this method depends on whether the solvent causes any significant change in the properties of the asphalt. Although benzene is the solvent most widely used in asphalt technology, chlorinated hydrocarbons are also used by some asphalt research laboratories. In a study surveying the effect of the solvents generally used in the recovery process, trichloroethylene and trichloroethane were reported to cause marked hardness in the recovered asphalts.[1]

Analysis of asphalt before and after recovery would help understanding of the fundamental changes involved and, accordingly, how the asphalt hardness came about. Compositional studies of asphalts have been conducted by several investigators[2–4] but the methods of analysis used were quite detailed. The development of a simplified analytical procedure,[5] whereby an asphalt can rapidly be fractionated into distinct classes of components, makes it possible to characterize individual fractions and to follow any change in asphalt composition.

This investigation was undertaken in an examination of the role of chlorinated solvents in hardening recovered asphalts and reports the results in terms of change in properties, as obtained by rheological measurements on the whole asphalts and compositional analysis of the fractionated asphalts. The work reported was done with a Kuwaiti asphalt, but similar effects have been observed with an Egyptian Western Desert asphalt as well as those reported on earlier,[1] so the effect seems a general one.

EXPERIMENTAL

The asphalt used was an atmospheric heavy-end fraction of Kuwait oil and all chemicals were reagent grade. Asphalt samples (200 g) were each treated four times with trichloroethylene or 1,1,1-trichloroethane according to a reported procedure.[1] The solvent was then distilled in a rotary flash-evaporator at 100° to avoid any oxidation or overheating of the asphalt.

The softening point and penetration of the original and recovered asphalts were measured by standard methods.[6] The asphalts were then separated into their major components by precipitation of asphaltenes with n-hexane, and fractionation of petrolenes by adsorption chromatography.[5] The asphaltic fractions were analysed for C, H, N and Cl.

Vanadium and nickel were determined by electrothermal atomic-absorption spectroscopy with a Perkin–Elmer 300S spectrometer with HGA-72 graphite furnace and deuterium background-correction. Teflon bombs were used for the decomposition of samples at 190° with a mixture of hydrochloric, nitric and perchloric acids. The standards were aqueous solutions of sodium metavanadate and nickel ammonium sulphate at an acidity similar to that of the test solutions. Blanks were obtained by treating pure paraffins in the same way to give a similar matrix. The metals were determined, in an argon atmosphere, at the resonance wavelengths 318.5 nm (V) and 232 nm (Ni).

The n.m.r. spectra were measured on a Varian-A60 spectrometer, with tetramethylsilane as internal standard.

Table 1. Rheological and compositional change in treated asphalts

Property	Asphalt		
	Untreated	Trichloro-ethylene-treated	Trichloro-ethane-treated
Softening point, °C	50	54	62
Penetration at 25°C (100/5)	52.3	44.3	42.7
Petrolenes, % w/w			
Saturates	16.5	13.0	10.6

Polar aromatics	32.0	33.0	35.0
Asphaltenes, % w/w	11.5	20.3	21.8

RESULTS AND DISCUSSION

To find whether the consistency of asphaltic materials has changed, rheological properties such as softening point and penetration are usually measured. Differences in these properties for trichloroethylene- and trichloroethane-treated asphalts are given in Table 1 along with the properties of untreated asphalt, as reference. The increase in softening point and decrease in penetration are indicative of hardening in the treated asphalts. The asphalt recovered from trichloroethane is much harder than that recovered from trichloroethylene. Table 1 also gives the relative proportions of the major fractions of the asphalts. The effect of the chlorinated solvents is manifested by the decrease in saturates and naphthene-aromatics, slight increase in polar aromatics and substantial increase in asphaltenes. The effect is more pronounced with trichloroethane.

Investigation of the chemical characteristics of the complex matrix of whole asphalts is undoubtedly difficult. To obtain useful results more easily, only the asphaltic fractions were investigated. The change in their carbon and hydrogen content is shown in Table 2. The slight increase in the C/H ratio for all fractions in going from untreated asphalt to trichloroethylene-treated to trichloroethane-treated asphalts reflects the chemical changes that might have taken place during the extraction with chlorinated solvents. The reactions most likely to be responsible for such changes are partial cyclization of saturates and aromatization of the naphthenes formed and of those already present. The latter reaction may offer an explanation for the decrease in naphthene-aromatic fraction (Table 1), which is due to aromatization of the naphthenes present in that fraction.

The structural changes in the asphaltic fractions were examined by n.m.r. spectroscopy. The chemical shifts for hydrogen, seen in the spectra of saturates (Fig. 1) are: H_a, 0.88; H_b, 1.23; H_c, 2.35 (untreated asphalt)–2.50 (treated asphalts); H_d, 7.33 ppm. Signals of type a are assigned to the CH_3-groups of saturated hydrocarbons or side-chains farthest from aromatic rings, whereas signals b and c represent CH_3, CH_2 or CH-groups of saturated hydrocarbons, or side-chains that are β and α, respectively, to aromatic rings. Signals of the type d are due to aromatic protons.

The decrease in signals a and b for the recovered asphalts is accompanied by a slight increase in signals c and d. Corresponding changes in the integrated signals were observed. These spectral differences were interpreted as due to a decrease in both side-chain length and degree of substitution on aromatic rings.[7] The change in integrated signal with treatment of the asphalts was taken to imply a decrease in the total hydrogen content of the saturates in the treated asphalts. This indicates that the composition of the samples shows a trend during extraction and recovery, for conversion of saturates into more condensed ring structures.

The n.m.r. spectra of the other components showed similar patterns revealing increased cyclization and aromatization. The spectra of the asphaltenes separated from trichloroethane-treated asphalt showed more increase in signal d than any other fraction, reflecting a higher degree of aromatization.

Analysis showed that chlorine appears to be incorporated in the fractions from the treated asphalts. The results, in terms of Cl/H ratio, are listed in Table 2. The higher ratio for polar aromatics than for asphaltenes is consistent with the higher aromaticity of the latter fraction. The data suggest that a free radical chlorination may occur during the extraction. The notable hardness of the treated asphalts and the significant increase in their content of asphaltenes can be explained as due to free radicals coupling with other

Table 2. Change in carbon–hydrogen content and incorporation of chlorine in components of treated asphalts

Components	Asphalt

free radicals or with neutral species, producing high molecular-weight materials in either reaction.

An esr investigation on the role of radicals in the aging of coal liquids[8] showed that some oil components were converted into asphaltenes during aging. Those components were rich in free spins and free radicals were also characterized in the asphaltenes formed. Another esr study has reported that the concentration of free radicals was observed to increase with increasing degree of cyclization and aromatization in asphaltenes.[9] These findings suggest that the increase in the content of asphaltenes and hence in the hardness of the recovered asphalts is very probably due to increased aromaticity and to combination of free radicals with neutral species.

Although it has been indicated that characterization of petrolenes contributes a great deal more toward characterizing the whole asphalt,[10] asphaltenes have recently been reported as significant in characterizing asphalts, and hence parent crudes, by means of their trace metal content.[11] Accordingly, analysis for vanadium, nickel and nitrogen (since the two metals mostly occur as metalloporphyrins in oils *etc.*) might help to give a composite picture of the structure of the whole asphalt. The effect of chlorinated solvents on trace-element content should therefore also be considered in attempts to detect any structural differences between the original and treated asphalts. The analytical data are given in Table 3. Each metal concentration is an average of five results and the relative standard deviation ranges from 5% for Ni to 7% for V. Recovering the asphalts from the chlorinated solvents decreased the levels of these elements, the effect of trichloroethane again being greater than that of trichloroethylene. The decrease in the trace metal content is associated with decrease in nitrogen content, indicating that during the course of extraction and recovery, the prophyrin content and consequently the level of porphyrin–metal complexes decrease. This is in agreement with the fact that a significant proportion of the metallic constituents of petroleum is relatively volatile.[12] The effect is particu-

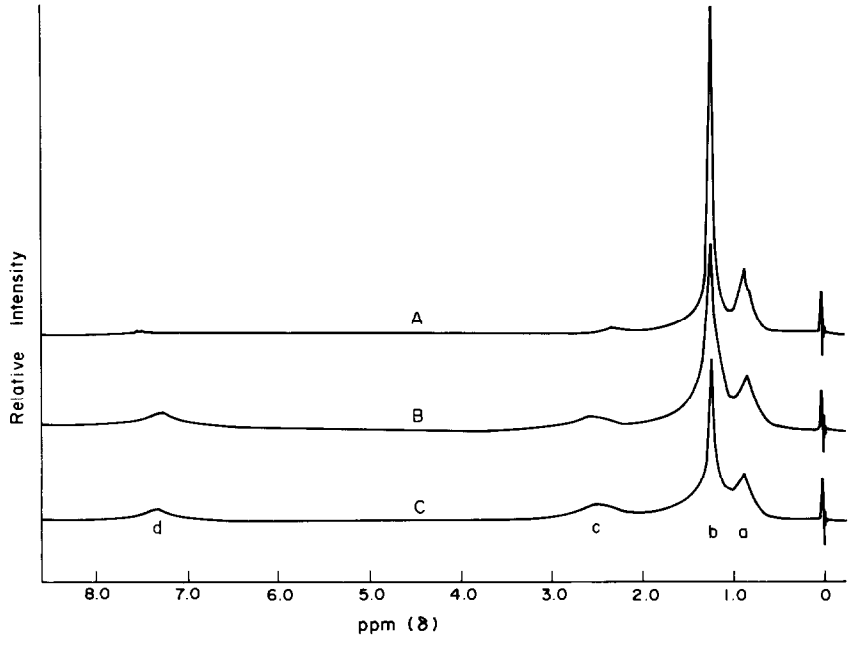

Fig. 1. n.m.r. spectra of saturated fractions of asphalts: A, untreated; B, trichloroethylene-treated; C, trichloroethane-treated.

larly apparent in the asphaltenes, for which the V/Ni index is comparable despite the variation in the individual concentrations of the two metals. The marked difference in V/Ni ratio between the naphthene-aromatics and polar aromatics suggests that the vanadium compounds are much more volatile than the nickel compounds in these fractions, whereas there is little difference for those in the asphaltenes. The V/Ni ratio may therefore be a significant characteristic for asphaltic heavy-end fractions and should perhaps be related to the study of asphalt composition.

CONCLUSIONS

Extraction of asphalts from pavement samples with trichloroethylene or trichloroethane usually causes a change in their rheological and chemical properties, rendering them markedly harder. Such changes are undesirable as they will certainly interfere in investigation of the effect of aging on the properties of asphalts.

A SOLVENT EXTRACTION–SPECTROPHOTOMETRIC DETERMINATION OF BISMUTH(III) AS TETRA-n-BUTYLAMMONIUM TETRAIODOBISMUTHATE

KIYOSHI HASEBE and MITSUHIKO TAGA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

(*Received* 3 *February* 1982. *Revised* 1 *July* 1982. *Accepted* 13 *July* 1982)

Summary—A solvent extraction–spectrophotometric method has been developed for determination of bismuth in the form of tetra-n-butylammonium tetraiodobismuthate(III). The effects of pH, the concentrations of tetra-n-butylammonium and iodide ions, and the nature and amount of the organic solvent have been studied. Tetra-n-butylammonium was found to be the most useful cation for extraction of tetraiodobismuthate with chloroform, giving quantitative extraction. The optimum pH is <3, and the extracted species is stable for at least a day at room temperature. Bismuth can be determined at the $10^{-5}M$ level in aqueous solution, the relative standard deviation being 1.7%.

Bismuth compounds are used in pharmaceuticals and cosmetics, but there are a few reports on determination of bismuth in these materials.

The reaction between iodide and bismuth(III) in aqueous solution has been discussed in the literature[1,2] but reactions between the tetraiodobismuthate anion and high molecular-weight cations have been comparatively little studied. Buděšínský and Vaníčková[3,4] have used tetraiodocadmate(II) and tetraiodobismuthate(III) (BiI_4^-) as counter-ions for ion-pair formation with organic bases such as caffeine, hexamethylenetetramine and antipyrine, and have determined these organic compounds in this way gravimetrically. Matsuo *et al.*[5] have also used the ion-pair complex of BiI_4^- with tetradecyldimethylbenzylammonium ions for the determination of bismuth. Methods involving ion-pair formation are very useful because they can provide simultaneous concentration and separation of chemical species from the matrix. The present work aimed at finding the most suitable and effective counter-ion for the separation and determination of bismuth by extraction of a BiI_4^- ion-association complex.

EXPERIMENTAL

Reagents and materials

The bismuth solution was prepared from analytically pure $Bi(NO_3)_3 \cdot 5H_2O$ and standardized complexometrically with Xylenol Orange as indicator. All solvents were purified according to Weissberger.[6] Analytical-reagent grade potassium iodide, tetra-n-butylammonium iodide (Bu_4NI), cetylpyridinium chloride, and Zephiramine® (benzyldimethyltetradecylammonium chloride, Dojin Chem. Co.) were used without further purification. All the other chemicals were of analytical-reagent grade. Two kinds of medical cream were used as test samples.*

*The sale of creams containing bismuth salts is now prohibited by law in Japan.

Apparatus

Absorbances were measured on a Shimadzu UV-200 double-beam spectrophotometer with 1-cm glass cells. A Hitachi-Horiba glass-electrode M-5 pH-meter was used.

RESULTS AND DISCUSSION

Effect of pH and acid concentration

At pH >3, there is a decrease in extraction yield with increasing pH, probably because of precipitation of bismuth as hydroxo-species.[7] At pH <3 there is no shift in the wavelength for maximum absorption (λ_{max}) and the absorbance at λ_{max} remains constant.

Matsuo *et al.*[5] used Zephiramine as counter-ion for ion-pair formation with BiI_4^- and reported that the absorbance of the methylene chloride extract remained unchanged even when the extraction was from an aqueous solution of pH 5. We also have studied various high molecular-weight ions. Zephiramine, cetyltrimethylammonium, or cetylpyridinium easily form emulsions with tetraiodobismuthate(III) and chloroform, and difficulties arise in separation of the phases. On the other hand, when Bu_4N^+ is used as the counter-ion there is a clean separation of the two layers and the absorbance is reproducible. Tetramethylammonium, which has smaller formula weight than Bu_4N^+, gives a lower molar absorptivity, probably because of the difference in molecular cross-section. The pH is not critical provided it is not above 3.

Effect of Bu_4N^+ concentration

For concentrations of bismuth(III) and iodide of $5 \times 10^{-5}M$ and $0.1M$, respectively, in the aqueous phase, the absorbance of the extract is constant if the Bu_4N^+ concentration is more than $7 \times 10^{-4}M$. Therefore, the concentration of Bu_4N^+ should be at least 14 times the concentration of bismuth(III).

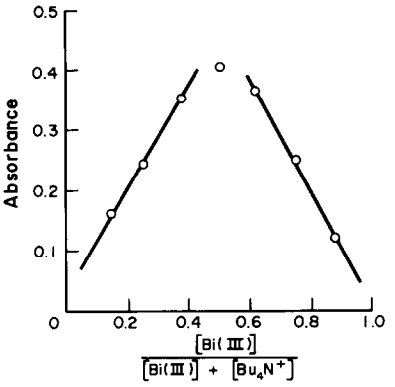

Fig. 1. Continuous variations plot. $[Bi(III)]_{aq} + [Bu_4NI]_{aq} = 8.0 \times 10^{-5}M$; $[KI]_{aq} = 2 \times 10^{-2}M$; pH 0.90. Volume of aqueous phase, $V_{aq} = 10$ ml; volume of organic phase, $V_{org} = 5.0$ ml; wavelength, $\lambda_{max} = 490$ nm.

Composition of the ion-pair complex

The continuous variations method with measurement at λ_{max} (490 nm), showed that a 1:1 complex was formed (Fig. 1). The small absorbance observed even at zero mole fraction of bismuth might be due to formation of $Bu_4N^+I_3^-$, some iodide being oxidized to I_3^- by contaminants. This oxidation reaction can be satisfactorily eliminated by the addition of phosphinic acid as a reducing agent.[8,9] A similar result was obtained by the mole-ratio method. The ion-pair complex, $Bu_4N^+ \cdot BiI_4^-$ predominates under the given conditions, making it advantageous for analytical use.

Organic solvent

Matsuo *et al.*[5] used methylene chloride for the extraction, but this solvent is much more volatile than the other solvents, and also more difficult to handle than chloroform, 4-methyl-2-pentanone (MIBK), *etc.* However, chloroform was chosen rather than MIBK as the extraction solvent because of the good extraction yield and ease of handling.

Effect of the phase-volume ratio

When other conditions were kept within the optimal ranges, the absorbance was almost independent of the aqueous:organic phase-volume ratio if this was less than 12, but increased with increasingly higher ratios. This is attributed to dissolution of some of the chloroform in the aqueous phase, thus decreasing the effective volume of the chloroform extract. Therefore the volume ratio should be less than 12. However, if the water used is presaturated with chloroform there should be less loss of the solvent.

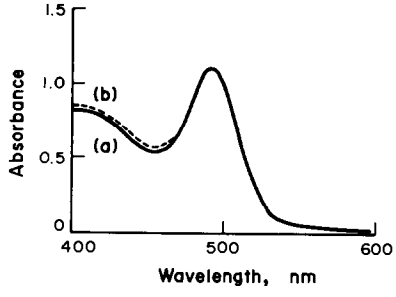

Fig. 2. Absorption spectra of $[BiI_4^-][Bu_4N^+]$ complex in chloroform extracts. Conditions: $[Bi(III)]_{aq} = 5.0 \times 10^{-5}M$; $[KI]_{aq} = 2.0 \times 10^{-2}M$; $[Bu_4NI]_{aq} = 2.5 \times 10^{-3}M$; $[H_3PO_2]_{aq} = ca.\ 1\%$; $V_{aq} = 25$ ml; $V_{org} = 5.0$ ml; pH 1.0. (a) Extract *vs.* reagent blank. (b) Extract *vs.* $CHCl_3$.

Effects of shaking time and standing time

The absorbance of the extract remained constant for shaking times from 30 sec to 6 min (at ~250 strokes/min), and at room temperature showed no change with storage time of up to a day. The yield in a single extraction (shaking for 3 min) was almost quantitative, 98% for a volume ratio of 5:1. A second extraction makes the yield completely quantitative.

Absorption spectra

The absorption spectrum of $Bu_4N^+ \cdot BiI_4^-$ in chloroform extracts is shown in Fig. 2. Beer's law is obeyed up to an absorbance of 1.55 for $7.00 \times 10^{-5}M$ bismuth(III) in the aqueous phase by using chloroform extraction. The corresponding linear regression equation and the coefficient of correlation, r, are

$$\text{Absorbance} = 0.0106X + 0.0013$$
$$r = 0.999$$

where X is the weight (μg) of bismuth extracted into 5.0 ml of chloroform. The conditional molar absorptivity, found by using $2.00 \times 10^{-5}M$ bismuth solution was 1.13×10^4 l.mole^{-1}.cm^{-1} at 490 nm in chloroform (*cf.* 8.2×10^3 l.mole^{-1}.cm^{-1} at 340 nm in aqueous solution[10]).

