TALANTA REVIEW*

SEPARATION OF TRACE ELEMENTS IN SOLID SAMPLES BY FORMATION OF VOLATILE INORGANIC COMPOUNDS

K. BÄCHMANN

Fachbereich für Anorganische Chemie und Kernchemie Technische Hochschule Darmstadt, 6100 Darmstadt, FRG

(*Received* 2 *March* 1981. *Accepted* 31 *May* 1981)

Summary—Methods for the separation and determination of trace elements by volatilization and by gas chromatography are reviewed. Examples are given of typical separations and apparatus suitable for inorganic gas chromatography is described.

Trends in the development of analytical methods for inorganic substances are the determination of very low concentrations of elements, the simultaneous determination of many elements (multielement analysis), the determination of different species of the overall concentration of an element and increasing precision and accuracy.

High-purity substances used in optical waveguides, metals and semiconductor materials, should have concentrations of trace elements which are often lower than the detection limits of the analytical methods available. Very low concentrations are often responsible for large effects, especially in biochemical systems.

Complete analysis of a system requires the determination of many elements. The simplest cases are high-purity materials, for which the influence of an element on the conductivity or light absorption can easily be estimated. Much more complicated are biochemical or environmental systems, where the effect of one element depends on the concentration of other elements present.

In many analytical problems it is important to know the species or the phase (for example, aerosol or gas phase) of an element. Since the common methods of molecular analysis are often restricted to higher concentrations it is necessary to obtain indirect information about the species by its chemical behaviour during separation.

It is necessary in all analytical fields to increase accuracy and precision. For example, the laws against environmental hazards require more precise determinations.

These four requirements must have a considerable impact on future trends in analytical research. Since systematic errors may be due to the interference of other elements, one possibility of increasing accuracy is to carry out a complete separation which allows comparison with a standard. If we compare instrumental analyses and combined systems in which instrumental determination is preceded by separation, then the main drawback of instrumental analysis is interference from other elements, while that of combined systems is contamination from reagents and losses due to adsorption.

Any separation method suitable for trace elements should minimize contamination and loss. The contamination problem can be reduced by working in closed systems and using purified reagents. The loss of trace elements can be avoided by using small surface areas and high temperature. We have found that the general requirements for separation procedures in ultratrace analysis are met by using the gas phase.[1–17] The gases used (*e.g.*, Ar, N_2, O_2, Cl_2, HCl, CCl_4) can be highly purified with respect to the trace elements usually determined. The surface area can be kept small and the whole separation carried out in one container. Losses of trace elements at high temperatures can be neglected. In experiments on separation of only a few atoms per hr of element 104, as its tetrachloride, it has been found[18,19] that at high temperatures no losses due to adsorption occur. Furthermore, it is easy to purify all containers since pretreatment at high temperatures with gases such as Cl_2 will clean the surface completely, but caution has to be exercised with elements which diffuse through quartz.

In Table 1 gas-phase separations are compared with the most important alternative separation method, extraction. More than 50% of all preconcentration methods depend on extraction, whereas only about 7% are carried out in the gas phase.[20] The table differentiates between a single-stage and a multistage

Table 1. Comparison of extraction and gas phase separation in trace element analysis

	Separation factor	Number of elements or problems	Technology	Time	Detection limit
Extraction	Medium	Not limited	Simple	Fusion takes time, whereas single extraction is fast	Limited by purity of reagents, and lowest possible volume for sample dissolution and extraction
Extraction chromatography	High		Complicated	~0.5 hr	
Volatilization	Medium	Limited	Complicated	~2 hr	In many cases only limited by the detector sensitivity
Gas chromatography	High	Not limited	Complicated	~0.5 hr	

separation, *viz.* extraction and partition chromatography, or volatilization and gas chromatography. Volatilization is a much more complex process than extraction, since the equilibria in extraction, *e.g.*, from an aqueous into an organic phase, can be described by a distribution coefficient, whereas volatilization from a solid sample involves the conversion of a non-volatile into a volatile compound, transport to the surface of the sample, and desorption or evaporation. For many samples volatilization is a direct process since they are present in the solid phase and a fusion is necessary. In gas-phase reactions the same factors are involved as in extraction, namely the composition of the two phases, but in addition temperature plays an important role.[21]

The enrichment factor obtained in volatilization is much higher than that obtained in extraction. For example, if a trace element is volatilized from a 1-g sample, the total amount of the trace element can be used for the determination. For the dissolution of a 1-g sample at least 10 ml of aqueous phase are necessary, and for the extraction 2 ml of organic phase. If 50 μl are used in an absorption spectrophotometer, a factor of 40 is lost compared with the gas-phase separation.[22] The comparison between extraction chromatography and gas chromatography is more complicated. In both cases high enrichment factors are necessary, since the capacity of the stationary phase is limited.

This survey deals principally with solid samples which can be treated in four ways: (*a*) by direct analysis, (*b*) by hybrid techniques, (*c*) by volatilization, (*d*) by fusion and dissolution.

The most commonly used method is fusion, followed by direct analysis. In atomic spectroscopy the process of atomization (flame, plasma, or electrothermal heating) is a separation process, with the drawback that it cannot be regulated. Even more serious are the matrix effects, which permit direct analysis only in special cases or with the use of very similar reference standards. Therefore, hybrid methods[23] in which breakdown and vaporization of the sample take place in a separate device are preferable. Because it is not possible with this technique to run a lengthy temperature programme with different reactive gases, complete separation involving volatilization and detection is preferable. However, thermodynamic and kinetic factors rule out direct analysis of most solid samples.

The choice of volatilization or gas chromatography for a separation depends on the analytical problem and the detection system available. Figure 1 illustrates the relation between gas chromatography and volatilization. With solid samples, gas chromatography can only be a secondary process after the volatilization which gives the first enrichment. Ideal gas chromatography is not possible with amounts higher than 3 μg.[17] In gas chromatography a non-selective detector can be used, whereas volatilization requires a specific detector. For analysis of solutions it is time-consum-

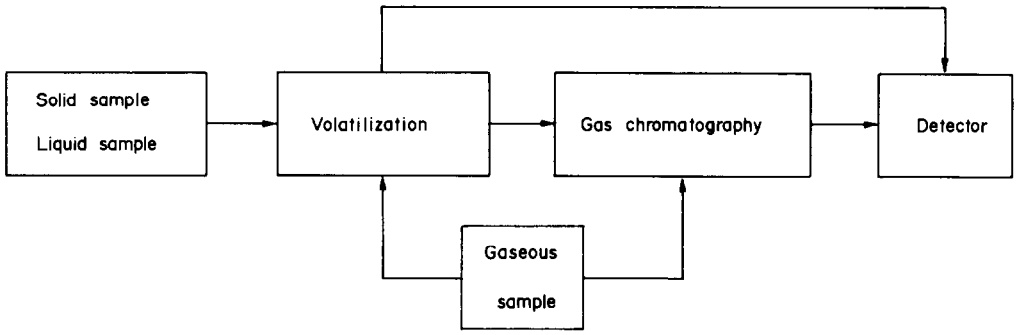

Fig. 1. Relationship between volatilization and gas chromatography.

ing to evaporate the solvent before the separation step, so extraction or precipitation is preferable.

An important reason for choosing a gas-phase separation is the variety of detection systems available. For example, in atomic spectroscopy the formation of gaseous compounds precedes atomization and is often subject to interference by other elements if it involves volatilization of a solvent. It is therefore advantageous to use a gas-generation system that preferentially volatilizes from solution a compound of the element of interest. For these reasons, a gaseous system is more free from interferences than a solution system. The use of an MIP (microwave-induced plasma) is much easier, *e.g.*, with gases. In many cases a chlorine atmosphere in a plasma or d.c. arc is advantageous[24,25] and its possible influence must at least be taken into acount.[26,27]

VOLATILIZATION

Volatilization can be used as a separation step with both liquid and solid samples. In this review the discussion is restricted to solid samples or those samples in which a solid residue is analysed after evaporation of the liquid matrix. Volatilization from liquids is used in the case of hydride generation and more recently in nickel carbonyl formation.[28]

Apart from a few isolated instances such as evolution of H_2S, SiF_4, H_2SiF_6 and SnI_4, volatilization was introduced into analytical chemistry mainly by Geilmann and co-workers. Table 2 summarizes examples characterized by the volatilization of one very volatile element from a non-volatile matrix. Very low concentrations have been determined only in the last few examples. Geilmann defined this method of separation as "evaporation" analysis, since an element is evaporated out of the matrix. We have tried to develop this method to separate as many elements as possible by using reactions which lead to volatile compounds. We use the term "volatilization" when the volatile compound is formed in the first step. This development is facilitated by the use of radioactive tracers and high-resolution γ-spectroscopy.

Table 3 summarizes the elements which form molecules that volatile below 1000°. The temperature is limited because most parts of the volatilization apparatus are made from fused silica. The elements in parentheses form volatile compounds only under special conditions, *e.g.*, molybdenum can be transported in an oxygen stream in the presence of water. Table 3 is not complete, since metal chelates and organometallic compounds have been intentionally omitted. In ultratrace analysis, organic compounds are less advantageous because of incomplete formation and owing to decomposition and adsorption on the vessel walls.[41]

The construction of volatilization apparatus depends to some extent on the methods of separation

Table 2. Typical examples for the separation of trace elements by evaporation from solid samples

Matrix	Element	Temperature, °C	Yield, %	Amount	Gas stream	Reference
ZnO	Cd	300/750	100	2–3000 ng	H_2/N_2	29
Compounds	Zn	1000/1200	100	μg–mg	H_2	30
Al, Ga, In	Zn	1000/1150	91.0	20–1000 ng	H_2	31
Bauxite	Be	1000	100	5–100 ng	O_2	32
Bauxite	Zn	1150	100	30 μg	H_2	33
Solid samples	Tl	1000	100	2–1000 ng	H_2	34
Cu	Se	1000	96.7	2 μg	—	35
Cu	Se	1150	100	1 ng	O_2	36
Al	Cd, Zn	600–700	100	20 pg	H_2/Ar	37
Aerosol	Cd	600–700	100	0.15–0.25 μg	H_2/N_2	38
Rock	Bi, Cd, Tl	1000–1200	95–100	10–100 pg	H_2/N_2	39
Plant	Pb	1000	100	ng–μg	H_2	40
Metals, Si, SiO_2	B	190	100	ng–μg	HF and H_2O	5

Table 3. Suitable inorganic volatile compounds for the concentration of trace elements

Type of compound	Elements which form suitable volatile compounds (25–1000°C)
Chlorides	Ti, Zr, Hf, V, Nb, Ta, (Cr), Mo, W, Tc, Re, Mn, Fe, Ru, Os, Au, Zn, Cd, Hg, Al, Ga, In, Tl, Si, Ge, Sn, Pb, P, As, Sb, Bi, S, Se, Te, Po, Ce
Fluorides	Ti, Zr, Hf, V, Nb, Ta, Mo, W, Tc, Re, Ru, Os, Rh, Ir, Hg, Si, Ge, Sn, P, As, Sb, Bi, S, Se, Te
Oxides	S, Se, Te, Po, (As), Tc, Re, Ru, Os, (Mo, W), Zn, Cd, Hg, (Ir)
$AlCl_3$-complexes	Lanthanides, actinides, Ca, Sr, Ba, Ra, Fe, Co, Ni, Cu, Pd, Pa, Mo
Elements	Noble gases, halogens, O, S, Se, Te, Po, N, P, As, Sb, Bi, Sn, Pb, Tl, Zn, Cd, Hg, (Li, Na, K, Rb, Cs, Fr)
Hydrides	As, Se, Sn, Pb, Te, Sb, Bi

and subsequent detection used. Several different types of separation method are possible. (1) A gas may react with only the trace element to form volatile compounds, while the matrix remains non-volatile. (2) A reactive gas forms a volatile compound with the matrix, while the trace elements remain non-volatile. (3) The gas reacts with both matrix and trace elements to form volatile compounds. (4) The gas reacts with both matrix and trace elements, but only the latter form volatile compounds. (5) A solid substance is used for forming volatile compounds.

In practice, trace and matrix elements may behave in a manner intermediate between the extremes formulated above. The examples quoted in Table 2 are characteristic of the first types although no reactive gases are used (except for some reductions with hydrogen). In the first type it is possible that part of the trace elements will not react because they are occluded. The second type is suitable for matrix elements which are volatile in an oxygen stream, *e.g.* Li, Na, K, Cs, Cd, Tl and Pb. In the third type no separation occurs during reaction and volatilization, but may be achieved in subsequent temperature-programmed fractional distillation or desorption. An advantage is that reaction is complete, so no trace elements are occluded. Applications are in the analysis of high-purity metals, *e.g.*, of Al, Nb and Ta by chlorination of the matrix and trace elements. The fourth type is more attractive than the first, but there are few cases to which it may be applied. The fifth type is exemplified by the addition of sodium borohydride ($NaBH_4$) for the formation of volatile hydrides, but the disadvantage is that contamination is greater than that encountered in reactions with the gas.

Volatilization of trace elements

Figures 2[39,42] and 3[43] illustrate two experimental arrangements suitable for separations of the first four types. The apparatus consists of three parts: (*a*) gas regulation and purification, (*b*) oven with temperature programming and control and (*c*) condensation or adsorption with temperature regulation. There may be a fraction-sampling device, depending on the nature of the detection system. Suitable gases include inert gases, *e.g.*, N_2, He, Ar, reactive gases, *e.g.*, H_2O, O_2, H_2 and halogenating gases, *e.g.*, CCl_4, Cl_2, HCl, Br_2, BBr_3, F_2, HF and complexing gases, *e.g.*, $AlCl_3$. When a complexing gas is used, the advantage of low contamination by the reagent is lost, since it is diffi-

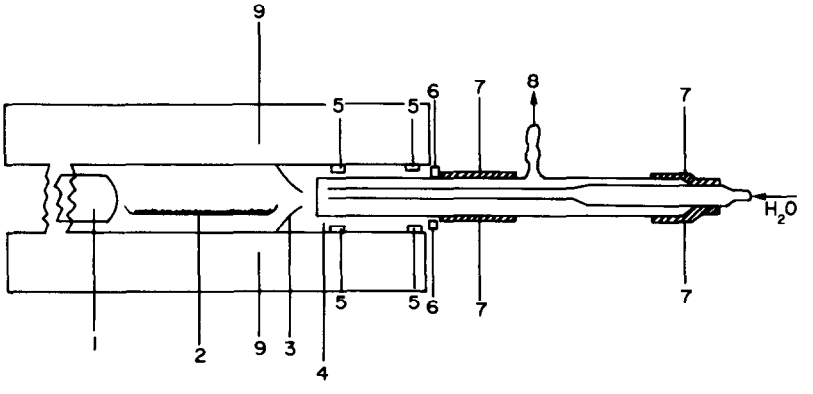

Fig. 2. Arrangement for the evaporation of elements from solid samples: 1, diffusion device; 2, boat; 3, nozzle; 4, cold finger; 5, holdfast; 6, holdfast spacer; 7, rubber tube; 8, pump; 9, oven. (By permission of the copyright holders, Springer-Verlag, Berlin).

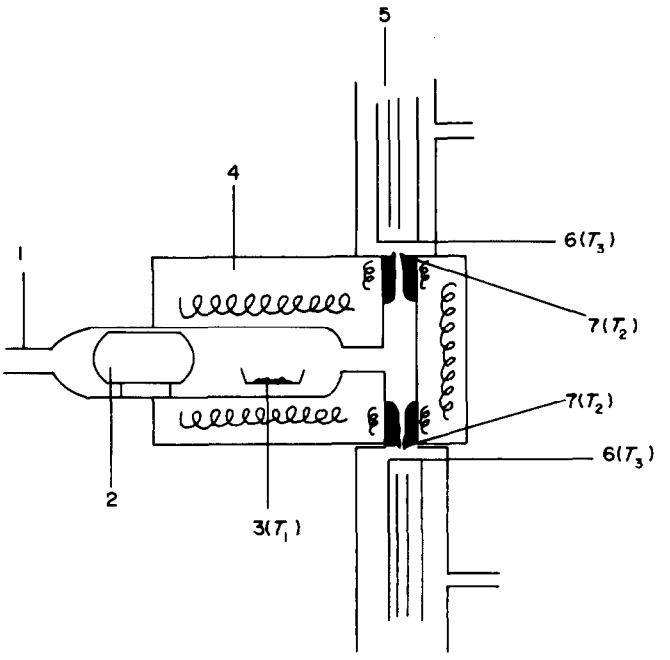

Fig. 3. Experimental arrangement of the volatilization device:[43] 1, input of reactive or inert gas; 2, diffusion device (quartz) to prevent back-diffusion; 3, sample (T_1 = volatilization temperature); 4, oven; 5, cold finger; 6, graphite plate (T_3 = 15°); 7, quartz capillary (T_2 = T_1 + 100°).

cult to purify it sufficiently. The constancy of gas flow-rate is not important, but high purity of the gas is often essential. In particular, the presence of O_2 or H_2O in chlorinating gases or in inert gases, even at low concentrations, can lead to the formation of non-volatile oxides or rather involatile oxychlorides, so that no separation is possible. It is therefore necessary to purify the gases or to add a scavenger for the interfering impurity. Oxygen can be removed, for example, with a molecular sieve cooled by liquid nitrogen. Reactive gases are more effectively purified by the addition of a scavenger, *e.g.*, carbon tetrachloride is decomposed at above 500°, forming radicals which scavenge oxygen. If boron tribromide is added to bromine, the oxygen in the bromine is scavenged. A very effective way of eliminating oxygen is the use of mercury in aluminium containers. With this system and a low gas velocity it is possible to purify inert gases to an oxygen level lower than 10^{-23} Pa.[44,45] It is important to purify the gases from the elements to be determined. Since most metals are retained on aerosol paricles, a filter must be used.

If more complex mixtures must be resolved, the oven should be equipped with a temperature programme and a facility for changing gas streams. If the apparatus is to be used for only one problem, *e.g.*, the evaporation of cadmium from various matrices, then the temperature programme may be omitted. The gas velocity should be high, so that there is no back-diffusion of the volatile trace elements into the cold zone. If volatilization is to be used, the trace element should be either completely volatilized or a reproducible amount evaporated. The best way to monitor this and to optimize the separation is to use radionuclides, either by activating the sample or by adding tracers. In the latter case, the added radionuclide should be in the same chemical state as the trace element in the sample. In some cases, neither activation nor addition of a radionuclide will make it possible to determine low concentrations of the elements. In such cases the investigation requires a second analytical determination to find the volatilization yield. An additional check for the volatilization yield can be made with reference materials.

The volatilization depends on the amount of sample, the temperature and the amount of the trace element relative to matrix elements or compounds which interfere. The amount of sample determines the time of volatilization. In theory, there is no limit to the amount of sample which can be used (we have used up to 5 g of sample), but for fast volatilization the surface area exposed to the carrier gas should be high and the adsorption enthalpy of the volatilized elements low. At the time of separation the grain size of the sample should be as small as possible. The temperature should never be so high that the sample melts, since most of the volatile compounds would dissolve in the molten sample. One special modification is that of surface analysis, in which a melt extracts the trace element out of the surface layer and the liquid layer is then volatilized together with the trace elements. This method has been used for the surface analysis of tantalum, with indium as the liquid phase.[46]

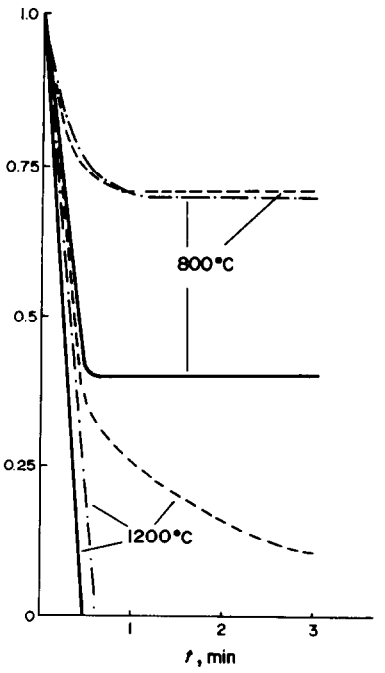

Fig. 4. Release of Pt, Ir, Os and Re from Au: (——) Re, (—·—·—) Os, (– – – –) Ir. (By permission of the copyright holders, Springer-Verlag, Berlin).

The relationship of volatilization to temperature is more complicated than would be expected because in addition to evaporation, diffusion and reaction processes take place. For example, a reaction with the main component in the sample might lead to a difference in the temperature at which trace elements are released. In Fig. 4[1,17] an example is shown in which platinum, osmium, iridium and rhenium are released from gold at different temperatures. The interesting fact is that only a certain fraction of the element is released at any given temperature and is not increased by prolonging the heating. There is no reasonable explanation for this phenomenon, but in trace analysis such anomalous effects are often encountered.

Figure 5[1] shows that the release of zinc is concentration-dependent. At the two highest concentrations of 215 and 187 μg/g, part of the zinc is released at a lower temperature. This behaviour may be interpreted by assuming that part is volatilized, while the remainder forms a compound which is not volatile.

A crucial part of separation by volatilization is the collection of the volatilized trace elements by condensation or adsorption. There is also the possibility of an on-line determination of the volatile compounds (see later). The yield of condensate and the reproducibility depend on the diameter of the capillary (see Fig. 3), the gas velocity, the distance from the capillary to the collector plate, the shape of the collector plate, the temperature in the capillary, and the temperature and coating of the collection surface. Collection on the surface of a tube or in a liquid is also possible.

The geometrical parameters can be optimized for all problems, but the temperature and stationary phase on the collection plate vary for different elements or compounds. One problem is to avoid the condensation of the trace element in the capillary. This may be achieved either by inserting the collection plate into the oven (Fig. 2) and cooling, with the attendant disadvantage of a temperature gradient on the collection plate, or by heating the capillary (Fig. 3). Heating of the capillary allows the temperature gradient to be optimized by choice of the capillary temperature, because the temperature T_1 of volatilization and T_2 of condensation are determined by physical or chemical requirements. The space between the capillary and the tube itself should be filled with quartz powder to provide a high heat-capacity at the end of the capillary, where cooling from the collection plate is possible.

The use of different coatings on the collection surface may give selectivity for certain trace compounds. For example, zirconium chloride is retained on a coating of sodium chloride even at a temperature of 400–500°.

Additional heating can be done with a heating coil between the quartz tube and the capillary (Fig. 6),[19] but because of the small space available it is not possible to reach very high temperatures. Calculations on the distribution of the trace compounds on the collection surface are difficult since most of the diffusion coefficients are unknown. Therefore, we have measured some of the distributions by using radionuclides. With iodine it is possible to deposit more than 90% of the trace compounds on a spot 8 mm in diameter and with cadmium on a 4-mm spot.[43] The distribution of the iodine is Gaussian, so most of the iodine is within a 3-mm circle.

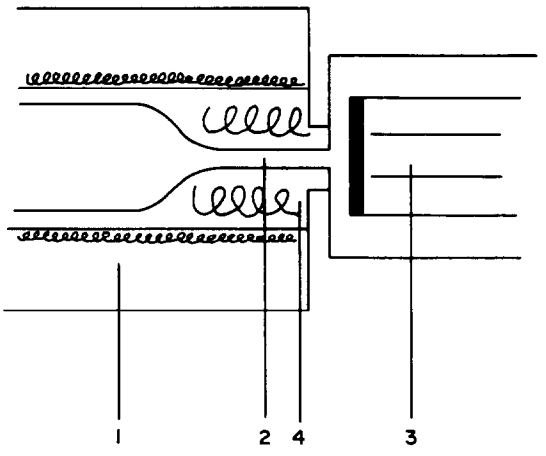

Fig. 6. Arrangement for heating capillary: 1, oven; 2, capillary, 3, cold finger; 4, additional heating.

The simplest example of volatilization as a separation method is the volatilization of one element. When only one element is to be separated, careful temperature programming must be used. This is particularly so in the case of chlorides, because many elements form volatile chlorides. In the case of the pure elements in a stream of inert gas, or hydrogen, or sometimes oxygen, it is possible to separate the element to be determined, either alone or at least accompanied only by elements which do not interfere.

A critical factor is the collection of the volatile species. Figure 7 shows an example where selenium is determined in a copper matrix.[36] The selenium dioxide is trapped in a U-tube by condensation with oxygen. In a gas stream there is always the possibility of the formation of aerosols which are unlikely to be adsorbed, owing to their slow diffusion.

Table 4 lists those elements which can be volatilized either directly or as oxides. These elements are more suitable for separation by volatilization than those which form volatile chlorides. A number of these elements are important in environmental problems, *e.g.*, Se, As, Cd, Pb and Hg. The high volatility of these elements is often the reason for losses in the fusion of samples, and therefore it is advantageous to use this volatility for their separation from solid samples. A difference in the volatility of the oxides or elements can be used for the separation of two volatile elements: thus Geilmann and Hepp[29] have shown that it is possible to separate cadmium from zinc. Cadmium oxide is reduced in a hydrogen stream at temperatures below 300°, whereas zinc oxide is not reduced at temperatures below 360°. It is therefore possible to reduce the cadmium oxide first and then to evaporate the cadmium at a temperature at which the zinc oxide is not volatile: the zinc oxide can then be reduced and the zinc volatilized. Geilmann and Hepp have separated cadmium in this way from a zinc oxide matrix and have separated cadmium and zinc from pure aluminium.

Volatilization of the matrix

In some cases all the trace elements are volatilized at the same time or temperature. An example[3] is that of aluminium, which forms aluminium chloride at about 500° with chlorinating agents. This is similar to most metals which form volatile chlorides, so that a separation requires several temperature-programmed volatilizations.[3] When pure aluminium is chlorinated with hydrogen chloride, most of the trace elements are evaporated at about the same temperature of 450°. Even sodium is partly evaporated because it forms a volatile complex ($NaAlCl_4$). In a second step the condensed chlorides may be volatilized in a stream of argon or argon/HCl. The trace elements can thus be separated from the matrix ($AlCl_3$), but the behaviour is complicated by the formation of complexes of $AlCl_3$ and $ZnCl_2$. This complication can be avoided by first forming aluminium trifluoride (AlF_3), which is non-volatile and subsequently reacting it with hydrogen chloride.

A less complicated case is volatilization of the matrix alone. This is only possible when the matrix is much more volatile than the trace elements. This is seldom the case for chlorides, but is possible for elements or oxides and is more attractive when the sample contains only one major matrix element or compound. To this category belong reagents such as

HF, HCl, HNO_3 as well as important products such as $AsCl_3$, $SiCl_4$, $SnCl_4$, PCl_3, and $TiCl_4$.[48,49]

We have studied the possibilities of using matrix volatilization in the analysis of optical waveguide materials. The trace elements of interest are those absorbing light in the range 900–1000 nm, *e.g.*, Cu, Cr, Co, Fe, Mn, Ni and V. Table 5[5] summarizes the compounds investigated and the conditions for matrix volatilization. The waveguide materials are striking examples of the superiority of volatilization analysis.

In addition, a number of chemicals used for MOS products and in semiconductor production can be analysed by using volatilization, *e.g.*, NH_4F, PbF_2, CdS, CdSe, CdTe, GaAs, Si and In.[50] Its use in the investigation of refractory materials and uranium should also be mentioned.

The situation is more complicated when the matrix consists of several elements or compounds. For example, the main constituents in biological, geological and water samples are alkali metals, alkaline earth metals, iron and aluminium in the form of silicates, chlorides and phosphates. For these complex matrices the anionic composition is important when a separation by volatilization is considered. The volatilization of alkali metals from biological materials is interesting since these metals interfere in the determination of many other elements. We have found that in biological materials it is possible to evaporate about 90% of the alkali metals. The residual amount depends on the anions present in the sample. It is possible to evaporate the carbonates, nitrates, sulphates and even halides, but it is not possible to evaporate the phosphates or silicates. Biological systems are investigated in more detail with respect to the very volatile elements, *e.g.*, As, Se and Cd, which can be evaporated in an oxygen[51] or hydrogen[52] stream. For a number of other elements volatilization as the chlorides is possible.

The determination of anions by use of volatilization

For the determination of O, S, C and N in metals, vacuum extraction at high temperature has long been used. A more recent development is the determination of halides by volatilization at high temperatures. Farzaneh and Troll have determined fluoride in rocks by pyrohydrolysis[53,54] with the formation of H_2SiF_6 which is collected in sodium hydroxide solution. Burguera and Townshend[55] have used the formation of SiF_4 for the same purpose. The disadvantage of these methods is the need to add reagents in order to form the volatile compounds. Such methods are not suitable for really low concentrations of fluoride. Chlor-

ide is determined in rocks[56] by a similar method with hydrogen chloride. Evans and Moore[57] used a combustion–ion chromatographic determination of chloride in silicate rocks but did not show whether the method was applicable in the nanogram range. Because of inhomogeneities in the anion distribution it is difficult to prepare appropriate standards.

We have used the formation of volatile chromyl chloride in order to determine hydrogen chloride in air.[58] The volatile CrO_2Cl_2 is decomposed in a graphite tube and the chromium determined by atomic-absorption spectrophotometry.

Application of volatilization in radioecology (plutonium and americium)

A number of radionuclides important in radioecology are suitable for an enrichment technique using volatilization. Examples are ^{210}Pb, ^{210}Po, ^{222}Rn (for ^{226}Ra), ^{129}I, ^{239}Pu, ^{241}Am and ^{240}Pu. One of the important analyses in radioecology is the determination of very low amounts of plutonium (10^{-15} g) in soils, plants, air and water, since it is necessary to obtain background values for the ubiquitous plutonium and to obtain information about the transportation of plutonium in ecological systems. The classical method for the separation of plutonium is a combination of precipitation, extraction and ion-exchange, with the last step being electrolysis on a disc followed by α-spectroscopy. This procedure is time-consuming and cannot be automated. It is possible to separate very low concentrations of plutonium from relatively high amounts of sample material by a combination of differential reaction rates, fractional distillation and chromatography. Figure 8 shows the process schematically. In the first step, plutonium is volatilized together with aluminium chloride in a stream of chlorine and carbon tetrachloride. A number of other elements, including alkali metals, are also volatilized, but they are deposited in the temperature gradient in different zones. The main interference with plutonium is from $FeCl_3$, $MnCl_2$, $ZnCl_2$ and $PbCl_2$. In the second step, the temperatures at different points in the oven are changed (as is shown in Fig. 8) and the chlorine supply is cut off. Under these conditions, $AlCl_3$ and $FeCl_3$ are evaporated and at higher temperatures $ZnCl_2$ and $PbCl_2$. $PuCl_3$, $AmCl_3$ and $MnCl_2$ are left. The principle of this separation is that Pu is deposited as $PuCl_3$ and may only be transported as $PuCl_4$ by oxidizing chlorinating agents. In the third step, in which a stream of chlorine is used, $PuCl_4$ and $AmCl_3$ are evaporated and then deposited at different temperatures on a disc. This analysis is faster than the classical method and can be fully automated. This example is characteristic of the complex reactions which take place at high temperature and are not yet fully understood. In order to predict such separations it is necessary to discover more about complex formation in the gaseous phase, *e.g.*, of $AlCl_3$ with other chlorides.

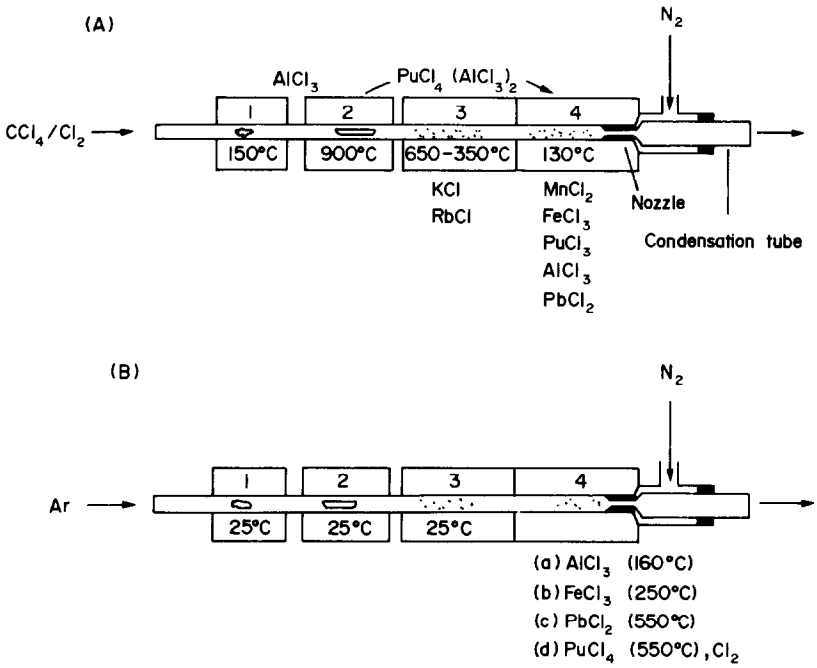

Fig. 8. Procedure for the separation of plutonium from soil with $AlCl_3$ as carrier gas: (A) volatilization of the chlorides and transport with $AlCl_3$; (B) separation of the chlorides by sublimation at different temperatures.

Figure 9[59] illustrates the differing behaviour of plutonium on volatilization in streams of HCl, Cl_2 and CCl_4/Cl_2.

GAS CHROMATOGRAPHY OF INORGANIC COMPOUNDS

Inorganic gas chromatography is in a state of development far behind that of organic gas chromatography. The reasons are the non-availability of commercial gas chromatographs working at above 500°, the difficulty in finding suitable instrumentation for handling highly corrosive gases, and the superiority of other methods of elemental analysis. This last reason is no longer important since in ultratrace analysis new methods have to be developed. In those cases where volatilization does not result in a separation permitting determination without interference, it is necessary to carry out a gas chromatographic separation. There are several reasons for the choice of gas chromatography as a separation method.

(1) In gas chromatography, separation is almost complete so there is no interference from other elements and this means that a real comparison between standard and sample can be made.

(2) When gas chromatography is used it is possible to use a scanning spectrometer and to determine several elements in one microsample.

(3) When an element is characterized by its retention volume or retention time it is possible to use a non-selective detector.

(4) It is possible to analyse for several different species derived from one element.

Table 6 compares organic with inorganic gas chromatography. Inorganic gas chromatography can be defined as the chromatography of volatile inorganic compounds and that means that metal chelates are not included. Gas-phase separation of chelate compounds or metal organic compounds will not be dealt with in this review. Also omitted is the separation of low-boiling gases such as O_2, N_2, CO and CO_2. The literature on such separations up to 1972 has been reviewed by Rüssel and Tölg.[60]

The main difference between inorganic and organic gas chromatography is that the latter determines compounds, while the former is used mainly for the determination of elements. The element should form a compound suitable for gas chromatographic separation. In some cases, *e.g.*, air analysis, volatile compounds are separated directly and it is important that no reactions should occur on the column which would destroy information about their nature. A second feature is the use of a reactive mobile phase. Reactive gases influence the separation in three ways. (1) Non-volatile compounds [*e.g.*, $LaCl_3(AlCl_3)_4 \rightarrow LaCl_3 + 4AlCl_3$], formed by decomposition of volatile compounds on the surface of the stationary phase can react again with the reactive gas to form a volatile compound. (2) The properties of the stationary phase may be changed by adsorption of the reactive mobile phase. (3) The reactive gas can be self-purifying, reacting with impurities in it, so that interfering reactions

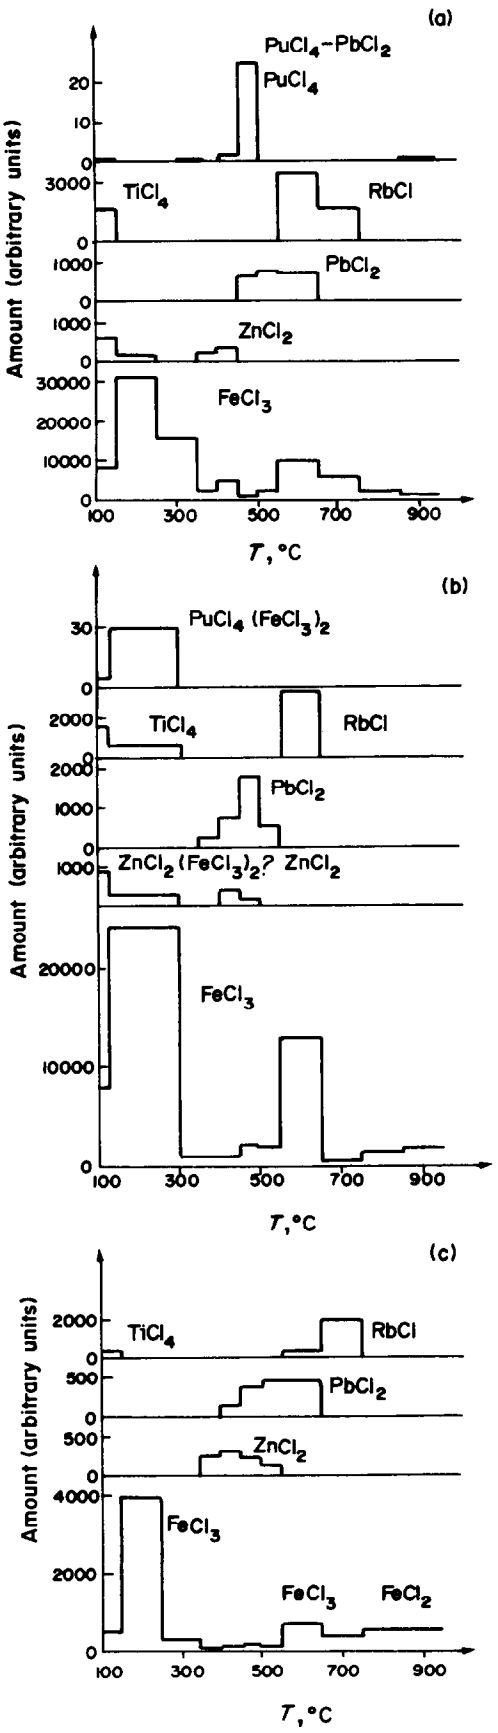

Fig. 9. Sublimation of chlorides as a function of temperature: (a) using N_2/CCl_4 as reactive gas, (b) using Cl_2/CCl_4 as reactive gas. (Reprinted from *Anal. Chem.*, 1980, **52**, 620, by permission of the copyright holders, the American Chemical Society).

are avoided. In particular, BBr_3 and CCl_4 may be used as scavengers for H_2O or O_2. Further differences from organic gas chromatography are the high temperatures and the wide range of temperatures used. This means that the materials of construction for an inorganic gas chromatography must be different from those of a commercially available apparatus and that the properties of the stationary phase may change during the course of a separation.

Table 7 gives a compilation of typical inorganic gas chromatographic separations used for trace element analysis. The separation of volatile hydrides has been investigated.[69,75,76] In most cases the hydrides were generated from aqueous solution by the addition of sodium borohydride. A Poropak Q column was used[69] for the separation of GeH_4, AsH_3, SnH_4 and SbH_3. The oven was temperature-programmed at 8°/min from 75 to 120°. The formation of hydrides in aqueous solution is influenced by the presence of other elements, so this method is limited by interferences. It does not make sense to use a very selective and sensitive gas chromatograph in conjunction with hydride evolution, which is subject to interference by many elements.[82] The formation of hydrides from solid substances is complicated, since the hydrides are decomposed at high temperatures, but high temperatures are necessary for diffusion. We have some preliminary results for the reaction of H_2 with Se and As in biological samples.[52] Part of the Se and As forms hydrides so that analysis is possible. For the detection of hydrides after separation, flame ionization, atomic absorption, mass spectrometry and a katharometer were used. In the last case, the hydrogen produced by decomposition of the hydrides in a furnace at 1000° is detected.

The chemical group most extensively studied for inorganic gas chromatography is the chlorides. The bromides and iodides are often likely to decompose at high temperatures, and the fluorides have high boiling points and are reactive, so quartz columns are unsuitable. A typical separation of chlorides is shown in Fig. 10.[7] Complete separation is not necessary when a specific detector is used. It can be seen that uranium gave a broad peak owing to its high amount (>100 mg) and that bismuth gave two peaks due to $BiCl_3$ and $BiCl_x$. Under certain conditions two compounds may be formed, and this is undesirable in an analysis. The sequence of elution of the chlorides (valid for all compounds) is not dependent on the heats of evaporation (vapour pressure or boiling point) in ideal chromatography, but on the heats of adsorption. However, in many cases, the boiling points give a guide to the sequence.

Table 6. Comparison of organic and inorganic gas chromatography

	Organic gas chromatography	Inorganic gas chromatography
Temperature range	Up to 400°C	Up to 1000°C
Separation mechanism	Distribution, adsorption	Distribution, adsorption (with complex formation, transport reaction)
Stationary phase	—	Change of stationary phase as a function of temperature
Mobile phase	Inert	Reactive gases: reactions with the analyte and the stationary phase
Detector	Often non-selective	Selective and placed outside of the column
Identification	Often retention time	Often by spectroscopic data

Figure 11 shows the separation of volatile oxides.[11] In addition to the elements giving typical volatile oxides such as osmium and ruthenium, there are also elements, such as iridium, which are transported in an oxygen stream by reaction with the mobile phase. When water is present, molybdenum is transported as H_2MoO_4. When a potassium chromate filter is inserted into the column, technetium and rhenium are retained as rhenate and technetate. These are methods for gaining more selectivity. The separation of rare earths with $AlCl_3$ is listed in Table 8. This shows the interesting possibility of forming highly volatile compounds from non-volatile chlorides. From the point of view of trace element analysis the use of $AlCl_3$ would contaminate the sample with most of the common trace elements, and $AlCl_3$ cannot be purified because of its property of complex formation.

Another group of compounds not suitable for trace element analysis is the metal carbonyls. Pommier and Guiochon have separated Fe, Cr, Mo and W as carbonyls on squalane, but no analytical application has been reported.[81]

High-temperature gas chromatograph for inorganic compounds

Several problems have to be solved for gas chromatography to be applied to inorganic compounds. For the volatilization of many inorganic compounds, temperatures up to 1200 K are necessary. Since most inorganic compounds react with metal surfaces at high temperatures, all contact with metal or similar reactive materials has to be avoided. Stationary phases have to be found which are stable up to the high temperatures needed.

The chromatographic column can be made of fused quartz and one end serves as an injection area ("on-column injection"), so the use of fittings or unions is avoided, as shown[15] in Fig. 12. The elements or compounds under investigation are in contact only with quartz, which is chemically inactive. Two methods of separation are available, direct evaporation and intermediate trapping. The column section and experimental arrangements for both methods are shown in Fig. 13. In direct evaporation (13a), the sample is introduced into the evaporation zone, which can be

$HfCl_4$ on graphite	—	ICl	—	90

heated with a small oven (10 cm length) to temperatures higher than 1300 K. The sample may be contained in a small porcelain or quartz boat or injected directly with a syringe. This method is useful if the conditions in the reaction zone can be chosen, so that the evaporation/desorption or reaction with the reactive component of the carrier gas is sufficiently fast for a narrow sample input profile to be obtained. In intermediate trapping (13b), the difference from direct evaporation is that the volatile compounds are not directly flushed into the chromatographic section of the column, but are first adsorbed at 20° on a short

(By permission of the copyright holders, Springer-Verlag, Vienna).

section of the column, which acts as a trap. To start the separation, the column is moved so that the trapping section is in the column oven, which is kept at the temperature required for the chromatography. If a temperature programme is used in which the initial temperature is such that all components are trapped at the beginning of the column, the arrangement in Fig. 13a may be used, which simplifies the experiments considerably. Both ovens are electrically heated and consist of 1-mm Kantal wire wound on ceramic tubing. The evaporation oven is 100 mm long and the column oven 830 mm. The temperature distribution inside the ceramic tube is sufficiently uniform for chromatographic experiments.

Special problems arise when fluorides are being separated, because there is no material which is completely inert to all inorganic fluorides. Nickel, monel metal, aluminium and polymers such as Kel-F powder are reasonably resistant.[61]

Influence of the mobile phase

In inorganic gas chromatography the mobile phase is not only a carrier gas, but can also influence the separation. One important point is that the decomposition of a chloride, leading to a non-volatile chloride adsorbed on the stationary phase, results in the irreversible loss of trace elements, while in the presence of

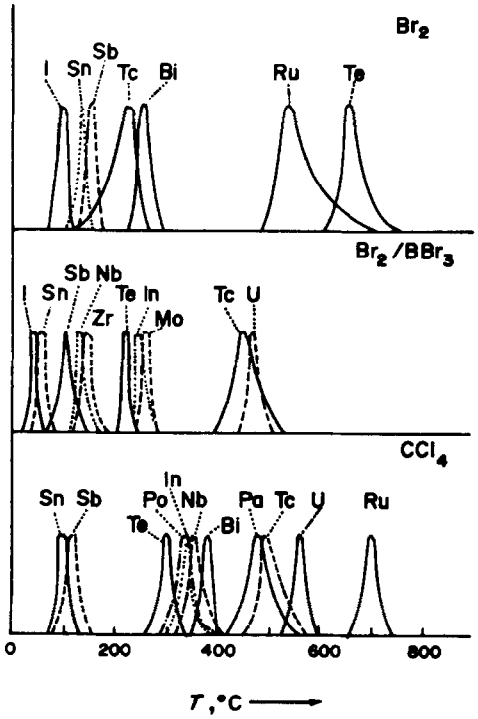

Fig. 14. Temperature-programmed separation on silica with different reactive gas mixtures. (By permission of the copyright holders, Springer-Verlag, Vienna).

the reactive gas a volatile compound can be reformed. This is one of the advantages of the use of inorganic compounds rather than metal organic compounds, which are not easily reformed. Owing to the high excess of reactive gas, the equilibrium favours the metal chloride with the higher valency, which is usually more volatile. A second important point is that the reactive gas can be self-purifying as already mentioned. Molecules such as CCl_4 or BBr_3 decompose at a certain temperature and form radicals, which can react with O_2 or H_2O, thus scavenging these impurities. This is important because the formation of oxyhalides must be avoided. Careful purification of the gas before its admission to the gas chromatograph is, nevertheless, still necessary. Juvet and Fisher[67] used ClF_3 for the deactivation of moisture and organic materials in the column before the analysis of fluorides.

A third effect of the mobile phase is an alteration of the surface of the stationary phase. Figure 14 shows a separation of bromides on a quartz surface and it can be seen that in the case of Tc and Te the retention time is changed by the addition of BBr_3.[9] This might be due to the formation of complexes of BBr_3 with the surface or, more probably, by the scavenging effect of BBr_3 and the elimination of oxygen. When a real equilibrium is involved, as in the case of the separation of $AlCl_3$ complexes of rare earths, the partial pressure of the mobile phase influences the separation. In most other cases a partial pressure of about 1 mmHg of the reactive gas in argon or nitrogen is sufficient for the separation. Sometimes the separation can be carried out in an inert gas stream.

Influence of the stationary phase

Table 8 lists the stationary phases used in inorganic gas chromatography. They fall into five groups. The first group includes stationary phases common in organic gas chromatography, *e.g.*, silicone oil and squalane. They are mainly used for separations of low boiling gases such as CO and H_2, or $SiCl_4$, $GeCl_4$, $SnCl_4$, $TiCl_4$, or mercury compounds. Conditioning of the stationary phase with the same mobile phase is always necessary before separation when the surface is changed by a reactive gas. In addition, it is sometimes necessary to run two or three separations of the trace elements before the first quantitative determination is carried out. The second group consists of quartz, graphite, or molecular sieves. It also contains Al_2O_3 and silica gel, which together with activated carbon have the highest surface areas. The third group comprises metal salts, the salt chosen depending on the volatile species being separated. In the case of chlorides, chloride salts are used as the stationary phase to avoid the complication of reaction with a stationary phase and the formation of new compounds. For adsorption chromatography a stationary phase with a very high boiling point is used, and for the separation complex formation with a solid phase is used. The fourth group consists of liquid stationary phases such as fused metal salts of low melting point, usually as eutectic mixtures. The fifth group consists of supports such as silica gel, graphite, or modified Al_2O_3 coated with inorganic salts so as to exploit the high surface area and the advantage of adsorption chromatography.

Although up to now there has been no direct information about the structures of surface complexes, we have shown by the determination of thermodynamic data that there is evidence for the following simplified picture of the chemisorbed state in adsorbent–adsorbate systems. The interaction between the chemisorbed molecules and the surface is, in principle, a Lewis acid–base interaction. This is the main type of interaction between surface and adsorbed molecule. Van der Waals forces may take part in the adsorbent–adsorbate interaction, but cannot explain the observed adsorption enthalpies. The chemisorbed molecules act as Lewis acids and the surface adsorption sites act as Lewis bases. Surface sites may act as uni- or multidentate ligands, depending on the chemisorbed molecule. There is no evidence as to whether a single surface site may act both as a uni- and as a multidentate ligand, or can play only the one role or the other. The adsorbed molecules have limited degrees of freedom [rotational, vibrational and translational (from site to site)]. The restriction of the rotational, vibrational and translational movements depends on the strength of the chemisorptive bond.

Giddings[91] laid the basis for a theoretical treatment of gas–solid chromatography. The coefficient of adsorption/desorption exchange, C_K, is much smaller than the term for resistance to mass transfer in the liquid phase, C_L, which it replaces in the van Deemter equation, and hence better resolution is obtained. Furthermore, in trace element separation the losses in the liquid phase are higher owing to impurities and irreversible adsorption on the support. In gas–solid chromatography it is possible to clean the surface by suitable treatment with a reactive gas at high temperature. Di Corcia *et al.*[92] showed that by treatment at 900° with a hydrogen stream, separations on graphitized carbon were considerably improved. Several factors influence the separation properties of a graphite surface. Graphite has a surface structure completely different from that of quartz or ionic chlorides. The layer lattice structure of graphite favours absorption of volatile chlorides rather than adsorption. At higher temperatures graphite may have a reducing effect on the chlorides of elements with easily accessible lower oxidation states, such as molybdenum.

Dependence of the separation on temperature

Gas chromatographic separations can be carried out either isothermally or with temperature programming. In Fig. 15 the isothermal separation of some elements at different temperatures is shown.[7] At the first three temperatures the retention time decreases continuously as expected. At 700° niobium shows a behaviour completely different from that at 800°, as

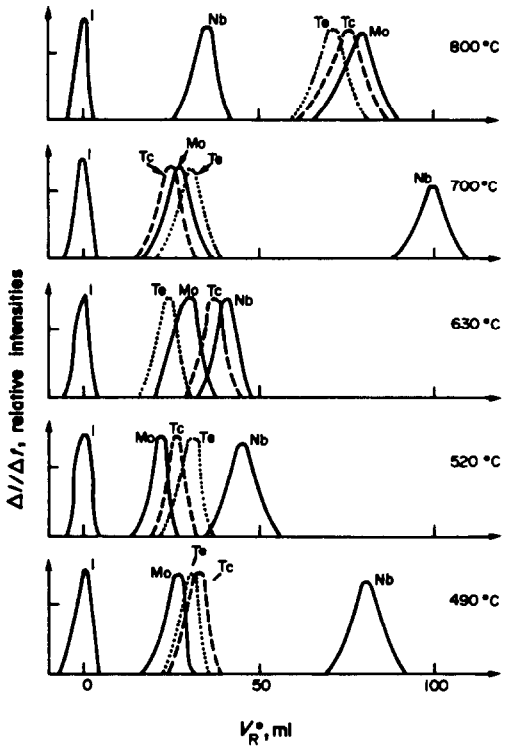

Fig. 15. Some gas chromatographic separations of inorganic chlorides with KCl as stationary phase at different temperatures. (By permission of the copyright holders).

do tellurium, technetium and molybdenum. This is due to the change from adsorption to distribution chromatography, since potassium chloride melts at 770°. Temperature-programmed separation is generally superior to isothermal separation. In temperature-programmed gas chromatography we used an increase of 2–24 deg/min. The errors in retention times are somewhat larger than those obtained in isothermal gas chromatography. In temperature-programmed gas chromatography it is very difficult to achieve an absolutely temperature-independent gas flow-rate. For optimization of a separation both temperature and gas flow should be programmed.

Optimization of a gas chromatographic separation

In optimization of inorganic gas chromatography the three important parameters are the reactive gas, the temperature and the stationary phase. They determine the optimization of the thermodynamic and not the kinetic behaviour. Separation between two components is widest when the retention ratio $r_{2,1}$ is high. The ratio is defined in terms of the retention times t_1 and t_2 or of ΔH, ΔS and T:

$$r_{2,1} = \frac{t_2}{t_1} = \exp\left[\frac{(\Delta S_2 - \Delta S_1)}{R} - \frac{(\Delta H_2 - \Delta H_1)}{RT}\right]$$

ΔH and ΔS depend on the nature of the stationary phase and therefore an optimization with respect to ΔH, ΔS and T is possible, if these values are known. We have carried out determinations of these values for most of the known chlorides at different stationary phases. It is interesting that compounds of similar structure show similar enthalpies and entropies, so by gas chromatography some information about the structure of the gaseous species and perhaps of the surface complexes can be obtained. Figure 16 shows the retention ratio as a function of temperature and different stationary phases for $MoCl_5$, $TeCl_4$ and $NbCl_5$. A high retention ratio means a satisfactory separation. Thus CsCl should be used as stationary phase at a relatively low temperature, and this would give a separation between Mo and Te, but not between Mo and Nb, for which graphite could be used at higher temperatures. Hence two columns, one coated with CsCl and one with graphite could be used to solve this separation problem at different temperatures.

Dependence of the separation on the amounting material

Successful gas chromatography is only possible when true adsorption takes place and not condensation. Figure 17 shows plots[93] of the enthalpy and of adsorption entropy of $NbCl_5$ on quartz against adsorption density and it can be seen that over an adsorption range of about 10 orders of magnitude ΔH and ΔS are constant and then ΔH decreases and ΔS increases over the adsorption range where the monolayer is becoming complete (about 75% of the surface is covered) and the formation of a second layer begins, *i.e.*, the adsorption is followed by condensation, and the curve becomes linear again at about -14 kJ/mole for ΔH and $14\,\text{cal.deg}^{-1}.\text{mole}^{-1}$ for ΔS. For many chlorides and stationary phases a correlation can be found between the adsorption and evaporation enthalpies. We have investigated the separation of $HfCl_4$ and $ZrCl_4$ as a function of the amount of the two components, and found that separation under ideal conditions is possible up to about 3 μg. At higher concentrations fractional distillation and not chromatography is the separation process, though this does not mean that a separation is impossible (as demonstrated in Fig. 14) for 100 mg of uranium.

Optimization of kinetic parameters

The chromatographic resolution is given by the distance between peaks (determined by ΔH, ΔS and T) and the peak width.[40] The plate number ($n = t_{dr}^2/\sigma^2$) is often used (where t_{dr} = overall retention time and σ = standard deviation of t_{dr}), because it is a useful expression for column performance and resolution. The use of plate numbers implies that the simplifying assumption that the peaks are Gaussian is justified because the peaks are symmetric with very little tailing or fronting, and is also necessary because exact determination of peak shape is quite difficult. The plate number of a chromatographic separation depends on several factors. The sample input profile,

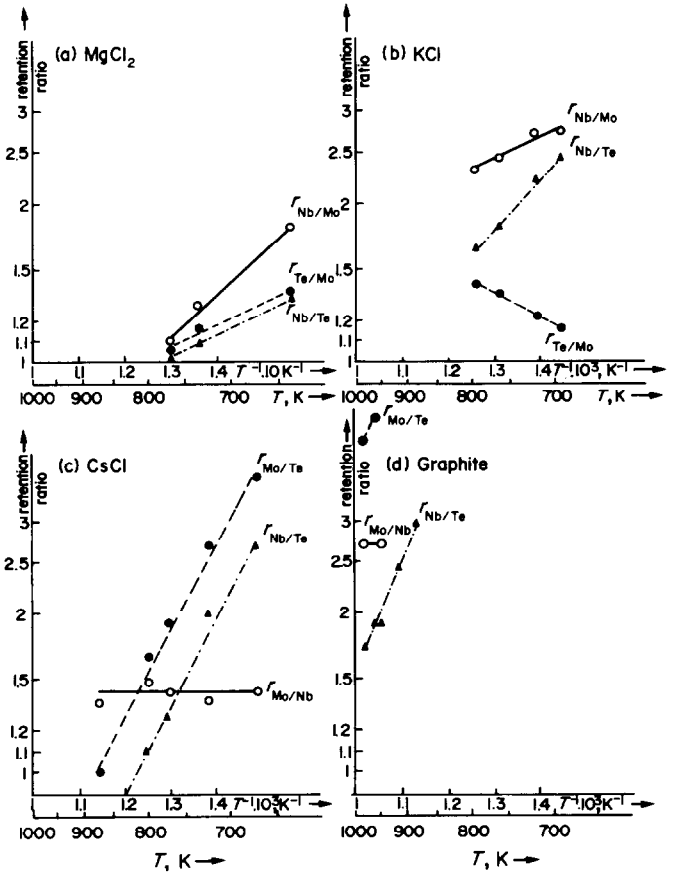

Fig. 16. Retention of Nb, Mo and Te chlorides as a function of the inverse of the temperature (ln r *vs.* T^{-1}) for different stationary phases: (a) $MgCl_2$, (b) KCl, (c) CsCl, (d) graphite.

ideally infinitely narrow, in reality contributes considerably to the final peak width, especially in trace element analysis, where the sample is introduced by rapidly heating a small column section in which the synthesized compounds have been trapped at room temperature. The time taken to heat the samples from room temperature to a temperature necessary for volatilization ranges from 10 to 30 sec.

Owing to the high temperature, the small particle size and the low flow velocity, radial diffusion is fast compared with the other processes determining the adsorption and desorption rates. Therefore, the peak shape (or relative variance RV), given by

$$\mathrm{RV} \equiv \frac{\sigma^2}{t_{\mathrm{dr}}^2} \equiv \frac{1}{n}$$

depends mainly on longitudinal diffusional band-spreading and the desorption and adsorption rates. Under these conditions the RV of the peak can be calculated from the equation:

$$\frac{1}{n} \equiv \mathrm{RV} = \frac{1}{x}\left[\frac{2\gamma D}{u} + \frac{2qu}{(1+q)^2 k_{\mathrm{d}}}\right] \qquad (1)$$

where k_{d} is the adsorption rate constant (dimensions $1/t$), and q the capacity factor or distribution ratio:

$$q = K_1 \frac{v_{\mathrm{s}}}{v_{\mathrm{m}}} = K_2 \frac{a_{\mathrm{s}}}{v_{\mathrm{m}}}$$

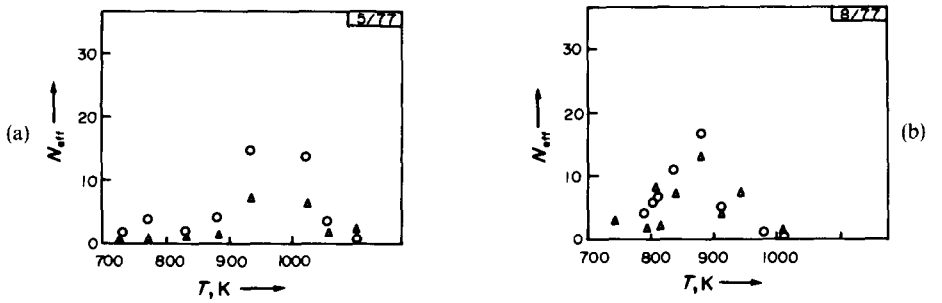

Fig. 18. Effective plate number as a function of temperature. Column 75 × 8 cm, particle size 25 mesh; △ tellurium chloride, ○ niobium chloride, □ molybdenum chloride; (a) NaCl surface, 2 ml/min N_2 (100 mmHg CCl_4), (b) graphite surface, 2 ml/min N_2 (100 mmHg CCl_4).

v_s and v_m being the volumes of solid and mobile phase per unit length of column, a_s the surface area per unit column length and K_1 and K_2 equilibrium constants. For K_1 the concentration in the stationary phase is expressed as concentration per unit volume of solid and for K_2 as concentration per unit area of solid phase. Equation (1) can be derived from the expressions[94] for σ and by omitting the pore-diffusion terms and taking account of the fact that the surface concentration in gas–liquid chromatography can be substituted by the surface concentration in adsorption chromatography, if the effective film thickness is set equal to unity and the equilibrium in the stationary phase is reached instantaneously. By use of equation (1), the desorption rate constants can be calculated from the experimental data, with a gas diffusion coefficient estimated from molecular kinetics.

A comparison between the adsorption enthalpies and the activation energies of desorption calculated from the temperature dependence of the retention volumes and the desorption rate constants, shows that the values are quite similar, which is an indication that no specific interaction between adsorbate and adsorbent occurs.

More information about the efficiency of a separation than that given by the theoretical plate number n can be obtained from the effective plate number N_{eff}.

$$N_{eff} = \left(\frac{t_{dr} - t_d}{\sigma_t}\right) = \left(\frac{t_r}{\sigma}\right) \qquad (2)$$

where t_d = desorption time and t_r = retention time. The relation between N_{eff} and n is given by:

$$N_{eff} = N/(1 + t_d/t_r)^2. \qquad (3)$$

As t_r decreases rapidly with increasing temperature, N_{eff} will be small at temperatures where $t_r \ll t_d$. At low temperatures where $t_r \gg t_d$, n is small owing to the low desorption rate constants and therefore N_{eff} is small. Consequently N_{eff} has a maximum at temperatures where n is large (fast establishment of desorption equilibrium) and $t_r \geqslant t_d$. Unfortunately, these two conditions are in conflict since a temperature rise increases the desorption rate and decreases the retention time. Figure 18 shows the temperature dependence of N_{eff} for two different experimental conditions. There is always a definite maximum, but it is of differing height and at different temperatures because of the different interactions determining the adsorption equilibrium and the rate of equilibrium establishment. Experimental results have shown that if capillary columns are used (instead of a column of 8 mm bore) the peak width is considerably reduced. The plate numbers are increased from about 20 to 1000. With this arrangement, even $ZrCl_4$ and $HfCl_4$[17] and the adjacent lanthanide chlorides are separable (Fig. 19).[71,72]

Gas chromatography of inorganic anions

Anions cannot be separated directly by gas chromatography, but compounds with highly electronegative elements such as HF, HCl, HBr and H_2S can be separated. The separation of sulphur compounds at the ng/l. level in air has been investigated by Bruner *et al.*,[87] who used graphitized carbon black treated with 0.5% H_3PO_4 and 0.3% Dexsil. These authors also separated HCl and HF on Graphon (graphitized carbon) treated with benzophenone and a polyfluoro ether, but unfortunately gave no details of amounts. Compounds of high polarity are difficult to handle by gas chromatography at low concentrations, since the chance of loss at an activated site is high. A survey of the chromatography of gaseous compounds of environmental interest was made by Fishbein.[95] The separation of very low concentrations of polar compounds such as HF and HCl and of anions such as Cl^-, F^-, SO_4^{2-} and PO_4^{3-} is made possible by use of derivatives.[96] Since the derivative is always an organic compound, the gas chromatography presents no new aspects or problems.

THERMOCHROMATOGRAPHY

Thermochromatography is a separation method which uses a thermal gradient in a column. The method was introduced in organic gas chromatography by Zhukhovitskii and Turkeltaub.[97] They used a moving gradient and obtained better resolution, but the method has never gained importance. It was used mainly in radiochemical separations, but

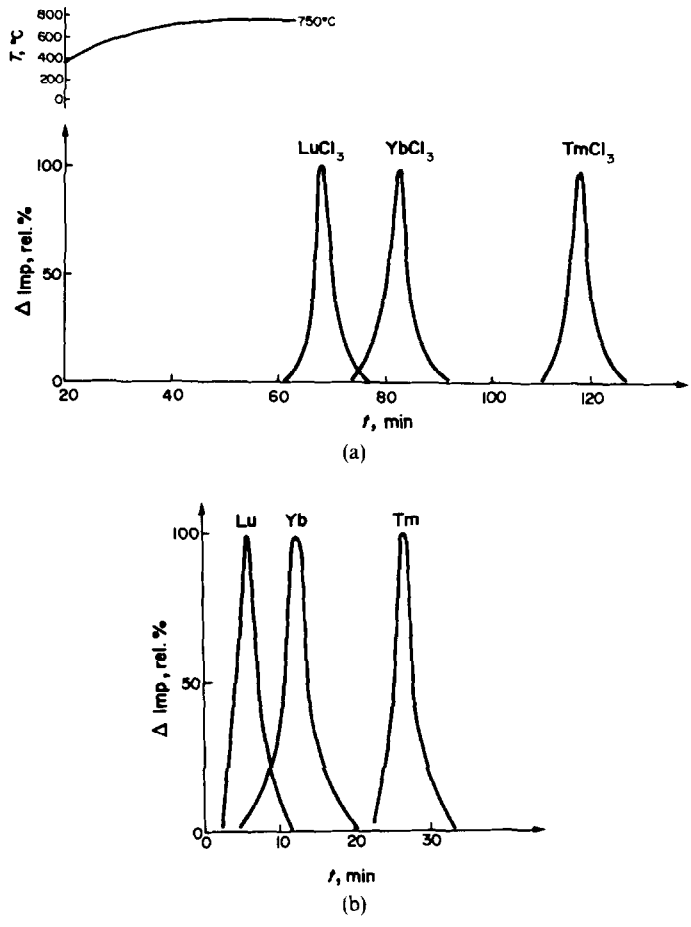

Fig. 19. (a) Separation of $LuCl_3$, $YbCl_3$ and $TmCl_3$: gas flow Cl_2 1 l./hr; temperature 20–750°; length 1 m; bore 8 mm; packing quartz powder, particle size 0.1–0.2 mm. (b) Separation of $LuCl_3$, $YbCl_3$ and $TmCl_3$ as $AlCl_3$ complexes: gas flow $N_2/AlCl_3$ 0.7 l./hr; temperature 200° length 1 m; bore 4 mm; packing quartz powder, particle size 0.2–0.28 mm.

with a static gradient in order to deposit certain elements at certain positions in the column. The possibilities of thermochromatography in trace element analysis have never been closely investigated. A separation, not as a function of time as in normal gas chromatography, but as a function of distance (from the starting point) should have advantages such as the ability to determine elements at any convenient time and with different detectors. A column with a thermal gradient can be used directly after sample volatilization in an oven since the time of volatilization does not affect the position at which the element or compound is deposited. However, the position in the tube is time-dependent until the final distribution is reached. The advantage of this method is that the selectivity can be increased by subsequent heating of certain restricted zones and desorption of the element into a detector. In this way, one element after another can be introduced into the detector. The temperature at the final positions of the elements lies always between the boiling and melting points of the appropriate compound. The disadvantage of this method is that the deposition zones are rather broad. There is an experimental difficulty in the evaporation of the compounds into the detection system. The separation between the zones must be wide enough to avoid the evaporation of two adjacent zones at the same time. The selectivity can be further increased by combining a thermal gradient with the use of different stationary phases. The resolution is improved if an element which forms stable compounds at a certain temperature is deposited in a narrow zone coated with the appropriate stationary phase. For the detection it is necessary to decompose the compound formed. In Table 9 a number of characteristic thermochromatographic separations are listed.

SPECIATION

It is becoming more and more evident that in the study of environmental pollution from metal compounds it is insufficient to determine only the total concentration of the metal. The chemical form of the pollutant is also important. For gaseous samples (air)

and liquid samples (water) a number of methods such as gas chromatography[106–110] coupled with atomic-absorption spectrometry, atomic fluorescence, atomic emission, or extraction have been applied. For solid samples it is much more difficult, since the normal procedure of producing a solution may change the chemical state.

For solid samples it may be possible to exploit the different extraction behaviour of different trace compounds. A second possibility is to use the selective volatilization of the element in different chemical states. We have found that only part of the arsenic in a sample is released as arsine in a stream of hydrogen. In this case it is not the species present which is important, but the rate of formation of a volatile compound.[111] The release of the gaseous compound depends on the diffusion and desorption of the various species in which the element is present. Even if a reactive gas is used as mobile phase and new compounds are formed with the elements, it has to be assumed that the original compounds will react in different ways and at different temperatures. This means that the release of the element during volatilization will at least partly reflect the pattern of the compounds. If it is only the total concentration of the element which is required, this effect is undesirable and may result in part of the element not being released. For example, selenium in biological samples can be evaporated as Se or SeO_2 but not as SeO_4^{2-}. On the other hand, when information about the species is desirable, the effect might be used for an indirect determination of the different species. This experimental procedure is used in thermal analysis, when a temperature gradient is used for the analysis of compounds on the macro scale, *e.g.*, the water content of salts. It has not been investigated on the micro scale, but in some cases may prove to be the only method of obtaining information. This might be the case for biochemical problems, such as the analysis of aerosols.

Three approaches have been used. The first is direct injection into the graphite tube of an atomic-absorption spectrophotometer with continuous signal recording of the output for an element. In some cases the pattern of formation of the free atoms allows conclusions to be drawn about the original species present. One problem is that the time-dependent signal is subject to interference by all other elements present and in many cases a quantitative measurement is not possible. The second, and more flexible, system is one in which the volatilization and atomization sections are separated[112,113] (Fig. 20). This arrangement permits the use of different temperatures in the two sections, but it is not possible to use the most suitable reactive gas for the volatilization. However, it is possible to determine more than one element in a sample by using a temperature programme. The most promising approach with great flexibility and applicability is the third, involving a complete separation of the detection and volatilization steps. In this case it is possible to use different reactive gases and a slow temperature programme for the separation. With one device a great number of samples can be treated without using the detection system. Especially interesting are the compounds of toxic elements such as As. We have begun an investigation[111] of the behaviour of

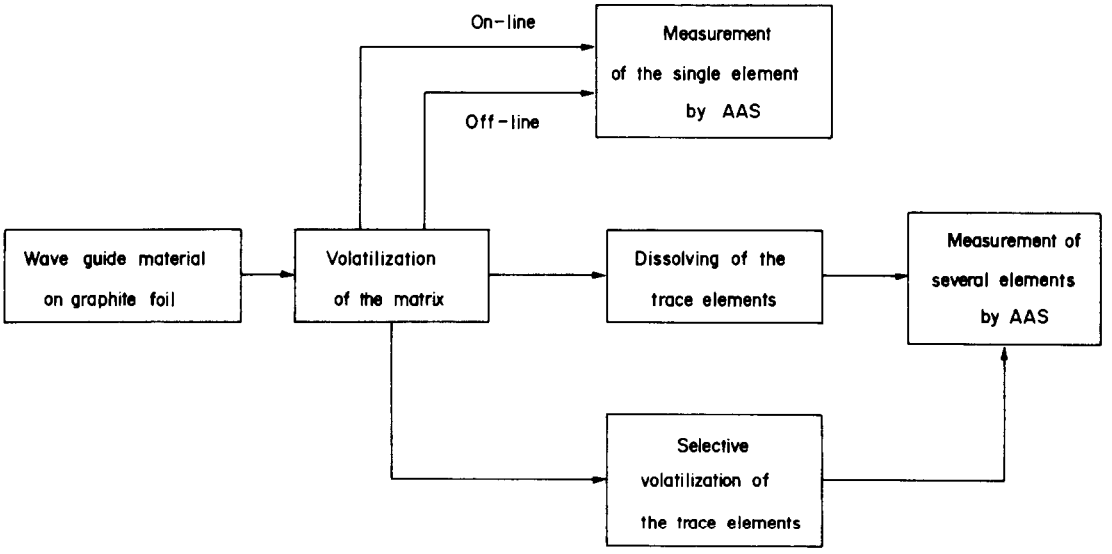

Fig. 20. Scheme for matrix volatilization and coupling with AAS.

arsenic compounds in a stream of hydrogen and the results show that differentiation is possible.

COUPLING OF VOLATILIZATION OR GAS CHROMATOGRAPHY TO DETECTION SYSTEMS

As shown in Fig. 21 it is possible to couple inorganic gas chromatography or volatilization with a number of different detection systems.[5] In gas chromatography the detection system must be suitable for on-line coupling, whereas in volatilization off-line coupling is also possible. The most familiar combination in organic gas chromatography is with mass spectrometry (GC/MS). This has not been used in inorganic gas chromatography (with analytical aspects) because of technological problems due to the corrosive nature of the reactive gases and the high temperatures involved, but in principle it should be possible to solve these problems. For on-line detection spectroscopic methods such as atomic absorption, atomic emission, or atomic fluorescence are possible, as is the measurement of radioactivity. For X-ray fluorescence and electroanalytical methods an off-line method is preferable. There is no direct experience with electroanalytical methods, but when an element is collected on a suitable collector and is suitable for an electroanalytical determination, no problems should arise. The choice of on-line and off-line coupling may be decided by the detection limit when very low concentrations must be determined. Any on-line coupling will result in a broadening of the detection signal which increases the detection limit.

Figure 22 shows[5] the different possibilities for coupling volatilization or gas chromatography with atomic-absorption spectrometry. A direct combination of volatilization with atomic spectroscopy is only possible when the volatile compound is released rapidly. If the amount of sample is large, volatilization takes too long and a very broad peak is observed. Therefore, this method should only be used in exceptional cases such as the direct volatilization of Hg. The off-line mode has the disadvantage that only one element can be determined at a time. This could be dealt with by selective desorption or decomposition before the atomic-absorption measurement or by using a gas chromatographic separation, but the AAS light source would have to be changed between successive admissions of species. It would be easier to use emission spectroscopy with a simultaneous detec-

tion system. For all off-line measurements a collection system is necessary and three methods are available; collection on a plate or disc, collection in a capillary tube and collection in a liquid. In the first two cases, the elements collected can be dissolved and determined by classical methods. The disc is preferable for radioactivity counting, X-ray fluorescence of thin layers and for atomic spectroscopy (with thin foils suitable for introduction into an oven). The capillary tube is preferable for direct use in an oven and, in certain cases, together with a temperature gradient for selective desorption. Collection in a liquid is only possible with very volatile compounds, because it is impossible to heat the end of the capillary to prevent condensation of high-boiling components. We have measured distributions in tubes and on plates and found that there is incomplete condensation, depending on the flow-rate and the distance from the end of the capillary. One method of collecting very small amounts of volatile species such as selenium or selenium dioxide is to carry out a co-condensation with an inert gas. Meyer *et al.*[35] have used this principle in the condensation of Se. Optimization of these methods is only possible with the aid of radionuclides. A future development for X-ray fluorescence might be collection on a thin band which is moved slowly at the end of the capillary. For off-line determination after gas chromatography, this might be preferable to the use of a sample changer with plates.

When the volatilization or gas chromatography is coupled with spectroscopic detectors, some of the problems associated with liquid or solid samples do not arise, but the formation of the gaseous compound is always subject to matrix interference. Further, the gaseous compound is introduced into the detection system, no evaporation energy is needed, so no quenching effects occur, and a microwave-induced plasma can be used instead of an inductively coupled plasma for the emission spectroscopy.

CONCLUSIONS

Volatilization and inorganic gas chromatography are separation and enrichment methods for inorganic trace analysis which have not been widely used. This is partly due to technological difficulties and the lack of commercially-produced equipment. Also, the behaviour of many elements and compounds at high temperatures is not known. There has not been much demand for this type of analysis, but the need for the determination of very low concentrations and for multielement analysis requires the development of new methods, and these gas-phase methods have a number of advantages which make them worth further investigation.

DETERMINATION OF TRACES OF TELLURIUM IN HEAT-RESISTING ALLOYS BY GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY AFTER CO-PRECIPITATION WITH ARSENIC

OSAMU KUJIRAI, TAKESHI KOBAYASHI, KUNIKAZU IDE and EMIKO SUDO

Metallurgical Chemistry Division, National Research Institute for Metals, Nakameguro, Meguro-ku, Tokyo 153, Japan

(*Received* 24 *February* 1981 *Accepted* 12 *June* 1981)

Summary—A simple analytical method has been developed for the determination of traces of Te in complex heat-resisting alloys by graphite-furnace atomic-absorption spectrometry. Nickel-base and cobalt-base heat-resisting alloys are dissolved in concentrated hydrochloric and hydrofluoric acids plus 30% hydrogen peroxide. Tellurium is separated from the matrix by co-precipitation with As and dissolved in nitric acid. Memory effects are eliminated by the oxidation of Te(IV) to Te(VI). Standard solutions for the calibration are prepared by the procedure used for the sample solution. The detection limit for Te is 0.05 ppm in the alloy.

Heat-resisting alloys are used, in jet engines or industrial gas turbines, under severe circumstances where high strength at high temperature is needed. Tellurium is known to have, even at trace concentrations, deleterious effects on the rupture life and elongation of Ni-base heat-resisting alloys.[1,2] The maximum allowable concentration of Te in Ni-alloy castings is given as 0.5 ppm in the SAE Aerospace Material Specification 2280.[3]

Traces of Te in heat-resisting alloys have been determined by neutron-activation analysis,[4] X-ray spectrometry,[5] emission spectrography[6] and graphite-furnace atomic-absorption spectrometry.[7–9] The first three methods[4–6] require preliminary separation of Te from the matrix. Direct determination of Te in solutions of Ni-base alloys by graphite-furnace atomic-absorption spectrometry[7] needs well-characterized standard alloys or standard solutions. Dulski and Bixler[8] also used this method, with a single-point standard addition for calibration. Traces of Te have been directly atomized from chips of Ni-base alloy[9] with commercial graphite furnaces. This method is superior to the solution method[7] in needing only a small sample, giving no molecular absorption and only a small risk of contamination, and saving analysis time because dissolution and preatomization heating are not required. However, it necessitates standard alloys for the calibration and is less accurate because the commercial graphite furnace is exclusively designed for liquid samples.

Attempts were made to determine traces of Te in solutions of heat-resisting alloys directly by graphite-furnace atomic-absorption spectrometry using the calibration curve method. The results were, however, unsatisfactory because the background absorption exceeded the correction capacity of the instrument.

Various separation methods for traces of Te have been reported.[10] Of these, co-precipitation of Te with arsenic as carrier[11–13] is simple and gives a high recovery for traces of Te. This method is selective and may separate traces of Te from large quantities of complex heat-resisting alloy in a single separation. We have combined it with graphite-furnace atomic-absorption spectrometry to obtain a simple analytical method for the determination of traces of Te in heat-resisting alloys. This method is suitable for routine analysis of large numbers of samples and applicable to a wide variety of complex samples, owing to the selectivity of the separation.

EXPERIMENTAL

Apparatus

A Perkin–Elmer Model 703 atomic-absorption spectrophotometer, equipped with a Model HGA-2100 graphite furnace and a deuterium background-corrector, was used. The light-source for Te determination was a Perkin–Elmer electrodeless discharge lamp (EDL) operated at 9 W with a Perkin–Elmer EDL power supply. The analytical wavelength used was 214.28 nm. The spectral band-width was 0.2 nm. The test solution (20 μl) was injected into the graphite furnace with a Perkin–Elmer Model AS-1 autosampling system. A part of the controller circuit was modified to proceed automatically with the high-temperature cleaning cycle immediately after the atomization cycle. The duration of the high-temperature cleaning cycle can be varied, up to about 15 sec. Absorbance was recorded with a Hitachi Model 056 recorder. A thermocouple or an optical pyrometer was used for measuring the temperature of the furnace. Argon was used as purge-gas.

Reagents and solutions

Tellurium stock standard solution (Te 1 mg/ml) was prepared by dissolving "Specpure" Te metal in the minimum of concentrated nitric acid, evaporating to dryness twice

with concentrated hydrochloric acid, and diluting with 0.3*M* hydrochloric acid. Working standard solutions were prepared daily from the stock standard solution.

Phosphinic acid (50%) was used as reducing agent. The other reagents were of analytical-reagent grade. Standard solutions of various metals were prepared by dissolving the high-purity metals in appropriate acids. An As^{3+} solution (As 1 mg/ml) was prepared by dissolving 0.660 g of arsenic (III) oxide in 10 ml of 5% potassium hydroxide solution and diluting to 500 ml with distilled water.

Heat-resisting alloys

Table 1 summarizes the chemical composition of the Ni-base and Co-base heat-resisting alloys used, listing the alloying elements present at the 0.1% level or above. Standard heat-resisting alloys containing known concentrations of Te were not available.

Procedure

Weigh 0.5 g of chips of a heat-resisting alloy into a 100-ml Teflon beaker. Add 10 ml of concentrated hydrochloric acid and 5 ml of concentrated hydrofluoric acid. Cover the beaker and heat the solution on a hot-plate. Add 10–15 ml of 30% hydrogen peroxide little by little and decompose it by prolonged heating. After complete dissolution of the sample, evaporate the solution to 15 ml. Add 4 ml of As^{3+} solution and 25 ml of concentrated hydrochloric acid, heat the solution to 90–100° and add 6 ml of 50% phosphinic acid (total volume: 50 ml). Continue the heating for 20 min, then allow the solution to stand for at least 5 hr at room temperature. Filter off the precipitate on a 9-cm Toyo Roshi No. 5B filter paper (4-μm average pore size, equivalent to Whatman No. 40 paper) and wash it thoroughly with 1*M* hydrochloric acid and distilled water. Dissolve the precipitate in 6 ml of hot 8*M* nitric acid added in several portions, followed by 1 ml of hot concentrated nitric acid. Wash the beaker and paper with distilled water, collecting the washings in a 25-ml standard flask. Add 2 ml of 0.1*N* potassium permanganate, and dilute to the mark with distilled water.

Prepare standard solutions for the calibration in the following manner. Add graded volumes of the working standard Te solutions to the mixtures of 30 ml of concentrated hydrochloric acid and 2–3 ml of concentrated hydrofluoric acid, dilute to 40 ml, add 4 ml of As^{3+} solution and heat. Add 6 ml of 50% phosphinic acid, then follow the same procedure as for the samples. Transfer the solutions into polystyrene cups on the turn-table of the instrument. Push the start button of the auto-sampling system, with the programme set as summarized in Table 2. Interrupt the flow of purge-gas during the atomization. Measure the absorbance of Te. Prepare a calibration curve and calculate the concentration of Te in the sample.

RESULTS AND DISCUSSION

Direct determination of Te in alloy solutions

Nickel-base heat-resisting alloys were dissolved in concentrated nitric acid and concentrated hydrofluoric acid, which are widely used for the dissolution of such alloys. This combination of acids was used only for the direct determinations. The concentrations of Te and matrices used were 0.005–0.025 μg/ml and 10–20 mg/ml, respectively. For the 10-mg/ml matrix concentration, 0.5 g of alloy was dissolved in 5 ml of concentrated nitric acid and 2 ml of concentrated hydrofluoric acid, and the solution was diluted to 50 ml with water. Optimum heating temperatures and times were selected. Because of the matrix effects, Ni and Cr were added to the standard solutions for the calibration, for matrix-matching, in an attempt to determine directly traces of Te in solutions of Ni-base heat-resisting alloys by the calibration curve method, but the accuracy and precision by this method were unsatisfactory. Even if the beam of the deuterium lamp was carefully aligned with that of the electrodeless discharge lamp and all conditions were optimized, the large background absorption due to the salts from the complex matrices could not be compensated for by the background corrector. The direct method was found applicable only when matrix-

matched standard solutions or standard alloys containing a known concentration of tellurium were used. The direct method is, however, impractical as a routine method because such standard alloys or solutions are difficult to obtain or prepare, and a separate set is needed for each alloy matrix encountered.

Co-precipitation of Te with As

It is generally necessary to separate Te from the matrix of heat-resisting alloys before graphite-furnace atomic-absorption spectrometry. Co-precipitation of Te with As was used as the separation method. A preliminary study showed that reduction with tin(II) chloride and subsequent co-precipitation with As carrier was not suitable for graphite-furnace atomic-absorption spectrometry. The small quantities of tin which remained owing to incomplete washing of the precipitate suppressed the Te signal. Phosphinic acid (50%) was found suitable as a reducing agent.

Co-precipitation conditions. Heat-resisting alloys (0.5 g) were dissolved in the mixture of concentrated hydrochloric acid, concentrated hydrofluoric acid and 30% hydrogen peroxide. The best conditions for the co-precipitation of traces of Te with As were established by experiments with a Ni-base heat-resisting alloy, René 95. For convenience, the volume of the solution was adjusted to 50 ml at the co-precipitation step. The quantity of Te added was 1.25 μg. The effect of acids on the co-precipitation was studied. The recovery of Te was almost constant (89–95%) when 1–10 ml of concentrated hydrofluoric acid was present in the 50 ml of solution. The recovery was calculated from the ratio of the absorbance for the test solution to the absorbance for a reference solution containing 1.25 μg of Te, 4 mg of As, 6 ml of 8*M* nitric acid, 1 ml of concentrated nitric acid and 2 ml of 0.1*N* potassium permanganate in 25 ml. The presence of 10 ml of concentrated hydrofluoric acid in the reference solution lowered its absorbance by about 10%, however.

The effect of hydrochloric acid concentration in the 50 ml of alloy solution was investigated from 3.0 to 8.6*M*. The recovery of Te was 89–93% over the concentration range 5.0–8.6*M*. The quantity of As^{3+} added was varied from 1 to 4 mg, and the recovery of Te was 95% for 3–4 mg of As^{3+}. Varying the volume of 50% phosphinic acid added between 2 and 8 ml had no effect on the recovery of Te, and 6 ml of 50% phosphinic acid was chosen as optimal. The recovery of Te was 95–98% when the solution was heated for 20–80 min at 90–100°, but the standing time at room temperature had a definite effect on the recovery. It was necessary to stand the solution for at least 5 hr, and preferably overnight, to obtain a high and constant recovery (90–91%) of Te. The standing time affects the completeness of reduction and/or coagulation of the precipitate. The bulk of the precipitate of Te and As was dissolved with 8*M* nitric acid and the rest with concentrated nitric acid. The volumes used were chosen by considering the minimum needed for dissolution of the precipitate, and the effect on the life of the graphite furnace. As a result, 6 ml of hot 8*M* nitric acid and 1 ml of hot concentrated nitric acid were used.

Memory effects. When elemental Te co-precipitated with As was dissolved in the 8*M* and concentrated nitric acid, memory effects were found. These effects were independent of the presence of As and the kind of reducing agent used. Figure 1 shows the recorder traces of the signals from TeO_3^{2-} and TeO_4^{2-} (1.25 μg of Te) dissolved in 2.5*M* nitric acid. Tellurium(IV) shows memory effects, but Te(VI) does not. It was confirmed by spectrophotometry with thiourea[14] that Te(IV) is obtained by the dissolution of elemental Te in the 8*M* and concentrated nitric acid. The reason why Te(IV) shows memory effects is not apparent. These effects were not eliminated by a prolonged high-temperature cleaning cycle. To eliminate the memory effects, the Te(IV) should either be oxidized to Te(VI) or extracted into an organic solvent to change the atomization mechanism of the Te. Oxidation of Te(IV) to Te(VI) was examined, and the memory effects were found to decrease on addition of 0.1*N* potassium permanganate, 2 ml of the permanganate solution eliminating the memory effects completely. According to the equation,

$$5Te^{4+} + 2Mn^{7+} \longrightarrow 5Te^{6+} + 2Mn^{2+}$$

only 0.2 μl of 0.1*N* permanganate would be needed to oxidize 1.25 μg of Te, and the rest of the 2 ml was presumably involved in oxidation of As(III) to As(V).

Effect of diverse elements. The effect of the alloying elements in the Ni-base and Co-base heat-resisting alloys on the co-precipitation was studied and, if they were co-precipitated with As, their effect on the atomic absorption of Te was also examined. The concentration of Te used was 0.025 μg/ml. The concentrations of the elements tested were 2 and 10 mg/ml, corresponding to 8×10^4- and 4×10^5-fold ratio,

respectively, to the concentration of Te. Table 3 shows the results. The precipitate was washed with 10% hydrofluoric acid, if necessary, before the washing with 1*M* hydrochloric acid and distilled water. When the effect of 10 mg/ml of Fe was studied, 8 ml of 50% phosphinic acid was used. As shown, the elements tested do not interfere with the co-precipitation and atomic absorption of Te, over the concentration range studied. It has been reported that small quantities of Se, Sn, Sb and Bi, which may co-precipitate with As, do not interfere with the atomic absorption of Te,[12] and in any case these elements present only as trace impurities in heat-resisting alloys.

Determination of Te in heat-resisting alloys

The proposed method was applied to the determination of traces of Te in a wide variety of practical Ni-base and Co-base heat-resisting alloys. The detection limit, defined as the concentration of Te which produces an absorbance twice the fluctuation of the base-line, was 0.05 ppm of Te in the sample. Table 4 summarizes the results of analysis of heat-resisting alloys for traces of Te by co-precipitation and graphite-furnace atomic-absorption spectrometry. The concentrations of Te found were all less than 0.05 ppm. To establish the validity of the method, known concentrations (equivalent to 0.50 and 2.50 ppm in the alloy) of Te were added to the alloy solutions and the total Te was determined. The average value ($\bar{x}$), standard deviation (σ) and relative standard deviation ($100\sigma/\bar{x}$) were obtained from 10 repetitive measurements of the absorbance of Te in the same solution. The concentrations of Te found agreed well with those added. It is concluded that the inter-element effects of the alloying elements of heat-resisting alloys are negligible. Analysis of 10 separately weighed samples of René 95, spiked with 0.50 ppm of Te, gave $\bar{x} = 0.50_4$ ppm, $s = 0.013$ ppm, $100s/\bar{x} = 2.5\%$.

DETERMINATION OF SULPHUR FUNCTIONS WITH IODOSO-COMPOUNDS

ASHUTOSH SRIVASTAVA*
Department of Chemistry, University of Jabalpur, Jabalpur-482001, India

(*Received* 26 *November* 1980. *Revised* 1 *June* 1981. *Accepted* 9 *June* 1981)

Summary—Iodoso derivatives, *e.g.*, *m*- and *p*-chlorophenyl, *m*- and *p*-methylphenyl and *p*-nitrophenyl-iodosoacetates and *o*-diacetoxyiodobenzoate, have been thoroughly investigated as oxidants and are proposed as analytical reagents for the determination of thiols, thioureas, isothiocyanates, organic sulphides, disulphides, xanthates, dithiocarbamates, amines and alcohols in aqueous and non-aqueous (acetic acid, acetonitrile, dimethylformamide) media. The error of the determination of thiols is 0.2% thioureas 0.5%, organic sulphides and disulphides 0.4%, isothiocyanates 0.4%, dithiocarbamates 0.4%, and xanthates 0.5%. All the methods are precise to 0.2–0.5%. It is also shown that the properties of the *o*-derivatives differ markedly from those of the *m*- and *p*-derivatives. The *o*-derivatives contain a 1-substituted 1,2-benzoiodoxilin-3-one ring system. The stability of this system is apparently associated with the size of the five-membered ring; other compounds in which iodine is apparently part of larger rings are less stable. *o*-Diacetoxyiodobenzoate appears to be the best analytical reagent of the iodoso series. The *m*- and *p*-iodosobenzoates are found unsuitable for quantitative oxidation of cysteine.

Among all the halogen compounds, iodoso-type compounds are peculiar to iodine. Similar compounds of other halogens either do not exist or are too unstable to be used as analytical reagents. The peculiarity of iodoso compounds lies in the fact that the iodine, even though in a positive oxidation state, must be linked to a carbon atom attached to a double bond. No stable compounds of positive iodine are known containing comparatively electropositive saturated aliphatic radicals.

Hellerman *et al.*[1,2] devised a method for determining cysteine with *o*-iodosobenzoate at pH 7, but when this was applied to enzymes, inactivation occurred. Hellerman concluded that this inactivation could result from competitive inhibition by the benzoate moiety rather than from any effect of –SH groups.

In the course of a systematic study of the determination of sulphur functions, we have considered the behaviour of a series of iodoso compounds. We have found that *m*- and *p*-derivatives of iodosobenzoates oxidize thiols quantitatively to the corresponding disulphides but do not oxidize cysteine to cystine stoichiometrically. *o*-Diacetoxyiodobenzoate[3] appears to be the best analytical reagent of the iodoso series because it possesses the qualities of *o*-iodosobenzoate[1,2] and of all the *m*- and *p*-derivatives of the phenyliodosoacetate series. It can be used in aqueous (pH 7) as well as non-aqueous media, *e.g.*, acetic acid, methanol, acetonitrile and dimethylformamide.

EXPERIMENTAL

Reagents

Preparation of o-diacetoxyiodobenzoic acid. A mixture of 70 ml of 30% hydrogen peroxide and 305 ml of acetic anhydride was stirred for 4 hr at 4°. *o*-Iodobenzoic acid (60.7 g) was then added to the solution, which was stirred for a further hour and kept overnight. Some *o*-diacetoxyiodobenzoic acid separated out and was filtered off. The filtrate, on concentration to small volume under reduced pressure (70 mmHg), yielded a second crop. The combined needle-shaped crystals were washed with ether and dried (over sodium hydroxide) in a vacuum desiccator; yield 63.0 g, m.p. 206°.

An aqueous *o*-diacetoxyiodobenzoate solution (0.05*M*) was prepared by adding a slight excess of 1*M* potassium hydroxide to the solid reagent and diluting to volume. It was standardized iodimetrically and a 0.01*N* solution was made by dilution.

Non-aqueous *o*-diacetoxyiodobenzoate solutions (0.05*M*) were prepared by dissolving the solid in glacial acetic acid, acetonitrile or dimethylformamide, and were standardized iodimetrically. The *p*- and *m*-methyliodosoacetates,[4] and *m*- and *p*-chlorophenyliodosoacetates[5] were prepared through the corresponding iodo-compounds,[6] and *p*-nitrophenyliodosoacetate[7] was prepared from the corresponding dichloride by reaction with lead acetate.

While all the procedures for preparing iodoso-compounds were found to be satisfactory, that of Pausacker[5] was found to be the simplest and most convenient. The products were recrystallized from anhydrous acetic acid and were freed from the solvent with dry air under suction, and were stored in a vacuum desiccator. The purity was determined by dissolving known weights in acetic acid (5–10 ml), adding 20 ml of 10% potassium iodide solution, diluting to 100 ml with water, and titrating the liberated iodine with thiosulphate. Samples of 99.5% purity could easily be prepared.

Stability of the stock solutions

The solutions are remarkably stable when kept in amber-coloured bottles, their strengths remaining unchanged for more than a month. Even in clear glass bottles, solutions are stable for up to 7 days. It may be pointed out that solutions of dichloramine-T and iodobenzene dichloride deteriorate quickly.

Test materials

Most of the thiols were gifts from Evans Chemetics, New

York. Diethyldithiocarbamate was a commercial product, the rest were prepared by the usual methods.[8,9]

Xanthates were prepared from the corresponding sodium or potassium alkoxide by reaction with carbon disulphide. The products were recrystallized by dissolution in acetone, filtration and precipitation by addition of petroleum ether.[10]

Amines, commercial grade, were distilled before use. All other chemicals used were of reagent grade.

Direct procedure for thiols in partially non-aqueous media

Thiols are quantitatively oxidized to their disulphides according to the equation:

$$2RSH + \xrightarrow{R'\text{-}IO} RSSR + I\text{-}R' + H_2O$$

where R′ = substituted benzoate moiety of the iodoso-derivative.

A sample containing 0.1–0.5 meq of thiol was weighed into a 150-ml Erlenmeyer flask containing 50 ml of distilled water. If insoluble in water, the sample was dissolved in 10–15 ml of acetic acid, acetonitrile or dimethylformamide and before titration a roughly equal volume of water was added, to make its concentration roughly 40–60% v/v. (Less water could be used if the sample is partially precipitated, but at higher acetic acid concentrations the reaction is slow and the end-point is not so sharp.) About 50 mg of potassium iodide and 1 ml of 1% starch solution were added and the solution was titrated with a 0.01*N* solution of any of the iodoso-compounds.

For potentiometric titrations, in a 100-ml beaker was used, with a modified calomel or antimony electrode as reference and a bright platinum were as indicator electrode.

Indirect procedure for thioureas

Thioureas are quantitatively oxidized to the corresponding urea and sulphate:

$$RNHCSNH_2 + 4R'\text{-}IO + H_2O \rightarrow RNHCONH_2 + H_2SO_4 + 4I\text{-}R'$$

where R = alkyl or aryl group, R′ = benzoate moiety of the iodoso-derivative.

Thiosemicarbazide reacts as follows:

$$NH_2CSNHNH_2 + 5R'\text{-}IO + 6H_2O \rightarrow N_2 + HCN + 5I\text{-}R' + H_2SO_4 + H_2O$$

A portion of sample containing 0.01–0.1 meq of thiourea (dissolved in water or acetic acid or acetonitrile) was pipetted into a 250-ml Erlenmeyer flask. If an organic solvent was used, enough water was added to make the organic solvent concentration 30–80% v/v. A measured and excessive volume of 0.05*M* iodoso-compound solution was added, then 30 min later a known and excessive volume of 0.05 *M* ascorbic acid (which reacts with the iodoso compound in a 1:1 molar ratio) or 0.05*M* mercaptoacetic acid and 3 ml of 1*M* sulphuric acid were added and after 30 sec the residual ascorbic acid or mercaptoacetic acid was titrated with 0.04*N* iodine, with starch as indicator. The ascorbic acid could also be titrated with 2,6-dichlorophenol–indophenol solution. A blank determination was also done.

Procedure for isothiocyanates

Organic isothiocyanates are quantitatively converted into the corresponding thioureas with n-butylamine in dimethylformamide at room temperature:

$$RNCS + C_4H_9NH_2 \rightarrow RNHCSNHC_4H_9$$

An aliquot (2–5 ml) of dimethylformamide solution containing 2–18 mg of organic isothiocyanate was taken in a 100-ml iodine flask and 3 ml of n-butylamine (approximately 0.1*M* solution in dimethylformamide) were added. The solution was diluted to 10 ml with the solvent and mixed. After 10 min to ensure completion of the reaction, about 50% excess of 0.05*M* iodoso compound solution was added, with enough water and acetic acid to make the acid concentration 30–80%. After 30 min the determination was completed in the same way as for thioureas.

Procedure for dithiocarbamates and xanthates

In acetonitrile medium dithiocarbamates and xanthates are quantitatively oxidized according to the equations

$$2RR'CSS^- \rightarrow (RR'CS.S)_2 + 2e$$

$$2ROCSS^- \rightarrow (ROCS.S^-)_2 + 2e$$

A sample containing 0.1–1.0 meq of dithiocarbamate or xanthate was dissolved in 20 ml of acetonitrile. About 35 ml of methanol and 50 mg of potassium iodide were added. The flask was stoppered and the reactants were mixed. The mixture was titrated with 0.05*N* iodoso-compound solution, to the appearance of the iodine colour. Methanol should be 60–80% of the total solvent at the end-point, or the reaction will be too slow.

Procedure for amines

In acetonitrile medium, primary and secondary amines are quantitatively converted by excess of carbon disulphide into the corresponding mono- or dialkyldithiocarbamate

$$2RNH_2 + CS_2 \rightarrow RNHCS.SNH_2R$$

$$2RR''NH + CS_2 \rightarrow RR'NCSSNH_2RR''$$

which can be titrated as just described.

The sample (10–40 mg), weighed directly or in an aliquot of amine solution in acetonitrile, was placed in a glass-stoppered flask containing about 20 ml of acetonitrile and 2–5 ml of carbon disulphide were added to it. The reactants were mixed, cooled to room temperature, and titrated as above.