Effect of foreign ions and materials

Several cosmetics such as skin creams and nail enamels may contain bentonite, silicic acid, aluminium oxide, calcium oxide, magnesium oxide and so on. However, the presence of these materials in 1000-fold concentration did not interfere with the measurement of bismuth, because they did not react with iodide to form a corresponding complex anion, but Hg(II), Cd(II) and Pb(II) interfered with determination of bismuth.

Elimination of organic components

Skin creams usually contain various organic components, including beeswax, white vaseline, isopropyl myristate, glycerol monostearate and so on. In order to determine bismuth in the creams, we had to eliminate these organic compounds because they interfered in formation of the ion-pair complex. Attempts to extract the inorganic compounds into an aqueous phase at pH 1 from solutions of the samples in n-hexane, diethyl ether or chloroform failed because some of the organic compounds also dissolved in the aqueous phase and then interfered with formation of the ion-pair complex. Thus, we removed the organic compounds by a wet-combustion procedure; the

Table 1. Recovery of bismuth added to skin creams (free from bismuth salts) prior to wet combustion; single extraction

Run	Bismuth added, μg	Found, μg	Recovery, %
1	52.3	51.2	98.0
2	52.3	49.8	95.3
3	52.3	50.7	97.1
4	104.5	101.4	97.1
5	104.5	101.9	97.5
6	104.5	102.4	98.0

Sample size: 1 g of skin cream. Aqueous phase 25 ml, organic phase 5 ml.

Sample*, g	Absorbance	Found, μg	Content, μg/g
0.4801	1.100	103.4	215
0.5091	1.200	112.8	222
0.2532	0.605	56.9	225
0.2558	0.600	56.4	220

*Weight of wet sample.

sample was easily decomposed with a mixture of concentrated nitric acid (10 volumes) and perchloric acid (1 volume). The decomposition was very slow if only the nitric acid was used, but the sample decomposed rapidly with the acid mixture. The caramel-like residue was easily decomposed by further addition of nitric acid.

Procedure

Weigh the sample (~1 g) accurately into a porcelain evaporating dish. Add concentrated nitric acid (10 ml) and perchloric acid (1 ml) and about 0.1 g of potassium sulphate to avoid spitting during the heating. Heat on a sand-bath until the mixture becomes dry. Repeat the treatment with the acid mixture 3 times. Dissolve the final residue in 10 ml of 2*M* nitric acid and transfer the solution into a separatory funnel. Add 2*M* potassium iodide (0.2 ml), 50% v/v phosphinic acid solution (0.5 ml), 0.1*M* Bu_4N^+I (0.25 ml), and chloroform (10 ml), and shake the funnel vigorously for 3 min. Measure the absorbance of the extract at 490 nm *vs.* chloroform. Determine the amount of bismuth by means of the calibration graph or the linear regression equation.

Recovery and sample analysis

Results obtained by the procedure described are given in Tables 1 and 2. The 95% confidence limits[11] calculated from the values in Table 2 are 213–227 μg.

A computational approach to the spectrophotometric determination of stability constants—II: application to metalloporphyrin-axial ligand interactions in non-aqueous solvents: D. J. LEGGETT, S. L. KELLY, L. R. SHIUE, Y. T. WU, D. CHANG and K. M. KADISH. (29 September 1982)
Determination of traces of osmium by the catalysed hydrogen peroxide–cyanocuprate(I) reaction: I. N. C. LING and G. SVEHLA. (1 October 1982)
Spectrophotometric determination of formaldehyde in air: PRATIMA VERMA and V. K. GUPTA. (1 October 1982)
Oxidimetric estimation of chloroamphenicol with aromatic sulphonyl monohaloamines: B. JAYARAM and S. M. MAYANA. (4 October 1982)
A novel rapid method for the preparation of manganese(IV) in solution: U. MURALIKRISHNA, K. SUBRAHMANYAM and MANNAM KRISHNAMURTHY. (4 October 1982)
A quantitative separation of lead, phosphate and vanadate: T. S. B. NARASARAJU, P. V. R. RAO and S. K. GUPTA. (4 October 1982)
Gravimetric determination of palladium with 2,3,4-pentanetrione trioxime: J. CACHO, M. A. LACOMA and C. NERIN. (6 October 1982)
Selective extraction and spectrophotometric determination of palladium with 2,3,4-pentanetrione trioxime: J. CACHO, C. NERIN and M. A. LACOMA. (6 October 1982)
Selective sorption and separation of some cations on titanium tungstoarsenate gel: S. K. SRIVASTAVA, SATISH KUMAR, C. K. JAIN and SURENDER KUMAR. (7 October 1982)
A titrimetric method for the determination of thiocarbonate sulphur in the presence of sulphite, thiosulphate and thiocyanate: K. SINGH and B. A. FODEKE. (7 October 1982)

Talanta. Vol. 29, p. i. 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Voltammetric study of boldine on a stationary platinum electrode: LUIS J. NUNEZ-VERGARA and J. A. SQUELLA. (8 July 1982)

Spectrophotometric determination of copper after separation by adsorption of its 1-phenyl-4,4,6-trimethyl-(1H,4H)-2-pyrimidinethiol complex on naphthalene: A. WASEY, R. K. BANSAL, M. SATAKE and B. K. PURI. (8 July 1982)

A highly sensitive spectrophotometric method for determination of trace amounts of arsenic in water: QIAN-FENG WU and PENG-FEI LIU. (9 July 1982)

A kinetic study of the oxidation of phenols and chlorophenols by metaperiodate: N. G. BUCKMAN, R. J. MAGEE and J. O. HILL. (9 July 1982)

An improved radiochemical procedure for low-level measurements of americium in environmental matrices: S. BALLESTRA and R. FUKAI. (9 July 1982)

Liquid-membrane dicyanoargentate-ion electrodes based on quaternary ammonium sites: YU RU-QIN and HUANG SHA-SHENG. (14 July 1982)

Application of tetraethylenepenta-amine (tetren) to the separation of metal ions on Chelex 100 chelating resin: KRYSTYNA BRAJTER and IWONA MIAZEK. (14 July 1982)

Studies on usefulness of cellulose ion-exchange resin (Cellex P) with phosphonic groups to separate metal ions—I: KRYSTYNA BRAJTER and IWONA MIAZEK. (14 July 1982)

Studies on usefulness of cellulose ion-exchange resin with phosphonic groups to separate metal ions—II: Separation of metal ions on Cellex P in presence of glycine as complexing agent: KRYSTYNA BRAJTER, URSZULA CIBOROWSKA and IWONA MIAZEK. (14 July 1982)

Spectrophotometric determination of gallium(III) after solvent extraction of its chloro-complex with Rhodamine B: YUKO HASEGAWA, TETSUYA INAGAKE, YUJI KARASAWA and ATSUSHI FUJITA. (15 July 1982)

A sensitive and specific resin-bead test for histidine, and its spectrophotometric determination with potassium bromate as reagent: K. G. VARSHNEY, S. ANWAR and S. Q. QURESHI. (16 July 1982)

Talanta, Vol. 29, p. I, 1982
Pergamon Press Ltd. Printed in Great Britain

OBITUARY

R. BELCHER
(1909–1982)

Ronald Belcher, Professor Emeritus, Birmingham University, died on 29 June 1982 after being ill for some months.

He was born in Nottingham in 1909. As a young assistant in coal chemistry research at Sheffield University from 1927, he was involved in analysis and was greatly stimulated by a period of training in microchemical techniques at the Pregl Laboratory in Graz. He studied part-time for the Associateship of the then Institute of Chemistry, passing the examinations in 1939 and being elected to the Fellowship in 1942.

From these modest beginnings, an interest in teaching analytical chemistry was aroused by a spell on the staff at Rotherham Technical College in the early 1940s and from 1946 at Aberdeen University. In 1948 he moved to Birmingham University and with the help of a few young colleagues, fired by his own enthusiasm, quickly established a large research team. Classical type investigations on indicators, etc., broadened over the ensuing thirty years to cover a host of subjects such as new organic reagents, submicro methodology, gas chromatography of metal chelates, membrane electrodes, kinetic methods, MECA spectroscopy.

Some 500 research papers, books and monographs testify to the prodigious work of Belcher, who not only inspired many from within Britain but attracted considerable numbers of postgraduate and postdoctoral students from abroad. Former pupils and collaborators now occupy prominent positions in various countries. He received the D.Sc. degree in 1955 and was appointed Professor of Analytical Chemistry in 1959.

Belcher's influence extended to active involvement in the affairs of numerous national and international bodies, notably the former Society of Analytical Chemistry and new Royal Society of Chemistry and in the International Union of Pure and Applied Chemistry. He received many honours and was invited to lecture extensively throughout the world. A fuller account of his career was given in *Talanta*, 1969, **16**, 757.

He will be missed, not least for his leadership as Chairman of the Editorial Board of *Talanta*, the journal he was instrumental in starting.

PAPERS RECEIVED

Preconcentration of copper from water by adsorption on zinc dust for determination by atomic-absorption spectrometry: S. A. TARAFDAR and M. RAHMAN. (7 June 1982)
Determination of silver in ores, concentrates, zinc process solutions, copper metal and copper-base alloys by atomic-absorption spectrophotometry after separation by extraction of the tribenzylamine–silver bromide complex: ELSIE M. DONALDSON. (7 June 1982)
Dosage spectrophotométrique des nitrosamines: Etude de differents paramètres analytiques: Z. EL ASSAF and M. HAMON. (8 June 1982)
Measurements of organic lead in air—A review: W. R. A. DE JONGHE and F. C. ADAMS. (8 June 1982)
Synthesis, separation by T.L.C., and analytical properties of the isomeric oximes derived from 2-amino-5-chlorobenzophenone: G. RAURET and J. S. MESTRES. (8 June 1982)
Benzylmalondihydroxamic acid as an indicator for complexometric titrations of iron(III): WALTER KOSMUS, KURT KALCHER, REINHARD PREININGER and JOHANNES RABER. (9 June 1982)
Determination of small amounts of Pr(III) and Nd(III) with 1-(2-pyridylazo)-naphthol-2 in aqueous ethanol medium: S. C. LAVALE and K. S. PITRE. (10 June 1982)
Determination of traces of selenium in heat-resisting alloys by graphite-furnace atomic-absorption spectrometry after co-precipitation with arsenic: OSAMU KUJIRAI, TAKESHI KOBAYASHI, KUNIKAZU IDE and EMIKO SUDO. (11 June 1982)
A generalized theory of quantitative analysis of multi-component ampholyte/acid, base/systems by stepwise potentiometric titration: F. BILLES and A. TÓTH. (14 June 1982)
Effect of calcium chloride and pH on some interactions of uranium(VI) with humic acid and bentonite in water: C. L. CHAKRABARTI, W. C. LI, K. NELSON and S. GUST. (14 June 1982)
Hydroxide complexes of lanthanides—V: Erbium(III) in perchlorate medium: J. KRAGTEN and L. G. DECNOP-WEEVER. (15 June 1982)
Hydroxide complexes of lanthanides—VI: J. KRAGTEN and L. G. DECNOP-WEEVER. (15 June 1982)
The role of human hair in recording the body zinc level, and the significance of hair sampling in clinical chemistry: WIEJIE CHEN and SONGGUANG REN. (16 June 1982)
Estimation of chloride in oxidizing media by use of ion-selective electrodes: G. SUBRAMANIAN, NAVIN CHANDRA and G. PRABHAKARA RAO. (16 June 1982)
Collection of metals in the atmosphere and their measurement by atomic-spectroscopy: A review: JOSEPH SNEDDON. (26 February 1982)
Determination of platinum in biological material by differential pulse polarography—I: Analysis in urine following complexation with sodium diethyldithiocarbamate: O. VRANA, V. KLEINWÄCHTER and V. BRABEC. (18 June 1982)
Spectrofluorimetric determination of traces of perchlorate by extraction with Rhodamine 6G: S. JAYA, T. PRASADA RAO and T. V. RAMAKRISHNA. (18 June 1982)
Synthesis and ion-exchange properties of amorphous, thermally stable stannic silicophosphate ion-exchanger: Separation of UO_2^{2+} from VO^{2+} and Zn^{2+}; Cu^{2+} from Al^{3+} and Ni^{2+}: S. D. SHARMA and B. C. LATHE. (21 June 1982)
Alkalimetric determination of α-amino-acids: SUMAN MUKHIJA, JYOTI TALEGAONKAR and K. S. BOPARAI. (21 June 1982)
Ion-exchanger ultraviolet spectrophotometry for uranium(VI): HIROHIKO WAKI and JOHANN KORKISCH. (21 June 1982)
Determination of alpha-emitting uranium isotopes in soft tissues by solvent extraction and alpha spectrometry: NARAYANI P. SINGH and MCDONALD E. WRENN. (19 May 1982)
Purified reagents for trace metal analysis: JOHN R. MOODY and ELLYN S. BEARY. (23 June 1982)
Purification of analytical reagents: J. W. MITCHELL. (23 June 1982)
Studies on the extraction of phosphomolybdate by polyether foam: ANJUM S. KHAN and A. CHOW. (25 June 1982)
Simultaneous determination of several trace metals by ASV after preconcentration by adsorption on C_{18}-bonded glass beads as PADAP complexes: SHIGERU TAGUCHI, TAKAYUKI YAI, YASUKO SHIMADA, KATSUMI GOTO and MINORU HARA. (30 June 1982)
Determination of the trimethylselenonium ion in urine by graphite-furnace atomic-absorption spectrometry: NORITAKA OYAMADA and MUTSUO ISHIZAKI (30 June 1982)
Ion-exchange properties of ceric molybdate and ceric tungstate: R. K. SRIVASTAVA and C. K. SAINI. (30 June 1982)
The use of an immobilized glucose oxidase cation-exchange resin column in the determination of glucose: NOBUTOSHI KIBA, KASUSHI ISHIDA, MASAKI TSUCHIYA and MOTOHISA FURUSAWA. (5 July 1982)
Determination of nitrite and mixtures of bromide and iodide with *o*-iodosobenzoate: KRISHNA K. VERMA and ANIL K. GULATI. (5 July 1982)

Talanta, Vol. 29, p. i, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Flow-injection analysis of oxidizable species with reverse-pulse amperometric detection: JOSEPH WANG and HOWARD D. DEWALD. (10 May 1982)

Optimization of instrumental parameters for square-wave anodic stripping voltammetry: E. B. BUCHANAN, JR., and D. D. SOLETA. (10 May 1982

A new method of caesium determination by thermal decomposition of caesium tetrathiocyanatobismuthate(III): ANDRZEJ CYGAŃSKI and TOMASZ MAJEWSKI. (11 May 1982)

Loss of mercury from dilute mercury(II) solution: Effect of bubbling gas through the solution: MASARU KIMURA and TOMOKO ARIKADO. (11 May 1982)

Spectrophotometric determination of nitrite: S. T. SULAIMAN and D. AMIN. (17 May 1982)

Donor–acceptor complexes in chemical analysis—I: Nanogram detection of *m*-dinitroaromatics. A re-evaluation of the spot-test based on the Janovsky reaction by conventional, resin and novel spot-tests: S. ASHFAQ NABI, SEEMA HAQUE and PUSHKIN M. QURESHI. (17 May 1982)

Système d'analyse et d'acquisition de données cinétiques piloté par microprocesseur: J. C. FONTAINE, P. LEVOIR and J. J. MEYER. (25 April 1982)

Detection and determination of cyanide ion—a review: H. B. SINGH, SUMAN MAHESHWARI and H. L. BAMI. (18 May 1982)

Indole as a reagent for nitrite in aqueous solution: S. A. RAHIM, N. A. FAKHRI and W. A. BASHIR. (18 May 1982)

Extraction of tetra-alkylammonium bromides into 1,2-dichloroethane + alkane mixtures: JAN CZAPKIEWICA and ANNA WOLINSKA. (18 May 1982)

Coulometric thermometric titration of halides in molten calcium nitrate tetrahydrate: ISTVÁN J. ZSIGRAI and DEZSÖ B. BARTUSZ. (19 May 1982)

The use of chloranil for the spectrophotometric determination of some tranquillizers and antidepressants: EL-SEBAI A. IBRAHIM, A. S. ISSA, M. A. ABDEL SALAM and M. S. MAHROUS. (20 May 1982)

Hydroxytriazenes as chelating agents in analytical chemistry: A review: D. N. PUROHIT, NIZAMUDDIN and ARUN M. GOLWALKAR. (20 May 1982)

Biosorbent based on mycelium of penicillium chrysogenum: Improvement of sorption efficiency for uranium by treatment with monochloroacetic acid: KABEL POSPIŠILÍK and RUDOLF JÍLEK. (24 May 1982)

Some modes of activation of biosorbent based on the mycelium of penicillium chrysogenum by using titanium compounds: RUDOLF JÍLEK, JOSEF NOVOSAD and KAREL POSPIŠILÍK. (24 May 1982)

An algorithm for reducing storage requirements in computer calculation of chemical equilibria: VIJAY S. TRIPATHI. (25 May 1982)

Coulometric generation of hydrogen ions from the oxidation of mercury in anhydrous acetone: RANDJEL P. MIHAJLOVIĆ and VILIM J. VAJGAND. (26 May 1982)

Determination of the proton ionization constants of oxalic acid and the ultraviolet spectra of the oxalate species for 3*M* perchlorate medium: J. J. CRUYWAGEN and J. B. B. HEYNS. (4 June 1982)

Some observations on the determination of essential minerals in some plant materials by atomic absorption and flame-emission photometry: S. A. THOMAS and M. E. ADIUKU-BROWN. (4 June 1982)

Determination of mercury in presence of chloride by use of the ternary complex Hg(II)/Xylenol Orange/Amberlite LA-2 in non-aqueous media: J. L. PERAL-FENDEZ, R. IZQUIERDO-HORNILLOS, A. CABRERA-MARTIN and R. GALLEGO-ANDREU. (4 June 1982)

Detection and determination of periodate in condensed phosphoric acid medium: N. KRISHNA MURTY and A. V. SURYANARAYANA. (4 June 1982)