Procedure for alcohols

About 5 ml of the alcohol were mixed with 3 g of powdered potassium hydroxide in a 50-ml ground-glass-joint flask fitted with a water condenser, and refluxed for 15 min. The liquid was then cooled and the supernatant clear liquid was decanted into a dry flask and chilled. About 4 ml of carbon disulphide were added from a tap-funnel during 5 min with vigorous stirring of the mixture. The heavy yellow precipitate was filtered off on sintered glass and washed with 25-ml portions of anhydrous diethyl ether.

The crude product was dissolved in the minimum of hot acetone. The solution was cooled and anhydrous diethyl ether was added to precipitate the product. The xanthate was filtered off, washed with ether, dried in a vacuum desiccator, then determined as above.

Procedure for disulphides and sulphides

Disulphides are oxidized stoichiometrically to the α-sulphones in dilute acetic acid

$$RSSR + 4OI\text{-}R' \xrightarrow{H_2O} RSO_2RSO_2 + 4I\text{-}R'$$

Organic sulphides are oxidized to sulphoxides

$$RSR + OI\text{-}R' \xrightarrow{H_2O} RSOR + I\text{-}R'.$$

A sample containing 0.1–0.5 mmole of sulphide or 0.02–0.08 mmole of disulphide was weighed into a 250-ml Erlenmeyer flask and dissolved in 15–20 ml of glacial acetic acid. About 50% excess of 0.05*M* iodoso-compound solution was added along with enough distilled water to make the acid concentration 30–80% v/v (the reactions are slow in anhydrous acetic acid and catalysed moderately by water; less water was used if the sample precipitated). The mixture was left for at least 30 min (50 min in the case of methionine and overnight for cystine) then a measured and

excessive volume of 0.05*M* ascorbic or mercaptoacetic acid was added along with 3 ml of 1*M* sulphuric acid. The mixture was then titrated with 0.05*N* iodine, with starch as indicator. Excess of ascorbic acid can also be titrated with 2,6-dichlorophenolindophenol. A blank determination was run separately.

RESULTS

Results for the determination of several thiols (Table 1) show that the iodoso-compound methods in non-aqueous media are generally sufficiently accurate, but cysteine and 3-mercaptopropionic, *o*-mercaptobenzoic and mercaptosuccinic acid are oxidized beyond the disulphide stage in an unaccountable fashion and hence the method is not recommended for them. 1-Butane thiol gave incomplete reaction with *o*-DIB and *m*-MPIA. Results for thioureas (Table 2) showed excellent recovery, especially when dilute sol-

fere but organic sulphides and disulphides do. In the determination of sulphides and disulphides, alanine, glycine, dextrose, and formic, cinnamic and formic acid can be tolerated.

Results for determination of alcohols by xanthate formation, isothiocyanate by thiourea formation amines by dithiocarbamate formation and of sulphides are summarized in Table 6. As a check, sulphides and disulphides were also determined by total sulphur analysis and by the method of Siggia and Edsberg.[31]

THE PROTONATED 4,4′-DIAMINOTRIPHENYLMETHYL CATION AS A REAGENT AND CYCLOHEXANONE AS AN ABSORBANT FOR SULPHUR DIOXIDE DETERMINATION

JACK L. LAMBERT, MICHAEL J. CHEJLAVA, MOHAMMED H. BEYAD and JOSEPH V. PAUKSTELIS

Department of Chemistry, Kansas State University, Manhattan, Kansas 66506, U.S.A.

(*Received* 30 *March* 1981. *Accepted* 7 *May* 1981)

Summary—Protonated 4,4′-diaminotriphenylmethyl cation, DATM, has been investigated as a colorimetric reagent for the determination of sulphur dioxide. The bisulphite addition compound with formaldehyde alkylates a primary arylamine group in the protonated reagent to re-establish resonance, and hence produces a colour that is proportional in intensity to the concentration of either bisulphite or formaldehyde (the other being in excess). The large bathochromic spectral shift results in a negligible blank correction. Cyclohexanone in aqueous solution has been found to stabilize bisulphite solutions for up to 6 hr. The stabilization by cyclohexanone has been compared with stabilization by tetrachloromercurate(II). The Beer-Lambert law is obeyed with good precision for both sulphite and formaldehyde determination.

The reaction product of bisulphite with formaldehyde in acid aqueous solution combines readily with protonated primary arylamine groups to form aminomethylsulphonates. The reaction regenerates the absorption in the visible region, which had been suppressed by protonation of the primary amine groups. Protonated pararosaniline is a versatile reagent for the determination of either sulphur dioxide[1–4] or formaldehyde[5]. Reactions which produce sulphite or formaldehyde quantitatively form the basis for analytical methods for sulphate aerosols (reduction to sulphite)[6] and ozone (formaldehyde formed from the ozonolysis product of the alkene eugenol).[7] A fundamental study of the primary arylamine–bisulphite–formaldehyde reaction was made by Nauman *et al.*[8] who studied similarities in the reactions of pararosaniline and aniline with bisulphite and formaldehyde. A significant contribution to the methods for sulphur dioxide was made by West and Gaeke,[9] who stabilized sulphur dioxide in sample solutions with tetrachloromercurate(II).

Two reagents of simpler structure than pararosaniline have been proposed for the determination of sulphur dioxide: *p*-aminoazobenzene[10] and *p*-nitroaniline.[11] In common with pararosaniline, these two reagents produce appreciable blanks. 4-Nitro-1,2-diaminobenzene[12] was proposed as a reagent with negligible blank correction, but gives lower sensitivity than pararosaniline.

The protonated 4,4′-diaminotriphenylmethyl cation, [DATM, benzylidenebis(4-aminophenyl) cation] has been synthesized and investigated as a reagent for sulphur dioxide. The possible stabilizing effect of cyclohexanone on aqueous solutions of sulphur dioxide (bisulphite) has also been investigated. As observed for the analogous triphenylmethane dyes, Malachite Green (which has *N*,*N*-dimethylamino groups in the *para*-position of two of the three phenyl rings), and Crystal Violet (which has *N*,*N*-dimethylamino groups on all three of the phenyl rings), two electron-donating amino-nitrogen atoms participate in a more linear resonating structure than three such nitrogen atoms do and hence produce a greater bathochromic shift from the faint yellow colour of the protonated reagents. The farther the shift toward the red, the less the absorption peaks in the ultraviolet region interfere to produce a blank correction at the absorbance maximum.

EXPERIMENTAL

Demineralized water was used for preparing all reagent solutions and for making dilutions. Chemicals used were reagent grade or the purest grade available.

Reagent[13]

Bis(4-amino)triphenylmethane, the leuco-base of the reagent, was prepared by heating a mixture of 27.9 g (0.3 mole) of aniline, 10.6 g (0.1 mole) of benzaldehyde, and 24 g (0.2 mole) of concentrated hydrochloric acid for 20 hr with vigorous stirring under reflux. The end of the condenser was closed with a plug of glass wool to prevent excessive oxidation of the aldehyde during the reaction period. The resulting mixture was treated with 12 g of sodium carbonate and the water removed with a rotary evaporator to leave a dark blue, tarry solid. The product was washed several times by decantation with water to remove excess of sodium carbonate.

The leuco-base so prepared (about 0.05 mole) was dissolved in 300 ml of water containing 20 ml of concentrated hydrochloric acid. Ice was added to bring the volume to 400 ml and the temperature to 0°. To the well-stirred solution was added, in one portion, 12.0 g (0.05 mole) of lead dioxide, and the stirring continued for 4 hr. An aqueous

solution containing 25 g of sodium sulphate was added to precipitate the reduced lead(II) as lead sulphate. Any unreacted lead dioxide and the precipitated lead sulphate were removed by filtration. On addition of 15 g of sodium carbonate to the filtrate, the carbinol form of the dye was precipitated and, after collection, was washed several times with water and dried. NMR (D_2O/d_6-DMSO) gave 4.75 (s, NH_2, 4H), 7.1–7.4 (m, aromatic, 13H). CMR (d_6-DMSO) gave 156.29, 146.43, 138.93, 137.26, 129.80, 128.96, 128.33, 126.15, 118.26.

The carbinol form of the dye was purified by dissolving it in chloroform and passing the solution through a column of basic alumina. A brown substance, thought to be an oxidation product, was removed from the column by washing with chloroform. The purified carbinol was eluted with 95% ethanol, dried, and converted into the protonated 4,4′-diaminotriphenylmethyl cation by treatment with hydrochloric acid. The λ_{max} of the cation is 560 nm and the molar absorptivity, ϵ, is 3.0×10^4 l.mole^{-1}.cm^{-1}.

Solutions

Reagent solution. Dissolve 0.5 g of DATM in 20.0 ml of concentrated hydrochloric acid and sufficient water to make 100.0 ml of solution.

Formaldehyde solution. Mix 2.0 ml of 37% aqueous formaldehyde solution and sufficient 0.005*M* hydrochloric acid to make 100.0 ml of solution.

Hydrochloric acid, 0.005M. Dilute 0.41 ml of concentrated hydrochloric acid to 1 litre.

Standard bisulphite solution for HSO_3^- calibration curves. Dissolve 0.128 g of sodium bisulphite, $NaHSO_3$, in water and dilute to exactly 1000 ml. This solution contains 104 ppm bisulphite ion, HSO_3^-, and must be prepared fresh as needed.

Cyclohexanone solution. Dissolve 25 ml of reagent grade cyclohexanone in water and dilute to 1000 ml.

Tetrachloromercurate(II) solution. Dissolve 27.2 g of mercury(II) chloride, (0.1 mole) in 20.0 ml of concentrated hydrochloric acid (0.24 mole) and water, and dilute to 500.0 ml.

Bisulphite solution for formaldehyde determination. Dissolve 0.50 g of sodium bisulphite, $NaHSO_3$, in water and dilute to 100.0 ml to make a 0.048*M* solution.

Calibration graphs

Three calibration graphs were prepared: for formaldehyde with excess of bisulphite in aqueous cyclohexanone solution; for formaldehyde with excess of bisulphite in aqueous tetrachloromercurate(II) solution; formaldehyde in aqueous cyclohexanone with excess of bisulphite present.

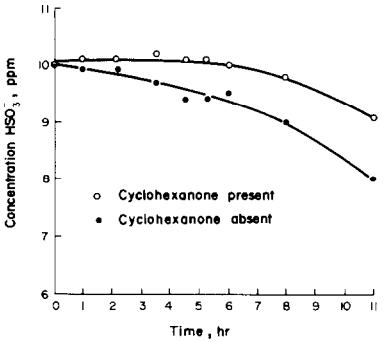

Fig. 2. Effect of cyclohexanone on the stability of 10-ppm bisulphite solutions.

The data shown in Fig. 1 represent two series of solutions. For each concentration on the line labelled HSO_3^-–cyclohexanone, 2.0 ml of cyclohexanone solution and the appropriate volume of freshly prepared standard bisulphite solution were diluted to 100.0 ml. For each determination, 10.0 ml of the bisulphite–cyclohexanone solution so prepared plus 1.0 ml each of the formaldehyde solution and the DATM reagent solution were mixed, heated at 50° for 30 min, and cooled, and then the absorbance was measured. Five determinations were made at each concentration.

For each concentration on the line labelled HSO_3^-–$[HgCl_4]^{2-}$ in Fig. 1, the appropriate volume of freshly prepared standard bisulphite solution was added to 50.0 ml of tetrachloromercurate(II) solution and sufficient water was added to bring the volume to 100.0 ml. For each determination, 10.0 ml of this bisulphite–tetrachloromercurate(II) solution plus 1.0 ml each of the formaldehyde solution and the DATM reagent solution were mixed, heated at 50° for 30 min, and cooled, and then the absorbance was measured. Five determinations were made at each concentration.

Figure 2 shows the stabilizing effect of cyclohexanone on 10-ppm bisulphite solution compared to 10-ppm bisulphite solution without cyclohexanone, for periods up to 11 hr before addition of formaldehyde and DATM reagent solutions.

The data shown in Fig. 3 show the response of the DATM reagent to formaldehyde in the presence of excess of bisulphite. The appropriate volume of formaldehyde solution at each concentration was diluted to 100.0 ml with 0.005*M* hydrochloric acid. For each determination, 10.0 ml of the properly diluted formaldehyde solution plus 1.0 ml

each of the 0.048*M* bisulphite solution and 1.0 ml of DATM reagent solution were mixed, heated at 50° for 30 min, and cooled, and then the absorbance was measured. Five determinations were made at each concentration.

RESULTS AND DISCUSSION

The violet-blue dye cation was decolorized in 0.2*M* hydrochloric acid solution, with formation of the diprotonated species. Only a small barely distinguishable peak was observed, at 405 nm. The blank correction was negligible. No reaction appeared to occur with formaldehyde alone, but with addition of bisulphite an aminomethylsulphonate group was formed and a blue-violet chromogen, $\lambda_{max} = 585$ nm, was reconstituted. According to Pate *et al.*[14] in their study of the corresponding pararosaniline reagent, in the presence of excess of formaldehyde only one bisulphite ion is required to re-establish resonance and colour in one dye cation. The reconstituted chromogen absorbs at a longer wavelength than the non-alkylated dye: 560 nm for the unprotonated dye cation and 585 nm for the aminomethylsulphonate derivative. For pararosaniline, the corresponding wavelengths are 544 nm and 560 nm, respectively. The bathochromic shift is thus greater by 9 nm for the more nearly linear harmonic oscillator DATM chromogen described here, than the shift observed with pararosaniline. The greater bathochromic shift is partially responsible for the lower blank, which is the principle advantage of the DATM reagent. The absorption maxima, along with the molar absorptivities that were available or calculable from the articles which described the previously proposed reagents, are included in Table 1 for comparison purposes. The molar absorptivities correspond approximately to the relative sensitivities of the reagents, although relative reactivities must also be taken into account.

Cyclohexanone stabilizes aqueous solutions of bisulphite for periods up to 6 hr (Fig. 2), after which slight progressive decomposition occurs. Without cyclohexanone present, decomposition (probably aerial oxidation to sulphate) starts to occur in a very short time. Cyclohexanone does not stabilize bisulphite nearly as efficiently as does tetrachloromercurate(II), which is effective for periods up to 2 weeks or more, but for collection periods up to 6 hr cyclohexanone solution is as efficient as tetrachloromercurate(II) as an absorbant for sulphur dioxide and far less of a toxic hazard than the mercury solution. The stabilizing reaction of bisulphite with cyclohexanone produces a substituted hydroxymethylsulphonate addition compound. Steric considerations, as observed with space-filling molecular models, suggest that the addition product will be less stable if the alkyl groups of the ketone are bulky. Cyclopentanone and cyclohexanone, of all the readily available water-soluble ketones, offer the minimum steric hindrance to formation of the hydroxymethylsulphonate addition product.

The calibration plot obtained with cyclohexanone as the stabilizing agent (Fig. 1) conformed closely to the Beer-Lambert law and the standard deviations for the individual concentration determinations were small. The calibration data obtained with tetrachloromercurate(II) as the stabilizing agent (also Fig. 1) produced a straight line that had a small intercept on the concentration axis and larger standard deviations for the individual concentration determinations.

The alkylation reaction can also be applied with good precision to the determination of formaldehyde, or substances which produce formaldehyde, as shown in Fig. 3.

Interferences (especially nitrogen oxides) have been thoroughly studied for the bisulphite–formaldehyde alkylation of primary amine reagents of the type investigated here. Nitrogen dioxide interference has been effectively eliminated by the use of sulphamic acid,[16] a strong acid which serves the same purpose as hydrochloric acid and which destroys the nitrous

acid formed along with nitric acid by the hydrolysis of the nitrogen dioxide.

DETERMINATION OF ASCORBIC ACID WITH *o*-IODOSOBENZOATE

ANALYSIS OF MIXTURES OF ASCORBIC ACID WITH METHIONINE AND CYSTEINE OR GLUTATHIONE

KRISHNA K. VERMA

Department of Chemistry, University of Jabalpur, Jabalpur 482001, India

(*Received* 8 *April* 1980. *Revised* 15 *December* 1980. *Accepted* 27 *April* 1981)

Summary—Ascorbic acid has been determined in pure solutions, pharmaceutical preparations, foodstuffs and biological fluids by titration with *o*-iodosobenzoate, with visual or photometric detection of the end-point, with leuco-2,6-dichlorophenolindophenol plus potassium iodide as indicator. Cysteine and glutathione, which interfere quantitatively, are masked by cyanoethylation; the cyanoethylated product and methionine have been determined with *o*-iodosobenzoate in the presence of acidified potassium bromide, with Methyl Red as indicator. Procedures are given for the analysis of mixtures of ascorbic acid with sulphur-containing amino-acids.

Oxidation of ascorbic acid with 2,6-dichlorophenolindophenol is extensively used for its determination,[1,2] but the value of this method is limited because the dye reacts with other reductants, *e.g.*, cysteine and glutathione, which are often present in biological fluids,[3] or with iron(II), which is sometimes found in foodstuffs.[4,5] Titration with *N*-bromosuccinimide has been claimed to be free from the shortcomings of the indophenol method,[6,7] but only the freshly prepared reagent should be used. Cysteine and glutathione also react with *N*-bromosuccinimide and vitiate the analysis.[8,9] Standard copper(II),[10] thallium(III),[11] hexacyanoferrate(III)[12] and iodine or iodate solutions[13,14] are more stable than *N*-bromosuccinimide but otherwise there seems to be no implicit advantage in using these reagents.

A new method for determination of ascorbic acid in pure solutions, pharmaceutical preparations, biological fluids and edible fruits is described here based on oxidation of ascorbic acid with *o*-iodosobenzoate which has already been studied kinetically.[15]

Ascorbic acid is titrated with standardized *o*-iodosobenzoate at neutral pH, with leuco-2,6-dichlorophenolindophenol plus potassium iodide as indicator; the end-point, which is shown by the appearance of the blue colour of the oxidized form of the indicator, is sharp, reproducible and stable. The reaction of *o*-iodosobenzoate with ascorbic acid at pH 7 is fast but that with iodide to yield iodine is slow, and it is the iodine produced that oxidizes the indicator. Therefore it is necessary to titrate the sample solution slowly in order to locate the correct end-point. However, a rapid titration can be used for orientation, followed by another in which all but about 1 ml of the titrant volume used in the first titration is added quickly and the titration is completed slowly. Starch–iodide mixture can also be used as indicator, but with dilute titrant solutions (0.001*M* or less) the end-point colour is harder to detect than that from the indophenol. For solutions containing only 10–40 μg of ascorbic acid the end-point should be detected photometrically. Iron(II) gives positive errors if the leuco-indophenol is used as indicator, presumably because it reduces the quinone dye, but starch–iodide indicator gives a stable and correct end-point. With dilute titrant solutions an indicator blank correction is necessary.

The redox potential of *o*-iodosobenzoate at 25° was found to be 1.21 V at pH 1, 1.08 V at pH 2, 0.53 V at pH 4 and 0.48 V at pH 7.

Mixtures of ascorbic acid with cysteine or glutathione have been analysed by first titrating the sum, according to the thiol compounds reacting

$$2RSH + OIC_6H_4CO_2^- \rightarrow RSSR + IC_6H_4CO_2^- + H_2O,$$

then determining the ascorbic acid alone in a second aliquot after reaction with acrylonitrile in phosphate buffer (pH 7), the thiol compounds undergoing quantitative cyanoethylation to yield thio-ethers which are inert to *o*-iodosobenzoate:

$$RSH + CH_2{=}CHCN \rightarrow RSCH_2CH_2CN$$

Cysteine or glutathione is obtained by difference. Bisulphite can be masked similarly:

$$HSO_3^- + CH_2{=}CHCN \rightarrow {}^-O_3SCH_2CH_2CN$$

In mixtures of ascorbic acid with methionine and cysteine or glutathione, the ascorbic acid and thiol contents are determined as before; methionine does not interfere. Then a third aliquot is cyanoethylated and titrated with *o*-iodosobenzoate after addition of acidified potassium bromide and Methyl Red. The

bromine formed in the titration oxidizes ascorbic acid to dehydroascorbic acid, whereas methionine and the cyanoethylated cysteine or glutathione are oxidized to their sulphoxides:

$$2HBr + OIC_6H_4CO_2^- \rightarrow Br_2 + H_2O + IC_6H_4CO_2^-$$

$$CH_3SCH_2CH_2CH(NH_2)CO_2H + Br_2 + H_2O \rightarrow CH_3SOCH_2CH_2CH(NH_2)CO_2H + 2HBr$$

$$RSCH_2CHCN + Br_2 + H_2O \rightarrow RSOCH_2CH_2CN + 2HBr$$

The methionine content is obtained by subtracting from the *o*-iodosobenzoate consumption for the third aliquot, the sum of the consumption for ascorbic acid and twice that for the cysteine or glutathione.

EXPERIMENTAL

Reagents

*o-Iodosobenzoate solution, 0.005*M. Prepared by dissolving 1.32 g of *o*-iodosobenzoic acid in 55 ml of 0.01*M* potassium hydroxide and diluting to 1 litre with water, standardized iodometrically[16] and diluted as required.

Phosphate buffer, pH 7. Prepared by dissolving 117.7 g of K_2HPO_4 and 44.1 g of KH_2PO_4 in 1 litre of water.

Leuco-2,6-dichlorophenolindophenol indicator solution. To 20 ml of 0.05% solution of the sodium salt of the indicator add about 5 ml of phosphate buffer and bleach the blue colour by dropwise addition of 0.05% ascorbic acid solution. The reduced indicator oxidizes when exposed to the air and it is necessary to decolorize the solution with ascorbic acid before use.

Methyl Red solution. A 0.04% solution in 95% ethanol.

Procedures

Determination of ascorbic acid. A solution containing 0.2–15.0 mg of ascorbic acid is mixed with 5 ml of phosphate buffer, 5–10 ml of water, 1 ml of indophenol indicator and about 50 mg of potassium iodide, and titrated with 0.001*M* *o*-iodosobenzoate when the sample solution contains up to 3 mg of ascorbic acid and with 0.005*M* titrant for larger amounts. The titration must be done slowly (5 ml of titrant per min) with swirling for 10 sec between addition of drops near the end-point (shown by the vivid blue colour of the oxidized indicator).

When the sample contains iron(II), 5 ml of 3% acetic acid, solution 5–10 ml of water, about 50 mg of potassium iodide and 1 ml of 0.5% starch are added, and the solution is titrated till the appearance of a blue colour.

Photometric determination of microgram amounts of ascorbic acid. Sample solution (10 ml or less) containing 9–45 μg of ascorbic acid is taken in a 200-ml titration cell and treated with 20 ml of phosphate buffer, 1 ml of indophenol indicator and 50 mg of potassium iodide, and made up to 100 ml with water and slowly titrated spectrophometrically at 600 nm with $5 \times 10^{-5}M$ *o*-iodosobenzoate. An indicator blank is also determined.

Determination of ascorbic acid in the presence of cysteine or glutathione. A known volume of sample is treated with 5 ml of phosphate buffer, 5–10 ml of water, 1 ml of indophenol indicator and 50 mg of potassium iodide, and titrated with *o*-iodosobenzoate, the concentration of titrant depending on the total titrand concentration.

To determine ascorbic acid alone, a known volume of sample is mixed with 5 ml of phosphate buffer, 5–10 ml of water and 0.5 ml of acrylonitrile. The flask is stoppered, shaken for 1 min and left for 15 min. Then 50 mg of potassium iodide and 1 ml of indophenol indicator are added and the ascorbic acid is titrated with *o*-iodosobenzoate.

Analysis of mixtures of ascorbic acid, methionine and cysteine or glutathione. First ascorbic acid plus cysteine or glutathione is determined as before, then the ascorbic acid alone is titrated in a second aliquot after cyanoethylation of the sulphydryl compound. To determine the total of the three components, a third aliquot of mixture is cyanoethyl-

ated, then treated with 5 ml of 0.1*M* sulphuric acid, 50 mg of potassium bromide and 2 or 3 drops of Methyl Red indicator, and titrated with 0.005*M* *o*-iodosobenzoate, until the Methyl Red is bleached. An indicator blank correction must be applied.

Applications of the method

Determination of ascorbic acid in pharmaceutical preparations. A finely ground tablet or a whole capsule is stirred with 30 ml of water for about 15 min. The residual solid is filtered off on a Whatman No. 42 paper and washed with water. The filtrate is made up to such a volume that 5 ml contains 1–10 mg of ascorbic acid. Injections are diluted directly. A suitable volume is titrated with 0.005*M* *o*-iodosobenzoate as described.

Determination of ascorbic acid in foodstuffs. Fruit juice is mixed with 5% metaphosphoric acid to precipitate proteins. The acidified juice is filtered, diluted so that 5 ml of solution contains 1–10 mg of ascorbic acid, and titrated with 0.005*M* *o*-iodosobenzoate, with starch–iodide as indicator. If bisulphite has been added as a preservative, mix 10 ml of fruit juice or squash with 5 ml of pH-7 phosphate buffer and 1 ml of acrylonitrite. After 5 min add 5 ml of 3% acetic acid, 20 ml of water, 50 mg of potassium iodide and 1 ml of starch solution, and titrate.

Determination of ascorbic acid in blood and plasma. Five ml of whole blood or plasma are added dropwise with shaking to 5 ml of 2% trichloroacetic acid solution, in a 25-ml centrifuge tube, stirred with a thin glass rod, allowed to stand for 5 min, and then centrifuged. The supernatant solution is separated and 5 ml of it are mixed with 3 ml of phosphate buffer, 0.2 ml of indophenol indicator and 50 mg of potassium iodide in a 25-ml Erlenmeyer flask, and titrated with 0.0001*M* *o*-iodosobenzoate to a distinct blue colour.

Determination of ascorbic acid in urine. Fifty ml of urine (preferably freshly passed) are mixed well with 5 ml of 2% metaphosphoric acid solution, and 10 ml of this acidulated sample are added to 5 ml of phosphate buffer, 0.5 ml of indophenol indicator and 50 mg of potassium iodide. The ascorbic acid is titrated with 0.001*M* *o*-iodosobenzoate to the appearance of a blue colour.

RESULTS AND DISCUSSION

The titration of ascorbic acid with *o*-iodosobenzoate is accurate in phosphate buffer of pH 6–7.5 (Table 1). The oxidation of iodide by *o*-iodosobenzoate at pH 5–6 is faster than at pH 7, but the oxidized indophenol indicator will be in its pink acid form and will give a less distinct end-point.

The following compounds in up to tenfold molar ratio to ascorbic acid do not interfere, whichever indicator is used: glucose, fructose, lactose, maltose, sucrose, starch, thiamine hydrochloride, riboflavin, citric, oxalic, formic, tartaric and maleic acids, glycine, alanine, tyrosine, tryptophan, methionine, cysteine, biotin, serine, proline, oxidized glutathione and urea.

Substances which interfere even when present in only small amounts include thiourea, thiosulphate and sulphide. Thiols also react with *o*-iodosobenzoate but can be eliminated by cyanoethylation as can bisulphite. Sodium hydroxide, sodium methoxide or benzyltrimethylammonium hydroxide, which are ex-

The excipients in the capsules are nicotinamide, thiamine hydrochloride, ribovflavine, calcium pantothenate, pyridoxine hydrochloride, folic acid, cyanocobalamin, ferrous fumarate, *etc.* Those in the injections are methyl- and propylparaben and calcium gluconogalactogluconate.

tensively used as catalysts in cyanoethylation,[17,18] have been found to destroy ascorbic acid and should, therefore, not be used. In phosphate buffer of pH 6–7.5 the cyanoethylation is complete and there is no effect on ascorbic acid.

Results for the photometric titration of microgram amounts of ascorbic acid are given in Table 2. In Table 3, the results are given for the analysis of mixtures of ascorbic acid with methionine and cysteine or glutathione, made from solutions of the components. Results for the determination of ascorbic acid in fruit juices and pharmaceutical preparations are presented in Tables 4 and 5 respectively. Most vitamin C capsules gave coloured solutions but the leuco-indophenol furnished a sharp end-point (greenish-blue in yellow solutions, violet in red solutions and vivid blue in colourless solutions). The exactness of this end-point

SHORT COMMUNICATIONS

DIRECT OXIDIMETRIC DETERMINATION OF THIOCARBONATE SULPHUR WITH FERRICYANIDE, USING IRON(II)–DIMETHYLGLYOXIME OR SODIUM NITROPRUSSIDE AS INDICATOR

K. SINGH, P. G. BHATIA* and R. D. GUPTA*
Department of Chemistry, Ahmadu Bello University, Zaria, Nigeria

(*Received* 24 *July* 1980, *Revised* 2 *June* 1981. *Accepted* 10 *June* 1981)

Summary—Direct determination of 15–50 mg of thiocarbonate sulphur can be achieved by a one-step titration with potassium ferricyanide, using iron(II)–dimethylglyoxime or sodium nitroprusside as indicator. Only one sulphur atom of the thiocarbonate ion undergoes oxidation to elemental sulphur, the other two separating as carbon disulphide.

Our current spectrophotometric studies on trithiocarbamate complexes of metals have required standardization of the ligand solution, which can be done by determining the thiocarbonate sulphur. A number of indirect methods have been reported for this, including gravimetric determination as thallium(I) trithiocarbamate,[1] and indirect titration[2,3] with iodine, iodate, chloramine-T, ferricyanide, permanganate or vanadate. In the ferricyanide method[3] an aliquot of sample containing not more than 17 mg of thiocarbonate sulphur was heated with a measured excess of 5*M* ferricyanide solution for 15–20 min at 60°. The mixture was then cooled to room temperature and the excess of ferricyanide determined by adding potassium iodide and sulphuric acid, and titrating with thiosulphate. The trithiocarbonate was oxidized completely to sulphate. We have now found a direct method for determination of 15–50 mg of thiocarbonate sulphur by titration with ferricyanide, using iron (II)–dimethylglyoxime or sodium nitroprusside as indicator.

EXPERIMENTAL

Reagents

Potassium ferricyanide, 0.10M. Prepared by dissolving the analytical reagent grade material in demineralized water, and standardized with sodium thiosulphate solution. Titrants of lower concentrations were prepared by dilution and standardized in the same manner.

Iron(II)–dimethylglyoxime indicator. Made by mixing 10 ml of 0.02*M* ferrous sulphate, 50 ml of saturated dimethylglyoxime solution in ethanol and 5 ml of concentrated ammonia solution.

Sodium nitroprusside indicator, 1% aqueous solution. Freshly prepared.

Potassium thiocarbonate, 1M. Prepared and standardized as reported earlier[3] and diluted as required.

Ammonia–ammonium chloride buffer, pH 9.4. Made by dissolving 50 g of ammonium chloride and 70 ml of concentrated ammonia solution in water and diluting to 1 litre.

Procedures

A. To a solution containing 15–50 mg of thiocarbonate sulphur (equivalent to 5–17 mg of oxidizable sulphur, *i.e.*, one third of the total sulphur), add 10 ml of pH 9.4 buffer and dilute to about 30 ml. Add 2 drops of iron(II)–dimethylglyoxime indicator and titrate with 0.05*M* potassium ferricyanide until the indicator complex changes from cherry red to yellow.

B. To a solution containing 15–50 mg of thiocarbonate sulphur, add 1 ml of sodium nitroprusside solution and 10 ml of pH 9.4 buffer and titrate with 0.1*M* potassium ferricyanide until the purple colour disappears or changes to pale yellow. Any pH in the range 8–10 is suitable.

DISCUSSION AND RESULTS

The results obtained showed that under the reaction conditions used, one of the three sulphur atoms in the trithiocarbonate ion is oxidized to elemental sulphur, the other two sulphur atoms separating as carbon disulphide. This stoichiometry is supported by amperometric studies[4] of the potassium thiocarbonate–ferricyanide reaction. Also, Charlot[5] found that sulphide was oxidized to elemental sulphur by ferricyanide, when iron(II)–dimethylglyoxime was used as indicator. The reaction between thiocarbonate and ferricyanide can be expressed as:

$$CS_3^{2-} + 2Fe(CN)_6^{3-} \rightarrow 2Fe(CN)_6^{4-} + CS_2 + S$$

1 ml of 0.10*M* $K_3Fe(CN)_6$

$\equiv$ 9.32 mg of K_2CS_3 $\equiv$ 1.603 mg of S

* Department of Chemistry, Katsina College of Arts, Science and Technology, Zaria, Nigeria.

Formation of carbon disulphide was confirmed by the acetone test.[6]

The results are quantitative for 15–50 mg of thiocarbonate sulphur (equivalent to 5–17 mg of oxidizable sulphur) with a relative error of less than 0.1%. With larger amounts of trithiocarbonate the carbon disulphide formed slowly reacts with the free alkali to re-form thiocarbonate, resulting in positive errors.

$$6OH^- + 3CS_2 \rightarrow 2CS_3^{2-} + CO_3^{2-} + 3H_2O$$

Sulphide interferes seriously, since it is also oxidized by ferricyanide. However, potassium thiocarbonate solutions free from sulphide can be easily prepared, and stored for long periods of time at pH $\geqslant$ 8.0 without undergoing any decomposition.

Acknowledgements—We are grateful to Professor U. D. Gomwalk, Head of the Department, for the facilities provided and his keen interest. Two of us (P.G.B. and R.D.G.) are also thankful to the Rector, Katsina College of Arts, Science and Technology for his encouragement and support.

BACTERIAL ELECTRODE FOR L-ARGININE

S. R. GROBLER*, N. BASSON† and C. W. VAN WYK

Research Group of the Medical Research Council, Faculty of Dentistry, University of Stellenbosch, Tygerberg 7505, South Africa

(*Received* 10 *March* 1981. *Accepted* 26 *May* 1981)

Summary—*Streptococcus lactis* bacterial cells are employed for the conversion of L-arginine into ammonia. An ammonia gas-electrode is used as a detector. The combination of bacterial action and the gas electrode responds linearly to L-arginine over the concentration range $8.0 \times 10^{-6} - 1.0 \times 10^{-3} M$, with a slope of 59.0 mV/decade and is selective with respect to other L-amino acids.

Enzymes coupled with an appropriate electrode are increasingly used in analysis. Progress in this field[1,2] has been delayed because the enzymes have to be isolated and purified. Furthermore, many enzymes which seem to be of analytical use are still not commercially available. Living micro-organisms, such as bacterial cells, have been used instead of enzymes.[1,3–5] *Streptococcus faecium* has been employed at the surface of an ammonia gas-sensing electrode[3] for the determination of L-arginine in the presence of a few amino-acids. However, this bacterial gas-electrode combination has certain disadvantages as an electrode, such as a slow response time of 20 min, and it is also not truly selective for L-arginine relative to glutamine, asparagine and urea.

This paper describes a bacterial sensor in which the living organisms, such as *Streptococcus lactis*, are employed in suspension. The sensor gives a selective to 18 other L-amino-acids. An ammonia gas-electrode was used to determine the amount of ammonia generated by the following micro-organism metabolic sequence of L-arginine:[6]

$$\text{L-Arginine} \xrightarrow[\text{deaminase}]{\text{arginine}} \text{citrulline} + NH_3$$

$$\text{citrulline} + H_3PO_4 \xrightarrow[\text{transcarbamylase}]{\text{ornithine}} \text{ornithine} + \text{carbamoyl phosphate}$$

$$\text{carbamoyl phosphate} + \text{ADP} \xrightarrow[\text{kinase}]{\text{carbamate}} \text{carbamic acid} + \text{ATP}$$

$$\text{carbamic acid} \longrightarrow CO_2 + NH_3$$

EXPERIMENTAL

Apparatus

An Orion model 95–10 gas-sensing combination electrode was used. Potentiometric measurements were made with a Radiometer PHM 64 research pH-meter connected to a Radiometer Servograph Pen-Drive REA 310 strip-chart reconder with a high sensitivity unit REA 112. Measurements were made in a cell kept at 30.0 ± 0.1° in a Haake model E1-V water-bath.

Reagents

All solutions were prepared with distilled water. L-Arginine and all other amino-acids, in the purest form available, were obtained from Sigma Chemicals Co., and were of analytical grade. *Streptococcus lactis* No. 19435 was obtained from the American Type Culture Collection, Rockville, Maryland. Todd-Hewitt broth and thioglycollate medium were purchased from Difco Lab., Michigan.

Procedure

The *Streptococcus lactis* strain was maintained (at 4°) in thioglycollate medium with excess of calcium carbonate added,[7] and transferred to fresh medium every 2 weeks. For experimental purposes *S. lactis* was grown aerobically in Todd-Hewitt broth for ~2 days at 37°. The bacteria cells were collected by centrifugation at room temperature, washed 3 times with 0.1*M* phosphate buffer (pH 7.80) and stored in the 0.1*M* phosphate buffer solution at 4° for at least 12 hr before use.

Approximately 3×10^{11} cells were washed twice with 0.1*M* phosphate buffer solution (pH = 7.80) and suspended in 5.00 ml of 0.1*M* phosphate buffer (pH = 7.80) in a temperature-controlled cell at 30°. They were kept in suspension by magnetic stirring. The ammonia electrode was preconditioned by soaking in buffer for several hours and was stored in 0.1*M* phosphate buffer (pH = 7.80) when not in use. It was immersed in 5.00 ml of phosphate buffer solution and calibration curves were constructed by adding successive portions of freshly prepared amino-acid solutions ($1.000 \times 10^{-2} M$). After the cells had been used they were washed 3 times and stored in 0.1*M* phosphate buffer (pH = 7.80) at 4°.

RESULTS AND DISCUSSION

The potentiometric response of the bacteria–ammonia electrode system at different ages to L-arginine is shown in Fig. 1. Within the L-arginine concentration range from $8 \times 10^{-6} M$ to $10^{-3} M$ the electrode system showed a linear response with a slope of 59.0 ± 3 mV/decade when new (Fig. 1). After 11 days the response slope was still the same (58.7 mV/decade) but the upper limit of the linear range had decreased to $4 \times 10^{-4} M$ L-arginine (Fig. 1). However, by the 20th day the response slope had dropped to 49 mV/decade and the linear range had narrowed to 1.0×10^{-5}–$1.6 \times 10^{-4} M$ for the same cell crop. The response time was 6–8 min when the bacteria–electrode system was new and was not dependent on the L-arginine concentration. However, the response time increased to ~12 min after 11 days and to ~18 min after 20 days (Fig. 1).

About $\sim 3 \times 10^{11}$ cells were used in 5 ml of buffer solution. Use of a smaller number of cells decreases the linear range of the calibration curve, whereas doubling the number stated has no influence on the linear range.

*Department of Chemistry.
†Department of Microbiology.

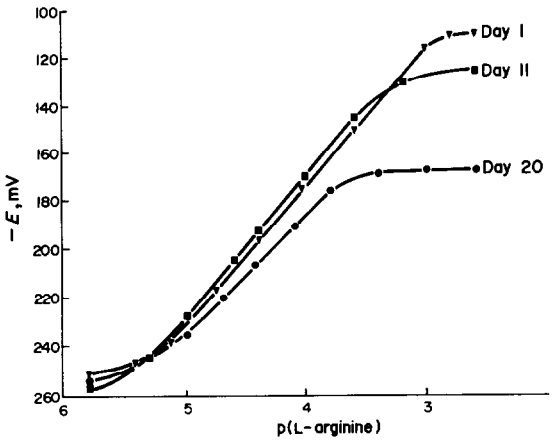

Fig. 1. Calibration curves for the bacteria–ammonia electrode combination when new, after 11 days and after 20 days; $T = 30°$, pH = 7.80, 0.10M phosphate buffer.

The specificity of the bacteria–ammonia electrode system was studied by measuring the electrode response to various amino-acids in 0.10M phosphate buffer (pH = 7.80) at 30°, up to a concentration of $10^{-3}M$ amino-acid. Negligible or no response was found to L-glutamine, L-asparagine, L-lysine, L-histidine, L-leucine, L-alanine, L-aspartic acid, L-valine, L-serine, L-glutamic acid, L-methionine, L-cysteine, L-proline, L-isoleucine, L-threonine, hydroxy-L-proline and L-citrulline. There was also no response to urea.

The response of the cell-electrode system was tested over a certain pH range (Fig. 2), since the bacteria (*S. lactis*) used can grow at a pH value of ~6–9.2,[8] and Todd-Hewitt broth, pH = 7.8, is recommended as nutrient. The highest pH would be the most favourable for the ammonia gas-electrode, but the linear range of the calibration curve at pH 8.20 (Fig. 2) was already narrowed to 8×10^{-6}–$8 \times 10^{-5}M$. Furthermore, the linear range was longest at pH = 7.80, with a reasonable slope (59.0 mv/decade), so pH = 7.80 was used in subsequent studies.

The use of Tris-HCl buffer instead of phosphate buffer caused only a small shift and a slightly lower slope (56.0 mV/decade, Fig. 2) of the calibration curve. Thus Tris-HCl buffer can be used in place of phosphate buffer.

Three calibration curves at three different temperatures are shown in Fig. 3. These temperatures were chosen because the optimum growth temperature for *S. lactis* is given as 30°. The slope of the calibration curve is highest at 37°, but the linear range is shorter than at 30°, while at 25° both the linear range and slope are smaller.

The response time of the bacterial electrode system (Fig. 4) is faster at higher temperatures, although the difference between response at 37° and 30° is small (~1 min). Therefore, a temperature of 30° was used, with pH 7.80 phosphate buffer in subsequent studies.

As the response time more than tripled when the bacteria were held on the electrode by means of a dialysis membrane, the cells were suspended in the buffer solution. The same effect has been found with other biological electrodes.[4] However, Rechnitz *et al.*[3] reported a bacterial electrode (*S. faecium*) for L-arginine, in which the bacteria were kept on the gas electrode and not suspended in the buffer, and the response time was 20 min. The linear range of our *S. lactis*-electrode system is significantly longer than that of the Rechnitz electrode. Furthermore, much smaller L-arginine concentrations can be determined with this electrode, though slightly higher L-arginine concentrations could be determined with the *S. faecium* electrode. The slope obtained from our electrode is higher than that from the Rechnitz electrode (52.5 mV/decade); both electrodes have the same lifetime. Our electrode is much more selective for L-arginine.

Reproducibility studies on a known amount of L-arginine in the presence of $1.00 \times 10^{-4}M$ concen-

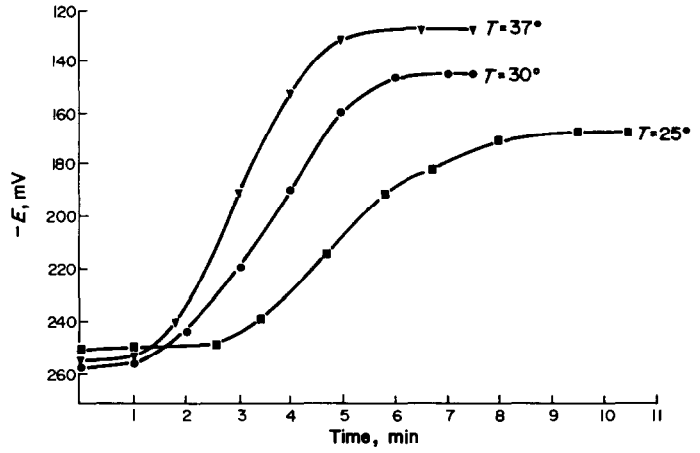

Fig. 4. Response curves at three temperatures. L-Arginine = $3.0 \times 10^{-4}M$, pH = 7.80, 0.10*M* phosphate buffer.

Table 1. Determination of a known amount of L-arginine in the presence of a mixture of other L-amino-acids and urea (see text), measured in 0.10*M* phosphate buffer at pH 7.80 (5 replicates)

L-Arginine, μg		
Taken	found	Std. devn.
52.5	52.5	3.3
169.8	169.7	8.2

trations of each of the other L-amino acids and urea are shown in Table 1. The L-amino-acid mixture shows a background ammonia concentration of $2.6 \times 10^{-4}M$, as measured with the ammonia electrode. Therefore, this blank ammonia concentration was taken into account in the L-arginine determinations. The results of Table 1 indicate that sufficient accuracy and precision can be obtained with the bacterial ammonia gas-electrode system. A possible use for the system would be the determination of L-arginine in body fluids and tissues.[9]

ESTIMATION OF IRON WITH SALICYLALDEHYDE HYDRAZONE

M. P. JAIN and SATYA KUMAR
Chemical Laboratories, D. Jain College, Baraut (Meerut), India 250611

(*Received* 29 *April* 1980. *Revised* 11 *April* 1981. *Accepted* 18 *May* 1981)

Summary—Iron is determined by precipitation as the reddish orange ferrous complex of salicylaldehyde hydrazone (SH) in the pH range 10.0–11.0. With ferric iron an unstable complex is formed which changes readily to the stable ferrous complex. The iron complex has a metal–ligand ratio of 1:2, contradicting the 1:3 ratio reported earlier. The reagent can be used for separation of iron from several ions.

The use of salicylaldehyde hydrazone (SH), one of the condensation products of salicylaldehyde and hydrazine, for the gravimetric estimation of copper and nickel has been reported.[1,2] In the present study it was observed that under suitable conditions SH forms a reddish orange iron(II) complex irrespective of the original oxidation state of the iron. It is stable in presence of tartrate, citrate and ammonium salts, but is partly soluble in EDTA and completely soluble in potassium cyanide solution and acetic or mineral acid. The ferrous complex is very stable and permits the separation of iron from a large number of ions by use of sodium potassium tartrate as masking agent.

The difficulty experienced in isolation of pure reagent (SH), free from salicylaldazine (SA), was overcome by following the recommendations reported by Okafor,[3] and later employed by us in the isolation of pure hydrazones of substituted salicylaldehydes,[4] *viz.* (*i*) the salicylaldehyde has to be added to the hydrazine, and slightly more hydrazine than required for a 1:1 molar ratio has to be used in order to avoid any formation of the azine; (*ii*) fairly dilute ethanolic solutions of both reactants should be used; (*iii*) the salicylaldehyde solution has to be added slowly and with stirring; (*iv*) the reaction is exothermic, so no heating is necessary.

EXPERIMENTAL

Pure SH free from SA was prepared by slowly adding 0.1 mole (12.6 g) of salicylaldehyde to slightly more than 0.1 mole (5.0 g) of hydrazine hydrate, both diluted with ethanol, shaking thoroughly after each addition. On cooling, creamy white flakes separated, which on recrystallization from methanol yielded shining white plates with m.p. 97.5°.

The reagent was used as a 1% solution in 1% aqueous potassium hydroxide solution. The iron solutions were prepared from ferrous ammonium sulphate and ferric alum and standardized by the oxine method.[5] Analytical-reagent grade chemicals were used whenever possible.

Excess of reagent solution was added to slightly ammoniacal ferrous ammonium sulphate or ferric alum solution containing sodium potassium tartrate. The precipitate formed was collected, washed, and dried at 110°. The dried product was decomposed by heating with nitric acid and then fumed with sulphuric acid, and the iron content determined by the oxine method.[5] The ligand content of the product was determined by adding hydrochloric acid and titrating with potassium periodate in presence of iodine monochloride.[6] Analysis gave 82.7% ligand, 16.9% iron. $(C_7H_7ON_2)_2Fe$ requires 82.86% ligand, 17.14% iron.

The complex is stable up to 200° and can be dried to constant weight at 110–160°.

The freshly precipitated complex is appreciably soluble in benzene, chloroform and carbon tetrachloride, but when dried is almost completely insoluble in these solvents. The complex is soluble in excess of ammonia or strong alkalis as well as in acids.

Determination of iron(II) or (III)

The sample solution, containing 5–30 mg of iron(II) or (III) and 10 ml of 10% sodium potassium tartrate solution is adjusted to pH 10.0–11.0 with ammonia, diluted to 125 ml and warmed to 70–80°. The iron is precipitated by addition of excess of reagent solution. The precipitate is digested for 30 min on a water-bath, cooled, filtered off, washed with water and dried at 110–130° to constant weight. The results are given in Table 1.

Determination in presence of interfering species

Mn^{2+}, Co^{2+}, UO_2^{2+}, Hg^{2+}, Zn^{2+}, Pd^{2+}, Ag^{+}, Cd^{2+}, Ni^{2+} and Cu^{2+} interfere. However, silver can be eliminated beforehand by precipitation as sulphide or chloride, and palladium, mercury and cadmium by precipitation as sulphide. Mercury(II) interference can also be eliminated by complexing it with 2–3 g of potassium iodide in alkaline medium (tolerance limit 50 mg). Nickel and copper can be precipitated with salicylaldehyde hydrazone from 0.1*M* potassium hydroxide medium containing 4–5 g of sodium potassium tartrate; the iron complex is not precipitated. The precipitate is washed first with 1.0% potassium hydroxide solution, then with hot water; the pH of the combined filtrate and washings is then lowered to 10.0–11.0 with acetic acid to precipitate the iron. Cobalt, zinc and manganese require preliminary separation of the iron by double precipitation of the hydroxide under conditions precluding their co-precipitation. Uranium also requires a preliminary separation of the iron. Results for determination of iron in presence of masking agents and other ions are given in Table 2.

Table 1. Estimation of iron(II and III) with SH

Fe(II or III) taken, *mg*	Fe(II) found, *mg*	Fe(III) found, *mg*
5.0	4.97	4.99
10.0	9.98	10.02
15.0	14.94	14.99
20.0	20.04	19.93
25.0	25.05	24.98
30.0	29.93	29.98

Table 2. Estimation of 20.0 mg of iron(II) with SH in presence of masking agent and diverse ions

Fe(II) found, *mg*	Species added
19.93	Sodium citrate (2 g)
20.04	Sodium thiosulphate (200 mg)
19.95	Sodium oxalate (100 mg)
20.07	Ammonium sulphate (50 mg)
19.93	Mg^{2+} + Be^{2+} (20 mg each)
19.95	Al^{3+} + Cr^{3+} (20 mg each)
20.07	Cu^{2+} (20 mg)*
19.90	Ni^{2+} (20 mg)*

* Separated as described in text.

Table 3. Analysis of alloys

Alloy	Iron present, %	Iron found, %
Nilo 'K' Wire	53.2	53.0
BCS 235/18/8 Stainless steel	68.4	68.7
BCS 241/1 Stainless steel	71.0	71.2

Analysis of ferrous alloys

The sample is dissolved in dilute nitric acid and the insoluble material filtered off. The filtrate is evaporated with sulphuric acid to fumes of sulphur trioxide. The residue is diluted with water and hydrogen sulphide is passed through the solution. The precipitated sulphides were filtered off and washed with water. The hydrogen sulphide is boiled out of the filtrate, which is then oxidized with nitric acid and the iron is precipitated as ferric hydroxide with ammonia in presence of ammonium chloride, and the iron is estimated as already described. Results are given in Table 3.

RESULTS AND DISCUSSION

Salicyladehyde hydrazone (SH) precipitates iron quantitatively as a reddish orange ferrous complex $(C_7H_7ON_2)_2Fe$ in the pH range 10.0–11.0, irrespective of whether ferrous or ferric iron is initially present, because the reagent itself is a good reducing agent and reduces the ferric iron as reported earlier.[1,2] The reagent is unstable in presence of oxidizing agents, and is converted into the more stable salicylaldazine (SA), another condensation product of salicylaldehyde and hydrazine.

Ray[7] isolated SH for use as a spectrophotometric reagent for copper and iron *etc.*, and found a metal–ligand ratio of 1:1 for copper and 1:3 for iron.[8,9] Our earlier study indicated a metal–ligand ratio of 1:2 for the copper complex,[1,2] which was later supported by the infrared and microanalysis study made by Okafor.[3] The present study indicates the same metal–ligand ratio (1:2) for the iron complex as well.

The conflict between our findings and those of Ray *et al.*[7–9] may arise from the difficulty of ensuring that the reagent is free from salicylaldazine. The yellowish colour of their reagent and its solution in acetone, the use of ferric perchlorate (an oxidizing agent) for preparation of the metal complex, and the low pH used indicate that there was probably partial conversion of SH into SA, resulting in formation of an altogether different complex species. Their report[9] that the reddish brown colour of their complex faded on standing in contact with the aqueous phase, and that an extremely large excess (260-fold) of reagent was needed for full colour development further indicates that a very weak and unstable SH complex of iron(III) might have been formed, which then changed to the stable iron(II) complex.

(*Received* 30 *March* 1981. *Accepted* 9 *June* 1981)

Summary—A method for determining the fatty-acid composition of soybean oil by using high-pressure liquid chromatography (HPLC) is discussed and compared with the determination using gas chromatography. The oil is saponified and an aliquot is treated directly to form the *p*-bromophenacyl esters of the fatty acids, which are separated by gradient-elution HPLC. It is shown that glycerol does not interfere with the esterification, thus obviating the solvent extraction previously used to isolate fatty acids from biological samples.

The analytical determination of fatty-acid compositions in polyunsaturated vegetable oils is important in nutritional labelling. The methods now in use involve gas chromatography.[1–3] However, problems still exist with this method. Artifact formation during esterification of fatty acids with boron trifluoride in methanol,[4] geometric isomerization and thermal degradation,[5] double-bond migration,[6,7] and irreversible retention of polyunsaturated fatty esters[8–10] have been the major problems reported. The thermal lability of the unsaturated esters is a major cause of these problems. Difficulties are also encountered with high molecular-weight esters, because their volatility is low.

In recent years high-pressure liquid chromatography (HPLC) has become a popular technique for the separation of thermally labile compounds. While HPLC methods have been developed for separating lipid materials, one of the major problems with these methods is the use of refractive-index detection, which is not suitable for trace analysis.

Ultraviolet detection is the most commonly used in HPLC for microanalysis. Triglycerides do not absorb strongly at the wavelengths commonly used (254 or 280 nm). Therefore, ultraviolet absorbing derivatives must be prepared. The most widely used derivatives have been phenacyl and substituted phenacyl esters. Borch[11] and Jordi[12] demonstrated the usefulness of HPLC, with ultraviolet detection at 254 nm, for separating these esters. Octadecylsilane-bonded silica-packed columns were used with gradient-elution liquid chromatography to obtain the separations. Separation time was 3–4 hr per sample.

The acid composition of bacterial samples,[13–16] fingertips,[17] and river water[18] was determined by methods based on these separations. Fatty acids found in human blood plasma[19] and butter[20] were analysed by use of an octylsilane-bonded silica column. In these methods, the fatty acids were isolated from the saponification mixture by solvent extraction before conversion into suitable derivatives. This procedure minimized potential interference.

In this paper, a method of determining the fatty acid composition of soybean oil by using high-pressure liquid chromatography is discussed. The soybean oil is saponified, then, without solvent extraction, the resulting acids are esterified to form the *p*-bromophenacyl esters, with 18-crown-6 as the catalyst. The esters are analysed quantitatively on an octylsilane-bonded silica column. A similar esterification procedure and HPLC separation was used by Tweeten and Wetzel[21] to determine fatty-acid compositions in grain and feed extracts. They chromatographed the esters isocratically on an octyldecylsilane-bonded silica column with a methanol–water mobile phase. Palmitic and oleic esters were not separated with this

system. In the method reported here, an acetonitrile–water gradient was employed, which separated the palmitic and oleic esters with a total separation time of 1 hr per sample. To assess the efficacy of this method, determinations of fatty acid composition by HPLC and by gas chromatography were compared, and the results found in reasonable agreement. In addition, a separate experiment was conducted to determine whether glycerol, a by-product of the soybean oil, interferes with the esterification. Because it does not, the need for solvent extraction is obviated.

MATERIALS AND METHODS

Standard preparation

A stock solution of fatty acids was prepared by dissolving 0.015 g each of palmitic, oleic, linoleic, and linolenic acids and 0.001 g each of arachidic and behenic acids in 10 ml of chloroform. A 0.3-ml aliquot of this solution was transferred to a 3.5-ml reaction vial and evaporated to dryness under nitrogen. As an internal standard, 0.15 ml of a lauric acid stock solution (0.02 g of lauric acid dissolved in 10 ml of methanol) was added to the vial. The acids were neutralized with 0.1*M* methanolic potassium hydroxide to a phenolphthalein end-point. The solution was evaporated to dryness under nitrogen and the residue was esterified (see below). The concentration of the standard esters was in the 300-μg/ml range (20 μg/ml for arachidic and behenic acids).

Sample preparation

A 0.2-g sample of soybean oil (Standard Food Grade; iodine value 130) was saponified with 50 ml of 0.5*M* methanolic potassium hydroxide by refluxing for 10 min. A 0.5-ml aliquot of the cooled solution was transferred to a 3.5-ml reaction vial and spiked with 0.15 ml of lauric acid internal standard solution. The solution was neutralized with 0.5*M* methanolic hydrochloric acid to a phenolphthalein end-point and evaporated to dryness under nitrogen. The residue was esterified according to the following procedure.

Esterification procedure[22,23]

A Reacti-Therm Heating/Stirring Module (Pierce Chemical Co.) was used. To each of the standard and sample residues, in the 3.5 ml screw-cap septum vials, 1 ml of the alkylating reagent (0.1*M* α-*p*-dibromacetophenone/0.005*M* 18-crown-6, Aldrich Chemical Co.) and 2 ml of acetonitrile (Burdick and Jackson Laboratories) were added. The vials were sealed, and heated at 80° for 30 min with constant stirring. The solutions were filtered through a 0.5 μm Fluoropore filter (Millipore Corp.) before HPLC analysis.

HPLC analysis

The *p*-bromophenacyl esters were separated by use of a Waters Associates ALC/GPC 244 liquid chromatograph equipped with a 6000A pump and a 660 solvent programmer. A Hibar-11 column with Li Chrosorb RP-8 packing (Merck; 10 μm particle size, 250 mm long, 4.6 mm internal diameter) was used for the separation. Chromatograms were recorded on a Sigma 10 Chromatography Data Station (Perkin-Elmer Corp.).

HPLC-grade water was obtained from a Milli-Q water purification system (Millipore Corp.). The acetonitrile used was HPLC grade from Burdick and Jackson Laboratories. The gradient-elution conditions employed were: 70% acetonitrile/water to 100% acetonitrile at 2 ml/min over a 50-min period with a concave gradient (curve 7 on the solvent programmer). Detection was at 254 nm. Peaks were identified from relative retention times measured with respect to the laurate internal standard peak. Measurement of peak height was used for quantification. Relative response factors were determined for each ester. Ester concentrations were converted into acid concentrations before normalization calculations were performed.

Glycerol interference experiment

Because glycerol was the major by-product in the soybean oil saponification mixture, an experiment was performed to determine whether glycerol interfered with the esterification. A standard solution of fatty acids with a composition typical of soybean oil was spiked with glycerol at two concentration levels and esterified. The esters were separated by HPLC. Peak heights for the spiked and unspiked esters were then compared.

Gas chromatography (GLC)

The fatty-acid composition of the soybean oil sample was also determined by a standard gas chromatography method. Methyl esters of soybean oil fatty acids were prepared according to A.O.C.S. Official Method Ce 2-66.[2] The fatty-acid composition was determined according to A.O.C.S. Official Method Ce-1-62.[2]

RESULTS AND DISCUSSION

The peak heights for *p*-bromophenacyl esters are given in Table 1. As can be seen from the data, the additions of glycerol did not appear to cause interference.

Accurate neutralization of the fatty-acid solutions was necessary to obtain high esterification yields. This proved to be the most difficult step. Lauric acid was used as an internal standard so that the sample esterification yields could be monitored relative to a single

Table 1. Peak heights of *p*-bromophenacyl esters with and without glycerol in the esterification step

Component	Concentration of ester, μg/ml	No glycerol, mm	Glycerol 189 μg/ml, mm	Glycerol 594 μg/ml, mm
Palmitate	90	38.2	40.2	39.7
Stearate	64	14.8	15.4	15.9
Oleate	258	54.3	55.1	54.3
Elaidate	74	18.3	18.9	18.3
Linoleate	804	144.4	149.8	147.4
Linoelaidate	77	15.0	15.2	14.9
Linolenate	135	9.5	9.8	9.5

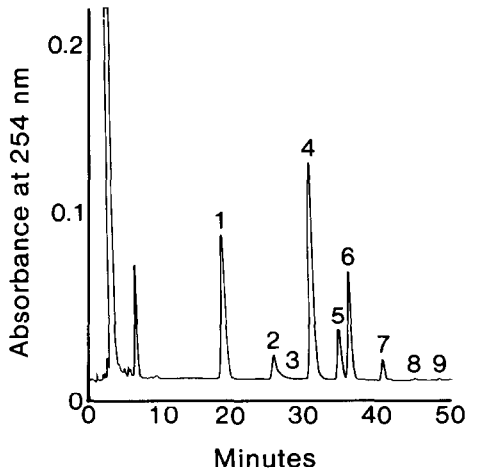

Fig. 1. HPLC chromatogram of *p*-bromophenacyl esters of soybean oil fatty acids on a Li Chrosorb RP-8 column. Peak identification: 1, laurate (internal standard); 2, linolenate; 3, γ-linolenate; 4, linoleate; 5, palmitate; 6, oleate; 7, stearate; 8, arachidate; 9, behenate.

standard. The peak height ratio (sample/standard) for the laurate ester was 1.02.

For each ester, a plot of peak height *vs.* concentration of ester was linear over the concentration range 10–600 μg/ml. Correlation coefficients for the major esters were palmitate 0.9971; stearate 0.9927; oleate 0.9994; linoleate 0.9995; linolenate 0.9989.

Figure 1 shows a chromatogram of the HPLC separation of the *p*-bromophenacyl esters of soybean-oil fatty acids. Quantitative results are given in Table 2. The results are in reasonable agreement except for those obtained with γ-linolenic acid, which was not sufficiently resolved from linolenic acid for accurate quantification.

CONCLUSIONS

A method for the determination of the fatty-acid composition of soybean oil by HPLC has been developed. Separation times are less than 1 hr per sample on the octylsilane-bonded silica column. This is a significant improvement over the 3–4 hr separation time required for the octadecylsilane-bonded silica columns. The esterification is not significantly affected by glycerol, and this allows omission of the solvent extraction step used previously to isolate the fatty acids from biological samples. Preliminary results indicate that the HPLC method can be used as an alternative approach to the determination of fatty-acid composition of soybean oil, with accuracy and precision comparable to that of GLC. In this work, the problems encountered with GLC methods [4–10] were not observed. HPLC would be the preferred approach in situations where these problems arise.

Table 2. Fatty-acid composition of soybean oil by HPLC and GLC

Component	HPLC, %*	GC, %*†
Palmitic	10.38 ± 0.18	9.65 ± 0.04
Stearic	4.33 ± 0.13	4.08 ± 0.02
Oleic	23.18 ± 0.14	23.90 ± 0.04
Linoleic	53.66 ± 0.29	55.01 ± 0.03
Linolenic	6.16 ± 0.11	6.36 ± 0.02
γ-Linolenic	1.68 ± 0.05	0.59 ± 0.01
Arachidic	0.36 ± 0.05	
Behenic	0.25 ± 0.04	

* Average of three determinations ± standard deviation.
† Two minor components were unidentified: content 0.42 ± 0.01%.

TITRATION OF THIACETAZONE AND ISONIAZID WITH SODIUM METHOXIDE IN NON-AQUEOUS MEDIUM

ANUPA DAS and K. S. BOPARAI
School of Studies in Chemistry, Vikram University, Ujjain, 456010, M.P., India

(*Received* 2 *September* 1980. *Revised* 23 *May* 1981. *Accepted* 2 *June* 1981)

Summary—Thiacetazone and isoniazid dissolved in dimethylformamide can be accurately titrated with sodium methoxide in benzene–methanol mixture, with *o*-nitroaniline as indicator. Sodium 4-aminosalicylate does not interfere.

Iodometric determination of thiacetazone[1] is rather sensitive to variation in the amount of reagents, reaction time and temperature. Iodometry[2] based on the oxidation of thiacetazone to the semicarbazone is preferable to the method involving oxidation to the thiadiazole with ferric chloride in sulphuric acid medium, because of its practicality. Oxidation with alkaline hydrogen peroxide[3] is rather time-consuming. Gravimetric estimation[4] as the 2,4-dinitrophenylhydrazone gives low recovery but the argentimetric method[5,6] is satisfactory. Other methods include acidimetric titration[7], alkalimetric determination of acetic acid formed by hydrolysis,[8] and mercurimetric[9] and spectrophotometric determinations. Thiacetazone can be titrated in dimethylformamide medium with sodium methoxide solution in benzene–methanol, *o*-nitroaniline being used as indicator. This method offers the advantage over acidimetric determination[7] that it is unaffected by sodium 4-aminosalicylate, but isoniazid interferes quantitatively. Determination of isoniazid in this way is better than the alkalimetric determination[10] in diethylamine medium.

The end-points are sharp and stable for more than 5 min.

EXPERIMENTAL

Procedure

A weighed quantity of thiacetazone or isoniazid is dissolved in 25 ml of dimethylformamide. *o*-Nitroaniline (2 drops of 1% solution in benzene) is added and the solution is titrated with sodium methoxide solution in benzene–methanol (4:1) to a distinct orange colour. Blanks are run on the same volume of solvent, and their value deducted, For a sharp end-point the molarity of the sodium methoxide (0.05, 0.075 and 0.1*M* for thiacetazone, the binary mixture and isoniazid respectively) should be chosen so that the volume used in the titration does not exceed 8 ml.

RESULTS

The mean recovery for 49.9 mg of thiacetazone was 49.95 mg, standard deviation 0.14 mg (five replicates). The corresponding results for isoniazid (50.0 mg) were 49.8 mg and 0.13 mg.

When x mg of a mixture of pure thiacetazone (y mg) and isoniazid were titrated with V ml of sodium methoxide (molarity M), and the results were evaluated by means of the equation

$$y = \frac{236x - 32332VM}{99}$$

the recovery of both drugs was in the range 99.5–100.5% (15 replicates).

A DIRECT TITRIMETRIC METHOD FOR THE MICRODETERMINATION OF SOME PHENOTHIAZINE DERIVATIVES IN PHARMACEUTICAL PREPARATIONS

V. N. PATHAK and I. C. SHUKLA

Department of Chemistry, University of Allahabad, Allahabad, 211002, India

and

S. R. SHUKLA

Department of Pharmacology, M.L.N. Medical College, Allahabad 211002, India

(*Received* 22 *May* 1980. *Revised* 18 *May* 1981. *Accepted* 30 *May* 1981)

Summary—A micro method has been developed for the determination of some phenothiazine derivatives in pure form and in pharmaceutical preparations, 1–5 mg of sample being titrated directly with 0.02*M* *N*-bromosuccinimide, with Methyl Red as indicator. The error does not exceed ±1%.

Phenothiazine derivatives are used variously as antipsychotropic, anticholinergic and antihistaminic drugs,[1,2] and methods for their assay are important. Kasakalian and McGlotten[3] have reported determination by anodic oxidation of about 1.5 mg of chlorpromazine. Blažek[4] has used an amperometric method for the determination of 50 mg of chlorpromazine. Porter[5] has determined microgram quantities of chlorpromazine polarographically with 0.5*M* hydrochloric acid as supporting electrolyte. The pharmacology and assay of phenothiazine and prochlorperazine have been discussed.[6–9] Some new phenothiazine derivatives such as triflupromazine and trifluperazine have been estimated by Schrine.[10]

In this paper we describe a quick and convenient method for the microdetermination of phenothiazine derivatives with *N*-bromosuccinimide (NBS), a well-known brominating and oxidizing agent.[11,12]

EXPERIMENTAL

Sample solutions

These were prepared by dissolving 25 mg of sample in distilled water and diluting to volume in a 25-ml standard flask.

N-*Bromosuccinimide solution*, 0.02M

The reagent (0.3560 g) was dissolved in the minimum of warm distilled water, made up to 100 ml with cold distilled water, and standardized iodometrically.[13,14]

Procedure

A portion of solution, containing 1–5 mg of drug, was placed in a 100-ml titration flask, and 6 ml of 2*M* hydrochloric acid and 2 drops of 0.04% Methyl Red indicator solution were added. The mixture was titrated with 0.02*M* NBS until the indicator was decolorized. The excess of NBS was back-titrated iodometrically. The same volume of NBS was then titrated iodometrically under identical conditions. The amount of drug was calculated from the difference between volumes of NBS consumed in the blank and the determination.

$$\text{mg of drug} = \frac{(B - A)MN}{n}$$

where A = volume of NBS consumed by the blank (ml); B = volume of NBS consumed by the drug (ml); M = molecular weight of the drug; N = molar concentration of NBS; n = moles of NBS consumed per mole of the sample.

RESULTS AND DISCUSSION

The precision is shown in Table 1, and the accuracy (established by recovery tests based on determination of the drug content of spiked and unspiked samples) in Table 2.

The effects of variables such as temperature, acidity, NBS concentration and amount of sample were studied.

Temperatures above 26° tend to cause inaccurate results and create difficulty in detecting the end-point, because of decomposition of NBS at higher temperature. Room temperature (~25°) is the most suitable.

The reaction of phenothiazine derivatives with NBS at pH 4–5 is not quantitative and gives variable results. An approximately 0.08–0.15*M* hydrochloric acid medium gives consistent and accurate results.

Table 1. Microdetermination of phenothiazine derivatives (1–5 mg) with NBS (10 variates)

Sample	Coefficient of variation, %
Chlorpromazine hydrochloride	0.3
Prochlorperazine di(hydrogen maleate)	0.8
Promethazine hydrochloride	0.3
Triflupromazine hydrochloride	0.4
Trifluperazine dihydrochloride	0.4

The best recovery was obtained with 0.02*M* NBS, which should be prepared just before use and kept in a cool dark place. Because the Methyl Red reacts with the reagent, the amount of indicator taken should be kept constant and only a small quantity (2 drops) should be used. Excipients do not interfere. The method is applicable to sample weights ranging from 1 to 20 mg.

¶ Medicare.

The value of n in the calculation equation is 20 for all the drugs tested, except prochlorperazine di(hydrogen maleate), for which it is 28 (the maleate consumes the extra NBS[15]).

Although its mechanism is not clear, the reaction could be useful for quality control. The method has not been tested in the presence of degradation products of the drugs, so it is not known whether it is suitable for metabolic studies. In the case of prochlorperazine di(hydrogen maleate), any maleic acid present, owing to poor preparation, will cause a positive error.

DETERMINATION OF TRACE QUANTITIES OF SELENIUM BY INDIRECT ATOMIC-ABSORPTION SPECTROPHOTOMETRY

M. VIJAYAKUMAR, T. V. RAMAKRISHNA* and G. ARAVAMUDAN
Department of Chemistry, Indian Institute of Technology, Madras 600036, India

(*Received* 29 *May* 1979. *Revised* 6 *April* 1981. *Accepted* 25 *May* 1981)

Summary—The selenium(IV)–iodide interaction in acid medium, leading to the liberation of iodine, has been utilized for the indirect determination of selenium by atomic-absorption spectrophotometry (AAS). The iodine is extracted into benzene and subsequently reductively stripped into an aqueous solution of ascorbic acid. After extraction of the resulting iodide as tris(1,10-phenanthroline)cadmium(II) iodide into nitrobenzene, the cadmium content of the organic extract is determined by AAS. Beer's law is applicable up to 0.75 ppm of selenium. The few interferences are readily overcome. The chemical yield in the system is about 80% overall.

Direct methods for the determination of traces of selenium by atomic-absorption spectrophotometry (AAS) are not satisfactory because of the strong absorption by flame gases and extraneous matter at the wavelength (196.0 nm) of the selenium resonance line,[1] and because selenium dioxide sublimes. These methods have been improved to a great extent by using the hydrogen selenide generation techniques,[2–5] but these are not well suited for routine analysis.

Lau and Lott have reported a sensitive indirect AAS method for the determination of selenium, based on the reaction of palladium(II) with piazselenols[6] (sensitivity 16 ng/ml), but the method is critically pH-dependent and rather time-consuming because of the nature of the chemical reactions involved.

The reaction of selenium(IV) with acidified iodide to liberate iodine is well known. In the present study the feasibility of using this reaction for determining selenium by recovering the iodine completely, reducing it to iodide and adapting the indirect AAS procedure for the determination of iodide reported by Yamamoto *et al.*,[7] has been examined.

EXPERIMENTAL

Apparatus

A Carl Zeiss PMQ II spectrophotometer with FA-2 flame unit provided with a 5-cm long air–acetylene burner head and a d.c. power supply to provide a stabilized current in steps from 3 to 60 mA to a demountable Westinghouse cadmium hollow-cathode lamp.

Reagents

All reagents were of analytical grade.

Standard selenium(IV) solution (2.5 ppm). Prepare a 1000-ppm solution of selenium(IV) by dissolving 0.3482 g of pure selenium dioxide in water and making up to 250 ml with water. Dilute this solution to obtain the 2.5-ppm selenium standard.

Cadmium phenanthroline sulphate (CPS) solution, 2.5 mM. Dissolve 0.3226 g of $3CdSO_4.8H_2O$ and 0.9208 g of 1,10-phenanthroline hydrate in water and dilute to 500 ml.

Procedure

Transfer an aliquot of sample solution not exceeding 12.5 ml in volume and containing up to 12.5 μg of selenium(IV) into a 60-ml separating funnel. Add 5 ml of 5*N* sulphuric acid and 2.5 ml of 1% potassium iodide solution and dilute to 20 ml. Shake this for 2–3 min with 5 ml of benzene. Allow the phases to separate and discard the aqueous phase. Wash the organic extract with three 15-ml portions of distilled water, then shake it gently with 5 ml of 0.05% ascorbic acid solution for about 1 min. Allow the phases to separate, transfer the aqueous phase into another 60-ml separating funnel, wash the organic phase with two 5-ml portions of water and add the washings to the aqueous phase. To the combined aqueous extracts add 2.5 ml of 2.5 m*M* CPS solution and extract the $Cd(Phen)_3^{2+}$–$2I^-$ ion-pair into 5 ml of nitrobenzene by shaking the solution for 2–3 min. Prepare a reagent blank similarly.

Aspirate the nitrobenzene extracts into the air–acetylene flame and determine their cadmium content, using the following instrumental parameters: lamp current 10 mA; wavelength 228.8 nm; air flow-rate 6.3 l./min; acetylene flow-rate 0.6 l./min. Use the blank to set the read-out to zero absorbance. Prepare a calibration graph covering the range from 2.51 to 5.0 μg of selenium(IV).

RESULTS AND DISCUSSION

Benzene was chosen for extraction of the iodine liberated by the reaction of selenium(IV) with iodide in acid medium, because (*i*) the distribution coefficient for iodine between benzene and water is high, and (*ii*) it is easier to wash an extract if the wash-liquid has

* To whom correspondence should be addressed.

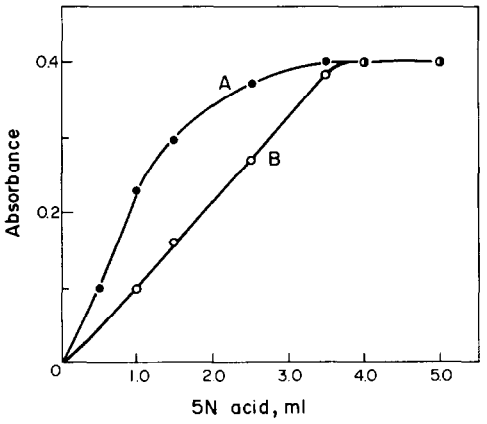

Fig. 1. Effect of acidity: 10 μg of Se(IV) + x ml of 5N acid (A, HCl; B, H_2SO_4) + 2 ml of 1% KI solution in 20 ml. The iodine liberated was extracted into 5 ml of benzene. The rest of the procedure was that given in the text.

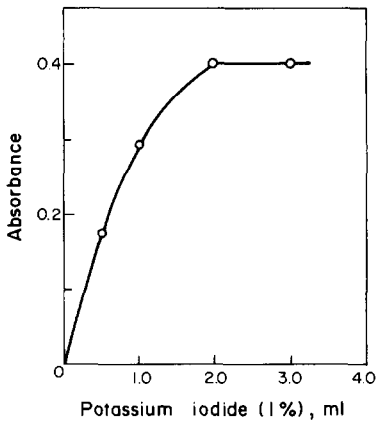

Fig. 2. Effect of potassium iodide concentration: as in Fig. 1 with 5 ml of 5M HCl and x ml of 1% KI solution.

the higher density. The iodine was quantitatively stripped with ascorbic acid solution and the iodide produced was determined by extracting it as the tris(1,10-phenanthroline)cadmium(II) iodide complex into nitrobenzene and measuring the cadmium content of the extract by atomic-absorption spectrophotometry.[7]

Figures 1 and 2 show the influence of acidity and concentration of potassium iodide on the reaction of selenium(IV) with iodide and the extraction of iodine into benzene. From these experiments, overall concentrations of 1.2M sulphuric acid and 7.5 mM potassium iodide were chosen as optimum.

Mixing the phases for 2–3 min was found to be sufficient for quantitative extraction of the iodine liberated. Longer mixing caused the iodide in the aqueous phase to undergo aerial oxidation, resulting in high blank values. Slight variations in the volume of the aqueous phase was found not to affect the selenium recovery.

Beer's law and precision

Linear calibration curves passing through the origin were obtained for selenium in the range 0–15 μg. The relative standard deviation (21 determinations) was 2%.

Effect of diverse ions

A number of cations and anions were examined for interference in the procedure, when 1 mg of the ion was present along with 5 μg of selenium. Table 1 gives the results. Interfering ions are underlined.

Ag, Tl(I), Bi and Pb were precipitated as their iodides and dispersed in the organic phase. Their interference was eliminated by repeatedly washing the benzene extract with a solution of citric acid till all the precipitate disappeared from the organic phase. Fe(III) and Sb(V) interfered by oxidizing iodide to iodine and were masked by fluoride before the addition of potassium iodide. VO_3^- was reduced with Fe(II) and the Fe(III) formed was masked with fluoride. As(V) was masked with molybdate. NO_2^- was destroyed by the addition of sulphamic acid. Sn(II) and As(III) interference is not of any consequence, as they are oxidized during the wet digestion step used for decomposition of samples.

Chemical yield

Theoretically, 1 μg of selenium should produce 2.84

Table 1. Interference studies

μg of cadmium in the final solution, but in practice it was found to yield only 2.3 μg, a yield of about 80%. Examination of the various steps showed that the phase-volume ratios used, combined with the various washing steps and other experimental conditions, would account for the loss. Thus in the extraction of iodine, the side-reaction with the excess of iodide in the aqueous phase (to form the tri-iodide ion), together with the phase-volume ratio results in 94% extraction. The yield is diminished by 2% by the water-washes. In the extraction of the cadmium complex the distribution coefficient (established by radiotracer experiments) is quite low, and this, combined with the rather large phase-volume ratio ($V_{aq}:V_{org} = 3.5$), results in an extraction yield of only 90% in this step. The overall yield should thus be $92 \times 90/100 = 83\%$, in fairly good agreement with experiment. However, provided the volumes used are not too different from those specified, the loss will be compensated for in the calibration procedure.

If repetitive washing with citrate solution is needed for removal of interference of silver *etc.*, the recovery will be correspondingly lower and a similarly treated set of standards should be run or the standard-addition method used.

Applications

The ability of the method for analysis of plant materials was studied, with use of nitric acid–perchloric acid mixtures for attacking the samples.[8] Cane sheath and neem leaf samples (5 g) were used and the final acid digest was heated with concentrated hydrochloric acid to reduce any selenate to selenite. The solutions were finally made up to 100 ml and 5- and 10-ml aliquots were analysed. The samples did not contain any selenium, and recoveries were determined by the addition of 50 and 100 μg of selenium to the plant samples before the decomposition. The results were all satisfactory. When these experiments were repeated with 1.0 and 2.5 μg of selenium as spikes, the recoveries were 80–120% at the 1-μg level and 96–120% at the 2.5-μg level (per 5 g of sample).

CONCLUSIONS

The method is superior to the indirect method based on the determination of palladium, reported by Lau and Lott,[6] in that it is more rapid and less rigorous in its experimental conditions. It is also three times as sensitive, because cadmium gives higher sensitivity than palladium in AAS.

ANALYTICAL DATA

IONIZATION CONSTANTS AND FLUORESCENCE EXCITATION AND EMISSION SPECTRA OF THE ISOMERIC BENZO[*a*]PYRENE PHENOLS

A. C. CAPOMACCHIA, V. KUMAR and C. BRAZZEL

Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602, U.S.A.

(*Received* 30 *March* 1981. *Accepted* 4 *July* 1981)

Summary—The acid dissociation constants, for the ground and lowest excited singlet states of the benzo[*a*]pyrene phenols, are reported, and correlated with current thought on carcinogen activation. The corrected fluorescence excitation and emission spectra of these compounds and their anions are recorded. The shifts caused by ring hydroxylation of the parent compound, and the relative spectral band intensities for each phenol are compared to those of pyrene, in a brief assessment of spectral transition polarization in the phenols.

This study is an extension of our earlier work which described both the ground and excited state protolylic equilibria of two mono- and three dihydroxy benzo-[*a*]pyrenes.[1] The ground and excited state ionization constants for all the isomeric benzo[*a*]pyrene phenols have not previously been investigated, and should be of use to workers who employ fluorescence analysis for these metabolites of benzo[*a*]pyrene.

EXPERIMENTAL

Materials

The twelve monohydroxy benzo[*a*]pyrenes, 1-OH-BP–12-OH-BP, were supplied by J. N. Keith, ITT Research Institute, Chicago. These compounds were available to us in lots of 5 mg or less. All were used without further purification but their purity was established by comparing the absorption and corrected fluorescence excitation spectra of their dilute ethanolic solutions, and from their fluorescence emission, and by HPLC. Stock ethanolic solutions (*ca.* $1.0 \times 10^{-6} M$) of these agents were prepared fresh weekly and stored in the dark at 10°. Daily purity checks were conducted to ensure that no decomposition had occurred. Solid samples were kept in a freezer at −10°. Basic solutions were prepared by dilution of carbonate-free sodium hydroxide with distilled demineralized water. Similar water was used to make acidic solutions from Baker reagent-grade sulphuric acid, and these were standardized by means of the corrected Hammett acidity scale of Jorgenson and Hartter.[2] Solutions for intermediate pH values were prepared by dilution of sulphuric acid or sodium hydroxide solution. Buffer solutions were not used, because of their possible interference in fluorimetric titrimetry.[3]

Methods

Solutions for the fluorimetric study of acid–base character were prepared by adding 100 μl of stock ethanolic hydrocarbon solution to 2 ml of acid or base which had been pipetted into a 2-ml cuvette. The mixed solvent had no apparent effect on the spectra. After addition of the hydrocarbon, each solution was mixed rapidly with a Teflon paddle. The spectrum of each solution was recorded within 1 min. All acid–base studies were conducted in triplicate. Values of pK_a and pK_a^* were obtained graphically from plots of fluorescence excitation and emission intensity respectively, *vs.* pH or Hammett acidity.

Apparatus

Corrected excitation and emission fluorescence spectra were obtained with a Perkin–Elmer MPF-44A spectrofluorimeter with 1-cm quartz cells. Spectra were corrected for the wavelength response of the light-source, photomultiplier tube, and optical system by means of a microprocessor. Electronic absorption spectra were taken in 1-cm silica cells on a Cary 118 spectrophotometer. All spectral measurements were made at room temperature, 24 ± 2.0°. A modular Altec HPLC system with a single-piston pump, a 254-nm single-wavelength detector, a μ-Bondpak C-18 column and a CO:PELL ODS pre-column eluted with methanol:water (7:3) was used to check the hydrocarbon purity. Microlitre portions of ethanolic hydrocarbon solutions were delivered with a 100-μl syringe (Precision Sampling Corp.). A Corning Model 12 pH-meter with a Sensorex 5300 C silver–silver chloride–glass combination pH-electrode was used.

RESULTS

The corrected fluorescence excitation and emission spectra of the neutral and anionic species of each of the twelve monohydroxybenzo[*a*]pyrenes, are presented in Figures 1–12.

The fluorescence excitation of the twelve phenols was quenched as the solution acidity was decreased from 7 to 12. In contrast, that from the twelve phenolate anions increased over the same pH range. The effects were monitored at the respective emission maxima. The ground-state acid dissociation constants were determined from the mid-point of quenching, enhancement or both, depending on the severity of spectral band overlap between the two species

Figs. 1–12. The corrected fluorescence excitation and emission spectra of the isometric benzo[*a*]pyrene phenols (——) and phenolate anions (---) in numerical order of OH substitution position.

(Table 1). Formation of the anion resulted in a shift of the entire spectrum to longer wavelengths (red shift) relative to the spectrum for the neutral molecule. The shift was accompanied by some loss in vibrational fine structure for all the compounds except 2-, 8- and 10-OH-BP. For 2-OH-BP the spectral bands in the wavelength region 330–410 nm demonstrated a slight shift to shorter wavelengths (blue shift) when compared with those for the phenol, while those in the wavelength region 240–330 nm demonstrated a red shift. For 8-OH-BP, formation of the anion resulted in quenching of the band system between 340 and 410 nm. However, the shorter wavelength bands demonstrated a large red shift. The compound 10-OH-BP gave a very slight red slight red shift of the entire excitation spectrum upon formation of the anion.

The fluorescence emission from the phenols was quenched as the solution acidity was varied from $H_o - 1.57$ to pH 7.0. Corresponding to the disappearance of the shorter wavelength (and usually structured) emission bands of the phenols, was the appearance of a new diffuse emission band at much longer wavelengths, belonging to the anions. The exception was 10-OH-BP, which did not give a fluorescent anion. Both the disappearance of the neutral species and the appearance of the anion were monitored at the excitation maxima of band system 2 (370–390 mm), belonging to the neutral molecule. The excited-state acid dissociation constants were determined from the mid-point of both the disappearance and appearance of this spectral band for all the compounds except 10-OH-BP, for which only the disappearance of the emission from the neutral species was plotted.

The band structures remained unchanged throughout each acid–base reaction, showing that no decomposition was occurring.

Table 2 shows the difference in excitation energy shifts between BP and its hydroxyl derivatives. For spectral band systems 1 and 4 (400–425 and 255–280

[a]Corresponds to the bands lying at 400–425 nm in Figs 1–12; [b]corresponds to the bands lying at 370–390 nm; [c] corresponds to the bands lying at 290–310 nm; [d]corresponds to the bands lying at 255–280 nm; [e]from the estimated band maxima.

mm respectively), substitution in the 1-, 12-, 5- or 6-position gives a smaller $\Delta\nu$ value than for band systems 2 and 3 (370–390 and 290–310 nm respectively). In contrast, substitution in the 3-, 8- or 9-position gives a greater $\Delta\nu$ for band systems 1 and 4 than for 2 and 3.

The band shapes and intensities of the spectra for the neutral species shown in Figs. 1–12 bear a much closer resemblance to those for both BP and pyrene than to those for the polyacenes or polyphenes such as anthracene or benz[*a*]anthracene, except for 1,2-benztetraphene (1,2-benz-benz[*a*]anthracene) which has an absorption spectrum[4] almost identical in structure to that of BP.

The relative spectral band intensities generally follow the pattern band 2 > band 1 and band 4 > band 3. Exceptions to this are observed only for bands 3 and 4, where for 7-, 9- and 12-OH-BP band 3 = band 4, and for 10-OH-BP band 3 > band 4. No mirror image relationships were discernible between the fluorescence excitation and emission spectra for any of the compounds examined.

DISCUSSION

Protolytic equilibria

The red shift in both the excitation and emission spectra of the twelve isomeric phenols from formation of the phenolates and their increased acidity in the lowest excited singlet state, are characteristic of molecules bearing electron-donating substitutes.[1] Both the red shifts and the relative differences in acidity of the hydroxyl groups, in the ground and lowest excited singlet states, are indicative of the degree to which intramolecular charge-transfer occurs. The pK_a values in Table 1 differ by as much as 2.5. The differences become more interesting when the comparative magnitudes of these values are examined for the compounds suspected of undergoing metabolic conversion to form active carcinogens. Figure 13 shows that the positions which possess the greatest relative basicity are those comprising the "bay region"[5] and Pullman's "K region".[6] The greater basicity of the hydroxyl groups when substituted in these regions, the 4-, 5-, 8-, 10- and 11-positions, indicates a localization of charge near these carbon atoms. Current theory on carcinogen activation implicates both the "bay" and "K" regions as primary sites of metabolic epoxidation.[6] A correlation between epoxide metabolites and the π-bond densities of some aromatic hydrocarbons has indicated that metabolism of these aromatic hydrocarbons to the epoxide occurs by way of electrophilic attack on a π-bond.[7,8] More recent work indicates that metabolic epoxidation occurs at an electron-rich region at or near the "bay region".[1] Calculations have been employed to show that the sites on BP most reactive toward metabolic epoxidation are the 4–5, 7–8 and 9–10 π-bonds.[9] These three bonds and to a lesser degree the 11–12 π-bond are believed to exist as partially localized ethylenic π-bonds.[9] Therefore, the correlation between the pK_a values in Table 1 and current work on the activation of aromatic hydrocarbons indicates that simple acid–base studies can be employed to predict and verify regions of π-electron localization, and perhaps metabolic attack, on suspected carcinogens that demonstrate protolytic activity.

A similar correlation was not observed for the pK_a^* values. Thermal relaxation processes which occur before the molecule enters the lowest excited singlet state may account for this. Solvent-cage reorganization presumably alters the molecular dipole moment relative to that in the ground state. This, in turn, alters the interaction of the electronic vector of the hydroxyl groups with the excited-state dipole, so that position-by-position it differs from that of the ground state. The lack of correlation between pK_a^* values and the "bay" and "K" regions, in contrast to that observed for the ground-state constants, implies that in the lowest excited singlet state these molecules do not possess these regions. However, if we presume that the pK_a^* values are also indicative of charge localization regions in the BP phenols, then Table 1 indicates two such regions centered on the 2- and 3-position and on the 9-position. It is interesting to note that a straight line connecting the "bay" and "K" regions, if pivoted counterclockwise, would also connect the 9-position with the 2- and 3-positions (Fig. 13). Perhaps these molecules, when in the lowest excited singlet state, possess different electron-rich reactive regions from those for the ground state.

Assessment of polarization direction

The band systems we label 1–4 correspond to the α, p, β and β' bands, respectively, for the parent com-

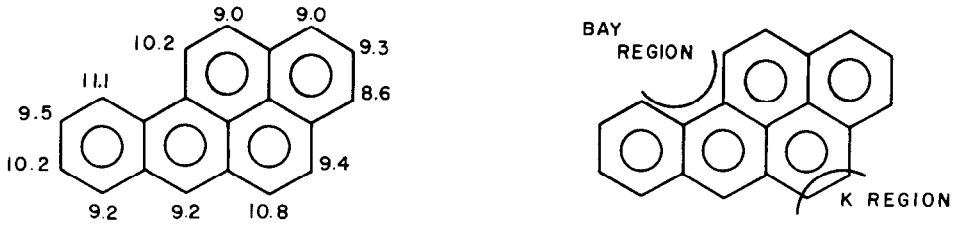

Fig. 13. The pK_a values at each hydroxy position and the most reactive regions on BP.

pound, BP, as designated by Clar.[10] The α, ρ and β designations correspond to Platt's $'L_b$, $'L_a$ and 'B spectral band designations for the catacondensed aromatics.[11] The subscripts a and b refer to polarization of the molecule perpendicular and parallel to its long axis, respectively. For pyrene, a pericondensed aromatic, the meaning of the subscripts is reversed so that a and b refer to polarization parallel and perpendicular to the long axis, respectively.[4,12] The shifts presented in Table 2 indicate that band systems 1 and 4 are long-axis (l) polarized while 2 and 3 are short-axis (s) polarized *i.e.* l, s, s, l, for bands 1–4.

However, this result is contrary to that expected from comparing the relative intensities of bands 1 and 2 or of bands 3 and 4. The lower intensity of band 1 relative to band 2 and the generally lower intensity of band 3 relative to band 4 indicate that the direction of polarization should be s, l, s, l for bands 1–4, respectively. The latter assignment is the same as that determined for the first four transitions of pyrene, $'L_b \leftarrow 'A$, $'L_a \leftarrow 'A$, $'B_b \leftarrow 'A$ and $'B_a \leftarrow 'A$, respectively.[12] The disagreement between the spectral shifts reported in Table 2 and the relative band intensities (Figs 1–12) may indicate that the first two transitions of BP are not purely long- or short-axis polarized. This possibility has been shown to exist for benz[*a*]anthracene.[12] The third and fourth transitions are clearly like those in pyrene and should have the same polarization direction and band assignments.

ANNOTATIONS

THE POSSIBILITY AND ACCURACY OF POTENTIOMETRIC EQUILIBRIUM STUDIES AT VERY HIGH LIGAND TO METAL CONCENTRATION RATIOS

I. FÁBIÁN* and I. NAGYPÁL

Institute of Physical Chemistry* and Institute of Inorganic and Analytical Chemistry,

(*Received* 11 *March* 1981. *Accepted* 10 *June* 1981)

Summary—The possibility and accuracy of potentiometric equilibrium studies are analysed by use of the rules of the implicit function-systems for the mass-balance equations. The conditions necessary for the use of potentiometry at very high ligand to metal concentration ratios are briefly outlined. The effect of the total ligand (glycine) concentration on the measured pK is studied experimentally and interpreted in terms of the change in the difference in diffusion potential between the reference half-cell and the solution.

For our NMR relaxation studies on transition metal complexes in solution,[1–3] knowledge of the composition and stability of the complexes formed is a prerequisite. The equilibrium relations of the complexes of vanadium(IV) and chromium(II) with nitrogen-donor ligands have had to be studied at high ligand excess, to avoid hydrolysis of the metal ions.

It seems almost a general belief that the use of pH-titration methods should be restricted to comparatively low (from 1:1 to ~20:1) ligand to metal concentration ratios. The work of Ciavatta *et al.*,[4] who studied the nickel(II)–glycine system in 1M glycine medium, is an exception.

Several papers[5–8] deal with the theory and accuracy of the pH-titration determination of protonation and stability constants, but none deals with the use of the method at high ligand excess. This and our own needs led us to examine the situation. The results are summarized in this paper.

MATHEMATICAL CONSIDERATIONS

For simplicity, a system containing only HA and MA species besides the components H, A and M is analysed, for which the mass-balances are

$$T_H = [HA] + [H] - [OH]$$
$$= \beta_{HA}[H][A] + [H] - K_w/[H]$$
$$T_A = [HA] + [MA] + [A]$$
$$= \beta_{HA}[H][A] + \beta_{MA}[M][A] + [A]$$
$$T_M = [M] + [MA] = \beta_{MA}[M][A] + [M]$$

where

$$\beta_{HA} = [HA]/[H][A]$$

and

$$\beta_{MA} = [MA]/[M][A].$$

T_H, T_A and T_M are the total concentrations of proton, ligand and metal ion respectively. The criteria for the applicability of pH titration are the $\partial \log \beta_{MA}/\partial pH$ and $\partial \log \beta_{MA}/\partial T_H$ derivatives, which express the effect of unit error in pH or T_H on the accuracy of $\log \beta_{MA}$. These derivatives may be obtained by applying the rule of differentiation of implicit-function systems to the mass-balance equations, as done earlier for homogeneous equilibrium systems.[9,10]

$$\frac{\partial \log \beta_{MA}}{\partial pH} = -\frac{[H] + [OH]}{\bar{n}(1-\bar{n})T_M} - \left(1 + \frac{[H] + [OH]}{[HA]}\right) \times \left(1 + \frac{[A]}{\bar{n}(1-\bar{n})T_M}\right) \quad (1)$$

$$\frac{\partial \log \beta_{MA}}{\partial T_H} = -\frac{0.4343}{[HA]} - \frac{0.4343(T_A - \bar{n}T_M)}{\bar{n}(1-\bar{n})[HA]T_M} \quad (2)$$

where $\bar{n} = [MA]/T_M$. (The details of the mathematically simple but rather lengthy derivation are available for the interested reader on request.)

Representative results of calculations based on these equations are illustrated in Figs. 1–3. Figure 1 shows the $\partial \log \beta_{MA}/\partial pH$ functions for $\log \beta_{HA} = 12$, $\log \beta_{MA} = 8$ and $T_M = 0.001M$, at different T_A/T_M ratios. It is seen that increasing the T_A/T_M ratio shifts the measurable region of complex formation towards lower pH-values, but the experimental data between

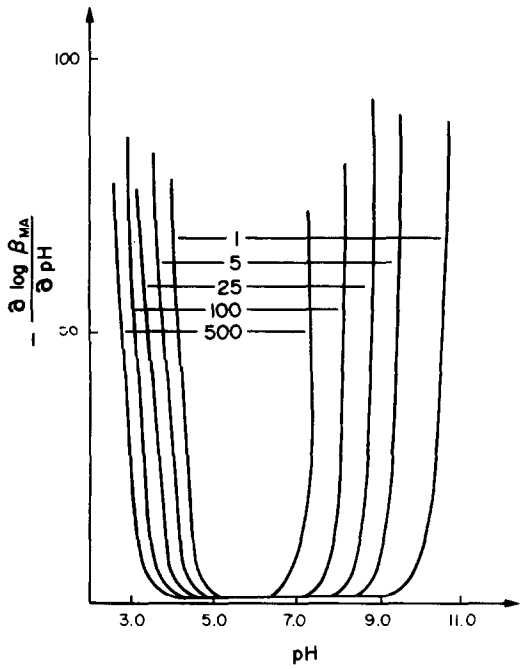

Fig. 1. $\partial \log \beta_{MA}/\partial pH$ as a function of pH at different T_A/T_M concentration ratios: $\log \beta_{HA} = 12$, $\log \beta_{MA} = 8$, $T_M = 0.001M$. The numbers on the arrows are the T_A/T_M ratios.

pH 4 and 6 may be evaluated for $\log \beta_{MA}$ even with 500-fold ligand excess.

The $\partial \log \beta_{MA}/\partial pH$ function for various $\log \beta_{HA}$ values, a fixed value for the equilibrium constant for $HA + M \rightleftharpoons MA + H$, and a 250-fold ligand excess is shown in Fig. 2.

It is seen that the extremely high ligand excess can only be used if $\log \beta_{HA} > 7$, *i.e.*, with ligands containing aliphatic amine or phenolic hydroxyl groups.

Figure 3 shows that the ligand excess has no significant effect on the $\partial \log \beta_{MA}/\partial T_H$ function, *i.e.*, the error in the volume or concentration of the titrant is almost the same at low and high ligand to metal concentration ratio.

On the basis of these results, the following conclusions can be drawn.

(1) The ligand used to make up the solutions to be titrated should be in a single stoichiometric form H_jA. Thus, even if there is a small error (some tenths of 1%) in the initial total ligand (T_A^0) and proton (T_H^0) concentrations, if this error is comparable with T_M^0 (the initial total metal concentration), their difference ($T_H^0 - jT_A^0$) should be negligible in comparison with the total metal concentration. If a metal–ammine complex is to be studied for example, the initial solution should be made up with ammonium chloride rather than from aqueous ammonia solution and hydrochloric acid.

(2) The complex formation should take place in a pH-region where protonation of the ligand does not have a significant buffer effect.

Besides these conclusions drawn from the mathematical analysis, the following chemically evident considerations should be regarded.

(1) The ligand should be extremely pure, since a very small percentage of complex-forming impurities may cause a completely erroneous result.