Talanta, Vol. 29, p. i, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Spectrophotometric determination of copper with 2,2′-dihydroxy-5,5′-dimethylchalkone-ethylenediamine (DDCE): D. R. GAONKAR, B. K. BRABHAKAR and V. H. KULKARNI. (7 April 1982)
Application of silica gel coated with polyamide crown resin in ion chromatography: MANABU IGAWA, HIROSHI TAKAGI, MASAO TANAKA and TAKEO YAMABE. (7 April 1982)
Some analytical applications of chlorbromamine-B: B. N. USHA, RANGASWAMY and H. S. YATHIRAJAN. (7 April 1982)
Optimized determination and distribution study of mercury in sea-water samples: V. SIMEONOV and G. ANDREEV. (7 April 1982)
Analysis of some synthetic co-polymers from their titration curves in non-aqueous media: S. K. CHATTERJEE, R. L. PANDITH and L. S. PACHAURI. (8 April 1982)
Gel speciation studies using trace-level concentrations of bivalent ions: YVES MERLE and JACOB A. MARINSKY. (13 April 1982)
Spectrophotometric studies of the reactions of pentacyanoferrate(II) complexes with three *N*-heterocyclic aldoximes: NICOLETTA BURGER and VINKA KARAS-GAŠPAREC. (13 April 1982)
Determination of *tert.*-butylhydroquinone in edible oils by differential pulse polarography: N. THUNYAUDOM TONMANEE and V. S. ARCHER. (8 April 1982)
Preconcentration of heavy and rare-earth elements by Donnan dialysis: JAMES E. DINUNZIO, ROBERT L. WILSON and F. PETER GATCHELL. (15 December 1981)
Potentiometric determination of certain α-aminohydroxy-compounds by use of an ammonia gas-sensing electrode: D. P. NIKOLELIS, C. E. EFSTATHIOU and T. P. HADJIIOANNOU. (14 April 1982)
Spectrophotometric determination of NO_2 in the working atmosphere: B. G. ZHELYAZKOVA, P. B. VARDEV and N. D. YORDANOV. (15 April 1982)
Neutron-activation analysis for sodium in biological samples by using an Am-Be source: D. V. PARWATE, S. K. MUKERJEE and A. N. GARG. (15 April 1982)
Spectrophotometric determination of micro amounts of nitrite in water and soil: QIAN-FENG WU and PENG-FEI LIU. (20 April 1982)
The origin of systematic errors of background measurements in Zeeman atomic-absorption spectrometry: H. MASSMANN. (3 April 1982)
Preparation and characterization of graphite modified metallic electrodes: The graphite spray electrode: J.-M. KAUFFMANN, A. LAUDET, G.-J. PATRIARCHE and G. D. CHRISTIAN. (22 April 1982)
Determination of procaine benzylpenicillin: NAYANA KANE and K. S. BOPARAI. (27 April 1982)
A method of separation of molybdenum by extraction of Mo(VI)–ferron with isoamyl alcohol: USHA DHINGRA and L. R. KAKKAR. (27 April 1982)
Extractive spectrophotometric determination of trithiocarbonates and mercaptans (through trithiocarbonate formation) with bismuth(III); BALBIR CHAND VERMA, SAROJ CHAUHAN and MALKIAT SINGH. (28 April 1982)
The stability of oxovanadium(IV)–propionate, –butyrate and –isobutyrate complexes in aqueous solution: ADRIANA LORENZOTTI, DANTE LEONESI, AUGUSTO CINGOLANI and ANGELO TUROLLA. (28 April 1982)
Conductometric titrations of mixtures of phenols and carboxylic acids in 2-methoxyethanol: ELISA NEVIANI GILIBERTI, CARLO PRETI, LORENZO TOSSI and GIUSEPPE TOSI. (28 April 1982)
Spectrophotometric determination of carbon monoxide with ruthenium(II) octaethylporphyrin: A. CORSINI, A. CHAN and H. MEHDI. (19 April 1982)
An application of computers in analytical chemistry: The calculation of the optimum acidity of reaction between metal ions and organic reagents in solution: S. W. ZHANG, F. Y. PAN and J. YAO. (29 April 1982)
Contamination as a limiting parameter in trace analysis: L. KOSTA (29 April 1982)
Kinetic detection of the end-point in titrations involving slow reactions: Direct titration of polyhydroxy-compounds with periodate: C. E. EFSTATHIOU and T. P. HADJIIOANNOU. (30 April 1982)
Simultaneous fluorescence, photoacoustic, and two-photon photoionization detection for liquids in a cuvette: E. VOIGTMAN and J. D. WINEFORDNER. (7 May 1982)

Talanta, Vol. 29, p. I, 1982
Pergamon Press Ltd. Printed in Great Britain

THE LOUIS GORDON MEMORIAL AWARD

The Editorial Board and Publisher of *Talanta* take great pleasure in announcing that the Louis Gordon Memorial Award for 1981 (for the paper judged to be the best written of those appearing in *Talanta* during the year) will be made to Dr. Lars Kryger, of Aarhus University, Denmark, for his paper "Interpretation of Analytical Chemical Information by Pattern Recognition Methods—A Survey" (*Talanta*, 1981, **28**, 871).

Talanta. Vol. 29, p. i. 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Metal complexes of cyclic tetra-azatetra-acetic acids: RITA DELGADO and J. J. R. FRAUSTO DA SILVA. (5 February 1982)
Simultaneous determination of bromide and chloride in natural waters by ion-exchange chromatography and direct potentiometry with an ion-selective electrode: H. AKAIWA, H. KAWAMOTO and M. OSUMI. (8 February 1982)
Synthesis of some new *ortho*-thioazo ligands and evaluation of their metallochromic properties: D. L. PRINGLE, M. T. MOHABBIS, M. H. MAHONEY, C. H. SOTAK and J. M. SULLIVAN. (8 February 1982)
New spectrophotometric method for determination of cefazolin: P. PAPAZOVA, P. R. BONTCHEV and M. KACAROVA. (9 February 1982)
The analysis of copper(II) by fluorescence. A review: M. ROMAN, A. FERNANDEZ-GUTIERREZ and A. MUÑOZ de la PEÑA. (9 February 1982)
A survey of the information on co-ordination compound features that can be gained by the electroanalytical approach: GINO BONTEMPELLI, MILLA ANDREUZZI-SEDEA and MARIO FIORANI. (10 February 1982)
Formation constants and thermodynamic functions for some tervalent rare-earth metal complexes with *p*-sulphosalicylidene sulphanilamide: G. P. SENGUPTA and C. R. BERA. (12 February 1982)
The spectrophotometric study of the europium–Xylenol Orange complex and the simultaneous chelometric determination of europium and zinc: CHENG-MIN LIU, XI-TSENG CHIH and SHU-CHUAN LIANG. (18 February 1982)
Study of semicarbazones and thiosemicarbazones derived from 1,2-napthoquinone, as acid–base indicators: Evaluation of their transition limits through the chromaticity co-ordinates: A. IZQUIERDO, E. BOSCH and V. RODRIGO. (19 February 1982)
Note on the uranyl complexes of EDTA: M. LURDES, S. S. GONÇALVES, A. M. ALMEIDA MOTA and J. J. R. FRAUSTO DA SILVA. (19 February 1982)
Solid-state halide-selective electrodes: Studies in quaternary ammonium halide solutions with special reference to the determination of surfactants: H. GOMATHI, G. SUBRAMANIAN, NAVIN CHANDRA and G. PRABHAKARA RAO. (22 February 1982)
Determination of tin in poly(vinyl chloride) by atomic-absorption spectroscopy: JAMIL ANWAR and I. L. MARR. (22 February 1982)
Determination of barium in sulphide ores, concentrates and other geological samples by flame atomic-absorption spectrometry: K. D. SHARMA. (23 February 1982)
Validation of the sulphur concentration of selected iron-base NBS standard reference materials by isotope-dilution spark-source mass spectrometry: R. W. BURKE, P. J. PAULSEN, E. J. MAIENTHAL and G. M. LAMBERT. (16 February 1982)
Ternary complexes of Cu(II) and Ni(II) chelates of EDTA and DCTA with cyanide and ethylenediamine: J. KORSSE, L. A. PRONK, C. VON EMBDEN, G. LEURS and P. W. F. LOUWRIER. (24 February 1982)
Titrimetric microdetermination of certain sulphur-containing organic compounds by oxidation with alkaline potassium permanganate: K. K. TIWARI and R. M. VERMA. (25 February 1982)
Radiochemical determination of cobalt in environmental samples: C. D. JENNINGS and T. M. BEASLEY. (20 December 1981)

Talanta. Vol. 29, p. i, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Synthesis and properties of a chelating resin containing triazolethiol groups: ATSUSHI SUGII, NAOTAKE OGAWA and YOSHIHISA HAGIWARA. (8 January 1982)
Elution and spectrophotometric determination of gold after its separation from non-volatile platinum metals by column extraction chromatography: A. FLIEGER and S. PRZESZLAKOWSKI. (8 January 1982)
A differential photochemical titrimetric method for the estimation of mixtures of thallium(III) and iron(III): S. R. SAGI, K. APPA RAO and M. S. PRASADA RAO. (8 January 1982)
Extractive spectrophotometric determination of antimony with 2-(3,5-dibromopyridylazo)-5-dimethylaminophenol as reagent: GAO JIA-LONG, CHEN TUNG-YUCH and LIU XI-LIN. (11 January 1982)
Ion-exchange separation and atomic-absorption determination of trace elements in silicates: J. P. RAWAT, MASOOD ALAM and M. S. RATHI. (13 January 1982)
Chloroform extraction of ethyl xanthate complexes from sulphuric acid media: ELSIE M. DONALDSON and E. MARK. (13 January 1982)
Determination of rare earths in lanthanum oxide by inductively-coupled plasma emission derivative spectrometry: HAJIME ISHII and KATSUHIKO SATOH. (14 January 1982)
Selenium in environmental water: Determination, concentration levels and speciation: H. ROBBERECHT and R. VAN GRIEKEN. (14 January 1982)
An improved sensitive assay for polonium-210, using a background-rejecting extractive liquid scintillation method: G. N. CASE and W. J. MCDOWELL. (14 December 1981)
Analysis of variance applied to determinations of equilibrium constants: A. BRAIBANTI, F. DALLAVALLE, G. MORI and B. VERONI. (14 January 1982)
Causes and elimination of systemic errors in the determination of iron and cobalt in aqueous solutions in the ng/ml and pg/ml range: K. GRETZINGER, L. KOTZ, P. TSCHÖPEL and G. TÖLG. (14 January 1982)
Sample contamination as source of errors in trace element analyses of biological samples: JACQUES VERSIECK, FABRICE BARBIER, RITA CORNELIS and JULIEN HOSTE. (14 January 1982)
Losses of metabolically incorporated selenium in common digestion procedures for biological material: H. J. ROBBERECHT, R. E. VAN GRIEKEN, P. A. VAN DEN BOSCH, H. DEELSTRA and D. VANDEN BERGHE. (14 January 1982)
The minimization of accuracy risks in voltammetric ultratrace analysis for heavy metals in natural water: LEON MART. (18 January 1982)
The role of radiotracers in the development of trace element analysis: V. KRIVAN. (14 January 1982)
On the digestion of human blood and plasma for the determination of selenium: M. VERLINDEN. (19 January 1982)
Pretreatment studies for the determination of Zn, Cd, Pb, Cu, Sb and Bi in suspended particulate matter and plankton by differential pulse anodic-stripping voltammetry with a hanging mercury drop electrode: G. GILLAIN. (19 January 1982)
Determination of the stability constants of metal complexes of five phosphonic acids: J. L. OWENS and J. L. DAVIS. (4 September 1981)
Change in consistency and composition of trichloroethylene- and trichloroethane-treated asphalts: MA. ABU-ELGHEIT and M. J. IJAM. (21 January 1982)
Derivative hydrodynamic modulation voltammetry: JOSEPH WANG. (21 January 1982)
Determination of copper, cadmium, lead and bismuth in phosphoric acid solutions by atomic-absorption spectrometry after extraction with diethylammonium diethyldithiocarbamate and butyl acetate: B. NIKOLOVA and N. JORDANOV. (21 January 1982)
Separation and quantitation of copper, zinc, cobalt and vanadium by paper chromatography: S. S. JOSHI and R. H. HARDIA. (22 January 1982)
On the storage of the sodium borohydride solution used in the hydride generation–atomic-absorption technique: RAGNAR BYE. (25 January 1982)
Spectrophotometric study of the analytical possibilities of the reactions of phenol with halogens and interhalogens: F. BOSCH and G. FONT. (25 January 1982)
Determination of phosphorus and tungsten in heteropoly acids by EDTA-titration: HIROMU HAYASHI and J. B. MOFFAT. (2 February 1982)
Separation–spectrophotometric determination of Co(II) and Mn(II) in the thiocyanate system: KAMIN KHAN and M. AMIN. (2 February 1982)
Determination of stability constants for binary and ternary complexes of chromium(III): Equilibrium studies with dicarboxylic acids: KORA VENKATA CHALAPATHI, THIRUMALACHAR RAMASAMI, DORISWAMY RAMASWAMY and MUCHI SANTAPPA. (3 February 1982)
Highly sensitive and selective spectrophotometry for determination of silver with Cadion 2B and Triton X-100: WEI FU-SHENG and YIN FANG. (3 February 1982)
A solvent extraction–spectrophotometric determination of bismuth(III) as tetra-n-butylammonium tetraiodobismuthate: KIYOSHI HASEBE and MITSUHIKO TAGA. (3 February 1982)
Influence of colloidal charge on response of pH and reference electrodes: The suspension effect: DONALD P. BREZINSKI. (3 February 1982)

Talanta, Vol. 29, p. i, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Qualitative and semiquantitative determination of nickel in aqueous solution with dimethylglyoxime-loaded foam: A. B. FARAG, A. M. EL-WAKIL and M. S. EL-SHAHAWI. (18 December 1981)
A photometric study of the complexation between Alizarin complexan and Zn(II), Ni(II), Pb(II), Co(II), Cu(II): WU XING and FOLKE INGMAN. (21 December 1981)
Studies on synthetic inorganic ion-exchangers—V: PRITAM SINGH THIND and HARBANS SINGH. (21 December 1981)
Rapid potentiometric titration of iridium(IV) with hydrazine sulphate: JAIM LICHTIG, RUTH L. OLIVEIRA and GRACILIANO O. NETO. (21 December 1981)
The iodometric standardization and biamperometric determination of iridium(IV): JAIM LICHTIG. (21 December 1981)
Structural investigation of a new organic antiseptic (Taurolidine): spectroscopic study of its stability and equilibria in various solvents: F. ERB, N. FEBVAY and M. IMBENOTTE. (22 December 1981)
Formation constant and stoichiometry of the acetonitrile:18-crown-6 complex by nuclear magnetic resonance, Raman and infrared spectroscopy: HARVEY S. GOLD and MICHAEL R. RICE. (10 December 1981)
Analytical use of the kinetics of complex formation: Simultaneous determination of iron and cobalt by differential methods: L. BALLESTEROS OLMO and D. PEREZ-BENDITO. (31 December 1981)
A new graphical method based on stoichiometric dilution for the classification of binary complexes with mole ratio 1:1: HE XI-WEN and DONALD P. POE. (31 December 1981)
Study of the reaction of phenylarsenazo with chromium(III): SUN FU-SHENG. (31 December 1981)
Extraction chromatography using macroreticular polymer beads impregnated with monothiodibenzoylmethane solution: ATSUSHI SUGII, NAOTAKE OGAWA and HISASHI YAMAMURA. (31 December 1981)
Differential pulse polarographic determination of *N*-nitrosoproline in uncooked meat: KIYOSHI HASEBE and JANET OSTER-YOUNG. (1 December 1981)
Differential pulse polarographic determination of orthophosphate in aqueous media: SUE C. HIGHT, FREDRICK BET-PERA and BRUNO JASELSKIS. (7 January 1982)
Sensitive spectrophotometric determination of traces of zirconium with 2-(6-bromo-2-benzothiazolylazo)-5-diethylaminophenol in the presence of sodium lauryl sulphate: CHAO-PING ZHANG, DA-YONG QI and TIAN-ZE ZHOU. (7 January 1982)
Extraction–radiochemical investigation of the ternary ion-association complex of Sb(V) with Thiazolyl Blue (MTT) in strongly acidic solutions: A. V. ALEXANDROV, S. KOSTOVA and J. HÁLA. (7 January 1982)
Trace element analysis by particle and photon induced X-ray emission spectroscopy: B. GONSIOR and M. ROTH. (7 January 1982)
Flow-injection analysis of silicate rocks for total iron and aluminium: TADASHI MOCHIZUKI, YASUHIKO TODA and ROKURO KURODA. (7 January 1982)
An evaluation of cellulose as a substrate for room-temperature phosphorescence: R. P. BATEH and J. D. WINEFORDNER. (7 January 1982)

TALANTA ADVISORY BOARD

S. B. SAVVIN is Professor of Analytical Chemistry in the Vernadsky Institute of Geochemistry and Analytical Chemistry, USSR Academy of Sciences. He was born in 1931 in Moscow. He graduated as an Engineer-Technologist-Chemist from the Mendeleev Institute of Chemical Technology, Moscow in 1953 and received his doctorate in 1968. His research interests are organic reagents and chelate sorbents, their synthesis, analytical application, and theory of analytical action, and also spectrophotometry and luminescence co-ordination chemistry. He has been author or co-author of 300 research papers and some monographs: "Organic reagents of the arsenazo III group" (1971), "Electronic spectra and structure of organic reagents" (1974), etc. Well known are his works on the synthesis of arsenazo III and many of its analogues (2,7-bisazo derivatives of chromotropic acids), which are valuable spectrophotometric reagents for the determination of more than 40 elements. He is head of the laboratory for organic reagents, vice-president of the Analytical Chemical Council of the Academy of Sciences of the USSR, currently a member of the Editorial Boards of *Zh. Analit. Khim.* (USSR) and *Analusis* (France), editor-in-chief of the series of monographs "Analytical Reagents" (USSR Academy of Sciences), and a member of the Commission on analytical reactions and reagents, in the Analytical Division of IUPAC.