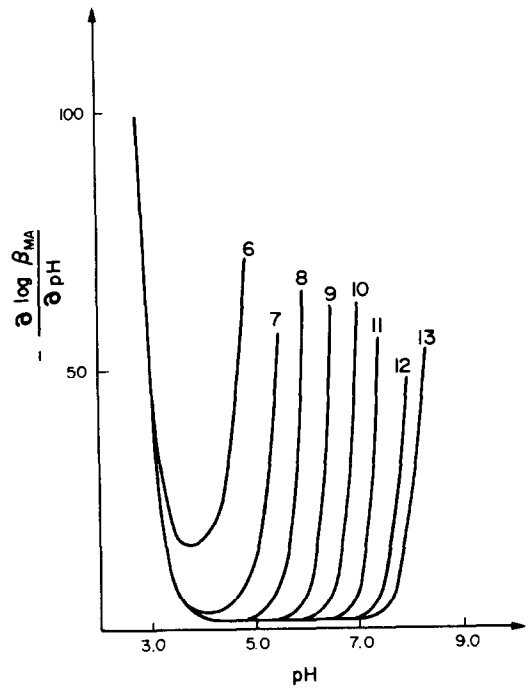

Fig. 2. $\partial \log \beta_{MA}/\partial pH$ for 250-fold ligand excess and different $\log \beta_{HA}$ values. The equilibrium constant for $HA + M \rightleftharpoons MA + H$ is the same (10^{-4}) in all cases.

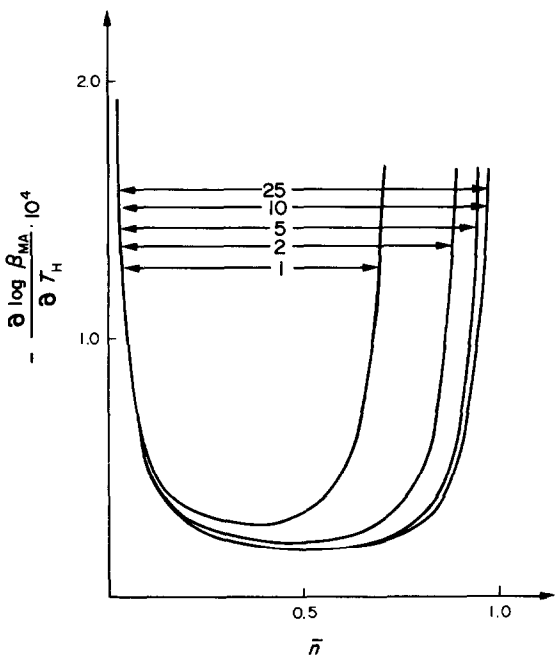

Fig. 3. $\partial \log \beta_{MA}/\partial T_H$ as a function of $\bar{n}$ at different T_A/T_M concentration ratios.

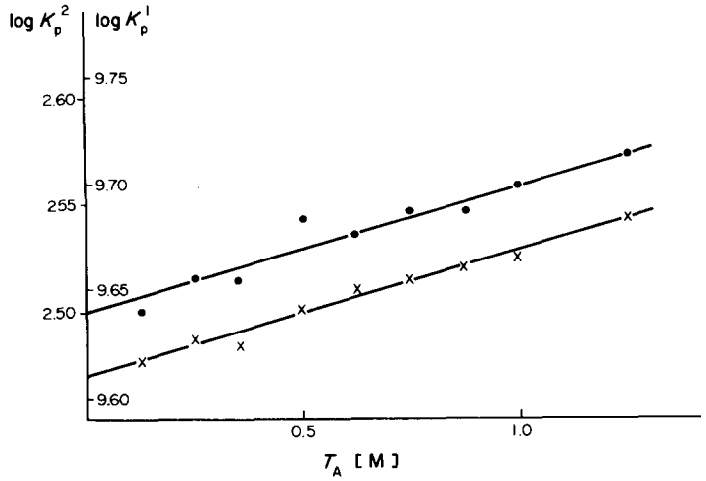

Fig. 4. The protonation constants of glycine as a function of the total glycine concentration. $I = 1M$ $NaClO_4$; 25°C.

(2) At high ligand excess, the ligand concentration may become comparable with the concentration of electrolyte added to ensure constant ionic strength, so the constancy of the standard state may be questionable.

These conditions have been investigated by measuring the pK values of glycine in 1M sodium perchlorate at total glycine concentrations up to 1.25M.

EXPERIMENTAL

Determination of the protonation constants of glycine

The titrations were at 25 ± 0.1°, with a Radiometer PHM-52 type pH-meter and GK 2301 combined electrode filled with saturated sodium chloride solution instead of potassium chloride solution in the calomel section. The glycine (Reanal) was recrystallized twice from aqueous ethanol. The sodium perchlorate was prepared from Merck p.a. sodium hydroxide and perchloric acid. The electrode system was calibrated for $-\log[H^+]$, according to Irving *et al.*,[6] from the perchloric acid-sodium hydroxide titration curve in 1M sodium perchlorate medium.

Table 1. Composition of the solutions studied for the determination of the protonation constants of glycine, and the result of the pH-titration investigation

T_H, M	T_A, M	log K_p^1	pH-range	log K_p^2	pH-range

1.2987	1.2490	9.713	7.66–8.44	2.533	3.91–4.98

$$K_p^1 = \frac{[HA^\pm]}{[H^+][A^-]}; \quad K_p^2 = \frac{[H_2A^+]}{[H^+][HA^\pm]}.$$

The standard deviation of individual log K_p values is less than 0.003 in all cases.

RESULTS

The initial concentrations of the 25-ml samples are collected in Table 1, together with the pH-ranges which were measured and used to calculate the two protonation constants. The dependence of the constants on the total glycine concentration is shown in Fig. 4.

The standard deviation (there was no bias) of the constants showed that any acid–base impurity in the glycine was below 0.01%, otherwise it would not have been possible to obtain self-consistent pK values from the pH-ranges far away from the half-neutralization points. It is seen, moreover, that both protonation constants change in the same way as a function of the total glycine concentration. There may be two reasons for a change in the observed pK:

(*i*) a change in the activity coefficients, *i.e.*, the standard state is no longer constant;

(*ii*) a change in the diffusion potential between the calomel electrode (filled with saturated sodium chloride solution) and the solution studied, as a consequence of the change in the total glycine concentration.

In case (*i*) the two pK values would change differently, because the change in charge in the two processes are basically different:

$$H^+ + A^- \rightleftharpoons HA^\pm$$
$$HA^\pm + H^+ \rightleftharpoons H_2A^+$$

A completely different dependence of the two pK values on the ionic strength was found earlier.[11]

In case (*ii*), however, parallel changes would be expected and were found. Thus it may be concluded that in the case of glycine there is no change in the

standard state even if the concentrations of the supporting electrolyte and the ligand are comparable.

Change in the diffusion potential should be taken into account, however, when the metal complexes are studied. The simplest way to do this is to use the pK values extrapolated to $T_A \rightarrow 0$, and to correct the measured pH with an appropriate factor read directly from Fig. 4. This procedure was used during the pH-titration study of the VO^{2+}–glycine system, the result of which will be given in a succeeding paper.

COPPER(I) ACTIVITY OF THE COPPER(II) ION-SELECTIVE ELECTRODE

HANS STÜNZI

Medical Chemistry Group, John Curtin School of Medical Research, Australian National University, P.O. Box 334, Canberra City, A.C.T. 2601, Australia

(*Received* 23 *March* 1981. *Accepted* 11 *June* 1981)

Summary—The Orion copper(II) ion-selective electrode responds well to copper(II) ions in aqueous medium. However, in the presence of acetonitrile and copper(I) ions, it can behave as a copper(I) ion-selective electrode with Nernstian behaviour.

The Orion cupric ion-selective electrode seems to be well suited to the determination of stability constants of copper(II) complexes,[1] as long as the ligands are not too negatively charged.[2] Hence this electrode was used in an investigation of complex formation in aqueous solution by 5-sulphonatoisatin β-thiosemicarbazone.[3,4] However, the parameters pCu, pH and pL could not be combined into stability constants. The thiosemicarbazone reduced copper(II) to copper(I). An assumption that the electrode responded to free copper(I) concentration seemed to fit with the data. This agreed with theoretical considerations[2,5] which showed that the solid-state copper electrode is essentially a copper(I)-sensitive electrode. Experimental confirmation of the behaviour of the electrode towards copper(I) was sought by using acetonitrile as ligand, since this is known to stabilize copper(I).

EXPERIMENTAL

Materials

Potassium nitrate ("AnalaR") was recrystallized from water. Acetonitrile ("Ajax Unichrom") was used without further purification. $Cu(CH_3CN)_4ClO_4$ was synthesized by adding sodium perchlorate to an equilibrated mixture of copper(II) nitrate and copper metal in acetonitrile.[6] The white precipitate was recrystallized from acetonitrile.

Instrumentation and measurements

The pCu values were determined with the electrode assembly Cu-electrode (Orion 94-29A) ‖ solution | 1.8*M* KNO_3 + 1.8*M* KCl | 3.5 *M* KCl | calomel. A glass electrode (EIL all-purpose standard) was used for pH measurements,[7] with the same (external) reference electrode. The electrodes were connected to an Orion 801A pH-meter through an Orion 605 manual electrode switch.

The measurements were carried out in aqueous 0.15*M* potassium nitrate at 37° with constant stirring. High-purity nitrogen was bubbled through a solution of cuprous chloride in 1*M* hydrochloric acid, then 2*M* potassium hydroxide and water [where appropriate, containing copper(I) and acetonitrile]. The copper electrode was routinely calibrated overnight with $10^{-4}M$ copper nitrate in 0.15*M* potassium nitrate at pH 4. The Nernst equation

$$E = E^0 + \frac{RT}{nF} \ln[Cu^{2+}]$$

correlates the measured potential E with the copper(II) concentration. E^0 was obtained from

$$E^0 = E + (S/2)\,pCu^{2+}$$

with $pCu^{2+} = -\log[Cu^{2+}]$ and $S = 61.6$ mV. It varied from 295 to 300 mV. The difference between the E values for 10^{-4} and $10^{-2}M$ copper nitrate was 61.0 mV, which is near to the expected 61.6 mV. Hence, there was no interference[5] from the trace of chloride leaking out of the salt bridge. Additionally, alkalimetric titrations of solutions containing copper(II) and excess of histidine or glycine were performed to check the response of the electrode (stability constants for the copper histidine and glycine complexes were taken from Stünzi and Perrin[8]). From pH 2.5 to 10 and for pCu^{2+} values between 4 and 17.5, the experimental and calculated pCu^{2+} values agreed to within 0.07. (The pH-dependence of the cupric ion-selective electrode seems to be less serious than suggested by Sekerka and Lechner.[9])

In agreement with Westall *et al.*,[5] interference lowered the measured potential in copper(II) solutions with acetonitrile concentrations above 0.9*M*.

RESULTS AND DISCUSSION

The behaviour of the Orion cupric ion-selective electrode towards copper(I) ions was investigated. Titrations were carried out in aqueous solutions containing acetonitrile. To solutions 0.2–2*M* in acetonitrile [$I = 0.15M$ (KNO_3), 37°, pH 4] were added increments of a freshly prepared solution of $Cu(CH_3CN)_4ClO_4$ (0.1*M*) in acetonitrile. The potential became stable within 1–10 min. The corresponding pCu^+ values were calculated from the total acetonitrile concentrations and from the stability constants for the copper(I) acetonitrile complexes: $\log K_1 = 3.28$, $\log \beta_2 = 4.35$ and $\log \beta_3 = 4.39$.[10] The stability constants (measured in 0.2*M* $NaNO_3$ medium at 20°) were used without correction for the change in experimental conditions. Thus, $pCu^+ = -\log[Cu^+]$ was obtained from the equation

$$[Cu^+] = [Cu^+]_{tot}/(1 + K_1[L] + \beta_2[L]^2 + \beta_3[L]^3)$$

where $[Cu^+]$ and $[L]$ are the free copper and acetonitrile concentrations and $[Cu^+]_{tot}$ is the total copper concentration. Assuming Nernstian behaviour ($S = 61.6$ mV) an $E^0(Cu^+)$ value was calculated:

$$E^0(Cu^+) = E + S pCu^+$$

Table 1. Titration of 50 ml of 0.38*M* acetonitrile with 0.1*M* $Cu(CH_3CN)_4ClO_4$ in acetonitrile [I = 0.15*M*(KNO_3), 37.0°, pH 4]

ml added,	$[CH_3CN]$, *M*	$[Cu^+]_{tot}$, m*M*	pCu^+*	*E*, *mV*	$E^0(Cu^+)$, *mV*
0.05	0.40	0.10	7.78	210.5	690.9

0.80	0.67	1.54	7.09	253.1	691.1

* Calculated (see text).

The $E^0(Cu^+)$ values were reasonably constant throughout a titration (Table 1), indicating Nernstian response of the copper electrode to copper(I) ion.

In order to make the result independent of the reference electrode, the difference between $E^0(Cu^+)$ and $E^0(Cu^{2+})$ is used. Table 2 gives the summary of the experiments done. At acetonitrile concentrations between 0.1 and 0.3*M* the readings were unstable and could only be read within ±3 mV. The decrease in the potentials with time was indicative of oxidation and/or disproportionation. Oxidation was evident from the increase of the pH values. The stability of the system improved at 0.4*M* acetonitrile concentration.

For acetonitrile concentrations between 0.4 and 2*M*, the result was

$$E^0(Cu^+) = E^0(Cu^{2+}) + 399 \text{ mV}$$

The response was good down to $10^{-4}M$ total copper concentration and was still satisfactory at $10^{-5}M$ (Table 2).

If the measured potentials have already been converted into "pCu^{2+}" values, the pCu^+ values are obtained from

$$pCu^+ = \tfrac{1}{2}\text{"}pCu^{2+}\text{"} + 6.48$$

For solutions containing Cu^{2+} and Cu^+ a mixed potential would be expected:

$$E = E^0(Cu^+) + S\log([Cu^+] + K[Cu^{2+}]^{\frac{1}{2}})$$

with $\log K = -6.48$, where $\log K$ is the selectivity constant. The Orion cupric ion selective electrode is hence essentially a copper(I) electrode. This is consistent with its composition: a silver-contacted Ag_2S–Cu_2S membrane.[11] A similar selectivity $\log K = -5.9$)[12] has been found for a copper electrode with a Cu_2S membrane. It was assumed that the sensitivity to Cu^{2+} was the result of the exchange reaction

$$Cu^{2+} + Cu_2S = CuS + 2\,Cu^+$$

Thus, $\log K$ was calculated to be -6.6,[12] and -6.2.[13] This suggests that the Orion electrode responds to Cu^{2+} by the same exchange reaction.

Addition of copper(II) at the end of the titrations did not change the observed potential significantly although a change of 18 mV would have been expected for $pCu^+ \simeq 7.8$ and $[Cu^{2+}] = 2mM$. This insensitivity towards Cu^{2+} is surprising in view of the generally accepted assumption that acetonitrile does not complex copper(II). It is, however, in agreement with the observation that with low concentrations of Cu^{2+} in aqueous acetonitrile the potentials are too small. This "interference" with the Ag/Ag_2S–Cu_2S electrode has not yet been explained. (For the graphite-contacted Ag_2S–CuS electrode, however, the mechanism of interference is discussed in refs. 5 and 14.)

Table 2. Summary of experiments done

Conclusion

Under conditions where copper(I) is stable, the Orion cupric ion selective electrode behaves as a copper(I) electrode. The response is Nernstian within the experimental precision. Hence, this electrode appears to be suitable for studying the stability of copper(I) complexes with ligands that preferentially stabilize this ion (*e.g.*, sulphur-containing ligands).[15]

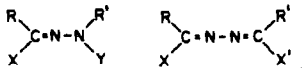
(*Received* 26 *May* 1980. *Revised* 8 *April* 1981. *Accepted* 27 *May* 1981)

Summary—Applications of hydrazones in inorganic analysis since 1950 are reviewed.

Hydrazones are azomethines characterized by the grouping >C=N–N<. They are distinguished from other members of this class (imines, oximes, *etc.*) by the presence of the two interlinked nitrogen atoms. The hydrazone grouping occurs in organic compounds of the types:



(I) (II)

where R and R′ = H, Alk, Ar, RCO, Ht (heterocyclic group); Y = H, Alk, Ar, Ht, RCO; X and X′ = H, Alk, Ar, Ht, Hal, OR″, SR, CN, SO_2R, NO_2, NHNR″R‴, N = NR″, COOR″, CONR″R‴. The general name "hydrazone" is used for all the compounds having structure (I). Compounds of type (II) are termed "azines".

Nomenclature

Hydrazones are usually named after the carbonyl compounds from which they are derived; thus benzaldehyde and phenylhydrazine give benzaldehyde phenylhydrazone. The name originally used was benzylidenephenylhydrazine. Some authors have recently reverted to this system, which is, however, cumbersome when applied to more complex hydrazones. Bishydrazones of α-diketones are commonly called osazones. The nomenclature commonly used in the literature is often not in accord with IUPAC rules.

Preparation

Hydrazones, in general, are prepared by refluxing the stoichiometric amounts of the appropriate hydrazine and aldehyde or ketone dissolved in a suitable solvent. The compound usually crystallizes out on cooling. Detailed accounts of their preparations are given in a recent review.[1] Many hydrazones are now commercially available.

* Present address: Department of Chemistry, Massey University, Palmerston North, New Zealand.

Non-analytical applications

Many of the physiologically active hydrazones find application[2] in the treatment of diseases such as tuberculosis, leprosy and mental disorder, and aroylhydrazones (III) are also reported to possess tuberculostatic activity.[3,4] This is attributed to the formation of stable chelates with transition metals present in the cell.

R–CH=N–NH–CO–R′
(III)

Thus many vital enzymatic reactions catalysed by these transition metals cannot take place[5–7] in presence of hydrazones. Hydrazones also act as herbicides, insecticides, nematocides, rodenticides and plant-growth regulators. They show spasmolytic activity, hypotensive action and activity against leukaemia, sarcomas and other malignant neoplasms. Hydrazones are used as plasticizers and stabilizers for polymers and as polymerization initiators, antioxidants, *etc.* Hydrazones of 2-methylphthalazone[8] are effective sterilants for houseflies. 3-*N*-Methyl-*N*-(4-chloro-1-phthalazinyl) and 3-*N*-methyl-*N*-(4-oxo-1-phthalazinyl) hydrazones possess anthelmintic activity.[9]

ANALYTICAL APPLICATIONS

In analytical chemistry, the formation of hydrazones is extensively used in the detection, determination and isolation of compounds containing the carbonyl group. Photometric methods for determining aldehydes and ketones are based on their reaction with 2,4-dinitrophenylhydrazine to form the corresponding hydrazones.[10,11]

Spectrophotometric applications

Biscyclohexanone oxalyldihydrazone was one of the earliest used hydrazones for the spectrophotometric determination of copper. It gives a blue colour with traces of copper and is used for determination of copper in paper pulp products,[12] human serum,[13]

steel,[14,15] plants,[16,17] non-ferrous metals and alloys[18–20] and cadmium sulphide.[21] Ethylidene oxalyldihydrazone[22] has been used to determine copper in zinc and its alloys. A similar type of reagent, bis(ethylacetoacetate) oxalyldihydrazone,[23] is very selective and sensitive for copper. Oxalyldihydrazone has been used in presence of acetaldehyde for determination of copper.[24,25]

Lions and Martin[26] introduced pyridine-2-aldehyde 2-pyridylhydrazone (PAPH) and similar types of hydrazones and have made detailed physico-chemical investigations on their metal complexes.[27–29] This has opened a wide field for their use in analytical chemistry, which began in 1963 when Cameron *et al.*[30] published a survey of the visible spectra of aqueous solutions containing metal ions and PAPH. They stated that PAPH should be useful as a colorimetric reagent and as an acid–base indicator. PAPH has been used for the determination of copper in foodstuffs.[31] Quddus and Bell[32] have studied the complexes formed between PAPH and Zn, Cd, Fe(II), Cu(II), Ni(II), Mn(II) and Pd. Distribution ratios of the complexes between chloroform and buffer solutions of various pH values have been determined. The sensitivity is increased by extraction. The analogous picolinaldehyde 2-pyridylhydrazone reacts with palladium(II)[33–35] and forms a ternary complex with cobalt(II) and eosin.[36]

2,2′-Bipyridyl 2-pyridylhydrazone (BPPH)[37] reacts with cobalt(II) to form an orange complex (λ_{max} 480 nm) which shows a bathochromic shift on addition of perchloric acid (λ_{max} 500 nm), giving a pink complex which is stable even in 50% perchloric acid medium. This reaction has been utilized in the spectrophotometric determination of cyanocobalamine[38] and of cobalt in sea-water and brine.[39] BPPH also reacts with iron(II),[40] zinc[41] and cadmium.[42]

2-Benzoylpyridine 2-pyridylhydrazone reacts with Fe(II), Co(II), Ni and Zn.[43] The reagent has also been sulphonated[44] and used for the preconcentration of trace metal ions by combined complexation and anion-exchange.[45] Asuero[46] introduced biacetyl bis(2-pyridyl)hydrazone as an analytical reagent and its reactions with several metal ions have been reported. Benzil mono(2-pyridylhydrazone)[47] reacts selectively with cobalt(II) in acid medium. The corresponding bishydrazone and the mono and bis(2-pyridylhydrazone)s of 2,2′-pyridil react with iron(II), copper(I), cobalt(II) and nickel.[48]

Two new pyridylhydrazones[49] have been prepared from quinoline-2-aldehyde and phenanthridine-6-aldehyde (PDAPH) and the latter has been used for the spectrophotometric determination of zinc.[50] Other pyridylhydrazones investigated include those of bi-2-quinolyl ketone for [Pd(II)][51] and biacetyl (monohydrazone) [for Co(II)].[52]

In investigation of the effect of substitution of a more extended π-system in the hydrazine moiety of nitrogen-heterocycle hydrazones, a new heterocyclic hydrazone, pyridine-2-aldehyde 2-quinolylhydrazone (PAQH) was introduced by Heit and Ryan.[53] Cobalt and nickel were selectively determined with it spectrophotometrically.[54] In the presence of thioglycollic acid, only the nickel complex is extractable into chloroform. The reagent can also be used for the determination of nickel in sea-water.[55] Prior concentration of the metal is not necessary. The reagent also complexes iron(II), copper(II)[53,56] and palladium(II).[57–59] Quinoline-2-aldehyde 2-quinolylhydrazone has been used for the determination of copper in sea-water[60,61] and tap-water.[62]

Other quinolylhydrazones investigated include those of 6-methylpicolinaldehyde [Pd(II)],[63] phenylpyruvic acid [Cu(II)][64], 2,2′-bipyridyl [V(V),[65] Zn,[66] Co(II),[67] Pd(II),[68,69] Rh(III)[70] and Fe(II), Ni, Cu(II), Cd, Hg(II)[71]], benzothiazole-2-aldehyde [Pd(II),[72] Cu(II)[73]], biacetyl (monohydrazone) [Co(II), Cu(II)],[74] benzil (monohydrazone) [Cu(II)][75], 2,2′-pyridil (bishydrazone) [Co(II),[76] Pd(II),[77] Cu(II), Zn, Cd, Rh(III), Hg(II)[78]], and monohydrazone [Zn, Cd, Hg(II),[78] Cu(II),[79] Rh(III),[80] Pd(II),[81] Fe(II),[82] Co(II), Ni[83]].

Frei *et al.*[84] have studied the extraction properties of chelates of Ni, Cu(II), Co(III), Fe(II), Zn and Cd with PAQH. Of the three organic solvents investigated (benzene, isoamyl alcohol and methyl isobutyl ketone) the last two gave solutions suitable for direct aspiration into the flame (for atomic-absorption spectroscopy) after an equal volume of ethanol had been added. The charged cobalt complex is believed to be extractable, under suitable conditions, as an ion-pair. The other extractable compounds are 1:2 (metal:hydrazone) chelates.

Singh and co-workers[71,85–89] introduced 2,2′-bipyridyl 2-pyrimidylhydrazone as an analytical reagent for V(V),[85] Co(II),[86] Zn,[87] Fe(II),[88] Pd(II)[89] and Ni, Cu(II), Cd and Rh(III)[71] and claimed it had advantages over the pyridyl and quinolylhydrazones.

A series of 2-benzothiazolylhydrazones have been described [benzothiazole-2-aldehyde for Cu(II), Co(II), Ni;[90] thiophene-2-aldehyde for Cu(II);[91] 5-chlorothiophene-2-aldehyde for Co(II),[92] Cu(II);[93] 2-furfural for Cu(II), Ag, Co(II), Hg(II), Ni, Zn;[94] 5-methylfurfural for Co(II);[95] 1-naphthaldehyde for Cu(II);[89] biacetylmonoxime for Pd(II);[96] 2-hydroxy-1-naphthaldehyde for Cu(II);[97] pyridine-2-aldehyde for Cu(II), Ni, Co(II), Pd(II), Fe(III);[53] pyruvaldehyde for Cd].[98] Libergott *et al.*[99] used isatin-2-benzothiazolylhydrazone for the determination of lead in plastic milk cartons.

Salicylaldehyde isonicotinoylhydrazone[100] was used for the spectrophotometric determination of gallium and indium at pH 6–6.5 (λ_{max} 390 and 380 nm). These complexes are extractable into pentanol. Since the aluminium complex is not extractable, it does not interfere. 2-Hydroxy-1-naphthaldehyde isonicotinoylhydrazone[101] has been used for the colorimetric determination of iron(II) and (III) in presence of each

other and other metals, and applied to various pharmaceuticals, and for Mo(VI) in steels.[102]

The complexes formed by vanadium(V) in acidic 50% aqueous ethanol medium with acetone isonicotinoylhydrazone and with 4-hydroxybenzaldehyde isonicotinoylhydrazone have been examined,[103] and used for spectrophotometric determination of vanadium. The 2-hydroxy isomer has been used for Al,[104] and Zn, Co(II), Ni and Mn(II).[105] The gossypol derivative reacts with U(VI)[106] and Ti(IV).[107] *o*-Hydroxybenzaldehyde benzoylhydrazone reacts with zinc and manganese(II);[105] the hydrazone of isonicotinic acid and naphthyl methyl ketone reacts with titanium(IV).[108]

A number of simple hydrazones have been examined: of salicylaldehyde for Fe(III),[109] Co(II),[109] Cu(II),[110] Pd(II),[111] Os(VIII);[111] of *o*-hydroxyacetophenone for Ni;[112] of 6-methylpicolinaldehyde for Cu(I);[113] of 2-benzoylpyridine for Fe(II);[114] of biacetylazine for Cu(I);[115] of bis(6-methyl-2-pyridyl)glyoxal dihydrazone for Cu(I).[116]

Recently Schilt *et al.*[117–119] have introduced a large number of ferroin-type hydrazones and tabulated properties of their complexes with Cu(I), Fe(II), Co(II) and Ni.

Several new hydrazones are prepared *in situ* and applied for the spectrophotometric determination of metal ions. The product (λ_{max} 490 nm) which results from the interaction of biacetyl, hydrazine and iron(II) has been applied to the colorimetric estimation of iron.[120,121] The interferences are the same as in the determination of iron(II) with 1,10-phenanthroline and 2,2′-bipyridyl, but the method is cheap and simple. Mohr's salt behaves differently from ferrous sulphate, owing to the reaction of the ammonium ion with the biacetyl. Zinc, cadmium and aluminium can be tolerated in large amounts, and addition of EDTA and citrate masks many possible interferents. Iron(III) can be determined after reduction to iron(II). The complex can also be extracted into nitrobenzene.

The coloured complex formed by Fe(II) and α-pyridyldihydrazone (used as such or synthesized *in situ*), has been investigated.[122] The complex can be extracted into nitrobenzene and its absorbance measured at 486 nm. Mn(II), Al and Cd do not interfere but ions which complex Fe(II) interfere seriously. Other ferroin-type reagents used for traces of iron[123] are 2,2′-bipyridylglyoxal dihydrazone, biacetyl dihydrazone and phenyl 2-pyridyl ketone hydrazone.

The bis(phenylhydrazone) of oxamide is oxidized by Cu(II), Hg(II), Fe(III), $Fe(CN)_6^{3-}$ or chlorine water to give violet or blue species extractable into chloroform. Based on this phenomenon, photometric methods have been developed[124] for the microdetermination of these ions or chlorine and also for determination of the hydrazones by means of ferricyanide. Bahr *et al.*[125] used biacetyl di(thiobenzoylhydrazone) for the photometric determination of copper.

The bis(4-hydroxybenzoylhydrazone)s[126] of glyoxal, methylglyoxal and dimethylglyoxal form coloured chelates with several cations. The glyoxal derivative has been proposed as a reagent for the determination of calcium and cadmium (in the presence of cyanide or citrate, respectively, when other cations are present).

Miscellaneous reagents include 2,2′-bipyridyl phenylhydrazone for Pd(II);[127] pyridoin phenylhydrazone for Cu(I)[128] and Pd(II);[129] picolinaldehyde 4-nitrophenylhydrazone for Pd(II);[130] biacetylmonoxime *p*-nitrophenylhydrazone for Co(II);[131,132] pyridine-2-carbaldehyde 2-hydroxybenzoylhydrazone for Ni and Zn,[133] and for Fe(II)[134] and V(V);[135] benzil bis(2-hydroxybenzoylhydrazone) for Ti(IV);[136] salicylaldehyde benzoylhydrazone for Cu(II) and Pd(II);[137] picolinaldehyde 1-thionaphthylhydrazone[138] and biacetyl bis(thiobenzoylhydrazone)[125] for Cu(II); the 2-(2-hydroxyphenylhydrazone) of ethyl 2,3-dihydroxybutyrate for Co(II);[139] anthranilic acid isopropylidenehydrazide for V(V);[140,141] 2-methylisonicotinic acid salicylidenehydrazide for Ti(IV);[142] 6-methyl-2-pyridylaldehyde 2-quinolylhydrazide for Cu(II)[143] and di-2-pyridyl ketone 2-furancarbothiohydrazone[144] for Cu(II), Ni, Co(II), Fe(II) and Re(VII).

Fluorimetric applications

The fluorescence of the zinc complex formed at pH 8 with PAQH in chloroform has been measured at 535 nm with excitation at 485 nm, to determine 0.026–0.31 ppm of zinc.[145] The main interference is from Co(II), Cd, Cu(II), Hg(II), Fe(II), Ni, CN^- and SCN^-; in their absence the accuracy is high.

Organothiophosphorus pesticides have been determined by fluorimetry *in situ* after TLC separation on silica gel.[146] The process involves bromination and spraying with a mixture of Mn(II) and salicyl-2-aldehyde 2-quinolylhydrazone. A direct relationship exists between the sensitivity and the number and oxidation state of the sulphur atoms in the pesticides.

The fluorescence of the isonicotinic acid hydrazones of a number of carbonyl compounds (2-hydroxy-1-naphthaldehyde, salicylaldehyde, 2-hydroxy-*m*-tolualdehyde, 3-hydroxy-*p*-tolualdehyde, 4-hydroxy-*m*-tolualdehyde, 3-chloro-2-hydroxybenzaldehyde, 5- chloro-2-hydroxybenzaldehyde and 2-hydroxyacetophenone) has been examined.[147] In the presence of aluminium, these hydrazones give a yellowish-green fluorescence in an acetate buffer, while under similar conditions the parent carbonyls exhibit only feeble fluorescence. The fluorescence intensity of the hydrazone of 2-hydroxy-1-naphthaldehyde (in the presence of aluminium) is particularly strong, and the aldehyde is found to be a good reagent for the fluorimetric determination of 0.1–1 ppm of isonicotinic acid hydrazide.

Four derivatives of 2-hydroxy-1-naphthaldehyde hydrazone have been synthesized, and the fluorescence due to the reaction between these hydrazones and various metal ions indicates[148] that they are use-

ful for the detection of aluminium. 2-Hydroxy-1-naphthaldehyde benzoylhydrazone gives the strongest fluorescence. A fluorimetric method for the determination of 0.1–1 ppm of aluminium with this reagent at pH 4.6 (acetate buffer) in a mixed solvent medium of methanol and dimethylformamide has been established.

In alkaline medium (preferably 0.1*M* potassium hydroxide), calcium forms a fluorescent 1:1 complex with 8-hydroxyquinaldehyde 8-quinolylhydrazone.[149] The method has been used for determination of down to 0.1 ppm of calcium in potassium chloride and methyltrichlorosilane. The fluorescence is measured at about 510 nm (with excitation at around 420 nm). Ivanova *et al.*[150] used this reagent for fluorimetric determination of traces of calcium in alkali-metal chlorides and iodides.

The zinc, aluminium, scandium and gallium complexes of β-resorcylaldehyde acetylhydrazone[151] exhibit blue fluorescence. The fluorescence intensity of the scandium complex is appreciable (excitation at 406 nm). The reaction is used for the determination of scandium (1–18 μg) in acetate buffer medium (pH 6). Chromium, nickel, cobalt and iron(III) interfere by decreasing the fluorescence intensity and zinc and aluminium by increasing it.

The most sensitive reagent for the fluorimetric determination of aluminium is salicylaldehyde formylhydrazone,[152] but the fluorescence intensity takes at least 7 min to become stable; 0.03–0.88 ppm of aluminium can be determined with a relative error of $< 1\%$.

Taniguchi *et al.*[153] used 2-hydroxy-1-naphthaldehyde benzoylhydrazone for the fluorimetric titration of copper(II). The 2-hydroxy-1-naphthylmethylene hydrazide of 4-methoxybenzoic acid was used by Dolgorev *et al.*[154] for the fluorimetric determination of scandium in rare-earth oxides. Recently bipyridylglyoxal diphenylhydrazone was used for the fluorimetric determination of gold(III).[155]

Heterocyclic hydrazones of *o*-hydroxyaldehydes have been studied[156] as reagents. They are promising for Zn, Al, Ga, In, Sc, *etc.* Salicylaldehyde 2-quinolylhydrazone (SAQH) and β-resorcylaldehyde 2-quinolylhydrazone (RAQH) are suitable for the fluorimetric determination of zinc in 80% ethanol and tris-buffer (pH 6.9–7.2). Salicylaldehyde 2-pyridylhydrazone (SAPH), β-resorcylaldehyde 2-pyridylhydrazone (RAPH) and 2-hydroxy-1-naphthaldehyde 2-pyridylhydrazone (HNAPH) are suitable for the fluorimetric determination of aluminium in 70–80% ethanol and acetate buffer (pH 4.5). HNAPH is also used for the fluorimetric determination of gallium, indium and scandium in 70% ethanol and acetate buffer (pH 3.9–4.5).

The bis(4-hydroxybenzoylhydrazone)s of glyoxal, methylglyoxal and dimethylglyoxal form coloured chelates with several cations.[126] The chelates formed are fluorescent, the fluorescence from the lanthanum chelates being the most intense.

Gravimetric applications

An ethanolic solution of resacetophenone phenylhydrazone[157] quantitatively precipitates copper from ammoniacal solutions without rigid control of the experimental conditions; up to 32 mg can be accurately determined in the presence of cadmium.

Of eight phenylhydrazone derivatives of phenolic aldehydes and ketones, salicylaldehyde phenylhydrazone[158] was found to be the best gravimetric reagent for copper(II). A 10% ethanolic solution of the reagent was used and the precipitate was ignited to the oxide. Copper(II) in amounts of 25–60 mg was determined with an error of $< 0.1\%$ in the presence of 100 mg of cadmium.

o-Hydroxyacetophenone phenylhydrazone[159] was found to be the best among the various hydrazones tested for palladium(II). It is possible to determine 15–47 mg of palladium; the precipitate is ignited to the metal.

Schwartz and Dickmann[160] used biacetyl bis(salicylohydrazone) and biacetyl bis(5-bromosalicylohyrazone) for the gravimetric determination of zinc and cadmium. With the former, 7–98 mg of zinc and 12–116 mg of cadmium can be determined, but only 40 mg of zinc with the bromo-derivative. Rastogi *et al.*[161] used benzoyl salicylal hydrazone, *i.e.*, benzoic acid salicylidenehydrazide (in acetone) for the gravimetric determination of copper(II).

Patal *et al.* used the benzoyl[162] and salicyl[163] hydrazones of 2-hydroxyiminoacetoanilide and 2-hydroxyiminoaceto-*o*-tuluidine for the gravimetric estimation of palladium(II) in the presence of copper(II) and nickel(II). The pH range for precipitation is very wide. Salicylaldehyde hydrazone[164] was used for the gravimetric determination of 5–30 mg of copper or nickel at pH 10.5–13. Prior separation of silver as its chloride and uranium as peruranate is necessary. Copper can be determined in the presence of nickel at pH 11–12 in the presence of EDTA.

Potentiometric studies

The stability constants of the complexes formed by pyridine-2-aldehyde 2-pyridylhydrazone with copper, zinc, cadmium, manganese, iron and nickel have been reported.[165] The formation and deprotonation equilibria[166] have been studied for iron(II) complexes of the three terdentate chelating agents, 6-methylpyridine-2-aldehyde 2-pyridylhydrazone, pyridine-2-aldehyde 2-pyrimidylhydrazone and pyridine-2-aldehyde 3'-methyl-2'-pyrazinylhydrazone. The respective stability constants were log β_1: 6.3, 6.0, 7.9; log β_2: 12.6, 14.0, 15.6; the acid dissociation constants of the respective protonated bis-complexes were pk_1: 6.28, 4.56, 4.12; pk_2: 7.95, 6.09, 5.61.

The acid dissociation constants for β-resorcylaldehyde acetylhydrazone in 40% aqueous ethanol have been measured[151] potentiometrically and spectrophotometrically. The stability constants of the 1:1 scandium complex has been determined.

The stability constants of the bivalent metal complexes with salicylaldehyde hydrazone,[167] which have been determined potentiometrically in 75% aqueous dioxan, follow the order $UO_2^{2+} > Pb^{2+} > Co^{2+} > Zn^{2+}$; for those with *o*-hydroxyacetophenone hydrazone in 50% aqueous dioxan the order is $UO_2^{2+} > Cu^{2+} > Co^{2+} > Ni^{2+}$.

The chelates of pyridine-2-aldehyde 2-benzothiazolylhydrazone and pyridine-2-aldehyde 2-quinolylhydrazone[53] have been studied potentiometrically in 1:1 dioxan–water media. The ligands react with iron(II), nickel, zinc and cadmium to form octahedral complexes. The titration curves for these reactions show only one break, which corresponds to the neutralization of perchloric acid plus two equivalents of hydrogen-ion per mole of metal added and is indicative of the formation of the bis-chelates. The copper reaction, in which both mono and bis-chelates are found, is described in detail.

Applications as indicators

The complexes of bivalent Cu, Zn, Cd, Fe and Ni with pyridine-2-aldehyde 2-pyridylhydrazone (PAPH) have been used as acid–base indicators[168] in titration of weak and strong acids and bases. Based on the extraction of their intensely coloured deprotonated forms into organic solvents, the copper, nickel and iron complexes have been used as extraction indicators[169] in titrations of strong acids and bases.

The zinc and cadmium complexes of 2,2′-bipyridyl 2-pyridylhydrazone have been proposed as indicators in acid–base titrations[170] in aqueous solution, the apparent p*K* values being 8.5 and 9.5, respectively. The indicators give sharp end-points and have proved to be similar in behaviour to phenolphthalein.

Chugreeva[171] suggested the use of the *p*-nitrophenyl- and 2,4-dinitrophenylosazones of dihydroxytartaric acid and the 2,4-dinitrophenylhydrazone of acetone, which behave as acid–base indicators at pH 11.5–13.5 and may be used in solutions with high concentrations of salts, ethanol and protein in the temperature range 0–80°, and also[172] for the determination of free sodium hydroxide in mixtures with alkali-metal carbonates, aqueous ammonia, potassium cyanide, sodium phenoxide, sulphacetamide and sulphapyridine sodium.

Some *p*-nitrophenylhydrazones have proved to be better indicators because of their high stability and readily observable colour changes. Studies have been made of the change of the absorption spectra with pH, the useful pH-ranges, and stability of the colours of the *p*-nitrophenylhydrazones derived from crotonaldehyde and acraldehyde,[173] furfuraldehyde and some furfuraldehyde derivatives,[174] benzaldehyde and its 4-nitro-4-hydroxy-, 2,4-dihydroxy- and 4-dimethylamino- derivatives among others[175] and the *p*-nitro and 2,4-dinitrophenylhydrazones derived from 4′-nitroacetophenone.[176]

The potassium salt of benzaldehyde *p*-nitrophenylhydrazone[177] has also been studied. Likewise, the phenylhydrazones of pyridine 2-aldehyde and pyridine-4-aldehyde, when used as indicators for titration of a base with an acid, change from colourless to yellow, and are suitable for use in spectrophotometric titrations.[178]

The *p*-nitrophenylhydrazone of pyridine-2-aldehyde has recently been proposed as an indicator[179] for colorimetric pH measurements. Katiyar *et al.*[180] have proposed *N*-isonicotinoyl *N*′-salicylidenehydrazine as a metallochromic indicator for iron.

Applications as spot-test reagents

Singh[71] has used 2,2′-bipyridyl 2-quinolylhydrazone and 2,2′-bipyridyl 2-pyrimidylhydrazone as spot-test reagents for the detection of iron, cobalt and copper.

p-Dimethylaminobenzaldehyde isonicotinoylhydrazone forms an intensely orange–yellow precipitate with mercury(I or II) in slightly acidic, neutral or slightly alkaline medium.[181] The *p*-diethylaminobenzaldehyde compound behaves similarly but with lower sensitivity for mercury(II).

Libergott *et al.*[182] used pyruvylidine-2-hydrazinobenzothiazole in benzene for the selective detection of cadmium, an orange colour being developed with an alkaline test solution. The test is highly selective in presence of cyanide, the tetracyanocadmate complex being demasked with formaldehyde.

Sawicki *et al.*[183] used benzaldehyde 2-benzothiazolylhydrazone for the detection of nitrite in presence of *p*-aminobenzene.

An ethanolic solution of biacetylmonoxime benzothiazolylhydrazone[184] gives a red–violet product (extractable into chloroform) with palladium(II) in acidic or alkaline medium. Cyanide interferes in acidic and cobalt in alkaline medium.

If one drop of 0.05% acetophenone *m*-nitrophenylhydrazone solution and 1 ml of 0.05*M* sodium hydroxide are mixed with 5 μg of Mg^{2+}, a rose–violet precipitate is formed.[171]

Anand *et al.* used the 2,4-dinitrophenylhydrazones of biacetylmonoxime,[185] 4-methylpentane-2,3-dione-2-oxime[186] and hydroxyiminoacetophenone[187] and the *p*-nitrophenylhydrazones of pyruvaldoxime,[188] 4-methylpentane-2,3-dione-2-oxime,[186] hydroxyiminoacetophenone[187] and 3-hydroxyiminopentane-2-one[189] for selective and sensitive detection of cobalt. Feigl *et al.*[190] also used the *p*-nitrophenylhydrazone of biacetylmonoxime (cobaltone I) for the detection of cobalt.

Other applications of hydrazones

Copper(II) (1–16 μg) has been determined by amperometric titration[191] in 0.15*M* sodium acetate (containing gelatine) as supporting electrolyte, with ethanolic resacetophenone phenylhydrazone solution. There is no interference from a 10-fold ratio (to Cu) of Ni, Zn or Cd. Iron(II) interferes, but an amount equal to that of copper can be tolerated if sodium fluoride is added as masking agent. The method has been used

in analysing nickel–silver. Recently Jain *et al.*[192] used ethyl cyanoglyoxalate 2-carboxyphenylhydrazone for the selective amperometric determination of thorium.

The complex of cobalt(III) with pyridine-2-aldehyde 2-pyridylhydrazone (PAPH) has been used in the nephelometric determination[193] of silver and mercury(II). The procedure is based on adduct formation of these ions with $Co(PAPH)_2^+$, in which the two unco-ordinated (imino) nitrogen atoms are peripheral and interact with the silver or mercury(II). The adducts formed correspond to the formulae $[Co(PAPH)_2]ClO_4.AgNO_3$ and $[Co(PAPH)_2].ClO_4.Hg(NO_3)_2$.

Pyridine-2-aldehyde 2-quinolylhydrazone (PAQH) has been used as detection agent for cobalt, nickel and copper after their TLC separation.[194] Frei *et al.*[195] have separated the PAQH complexes of Fe, Ni, Cu and Co chromatographically and determined them semiquantitatively in the presence of up to 10-fold amounts of interfering metal ions. Diffuse reflectance spectroscopy,[196] and ring-oven separation and circular chromatography[197] have been used for the same purpose.

Biacetyl bis(thiobenzoyl) hydrazone and pentane-2,3-dione bis(4-methoxythiobenzoyl) hydrazone[198] form coloured complexes with a large number of metal ions. Most of the complexes can be extracted into chloroform containing pyridine or into isobutyl methyl ketone in the presence of tetrahydrofuran and may be separated by TLC.

Conclusions

These reagents are in general useful for determination of a limited number of metals (Co, Cu, Cd, Zn, Ni, Mn, Fe, V, Hg, Mo, Ti, U, Pd, Re, Rh, Os) but are highly selective for virtually only cobalt, thanks to its ability to form inert complexes.

SPECTROPHOTOMETRIC DETERMINATION OF SILVER WITH 2-(3,5-DIBROMO-2-PYRIDYLAZO)-5-DIETHYL-AMINOPHENOL IN THE PRESENCE OF ANIONIC SURFACTANT

SHUI-CHIEH HUNG, CHANG-LING QU and SHUI-SHENG WU

Institute of Environmental Chemistry, Academia Sinica, P.O. Box 934, People's Republic of China

(*Received* 11 *May* 1981. *Accepted* 5 *August* 1981)

Summary—A sensitive and selective spectrophotometric method for silver has been established by reacting silver(I) with 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol (3,5-diBr-PADAP) in the presence of an anionic surfactant, sodium lauryl sulphate. The molar absorptivity is 7.7×10^4 l.mole^{-1}.cm^{-1} at 570 nm. The molar ratio of silver to 3,5-diBr-PADAP is 1:2. Beer's law is obeyed from 0.1 to 1 ppm of silver. With EDTA as masking agent, common ions do not interfere. The method has been applied to the determination of silver in waste water.

In continuation of investigations on the use of anionic surfactants in the spectrophotometric determination of silver, the colour reactions of silver with some pyridylazo compounds in the presence of anionic surfactants have been studied, and it has been found that the silver complex formed with 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol (3,5-diBr-PADAP) in the presence of sodium lauryl sulphate (SLS) gives a higher sensitivity than the 2-(5-chloro-2-pyridylazo)-5-dimethylaminoaniline complex studied previously.[1] Its molar absorptivity is 7.7×10^4 l.mole^{-1}.cm^{-1} at 570 nm, and it is one of the most sensitive colour reactions known for silver. With EDTA as masking agent at pH 5, this reaction is specific for silver. This paper reports the investigation of optimum conditions for the reaction and a simple and sensitive method for the determination of silver in waste-water.

EXPERIMENTAL

Reagents

Silver standard solution, 1 mg/ml. Dissolve 0.158 g of silver nitrate in 100 ml of 0.1*M* nitric acid, and store in a brown flask. Dilute the solution as required.

3,5-DiBr-PADAP ethanolic solution, 5×10^{-4}M. Dissolve 0.020 g of 2-(3,5-dibromo-2-pyridylazo)-5-diethylaminophenol in 100 ml of absolute ethanol.

The 3,5-diBr-PADAP was synthesized according to Johnson and Florence's procedure[2] with minor modifications, namely, use of 3,5-dibromo-2-aminopyridine instead of 5-bromo-2-aminopyridine, sodium ethoxide in absolute ethanol instead of sodium amide in toluene, butyl nitrite instead of isopentyl nitrite, and recrystallization from 95% ethanol instead of aqueous ethanol (1:1). Yield, *ca.* 30%. Orange-red needles, m.p. 159–160°. Analysis gave, C 42.3%, H 3.7%, N 13.1%, Br 37.7%: $C_{15}H_{16}N_4OBr_2$ requires C 42.11%, H 3.77%, N 13.09%, Br 37.33%.

SLS solution, 1%. Dissolve 1 g of sodium lauryl sulphate in 100 ml of water.

Buffer solution, pH 5. Adjust 0.1*M* acetic acid with 0.1*M* sodium acetate to pH 5, using a pH-meter.

EDTA solution, 0.1M. Dissolve 3.7 g of disodium ethylenediaminetetra-acetate dihydrate in 100 ml of water.

Potassium citrate solution, 5%.

Sodium thiosulphate solution, 7%.

Unless otherwise stated, all reagents used were of analytical-reagent grade, and demineralized water was used throughout.

RESULTS AND DISCUSSION

In a search for a more sensitive reagent for silver, we synthesized twelve pyridylazo compounds as listed in Table 1, and compared the characteristics of their reactions with silver in the presence of an anionic surfactant, sodium lauryl sulphate. From Table 1, it can be seen that reagent IV is the most sensitive. Its sensitivity is higher than that of two analogous compounds containing only one halogen atom substituted in the pyridine ring, *viz.* reagents V and VI; several of the sulphonated reagents do not produce a colour at all with silver.

Spectral characteristics

The absorption spectra of 3,5-diBr-PADAP alone, of 3,5-diBr-PADAP–SLS and of 3,5-diBr-PADAP–SLS–Ag in aqueous solutions at pH from 2 to 11 have been studied. The spectra at pH 5 are shown in Fig. 1. Aqueous solutions of 3,5-diBr-PADAP over the pH-range given above are all orange-yellow and exhibit an absorption maximum within the range 455–465nm (curve A in Fig. 1). The addition of SLS to 3,5-diBr-PADAP causes no significant shift in the wavelength of maximum absorption of the 3,5-diBr-PADAP (curve B in Fig. 1). The ternary system, 3,5-diBr-PADAP–SLS–Ag, forms a red product and exhibits two absorption peaks at 530 and 560 nm (curve C in Fig. 1). The optimal wavelength for measurement of the silver complex is found to be 570 nm, against a reagent blank. However, in the absence of SLS the silver and 3,5-diBr-PADAP produce no colour change, which shows that the anionic surfactant is indispensable in the colour reaction.

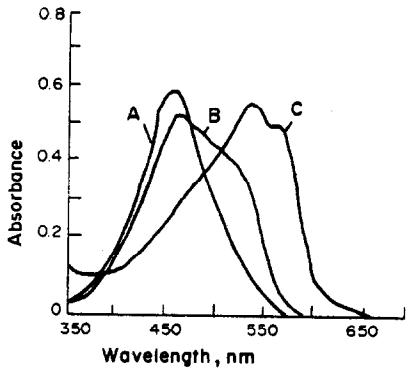

Fig. 1. Absorption spectra. A—3,5-diBr-PADAP ($1.5 \times 10^{-5}M$). B—3,5-diBr-PADAP ($1.5 \times 10^{-5}M$)-SLS (0.08%). C—3,5-diBr-PADAP ($1.5 \times 10^{-5}M$)-SLS (0.08%)-Ag^{+} (excess). (pH 5, 1-cm cells, against water).

Effect of pH

Because 3,5-diBr-PADAP produces colour reactions with a number of common metal ions, it was necessary to find a suitable masking agent and an optimum pH-value for the colour reaction of silver and 3,5-diBr-PADAP to be usable for practical determinations. Hence the colour reaction characteristics of silver and 3,5-diBr-PADAP at various pH-values in the presence and absence of EDTA were studied. It was found that the absorbance of the silver complex in the absence of EDTA remains constant at pH 3–9, but it decreases to different extents after addition of EDTA. Fortunately, at pH 5 and in the presence of EDTA, the absorbance of the silver complex remains essentially the same as in the absence of EDTA, while the absorbance of the reagent blank is lower. Hence pH 5 and EDTA as masking agent are chosen for the determination of silver.

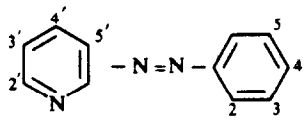
Effect of reagent concentration

The chosen final concentrations of the reagents ($3.5–4.5 \times 10^{-5}M$ 3,5-diBr-PADAP, 0.05–0.1% SLS, 0–0.01M EDTA and 0–1% potassium citrate) are those giving maximum absorbance.

Effect of time and temperature

The colour stability was studied at 25° by measuring the absorbance at regular time intervals. Maximum absorbance was attained after 2 min in the absence of EDTA, or after 15 min in its presence, and then remained constant in both cases for at least 6 hr.

Table 1. Reaction characteristics of silver with some pyridylazo compounds in the presence of sodium lauryl sulphate

Reagent*	pH	Reagent λ_{max}, *nm*	Complex λ_{max}, *nm*	Wavelength for measurement, against reagent blank, *nm*	Molar absorptivity, 10^4.l.mole^{-1}.cm^{-1}
					


I 3-Cl,2-NH_2,4-$N(CH_3)_2$	10	470	500	530	6.7
II 3′-Cl,2,4-diamino,5-CH_3	7	470	520	520	3.9
III 3′,5′-dibromo,2,4-diamino	10	495	500	530	2.5
IV 3′,5′-dibromo,2-OH,4-$N(C_2H_5)_2$	5	460	530	570	7.7
V 3′-Cl,2-OH,4-$N(C_2H_5)_2$	5	442	545	547	5.0
VI 3′-Br,2-OH,4-$N(C_2H_5)_2$	5	490	549	560	5.3

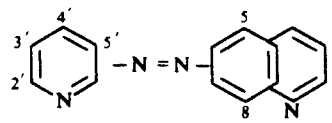
VIII 3′Cl,4,5-diamino	11	540	580	620	2.0
IX 3′-Cl,2-NH_2,6-SO_3H	6–11	No colour reaction			
X 3′-Cl,2-OH,3,6-di-SO_3H	4–9.5	No colour reaction			
					


XI 3′-Cl,8-OH	7.5	450	510	510	1.1
XII 3′-Cl,5-SO_3H,8-OH	4–9.5	No colour reaction			

* The syntheses of the reagents except No. IV (3,5-diBr-PADAP) will be published elsewhere.

The absorbance of the silver complex varies with temperature; raising the temperature decreases the absorbance and *vice versa*, but the measured absorbance is always the same at the same temperature irrespective of whether the solution has been heated or cooled to that temperature. It seems likely that the decrease in absorbance with increase in temperature arises from dissociation of the complex. Therefore, all absorbance measurements should be made, as far as possible, at the same temperature.

Beer's law

Under the optimized conditions established, a linear calibration graph was obtained for 0.1–1.0 ppm of silver. The apparent molar absorptivity was found to be 7.7×10^4 l.mole^{-1}.cm^{-1} at 570 nm.

Composition of the complex

The nature of the complex was investigated by the continuous variation and molar-ratio methods at a definite SLS concentration. The molar ratio of silver to 3,5-diBr-PADAP in the complex was found to be 1:2.

Effect of diverse ions

The selectivity of the method was investigated by the determination of 0.5 ppm of silver in the presence of a number of other ions. An ion was considered to interfere if the absorbance obtained differed by more than $\pm 2\%$ from that for silver alone. The following ions, added as nitrate or sulphate, cause no interference at the M:Ag weight ratio given: Al(III) $\leqslant$ 400, Bi(III) $\leqslant$ 100, Cd(II) $\leqslant$ 200, Cu(II) $\leqslant$ 200, Co(II) $\leqslant$ 20, Cr(III) $\leqslant$ 50, Pb(II) $\leqslant$ 200, Cr(VI) $\leqslant$ 10, Fe(II) $\leqslant$ 100, Fe(III) $\leqslant$ 200, Ni(II) $\leqslant$ 100, La(III) $\leqslant$ 200, Y(III) $\leqslant$ 200, Mn(II) $\leqslant$ 200, Hg(II) $\leqslant$ 200, V(V) $\leqslant$ 100, Th(IV) $\leqslant$ 100, W(VI) $\leqslant$ 100, Zn(II) $\leqslant$ 400, In(III) $\leqslant$ 20, Ca(II) $\leqslant$ 500, Sr(II) $\leqslant$ 200, Ba(II) $\leqslant$ 100, Mg(II) $\leqslant$ 400 and alkali metals $\geqslant$ 1000. Among anions, phosphate, acetate, fluoride, perchlorate, carbonate, sulphate, nitrite, hexametaphosphate and oxalate (added as the alkali metal salts) do not interfere even when their weight is at least 400 times that of silver, but chloride, iodide, bromide, cyanide, thiocyanate and thiosulphate interfere seriously.

Reactions of 3,5-diBr-PADAP with some other metal ions

With many metal ions, 3,5-diBr-PADAP forms coloured products which are extractable into organic solvents. We expected that other ions besides silver could also form water-soluble complexes in the presence of anionic surfactant and 3,5-diBr-PADAP, and this proved to be so. The characteristics of some of these metal complexes are summarized in Table 2. We expect that these reactions may be used for spectrophotometric determinations without extraction, and we are continuing these studies.

Application

The proposed method has been applied to the determination of silver in the waste-water from photographic film factories. By fuming the sample with nitric and sulphuric acids, interfering substances such as chloride, bromide, thiosulphate, organic compounds, *etc.* can be driven off.

Procedure

Take a sample containing less than 25 μg of silver in ~20 ml in a 50-ml beaker. Add 5 drops of 30% hydrogen peroxide, 1 ml of nitric acid (1 + 1) and 1 ml of sulphuric acid (1 + 1). Evaporate to fuming, and heat for 2–3 min more. Cool to room temperature, add 1 ml of nitric acid (1 + 1) and carefully rinse the beaker wall with about 5 ml of water. Warm the solution to dissolve any residue, and then transfer into a 25-ml standard flask. Add 1 ml of 5% potassium citrate solution, 1 drop of phenophthalein indicator solution, and then 4*M* sodium hydroxide dropwise until the solution turns red, then nitric acid (1 + 5) dropwise to discharge the colour. Finally, add 2 ml of pH-5 buffer, 1 ml of 0.1*M* EDTA, 2 ml of 1%

Table 2. Reaction characteristics of some metals with 3,5-diBr-PADAP in the presence of sodium lauryl sulphate

Metal	pH	λ_{max} (against water), *nm*		Wavelength of measurement (against reagent blank), *nm*	Molar absorptivity, 10^4 *l.mole*$^{-1}$.*cm*$^{-1}$
Ni(II)	5	530	575	575	1.2
Cu(II)	5	530	580	580	1.0

Pb(II)	8	580		580	0.6
Y(III)	8.5	570	600	570	0.82
In(III)	5	550	580	580	0.92

Table 3. Comparison of analytical results for samples

Sample	AAS method, *ppm*	Proposed method, *ppm*
1	0.40	0.39
2	0.75	0.79
3	0.86	0.84
4	1.7	1.56
5	5.2	4.98

SLS solution and 2 ml of $5 \times 10^{-4}M$ 3,5-diBr-PADAP in ethanol, and dilute to the mark with water. Mix and let stand for 20 min at room temperature. Measure the absorbance at 570 nm in a 1.0-cm cell, against a reagent blank prepared by adding 2 drops of 7% sodium thiosulphate solution to the rest of the test solution and mixing to discharge the colour.

Prepare the calibration curve by taking a series of 20-ml portions of water to which 1, 5, 10, 15, 20 and 25 μg of silver (as standard solution) have been added, and treat according to the method above.

Results

Recovery studies were performed with different amounts of silver, and the recoveries were found to be >90%.

The analytical results obtained by the recommended method agreed well with those from atomic-absorption spectrophotometry (Table 3).

Eight replicate portions of a waste-water sample containing silver were analysed individually by the recommended procedure and gave an average value of 0.77 ppm with a standard deviation of 0.02 ppm.

Acknowledgement—The authors wish to thank Professor Shu-Chuan Liang, Institute of Chemistry, Academia Sinica, Peking, for his valuable advice and generous help.

SELECTION OF THE COUNTER-CATION IN THE SOLVENT EXTRACTION OF ANIONIC CHELATES: SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF COBALT WITH 2-NITROSO-1-NAPHTHOL-4-SULPHONIC ACID AND TETRABUTYLAMMONIUM ION

SHOJI MOTOMIZU and KYOJI TÔEI

(*Received* 20 *February* 1981. *Accepted* 31 *July* 1981)

Summary—The importance of selecting the most suitable counter-cation in the solvent extraction–spectrophotometric determination of an anionic metal chelate containing a sulphonic acid group is demonstrated and discussed. In the case of cobalt and 2-nitroso-1-naphthol-4-sulphonic acid (nitroso-NW acid), the most suitable counter-cation is the tetrabutylammonium ion (Bu_4N^+): in this case only the ion-pair of the anionic cobalt chelate is extracted into chloroform and the excess of the nitroso-NW acid remains in the aqueous phase. The absorption maximum of the chelate in chloroform is at 307 nm, at which the molar absorptivity is 6.5×10^4 l.mole^{-1}.cm^{-1}. The absorbance of the reagent blank at 307 nm is less than 0.010. By use of nitroso-NW acid and Bu_4N^+, trace amounts of cobalt may be determined in nickel salts and in iron and steel samples.

Many studies of solvent extraction with long-chain amines or quaternary ammonium salts have been made since Ziegler *et al.* reported the extraction of an anionic chelate of iron(III) and 7-iodo-8-hydroxyquinoline-5-sulphonic acid with tributylammonium ion into amyl alcohol.[1] In almost all of the studies reported to date, preference has been shown for counter-cations which are also extractable, as a result of which the excess of reagent is extracted. In spectrophotometric methods the reagent blank will then be larger if there is appreciable overlap of the absorption spectra of the species extracted. The sensitivity and precision will suffer accordingly.

Ishibashi and Kohara studied the extraction of cobalt with nitroso-NW acid and Amberlite LA-2 into toluene.[2] The absorbance was measured at 530 nm, at which the molar absorptivity was low: 1.76×10^4 l.mole^{-1}.cm^{-1}. Adam and Přibil studied the extraction of cobalt with nitroso-R acid and trioctylmethylammonium chloride into chloroform.[3] The absorbance in this case was measured at 500 nm. In these methods, as the excess of reagent was co-extracted with the chelate, it was impossible to measure the absorbance at the wavelength of maximum absorption of the chelate, where the absorbance of the reagent blank was very large, and the absorbance measurements were seriously disturbed by the co-extracted anions.[3]

In this work, several extraction equilibrium constants have been determined, and conditions have been found for the selective extraction of the anionic chelate of cobalt(II) and 2-nitroso-1-naphthol-4-sulphonic acid (nitroso-NW acid). A highly sensitive spectrophotometric method for cobalt has been developed and applied to the determination of cobalt in practical samples.

EXPERIMENTAL

Apparatus

A Shimadzu UV 300 recording spectrophotometer and a Shimadzu QV-50 spectrophotometer were used with 10-mm quartz cells.

Reagents

2-Nitroso-1-naphthol-4-sulphonic acid. The reagent was obtained by nitrosation of the parent compound in aqueous solution with sodium nitrite.[4,5] The crude nitroso compound was recrystallized twice from dilute hydrochloric acid solution. Aqueous solutions were used.

Cobalt(II) solution. Solutions of cobalt chloride hexahydrate were standardized by EDTA titration.

Quaternary ammonium, tetraphenylarsonium and tetraphenylphosphonium chloride solutions. Commercially available salts were dried under reduced pressure (about 5 mmHg) and at 50–60° to constant weight, and were dissolved in distilled water.

Buffer solutions. Phosphate buffer solution (0.5*M*, pH = 8) and trisodium citrate solution (2*M* or 1.5*M*) were used.

Wash solution. Ammonium sulphate (0.05*M*)—ammonia (0.1*M*) buffer solution containing 0.002*M* EDTA.

Chloroform. Used without further purification, and saturated with water by shaking with water before use.

All reagents used, except nitroso-NW acid, were of analytical reagent grade.

Table 1. Extraction constants (log K_{ex}) for the ion-association complexes

General procedure

A 50-ml portion of the aqueous solution of quaternary ammonium, tetraphenylarsonium or tetraphenylphosphonium chloride ($C^+.Cl^-$, $10^{-4}M$) was transferred to a separatory funnel and the solution of the sodium salt of the anion (A^-) was added in 10–100-fold molar excess with respect to the $C^+.Cl^-$. This solution was shaken with 50 ml of chloroform. The separated organic phase was shaken with a fresh solution of anion, A^-, containing a 10–100-fold molar excess of the cation (C^+). Then 5-ml portions of the organic phase and of an aqueous solution containing various amounts of the anion (A^-) were shaken in 25-ml stoppered test-tubes for about 30 min to ensure extraction equilibrium was reached. After phase separation, the concentrations of quaternary ammonium, tetraphenylarsonium, or tetraphenylphosphonium salt in the organic and in the aqueous phases were determined with potassium tetrabromophenolphthalein ethyl ester according to Tsubouchi.[6]

From the concentrations of C^+ in the aqueous and organic phases, the distribution ratio was calculated, the values of D^{-1} were plotted against the values of $[A^-]^{-1}$, and values of K_{ex} were calculated from the slopes. The results obtained for several cations and univalent anions are shown in Table 1.

RESULTS

Determination of the extraction constants of univalent–univalent ion-pairs

An extraction system in which a univalent cation (C^+) and a univalent anion (A^-) form only one kind of ion-pair (C^+A^-) in the aqueous phase, and in which the extracted ion-pair does not dissociate or aggregate, involves the following equilibria:

$$C^+ + A^- \rightleftharpoons C^+.A^-; \quad K_A = [C^+.A^-]/[C^+][A^-] \tag{1}$$

$$C^+.A^- \rightleftharpoons (C^+.A^-)_{org}; \quad K_D = [C^+.A^-]_{org}/[C^+.A^-] \tag{2}$$

where the subscript org refers to the organic phase, and absence of a subscript indicates the aqueous phase.

The distribution ratio (D) of C^+ between the aqueous and organic phases, and the extraction constant (K_{ex}) refer to

$$D = [C^+.A^-]_{org}/([C^+] + [C^+.A^-]) \tag{3}$$

$$K_{ex} = [C^+.A^-]_{org}/[C^+][A^-] = K_D K_A \tag{4}$$

From equations (1)–(4), the following equation can be derived:

$$D^{-1} = K_D^{-1} + (K_{ex}[A^-])^{-1}. \tag{5}$$

Plots of D^{-1} against $[A^-]^{-1}$ should be linear; from the intercept on the y-axis and the slope, K_D and K_{ex} can be calculated.

In the general case, for formation and extraction of a single species $C_n^+.A^{n-}$, we can write

$$K_{form} = [C_n^+.A^{n-}]/[C^+]^n[A^{n-}] \tag{6}$$

$$K_D = [C_n^+.A^{n-}]_0/[C_n^+.A^{n-}] \tag{7}$$

$$D = n[C_n^+.A^{n-}]_0/([C^+] + n[C_n^+.A^{n-}]) \tag{8}$$

$$K_{ex} = [C_n^+.A^{n-}]_0/[C^+]^n[A^{n-}] = K_{form}.K_D \tag{9}$$

$$\frac{1}{D} = \frac{1}{K_D} + \frac{1}{nK_{ex}[C^+]^{n-1}[A^{n-}]}. \tag{10}$$

Equation (10) is rather intractable from a practical point of view, but from equation (9) we can deduce

$$\log[C^+] = \frac{1}{n}\log\frac{[C_n^+.A^{n-}]_0}{[A^{n-}]} - \frac{1}{n}\log K_{ex} \tag{11}$$

Hence when the total concentrations of the anion species in the two phases are equal, $\log[C^+]$ is equal to $1/n \log K_{ex}$ (Table 2). In a practical sense, it is useful to compare the values of $1/n \log K_{ex}$ for the various systems, as shown in Fig. 1.

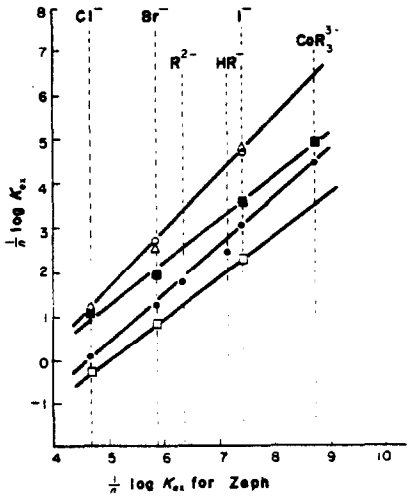

Fig. 1. Plots of $1/n \log K_{ex}$ for different cations against $1/n \log K_{ex}$ for the tetradecyldimethylbenzylammonium cation (Zeph). Cations: (○) tetraphenylarsonium; (△) tetraphenylphosphonium; (■) dodecyltrimethylammonium; (●) tetrabutylammonium; (□) decyltrimethylammonium; solvent, chloroform.

$DeTMA^+$	3.5	1.3	2.0	4×10^{-3}
Bu_4N^+	4.5 (4.4)	1.9 (1.7)	2.7 (2.5)	6×10^{-4} (8×10^{-4})

The log K_{ex} values in parentheses are those determined experimentally.

Determination of the extraction constants for a univalent cation and multivalent anion association complex

Constants for the complexes with multivalent anions could not be determined by using equation (5). Accordingly, log K_{ex} was evaluated for R^{2-} and the cobalt complex anion (CoR_3^{3-}) by assuming that the concentration of the ion-association complex in the aqueous phase was negligibly small compared with the total concentrations of the reactants in the aqueous phase and that the species extracted into chloroform did not dissociate. The results obtained for tetradecyldimethylbenzylammonium (zephiramine; $Zeph^+$), dodecyltrimethylammonium and tetrabutylammonium ions are also shown in Table 1.

Selection of the most suitable cation for extracting the anionic chelate

The values of $1/n \log K_{ex}$ were plotted against the corresponding values for the zephiramine systems, as shown in Fig. 1. The points for a given counter-ion lie on a straight line, from which the extraction constants for other anions can be calculated if the corresponding constants for the zephiramine complexes are known.

The slopes of the plots for the tetraphenylarsonium and tetraphenylphosphonium systems were the highest and those for the dodecyltrimethylammonium and decyltrimethylammonium systems were the lowest. In Table 2, the estimated log K_{ex} values are shown. In Fig. 2, the curve of per cent extraction for the anionic cobalt chelate and for the chelating agent (R^{2-} and HR^-) against log $[C^+]$, calculated from log K_{ex}, are shown for the case of the tetraphenylarsonium cation. In Fig. 2, a value on the abscissa, at which the per cent extraction of the anion is 50%, corresponds to the value of $(\log K_{ex})/n$. It can be seen that the nitroso-NW acid in the R^{2-} form is less easily extracted than HR^- or the anionic complex. The optimal concentration of the counter-cation, at which as much of the chelate anion as possible and as little of the reagent as possible are extracted into the organic phase is intermediate between the values of $\frac{1}{3}\log K_{ex(CoR_3^{3-})}$ and $\frac{1}{2}\log K_{ex(R^{2-})}$, is shown in Table 2.

This difference between $\frac{1}{3}\log K_{ex(CoR_3^{3-})}$ and $\frac{1}{2}\log K_{ex(R^{2-})}$ was greatest for the tetraphenylarsonium and tetraphenylphosphonium cations, which should therefore give the most efficient extraction of the anionic chelate coupled with minimum co-extraction of the chelating agent, R^{2-}. However, as the extractability of

the tetraphenylarsonium and tetraphenylphosphonium ions is very large, the optimal concentration must be very low and is about $10^{-5}M$, as shown in Table 2, which is the same order as that of the anionic chelate. From a practical point of view it is not convenient to work with too low a concentration of the counter-cation.

The tetrabutylammonium cation shows a relatively large difference between $\frac{1}{3}$ log $K_{ex(CoR_3^{3-})}$ and $\frac{1}{2}$ log $K_{ex(R^{2-})}$. Figure 3 shows the variation in extraction (as %) for the anionic cobalt chelate and the chelating agent (R^{2-}), for the case where tetrabutylammonium ion is the counter-cation. As expected from Table 2 and can be seen in Fig. 3, when the extraction is carried out in the presence of the tetrabutylammonium ion at a concentration of about $10^{-3}M$, the anionic cobalt chelate can be extracted completely into chloroform, while the excess of the chelating agent in the form of R^{2-} is not extracted at all. Tetrabutylammonium ion is therefore recommended as the most useful counter-cation for this extraction of cobalt.

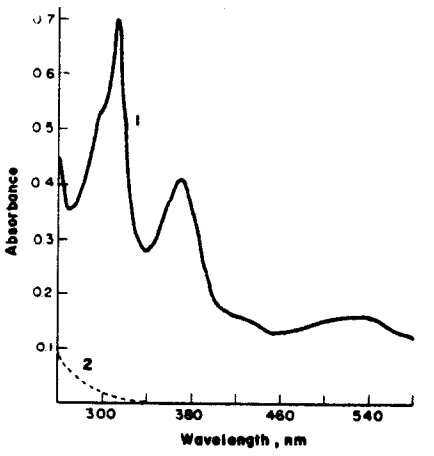

Fig. 4. Absorption spectra of the tetrabutylammonium ion-association complex of the cobalt–nitroso-NW acid anionic species, in chloroform.

Nitroso-NW acid, $2 \times 10^{-4}M$; tetrabutylammonium chloride, $10^{-3}M$; (1) [cobalt] = $1 \times 10^{-5}M$; (2) reagent blank; chloroform reference; pH = 8.6.

Solvent extraction–spectrophotometric determination of cobalt with nitroso-NW acid and tetrabutylammonium ion (Bu_4N^+)

Procedure. Pipette up to 5 ml of sample solution into a stoppered test-tube, and dilute to 5 ml with distilled water. Add 1 ml of trisodium citrate solution (2*M*) or 1.5 ml of 1.5*M* solution. Add 1 ml of nitroso-NW acid solution ($2 \times 10^{-2}M$), mix and allow to stand for 10 min. Add 1 ml of sulphuric acid (1 + 2) and 0.5 ml of $Bu_4N^+.Cl^-$ solution (0.01*M*). Shake with 5 ml of chloroform for 10 min. Discard the aqueous phase, and shake the organic phase with 5 ml of washing solution for about 5 min. After the phases have separated, measure the absorbance of the organic phase at 307 nm.

Absorption spectra and calibration graph. Figure 4 shows the absorption spectra for the cobalt complex and for the reagent blank. The linear range for the calibration plots was 0–$1.5 \times 10^{-5}M$ and the molar absorptivity was 6.5×10^4 l.mole^{-1}.cm^{-1} at 307 nm, with the absorbance of the reagent blank being about 0.003.

Effect of other ions. Nitroso-NW acid also reacts with iron(II), iron(III), copper and nickel ions to form coloured complexes which are extracted to some extent into chloroform with Bu_4N^+ and thus cause positive errors. It was for this reason that citrate buffer is used, since it also acts as a complexing agent.

The calibration graph is linear and nickel, copper(II) and iron(III) at concentrations of 0.02*M* do not interfere. As shown in Table 3, other metal and non-metal ions commonly present in practical samples do not interfere.

Determination of cobalt in pure nickel salts. Trace amounts of cobalt in commercially available nickel salts were determined. The nickel salts were dissolved in distilled water and portions of the sample solutions were used. The results obtained are shown in Table 4. The recovery tests were also good.

Determination of cobalt in iron and steel samples. Micro amounts of cobalt in standard iron and steel samples were determined by the following procedure.

Weigh accurately about 0.1 g of the iron or steel sample and dissolved it in 5 ml of hydrochloric acid

(1 + 2) and 4 ml of hydrogen peroxide (about 30%). Evaporate the resulting solution to about 1 ml and add 0.5 ml of sulphuric acid (1 + 2), then dilute with distilled water to 100 ml. Take a suitable size of aliquot for the cobalt determination.

The results obtained for some standard steels are shown in Table 5. The cobalt contents obtained by the recommended procedure are all in good agreement with the certificate values for cobalt.

DISCUSSION

Many studies have been carried out on the solvent extraction of anionic chelates. In such extraction systems, long-chain amines or alkyl ammonium ions have usually been preferred, though these compounds do not necessarily give the best results. The most undesirable effect is the increase in the reagent blank owing to the co-extraction of the excess of the reagent, which often leads to disadvantages in the spectrophotometric analysis as follows: (1) interference from other anions such as halogen ions is more likely, and (2) the absorbance of the reagent blank becomes rather large. This study has shown that by using a suitable counter-cation it is possible to extract only the anionic chelate into the organic phase, and thus to overcome the two problems just mentioned.

In the proposed solvent extraction–spectrophotometric determination of cobalt with nitroso-NW acid, the tetrabutylammonium ion was found to be the most useful counter-cation. As it extracts very little of the excess of nitroso-NW acid into chloroform, and the measurement can be made at the maximum absorption wavelength (307 nm). As the reagent blank at this optimum wavelength is very small, long-path cells (10 cm) can also be used, giving a ten-fold increase in sensitivity. In such cases, cobalt at concentrations of 0–1.5 × $10^{-6}M$ could be determined.

By using the method recommended in this study, it is possible to determine trace amounts of cobalt in nickel salts and in samples of iron and steel.

As discussed in this study, the selection of the most suitable counter-cation is very important in such solvent extraction–spectrophotometric determinations, and in some of the extraction systems studied earlier the most suitable counter-cation may not always have been chosen.

Department of Chemistry, University of Delhi, Delhi-110007, India

(*Received* 3 *July* 1979. *Revised* 15 *June* 1981. *Accepted* 6 *July* 1981)

Summary—Analytical aspects of the chemistry of substituted pyrimidines are reviewed.

Pyrimidine can be considered as derived from pyridine. It is a weaker base (pK_a 1.3) than the related compounds pyridazine, pyridine and imidazole. Considering the distribution of π-electron densities and the resonance hybrids representing the pyrimidine and pyridine molecules, it is inferred that the C_5 position of pyrimidine should correspond to C_3 in pyridine and be the most susceptible to electrophilic attack. Similarly, positions 2, 4 and 6 in pyrimidine should correspond to 2 and 4 in pyridine. Substituents at these positions should have comparable reactivities.[1]

Pyrimidine (pK_a 1.3)

Pyridazine (pK_a 2.33)

Pyridine (pK_a 5.23)

Imidazole (pK_a 7.2)

Pyrimidine derivatives and compounds in which the pyrimidine ring is a part of a more complex system were amongst the first compounds to be synthesized. They are vital compounds, widely distributed in living organisms. The chemistry[2–8] and the biochemical aspects[9–14] of the pyrimidines have been extensively reviewed. Recently, the stereochemistry of metal–pyrimidine complexes has also been reviewed.[15] The compounds have long been extensively used for analytical work, and these aspects are reviewed in this article, together with methods for analysis of the compounds themselves.

Barbituric acids

Their determination and applications have been reviewed.[16] The electrochemical methods are more sensitive than colorimetric and titrimetric methods for their determination. Differential pulse polarography has been used for determination of phenobarbital in blood (detection limit 0.1 μg/ml),[17] and traces of barbituric and 2-thiobarbituric acids,[18] and polarography for phenobarbital and methyl phenobarbital in human plasma (detection limit 3.5–5.5 μg/ml).[19] Diallyl and isopropyl barbituric acids can be potentiometrically titrated,[20] by using bromination reactions, the titrant being lead tetra-acetate in presence of excess of bromide. Phenobarbital, amobarbital, barbital, allyl isobutyl barbituric acid, pentobarbital and secobarbital can be determined by differentiating nonaqueous titration in methyl isobutyl ketone with sodium methoxide in benzene–methanol mixture.[21]

Phenobarbital, amobarbital and secobarbital have been similarly determined in tetramethylurea[22] and sulpholane[23] media with tetrabutylammonium hydroxide, the recovery for 0.1–0.3 mmole of compound being 97.5–104.4% and 99–101%, respectively. In 3-methyloxazolidin-2-one medium, barbitone, amylobarbitone and quinalbarbitone can also be titrated.[24] Barbituric acid in acetic acid medium can be titrated[25] potentiometrically with mercury(I) acetate. A conductometric method for the determination of alo-, amo- and phenobarbital in pharmaceuticals has been reported.[26] Barbituric acid derivatives can be determined amperometrically[27] and coulometrically[28] in aqueous and water–acetone media. Sodium barbiturate has been used to give a colour reaction with the product of reaction between chloramine-T and cyanide or thiocyanate.[29] 2-Thiobarbituric acid has been used for amperometric titration of copper.[30]

Violuric acids

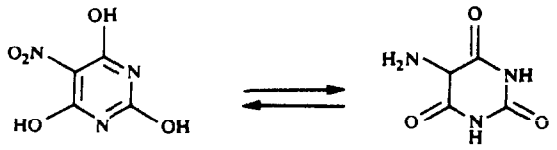
Applications of violuric acids as analytical reagents have been reviewed by Singh *et al.*[31] Little work of analytical interest has since been reported.

Dilituric acids

Dilituric acid was first prepared in 1845.[32] Many of its salts were examined[32,33] but up to 1940 almost no work except its examination as a precipitant for or-

* To whom correspondence should be addressed.

ganic and inorganic bases[34] was reported.



Dilituric acid (5-nitrobarbituric acid)

The nearly white crystalline acid gives a yellow solution in water (λ_{max} at 218 and 318 nm, shoulder at 237 nm). The peaks at 218 and 318 nm have been attributed to primary and secondary ionization of the acid respectively.[35] The acid decomposes explosively at about 185° on heating.[35] The optical properties of the dilituratcs of primary and secondary amines and amino-acids have been utilized for identification of these compounds;[36–38] alkaloids have been similarly characterized.[39] Dilituric acid has been used for gravimetric determination of potassium[40,41] and indirect colorimetric determination of potassium[42,43] and of magnesium[44] from the absorbance of the residual dilituric acid after precipitation of the cation.

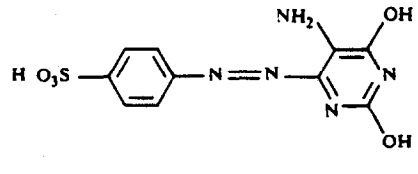
Copper, nickel, cadmium and cobalt have been determined gravimetrically[45] and lead, potassium and magnesium thermogravimetrically.[46] The dilituratcs of the alkali metals,[47] silver, lead, thorium and manganese[48] have also been examined thermogravimetrically. Their thermal stability is adequate for gravimetric determinations but the lithium, sodium and silver salts are too soluble for gravimetric purposes. The other metals can be determined with an average deviation of 0.5%. Rubidium and caesium can be determined by X-ray fluorescence.[49] The solubilities and thermolysis curves of ethylenediamine, polymethylenediamine and quinine dilituratcs have been examined.[50] Ethylenediamine and quinine can be determined gravimetrically, but the solubilities of the polymethylenediamine dilituratcs increase with increasing number of carbon atoms in the chain. Trimethylenediamine dilituratc is an exception, however, being more soluble than expected, presumably because of the internal hydrogen-bonding possible in this polymethylenediamine.[51] The crystalline nature of these organic salt dilituratcs makes it easy to identify them by X-ray powder diffraction methods.[52]

Nutiu and co-workers[53,54] synthesized the 2-thio derivative of dilituric acid and studied its analytical potentialities. It gives precipitates with alkali and alkaline earth metals. The precipitates dissolve in alkaline medium, giving intense yellow colours. The compound is not very suitable for gravimetric determination, errors being as high as 2.5%, but the intense yellow colour of the potassium salt in alkaline medium is suitable for spectrophotometric determination at 410 or 420 nm.

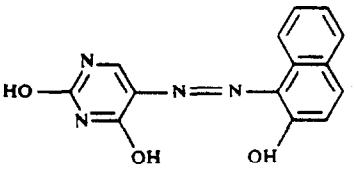
Uracils

X-Ray diffraction studies[55] have shown that the arrangement of atoms in crystalline uracil (2,4-dihydroxypyrimidine) is analogous to that in pyridone. Complexation of palladium(II) with uracil,[56,57] 2-thiouracil[57] and 6-methyl-2-thiouracil[57] has been investigated photometrically. All the complexes have maximum absorption at 380 nm and are suitable for determination of palladium in acidic medium (pH < 2.0). Platinum and gold interfere. Uracil forms a 1:1 metal:ligand complex, the other two form 1:2 complexes.[57]

5-Aminouracil forms a red complex with Ru(III) at pH 2.9–4.0 (λ_{max} 480 nm, ϵ 7.6×10^3 $l.mole^{-1}.cm^{-1}$) on heating for 1 hr on a steam-bath, and a red complex with Os(VIII) in alkaline medium, without heating.[58] Its azo-dye (I) is used as an indicator in chelatometric titrations[58] of Zn, Cd and Hg. 1-(2,4-Dihydroxy-5-pyrimidylazo)-2-naphthol (II), obtained by coupling β-naphthol with diazotized 5-aminouracil, finds use as an indicator[58] in titration of MoO_4^{2-}, WO_4^{2-} and PO_4^{3-} with lead nitrate.



(I)



(II)

5,6-Diaminouracil (λ_{max} 255–265 nm, $\epsilon = 2 \times 10^4$ $l.mole^{-1}.cm^{-1}$) has been used for the spectrophotometric determination of Ru(III) and Os(VIII)[59,60] but tolerance for other platinum metals in these determinations is poor.

6-Aminouracil can be hydrolysed by hydrochloric or *p*-toluenesulphonic acid to barbituric acid, which in turn can be condensed with Ehrlich's reagent to give a benzylidene compound. This reaction has been used to determine the uracil colorimetrically.[61]

Metal complexes of thiouracils are used for determination of the ligands. 5-Iodo-6-benzyl- and 5-butyl-6-methyl-2-thiouracil can. be potentiometrically titrated with mercury(II) acetate.[62] 2-Thiouracil, 6-methyl-2-thiouracil and 2,4-dithiouracil can be similarly determined with silver nitrate.[63]

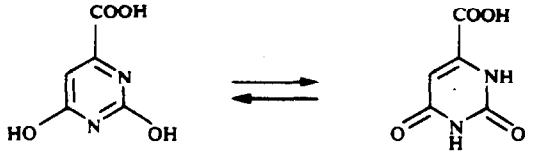
Ružička and Lyčka[64] prepared 1,3-dimethyl-5-nitroso-6-aminouracil and characterized its salts with alkali metals, Cu(II), Ag(I), Hg(I), Hg(II), Ni(II) and Pd(II). Copper and nickel were determined gravi-

metrically and polarographically. 1,3-Dimethyl-4,5-diaminouracil (DAL)[65] is a very selective and sensitive colorimetric reagent for Co(II) in alkaline medium (phosphate buffer, pH 11.2), but Fe(III), Cu(II) and Ag(I) interfere at fairly low levels.[65]

Au(III) is colorimetrically determined with 5-(*p*-ethoxyanilino)-5,6-dihydrouracil[66] at pH 6.0–6.5. The complex (λ_{max} 520 nm) is extractable into a 1:1 mixture of chloroform and toluene.

Orotic acids

Orotic acid (2,6-dihydroxypyrimidine-4-carboxylic acid, **III**) was first studied analytically by Selleri and Caldini.[67] They determined sodium and potassium gravimetrically (at pH 6.5–8.5 and 3° in ~80% methanol or ethanol medium), the reagents being the highly soluble ammonium or substituted ammonium salts of orotic acid. Potassium can be determined in presence of NH_4^+, Li^+, Cu^{2+}, alkaline earth metals, Al^{3+}, Fe^{3+} and Ni^{2+}. Babbie and Wagner[68] used *N,N*-dimethylethanolammonium orotate for the gravimetric determination of rubidium and caesium at pH 6.8. The error obtained was within ±0.5% but the precipitation mixture had to be kept in the refrigerator for 2 hr before filtration. Several substituted orotic acids (as the *N,N*-dimethylethanolammonium salts) were extensively studied[69] as potential reagents for precipitation of alkali metals, but it appeared that substitution generally results in an increase in the solubility of the alkali metal salts. However, it was found that uracil-3-acetic acid was selective for lithium, 5-ethylorotic acid for sodium and 5-methyluracil-3-acetic acid for potassium.



(III)

Orotic acid forms 1:1 complexes with copper(II) at pH 3–8,[70] with cobalt(II) at pH 6–10[71] and zinc at pH 6–9.[72] Nickel and cadmium also react. 2-Thioorotic acid has also been examined.[73,74] It reacts with 17 metals in ammoniacal medium, but with only a few at pH < 3, and gives better sensitivity than orotic acid.[73] It has been used as developing reagent in the paper chromatographic separation of metal ions present in alloys.[74] Thallium(I) can be determined amperometrically or gravimetrically[74] without interference from Cu(II), Co(II) and Ni(II).

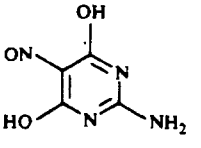
Pandey *et al.*[75–77] have examined the complexes of 2-thio-orotic acid with Ag(I), Cu(I), Ti(I), Hg(I), Zn(II), Cd(II), Hg(II), Fe(II), Co(II), Ni(II), Pd(0,II,IV), Pt(0,II,IV) and Rh(I,III).

Other pyrimidinols

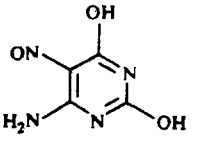
Many other types of hydroxypyrimidines (pyrimidinols) also find wide use as analytical reagents. 2,4,5-Trihydroxypyrimidine[78] (isobarbituric acid) undergoes reactions similar to those of 2,3-dihydroxypyridine[79,80] and reacts with iron(III) to form blue 1:2 (λ_{max} 590 nm, ϵ 600) and red 1:3 (λ_{max} 500 nm, ϵ 4.8×10^3) complexes at pH 2.0–4.5 and 4.6–11.0, respectively. The complexes can be used as acid–base indicators. Iron is determined spectrophotometrically as the red complex. The Ru(III)–4,5-diamino-6-pyrimidinol complex (λ_{max} 530 nm, ϵ 6.5×10^3) formed in acidic medium is suitable for spectrophotometric determination of the metal,[81] but the other platinum metals interfere and a preliminary separation is necessary. The ligand forms a highly unstable brown complex (λ_{max} 470 nm) with Os(VIII),[82] but the addition of mercury(II) perchlorate to this complex gives a pink colour (λ_{max} 500 nm; Os:Hg:ligand = 1:2:2) which can be employed to determine osmium at pH 8.5–11.0.

2,4,5-Triamino-6-pyrimidinol is used to determine Ru(III) and Os(VIII) photometrically.[83,84] It reacts with ninhydrin[85] to give a purple complex (λ_{max} 555 nm) that can be used to determine it in plants.

The complexation reactions of Fe(II), Co(II), Ru(III) and Rh(III) with 2-amino-5-nitroso-4,6-pyrimidinediol (**IV**) and 6-amino-5-nitroso-2,4-pyrimidinediol (**V**) have been studied spectrophotometrically and used in determination of these metals.[86–88] For ruthenium, reagent (**V**) is more sensitive and selective than (**IV**) but for determination of iron (**IV**) is superior.[86,87]



(IV)



(V)

4-Amino-5-nitroso-2,6-pyrimidinediol forms complexes with Fe(II), Co(II), Ru(III) and Rh(III)[88–90] and can be used as an indicator for EDTA titration of iron.[90] The cobalt complex is inert and does not decompose when the solution is made 6*N* with respect to hydrochloric, perchloric or sulphuric acid, making the reagent very selective for cobalt. Generally, nitrosopyrimidinols have been found to be more sensitive than nitrosophenols for cobalt, iron and ruthenium. 4-Amino-5-nitroso-2,6-pyrimidinediol is the most sensitive for cobalt.

Iron(II) gives a 1:4 complex with 2,6-diamino-5-nitroso-4-pyrimidinol (λ_{max} 653, ϵ 2.0×10^4) which is used for spectrophotometric determination of iron.[91]

2,4-Diamino-5-nitroso-6-pyrimidinol forms a bluish green complex (λ_{max} 650 nm) with iron(II) and is used for the photometric determination of 0.9–3.7 ppm of the metal at pH 7.0–8.5 or as indicator in the EDTA titration.[92] It is also used for spectrophotometric determination of Ru(III) and Rh(III).[59,88] This reagent and 2,6-diamino-4-pyrimidinol are fairly sensitive for nitrite detection[93] by diazotization and coupling to

azo dyes. The closely related 2,4-diamino-6-pyrimidinol has long been used for this purpose.[94]

Complexation with 2-mercapto-5-(4-methoxybenzyl)-4,6-pyrimidinediol has been used for potentiometric, conductometric and amperometric titration of gold (III) in hydrochloric acid medium.[95] 4,5-Diamino-2-mercapto-6-pyrimidinol acts as a very selective and sensitive reagent for detection and determination of osmium(VIII) in 1.0–6.0*M* sodium hydroxide.[96] The red 1:2 (Os:ligand) complex (λ_{max} 520 nm, ϵ 2.7 × 10^4) obeys Beer's law up to 8.0 ppm metal concentration. The iron and platinum group metals do not interfere. Ruthenium(III) forms a red 1:2 complex (λ_{max} 540 nm, ϵ 9.6 × 10^3) on heating at pH 2.2–3.3, which is also used for determination of the metal, but the method is not very selective. Both the Ru and Os complexes are cationic and not extractable into organic solvents. 4,5-Diamino-2-methyl-4-pyrimidinol also gives complexes with ruthenium[59] and osmium,[60] suitable for their spectrophotometric determination.

Cu(II), Fe(II), Co(II), Ni(II), Ru(III), Rh(III), Pd(II) and Os(VIII) form complexes with 4-amino-2-mercapto-5-nitroso-6-pyrimidinol, suitable for their spectrophotometric determination.[97–101] The complexes are not extractable into organic solvents, contain the metal and the ligand in 1:1–1:3 ratio and conform to Beer's law. A comparative study with 4-amino-2-methyl-5-nitroso-6-pyrimidinol shows that the thiol derivative is more sensitive (ϵ 6.1 × 10^3–4.8 × 10^4) and forms the metal complexes at higher pH. On the other hand, the methyl derivative is a more selective reagent, particularly for determination of iron.

In a recent study, the blue water-soluble Fe(II)–1,3-dimethyl-5-nitroso-2-thio-oxoperhydropyrimidine-4,6-dione complex (λ_{max} 630 nm; metal–ligand 1:3) has been found suitable for the spectrophotometric determination[102] of iron at pH 5.5–6.8. Large amounts of Cu(II) and Co(II) do not interfere. 6-Amino-2-benzylthio-5-nitroso-3,4-dihydropyrimidine[103] is also used for determination of iron(II) at pH 5–6.5.

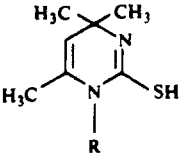
Pyrimidinethiols

Pyrimidine-2-thiol, 2,4-diaminopyrimidine-6-thiol, 2,6-diaminopyrimidine-2-thiol and 2,5-diaminopyrimidine-2,6-dithiol have been synthesized and explored for their analytical utility.[104,105] They give many useful reactions with metal ions—the most significant (sensitivity given in parentheses, ppm) are those of pyrimidine-2-thiol with Pd (1), Cu (2), Hg^+ (2), Bi (2) and Cd (10); 2,4-diaminopyrimidine-6-thiol with Pd (1) and Co (2); 2,6-diaminopyrimidine-2-thiol with Co (1) and Pd (2) and 2,5-diaminopyrimidine-2,6-dithiol with Se^{4+} (0.4) and Bi (5). The introduction of the 2-amino group does not significantly affect the reactivity, but a thiol group at C_6 has a stronger reducing character than at C_2.

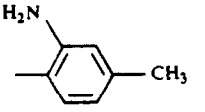
Chan[106] used 4,5-diamino-6-pyrimidinethiol for spectrophotometric determination of Se(IV) at pH 1.2–2.5 or still lower. The yellow complex formed (λ_{max} 380 nm, ϵ 1.92 × 10^4) conforms to Beer's law from 0.1 to 2.5 ppm of selenium. The absorbance is measured within 30 min of addition of the reagent to avoid precipitation of elemental selenium. Though Bi(III) and Te(IV) interfere, the presence of a 50-fold amount of transition metals does not affect the determination. The method is used to determine traces of Se in semiconductors.

Alkyl and aryl substituted 4,4,6-trimethyl-1H,4H-pyrimidine-2-thiols (**VI–XVII**)[107] react selectively with palladium(II), forming yellow complexes extractable into non-polar solvents.

(**VI**) R = H; (**VII**) R = C_2H_5; (**VIII**) R = C_3H_7;
(**IX**) R = n-C_4H_9; (**X**) = R = C_2H_5;
(**XI**) R = $C_6H_4OCH_3$ (anisyl)
(**XII**) R = *p*-$C_6H_4NO_2$; (**XIII**) R = C_6H_{11} (cyclohexyl); (**XIV**) R = $C_{10}H_7$(α-naphthyl);

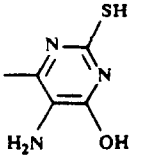


(**XV**) R =



(**XVI**) R = *p*-$C_6H_4OC_2H_5$ (phenacyl);

(**XVII**) R =



By extractive procedures, microgram amounts of Pd can be photometrically determined[108–113] in presence of milligram amounts of many metal ions, including platinum group metals.

The abovementioned pyrimidine-2-thiols except (**XV**) are also used for the spectrophotometric determination of osmium.[112–116] With the α-naphthyl derivative (**XIV**) palladium and osmium can each be determined in presence of large amounts of the other, because at acidity lower than 4*M* (hydrochloric acid)

osmium cannot be extracted with a chloroform solution of the thiol, but palladium can be completely extracted. Simultaneous determination, without prior separation of the metals, is also reported.

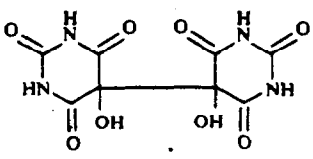
Bismuth(III) and tellurium(IV) react with the thiol (VI) forming orange-red (λ_{max} 500 nm, ϵ 1.27 × 10^4) and yellow (λ_{max} 385 nm, ϵ 1.26 × 10^4) complexes[117] respectively. The other derivatives (VII–XII) do not undergo complexation with these metals. It appears that steric effects become operative because Bi and Te are larger than Pd. The orange-red bismuth complex formed in 1.5–3.0*M* perchloric acid is extracted into chloroform and the metal determined accurately in the concentration range 4.0–14.6 ppm. The tellurium complex (not extractable) is also used in determination of 1.5–7.0 ppm of the metal in 1.8–2.5*M* perchloric acid medium.

Palladium(II) and osmium(VIII) react with 1-amino-, 1-anilino- and 1-(2',4'-dinitroanilino)-4,4,6-trimethyl-1H,4H-2-pyrimidinethiols in 1:2 metal–ligand ratio, forming coloured complexes extractable into non-polar solvents.[118] The ligands are very selective and the two metals can be determined in presence of large amounts of several ions, including Fe(III), Co(II), Ni(II), Ru(III), Rh(III), Ir(III) and Pt(IV). The anilino and 2',4'-dinitroanilino derivatives form two coloured complexes with ruthenium(III), iridium(III), rhodium(III) and platinum(IV), depending upon the acidity of the solution.[119–121] The yellow complexes formed in acidic medium (pH < 3) are anionic and may be assigned structures of the type $[ML_2Cl_2]^-$ (for the Ru, Rh and Ir-complexes) and $[MLCl_4]^-$ (for Pt), if LH represents the bidentate ligand. The extractable complexes formed at pH > 3 may be regarded as ML_3 (for Rh, Ru and Ir) and ML_2Cl_2 (for Pt). If reduction of Pt(IV) to Pt(II) occurs during the complexation with thiol, the probable structures will be $[PtLCl_2]^-$ and PtL_2 for the yellow and the extractable complex respectively. Possibilities for use of these complexes for analytical purposes have been explored.