TAL. 29/3—A

Talanta. Vol. 29. p. i. 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Applied potential and radiotracer studies on poly(vinyl chloride) matrix ion-selective electrode membranes: B. DOYLE, G. J. MOODY and J. D. R. THOMAS. (11 November 1981)
Analytical properties of α-mercaptophenylacetic acid: A. IZQUIERDO, MA. D. PRAT and M. FILELLA. (11 November 1981)
Application of methopromazine for the extractive spectrophotometric determination of platinum: ANATOL KOJLO and HELENA PUZANOWSKA-TARASIEWICZ. (11 November 1981)
Spectrophotometric and analogue derivative spectrophotometric determination of ultramicro amounts of cadmium with cationic porphyrins: HAJIME ISHII, KATSUHIKO SATOH, YASUHIRO SATOH and HIDEMASA KOH. (13 November 1981)
Determination of uric acid in water by reaction with tetramercurated fluorescein: MIECZYSLAW WROŃSKI. (13 November 1981)
Liquid membrane electrodes based on rubidium and caesium cyanotriphenylborates: C. J. COETZEE. (13 November 1981)
The stability of metal–indicator complexes: Spectrophotometric investigation of thorium, hafnium and zirconium complexes with Methylthymol Blue and Xylenol Orange: STANISLAW KICIAK and ZBIGNIEW ŚWIT. (16 Nobember 1981)
Characterization and utilization of a long-lasting sessile-drop mercury electrode in differential pulse anodic-stripping voltammetric subtrace metal analysis of natural waters: R. ANDRUZZI, A. TRAZZA and G. MARROSU. (18 November 1981)
Conventional fluorescence spectrometry of polynuclear aromatic hydrocarbons in Shpol'skii matrices at 77 K: E. P. LAI, E. L. INMAN, JR. and J. D. WINEFORDNER. (23 November 1981)
The use of outer-sphere complex formation reactions in ion-exchange chromatography: Separation of maleate and fumarate ions: PÁL HALMOS and JÁNOS INCZÉDY. (23 November 1981)
Atomic-absorption spectrophotometric determination of antimony, arsenic, bismuth, tellurium, thallium and vanadium in sewage sludge: S. KEMPTON, R. M. STERRITT and J. N. LESTER. (23 November 1981)
Derivatives of carbohydrazine, thiocarbohydrazide and diaminoguanidine as photometric analytical reagents—I: Spectroscopic examination of the reagents and spectrophotometric study of the metal complexes formed by 1,5-bis-[(2-pyridyl)methylene]carbonothioic dihydrazone and 1,5-bis-[(2-pyridyl)methylene]carbonimide dihydrazone: F. J. BARRAGÁN DE LA ROSA, J. L. GÓMEZ ARIZA and F. PINO. (23 November 1981)
Untersuchungen zur atomspektroskopischen Spurenanalyse in $A^{III}B^{V}$-Halbleitermikroproben—VI: Untersuchungen zur Schichtabtrennung, Profil- und Spurenanalyse an InSb-Materialien: I. R. SCHOLPAKOWA, O. I. SCHTSCHERBAKOWA, I. G. JUDELEWITSCH, N. F. BEISEL, K. DITTRICH and W. MOTHES. (20 October 1981)
Extraction of zinc, cadmium and mercury salicylates: VASUDHA V. MUDSHINGIKAR and V. M. SHINDE. (23 November 1981)
Direct titration of zinc by 1,2-propylenediaminetetra-acetate and Xylenol Orange: Theoretical predictions and experimental results: S. VICENTE-PÉREZ, J. M. PINILLA and A. FERNÁNDEZ. (24 November 1981)
Spectrophotometric determination of molybdenum with isonicotinic acid hydrazide in presence of resacetophenone semicarbazone: K. P. REDDY and S. BRAHMAJI RAO. (26 November 1981)
Quantitative treatment of substituent effects in the polarographic investigation of some potential antidiabetic arylazothiadiazines: WAHID U. MALIK and RAJEEV JAIN. (26 November 1981)
Studies on correlation of flash point of petroleum fractions: A mathematical model for the interconversion of Pensky Marten (closed cup) and Cleveland (open cup) methods: V. P. MALIK, B. GARUDADWAJAN, S. K. CHHIBBER and C. B. NAUTIYAL. (26 November 1981)
Determination of microamounts of some sulphur-containing ligands by a kinetic method: MADHU PHULL and P. C. NIGAM. (30 November 1981)
Reaction of mercury(II) and Xylenol Orange—VI: Effect of ROH/$CHCl_3$ extraction mixtures in the presence of diphenylguanidine: J. L. PERAL-FERNADEZ, R. IZQUIERDO-HORNILLOS, R. GALLEGO-ANDREU and A. CABRERA-MARTIN. (2 December 1981)
Reaction of mercury(II) and Xylenol Orange—VII: Complex extraction with a liquid anion-exchanger: J. L. PERAL-FERNANDEZ, R. IZQUIERDO-HORNILLOS, R. GALLEGO-ANDREU and A. CABRERA-MARTIN. (2 December 1981)
Determination of thiuram disulphides and a method for the analysis of thiuram disulphide–dithiocarbamate mixtures: BALBIR CHAND VERMA, HARMOHINDER SINGH SIDHU and RAJNISH KUMAR SOOD. (2 December 1981)
Flow-injection analysis and its early history: J. RŮŽIČKA and E. H. HANSEN. (2 December 1981)
Mercury determination in water by combined electrodeposition and low-pressure ring discharge emission spectroscopy: H. Z. WREMBEL. (4 December 1981)
Pollution-free method for the determination of iron in iron ore: S. KALLMANN and E. KOMARKOVA. (8 December 1981)
Separation of lead-203 from cyclotron-bombarded thallium targets by ion-exchange chromatography: T. N. VAN DER WALT, F. W. E. STRELOW and F. J. HAASBROEK. (14 December 1981)
Möglichkeiten zur Verbesserung der Auflösung in der Dunnschichtchromatographie: Eine Übersicht: H.-P. FREY and G. ACKERMANN. (14 December 1981)
Spectrophotometric determination of iron with resacetophenone thiosemicarbazone as a reagent in presence of 1,10-phenanthroline: K. HUSSAIN REDDY and D. VENKATA REDDY. (14 December 1981)
Extraction of anionic surfactants with copper(II)–ethylenediamine derivative complexes: SHIGAHIRO INOMATA, TOSHIO SUZUKI and KIYOSHI SAWADA. (14 December 1981)
Reactivity of potassium tetracyanomercurate with Ag(I), Ni(II) and Co(II): ALESSANDRO DE ROBERTIS and ATHOS BELLOMO. (14 December 1981)
Solvent effect on the extraction of thorium(IV) and uranium(VI) by di(2-ethyl-hexyl)phosphoric acid from nitric acid solutions: S. K. TOBIA, F. M. EL-ZAWAWI and L. H. KHALIL. (14 December 1981)
Dichlorohydantoin and dibromohydantoin as new oxidimetric titrants in non-aqueous media: M. P. RADHAMMA and P. INDRASENAN. (15 December 1981)
Anion-selective electrode based on inorganic gel membrane: Estimation of molybdate: S. K. SRIVASTAVA, A. K. SHARMA and C. K. JAIN. (17 December 1981)

Talanta. Vol. 29, p. I. 1982
Pergamon Press Ltd. Printed in Great Britain

TALANTA MEDAL

Presentation of the Talanta Medal to Professor J. Růžička by the Editor-in-Chief at Euroanalysis IV, Helsinki.

Talanta, Vol. 29, pp. i to ii, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Electrochemical reduction of morin at the DME: GIRISH DIXIT, RAVI RASTOGI and KAMALA ZUTSHI. (20 July 1982)

The simultaneous determination of decachlorobiphenyl, octachloronaphthalene and decachloro-1,4-dihydronaphthalene in mixtures by HPLC: ZLATA IVANOV, R. J. MAGEE and L. MARKOVEC. (22 July 1982)

Effect of buffers on the excited-state prototropic equilibria of benzimidazole: M. SWAMINATHAN and S. K. DOGRA. (22 July 1982)

Spectrophotometric determination of tellurium after co-precipitation of its morpholine-4-carbodithioate with microcrystalline naphthalene: C. L. SETHI, ASHOK KUMAR, M. SATAKE and B. K. PURI. (5 August 1982)

Determination of the total iron content in used lubricating oils by AAS, using emulsions: A. SALVADOR, M. DE LA GUARDIA and V. BERENGUER. (5 August 1982)

A nickel ion-selective electrode: NATALIA ZELICHOWICZ. (24 August 1982)

Selective complexometric determination of mercury with thiocyanate as masking agent: K. N. RAOOT, SARALA RAOOT and V. LALITA KUMARI. (24 August 1982)

Titrimetric determination of thorium with triethylenetetramine hexa-acetic acid as titrant and SPADNS as indicator: U. C. MAIWAL and K. SRINIVASULU. (25 August 1982)

The determination of thiols with diphenylpicrylhydrazyl as a spectrophotometric reagent: DONALD B. HUNSAKER, JR. and GEORGE H. SCHENK. (22 July 1982)

The acid strength of the thiol and amine groups in 1-methyl-4-mercaptopiperidine: determination of its macroscopic and microscopic ionization constants: H. BARRERA, J. C. BAYON, P. GONZALEZ-DUARTE, J. SOLA and J. VIVES. (25 August 1982)

Benzohydroxamic acid as a reductometric titrant: determination of cerium: FAHMIDA KHATOON and C. SUBBARAO. (25 August 1982)

Determination of aluminium in zinc–aluminium alloys with a Cu(II)-selective electrode: H. F. STEGER. (25 August 1982)

A new analytical method for nitric oxide, utilizing the oxidation to nitrite of nitric oxide co-ordinated to the ethylenediamine-tetra-acetato iron(II) complex: SHUNICHI UCHIYAMA and GIICHI MUTO. (25 August 1982)

New contributions to the decomposition of organic matter: Disintegration with molten alkali. Determination of arsenic and antimony in organic compounds: F. BOSCH REIG and J. V. GIMENO ADELANTADO. (25 August 1982)

Trends in using resilient polyurethane foams as sorbents in analytical chemistry: T. BRAUN. (25 August 1982)

Indirect determination of organic compounds by atomic-absorption spectrometry: E. R. CLARK and EL-SAYED A. K. YACOUB. (25 August 1982)

An ion-selective electrode method for the determination of chlorine in geological materials: P. J. ARUSCAVAGE and E. Y. CAMPBELL. (26 August 1982)

Quantitative determination of high molecular-weight polyethylene glycols by precipitation with iodine: M. FRANÇOIS and R. DE NEVE. (26 August 1982)

Fluorimetric behaviour of monothiosemicarbazones: A. GOMEZ-HENS and M. VALCARCEL. (26 August 1982)

Direct thermometric titrations at elevated temperatures: L. S. BARK and L. KERSHAW. (26 August 1982)

Iodometric microdetermination of boric acid and borax separately or in a mixture, by visual and potentiometric titration: R. SAXENA and R. M. VERMA. (26 August 1982)

Titrimetric determination of vanadium(IV) with DCTA: RAM PARKASH KULDIP SINGH, JITENDRA PAL KAUR and R. L. SINGHAL. (26 August 1982)

The effect of calcium hardness on the determination of fluoride with ion-selective electrodes: S. B. SANNI, J. A. W. DALZIEL and I. S. MU'AZU. (26 August 1982)

Analysis of certain pharmaceutical mixtures with chloramine-T: KRISHNA K. VERMA, ANIL K. GULATI and ANIL K. GUPTA. (26 August 1982)

Polarographic determination of phosphorus: R. PARDO, E. BARRADO, Y. CASTRILLEJO and P. SANCHEZ-BATANERO. (26 August 1982)

Some investigations on new polyphosphates by anion-exchange: TOSHIO NAKASHIMA and HIROHIKO WAKI. (27 August 1982)

Analytical reactions of 5-amino-orotic acid: B. ROY, AJAI K. SINGH and R. P. SINGH. (27 August 1982)

Application of cellulose anion-exchangers for separation of palladium–platinum and palladium–iridium, using glycine as complexing agent and atomic-absorption spectrometry (AAS) as detection method: KRYSTYNA BRAJTER and KRYSTYNA SŁONAWSKA. (27 August 1982)

Determination of iron, cobalt and zinc with polyurethane foam: A. CHOW. (27 August 1982)

Talanta, Vol. 29, pp. i to ii, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Determination of oxygen and nitrogen content of some medicinal plant materials by 14-MeV nentron-activation analysis: CH. L. NDIOKWERE and P. A. JERABEK. (1 March 1982)
Fluorometric determination of selenium in biological tissues: A re-examination: W. A. MAHER. (1 March 1982)
Determination of thiocyanate with aromatic halosulphonamides in acid and alkaline media: B. THIMME GOWDA and D. S. MAHADEVAPPA. (2 March 1982)
Oxydation vanadique de la parachlorobenzyl-4 diméthoxy-6,7 isoquinolèine en milieu sulfurique 5 M: E. POSTAIRE, M. TSITINI-TSAMIS, C. VIEL and M. HAMON. (4 March 1982)
The determination of trace arsenic, antimony, selenium and tellurium with various valences in water by atomic-absorption spectrophotometry after enrichment and separation with sulfhydryl cotton and hydride generation: MU-QING YU, GUI-QIN LIU and QINHAN JIN. (4 March 1982)
Theoretical calculation of relative sensitivity coefficients in spark-source mass-spectrometry for elements in metal matrices: WOJCIECH VIETH. (9 March 1982)
Chemical analysis of uranium and titanium niobotantalate metamict minerals by ion-exchange chromatography and spectrophotometric procedures: A. MAZZUCOTELLI, R. VANNUCCI, S. VANNUCCI and E. PASSAGLIA. (10 March 1982)
Polarographic behaviour of sodium 1,2,4-triazole-3(5)-thiol and its use in the amperometric determination of metal ions: A. L. J. RAO, B. S. BRAR and B. K. PURI. (12 March 1982)
Synthesis and analytical properties of 2-sulphoethyl imidodicarbonimidodiamide: J. MARTINEZ CALATAYUD, P. IBAÑEZ BLASCO and P. CAMPINS FALCO. (12 March 1982)
Polarography of mixed-ligand complexes of copper with some dibasic acids and ethylenediamine/propylenediamine: J. K. GARG, D. S. JAIN and P. S. VERMA. (12 March 1982)
Metal chelates of azo-pyridazine dyes—I: Chelating tendencies of benzoylacetone–monohydrazone-3-hydrazine-4-benzyl-6-phenylpyridazine (BAHP): ATEF A. T. RAMADAN, MAGDY H. SEADA and EMIL N. RIZKALLA. (15 March 1982)
The effect of incomplete spike reaction on the determination of trace metals in a complexing matrix by using standard additions: A. CORSINI, C. C. WAN and S. CHIANG. (8 March 1982)
Analytical applications of the photolysis of ferric lactate: A new photometric method for the determination of vanadium(V) and chromium(VI): Y. ANJANEYULU, R. N. SARMA, L. N. MURTHY and V. PANDURANGA RAO. (16 March 1982)
Spectrophotometric determination of microamounts of rhodium(II), palladium(II) and copper (II) with 3-hydroxy-2-methyl-1,4-naphthoquinone monoxime: MISS KAMINI, S. K. SINDHWANI and R. P. SINGH. (16 March 1982)
Referee analysis of precious metal sweeps and related material: SILVE KALLMANN. (17 March 1982)
Organosulphur behaviour in a GC/MS membrane interface: MICHAEL THOMPSON and MIRIAM STANISAVLJEVIĆ. (19 March 1982)
Application of the direct determination of fluoride by a specific-ion electrode to phosphoric acid samples with a high Al/F ratio: K. HAJDU and A. M. EYAL. (19 March 1982)
Determination of iron(III) and copper(II) by zero, first and second derivative spectrophotometry, with 4,6-dihydroxy-2-mercaptopyrimidine (2-thiobarbituric acid) as reagent: BASILIO MORELLI. (19 March 1982)
Application of hydrogen-activated platinum gauze to the adsorption deposition of trace amounts of silver before its determination by the ASA or ASV methods: ZOFIA BOGUSZEWSKA, BOGNA PALMOWSKA-KÚS. (22 March 1982)
Construction of a permanganate ion-selective electrode and its application to potentiometric titration: MASAMITSU KATAOKA, NAOKI UNKYO and TOMIHITO KAMBARA. (22 March 1982)
Determination of cadmium in urine by solvent extraction and atomic-absorption spectrophotometry with electroethermal atomization: MOHAMMAD JAWAID and BIRGER LIND. (23 March 1982)
Polarographic determination of paludrine and chlorhexidine: F. TOMAS VERT, F. VICENTE PEDROS, J. MARTINEZ CALATAYUD and V. PERIS MARTINEZ. (23 March 1982)
Gatekeeping patterns in the publication of analytical chemistry research: T. BRAUN and E. BUJDOSÓ. (24 March 1982)
Spectrophotometric determination of acetaminophen in pharmaceutical preparations: AJAYA PRAKASH, A. K. MURTHY and I. C. SHUKLA. (24 March 1982)
Spectrophotometric determination of iron(III) after separation by adsorption of its 5,7-dichloro-oxine complex on microcrystalline naphthalene: MASATADA SATAKE, LIH-FEN CHANG, JU CHIENG YUH and B. K. PURI. (24 March 1982)
Studies on potentiometric stripping analysis: TUEN CHI CHAU, DE YU LI and YING LIANG WU. (26 March 1982)
Extraction of metal ions by a polyether-type polyurethane foam: G. J. MOODY, J. D. R. THOMAS and M. A. YARMO. (29 March 1982)
Determination of trace amounts of phosphate in river water by flow-injection analysis: SHOJI MOTOMIZU, TOSHIAKI WAKIMOTO and KYOJI TÔEI. (29 March 1982)
A method of separation of molybdenum by extraction of Mo(VI)-*o*-phenanthroline with isobutyl methyl ketone: USHA DHINGRA and L. R. KAKKAR. (30 March 1982)
Gains or losses of ultratrace elements in polyethylene containers: K. HEYDORN and E. DAMSGAARD. (30 March 1982)
Environmental specimen banking: A trace analytical challenge: M. STOEPPLER, H. W. DÜRBECK and H. W. NÜRNBERG; (30 March 1982)
A simple spectrophotometric method for the determination of nylidrin hydrochloride, isoxuprine hydrochloride and salbutamol sulphate from pharmaceutical preparations: R. T. SANE, V. G. NAYAK and V. B. MALKAR. (5 April 1982)
An extractive spectrophotometric method for the determination of tetramisole hydrochloride from pharmaceutical preparations: R. T. SANE and D. S. SAPRE. (5 April 1982)
Homogeneous enzymatic fluorescence immunoassay of serum IgG by continuous flow-injection analysis: TIM A. KELLY and GARY D. CHRISTIAN. (5 April 1982)

Determination of silicon by an indirect atomic-absorption method using carbon rod electrothermal atomization: J. F. TYSON and W. S. WAN NGAH. (5 April 1982)
Action de l'acide ascorbique sur les amines primaires et les acides α amines: D. BAYLOCQ, C. MAJCHERCZYK, A. RABARON and F. PELLERIN. (5 April 1982)
Rapid scan pulse voltammetry: LEON ASHLEY and SOLOMON L. LEVINE. (26 March 1982)
Simultaneous determination of stoichiometry, condensation degree and stability constant: A generalization of the molar ratio method: A. BELTRAN-PORTER, D. BELTRAN-PORTER, A. CERVILLA and J. A. RAMIREZ. (5 April 1982)
Solvent extraction separation of zirconium and hafnium: B. NANDI, N. R. DAS and S. N. BHATTACHARYYA. (6 April 1982)
Simultaneous determination of arsenic, antimony and tin by fast-scan differential pulse polarography and application to alloy steels: JIŘÍ LEXA and KAREL ŠTULÍK. (6 April 1982)
A direct titrimetric estimation of malic, tartaric and thioglycollic acids with ammonium hexanitratocerate(IV): B. MADHAVA RAO and K. P. DESAI. (6 April 1982)

Talanta, Vol. 29, pp. i to ii, 1982
Pergamon Press Ltd. Printed in Great Britain

PAPERS RECEIVED

Use of electrostatic preconcentration at high salt concentrations: P. A. MICHALIK and R. STEPHENS. (5 October 1981)
On the analytical method of calculating the derivatives of equilibrium concentrations: A. A. BUGAEVSKY and L. E. NIKISHINA. (6 October 1981)
Effect of interaction of thenoyltrifluoroacetone with neutral oxo-donors in the synergistic extraction of tervalent actinides: J. N. MATHUR and P. K. KHOPKAR. (6 October 1981)
Determination of trace arsenic in milk products and plastics by combustion in an oxygen bomb and sodium borohydride reduction–atomic-absorption spectrometry: HISATAKE NARASAKI. (6 October 1981)
Studies on the reaction of silver ions with triaminotriphenylamine: M. E. M. KHALIFA. (8 October 1981)
Determination of sulphur and nitrogen functions with potassium ferricyanide: ASHUTOSH SRIVASTAVA. (8 October 1981)
Spot-test detection of magnesium(II) with 2,4-dinitrophenylazoresorcinol: A. K. AHI. (8 October 1981)
The determination of trace amounts of Ca, Mg, Al, Sr, Ba, Mn, Cu and Zn in cerebrospinal fluid and serum by carbon-rod atomic-absorption spectrophotometry: A. MAZZUCOTELLI, M. GALLI, C. LOEB and C. ALBANO. (8 October 1981)
Homogeneity of solids. A proposal for quantitative definition: J. INCZÉDY. (9 October 1981)
Selective separation and differential determination of antimony(III) and antimony(V) by solvent extraction with *N*-benzoyl-*N*-phenylhydroxylamine and graphite-furnace atomic-absorption spectrometry with a matrix modification technique: SUN HAN-WEN, SHAN XIAO-QUAN and NI ZHE-MING. (12 October 1981)
A rapid procedure for the simultaneous determination of zirconium and hafnium in high-temperature alloys by means of a spectrophotometric masking approach: THOMAS R. DULSKI. (2 October 1981)
Determination of indium by hydride generation and atomic-absorption spectrometry: I. S. BUSHEINA and J. B. HEADRIDGE. (14 October 1981)
Long-term stability of valinomycin-active ion-selective membranes: J. J. GRIFFIN and G. D. CHRISTIAN. (14 October 1981)
Studies on the nature of reactions and species involved in potentiometric determination of uranium: S. G. MARATHE, B. N. PATIL, VEENA BHANDIWAD and KESHAV CHANDER. (15 October 1981)
Origin of double peak signals for trace lead, bismuth, silver and zinc in a microamount of steel in atomic-absorption spectrometry using direct electrothermal atomization of solid samples in a graphite-cup cuvette: KUNIO TAKADA and KICHINOSUKE HIROKAWA. (15 October 1981)
Colorimetric determination of some sympathomimetic amines: A. ABOU OUR, M. I. WALASH and F. B. SALEM. (16 October 1981)
Diffusion coefficients and complex equilibria in solution—I: Theory; diffusion coefficients of complex species: D. R. CROW. (16 October 1981)
Diffusion coefficients and complex equilibria in solution—II: Approximate evaluation of formation constants: D. R. CROW. (16 October 1981)
Spectrophotometric determination of trace amounts of aniline by diazotization coupling with *N*-(1-naphthyl)ethylenediamine and extraction: GEORGE NORWITZ and PETER N. KELIHER. (2 October 1981)
Comportement électrochimique des thiocyanosulfates: Y. AUGER, G. DELESALLE, J. C. FISCHER and M. WARTEL. (7 May 1981)
Identification of the reduced species of ^{99}Tc by chromatographic and spectrophotometric techniques: S. A. ADELUSI. (21 October 1981)
Effect of cationic surfactant on the formation of ferron complexes: KATSUMI GOTO, SHIGERU TAGUCHI, KANJI MIYABE and KEN-ICHI HARUYAMA. (22 October 1981)
Analytical investigation of the properties and uses of a new hydrophobic molecular sieve: G. M. W. SHULTZ-SIBBEL, D. T. GJERDE, C. D. CHRISWELL, J. S. FRITZ and W. EMILE COLEMAN. (19 October 1981)
A serial ASCII keyboard-printer: D. F. MARINO and J. D. INGLE, JR. (26 October 1981)
The determination of gallium(III) by potentiometric stripping methods: J. ADAM. (26 October 1981)
Determination of thorium and scandium by a special modification of chronopotentiometry–potentiometric stripping analysis: J. ADAM. (26 October 1981)
Some applications of ligand-exchange—II: Separation of phenolic compounds: B. M. PETRONIO, E. DE CARIS and L. IANNUZZI. (27 October 1981)
Silica gel with adsorbed Adogen 464 as an analytical sampling tool: P. BATTISTONI, S. BOMPADRE and G. FAVA. (27 October 1981)
Indirect amplification method for determining cerium and chloramine-T by differential pulse polarography: S. T. SULAIMAN and D. AMIN. (28 October 1981)
Reaction of mercury(II) and Xylenol Orange—IV: Influence of water-soluble alcohols on the complex formation: A. CABRERA-MARTIN, R. GALLEGO-ANDREU, R. IZQUIERDO-HORNILLOS and J. L. PERAL-FERNANDEZ. (28 October 1981)
Reaction of mercury(II) and Xylenol Orange—V: Pure hydroxylic solvent effect on the extraction in presence of diphenylguanidine: A. CABRERA-MARTIN, R. GALLEGO-ANDREU, R. IZQUIERDO-HORNILLOS and J. L. PERAL-FERNANDEZ. (28 October 1981)
Plutonium coulometry: G. L. SILVER. (30 October 1981)
On the interpretation of the anionic interferences in atomic-absorption spectrophotometry: AMIN M. ABDALLAH and M. A. KABIL. (30 October 1981)
A comparison between secondary-ion mass spectrometry (SIMS) and spark-source mass spectrometry for the quantitative analysis of steel wire: M. VAN CRAEN, J. VERLINDEN, R. GIJBELS and F. ADAM. (4 November 1981)
Nicolae Teclu (1839–1916): A pioneer of flame spectroscopy: G. E. BAIULESCU, S. MOLDOVEANU and T. S. WEST. (4 November 1981)
Extraction-spectrophotometric determination of niobium with dibenzo-18-crown-6 and thiocyanate: D. BLANCO GOMIS,

S. ARRIBAS JIMENO and A. SANZ-MEDEL. (4 November 1981)

Analytical properties of 1,3-cyclopentanedione bis(4-methylthiosemicarbazone) monohydrochloride: M. ROMAN CEBA, J. C. JIMENEZ SANCHEZ and T. GALEANO DIAZ. (4 November 1981)

Titration of vanadium(IV) with cerium(IV) sulphate, with ferroin as indicator, in aqueous alcohol as a facile reaction medium: K. SRIRAMAM, N. RAMABRAHMA SASTRY and G. S. N. SASTRY. (6 November 1981)

Performance of the Orion 97–70 total residual chlorine electrode at low concentrations and its application to the analysis of cooling waters: N. A. DIMMOCK and D. MIDGLEY. (30 October 1981)

Spectrophotometric determination of some phenols with sodium metaperiodate and aminophenols: C. S. PRAKASA SASTRY, K. E. RAO and U. V. PRASAD. (6 November 1981)

Adsorption of chromium(VI) on silica gel impregnated with Adogen 464 and its determination by furnace atomic-absorption: P. BATTISTONI, S. BOMPADRE, G. FAVA and G. GOBBI. (6 November 1981)

TALANTA ADVISORY BOARD

The Editorial Board and the Publisher of *Talanta* take pleasure in welcoming the following new members of the Advisory Board of the journal.

D. T. BURNS
E. M. DONALDSON
R. J. MAGEE
F. PELLERIN
S. B. SAVVIN

They also wish to record their sincere thanks for the help given by

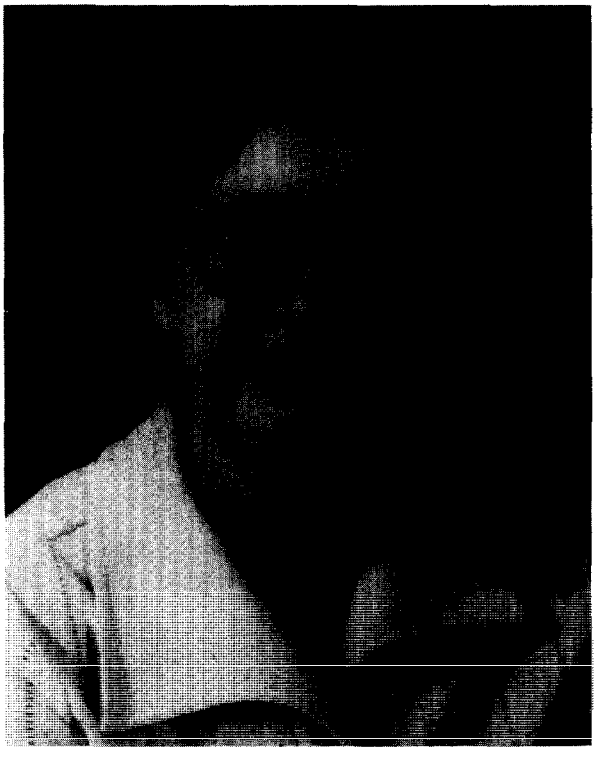
J. BARTOS
C. B. BELCHER
A. CORSINI
F. KILLER
C. LITEANU

who retire from the Advisory Board.

Biographical notes on some of the new members (and Professor Shu-Chuan Liang, who was appointed to the Board in 1981) appear below. Professor Savvin's notes will follow later.

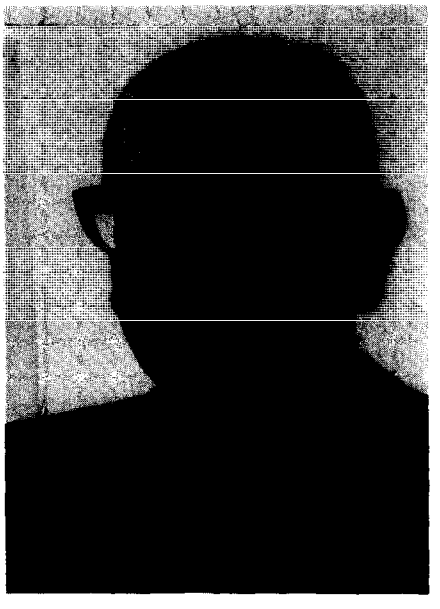
PROFESSOR BURNS graduated in chemistry at Leeds University (1955) where he stayed on to do research in physical chemistry, obtaining a Ph.D. in 1959. His first full time appointment, in 1958, was to Medway College of Technology as Assistant Lecturer in Physical Chemistry, and he became Lecturer in physical chemistry and also an Associate of the Royal Institute of Chemistry in 1959. In 1963 he joined the staff of the late A. I. Vogel at Woolwich Polytechnic as Senior Lecturer in Inorganic and Analytical Chemistry. He joined the Society for Analytical Chemistry and returned to the Midlands in 1966 upon appointment to Loughborough University of Technology as Senior Lecturer and Head of the Analytical Chemistry Section. He became Reader in 1971 and obtained the first substantive D.Sc. of Loughborough in 1972. In 1975 he was appointed to the established Chair of Analytical Chemistry in the Queen's University of Belfast. He became a Fellow of the Royal Institute of Chemistry in 1968, and the Institute of Chemistry in Ireland in 1976, was awarded the James Taylor Prize of

the Sheffield Metallurgical and Engineering Society in 1970, gave the 31st Pearson Lecture at Whitcliffe Mount School in 1975, the Opening Lecture at Euroanalysis III 1978, and is to give the Royal Society of Chemistry's endowed Theophilus Redwood Lecture in 1982. Professor Burns has been active in the Analytical Division of the Royal Society of Chemistry and its forebears as follows: past member of Council and Chairman of the Midlands Region, past Chairman and past Secretary of the Education and Training Group, past Chairman of the Northern Ireland Sub-Committee of the Scottish Region; he has also assisted in the organization of several conferences, and is currently a member of Council as Honorary Secretary to the International Affairs Committee, and a member of the Northern Ireland Region and the Microchemical Methods Group Committees. He is an associate member of IUPAC Commission V/1. Current research interests include ion-association extraction systems, elemental analysis, HPLC of organometallics, anions, medicinal compounds and their metabolites, and characterization of poteen and fire-accelerant residues. He has co-authored several books and published over 170 research and review papers including several on his hobby—the study of the history of analytical chemistry. Professor Burns' main administrative contribution to the University is concerned with Health, Safety and Welfare at Work as Chairman of the University Safety Committee, *ex officio* membership of subcommittees, and a watching brief over 32 area committees.

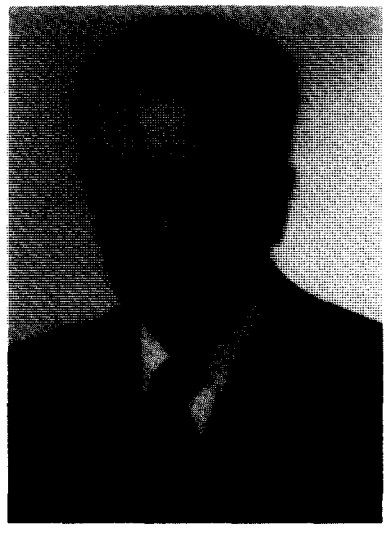


ELSIE M. DONALDSON was born in 1929 in Winnipeg, Manitoba, Canada, and obtained her B.Sc. degree in chemistry from the University of Manitoba in 1951. In August 1951, she joined the staff of the Mines Branch of the Department of Mines and Technical Surveys in Ottawa, Ontario (now the Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources) where she is currently the head of the Research and Special Projects Group of the Mineral Sciences Chemical Laboratory. Her research interests are in solvent extraction and analytical chemistry with special emphasis on the development of instrumental methods for the determination of trace and small amounts of elements in rocks and in diverse ores and alloys. She has published about 40 papers and reports in these fields and has authored a book dealing with the analysis of rocks, ores and related materials. A second edition of this book is in progress. She is a member of the Chemical Institute of Canada and was a joint winner in 1971 of Talanta's Louis Gordon Memorial Award.

PROFESSOR SHU-CHUAN LIANG was born in 1912 in Chefoo, China. He obtained his B.Sc. from Yenching University, Peking in 1933, then studied for his Dr. phil. nat. (1937) at the University of Munich, Germany. After a short stay in the laboratory of Professor (at that time Dozent) F. Hecht in Vienna, Dr. Liang returned to China to teach analytical chemistry at West China Union University and then at Chungking University. In 1947 he joined Academia Sinica, and was elected a member of the Academy in 1955. From 1955 to 1965 he served as editor-in-chief of the journal *Acta Chimica Sinica*. He is a member of the editorial boards of *Oceanologia et Limnologia Sinica* and *Fenxi Huaxue* (*Chinese Journal of Analytical Chemistry*). He is particularly interested in the analytical chemistry of rare elements and also micro and trace analysis. He is the author of more than seventy papers.



PROFESSOR R. J. MAGEE is a native of Northern Ireland, and holds the degrees of B.Sc., M.Sc., Ph.D., D.Sc. He is also a Fellow of the Royal Australian Chemical Institute, the Institute of Chemistry in Ireland, and the Royal Chemical Society. He has held posts ranging from Assistant Lecturer, through all grades up to Professor. He is currently Foundation Professor at La Trobe University, in the Department of Inorganic and Analytical Chemistry. He has held visiting professorships at the Case Institute of Technology, Trinity College Dublin, Carleton University, Graz University, Athens University, the Indian Institute of Science and the National University of Malaysia. He is interested in research on inorganic and analytical chemistry, including thermal, spectral, magnetic and structural studies on metal complexes, with particular reference to sulphur ligand complexes, studies on the electrochemistry of transition-metal systems and the kinetics and mechanisms of electrode processes, and the use of electroanalytical and thermoanalytical methods in the determination of potentials in natural waters and the atmosphere. He has published some 280 papers on the main areas of his research interests.



PROFESSOR PELLERIN was born in 1923 in Normandy, and is now Professor of Pharmacy in the University of Paris (South). His research activities in analytical chemistry have developed along two lines. The first is organic functional group analysis, including study of organic solvents for protometric and functional analysis reactions in two-phase solvent systems, and various studies on the reactivity and stability of organic molecules as a function of structure. The second line involves studies on analytical chemistry applied to pharmaceuticals, including quality control, study of additives (colours, preservatives, antioxidants), and studies of stability. The results obtained in this last branch of work have led him to consider the plastics used in the pharmaceutical and surgical fields. The interaction between plastics and pharmaceuticals or biological media originates (and finds its explanation) in the relation between the physicochemical properties and the structure and composition of the materials. In this domain, Professor Pellerin has been especially concerned with the role of the reactivity of organic molecules and the chemical properties of the functional groups. Professor Pellerin is the Secrétaire Technique de la Commission de Pharmacopée Française, Member of the National Academy of Pharmacy, and President of the Analytical Division of IUPAC.

NOTICE

AMERICAN VACUUM SOCIETY

29TH NATIONAL VACUUM SYMPOSIUM AND SHOW

15–19 NOVEMBER 1982

Baltimore Convention Center, Hyatt Regency Hotel, Baltimore, MD

The 29th National Symposium of the American Vacuum Society will be held at the Baltimore Convention Center, Baltimore, Maryland, 15–19 November 1982. Topics include Electronic Materials and Processing, Surface Science, Thin Films, Vacuum Technology, Fusion Technology, Vacuum Education and Vacuum Metallurgy. There will also be a comprehensive exhibit of related equipment and a number of short courses.

SESSION TOPICS

ELECTRONIC MATERIALS AND PROCESSING
Metal-Semiconductor Interfaces
Atomic and Electronic Structure of Semiconductor Surfaces
Growth and Structure of Interfaces of Electronic Materials (Poster Session)
Epitaxy and Growth (MBE)
Beam Processing
Oxide–Semiconductor Interfaces
Dry Processing
Microanalysis of Electronic Devices

SURFACE SCIENCE
Reactions and Interactions at Surfaces
Electronic Structures and Bonding
Surface Geometries
Radiation-Induced Surface Chemistry and Physics
Vibrational Properties
Absorption and Defects
Exciting New Directions
Surface Science (Poster)
Post-Deadline Discoveries (Special Evening Session)

FUSION TECHNOLOGY
Design and Construction of Large Vacuum Systems
Leak Testing and Leak Repair of Plasma Devices
Plasma Diagnostics
Plasma–Wall Interactions
Vacuum Materials Development
Inertial Confinement Target Development
Handling, Storage and Recovery of Radioactive Gases
Neutral and Negative Ion Beam Injection Technology
Fueling of Plasma Devices
Industrialization of Fusion Power (Special Evening Session)

THIN FILMS
Ion Beam Sputtering and Deposition
Ion Beam Induced Chemical Sputtering
Techniques for Modifying Thin-Film Properties
Sputtering of Multicomponent Materials
Surface Preparation for Thin Film Deposition
Thin Films for Biomedical Applications
Ohmic Contacts and Metallization Thin-Film Physics (Special Poster Session)

VACUUM TECHNOLOGY
Mechanical Motion in Vacuum
Reliability of Vacuum Measurements
Computer Uses in Vacuum Equipment and Processes
Vacuum Joints, Bonding and Seals
Storage Rings
Vacuum Processes for Microelectronics
High Vacuum Insulation and Switch Design
Microbalance Techniques

FUSION TECHNOLOGY/VACUUM TECHNOLOGY
Pumping and Pressure Measurements in Fusion Devices
ASTM (E-42 Committee)
Quantitative Interface Analysis

EDUCATION

VACUUM METALLURGY

NOTICE

1983 PITTSBURGH CONFERENCE AND EXPOSITION ON ANALYTICAL CHEMISTRY AND APPLIED SPECTROSCOPY

The 34th Pittsburgh Conference and Exposition on Analytical Chemistry and Applied Spectroscopy will convene 7–12 March 1983 in Atlantic City, New Jersey, USA. Atlantic City was chosen as the meeting site for the 4th consecutive year because of the very successful 1982 Conference and Exposition.