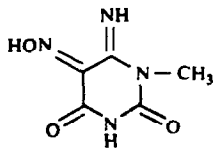
Alloxans

The reactions of alloxan (the degradation product of uric acid) with Ag(I), Hg(II), Pb(II), Fe(II) and Fe(III) were reported[122] in 1940. Alloxan was subsequently used for the colorimetric determination of thiophene[123] and identification of amino-acids[124] after their chromatographic separation. It is, however, less sensitive than ninhydrin for this purpose.

Alloxan is reduced to alloxantin (XVIII) by hydrogen sulphide. The reaction of iron(II) with alloxantin to form dihydroxydiferrodialloxantin has been used[125] to detect iron (limit of identification 1.7 μg).



(XVIII)



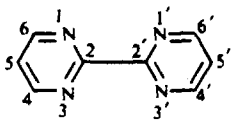
(XIX)

The ligand forms a yellow complex with molybdate[126] (λ_{max} 400 nm) at pH 3.3–3.9, which obeys Beer's law up to 25 ppm of Mo. Up to at least a 10-fold amount of tungstate, 40-fold amount of Zn(II), Co(II) or Ni(II) and 20-fold amount of Mn(II) will not interfere, but Cr(III), oxalate, tartrate, citrate and vanadate should be absent. The thiosemicarbazone of alloxan has also been prepared and used[127] for the detection of Cu(II), Cu(I), Ag(I), Hg(II) and Ni(II).

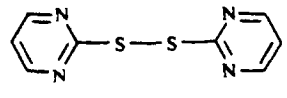
1,3-Dimethyl-4-imino-5-oximino alloxan (XIX) finds use as a reagent for spectrophotometric determination of copper[129] (λ_{max} 382 nm, 1:1 complex at pH 7–9.5) and gravimetric determination of palladium.[129] Fe(II), Co(II), Ni(II) and Pd(II) interfere in the copper determination. The red palladium complex is precipitated quantitatively at pH 1–3 and dried at 100–110°. It may be dissolved in formamide and the metal determined colorimetrically. Cu(II), Au(III), Co(II), Ni(II), Os(VIII), Ir(IV) and Pt(IV) interfere.

Bipyrimidines

Bly and Mellon prepared[130] 2,2'-bipyrimidine (m.p. 113–115°, p*K* 0.6) and studied[131] its complexation reactions with 30 metals, those with Cu(I) and Fe(II) being particularly useful. The absorption characteristics of the Fe(II)-complex (λ_{max} 490 nm, ϵ 5.0 × 10^3, stability constant 3.4 × 10^7) are similar to those of Fe(II) complexes with 2,2'-bipyridyl and 1,10-phenanthroline. The complex is insensitive to pH in the range 2–6, contains metal and the ligand in 1:3 ratio (dominant species) and conforms to Beer's law from 1 to 10 ppm of iron. Many ions, but not Cu(I), do not interfere.

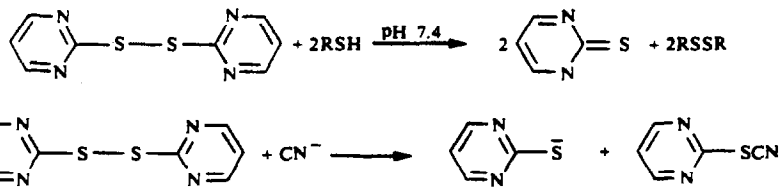


Bipyrimidine



Dithiodipyrimidine

2,2'-Dithiodipyrimidine is used to determine the thiol group[132] and cyanide ion[133] on the basis of the reactions:



The absorbance of the thiol is measured photometrically and related to the concentration of RSH or CN^-.

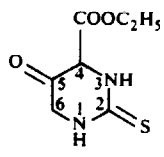
Other substituted pyrimidines

The complexation of Fe(II), Co(II), Ru(III) and Ir(III) with 5-nitroso-2,4,6-triaminopyrimidine has been studied.[134] The ligand is particularly useful for sensitive determination of ruthenium without interference from 10-fold amounts of other platinum metals. 2,4,5,6-Tetra-aminopyrimidine is also used for ruthenium and osmium determination.[135]

2-Amino-6-methylthio-4-pyrimidine carboxylic acid and 6-methoxy-2-methylthio-4-pyrimidine carboxylic acid[136] have been used for photometric determination of Ag(I)[137] and Mn(VII),[138] respectively. The silver complex (λ_{max} 375 nm, ϵ 2.09 × 10^3), obeys Beer's law up to 5 × $10^{-4}M$ Ag. However, many cations partially destroy the complex or are precipitated and adsorb the colour. The manganese determination is based on reduction of permanganate to green manganate (in alkaline medium) by 6-methoxy-2-methylthiopyrimidine-6-carboxylic acid, and measurement of the absorbance of the Mn(VI) at 580 nm (ϵ 1.48 × 10^3). Metal ions do not interfere unless they precipitate as hydroxides and adsorb some of the manganese.

The fluorescence intensity of 4,6-bis(methylthio)-5-aminopyrimidine decreases in proportion to the amount of osmium tetroxide added to it.[139] At liquid-nitrogen temperature, as little as 10 ng of OsO_4 per ml can be detected. The intensity is not affected by variation in pH from 3 to 12. In determination of OsO_4 at the 1-ppm level, 10 ppm of Ir(III), 1 ppm of Fe(III) and 1 ppm of Pd(II) do not interfere. The metal:ligand ratio is 2:3. The decrease in fluorescence is attributed to complexation, with the first site of reaction at the NH_2 group.

Sheppard and Brigham[140] have synthesized 2-thio-5-keto-4-carbethoxy-1,3-dihydropyrimidine (**XX**) and its metal complexation reactions have been investigated.[140,141] The reagent is suitable for silver(I) in acidic medium (detection limit 1 part in 10^6) and employed in its colorimetric determination.[141] For 20 μg of Ag(I), the tolerance limits (in mg) for other metals are: 2.0 for Fe(III); 1.5 for Zn(II), Cu(II), Pb(II), Mn(II) and Ni(II); 1.0 for Cd(II); 0.5 for Co(II).



(XX)

Conclusions

In general, this class of reagents tends to be versatile in the sense of a wide range of application, but to suffer from a lack of selectivity in many of the uses. A few of the reagents, however, do show considerable promise.

EXTRACTIVE SPECTROPHOTOMETRIC DETERMINATION OF NON-IONIC SURFACTANTS IN WATER

KYOJI TÔEI, SHOJI MOTOMIZU and TÔRU UMANO

Department of Chemistry, Faculty of Science, Okayama University, Tsushima-naka 3-1-1, Okayama 700, Japan

(*Received* 3 *March* 1981. *Accepted* 3 *July* 1981)

Summary—The solvent extraction of non-ionic surfactants with potassium chloride and tetrabromophenolphthalein ethyl ester potassium salt has been studied, and a method developed for determining trace amounts of non-ionic surfactants in water spectrophotometrically. Various non-ionic surfactants of general type $RO(CH_2CH_2O)_nH$ (where R is an alkyl or alkylphenyl group and n is the number-average degree of polymerization) are extracted quantitatively into *o*-dichlorobenzene from the water sample, and reacted in the organic phase with tetrabromophenolphthalein ethyl ester potassium salt to give a coloured product, the absorbance of which is measured at 620 nm.

Non-ionic surfactants, $RO(CH_2CH_2O)_nH$ are widely used in industrial and domestic detergents and it is increasingly necessary to determine these surfactants in water. This can be done at trace levels with potassium picrate as reagent and 1,2-dichloroethane as extracting solvent.[1,2] The reaction is based on coordination of the polyether chain to the potassium cation, in much the same way as potassium ions form complexes with crown ethers.[3] The complexed potassium ion is extracted as its ion-pair with picrate, which is the anionic chromophore measured in the spectrophotometric determination.

In our investigation tetrabromophenolphthalein ethyl ester potassium salt (TBPE-K) was used instead of potassium picrate to improve the extractability and sensitivity. The molar absorptivity of the TBPE complex was 5–6 times that of the picrate complex.

EXPERIMENTAL

Apparatus

A Hitachi Perkin–Elmer model 139 spectrophotometer and a Hitachi EPS-3T recording spectrophotometer were used, with glass cells of 10 mm path-length.

Reagents

Tetrabromophenolphthalein ethyl ester potassium salt solution. Dissolve 0.0525 g of TBPE-K in 50 ml of ethanol to make a $1.5 \times 10^{-3}M$ solution.

Potassium chloride solution (2*M*).

Buffer solution (*pH 7.8*). Prepared by mixing 1*M* potassium dihydrogen phosphate and 1*M* dipotassium hydrogen phosphate.

Polyoxyethylenealkyl(aryl) ethers. The non-ionic surfactants shown in Table 1 were examined. They were dried under reduced pressure (2–3 mmHg) at 50°, and known weights were dissolved in water.

Preliminary tests

The surfactant solution ($\leq$3 ml) was placed in a stoppered 25-ml test-tube, buffer solution ($\leq$1 ml), potassium chloride solution (2 ml) and reagent solution ($\leq$1 ml) were added, and the solution was made up to 7 ml with distilled water, mixed well and shaken vigorously (mechanical shaker) with 5 ml of 1,2-dichloroethane added by pipette. The absorbance of the organic phase was measured at 609 nm.

RESULTS AND DISCUSSION

In the preliminary tests, the absorption spectrum of the TBPE complex in dichloroethane was found to have its absorption maximum at 609 nm, which was therefore chosen for the measurement (Fig. 1).

The pH was adjusted with the phosphate buffer. The absorbance increased with the increase of pH, but the blank value rose abruptly at pH > 8, so then the measurements were made at pH 7.8.

When the amount of $1.5 \times 10^{-3}M$ TBPE-K was varied from 0.1 to 1 ml, the absorbance difference between a blank and 0.02 mg of Triton X-100 increased gradually with increase in the amount of reagent. Hence 0.7 ml was chosen as the volume of reagent, because it gave a relatively low blank absorbance (<0.05) and the absorbance difference was large and almost the same as with 0.8 ml of reagent.

The volume of 2*M* potassium chloride was selected as 2 ml, because the absorbance was constant with 2 ml or more of this reagent.

The shaking time needed is 15 min for complete extraction, and the phase separation takes 5 min.

Procedure 1

From these experiments procedure 1 was devised, the preliminary test procedure being followed, with the reagent volumes, *etc.*, quoted above. The sample solution taken ($\leq$3 ml) should contain 1–50 μg of non-ionic surfactant.

Calibration graphs and molar absorptivities

The calibration graph obtained for Triton X-100 (1–50 μg) by procedure 1 was linear and passed through the origin. The apparent molar absorptivity was 6.7×10^4 l.mole^{-1}.cm^{-1}, the molar concentration being calculated on the basis of $n = 10$. This molar absorptivity is over 5 times that for the potassium picrate system (1.2×10^4 l.mole^{-1}.cm^{-1}).

The molar absorptivities for several kinds of non-ionic surfactants were determined from the slopes of the calibration curves; the molar concentrations were calculated by using the degree of polymerization, n, or the number-average degree of polymerization, $\bar{n}$, shown in Table 1. The molar absorptivities increase linearly with n and $\bar{n}$ (Fig. 2). The relation between molar absorptivity and $\bar{n}$ is linear for $\bar{n} > 8$. Poly(ethylene glycol) derivatives having no surface activity give values not on the straight line, and give lower molar absorptivities. On the other hand, the values for non-ionic surfactants used commercially all lie on the straight line. This implies that the non-ionic surfactants which have the same polyoxyethylene chain length can catch the same amount of potassium ion, regardless of the kind of alkyl or alkylaryl groups, and the longer the polyoxyethylene chain, the more the amount of potassium combined. The pure $C_{12}H_{25}O$–compounds ($n = 6$ and 8) have higher molar absorptivities than the corresponding commercial products, and the molar absorptivity of the $C_{12}H_{25}O(CH_2CH_2O)_8H$–TBPE complex is 7.8×10^4 l.mole^{-1}.cm^{-1}, whereas that of the TBPE–Zephir-

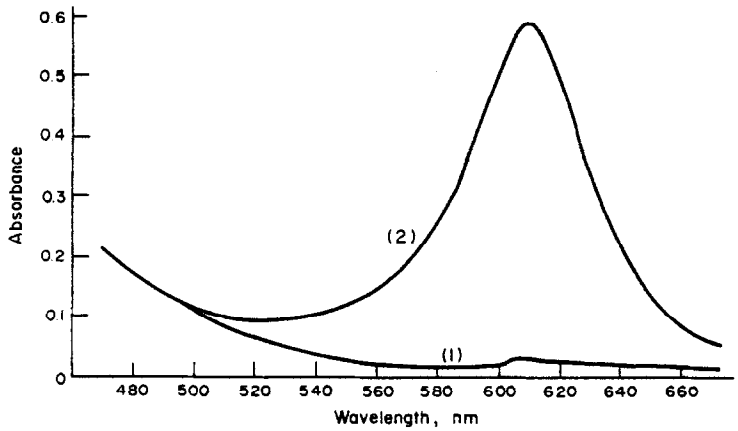

Fig. 1. Absorption spectra: (1) reagent blank; (2) $C_{12}H_{25}O(CH_2CH_2O)_8H$ (extra pure), 20 μg; solvent 1,2-dichloroethane; measured against solvent.

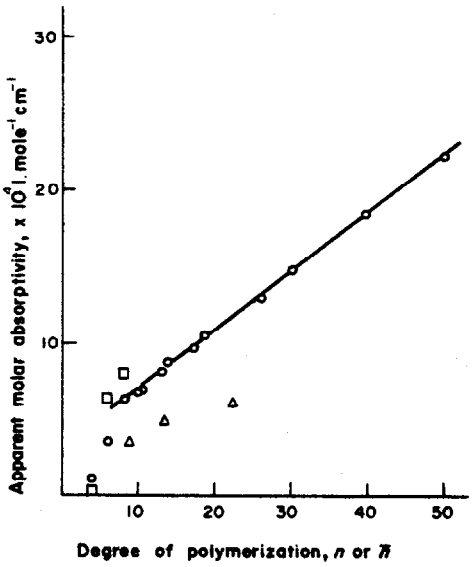

Fig. 2. Relationship between apparent molar absorptivity and degree of polymerization: ○, number-average degree of polymerization ($\bar{n}$); □, pure substance (degree of polymerization n); △, poly(ethylene glycol).

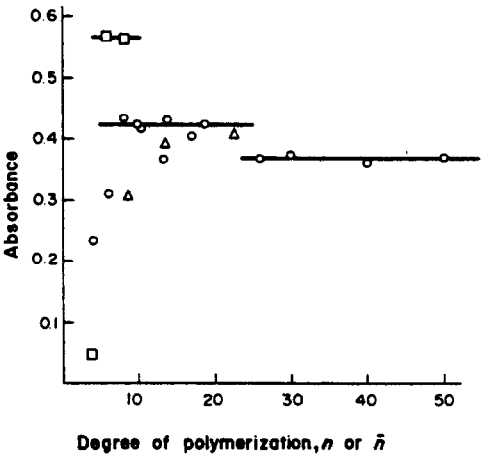

Fig. 3. Absorbances for 20 μg of surfactants: ○, number-average degree of polymerization ($\bar{n}$); □, pure substance (degree of polymerization n); △, poly(ethylene glycol), reference: reagent blank.

amine complex is 9×10^4 l.mole^{-1}.cm^{-1}.[4] Therefore, one mole of the pure surfactant ($n = 12$) or the commercial product ($n = 16$) would combine with one mole of potassium, and when n is 36–40, with two moles of potassium. It is known[5] that polyoxyethylene derivatives can form spirals which can trap potassium ions.

The molar absorptivities of the commercial products vary with the type of surfactant, making it seem that minute amounts of the commercial products in water could not be determined by this method. However, the number-average degree of polymerization of the commercial products is mainly 8–15, and the absorbance of a definite *weight* of the products is almost constant, about 0.042 per μg (Fig. 3), and the method is usable.

Application to water samples

The non-ionic surfactant content of water is usually so small that it must be concentrated into a small volume of organic solvent from a large volume of water sample, if our method is to be used. 1,2-Dichloroethane is not suitable as the extraction solvent, because of its solubility at large water:solvent phase-volume ratios; *o*-dichlorobenzene was chosen instead because it scarcely dissolves in water.

$C_{12}H_{25}O(CH_2CH_2O)_8H$, Triton X-100 and $C_9H_{19}O(CH_2CH_2O)_{17}H$ were determined by procedure 1, with dichloroethane and *o*-dichlorobenzene as solvents. The results are shown in Table 2. The absorbance maximum is at 620 nm for the *o*-dichlorobenzene system.

To concentrate the surfactant into 5 ml of *o*-dichlorobenzene from 200 ml of water sample, the procedure is as follows.

Procedure 2

Take 200 ml of water sample in a 250-ml separatory funnel and add 2 ml of 1*M* phosphate buffer (pH 7.8), 2 ml of 0.5*M* potassium sulphate, 20 ml of 4*M* potassium chloride as salting-out agent and 4 ml of 1.5×10^{-3}*M* reagent and mix well. Pipette 5 ml of *o*-dichlorobenzene into the funnel and shake it horizontally in the shaker for at least 30 min and then let stand for 10 min. Measure the absorbance of the organic phase at 620 nm.

Interferences. Among the ions generally present in natural water, Na^+, K^+, NH_4^+, Ca^{2+}, Mg^{2+}, SO_4^{2-} and Cl^- do not affect the determination. The interference of iron and aluminium is eliminated by adding 1 ml of 0.2*M* EDTA. However, large amounts of anionic surfactant disturb the determination, because of extraction of the ion-pair between the anionic surfactant and the cationic potassium complex with the non-ionic surfactant, causing negative errors. Hence elimination of the anionic surfactant is necessary

Table 2. The absorbances for 20 μg of non-ionic surfactant in dichloroethane (609 nm) and *o*-dichlorobenzene (620 nm) by procedure 1

Solvent	Absorbance*		
	$C_{12}H_{25}O(CH_2CH_2O)_8H$	Triton X-100	C_9H_{19}—⬡—$O(CH_2CH_2O)_{17}H$

* Reference: reagent blank.

Table 3. The absorbances of 20 μg of non-ionic surfactants by procedures 1 and 3

Surfactant	Absorbance* Procedure 1	Procedure 3
$C_{12}H_{25}O(CH_2CH_2O)_8H$ (extra pure)	0.561	0.559
Triton X-100	0.420	0.420
C_9H_{19}—⬡—$O(CH_2CH_2O)_8H$	0.436	0.436
C_9H_{19}—⬡—$O(CH_2CH_2O)_{17}H$	0.404	0.404
C_9H_{19}—⬡—$O(CH_2CH_2O)_{50}H$	0.368	0.237
C_9H_{19}—⬡—$O(CH_2CH_2O)_{86}H$	0.362	0.019

* Reference: reagent blank.

before determination of the non-ionic surfactant in water. *o*-Dichlorobenzene (5 ml) will give preferential extraction of the non-ionic surfactant, leaving the anionic surfactant in the water phase. The *o*-dichlorobenzene extract can then be analysed.

The procedure is as follows.

Procedure 3

Add 1 ml of 0.2*M* EDTA, 1 ml of 0.2*M* sodium sulphate and 5 ml of *o*-dichlorobenzene to 200 ml of water sample in a 250-ml separatory funnel and shake for 10 min on the shaker and let stand for 10 min. Transfer the organic phase into a stoppered 25-ml test-tube and add 1 ml of the 1*M* phosphate buffer (pH 7.8), 2 ml of 2*M* potassium chloride, 0.7 ml of the reagent solution and 4.3 ml of distilled water. Shake the test-tube on the shaker for 15 min and let stand for 5 min. Measure the absorbance of the organic solvent at 620 nm.

By this procedure anionic surfactants at concentrations below a few ppm do not disturb the determination. Various kinds of non-ionic surfactants were tested by procedures 1 and 3, and the results are shown in Table 3. The absorbances by the two procedures are almost the same as each other when n is 8–17, and the average absorbance is about 0.42 for 20 μg. When n is 50 or 86, the absorbances are low, especially for procedure 3, because of the low extractability of the surfactants into *o*-dichlorobenzene.

Table 4. Determination of non-ionic surfactant in river water

Sample	Pre-treatment	Absorbance*	Surfactant† ng/ml	Recovery, %
Asahi River§	(1)	0.012	4	96
	(4)	0.014	4	94
Zasu River‡	(1)	0.462	83	96
	(2)	0.377	68	100
	(3)	0.401	73	96
	(4)	0.129	24	93

Recovery was determined from results for addition of 2.5 or 5 μg pure surfactant (n = 8) to 200 ml of sample solution.

* Mean of three determinations. Reference: reagent blank.

† Obtained from the calibration curve made by using pure surfactant (n = 8).

§ Sampled on 3 March 1980. The concentration of anionic surfactant determined immediately after sampling was 32 ng/ml. The Asahi River is one of the three largest rivers in Okayama Prefecture.

‡ Sampled on 3 March 1980. The concentration of anionic surfactant determined immediately after sampling was 750 ng/ml. The Zasu River is one of the branches of the Asahi River and domestic waste-water flows into it.

Determination of non-ionic surfactant in river water

Procedure 3 was applied to 200-ml samples of river water; (1) immediately after sampling, (2) after storage of the sample in a glass bottle for 24 hr, (3) after filtration through No. 5C filter paper (Toyo Roshi Co. Ltd.), (4) after filtration through a membrane filter (0.45 μm), and recovery tests were done by adding 2.5 or 5 μg of pure surfactant (n = 8) to the sample solution. The results are shown in Table 4. The amount of non-ionic surfactant was decreased by treatments (2), (3) and (4). This implies that the non-ionic surfactant is adsorbed on the filter paper or on the wall of the vessel on standing, and/or on some microparticles suspended in the water. Therefore, the determination should be done immediately after the sampling, without filtration. The method is accurate enough according to the recovery tests (about 95% recovery).

CONCLUSION

The polyoxyethylene chain in non-ionic surfactants can trap potassium ion to form a complex cation which can be extracted into dichloroethane or *o*-dichlorobenzene with TBPE as counter-ion, TBPE providing a sensitive anionic chromophore for subsequent spectrophotometric determination.

As anionic surfactants disturb the determination, non-ionic surfactants are separated from them by extraction into *o*-dichlorobenzene, the anionic surfactants remaining in the water phase, but this separation will not deal with more than a few ppm of anionic surfactants, and, unfortunately, these are widely used and generally present at about ten times the level of the non-ionic surfactants. Therefore, this method cannot be applied if the water sample contains more than a few ppm of anionic surfactants.

Acknowledgement—The authors are very grateful to Dr. T. Kariyone of Kao Soap Co. Ltd. for his kind gift of non-ionic surfactant samples.

ELECTROTHERMAL ATOMIC-ABSORPTION DETERMINATION OF VANADIUM

MAHMOOD M. BARBOOTI and FADHIL JASIM*

Department of Chemistry, College of Science, University of Baghdad, Baghdad, Iraq

(*Received* 24 *April* 1981. *Accepted* 30 *June* 1981)

Summary—Factors such as sample nature, matrix and heating programme have been found to influence both the sensitivity and precision of the determination of vanadium by electrothermal AAS. The reciprocal sensitivity, detection limit and precision (RSD) are 55 pg, 86 pg and 4%, respectively for aqueous solutions and 88 pg, 80 pg and 4% for organic solutions. Only tungsten and nitric acid have been found to interfere appreciably. Moderately concentrated sodium chloride solutions ($\leq 6\%$) can be analysed for vanadium (≥ 0.05 μg/ml) without background correction, as can the acid digests of phosphate rocks and crude petroleum samples.

The determination of vanadium by atomic-absorption spectrometry (AAS) can be considered as one of the earliest applications of the method using the fuel-rich oxy–acetylene flame.[1,2] The use of the nitrous oxide–acetylene flame[3,4] improved the performance to a level which compared favourably with that of X-ray fluorescence.[5] The flame AAS determination of vanadium suffers from chemical and spectral interferences which may be suppressed by the addition of aluminium[6] or iron[4] or the simultaneous nebulization of a reducing agent with the test solution[7] (by means of a T-tube). West *et al.*[8] determined vanadium indirectly by converting it into phosphovanadomolybdic acid and measuring the molybdenum by AAS. The sensitivity for vanadium can be increased for both the air–acetylene and nitrous oxide–acetylene flame systems by addition of organic solvents to the sample solutions. The determination of vanadium in organic solutions is affected by the compound used for the preparation of the standard solutions.[10] This effect was said to be removed by the addition of halogens to the organic solution,[11] but this treatment was later claimed to be inefficient.[12] Plasma jets have been used for the atomization of vanadium but the high temperature leads to low populations of atoms in the ground state compared with those in the excited state.[13] Solid samples have been directly analysed for vanadium with the aid of cathodic sputtering[14] and laser atomization.[15]

Electrothermal atomization (ETA) was first used by Donega and Burgess[16] for the AAS determination of vanadium with a graphite furnace. They used a graphite boat in a closed chamber with quartz windows and a gas pressure of 1–300 mmHg (H_2, N_2 or Ar). The sensitivity of the method was 0.6 ng. Graphite-furnace atomization was evaluated for use in the AAS analysis of petroleum and its products for vanadium and proved to be useful, because the method involves only simple dilution of the samples with organic solvents, followed by injection into the furnace.[17–19] A detection limit of 6.8 pg was obtainable with this method.[20] The method has also been used for the determination of the element in sea-water,[21,22] titanium dioxide,[23] carbonate rocks,[24] steels[25] and biological materials.[26] Several authors[27–29] have discussed the use of graphite furnaces coated with pyrolytic graphite or with metal carbides, for the atomization of vanadium. It has been shown that improved sensitivity and better graphite-tube performance can be obtained with the coated-tube furnaces. Nitric acid has a perceptible suppression effect in the AAS determination of vanadium with graphite furnaces, and this is attributed to the co-ordinative ability of the oxovanadium species in acidic solutions.[30] The addition of complexing agents or ammonia is useful in overcoming this suppression.[30]

It is the aim of the present work to study the determination of vanadium with a graphite-tube furnace and to apply the method to the analysis of samples having various matrix compositions.

EXPERIMENTAL

Apparatus

All measurements were performed with a Varian–Techtron model CRA-63 graphite furnace mounted in a Varian–Techtron AA-5 atomic-absorption spectrophotometer, as described earlier.[31] The operating conditions of the furnace are shown in Table 1. In all experiments a lamp current of 10 mA and a spectral bandpass of 0.2 nm were used but no scale expansion or damping. The 318.5 nm line from a Varian–Techtron hollow-cathode lamp was employed.

The voltage–time combinations used in drying and ashing were varied according to the composition of the sample solution injected. Unless otherwise stated, the atomization voltage was 9 V applied for 5–6 sec. The aqueous solutions were injected with an Excalibur "Autopette", and an

Sodium chloride	3.0	40	8.5	25		
Crude oil and xylene	2.5	40	6.0	35		

SGE 10-μl syringe was used for the injection of organic solutions.

Reagents

All reagents were of analytical-reagent grade. Demineralized distilled water was used for the preparation of solutions, dilution and final rinsing of the glassware. A BDH 1-mg/ml standard AAS vanadium solution was used as stock solution, and diluted to 50 μg/ml (weekly) and further to 5 μg/ml as required. The solutions analysed were made up to contain 5% hydrochloric acid (*i.e.*, 5 ml of the concentrated acid per 100 ml). Series of standard solutions were prepared in 2–6% sodium chloride. An organic vanadium standard solution (250 μg/ml) was prepared by dissolving the appropriate weight of bis(1-phenyl-1,3-butadione)oxovanadium according to Pradhan.[32] Two dilutions of this solution (25 and 2.5 μg/ml) were made with xylene immediately before analysis.

Sample preparation

The phosphate rock samples were digested as described previously.[31] Samples of crude oils were obtained from two oil fields in Iraq, namely, Khanakeen (sp.gr. 0.825) and Kirkuk (sp.gr. 0.954). The samples were diluted with xylene in the ratio 1:15–1:30, depending on the vanadium concentration levels. Both standard-addition and direct calibration methods were employed.

RESULTS AND DISCUSSION

Calibration

The analytical results from the calibration graphs are summarized in Table 2. The calibration graphs show a linear relationship between the absolute mass of the injected analyte and the measured absorbance, and were constructed from the results obtained by injecting different volumes of the same solution, as reported previously.[33]

Performance of the tube furnace

The tube furnace functions efficiently for 40–50 firings, and gives an average reciprocal sensitivity of 120 pg and a precision (RSD) of 3% at the 0.4-μg/ml level. After about 80 firings the precision deteriorates, as indicated in Fig. 1.

Table 2. Analytical results obtained for the ETA–AA of vanadium

Parameter	Aqueous solution	Organic solution
Upper linear boundary of the calibration graph, *ng*	9.0	3.0
Reciprocal sensitivity, *pg*	55	88
Detection limit (S/N = 2), *pg*	86	80
Relative std. devn., (8 results) %:		
for 0.2 μg/ml	4	4
for 1.5 μg/ml	2	—
for 1.0 μg/ml	—	3

With more than 40 firings, the sensitivity and precision also strongly depend on the temperature of the tube at the moment of injection, being superior when the injection is done at a tube temperature not below ~70°. These results may be explained by assuming that on prolonged firing the furnace coating deteriorates and becomes porous so that part of the sample (~30%) becomes irreversibly adsorbed. To avoid this behaviour the injection should be made at temperatures not below 70° because the solution then dries on contact with the tube surface and does not penetrate into the pores.

As the tube ages the absorption peak profile changes. The time for the first appearance of the signal remains the same for the whole of the tube life, but the peak maximum is gradually delayed, *i.e.*, the atomization time, τ_1, increases with tube age (Fig. 2). Sturgeon and Chakrabarti[27] showed that for uncoated tubes the atomization times for Mo and V

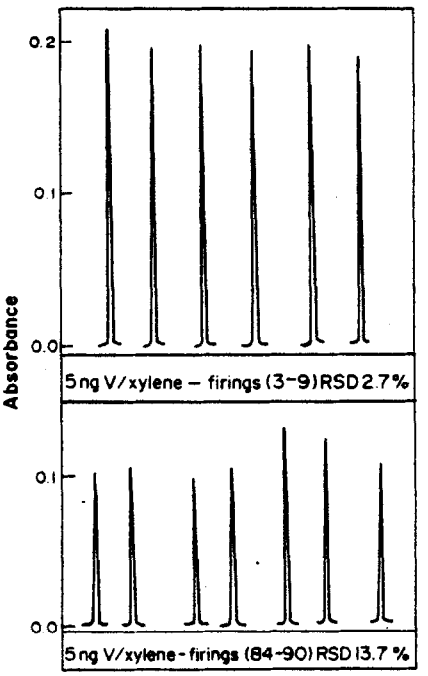

Fig. 1. Performance of a CRA-63 tube-furnace at two different stages of its life.

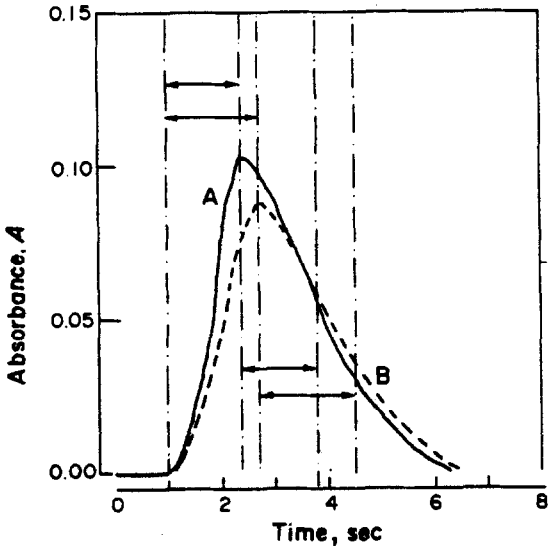

Fig. 2. Atomic-absorption signals of 2.0 ng of vanadium atomized at firing No. 23(A) and at firing No. 59(B).

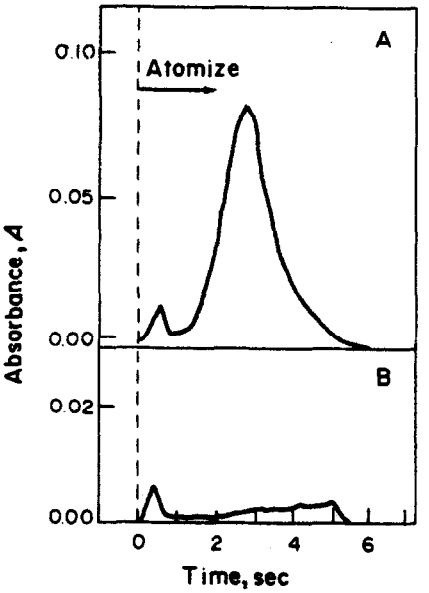

Fig. 4. Absorption signals of 1.0 ng of vanadium in the presence of 2.0 μg of calcium.

are longer than in the case of pyrolytically graphite-coated tubes. In this work, the gradual increase in atomization time indicates a gradual destruction of the pyrolytic graphite coating of the tube because of the high temperature used (2600°). The increase in the atomization time, τ_1, with tube age is accompanied by a corresponding increase in the residence time of the atoms, τ_2, so the ratio τ_1/τ_2 is almost constant. The constancy of the appearance time and τ_1/τ_2 suggests that the mechanism of vanadium atom formation does not change throughout the tube life.

Interference studies

The common elements interfering in the AAS determination of vanadium include those forming refractory compounds at high temperatures, such as Al, Ba, Mo, U and W, as well as Ca, Fe and Mg. Figure 3 summarizes the effects of increasing concentrations of the interfering elements on the AA signals obtained for a constant concentration of vanadium. It is clear that the element can be determined in the presence of ≤500-fold amount of Al, Mo and U, ≤1000-fold amount of Ca, Mg and Ba and ≤200-fold amount of Fe. The observations on the interference of Fe are in agreement with a recent report.[30] The determination of vanadium is difficult when more than 100-fold amount of W is present. This may be attributed to the formation of thermally stable species in the V–W–C system similar to those reported for Mo,[34] which are not decomposed under the heating conditions used. However, other investigators[29] have attributed this behaviour to the mechanical loss of analyte in the stable particles of tungsten formed at high temperatures. For Ca and Mg (≥1000-fold amount) the mechanism of the interference is different from that described above. At the beginning of the atomization stage a small but sharp absorption peak is noticed which decays rapidly and is followed by the rise of the AA peak of vanadium. With increasing concentrations of Ca or Mg, the small initial peak is

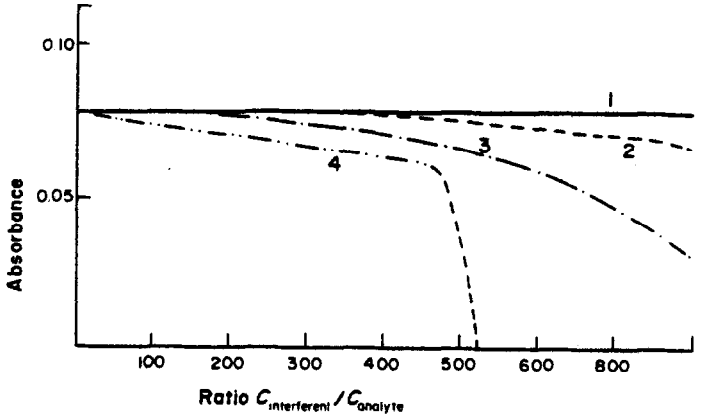

Fig. 3. Interference effects on the AA of vanadium, (1) Mg, Ca, Na and Ba; (2) Al, Mo and U; (3) Fe; (4) W.

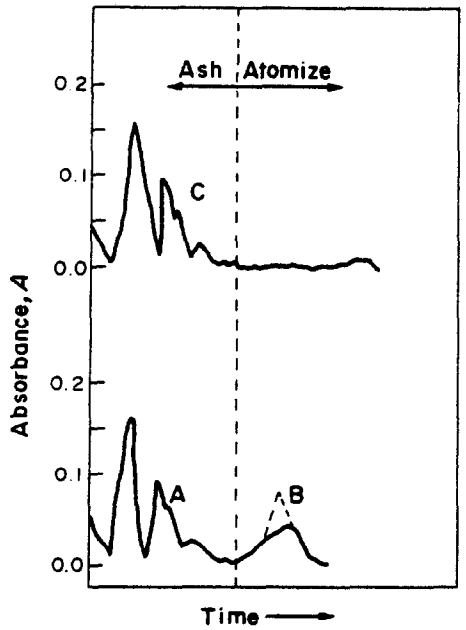

Fig. 5. Ashing and atomization signals of (A) brine diluted five times + 0.5 ng of vanadium; (B) 1.0 ng of vanadium; and (C) as for (A) but measured with a hydrogen lamp.

enlarged and examination of it by use of a hydrogen lamp shows it to be background absorption due to Ca or Mg molecular species, and making a negligible contribution to the AA peak of vanadium (Fig. 4). The nature of the electrothermal atomization of the element allows complete resolution of the background peak from the AA peak, because time is needed for the atomizer to attain the appearance temperature for vanadium (2200 ± 30 K).

Effect of sodium chloride

The determination of vanadium in sea-water and brines is important and so the ETA of vanadium in the presence of high concentrations (2–6%) of sodium chloride was investigated. The relatively high ashing temperatures possible in the ETA of vanadium eliminate these high concentrations of the salt during the ashing stage without any loss of the analyte. Incomplete ashing, however, results in a sharp, irreproducible peak appearing at the start of the atomization stage, before the AA peak of vanadium. This is due to the signal from the NaCl remaining in the furnace. The absorption traces obtained under the optimum heating conditions (Table 1), with a diluted brine sample to which known amounts of vanadium had been added, are shown in Fig. 5, which also shows the absorption signals obtained with a continuum source. It is clear that vanadium at the 0.1-μg/ml level can be determined in sodium chloride solutions of up to 6% concentration, without background correction.

Interference of acids

The effects of hydrochloric, nitric and phosphoric acids on the determination of vanadium have been investigated. The first two are the reagents usually used in the digestion of geological samples, while the third is the predominant species appearing in the acid digests of phosphate rocks. The AA signal is stable for a wide range of hydrochloric acid concentrations so there is no risk in using the acid for making up solutions to be analysed for vanadium. When a series of solutions, in which the concentration of nitric acid is increasing, is atomized, the AA signals for vanadium decrease correspondingly and this observation is in agreement with previous reports.[30] In the presence of increasing concentrations of phosphoric acid the AA signal of vanadium is slightly suppressed, a behaviour which may be attributed to the formation of stable vanadium phosphates.

In order to study the analysis of the phosphate rock digests, synthetic samples were made up containing the two major constituents, calcium and phosphate, in appropriate amounts together with vanadium. The results are interesting. The background peak due to calcium disappears and the suppression of the AA signal by the phosphoric acid is reduced. This shows the masking effect of the acid on calcium and the releasing action of calcium for vanadium in phosphoric acid medium. The most probable reason for these effects is the formation of calcium phosphate.

Determination of vanadium in phosphate rocks

Five phosphate rock samples have been analysed. Two were local standards with certified vanadium contents and three were analysed for the first time. The procedure of bracketing the unknown AA measurements with those of the standards is necessary

Table 3. Vanadium content of Iraqi phosphate rocks

Sample	Vanadium content, μg/g		
		Values found	
	Certified value	Std. addn.	Calibration graph
Standard phosphate rock, PH1	188	196 ± 4*	193 ± 6*
Standard phosphate rock, PH3	100	96 ± 5*	95 ± 4*
Core phosphate	—	46	45
Fine grain phosphate	—	366	362
Umm-Alradhuma phosphate	—	235	239

* Average of 8 determinations ± standard deviation.

Table 4. Vanadium content of Iraqi crude oils*

Sample	Vanadium content, μg/g		Deviation %
	Standard addition	Direct calibration	
Kirkuk crude oil	24.7	24.2	2
Khanakeen crude oil	15.9	16.5	3

* Recovery of vanadium added, 97.7%, RSD ± 3%.

to compensate for the variation in sensitivity resulting from the graphite-tube degradation. The method of standard additions was used to overcome matrix effects. The results are shown in Table 3. It can be seen that the standard-additions method gives values in agreement with those from the calibration graphs. These findings demonstrate the reliability of direct analysis of the acid digests of the phosphate rocks, *i.e.*, there is no need to use the standard-additions method in this case. The absorption traces show only the AA peaks of vanadium and a background correction is not necessary. In the standard-additions method it is obviously essential that all the measurements lie in the linear part of the calibration graph.

Determination of vanadium in crude oils

The crude oils supplied from the two fields have different vanadium contents, which reflect the mineralogy of the areas. The standard-addition and calibration-graph results are in agreement. The absorption profiles were checked by use of the hydrogen lamp and the removal of the matrix during the ashing stage was shown to be complete. This makes the use of background correction unnecessary. The results are listed in Table 4.

A POTASSIUM-SELECTIVE ELECTRODE WITH SOLID INTERNAL CONTACT

M. TROJANOWICZ, Z. AUGUSTOWSKA, W. MATUSZEWSKI, G. MORACZEWSKA and A. HULANICKI
Department of Chemistry, University of Warsaw, Warsaw, Poland

(*Received* 20 *January* 1981. *Revised* 16 *June* 1981. *Accepted* 30 *June* 1981)

Summary—The performance characteristics of potassium-selective electrodes made with valinomycin membranes plasticized with dioctyl adipate or sebacate, and with a solid silver contact or an internal solution, have been critically examined. The choice of electrode depends on a number of factors, including the interfering ion(s) present. The electrodes can be used for determination of potassium in natural waters.

The promising results obtained for calcium[1] and nitrate[2,3] selective electrodes with PVC membranes and solid internal contact have stimulated further investigations for the potassium selective electrode. The active membrane component used throughout this work was valinomycin, and the plasticizers were dioctyl adipate (DOA) or dioctyl sebacate (DOS) which had been proved to be effective[4,5] in similar electrodes.

Although several studies have been published concerning the mechanism of functioning of electrodes with solid contacts,[6,7] we thought it interesting to make a comparative study of some electrode characteristics, using sensors with a solid silver contact and with an internal solution. Among the parameters investigated were stability of the electrode potential, range of linear response, selectivity and dynamic parameters. Two practical analytical applications of the electrode were also developed.

EXPERIMENTAL

Electrodes and apparatus

The plastic PVC membranes containing valinomycin (Sigma, U.S.A.) and di-n-octyl adipate (DOA) or di-n-octyl sebacate (DOS) as plasticizers were prepared according to Fiedler and Růžička.[4] The construction of the exchangeable electrode tip is shown in Fig. 1. The plastic membrane (4), 5 mm diameter, is placed on the convex silver disc (3) and fixed with a threaded brass ring (2). The body (1) is machined from polypropylene. Unless otherwise indicated, 0.01*M* potassium chloride was used as the internal solution in the inner reference electrode and for electrode conditioning between measurements.

A double-junction reference electrode (Orion model 90-02) was used with a salt bridge filled with 10% ammonium nitrate solution. This system has been proved to have the lowest liquid-junction potential, in good agreement with the values calculated on the basis of the Henderson equation. The calculated differences in liquid-junction potential between 10^{-4} and $10^{-2}M$ potassium chloride and bridging solution containing various electrolytes were subtracted from the experimentally measured electrode slopes (Table 1). The resulting slopes were relatively constant and close to the Nernstian value. This was of importance when the electrode characteristics were measured in media of varied ionic strength.

The potential measurements were taken with a digital potentiometer (Orion model 701). The flame photometer used for comparative measurements was a "Flaphkol" (Zeiss, Jena).

RESULTS AND DISCUSSION

Measuring range, sensitivity and potential stability

Electrodes with a solid contact and those with an internal solution were systematically checked over a period of 6 months for response slope and linear range, in solutions of pure potassium chloride. For both types of electrode the slopes at 25° were found to be 56.5 ± 0.5 and 56.0 ± 0.5 mV/decade, respectively. No systematic drift of these values was observed during the lifetime of the electrodes. The estimated temperature coefficient in the range 25–50° was 0.47 mV/deg.

For both types of electrode the response range was linear down to pK 5.0, irrespective of the plasticizers used for making the membranes.

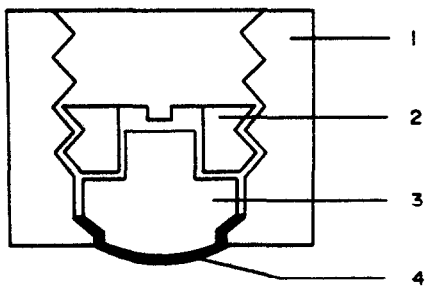

Fig. 1. Scheme of the electrode construction with the solid silver contact and PVC membrane: 1—polypropylene body, 2—brass ring, 3—silver contact, 4—PVC membrane.

Table 1. Effect of liquid-junction potential on the electrode response in the range from 10^{-4} to $10^{-2}M$ potassium chloride; electrode with DOA plasticizer and internal reference solution

Bridging electrolyte	Electrode response, mV/pK	
	Measured	Corrected for liquid-junction potential
$1M$ LiCl	75.5	56.0
$0.1M$ NaCl	67.0	56.0
$2M$ NaCl	66.0	53.9
$1M$ $NaNO_3$	67.0	56.7
$1.9M$ NH_4Cl	57.5	56.4
10% NH_4NO_3 ($1.2M$)	56.0	56.8

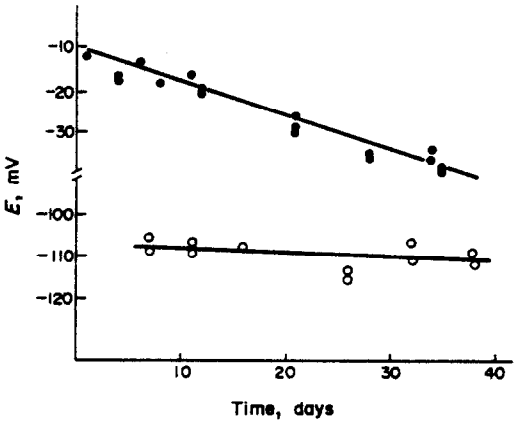

Fig. 2. Long-term potential drift for solid-contact potassium electrode (○) and electrode with internal solution (●).

On the other hand, differences were observed in the stability of the potential readings in spite of the fact that the membranes for both types of electrode were cut out of the same master membrane and were identically conditioned. For the DOA membranes the electrode with internal solution exhibited a regular shift of the potential reading at the rate of approx. 0.8 mV/day (Fig. 2). The potential of the electrode with solid contact, except for random variation over a range of a few millivolts, was constant during at least 6 weeks. This behaviour is significantly dependent on the plasticizer used. For the DOS membranes, the potential of both types of electrode decreased by 1.7 mV/day during two weeks but then became stable. Between measurements the electrodes were kept in $10^{-2}M$ potassium chloride.

Selectivity and interferences

The selectivity coefficients of the potassium electrodes were determined in mixed solutions[8] containing other alkali-metal cations, or ammonium or calcium ions, added as the chlorides. The concentrations used were $0.1M$ except for rubidium and caesium, for which, because of their greater interference, only $0.001M$ solutions were used. The selectivity coefficients, calculated from the intersections of the extrapolated linear portions of the calibration curves, were practically constant over a period of six months for the membranes containing DOA (Table 2). For the DOS membranes the selectivity coefficients had nearly the same values as for the DOA electrode with calomel paste as the internal reference system and were in good agreement with the data reported by Schindler *et al.*[7]

Because the effect of lipophilic anions on the response of the neutral carrier electrodes has been discussed widely in the literature,[9,10] calibration with potassium chloride, nitrate and thiocyanate was performed in the pK range from 1 to 6. In the case of DOS membranes both types of electrodes give similar deviation from linearity at concentrations above $10^{-2}M$.

These deviations amounted to 25 and 35 mV for the solid-contact and internal-solution electrodes, respectively, at a concentration corresponding to pK 1.2. Greater differences in the electrode response were observed for the DOA membranes. In potassium chloride and nitrate media the potential response was linear up to pK 1.2, but in the thiocyanate solutions the deviation for the solid-contact electrode was only 7 mV at pK 1.2, whereas for the internal-solution electrode at the same concentration the deviation was 39 mV, with the change from cationic to anionic function at pK 2 (Fig. 3). For DOS electrodes the change in function occurred at pK 2.5.

Table 2. Logarithms of selectivity coefficients for potassium membrane electrodes investigated (DOA membrane; measurements at different times after electrode construction)

Interfering ion	Electrode with internal solution		Solid-contact electrode		Values from Fiedler and Růžička[4]
	1 month	6 months	1 month	6 months	
Na^+	−4.40	−4.26	−4.28	−4.36	−4.22
Li^+	−4.42	−4.16	−4.40	−4.36	−3.62
NH_4^+	−1.94	−2.12	−2.10	−1.94	−1.88
Cs^+	−0.55	−0.52	−0.42	−0.42	−0.33

Ca^{2+}	−4.14	−3.80	−4.04	−3.96	−4.31

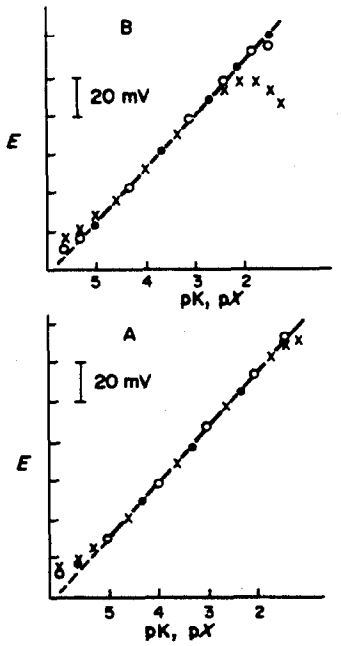

Fig. 3. Anionic interferences for solid-contact (A) and internal-solution (B) potassium-selective electrodes with membrane containing DOA as plasticizer: ●—Cl^-, ○—NO_3^-, ×—SCN^-.