PAPERS ARE REQUESTED IN THE FOLLOWING CATEGORIES:

01. Air Pollution Analysis
02. Atomic Absorption Spectroscopy
03. Atomic Fluorescence Spectroscopy
04. Automated Analysis—
    a. Laboratory
    b. Plant
05. Biochemical Pharmaceutical
06. Biomedical Pharmaceutical
07. Classical Chemical Analysis
08. Clinical Chemistry
09. Computer Applications
10. Electrochemistry
11. Electron Spin Resonance
12. Emission Spectroscopy
13. Flame Emission Spectroscopy
14. Fluorescence-Luminescence
15. Food Analysis
16. Forensic and Drug Analysis
17. Fourier Transform Methods—
    a. Infrared
    b. NMR
18. Gas Chromatography—
    a. Applications
    b. Instrumentation
19. Gel Permeation Chromatography
20. General Analysis
21. Infrared Spectroscopy
22. Ion Chromatography
23. Liquid Chromatography—
    a. Applications
    b. Instrumentation
24. Mass Spectrometry
25. Microwave Spectrometry
26. Microscopy
27. Mössbauer Spectrometry
28. New Instrumentation
29. New Instrument Concepts
30. Nuclear Magnetic Resonance Spectroscopy
31. Pesticide Analysis
32. Photoacoustic Spectroscopy
33. Plasma Emission Spectrometry—
    a. ICP
    b. DC
34. Polarography
35. Polymer Analysis
36. Process Stream Analysis
37. Raman Spectroscopy
38. Selective Ion Electrodes
39. Surface Analysis
    a. Auger
    b. ESCA
    c. SIMS
40. Thermal Analysis
41. Thin Layer Chromatography
42. Toxicological Analysis
43. Trace Analysis
44. UV–VIS Spectrophotometry
45. Water Pollution Analysis
46. X-Ray Diffraction/Emission Spectroscopy
47. Other (Please Specify)

Papers may be contributed in all areas of the disciplines of Analytical Chemistry and Applied Spectroscopy.

Those authors wishing to present papers at the 1983 Pittsburgh Conference should submit five copies of a 300-word abstract to:

Mrs. Linda Briggs, Program Secretary
Pittsburgh Conference
437 Donald Road, Department J-029
Pittsburgh, PA 15235, U.S.A.

The abstract should be complete and show:

(a) The title of the paper.
(b) The name of the author(s), the organization(s) in whose laboratory the work was done, and the address(es). Provide the *COMPLETE* mailing address of each author, including department and any other mailing code.
(c) The name of the author who will present the paper must be *underlined.*
(d) Sign and date the abstract page in verification that the paper and all material therein has not been published or previously presented.

The final date for receipt of abstracts is 15 August 1982. Abstracts received after this date cannot be guaranteed consideration for inclusion in the 1983 Technical Program.

In 1982, the Modern Laboratory Equipment presented at the Conference totalled 560 exhibitors occupying 1380 booths and 35 seminar rooms in which was displayed the latest equipment available in the areas of Analytical Chemistry and Spectroscopy. Anyone desiring to reserve exhibit space or to obtain additional information regarding the 1983 Exposition should contact:

Mr. Paul E. Bauer, Exposition Chairman
Pittsburgh Conference
437 Donald Road, Department J-029
Pittsburgh, PA 15235, U.S.A.

PROFESSOR WIKTOR KEMULA ON HIS 80th BIRTHDAY

Professor Wiktor Kemula started his research and teaching activity in 1925 in the Jan Kazimierz University in Lwów. In 1939 he was nominated as Professor of Inorganic Chemistry at the University of Warsaw, but he was unable to take up this post until 1945, when he contributed significantly to the reconstruction of the activity of the University Chemistry Section, of which he was Chairman for many years. In 1956–58 he was the Vice-Rector of the University. In 1969 he was moved to the Institute of Physical Chemistry of the Polish Academy of Sciences. Since 1956 he has been a member of the Polish Academy of Sciences. For many years Professor Kemula was very active in the Polish Chemical Society, being its President in 1955–60. In 1976 he was honoured by being elected the Honorary President of the Society. In 1955 he initiated the Committee for Analytical Chemistry of the Polish Academy of Sciences, and was its Chairman until 1980, when he was distinguished with the title of Honorary Chairman of the Committee. His activity also extended abroad. Since 1947 Professor Kemula has been a member of IUPAC, and from 1969 to 1972 was the President of the Analytical Chemistry Division.

The scientific achievements of Professor Kemula cover many aspects of physical and analytical chemistry. He has worked in spectroscopy, photochemistry, electrochemistry and chromatography, but his finest achievements are in anodic stripping polarography and chromatopolarography—in both fields he was considered the founder and best expert. He also obtained excellent results in HPLC and application of clathrates for separation of organic compounds. In total he has published more than 400 scientific papers and a few academic textbooks. He has presented the results of his studies in numerous international conferences and during his scientific travels to all significant centres in the world. From his former students twenty are presently professors working at universities and in scientific institutes. He has been awarded the State Prize several times, and also many honours abroad.

He is a member of The German Academy "Leopoldino". The Czechoslovak Chemical Society, The Royal Chemical Society and the New York Academy of Sciences, and an honorary member of the Japan Society for Analytical Chemistry and of the Société de Chimie Industrielle.

In spite of his 80 years Professor Kemula is still very active, participating in meetings, and helping his younger colleagues and co-workers with advice and experience. He always has at heart the development of science and the interests of his country. In his life he does not exclude other fields of human activity. He is a well-known connoisseur of music and the fine arts. He has a broad knowledge of history and is a brilliant source of information for all who have the opportunity to talk with him. On the occasion of his 80th birthday his former students, and his co-workers and colleagues wish him long years of further successes and good health.

PUBLICATIONS RECEIVED

The Principles of Ion-Selective Electrodes and of Membrane Transport: W. E. MORF, Elsevier, Amsterdam, 1981. pp. 416. DF1.170, US$83.00.

This is a book full of equations describing the behaviour of ion-selective electrodes, backed up by judicious comment on the relationship of the equations to practical experience. Mathematical results, rather than proofs, are presented and the great advantage of the book is that it sets out rival theories in a common notation and so makes comparison much simpler. It is not a book for the practising analyst, but I do strongly recommend it for the post-graduate student and full-time researcher in ion-selective electrodes.

The first 160 pages gives a general discussion of membrane potentials and membrane transport, including diffusion potentials and liquid-junction potentials. The rest of the book uses the theory to illustrate the behaviour of ion-selective electrodes in regard to response, limit of detection (to some extent) and especially selectivity. The chapters on solid-state (actually only silver compounds), liquid ion-exchange and neutral carrier electrodes are all very good. Glass electrodes are also covered and two rather make-weight chapters discuss time responses and gas-sensing and enzyme electrodes.

The text is a direct copy from double-spaced typescript but is reasonably legible. It is regrettable that the publishers did not employ an English editor to remove a few minor but quite frequently occurring Germanicisms: Morf's style is lucid and deserves better than this petty economy.

DEREK MIDGLEY

Membrane Filtration—Applications, Techniques and Problems: BERNARD J. DUTKA (editor) Dekker, New York, 1981. Pp. XI + 612. Price

This book, volume 17 in a series on Pollution Engineering and Technology, presents a detailed, up-to-date review of membrane filter technology. There are 21 chapters, written by 31 contributors from Brazil, Canada, Japan, New Zealand, South Africa, the U.K., and the U.S.A. The text is authoritative and international; four of the chapters present the current European, Japanese, New Zealand and South African views of membrane filtration, resulting from the differences in legislation and water purity standards that exist internationally.

This does not set out in any sense to be an analytical chemistry text, yet its contents are of great importance for analytical chemists engaged in a wide range of environmental and industrial applications involving water purification and processing. The first chapter gives an excellent account of the history of development of membrane filters, their modes of preparation, and characteristics. Other chapters are distinctly microbiological or bacteriological, reflecting the now established practice of removing coliforms and other organisms of faecal origin from potable water supplies by means of membrane filtration. The final chapter gives a good account of the extent to which membrane filtration has already become established in the fermentation, pharmaceutical, and other industries. There is clearly a lot of development potential left in this new technology; the importance for analytical chemists lies in the extent to which standards of water purity *etc.* will change for the better with a consequent demand for analytical methods of greatly improved sensitivity and specificity for all types of aqueous systems.

D. M. W. ANDERSON

Treatise on Analytical Chemistry, 2nd Ed., Part I, Vol. 5: P. J. ELVING, E. CRUSHKA and I. M. KOLTHOFF (eds.), Vol. 7: P. J. ELVING, E. J. MEEHAN and I. M. KOLTHOFF (eds.), Wiley-Interscience, New York, 1981. Vol. 5: pp. xxix + 668, £48.00. Vol. 7: pp. xxviii + 816, £48.00.

The superlatives that have already been lavished on the first edition of the treatise continue to be deserved by the second edition. These two volumes, like the preceding two issued (Vols. 1 and 2), show the great advances made in analytical science since 1959. Volume 5 deals with decomposition of samples, giving a brisk survey of the field, but most of the book (over 90%) deals with separation techniques, some of which were virtually undeveloped at the time of the first edition of the treatise. There are surveys of mechanical methods, membrane processes, ultrafiltration membranes, liquid membranes, crystallization and precipitation, bubble methods, distillation, solvent extraction, and countercurrent distribution, with a general introduction by Calvin Giddings. Volume 7 deals with optical methods, covering principles and equipment, luminescence methods (fluorimetry and phosphorimetry), infrared spectroscopy, emission spectroscopy, flame emission spectrometry, and atomic-absorption methods. As expected, the individual contributions are authoritative, well documented, and up to date, but the index is rather on the short side in view of the contents, and there is not enough cross-indexing or choice of key words. The reader looking for information on diode arrays as detectors, for example, would need to know that they were included under vidicons in the index or would need to scan the contents list rather carefully. This is a minor criticism, however, and analysts will turn as eagerly to this edition as they did to the first, for rapid and reliable orientation in any field of analytical chemistry.

NOTICES

ELECTROANALYSIS SYMPOSIUM

CARDIFF, WALES, 5–8 APRIL 1983

An international symposium on Electroanalysis in Biomedical, Environmental and Industrial Sciences, organized by the Electroanalytical Group and Western Region of the Analytical Division of the Royal Society of Chemistry, is to be held at UWIST, Cardiff, from Tuesday 5 April to Friday 8 April 1983. The first circular is now available and may be obtained from the Short Courses Section, UWIST, Cardiff, U.K.

CHEMOMETRICS IN ANALYTICAL CHEMISTRY

PETTEN, THE NETHERLANDS

15–17 SEPTEMBER 1982

The application of chemometrical techniques in analytical chemistry is of growing importance. However, there is still a gap between chemometrics and its application in daily analytical practice. Accordingly, the theme of the conference will be "Chemometrics in Analytical Chemistry", with special emphasis on practical applications. The scientific committee expects the selected topics to be of benefit to scientists active or interested in the introduction of chemometrics into analytical chemical practice. The scientific program will include invited plenary lectures, invited and submitted research papers.

Topics

Application and development of formal techniques for design, optimization and evaluation of analytical procedures and results.

Application of systems theory, operations research, information theory, statistics, and other chemometrical techniques in analytical chemistry.

Data retrieval, pattern recognition, artificial intelligence, etc.

Computerized signal- and data processing, optimum filtering techniques, noise reduction methods.

Education in chemometrics.

Secretariat address

International Conference on Chemometrics in Analytical Chemistry,
CAC-Holland Laboratory for Analytical Chemistry,
University of Amsterdam, Nieuwe Achtergracht
166, 1018 WV Amsterdam, The Netherlands

9th INTERNATIONAL SYMPOSIUM ON MICROCHEMICAL TECHNIQUES

AMSTERDAM, 28 AUGUST–2 SEPTEMBER 1983

ISM 83 will cover both pure and applied aspects of analytical chemistry related to microchemical techniques and trace-analysis, similar to the preceding symposia. Special attention will be paid to modern techniques as well as to newer fields of application such as flow-analysis; analysis of microvolumes, surfaces and thin films; analysis of aerosols, coal and fly-ash.

PUBLICATIONS RECEIVED

Ion-Selective Electrodes, 3: E. PUNGOR (ed.), Elsevier, Amsterdam, 1982. pp. 428. $100.00.

This book consists of the papers presented at a conference held in Mátrafüred, Hungary in October 1980. These papers are divided into four plenary lectures, five keynote lectures and twenty-three discussion papers. The first two groups of lectures constitute approximately one third of the book and true to the pattern of this style of lecture most specialist workers will have read or heard most of it all before. Each of the discussion papers is followed by an account of the questions and answers that arose from the presentation. Regardless of Professor Pungor's claim of equal division of time between presentation and discussion, I get the impression that question time was occasionally moribund and I feel that its inclusion adds little to the book. The discussion papers are predominantly theoretical and those directly concerned with analysis are in the minority. These papers are mainly from Eastern European countries and they give a fair indication of their current interests in ion-selective electrodes.

I consider this book contains too few interesting papers, and it could only be recommended to the specialist intent on complete coverage of his field.

K. TORRANCE

Separation and preconcentration methods in inorganic trace analysis: J. MINCZWESKI, J. CHWASTOWSKA and R. DYBCZYNSKI, Horwood, Chichester, 1982. pp. xi + 543. £37.50.

The aim of the authors in writing this book was to provide a text for both experienced and uninitiated analysts who work with methods for separating and preconcentrating trace constituents. Within the constraints that they have set themselves on the subject, they have succeeded, and produced a useful book. The authors have dealt with methods based on precipitation, co-precipitation, volatility of constituents, extraction, ion-exchange and reversed-phase chromatography. These aspects of analysis are dealt with in general terms and in sufficient detail for the book to be a practical aid in the laboratory. Each chapter reviews the subject and is followed by a full international and up to date collection of references which more than covers any detailed procedures which have been omitted from the text. The theoretical principles on which the methodology is based are discussed in sufficient detail to permit the application of the theory to practice.

The book is arranged in seven chapters. The first two deal with problems and working techniques in trace analysis. The third chapter discusses the problems associated with methods of precipitation and the application of these methods to trace analysis. Chapter 4 is concerned with volatilization of substances as an analytical technique and the problems of volatility associated with various ashing techniques. The fifth chapter is concerned with liquid–liquid extraction and the application of extractions in separation processes. A comprehensive review of the subject is dealt with in the text and in tabular form. Chapter 6 is the largest and perhaps the most detailed in the book and deals with the materials, theory and practice of ion-exchange chromatography. Various application methods are dealt with textually and in tabular form. The seventh is a brief chapter dealing with extraction chromatography, again theoretically and applied to practice.

Because of the field in which the authors work, there is slight bias towards the examination and solution of problems of trace analysis in nuclear research, but the book loses nothing by this and is easily read, a compliment to the authors and the translator.

PUBLICATIONS RECEIVED

Ion-Selective Electrodes, 3: E. PUNGOR (ed.), Elsevier, Amsterdam, 1982. pp. 428. $100.00.

This book consists of the papers presented at a conference held in Mátrafüred, Hungary in October 1980. These papers are divided into four plenary lectures, five keynote lectures and twenty-three discussion papers. The first two groups of lectures constitute approximately one third of the book and true to the pattern of this style of lecture most specialist workers will have read or heard most of it all before. Each of the discussion papers is followed by an account of the questions and answers that arose from the presentation. Regardless of Professor Pungor's claim of equal division of time between presentation and discussion, I get the impression that question time was occasionally moribund and I feel that its inclusion adds little to the book. The discussion papers are predominantly theoretical and those directly concerned with analysis are in the minority. These papers are mainly from Eastern European countries and they give a fair indication of their current interests in ion-selective electrodes.

I consider this book contains too few interesting papers, and it could only be recommended to the specialist intent on complete coverage of his field.

PUBLICATIONS RECEIVED

Liquid Chromatography of Polymers and Related Materials III (Chromatographic Science Series, Volume 19): JACK CAZES (ed.), Dekker, New York, 1981. Pages viii + 299. S.Fr. 108.

This third volume in the series comprises fourteen papers presented at the International GPC Symposium, October 1980. As in earlier volumes in the series most of the contributions deal with practical aspects of gel permeation chromatography (GPC). This volume includes such topics as characterization of oligomers, polyphosphazines and branched block copolymers, and applications of GPC to polyolefins and poly(olefin-sulphone)s. Two new developments in GPC columns are described—coiled microcolumns for fast GPC and polystyrene bonded silica as a column packing.

G. GORDON CAMERON

Nothing but Motion: DEWEY B. LARSON, North Pacific Publishers, Portland, Oregon, 1979. Pages xvi + 292. $9.50.

This book is an introduction to a new theory which is said to be applicable to the whole field of physical science. As the title implies, the author regards the entire universe as composed of motion and material objects as manifestations of this motion. While the notion of a "universe of motion" has a certain appeal in connection with the relativistic quandaries of space and time, this "reciprocal theory" does not look quite as satisfactory when applied to the more mundane problems of chemical science. This is in part due to the "college text" chemistry which is dealt with, and also to the unfamiliar notation which the new theory requires for its application in this area. Whether this book is Science Fact or Science Fiction is impossible for this reviewer to decide—but it certainly is thought-provoking.

R. ALAN HOWIE

Analysis of Pesticide Residues: H. ANSON MOYE (ed.), (Chemical Analysis, Vol. 58), Wiley, New York, 1980. Pages viii + 467. £25.75.

One might well ask 'Why write a monograph on this topic which is already covered by several well established handbooks?' The various authors have, I think, had different aims in mind, but each has contributed something useful to this volume. The chapter on chromatographic columns says much that will not be found in the standard reference texts and proves the necessity of saying it by analysing the performance of laboratories regularly engaged in pesticide analysis. This excellent introduction is followed by an updating review on detectors which also aims to assist the newcomer in choosing the most appropriate one for his problem. Shorter chapters on the application of TLC and HPLC to pesticide residue analysis are followed by one on the determination of chlorinated hydrocarbons. The chapter on acidic herbicides includes a number of detailed procedures, which is not the policy adopted in the other chapters, while chapter eight is almost a monograph in itself on organophosphorus pesticides, including much useful information on common and trade names, chromatographic data and so on. Carbamate insecticides are considered largely in terms of their determination by GLC after derivatisation, and then a small group of insect pheromones is dealt with, where the problem is one of resolving stereoisomers by GLC. An interesting and useful final chapter discusses U.S. Government requirements for pesticide residue analysis—this is a good guide to an administrator's jungle.

There is much useful information here, presented clearly and readably, though somewhat unevenly. A brief introduction covering classification of pesticides, their cycles in the environment, toxicities and uses, scale of production and persistence would have been a useful addition to what will certainly become a valuable complementary text to the official handbooks on the subject.

IAIN L. MARR

Colorimetric Chemical Analytical Methods: L. C. THOMAS, G. J. CHAMBERLIN and G. SHUTE, 9th Ed., Tintometer, Salisbury; Wiley, New York, 1980. $85.00.

This ninth edition of a book first introduced in 1953 still provides a useful series of methods relying on simple colorimetric equipment. The list of methods clearly includes many used by current users of the Lovibond Tintometer equipment: indeed one method (albeit with clear warning notices) still uses benzidine, at the insistence of an overseas user. The initial sections provide an introduction to the methods, including descriptions of ion-exchange resins, buffer solutions and the Lovibond range of apparatus. A section on the colorimetric determination of pH is followed by a section of some 27 organic methods, including ones for alcohol, amines, dichlorophen and sugars. Half of the book is devoted to the next section, on the determination of metals and other inorganic species. This section contains many well-known and useful methods. The next sections are concerned with methods used in biochemistry and related areas, and of toxic substances in air. The final section, entitled "Colour grading and quality tests", is a mixture of methods on colour grading of a variety of foods as a means of quality control, and of quality control tests such as the COD test.

This book is an invaluable source of simple methods which are suitable for use by lowly-qualified staff, and contains much information of value to the hardened analyst.

PUBLICATIONS RECEIVED

Solid Surface Luminescence Analysis: ROBERT J. HURTUBISE, Dekker, New York, 1981. pp. xi + 274. S.Fr. 94.00.

This book is the first of a series of monographs devoted to recent advances in the field of analytical chemistry. As such, it must be considered as an extended review of publications over the last two decades, rather than an authoritative textbook of standard reliable methods. Many may wonder about the necessity of bringing together in one volume information about so many disparate subjects. Among the subjects covered are the design of commercial and research instruments, the theory of scattering from solid surfaces, spectroscopic considerations and analytical applications in a number of quite different disciplines. In many cases the substances being analysed do not constitute an integral part of a surface, but are merely components of a mixture separated on some chromatographic matrix, so that the interest lies in the separation, rather than the nature of the surface. Further, many of the identifications, or determinations made on the surface, are familiar from similar measurements made in solution. Nevertheless, the text will be useful to the analytical chemist in providing a guide to the possibilities of working with samples in the solid phase, without the necessity of time-consuming and irreproducible extraction procedures.

J. R. MAJER

Handbook of Practical Organic Microanalysis: S. BANCE, Horwood, Chichester, 1980. pp. 206. £18.50.

This is a really practical book which gives readers the benefits of the author's many years experience in the microanalytical laboratory of a major industrial organisation. It is meticulously compiled and covers practical details and hints which would be invaluable to anyone setting up a traditional microanalytical laboratory. Of necessity, the accent is on traditional methodology, on tried and proven methods, some of which have now been overtaken by instrumental techniques, but nevertheless have their place in a well organized and comprehensive microanalysis laboratory. It is well indexed. Each chapter relates to a particular element or group of elements and opens with a general discussion on the method and the theoretical background. It then proceeds to a detailed account of the apparatus and method with practical hints which are not often seen even in a practical chemist's text book. Altogether the book is a mine of information and knowledge gained by first hand experience and should prove to be a most useful addition to any library.

DORIS BUTTERWORTH

Analysis of Non-Metals in Metals, GUNTHER KRAFT (ed.), Walter de Gruyter, Berlin, 1981. pp. xiv + 546. DM 148.

This book is a record of the Proceedings of the International Conference held in West Berlin, 10–13 June 1980. There are 36 papers printed in French, German and English, the French and German papers being provided with short summaries in English. In addition to communications describing analytical problems using conventional techniques, there are some which are concerned with more recent instrumental methods. There is a large section devoted to activation analysis, the activation being realized by neutron bombardement, by radiation with charged particles and by exposure to high-energy gamma-rays. Among the physical methods involving the use of large instruments included in the text are spark-source mass spectrometry, plasma emission spectrography, electron microscopy and Auger electron spectroscopy. The methods used are applied to the determination of non-metals in both ferrous and non-ferrous metals. The final paper is the one which will be of most general interest in that it discusses the provision of reference samples for the analysis of non-metals in metals.

OBITUARY

G. GOPALA RAO
(1908–1981)

G. Gopala Rao, retired Professor of Chemistry, Andhra University, died on October 26, 1981 after a prolonged illness.

After his early education at the Rajah's College, Kakinada and Maharajah's College, Vizianagaram, Gopala Rao proceeded to Allahabad, where he took his M.Sc. degree in 1929. He then joined for research under Professor Nil Ratan Dhar and received the D.Sc. degree in 1932. When Andhra University organized the Honours courses in Chemistry in 1932, Gopala Rao joined the Chemistry Department as a founder member of the Faculty and rose to be the Professor in 1946 and Head in 1949.

Gopala Rao's early research interests were in the field of photochemistry, with particular reference to the development of analytical methods by application of the chemical action of light. During the course of these studies, his research interests moved to redox analytical processes, in which his contributions are recognized as very profound. Simultaneously, Gopala Rao also pioneered studies in catalysis in analytical processes, which was a precursor of the kinetic methods in analysis, a topic of current interest. His outstanding contributions in these fields were acknowledged by his being invited to act as a Regional Editor of *Talanta*.

Gopala Rao had taken a very active interest in initiating innovative academic programmes. The credit for organizing a full-fledged MSc. Analytical Chemistry course in India in 1957, goes to him. He encouraged research activities among his junior colleagues, which helped to sustain active research in Andhra University in the field of Analytical Chemistry, right up to the present.

After retirement from service in November, 1968 Professor Gopala Rao continued active research work as a University Grants Commission Retired Scientist and as Emeritus Professor in the Chemistry Department till March, 1979. The fact that as many as 40 research papers on the Analytical Chemistry of selenium, tellurium, arsenic *etc*., were published during this period, shows his dedication for research. The total number of research papers published by him is about 250. An unfinished programme undertaken by him was the writing of a monograph on the role of complexation methods in analytical procedures.

Professor Gopala Rao was awarded the Honary Degree of Doctor of Science by Andhra University on the occasion of its Golden Jubilee celebrations, for his outstanding contributions to teaching and research.

Professor Gopala Rao is survived by his wife, four sons and three daughters.

PUBLICATIONS RECEIVED

Chlorinated Dioxins and Related Compounds: Impact on the Environment: Edited by O. HUTZINGER, R. W. FREI, E. MERIAN and F. POCCHIARI, Pergamon Press, Oxford, 1982. Pages 624, £37.50.

This is Volume 5 of the Pergamon Series on Environmental Science. It contains the proceedings of a workshop held in Rome in 1980—an attempt to bring together scientists of different disciplines in order to introduce a multidisciplinary and systematic approach to an emotive subject.

This major book succeeds admirably in presenting an up-to-date account of major environmental aspects of polychlorinated dibenzodioxins (PCDD) and chemically related compounds. The well laid-out text contains 52 refereed papers covering analytical methodology, the environmental fate and levels of PCDD, incineration, toxicology and metabolism as well as observations in man. The relationship between incineration and PCDD formation is particularly well documented, as are the scientific aspects of environmental findings around the town of Seveso after the accidental release of tetrachlorodibenzodioxin (TCDD).

Diagrams, graphs, photographs and tables are well reproduced and laid-out. The papers are well written and contain adequate up-to-date references. The summary and conclusions of the workshop and a good index serve to make this specialist text not simply a collection of important original papers, but more of a textbook covering all aspects of a topical subject of extreme importance. Purchase of this excellent book is recommended for all scientists interested in the environment.

D. M. W. ANDERSON

Undergraduate Instrumental Analysis, 3rd Ed.: JAMES W. ROBINSON, Dekker, New York, 1982. Pages xvii + 550. SFr. 75.

This book was originally written to provide undergraduates with a basic but comprehensive guide to instrumental analytical techniques. Its success is shown by the appearance of a third edition within 12 years. Although many books on instrumental techniques have been published in the last decade, only a few are really useful for a newcomer to the field. This one describes the principal features of most of the commonly encountered techniques in a simple and informative but sometimes idiosyncratic manner. Generally a non-mathematical approach has been adopted, except for a few simple and unavoidable mathematical equations, which makes the book easy to understand and probably helps to keep the student's interest in the text.

The latest edition consists of fifteen major chapters and an introductory section. The first chapter deals with the general concepts and definitions in analytical chemistry. The second and third chapters contain the basic laws and theories of spectroscopy, and provide a theoretical background for the next eight chapters, which are devoted to the different spectroscopic techniques. The last four chapters deal with chromatography, thermal analysis, mass spectrometry and electrochemistry. Each chapter ends with a bibliography, simple problems and some suggestions for experiments to familiarize the student with instrument handling. Most of the chapters have been revised and improved by adding recent developments in various techniques, and this has resulted in a significant expansion in the present edition.

It seems surprising, however, that the book contains little about atomic-fluorescence spectroscopy, which is an important and fully developed technique in analytical chemistry. Statements such as "A disadvantage of the method is that only one element can be determined at a time" and "solid samples must first be dissolved and the solution then analysed" (both from the atomic-absorption chapter) seem useful generalizations but may misguide the reader, since multichannel (or at least dual-channel) instruments are available and solid samples can also be analysed with carbon atomizers. Tables 7.1 and 9.2 (on flame temperatures) are not mutually consistent. The proof-reading seems rather careless.

However, these are minor points and do not affect the overall balance of the book, though they may cause problems for the student.

J. ANWAR

Advanced Mass Spectrometry: U. P. SCHLUNEGGER, Pergamon Press, Oxford, 180. Pages xii + 143. £12.50

Although completely new types of spectroscopy to aid structure elucidation of organic compounds are now rare, developments in existing methods continue and this book describes one of them. DADI (direct analysis of daughter ions)/MIKE (mass-analysed ion kinetic energy) spectrometry provides a method of deducing the origin of fragment ions in the mass spectrometer without recourse to traditional and time-consuming isotopic labelling.

The early chapters in the book describe ionization methods, basic concepts of mass spectrometry such as metastable ions, collisional activation and collision-induced dissociation and the design of single and double focusing mass spectrometers. Knowledge of these subjects is necessary to understand the basis of MIKE spectrometry in which the conventional Nier–Johnson geometry of the double-focusing mass spectrometer has been reversed, *i.e.*, the ions pass through the magnetic sector before the electrostatic sector. Certain ions such as the molecular ion are separated in the magnetic analyser and fragmented by collision with an inert gas in the second field-free region between the magnetic and electrostatic analysers. The electrostatic analyser separates the fragment ions and so a clear picture of the fragmentation of the ion initially separated in the magnetic analyser is obtained. A closely related technique—"linked scan"—is also described, and it too gives a "cleaner" picture of fragmentation patterns.

Chapters 6 and 7 (more than half of the book) provide a wide selection of examples of the power of DADI/MIKE spectrometry. Elucidation of the structure of complex natural molecules, including peptides (sequencing), is illustrated with many good examples. Frequently encountered isomerizations and rearrangements of ions in the mass spectrometer can also be detected and elucidated by using this technique.

The book is timely and coincides with the author's review in *Topics in Current Chemistry*, Vol. 95, in which the same subject is treated in less depth. The translation is generally good and the book should stimulate further interest in the subject. Non-specialists with a working experience of mass spectrometry should have little difficulty in understanding the concepts and hence broadening their view of mass spectrometry as an analytical tool.

A. R. FORRESTER

Talanta, Vol. 29, pp. iii to iv, 1982
Pergamon Press Ltd. Printed in Great Britain

PUBLICATIONS RECEIVED

Inorganic Reaction Chemistry, Vol. 2, Reactions of the Elements and Their Compounds, in two parts, A: **Alkali Metals to Nitrogen,** B: **Osmium to Zirconium:** D. T. BURNS, A. TOWNSHEND and A. H. CARTER. Ellis Horwood, Chichester, 1981. A, pp. 300, £27.50; B, pp. 280, £27.50.

These books are published as part of the Ellis Horwood Series in Analytical Chemistry and are linked to an earlier volume in the same series, "Systematic Chemical Separation" by Burns, Townshend and Catchpole, which is referred to as Volume 1 on the topic of Inorganic Reaction Chemistry. The reviewer has not yet seen Volume 1, which was published in 1980, but judged by the quality of the present volumes, the series of three books should provide an excellent up to date treatment of the separation reactions used in qualitative analysis and the specific reactions used for the identification of inorganic ions. Compared to older texts on this subject, the treatment contains much more detailed information on reactions with inorganic and particularly organic reagents, as well as a useful breakdown of reactions for the different oxidation states of relevant elements. All three books are products of the efforts, involving the detailed examination of suitable reactions, carried out by members of the Midlands Association for Qualitative Analysis. Since most reactions have been experimentally verified by members of the association, the practical detail is a valuable bonus, and the end result is an authoritative treatise on inorganic reactions which is much wider than that required for qualitative analysis procedures. As such the volumes will represent a laboratory handbook of considerable practical application in laboratories which suffer the submission of unknown substances for analysis.

The structure of the book as indicated by the subtitles, follows the alphabetical order of the elements. In a few cases such as the alkali metals, niobium and tantalum, rhenium and technetium, etc. elements have been grouped together because their chemistry and reactions are similar. Each chapter contains a brief summary of the chemistry of an element and its typical compounds, followed by a description of selected reactions of the element in the various forms in which it commonly exists. The selection of reactions for inclusion has been made after rejection of reactions considered unreliable. The reactions are simple and straightforward and can be carried out with apparatus no more extensive than a test-tube or spot-plate. The full range of reactions would, however, require an extensive collection of inorganic and organic reagents, although since numerous alternative reactions are given for each element or species, an exhaustive collection of reagents would rarely be needed. Remarks are also included on the toxicity of relevant elements and compounds. Numerous references to the reactions are given, and lists of the organic reagents referred to and useful solubility products are given in Appendixes. The two volumes are intended to go together, and as an aid in their use, the pages have been numbered consecutively through both volumes (apart that is from the pages at the beginning of each chapter which, although included numerically, have not been numbered). Advantage has been taken of this consecutive numbering, by the introduction of an index in volume 2, which covers both books. These volumes are obviously more suited to laboratory than library use and should be popular with both students and practising analytical chemists. A cheaper paperback version would be of great benefit and would ensure the wider appreciation of the valuable work carried out over many years by the authors and their colleagues in the Midlands Association for Quantitative Analysis.

J. M. OTTAWAY

Analysis of Drugs and Metabolites by Gas Chromatography–Mass Spectrometry, Vol. 7. B. J. GUDZINOWICZ and M. J. GUDZINOWICZ, Dekker, New York, 1980, pp. x + 557. S. Fr. 146.

This latest addition to the series devoted to descriptions of the analytical successes of the gas chromatograph–mass spectrometer combination deals with a recurrent contemporary problem, *viz.* the examination of inhaled smokes. The first section is concerned with the identification of the products of pyrolysis of tobacco, and also the analysis of the constituents of the original tobacco leaf. It is interesting that in the study of the polynuclear aromatic hydrocarbon fraction of cigarette smoke, the measurement of retention volumes plays a more significant part in the identification of individual compounds than does the mass spectrum.

The second section describes the application of the same techniques to the analysis of the chemical composition of the marijuana plant and the products of pyrolysis of marijuana. In the case of both intoxicants there are full descriptions of the methods used in the determination of metabolic products. As in previous volumes, there are always full experimental details of the apparatus used and precise summaries of results.

J. R. MAJER

Progress in Analytical Atomic Spectroscopy, Volume 2: C. L. CHAKRABARTI (ed.), Pergamon Press, Oxford, 1981, pp. v + 386. £33.00.

The second volume in this series contains five reviews, all written to a high standard by international authorites. "Atomic Fluorescence Spectrometry: Basic Principles and Applications", by Omenetto and Winefordner takes up almost half of the volume, and is an excellent comprehensive monograph on AFS. As might be expected, theoretical principles and recent novel developments and applications are particularly well covered, but early work too is adequately treated, much use having been made of clear and concise tables. "Trace Element Analysis of Food and Beverages by AAS", by Fricke, Robbins and Caruso, covers analytical atomic spectroscopy-based procedures, arranged by element, for the analysis of samples falling in this category. This review includes useful background information on how elements enter the food chain and, where appropriate, their role in nutrition, as well as extensive tables of published procedures. Subramanian and

Chakrabarti's "Determination of Trace Metals in Ultrapure Water", although one of the shorter contributions, is a useful concise introduction to possible problems and pitfalls for those contemplating (or completing) determinations at very low concentrations. "Interferences in Flame Spectrometry, their Elimination and Control", by Rubeška and Musil is a valuable account of current ideas on the nature of such interferences and underlying theoretical concepts. This contribution is to be commended for the way it brings together information from so many diverse sources to produce a concise and readable account which still manages to cover the topic in depth. Finally "Emission Spectroscopic Analysis Using Cool Flames, Part I" by Henden, Pourreza and Townshend is a summary, primarily based on the work done at Birmingham University, of external vapour generation systems for MECA. This review is however of value to anyone interested in vapour generation systems, regardless of whether they intend to use MECA or flame or plasma OES.

The book is well presented from camera-ready copy, and good value at the price by today's standards.

M. S. CRESSER

The Analysis of Explosives, JEHUDA YINON and SHMUEL ZITRIN, Pergamon Press, Oxford, 1981, pp. xii + 310. £9.35.

It may be considered that in the present disturbed era the appearance of a book devoted to the analysis of explosives is most timely, more particularly so when the book contains a chapter describing methods of detection of hidden explosives. In this modestly sized volume the authors have chosen to review all significant methods and analytical procedures for the determination of explosive materials. As a result, the treatment is often uneven, so that column chromatography methods, surely of only historical interest, are described in some detail, while the section on thermal methods consists only of a brief outline of the principles involved. Nevertheless, the text does contain a review of the more recent work on mass spectrometric methods. Apart from the familiar electron impact spectra, attention is drawn to spectra using alternative methods of ionization, such as field desorption and chemical ionization. Some reference is made to the production of negative ions from explosive materials, and to the less familiar fields of ionization at atmospheric pressure and plasma chromatography. While it is unlikely that many practising analytical chemists will be required to carry out routine examinations of explosive materials, it remains important that they should be capable of making such examinations when required, and therefore this text should be on their bookshelves.

J. R. MAJER

Analytical Isotachophoresis: F. M. EVERAERTS (ed.), Elsevier Amsterdam, 1981, pp. xi + 234. $58.50.

This book constitutes a record of the Proceedings of the 2nd International Symposium on Isotachophoresis held at Eindhoven, 9–11 September 1980. There are 29 short papers describing advances in the theoretical aspects of the subject, instrumentation and data handling, and applications to analytical problems. The versatility of the isotachophoretic method may be gauged by the diversity of the samples which have been submitted to analysis. These range from medium and high molecular-weight materials of biological origin to simple mixtures of condensed phosphates or carboxylate ions. The automation of the technique and the reduction of data with the aid of microprocessors is also considered. The book provides an overview of the state of development of a rapidly expanding analytical technique.

SECOND INTERNATIONAL CONFERENCE on CARBONACEOUS PARTICLES IN THE ATMOSPHERE

11–14 September 1983

Linz, Austria

organized by the
"Österreichische Gesellschaft für Mikrochemie und Analytische Chemie" in the
"Gesellschaft Österreichischer Chemiker"

CALL FOR PAPERS

The purpose of this conference is to provide an international forum for reviewing current research on characterization, sources, transport, formation, transformation, and effects of carbonaceous particles in the atmosphere. In the context of this conference, the term "carbonaceous particles" is used to describe organic and inorganic carbon-containing species associated with suspended particles.

Carbon is the largest elemental fraction of aerosol particles, and carbon-containing particles may influence global chemistry, cause loss of visibility, and adversely affect ecological systems, including human health. Carbonaceous particles and their gaseous organic precursors may also play an important role in cloud chemistry and physics, *e.g.*, in the formation of acid rain, and are important ingredients in the chemistry of polluted atmospheres.

During the last decade, there has been a dramatic resurgence of interest in this pollutant, as evidenced by the extent and diversity of research presented at the First Conference on Carbonaceous Particles in the Atmosphere, held at Lawrence Berkeley Laboratory, Berkeley, California, in 1978. That conference attracted 157 participants and 45 presentations.

The Second International Conference on Carbonaceous Particles in the Atmosphere (Linz, Austria) takes place 5 years after the first conference in Berkeley and focuses on the same general subject—carbonaceous particles.

Both invited and contributed presentations for this conference should be focused on (but not limited to) the following topics.

Sources, transport and atmospheric chemistry
Climate effects, visibility degradation and other physical effects
Analytical chemistry and measurement techniques, including sampling
Ecological, biological and human health effects, effects on materials

Conference Chairman:
Prof. Dr. H. Malissa

Conference Vice Chairman:
Prof. Dr. T. Novakov

Further information may be obtained from the Conference Secretary: Dr. H. Puxbaum, *Institute for Analytical Chemistry, Technical University of Vienna, Getreidemarkt 9, A-1060 Wien, Austria.*

3rd CONGRESS OF FUNDAMENTAL AND APPLIED MASS SPECTROMETRY

Palaiseau, France, 5–8 April 1983

This Congress is organized jointly by the Groupement pour l'Avancement des Méthodes Spectroscopiques et Physico-chimiques d'Analyse (G.A.M.S.) and the Ecole Polytechnique, Palaiseau.

Themes covered by papers in the fundamental field will include:

Negative Ions
The Chemistry of Positive Ions (Structure, Fragmentation Mechanisms, Kinetic Energy, *etc.*)
Photoionization by Laser and Collisional Excitation and in the applications field:

Identification and Analysis of Substances Affecting Man
Secondary Ion Mass Spectrometry

SECOND INTERNATIONAL CONFERENCE on CARBONACEOUS PARTICLES IN THE ATMOSPHERE

11–14 September 1983

Linz, Austria

organized by the
"Österreichische Gesellschaft für Mikrochemie und Analytische Chemie" in the
"Gesellschaft Österreichischer Chemiker"

CALL FOR PAPERS

The purpose of this conference is to provide an international forum for reviewing current research on characterization, sources, transport, formation, transformation, and effects of carbonaceous particles in the atmosphere. In the context of this conference, the term "carbonaceous particles" is used to describe organic and inorganic carbon-containing species associated with suspended particles.

Carbon is the largest elemental fraction of aerosol particles, and carbon-containing particles may influence global chemistry, cause loss of visibility, and adversely affect ecological systems, including human health. Carbonaceous particles and their gaseous organic precursors may also play an important role in cloud chemistry and physics, *e.g.*, in the formation of acid rain, and are important ingredients in the chemistry of polluted atmospheres.

During the last decade, there has been a dramatic resurgence of interest in this pollutant, as evidenced by the extent and diversity of research presented at the First Conference on Carbonaceous Particles in the Atmosphere, held at Lawrence Berkeley Laboratory, Berkeley, California, in 1978. That conference attracted 157 participants and 45 presentations.

The Second International Conference on Carbonaceous Particles in the Atmosphere (Linz, Austria) takes place 5 years after the first conference in Berkeley and focuses on the same general subject—carbonaceous particles.

Both invited and contributed presentations for this conference should be focused on (but not limited to) the following topics.

Sources, transport and atmospheric chemistry
Climate effects, visibility degradation and other physical effects
Analytical chemistry and measurement techniques, including sampling
Ecological, biological and human health effects, effects on materials

Conference Chairman:
Prof. Dr. H. Malissa

Conference Vice Chairman:
Prof. Dr. T. Novakov

Further information may be obtained from the Conference Secretary: Dr. H. Puxbaum, *Institute for Analytical Chemistry, Technical University of Vienna, Getreidemarkt 9, A-1060 Wien, Austria.*

3rd CONGRESS OF FUNDAMENTAL AND APPLIED MASS SPECTROMETRY

Palaiseau, France, 5–8 April 1983

This Congress is organized jointly by the Groupement pour l'Avancement des Méthodes Spectroscopiques et Physico-chimiques d'Analyse (G.A.M.S.) and the Ecole Polytechnique, Palaiseau.

Themes covered by papers in the fundamental field will include:

Negative Ions
The Chemistry of Positive Ions (Structure, Fragmentation Mechanisms, Kinetic Energy, *etc.*)
Photoionization by Laser and Collisional Excitation and in the applications field:

Identification and Analysis of Substances Affecting Man
Secondary Ion Mass Spectrometry
Applications of Isotopic Analysis

Details may be obtained from *G.A.M.S., 88 Boulevard Malesherbes, F 75008 Paris, France.*

EDITORIAL

This special issue on gains and losses in trace analysis is intended to form a "Paper Symposium", in which a number of papers on a common theme, written by invited experts in the field, are gathered together to give a survey of current developments and thinking. The idea of such an issue was long cherished by the late Professor Belcher, who was associated with *Talanta* from the inception of the journal, and we would therefore like to dedicate it to his memory. He was the moving spirit behind the issue, and though, unfortunately, he did not live to see it appear, he knew that all had been prepared. The organization of the symposium was very capably undertaken by Dr. Peter Tschöpel in Europe, with assistance from Dr. John Moody in the United States.

The gains and losses that arise in trace analysis can stem from any stage of the analysis, from sampling through to calculation and reporting of results, and can arise from the materials and equipment used, and from the techniques themselves. Practically all these aspects are dealt with in the symposium, and the perceptive reader will readily see that some sources of error are less obvious than others, the background errors in Zeeman atomic-absorption spectrometry being a case in point.

Devotees of dictionaries and analytical conferences will know that a symposium is a drinking party. Extraction methods are frequently used in trace analysis. We suggest that readers of this Paper Symposium on trace analysis may help this issue live up to its name, by drinking in the information given in it, and extracting the wisdom from its pages.

ERRATA

In the paper by K. K. Stewart in the November issue (*Talanta*, 1981, **28**, 789), equation (2) on page 795 should read

$$t(\text{eq}) = k_1 \ln (C_a/nC_b) + k_2$$

The name of the third author of the paper "Spectrophotometric determinations of isoniazid with metol and vanadate, ferricyanide or iron(III)", *Talanta*, 1981, **28**, 477, was incorrectly spelt, and should be S. S. N. Murthy.

NOTICES

INTERNATIONAL CONFERENCE AND EXHIBITION ON ANALYTICAL CHEMISTRY (SAC 83)

The University, Edinburgh, Scotland, July 17–23 1983

SYMPOSIUM ON "ANALYTICAL INORGANIC MASS SPECTROMETRY"

This Symposium is organized, on behalf of the delegates to the Symposium on Inorganic Mass Spectrometry held at EUROANALYSIS IV in Helsinki 1981, by Professor F. Adams and Dr. A. M. Ure in collaboration with the Analytical Division of the Royal Society of Chemistry.

The Symposium will take the form of a one-day programme of invited and contributed lectures on the themes of "ANALYTICAL APPLICATIONS AND METHODOLOGY" and "NEW TECHNIQUES AND INSTRUMENTATION". A poster session will also be provided and the Symposium will be concluded with an Open Forum Discussion Meeting on "FUTURE NEEDS AND DEVELOPMENTS". The Symposium will form a part of the wide-ranging Programme of SAC 83.

Contributed papers on any aspect of Analytical Inorganic Mass Spectrometry including IDMS, FTMS, LAMMA, PSMS, SIMS, SSMS, TSMS *etc.* will be welcomed.

All those interested in attending this Symposium and SAC 83 should request a copy of the SAC 83 2nd circular from The Secretary, Analytical Division, Royal Society of Chemistry, Burlington House, London W1V 0BN, U.K. Please also indicate your interest in the Symposium and/or your intention to present a paper at it if appropriate. The 2nd circular will be available in June 1982.

THE 23rd COLLOQUIUM SPECTROSCOPICUM INTERNATIONALE INCLUDING THE 10th INTERNATIONAL CONFERENCE ON ATOMIC SPECTROSCOPY

Amsterdam, 26 June–1 July 1983

Coverage of the following techniques is envisaged:

1. Atomic-emission spectroscopy
2. Atomic-absorption spectroscopy
3. Atomic-fluorescence spectroscopy
4. X-Ray spectroscopy
5. Infrared and Raman spectroscopy
6. Ultraviolet and visible spectroscopy
7. Methods for surface and thin film analysis
8. Mass spectroscopy for inorganic analysis
9. Laser spectroscopy

The fundamental and instrumental aspects of these techniques as well as their applications will be dealt with in either specialized sessions or more general symposia with a special emphasis on the following issues:

A. Detection systems
B. Standard reference materials and methods
C. Environmental analysis
D. Biological, clinical and pharmaceutical analysis
E. Analysis of metals and industrial materials

F. Geochemical and petrochemical analysis
G. Agricultural and food analysis

Internationally recognized authorities in these fields will review the current trends and future perspectives in the respective fields. Major efforts will be undertaken to promote interdisciplinary coverage and informal contacts. Plenary lectures will run consecutively and parallel sessions of oral presentations will be minimized by emphasizing the role of poster presentations.

An instrument exhibition will be held in the lounges around the lecture halls.

The conference languages are English, French and German.

Social events including a reception in the Rijksmuseum, a conference banquet, and an excursion featuring characteristics of the Netherlands will be organized.

Accompanying persons can choose from a variety of daily excursions.

1st INTERNATIONAL SYMPOSIUM ON DRUG ANALYSIS: FROM PHARMACEUTICAL PREPARATION TO DRUG MONITORING

Sponsored by the F.I.P.

Free University of Brussels (U.L.B.), Campus Plaine-1050 Brussels, 7–10 June 1983

The purpose of the symposium is to bring together people from Industry, Universities, Control laboratories and Hospitals to discuss the current status of analytical techniques, including instrumental applications as well as theoretical developments. The topics are as follows

(1) Naturally occurring drugs.
(2) Analytical problems in the development of drug formulation.
(3) Control of pharmaceutical specialities.
(4) Determination of drugs in food products for human or animal use.
(5) Determination of drugs in biological media, including drug monitoring.
(6) Research into toxic reactions due to drugs.

A limited number of plenary and keynote lectures will be given by invited speakers. Contributed papers will be either poster presentations or oral presentations.

Panel discussions may be organized.

The official languages of the conference are English, French and Dutch.

PROFESSOR RONALD BELCHER

Professor Belcher, Co-Chairman of the Advisory Board and Chairman of the Editorial Board of *Talanta*, was awarded an Honorary Doctorate of Science by the University of Saarbrücken in February 1981. The presentation was made by Professor Friedrich Tomi, Dean of the Faculty of Mathematical Sciences.

Die

Mathematisch-Naturwissenschaftliche Fakultät

der

Universität des Saarlandes

verleiht

unter der Präsidentschaft des Professors für Biogeographie
Dr. rer. nat. Paul Müller
und unter dem Dekanat des Professors für Mathematik
Dr. rer. nat. Friedrich Tomi

Herrn Ronald Belcher D. Sc.

Professor em. für Analytische Chemie
an der Universität Birmingham
die Würde eines

Ehrendoktors der Naturwissenschaften (Dr. rer. nat. h. c.)

Sie zeichnet damit einen vielseitigen Forscher aus, der bahnbrechende Methoden auf dem Gebiet der organischen und anorganischen Mikroanalyse entwickelt hat. Er bemühte sich um die Ausarbeitung eines umfassenden Systems der quantitativen Ultramikroanalyse, und es war ihm möglich, viele Probleme zu bewältigen, die mit der Herabsetzung vom Milligramm- in den Mikrogrammbereich verbunden sind. Mit der MECA-Spektroskopie gelang ihm der Vorstoß in den Nanogramm-Bereich.

Sein unermüdliches, höchst lebendiges Wirken verhalf der Analytik auf vielen Gebieten der Chemie und der Pharmazie weltweit zu Ansehen und Geltung.

Saarbrücken, den 9. Februar 1981

WORKING PARTY ON ANALYTICAL CHEMISTRY (WPAC) FEDERATION OF EUROPEAN CHEMICAL SOCIETIES (FECS)

European Analytical Column 5

By January 1982 the WPAC consisted of 27 national chemical societies of 21 European countries, represented by 26 delegates. Among the FECS member societies only the Portuguese Chemical Society, the Pancyprian Union of Chemists and the Turkish Chemical Society are not represented in the WPAC. The Romanian Chemical Society sent an observer to the last WPAC meeting.

The 12th meeting of the WPAC was held in Helsinki, 23 August 1981, on the occasion of the Euroanalysis IV conference. At this meeting Professor E. Pungor (Budapest) was elected as WPAC chairman for the period 1981–1984, and the following issues were discussed.

1. *Euroanalysis IV, Helsinki, 25th event of the FECS*

This conference was organized on behalf of the WPAC by the Association of Finnish Chemical Socieites as a broad spectrum conference and was attended by 750 participants (including 100 accompanying persons) from 39 countries. The number of papers presented was well over 250, including 17 invited plenary and keynote lectures, the latter to be published in a joint east–west issue of the series "Reviews on Analytical Chemistry" with the title "Euroanalysis IV", publishers: Akadémiai Kiadó (Budapest), Chemical Publ. Co. (Helsinki). The conference programme also included three "Special Sessions" (1, Analytical Chemistry, the Analyst and Society; 2, Symbolism in Analytical Chemistry; 3, Mass Spectrometry in Inorganic Analysis) and a commercial exhibition of analytical equipment and literature.

2. *FECS lecture 1981*

An FECS lecture, which is delivered annually on the occasion of a major event of FECS, was granted in 1981 to Professor Bengt Samuelson (Karolinska Institutet, Stockholm), who presented, at the invitation of the Association of Finnish Chemical Societies, an outstanding survey on "Leukotrienes: A New Group of Biologically Active Compounds" on 25 August 1981, at the Finlandia Hall, Helsinki, on the occasion of Euroanalysis IV.

3. *Euroanalysis V, 1984*

The next conference was announced as to be held in Cracow, Poland, 26–31 August 1984, at the Jagellonian University and the Technical University Cracow. The decision will be considered at the next WPAC meeting on 26 April 1982 in Munich. The topics of the special sessions will be decided, according to the report of the Polish delegation.

4. *Euroanalysis VI, 1987*

According to a decision at the last WPAC meeting, Euroanalysis VI will be organized on behalf of the WPAC by the French Chemical Societies in 1987 in France. The location is the subject of a later decision.

5. *Euroanalysis VII, 1990*

There has been an official bid of the Austrian Society of Microchemistry and Analytical Chemistry to hold this conference in 1990 in Vienna.

6. *COBAC II* (FECHEM Conference on Computer-Based Analytical Chemistry), *Munich* 28–29 April 1982

Organized by WPAC in co-operation with the Analytical Chemistry Division of the Gesellschaft Deutscher Chemiker. The following topics will be discussed.

On-line coupling of computers and analytical equipment, integrated process control systems, peripheral equipment.
Desk computers: application in computer-based interpretation of spectra.
Library search procedures, identification of substances by means of spectroscopic data.
Programs for analytical chemistry.
Pattern recognition.
Present status of computerization in clinical analysis.
Interpretation of clinical data.
Control of significance of clinical data.
Role of computerization in the bill of costs of a large laboratory.

7. *COBAC III*

This FECHEM conference is planned to be held as a special session of the Euroanalysis V conference. Professor Hippe (Rzeszow, Poland) has been proposed as conference chairman. Scientists interested in this

active field of research are invited to contact the secretary of WPAC (Professor R. Kellner, Institut für Analytische Chemie, Technische Universität Wien, A-1060 Wien, Getreidemarkt 9, Austria).

8. *Education in Analytical Chemistry*

As part of the preparation for the next FECHEM conference on Education in Analytical Chemistry (in connection with Euroanalysis V) a questionnaire was prepared to find out about the new situation in this field in Europe after the last FECHEM conference in Vienna 1980. All institutions active in the field of higher education in Analytical Chemistry are invited to apply for a copy of the questionnaire. Please write to the secretary of WPAC if you have not received your own copy.

9. *Chemometrics and Analytical Chemistry*

A definition of Chemometrics (as approved by the Chemometrics Society) and a model curriculum for chemometrics studies were presented by Dr. Christie (Oslo) and will be further discussed at the next meeting.

10. *Pending FECS sponsorship*

At the request of the new chairman, Professor Pungor, WPAC should ask for FECS sponsorship for

(*a*) Symposium on "Electrochemical Detection in Flow-Analysis", Matrafüred (Hungary), 17–20 October, 1982;

(*b*) Symposium on "Pattern Recognition", Matrafüred (Hungary), 20–22 October, 1982;

(*c*) FECHEM conference on GLP (date and location to be specified).

11. *Next (13th) meeting of the WPAC*

The Fachgruppe Analytische Chemie of the Gesellschaft Deutscher Chemiker invited WPAC to hold the 13th meeting in Munich in connection with the "Biochemische Analytik" and the "Analytika" on Monday, 26 April 1982.