The increasing anionic response of the electrode is related to penetration of the membrane phase by thiocyanate ions and the more advantageous behaviour of the solid-contact electrode is probably connected with the properties of the membrane–silver contact at the interface. For quantitative treatment of production of the membrane potential in the presence of an anion which penetrates the membrane, the processes on both the internal and external interfaces[11] must be considered. The steady-state concentration of an anion is connected with these processes, and the transport of a mobile anion will result in the anionic response characteristics of the electrode. For a solid internal contact the anion transport is limited to the membrane phase only. Therefore a relatively short time is needed for establishing the concentration of interfering anions in the membrane and the changes in potassium-ion activity are dominant among the potential-forming processes, and result in decrease of the anionic function of the electrode. The differences between electrodes made with different plasticizers may be attributed to differences in the mobilities of the anions in the membrane.

Dynamic characteristics

The response time for a given change in the potassium-ion activity also depends on the plasticizers used for making the membranes. For a potassium-ion activity change from 10^{-3} to $2 \times 10^{-2}M$ the potential difference between the 1st and 3rd, or 1st and 15th minute was measured, for solutions containing only a potassium salt or also a sodium or calcium salt (Table 3). The potential differences were somewhat smaller for electrodes with internal solution. The 15-min period for the test was chosen arbitrarily as being convenient for practical purposes. True equilibrium is not necessarily established in this time.

The potential differences were more significant, *i.e.*,

Table 3. Changes in electrode potential (mV) between 1st and 3rd and between 1st and 15th min after change of potassium concentration from 10^{-3} to $0.02M$ (DOS membrane; internal solution $0.01M$ KCl)

Interfering ion in external solution	Between 1st and 3rd min		Between 1st and 15th min

the electrode reacted more slowly to concentration changes, when the membrane contained DOA (Table 4). When 0.01*M* potassium chloride was used as internal solution the response was practically the same as for the solid-contact electrode, but larger than for the corresponding systems with DOS in the membrane. Much faster response was observed when the internal solution was more concentrated, provided the external solution concentration was greater than 0.01*M*. When the potassium chloride concentration is 0.01*M* on both sides of the membrane an equilibrium concentration of potassium ions is established within the membrane. Increasing the potassium ion concentration in the external solution causes diffusion of potassium ions, owing to the concentration gradient. When potassium ions reach the internal membrane–solution interface, they influence the equilibrium there, which results in slow changes in the electrode potential. When the internal solution concentration is greater than that of the external solution the concentration gradient is in the opposite direction and the membrane potential changes only at the external interface. In such a case the increase in potassium ion concentration in the membrane reduces the linear range of electrode response, the lower limit being pK 4.5.

Because interfering elements may also change the dynamic characteristics of the potential response[12] the effect of lithium, sodium and calcium was investigated (Table 4). In these measurements, increasing the concentration of the internal electrolyte solution gave more rapid equilibration of the potential readings (Fig. 4). The behaviour of the 1*M* potassium chloride electrode was nearly the same as that of the solid-contact electrode (Fig. 4), for which the potential at the internal membrane interface could be taken as constant.

The time needed to establish a constant potential reading mostly depends on the diffusion in the membrane but not in the aqueous phase.[13] Therefore the phenomena observed may be interpreted as follows. When present at high concentration, the interfering ions penetrate the membrane until a steady state is reached inside it, giving rise to a stable potential. The diffusion of potassium ions is disturbed by the other ions and therefore the final response is attained more slowly. This effect is successfully eliminated by using an internal solid contact or a concentrated internal solution.

Determination of potassium in river water

The potassium electrode with a solid contact and the DOA membrane was used for determination of potassium in river samples. A 50-ml sample was used, made 0.1*M* in sodium chloride. The multiple standard-addition method was used, with addition of at least eight 0.5-ml portions of 0.001*M* potassium chloride. After each addition the potential was recorded when the drift in reading was less than 0.2 mV/min. The results (Table 5) were evaluated graphically and also numerically with the program CALIB,[14] but the graphical method gave better agreement with the flame photometric determinations.

The possibility of using the electrode as a sensor in flow-injection analysis[15] was also tested. The same electrode was used in a specially designed electrode cell (Fig. 5). A 145-μl sample of river water was injected into a stream of 0.1*M* sodium chloride flowing at 8 ml/min. The reproducibility of the recorded peaks was better than 0.5%. The results were 3.3% lower than the flame-photometric values.

To obtain good results in the flow-injection analysis it was necessary to keep the dynamic characteristics of the detector as contant as possible. However, during the first few days of use of the electrode, some peak-height changes were observed (Fig. 6), the peaks becoming smaller with increase in electrode-condi-

tioning time, which suggests that the response time for the electrode increases. This may be due to increase in the thickness of the hydrophilic gel layer and to a growing contribution of the diffusion of ions through the layer. Similar facts have been observed for the plastic nitrate-selective electrode.[16]

CONCLUSIONS

Investigation has shown that both the solid-contact and internal-solution potassium-selective electrodes have similar characteristics. The behaviour of the solid-contact electrodes depends on the plasticizer used for the membrane preparation and may sometimes be more advantageous than that of the internal-solution electrode. For di-n-octyl adipate membranes the solid-contact electrode gives a more stable response, eliminates anionic interferences and improves the dynamic characteristics, especially in the presence of interfering ions. The electrodes described have been successfully used for determination of potassium in natural waters.

(*Received* 3 *March* 1981. *Accepted* 29 *June* 1981)

Summary—The extraction of uranium(IV) from phosphoric acid solutions with PMBP and PMBP–TOPO mixtures has been studied. The synergic extraction with PMBP–TOPO is more effective than the simple chelate extraction with PMBP and both systems are more effective than the synergic extraction of uranium(VI) with DEHPA–TOPO. It is established that the complexes extracted are $U(PMBP)_4$ and $U(PMBP)_4 \cdot TOPO$ for the chelate and synergic extraction respectively. The most probable uranium(VI) species in the aqueous phase (2.9–6.33*M* H_3PO_4) is the neutral complex $U(H_5P_2O_8)_4$. Analytical methods suitable for determination of uranium in phosphoric acid solutions have been developed. The highest sensitivity is achieved by combining the synergic extraction with the uranium(IV)–arsenazo III colour reaction.

The present paper deals with determination of the uranium content of phosphoric acid solutions by extraction photometric methods. Several techniques for this have been studied.[1] Among them is a method for low uranium content (0.02–0.2 g/l.) based on synergic extraction of uranium(VI) with di(2-ethylhexyl)phosphoric acid (DEHPA) and tri-n-octylphosphine oxide (TOPO), stripping as uranium(IV) with 8.6*M* phosphoric acid containing 20 g of iron(II) per litre and final determination with arsenazo III in acetate buffer. The calibration graph is linear but depends on phosphoric acid concentration. A similar method has been proposed in which tributyl phosphate is used instead of TOPO.[2] The TOPO system is the more effective.

The extraction of uranium(IV) with 1-phenyl-3-methyl-4-benzoylpyrazolone-5 (PMBP) has not been studied, but by analogy with the extraction behaviour of the actinide elements,[3,4] a high degree of extraction would be expected. On the other hand, the synergic extraction of uranium(IV) with β-diketones (other than PMBP) and neutral organophosphorus compounds has been investigated.[5,6] The greatest synergic effect was obtained with the relatively most acidic β-diketone, thenoyltrifluoroacetone (TTA) and the most basic neutral reagent TOPO. PMBP is a stronger acid than TTA, so it should give a larger synergic effect, and this system should therefore be worth investigation.

The extraction of uranium(VI) from phosphoric acid media with organic solutions of PMBP is of no practical importance, because of the high extractability of iron(III).[3,4] The iron(III) must be reduced to iron(II), and the uranium(VI) is simultaneously reduced to uranium(IV).[7]

EXPERIMENTAL

Reagents

Stock uranium(IV) solutions were prepared in the following manner. Uranium(VI) was reduced with zinc in 1–2 *M* hydrochloric acid, the reaction being stopped when a dark colour appeared [U(III)]; the excess of reductant was filtered off and after dilution of the filtrate to give a hydrochloric acid concentration of about 0.2*M*, uranium (IV) phosphate was precipitated with 1–2 ml of concentrated phosphoric acid. The precipitate was filtered off, washed with water until free from chloride, dissolved in concentrated phosphoric acid and diluted to the desired volume. The stock solution was about 0.01*M* in U(IV) and 5*M* in phosphoric acid. It was stable for at least a month. It was standardized by potentiometric titration with potassium dichromate. The uranium(VI) content was less than 0.3% of the total uranium concentration. Working solutions were prepared by dilution of the stock solution with the required quantities of phosphoric acid and water. The acidity was determined by potentiometric titration with sodium hydroxide.

Organic solutions of the extractants were made by dissolving weighed amounts in toluene. The PMBP was synthesized at the Institute of General and Inorganic Chemistry, BAS, Sofia, Bulgaria.

Procedures

Uranium determination in organic extracts. An aliquot of organic extract containing less than 35 μg of uranium is evaporated and mineralized with 1–2 ml of concentrated perchloric acid and 4–6 drops of 30% hydrogen peroxide in a sand-bath until a moist residue remains. The residue is dissolved at room temperature with 10 ml of a 0.5-mg/ml solution of arsenazo III in 7*M* nitric acid (prepared from the concentrated acid presaturated with urea) and the absorbance is measured at 655 nm against a reagent blank. If the sample contains phosphorus, as in the synergic extraction, aluminium nitrate must be added to the reagent solution. The uranium(VI) calibration standards and the samples must have a similar phosphorus content, which should have a molar concentration that is between $\frac{1}{3}$ and $\frac{2}{3}$ of that of the added aluminium.

An alternative is to determine the metal as uranium(IV). An aliquot of the organic extract containing less than 12 μg of uranium is decomposed as before. The moist residue obtained is dissolved with 5 ml of concentrated hydrochloric acid at room temperature, the uranium is reduced with 0.5 ± 0.02 g of medium-sized zinc granules, and 0.5 ml of 0.5% arsenazo III solution is added. The absorbance is measured at 665 nm against a reagent blank. If the sample contains phosphorus, the moist residue must be dissolved with 5 ml of 0.1*M* aluminium chloride solution in concentrated hydrochloric acid. The phosphorus content permissible is 0.05–0.35 mmole. The calibration standards and samples should not have a phosphorus content that is outside these limits.

Uranium determination in aqueous phase. An aliquot of the aqueous phase is appropriately diluted to known volume and a fraction of the resulting solution (containing up to 40 μg of uranium and 1–2 mmole of phosphoric acid) is transferred to a 10-ml standard flask. The uranium is oxidized by addition of 1% potassium permanganate solution dropwise until a pink colour appears, then the excess of oxidant is eliminated by dropwise addition of 1% ascorbic acid solution. Finally, 6 ml of 10*M* nitric acid–0.5*M* aluminium nitrate solution presaturated with urea) and 1 ml of 0.5% arsenazo III solution are added in succession and the mixture is diluted to the mark. The absorbance is measured at 655 nm against a reagent blank.

PMBP determination in the aqueous phase. An excess of copper sulphate solution is added, the solution is adjusted to pH 5, and the copper–PMBP complex is extracted into methyl isobutyl ketone. The copper in the extract is then determined by atomic-absorption spectrometry and the PMBP concentration calculated from it.[8]

Extraction tests

These were performed under the following conditions—aqueous:organic phase ratio 2:1; temperature 25 ± 1°; contact time 5 min at 200 strokes/min (this is long enough for extraction equilibrium to be attained.). The uranium concentration was determined in the phase with the lower uranium content, by the arsenazo III method. The PMBP left in the aqueous phase was determined.

RESULTS AND DISCUSSION

PMBP species

The possible association of PMBP in the organic phase was studied by distribution measurements. The distribution coefficients (D_{HA}) were obtained at various PMBP concentrations up to 0.75*M* and fixed phosphoric acid content in the aqueous phase. The D_{HA} values were 1450 ± 80, 1080 ± 50 and 125 ± 10 for 3.24, 4.82 and 8.92*M* phosphoric acid respectively, independent of the PMBP concentration up to the highest level tested. These results show that no association occurs.

In slightly polar solvents PMBP exists in enolic form and can undergo one dissociation and two protonation reactions in the aqueous phase.[3,4] At constant PMBP concentration in the organic phase, the inverse of the distribution coefficient can be expressed by the equation:

$$\frac{1}{D_{HA}} = \frac{1}{K_r} + \frac{K_d}{K_r[H^+]} + \frac{K_{p1}[H^+]}{K_r} + \frac{K_{p2}[H^+]^2}{K_2} \quad (1)$$

where K_r, K_d, K_{p1} and K_{p2} are the apparent equilibrium constants for the partition of neutral molecules, the dissociation and the two protonation constants respectively. Thus, the different processes can be studied by measuring the D_{HA} values at different phosphoric acid concentrations and solving equation (1). The hydrogen-ion concentrations were calculated according to Elmore *et al.*[9] The mean D_{HA} values and the corresponding experimental conditions are given in Table 1.

A statistical test of equation (1) indicated that the significant terms are those corresponding to the partition of neutral molecules and to the second protonation. Therefore, the best fit is obtained with the expression

$$\frac{1}{D_{HA}} = \frac{1}{K_r} + \frac{K_{p2}[H^+]^2}{K_r} \quad (2)$$

where $K_r = 1690 \pm 40$ and $K_{p2} = 0.32 \pm 0.02$.

These results indicate that the predominant PMBP species in the aqueous phase are the neutral molecules and the doubly protonated cation H_2PMBP^{2+}.

Another possible reaction is the association between PMBP and TOPO in the organic phase, but the D_{HA} values showed no dependence on TOPO concentration up to 0.25*M*. The values obtained were 1450 ± 60 and 790 ± 50 for 3.02 and 5.84*M* phosphoric acid respectively. The PMBP concentration in the organic phase was fixed at 0.50*M*.

The enolic form of PMBP is the active one in extraction processes. This form passes into the keto-

nic form as the solvent polarity is increased. In consequence, the addition of TOPO to the organic solution leads to a shift to the ketonic PMBP, and so the extraction of uranium should be affected. The influence of TOPO addition on the tautomeric equilibrium was studied photometrically by measuring the absorbance of the yellow enolic form in the visible region, where the ketonic form does not absorb. The variation in the fraction in the enolic form as a function of the amount of TOPO added, at two fixed PMBP concentrations, is given in Fig. 1. The results confirm that TOPO causes conversion into the ketonic form, the extent of conversion increasing if the total PMBP concentration is decreased. This must be taken into account in interpretation of the extraction data.

Extractable uranium(IV) complexes

The influence of PMBP concentration on the uranium distribution coefficient (D_U) was investigated and the stoichiometry of the complexes extracted was determined by plotting log D_U *vs.* log [PMBP] for different phosphoric acid concentrations. The graphs were linear, fitting the empirical equations:

(*a*) for 4.40*M* H_3PO_4

$$\log D_U = 2.13 + 4.03 \log[\text{PMBP}] \quad (3)$$

(*b*) for 5.35*M* H_3PO_4

$$\log D_U = 1.32 + 3.84 \log[\text{PMBP}] \quad (4)$$

If TOPO is present, corrections must be made for the decrease in enolic form concentration ($PMBP_e$). The D_U values and the corresponding enolic form concentrations give the empirical equation

$$log\ D_U = 3.84 + 3.89 \log[\text{PMBP}_e] \quad (5)$$

for 4.24*M* phosphoric acid. The results all suggest that four PMBP molecules are present in the complexes extracted. Moreover, the addition of TOPO enhances the uranium(IV) extraction, *i.e.*, a synergic effect is observed. The synergic extraction of uranium(IV) can take place by formation of a ternary complex. This process was studied by examining the influence of the TOPO concentration on the D_U values for constant phosphoric acid and PMBP concentrations. The results are given in Table 2 and Fig. 2. From the latter, a decrease in the synergic effect at a

9	0.150	0.2148	46.9	45.1	0.4795	71.9	68.8
10	0.200	0.2057	52.1	50.7	0.4730	85.7	84.1
11	0.250	0.2010	57.9	57.4	0.4665	93.7	97.4

molar ratio TOPO:PMBP > 1.4 is observed. In this region, the negative effect of the reduced enol concentration is not fully compensated by the ternary complex formation.

The number of TOPO molecules in the ternary complex cannot be accurately determined by a simple log–log plot, because of the decreased enol concentration. This problem was solved by use of the expression

$$D_U = C[\text{PMBP}_e]^4[\text{TOPO}] \quad (6)$$

where C is a composite term including the apparent equilibrium constant for the synergic extraction and the complex formation in the aqueous phase. This term may be considered constant at fixed phosphoric acid concentration.

Equation (6) was evaluated from the experimental data (see Table 2), with $[\text{PMBP}_e]^4[\text{TOPO}]$ as the independent variable. The resulting equations are:

(*a*) for 0.25*M* PMBP

$$D_U = 1.41 \times 10^5[\text{PMBP}_e]^4[\text{TOPO}] \quad (7)$$

(*b*) for 0.50*M* PMBP

$$D_U = 8.74 \times 10^3[\text{PMBP}_e]^4[\text{TOPO}] \quad (8)$$

The empirical equation (7) fits the experimental data well, but equation (8) does not. In the latter case, a new model allowing for co-existence of the ternary complex and the U(IV)–PMBP complex in the organic phase was proposed, giving

$$D_U = C_1[\text{PMBP}_e]^4 + C_2[\text{PMBP}_e]^4[\text{TOPO}] \quad (9)$$

where C_1 and C_2 include the apparent equilibrium constants for complex formation in the aqueous phase and the chelate and synergic extraction respectively. These two terms may be considered as constants at fixed aqueous phase composition. The empirical equation obtained is

$$D_U = 170[\text{PMBP}_e]^4 + 7550[\text{PMBP}_e]^4[\text{TOPO}] \quad (10)$$

Equation (10) fits the experimental data. The D_U values calculated from equations (7) and (10) are given in Table 2.

From the results it follows that the extractable complexes of uranium(IV) are $U(PMBP)_4$ and $U(PMBP)_4 \cdot TOPO$ for the chelate and synergic extraction respectively. In the latter case, both complexes can co-exist, if the PMBP concentration is high enough to give significant uranium(IV) extraction by itself.

Extraction curves

The plots of $\log D_U$ *vs.* $\log C_{H_3PO_4}$ for chelate and synergic extraction were linear, and described by the equations

(*a*) for chelate extraction

$$\log D_U = 5.07 - 6.56 \log C_{H_3PO_4} \quad (11)$$

(*b*) for synergic extraction

$$\log D_U = 5.27 - 6.44 \log C_{H_3PO_4} \quad (12)$$

where $C_{H_3PO_4}$ is the total phosphoric acid concentration in the aqueous phase.

The chelate extraction data were used in investigation of the complex formation in the aqueous phase. The phosphoric acid species were calculated according to Elmore *et al.*[9] and all possible reactions were tested. No satisfactory fit was obtained but the most significant uranium(IV) complexes in 2.9–6.33*M* phosphoric acid were $(U(H_3P_2O_8)_{4-n}(HPO_4)_n^{n-}$, where $n = 1$–4. The predominant species is the neutral complex $U(H_3P_2O_8)_4$. The difficulty in interpreting the data arose from uncertainties in the concentrations of the phosphoric acid species, and the fact that no convincing activity corrections could be made.

Equations (3) and (11) indicate that higher chelate extraction efficiency may be expected at lower phosphoric acid concentrations and higher PMBP concentrations. For example, at 2.84*M* phosphoric acid and 0.72*M* PMBP (20% w/v), the D_U value was 445 ± 85, high enough to guarantee quantitative extraction. The phosphoric acid concentration must be at least 2.5*M*, however, for the uranium(IV) to be stable.[7] On the other hand, quantitative synergic extraction at the mean phosphoric acid concentration in wet-process acid (4.3*M*) may be obtained if higher concentrations of the extractants are used. Thus $D_U = 420 \pm 80$ was obtained by extracting from 4.32*M* phosphoric acid with 0.64*M* PMBP and 0.16*M* TOPO.

Uranium determination

During these studies, no significant extraction of phosphoric acid was observed. Hence the addition of aluminium salts in the photometric determination is necessary only for the analysis of the synergic extraction extracts, because of the presence of TOPO.

Most common substances accompanying wet-process phosphoric acid do not interfere (up to the highest concentrations tested) in uranium determination by the four possible combinations of extraction systems and colour reactions. The substances and highest concentrations tested (in g/l.) were calcium 8; aluminium 8; titanium(IV) 0.1; vanadium(IV) 0.2; rare-earth elements (Ce and Y) 0.05; thorium 0.05; sulphate 30; free sulphuric acid 15; fluorosilicic acid 30.

The behaviour of iron required special attention. Both uranium(VI) and iron(III) ions were effectively reduced by the addition of zinc powder, to extractable uranium(IV) and non-extractable iron(II). To prevent iron oxidation and co-extraction, it was necessary to maintain reducing conditions during the extraction process. This was achieved by adding iron powder before the extractant. The iron-powder reaction is slower than that with zinc and continues during the separation process. In this way, an iron content of up to 8 g/l. in the phosphoric acid is prevented from interfering.

The extraction procedures developed are as follows.

Chelate extraction. Two ml of the phosphoric acid solution (~4.3*M*) are placed in a 10-ml extraction tube and diluted with 1 ml of water, then 10–15 mg of zinc powder are added, and when the hydrogen evolu-

Table 3. Analysis of phosphoric acid solutions

* From weight of U_3O_8 standard taken.

tion diminishes, 5–10 mg of iron powder are added and the uranium is extracted by shaking with 3 ml of 20% w/v PMBP in toluene for 5 min. The uranium is determined with arsenazo III (without addition of aluminium).

Synergic extraction. Three ml of the phosphoric acid solution (~4.3*M*) are placed in a 10-ml extraction tube and reduced as above, then the uranium is extracted by shaking with 3 ml of 0.64*M* PMBP–0.16*M* TOPO (in toluene) for 5 min. The uranium is determined by the arsenazo III method in presence of aluminium ions.

Finally, four phosphoric acid samples with known uranium contents were analyzed by the methods developed. The results are given in Table 3 and illustrate the suitability of the methods for uranium determination in this kind of sample. The combination of synergic extraction with the uranium(IV)–arsenazo III colour reaction allows the determination of very low uranium contents.

Conclusions

The methods developed are suitable for determination of uranium in phosphoric acid solutions. The highest sensitivity is obtained by combination of the synergic extraction with the uranium(IV)–arsenazo III reaction. The synergic extraction of uranium(IV) with PMBP and TOPO is more effective that the simple chelate extraction of uranium(IV) with PMBP, and both systems are superior to the synergic extraction of uranium(VI) with DEHPA–TOPO.[10]

EVALUATION OF DIFFERENTIAL PULSE ANODIC-STRIPPING VOLTAMMETRY AT A STATIONARY MERCURY-FILM ELECTRODE WITH STIRRED SOLUTION

JOSEPH WANG

Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 6 *May* 1981. *Accepted* 24 *June* 1981)

Summary—Differential pulse anodic-stripping voltammetry at a stationary mercury-film electrode with the solution stirred during the deposition step has been investigated. The sensitivity achieved by using such a simple set-up is similar to that obtained with a mercury-film rotating disk electrode. The effects of various experimental parameters on the peak current are described. Lead and cadmium were used as test systems, and gave detection limits of around $1 \times 10^{-10} M$ with 5-min deposition times.

A thin mercury-film electrode (TMFE) deposited on a glassy carbon substrate has been shown to be the most sensitive electrode used in anodic-stripping voltammetry (ASV) for trace metals analysis.[1] Studies to improve the ASV response usually involve comparison of different excitation waveforms employed in the stripping step (*e.g.*, differential pulse *vs.* linear scan[1]), or of different electrode configurations (*e.g.*, TMFE *vs.* hanging mercury drop[2]) or of different substrates (glassy carbon *vs.* impregnated graphite[3]). While considerable research effort has gone into these aspects, little attention has been paid to the choice of different convective modes that may be employed during the deposition (preconcentration) step.

The deposition step in ASV is usually facilitated by convective transport of the metal ions to the electrode surface. The overall sensitivity and precision are largely dependent on the effectiveness and reproducibility of the hydrodynamics, which controls the amount of the metal plated during the deposition step. Most work with the TMFE (*e.g.*, references 4 and 5) has involved the use of a rotating disk electrode to improve the rate of transport of ions. Other modes of mass-transport employed in ASV have included flowing solutions (used mainly in on-line analysis[6]), and stirred solutions (used mainly in conjunction with the hanging mercury drop electrode[7]). One of the major practical restrictions of the TMFE is the apparent need for a rotating disk assembly; the high price of such an assembly (around $2000) often precludes the adoption of this technique. The use of a rotating disk assembly also has some limitations in ultratrace analysis: the location of the motor and electrical connections above the cell significantly enhance the contamination risk.[4] Some researchers have employed a stirred solution in conjunction with ASV at a TMFE,[8] instead of a rotating electrode, but no comprehensive comparison has yet been published of ASV at a stationary TMFE in a stirred solution with ASV at a rotating disk electrode.

This report describes the results of such a comparison.

Conventional stirring apparatus, using, for example a magnetic stirring bar, is cheaper than a rotating disk assembly by a factor of 15–20, and is available in most laboratories. The motion produced by stirring was one of the earliest modes of transporting electroactive species to electrode surfaces.[9] This approach is now used mainly in dissolved oxygen meters[10] or in ASV at the hanging mercury drop electrode,[7] but has not become widespread for other applications. Recently we have exploited it for sensitive voltammetric measurements based on hydrodynamic modulation procedures.[11] In such measurements the detectability is limited by the noise level associated with the stirrer. However, this is not the case with ASV, which is an indirect technique where the actual measurement (stripping) step is usually performed on a quiescent solution. Overall, the combination of the efficient stirring mass-transport (during the deposition step) with the sensitive differential pulse approach (during the stripping step) results in extremely high sensitivity, obtainable with relatively simple instrumentation.

EXPERIMENTAL

Apparatus and instrumentation

A 200-ml (6.5-cm diameter, 7.5-cm high) Pyrex glass cell with a four-hole "Plexiglas" cover was employed. The working electrode was a mercury thin film deposited on a 0.75-cm diameter glassy carbon disk. The Ag/AgCl (satd. KCl) reference electrode and the spectroscopic graphite counter-electrode were supported in two of the holes in the cover. The working electrode was mounted on a rotating

disk assembly, allowing direct comparison of the stirred-solution ASV experiments with those of rotating-electrode ASV. A 3.5-cm long Teflon-coated stirrer bar was placed on the cell bottom, exactly below the centre of the working electrode. The cell was located in a reproducible position on a variable-speed magnetic stirrer (Sargent-Welch, No. 76490). A paper towel was placed between the cell and the stirrer to reduce changes in the solution temperature due to heat from the motor. The arbitrary scale of the stirrer controller was calibrated for the empty cell with a digital tachometer. The stirring settings 4–10 yielded stirrer speeds of 340, 425, 515, 660, 830, 1020 and 1165 rpm, respectively, with a reproducibility of about 3%. Accurate calibration was not feasible when the cell contained a sample solution, as the water–air interface interfered in the optical detection system of the tachometer. Since the viscosity of the solution may affect the stirring-rate, settings are reported throughout this paper. An EG&G Princeton Applied Research model 364 polarograph was used as a three-electrode potentiostat. Voltamperograms were displayed on a strip-chart recorder.

Reagents

All solutions were prepared from analytical-grade chemicals and demineralized water. Stock solutions, 2.5mM, of various metal nitrates were prepared and stored in polyethylene bottles. Portions of these solutions were diluted as required for standard-addition purposes. The mercury plating solution, 2.5mM mercuric nitrate, was similarly prepared. All samples were prepared in 0.1M potassium nitrate supporting electrolyte.

Procedure

The glassy carbon electrode was polished, at the start of the work, with 0.1-μm alumina slurry until a mirror-like finish was obtained. The ASV data were obtained by co-depositing the mercury film and the trace metals on the working electrode in the following manner. The sample and 4 ml of the mercuric solution (total volume, 200 ml) were introduced into the cell and deaerated, then the nitrogen delivery tube was raised above the solution, and a potential of -1.0 V was applied at the working electrode while the solution was stirred (stirrer setting, 7). After 6 min, the potential was switched to 0.0 V and held there for 2 min. The electrode was then ready for use in an analytical run. Background and sample determinations were carried out successively by applying the plating potential for a selected time suitable for the concentration levels concerned. The stirring was then stopped, and after a 10-sec rest period the metals were stripped from the mercury film by applying a differential pulse anodic potential-ramp with a 2 mV/sec scan-rate and 50 mV amplitude. The scan was terminated at 0.0 V and after 30 sec the system was ready for the next plating–stripping cycle. The mercury film was removed at the end of the day by wiping the electrode face with a soft tissue wetted with 2M nitric acid, and the electrode was rinsed with demineralized water.

RESULTS AND DISCUSSION

The equation for the differential pulse anodic-stripping peak-current at a TMFE is given[12] by $i_p = -0.138\, q/t$, where t is the pulse duration, and q the total charge passed during deposition, equal to $i_L t_{dep}$, where i_L is the limiting current for the deposition of the metal in question, and t_{dep} the deposition time. If the deposition potential is in the mass-transport-controlled region, then under forced-convection conditions i_L is given[13] by $i_L = nFAC_bM$, where n, F, A, and C_b have their usual meanings in ASV work, and M is the mass-transport coefficient, which is proportional to the flux of the ion at the electrode surface. M has the general forms $K\omega^x$ and $K'U^{x'}$ for a rotating TMFE and for a stationary TMFE in a stirred solution, respectively (ω is the rotation speed, U the stirring rate, and K, K', x, and x' are constants, characteristic of the hydrodynamics and electrode configuration). Combining these equations leads to the following expression for the ratio of the peak-currents at the rotating TMFE and at the stationary TMFE with stirred solution,

$$\frac{i_{p,\,\text{rotation}}}{i_{p,\,\text{stirring}}} = \frac{M_{\text{rotation}}}{M_{\text{stirring}}} = \frac{K\omega^x}{K'U^{x'}}$$

which means that under the same experimental conditions the peak current ratio is equal to the ratio of the concentration gradients (*i.e.*, fluxes) during the deposition step.

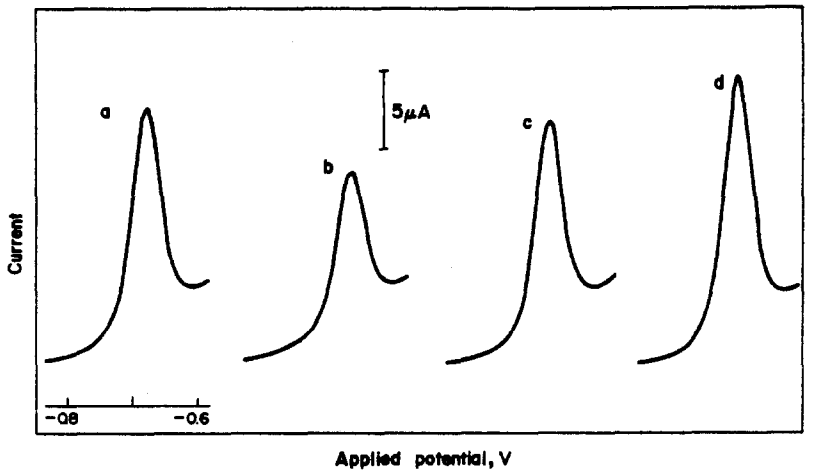

Fig. 1. Voltamperograms for $5.6 \times 10^{-6}M$ cadmium in 0.1M potassium nitrate, obtained with a stationary electrode in a stirred solution (a) and with a rotated electrode (b–d). Stirrer setting, (a): 8. Rotation speeds, 400 (b), 900 (c), and 1600 (d) rpm. Deposition step, 3 min at -1.0 V. Differential pulse amplitude, 50 mV. Scan-rate, 2 mV/sec.

Figure 1 compares differential pulse anodic-stripping peak-currents for the stationary electrode with stirred solution (a) and for the rotating electrode (b–d), obtained for $5.6 \times 10^{-8}M$ cadmium under otherwise similar experimental conditions. The peak-currents are of the same order of magnitude. The peak-current for the stationary TMFE with stirring at about 830 rpm is quite close to that for the rotating TMFE at 900 rpm and is 47% larger than that for the rotating TMFE at 400 rpm. As $i_{p,\,rotation}$ increases proportionately to the square-root of the rotational speed,[12] the peak-height at 1600 rpm is 15% larger than that for the stirred solution stationary TMFE. These results indicate that magnetic stirring does produce significant angular motion of the solution near the surface of the stationary disk electrode, resulting in similar flux values, M, and hence in similar sensitivities for the two methods.

Similar limits of detection would therefore also be expected, since the stripping step in both cases is usually carried out under the same conditions (stationary disk and quiescent solution), and thus background currents and noise levels are likely to be similar. Figure 2 illustrates the detectability which can be obtained with stirred solution (during the deposition) and a stationary TMFE; it shows a differential pulse anodic-stripping voltamperogram for $9 \times 10^{-10}M$ (0.1 ng/ml) cadmium and $6 \times 10^{-9}M$ (1.2 ng/ml) lead in $0.1M$ potassium nitrate solution, obtained by employing 5-min deposition. If the limit of detection is defined as the concentration giving a signal equal to the noise, its value for cadmium is around $1 \times 10^{-10}M$ (0.011 ng/ml). Even better detectability would be obtainable by using longer deposition periods. When stirring was used during the stripping step, the noise level was significantly larger, obscuring the peak currents of interest and raising the limits of detection.

Table 1 shows the dependence of the cadmium peak current on the stirrer setting. Increasing the stirring rate increases the peak current, but a maximum is reached at about stirrer setting 9 (about 1000 rpm). In addition, some difficulties occur at high stirring speeds because of vortex formation and frothing of the solution, producing tiny gas bubbles that cling to the mercury film. This problem gets worse the nearer the electrode is to the surface of the solution: though the distance between bottom of the beaker and electrode surface (in the range 1.5–3.5 cm) has no significant effect on the peak-current, interference due to gas bubbles is observed when this distance is larger than 2 cm (for the apparatus used). For these reasons stirring settings of 7 and 8 (about 660–830 rpm) and a distance of 1.5 cm between the disk surface and the bottom of the cell have been used throughout and are recommended for similar experimental conditions (different conditions, such as the size of the magnetic stirrer, may affect the efficiency of convective-transport).

Table 1. Dependence of peak-current or stirrer setting*

Stirrer setting	Approximate speed, *rpm*†	i_p, μA
4	340	6.1
5	425	6.5
6	515	8.0
7	660	8.4
8	830	9.4
9	1020	10.6
10	1165	10.8

* $5.6 \times 10^{-8}M$ Cd^{2+} in $0.1M$ KNO_3; deposition step, 2 min at -1.0 V; differential pulse amplitude, 50 mV; scan-rate, 2 mV/sec.
† Measured for an empty cell.

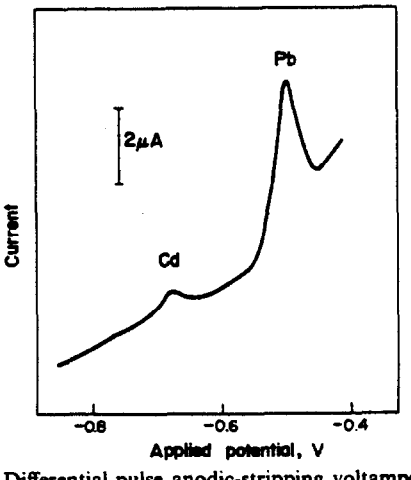

Fig. 2. Differential pulse anodic-stripping voltamperogram for $9 \times 10^{-10}M$ cadmium and $6 \times 10^{-9}M$ lead in $0.1M$ potassium nitrate. Deposition step, 5 min at -1.1 V. Stirrer setting, scan-rate and pulse amplitude, as in Fig. 1 (a).

The plot of peak-current *vs.* deposition period is linear for periods ranging from 1 to 7 min, with a slope of 2.2 μA/min for a $4.5 \times 10^{-8}M$ cadmium solution, but on extrapolation the straight line does not give $i_p = 0$ at $t_{dep} = 0$. The intercept, 1.05 μA, is attributed to plating-out of the metal ions during the slow scan from the deposition potential to the peak potential,[14] and to some of the metal ions stripped from the electrode during the pulse being replated into the mercury film in the waiting time between pulses.[12]

The precision was estimated by 10 successive measurements on a $1.3 \times 10^{-7}M$ lead solution over a 60-min period [conditions: 1-min deposition at -0.8 V; stirrer setting, scan-rate and pulse amplitude as in Fig. 1 (a)]. The mean peak-current was 17.5 μA with a range of 17.2–17.8 μA. The relative standard deviation over the complete series was 1.1%. The precision obtained compares favourably with that reported for the TMFE with other modes of convective transport.[14] This indicates that any heating effects of the stirrer motor have negligible influence on the precision. Over a 4-hr period of continuous operation with stirring, peak-currents for metal ions at the ng/ml level were found to decrease by about

15%. Such changes might be expected as a result of the gradual deterioration of the mercury film[15] or adsorption of the trace metals onto the cell and the electrode.[16] Mechanical stress is expected to cause less deterioration of the stationary TFME than of the rotating electrode, but on the other hand, the heat produced by the stirrer motor may affect the stability of response. The temperature was found to increase by 3–4° over the 4-hr period of continuous stirring, and the temperature coefficient of the diffusion coefficient is generally about 2–3% per degree.[17] Since the standard-addition method is generally used for calibration in ASV, these slow temperature changes do not affect the accuracy of the results, and if necessary the changes can be minimized by using electronically-generated stirring (*e.g.*, EG&G Model 305 stirrer) or thermostatic control of the cell assembly. In view of the results presented here, and the simplicity of the instrumentation and its operation, stripping analysis at a stationary TMFE with stirred solution may be considered as a rival approach to ASV at the rotating TMFE.

SPECTROPHOTOMETRIC DETERMINATION OF IRON AND REDUCING AGENTS WITH PPTS, A NEW WATER-SOLUBLE FERROIN-TYPE CHROMOGEN OF SUPERIOR SENSITIVITY

ALFRED A. SCHILT and MICHAEL R. DI TUSA

Department of Chemistry, Northern Illinois University, DeKalb, Illinois 60115, U.S.A.

(*Received* 30 *March* 1981. *Accepted* 16 *June* 1981)

Summary—A sulphonated derivative of 3-(4-phenyl-2-pyridyl)-5-phenyl-1,2,4-triazine has been prepared, its structure identified, and its chelation products with iron(II) and copper(I) identified and characterized. The water-soluble compound, referred to as PPTS, has been applied to the determination of iron in various types of samples and the spectrophotometric determination of trace quantities of certain reductants.

The most sensitive chromogenic reagent of the ferroin-type for iron found to date is 3-(4-phenyl-2-pyridyl)-5-phenyl-1,2,4-triazine.[1] Analytical applications for this reagent, however, are limited to non-aqueous solutions and extraction procedures because of its low solubility in aqueous solutions. To obtain a more useful water-soluble derivative of this compound we have prepared and characterized a sulphonated product which we refer to as PPTS. The structure of this compound and the stoichiometries of its iron(II) and copper(I) chelates are reported together with recommended procedures and results for the use of PPTS to determine iron in a variety of samples. Spectrophotometric determination of various reducing agents, based upon the reduction of iron(III) in the presence of PPTS, is also described.

EXPERIMENTAL

Reagents

The parent compound 3-(4-phenyl-2-pyridyl)-5-phenyl-1,2,4-triazine (PPT) was synthesized as described by Case[2] and sulphonated by the method of Cryberg and Diehl.[3] The sulphonated product was isolated as the ammonium salt, recrystallized from distilled water, and dried in air. Analysis gave C 44.3%, H 4.5%, N 15.2%, S 12.0%, H_2O 6.4%; $C_{20}H_{12}N_4(SO_3NH_4)_2.2H_2O$ requires C 44.44% H 4.47%, N 15.55%, S 11.86%, H_2O 6.7%. PPTS is also commercially available from the G. Frederick Smith Chemical Company (Item No. 728).

A 0.010*M* solution of PPTS [ammonium 3-(4-phenyl-2-pyridyl)-5-phenyl-1,2,4-triazine-disulphonate dihydrate] was prepared by dissolving 0.54 g of the reagent in 100 ml of distilled water.

Standard solutions of iron and copper were prepared from weighed amounts of the pure metals (electrolytic) dissolved in hydrochloric or nitric acid and diluted to known volumes with distilled water.

A 10% solution of hydroxylamine hydrochloride was prepared by dissolving 100 g in 900 ml of distilled water. Traces of iron and copper were removed by extraction with isoamyl alcohol.[4]

For the spectrophotometric determination of reducing agents, composite reagent solution was freshly prepared as needed. The concentrations of the components were $2.0 \times 10^{-3}M$ PPTS, $2.0 \times 10^{-4}M$ ferric chloride and $2.0 \times 10^{-3}M$ hydrochloric acid.

Buffer solutions were prepared for the pH range 4–6 by adding glacial acetic acid to 1*M* ammonium acetate, and for the range 8–10 by adding concentrated ammonia solution to 1*M* ammonium chloride. The pH 7 buffer was 1*M* ammonium acetate.

The standard reference materials (SRMs) used in testing the recommended procedure for the determination of iron in plant material were obtained from the U.S. National Bureau of Standards. The synthetic sea-water sample had known concentrations of iron, sodium chloride (30 g/l.) and sodium fluoride (0.022 g/l.).

Apparatus

Spectra and absorbances were recorded with a Cary Model 14 spectrophotometer (visible region), a Sargent-Welch Model 3-200 spectrophotometer (infrared), and a JEOL Model PFT 100 spectrometer [proton magnetic resonance (PMR)].

Determination of iron in plant matter

Transfer an accurately weighed 1-g sample of the plant material into either a 125-ml conical flask or a porcelain crucible, depending on whether wet oxidation or dry ashing is to be used. For wet oxidation use either of the procedures described on pages 75 and 76 in Ref. 5. For refractory substances the procedure on page 76 (with nitric, sulphuric and perchloric acids) is recommended. To dry ash the sample, first heat the crucible and contents at low temperature to char the sample, then at higher temperature to drive off most of the carbon, and finally at 800–900° to ash the sample completely. Cool to room temperature, moisten the ash with 1–3 drops of concentrated nitric acid, evaporate to dryness, and again ignite at 800–900° for 1 hr. Cool, dissolve the ash in 3 ml of 6*M* hydrochloric acid and transfer the solution quantitatively to a 100-ml standard flask. Wash the crucible with another 3-ml portion of 6*M* hydrochloric acid and rinse into the same flask. Dilute to volume with distilled water.

Pipette a 10-ml aliquot of the sample solution into a 25-ml standard flask and add 1 ml of 0.1*M* PPTS, 5 ml of

10% hydroxylamine hydrochloride solution, and 5 ml of 5*M* ammonium acetate (to adjust to pH 5–7). Dilute to volume with distilled water, and measure the absorbance at 565 nm. Also measure the absorbances of a blank and standards carried through the complete procedure (including the ashing or wet oxidation procedure used). Correct the absorbances for the blank and determine the concentration of iron in the sample from the data obtained for the standards.

Determination of iron in sea-water or potable water

Pipette a 50.0-ml sample of the water into a 125-ml glass-stoppered conical flask. Add by pipette 1.00 ml of 0.01*M* PPTS, 1.00 ml of 10% hydroxylamine hydrochloride solution and 2.00 ml of 5*M* ammonium acetate. Stopper the flask, heat the contents to 90–100°, and set aside to cool to room temperature. Measure the absorbance at 565 nm, using a 10-cm cell for ng/ml levels of iron. Carry a blank and one or more standards through the same procedure to deduce the unknown iron concentration.

Spectrophotometric determination of reductants

Into a glass-stoppered flask pipette 5.00 ml of the composite reagent solution and 5.00 ml of reductant sample solution. After the predetermined reaction time, measure the absorbance of the solution at 565 nm against a reagent blank (prepared at the same time as the test solution). Determine the concentration of the reductant by using a calibration curve obtained with standards treated in the same way as the unknown.

RESULTS AND DISCUSSION

The structure of PPTS, deduced from elemental and spectral analysis of the sulphonated product, is depicted in Fig. 1. The infrared and PMR spectra indicated that the phenyl groups were sulphonated in the *para* position, as found for other phenyl-substituted ferroin-type reagents.[6]

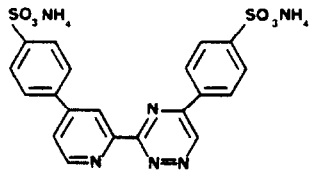

Fig. 1. Structure of PPTS.

The stoichiometry and formation constants for iron(II) and copper(I) chelates of PPTS in aqueous solutions at pH 7 were determined by a modification[7] of the mole-ratio method. A ligand to metal ratio of 3:1 and a conditional formation constant of 4.4×10^{15} were found for the iron(II) chelate. For the copper(I) chelate a ratio of 2:1 and a formation constant of 6.5×10^{9} were obtained. Unfortunately, the relative stabilities of the PPTS and PPT chelates cannot be directly compared because the formation constants of the PPT chelates are not determinable for aqueous solution owing to solubility limitations. However, PPTS forms much weaker complexes than 2,2′-bipyridyl,[8] presumably because of the electron-withdrawing effect of the sulphonate groups.

The spectral data for the iron(II) and copper(I) chelates of PPTS are compiled in Table 1 together with data for comparison with the PPT chelates. Since the PPT chelates are insoluble in water, the absorption characteristics were determined as a function of ethanol content of the solution. Thus the chelates of PPT and PPTS can be compared for similar conditions. Clearly, sulphonation has little effect on the molar absorptivity of the iron(II) chelate but an appreciable

Table 1. Molar absorptivities of PPTS and PPT complexes in aqueous and ethanolic solutions (pH 7)

effect on that of the copper(I) chelate. Similar effects were observed with sulphonation of 2,4-BDTP, PDT, PPDT and 2,6-BDTP,[6] all closely related to PPT. The high sensitivities of PPT and these chromogens for iron determination are thus retained when they are converted into water-soluble derivatives by sulphonation.

Interference studies, are summarized in Table 2. A test ion was deemed to interfere if it caused an error of ±3% in the determination of 0.84 ppm of iron. Only copper and chromium gave high results, because they formed coloured products with PPTS. The other metal ion interferences were due to competitive complexation, giving rise to incomplete chelation of iron and low results, though there was no spectral interference. Anion interference was due to competitive complexation of the iron by the anion. Cyanide interference can be easily avoided by acidification and

boiling before addition of PPTS and final adjustment to pH 7.

To evaluate its practical effectiveness, PPTS was used for determination of iron in a variety of samples. The results, complied in Table 3, provide several interesting conclusions. PPTS is seen to be highly sensitive and to give good precision and accuracy, but the recovery of iron is clearly dependent on the sample decomposition method used. Complete recovery was obtained more often when wet oxidation with the nitric–sulphuric–perchloric acid mixture was used. Furthermore, sample treatment and operator dexterity were less critical for the wet oxidation than for the dry ashing procedure. Finally, it was disturbing not to be able to reproduce the result reported by NBS for Tomato Leaves SRM 1573. We obtained essentially the same result with 1,10-phenanthroline in place of PPTS and are inclined to believe that our result adequately approximates the "true" iron content of SRM 1573.

The use of ferroin chromogens for the determination of reducing agents[8–10] is based on the reaction of the reductant with iron(III) and determination of the iron(II) produced. We therefore examined the usefulness of PPTS for determining trace amounts of certain reductants of biological or chemical interest. The results are summarized in Table 4. Only cysteine and ferrocyanide gave reasonably rapid and stoichiometric results. The other reductants tested proved slower and less complete in their reactions with iron(III) at room temperature but gave linear empirical calibration curves suitable for use if a strict time-schedule was kept. Colour formation was much faster at elevated temperatures (60–90°), so a heating step should enhance the sensitivity and shorten the reaction time. The reagent-blank absorbance increased slowly with time, more rapidly on heating, but the increase was reproducible and small relative to the absorbance for a sample. Uric acid and 2-thioethylamine, though not included in Table 4, were also found to reduce iron(III) on heating, so they too should be determinable by a proper modification of the procedure. It also appears probable that differences in reaction rates could be used for distinguishing between two or more reductants in a mixture, enabling multicomponent determinations to be made. Such applications and the development of optimum procedures are commended to those who recognize the merits of PPTS and its analytical potential.

SHORT COMMUNICATIONS

AN ENZYMATIC METHOD FOR TLC DETECTION AND DETERMINATION OF FENITROTHION IN WATER

S. UDAYA BHASKAR
c/o Biological Oceanography Division, National Institute of Oceanography, Dona Paula-403 004, Goa, India

(*Received* 2 *March* 1981. *Revised* 7 *July* 1981. *Accepted* 6 *August* 1981)

Summary—A simple enzymatic method is described for field TLC detection and determination of fenitrothion as fenitrooxon in water, with pig liver acetone powder as enzyme source. By this method, fenitrothion can be detected as fenitrooxon at ng levels and amounts ranging from 5 to 50 ng can be estimated.

The cholinesterase (ChE) inhibition technique is promising and practical for the detection and determination of organophosphorus pesticides.[1,2] An enzymatic method for TLC determination of parathion as paraoxon, with use of raw rat liver as the enzyme source, was reported by Nandakumar *et al.*[3,4] but can be used only in the laboratory. Bhaskar and Nandakumar[5,6] find that pig liver acetone powder is more advantageous than raw live sources, owing to its easy procurement and instant use. Hence, this is used as the enzyme source in the present method, which is suitable for field detection and determination of fenitrothion by thin-layer chromatography. The procedure takes only 1 hr and may find application in evaluation of fenitrothion residues in contaminated waters in remote places, rivers or lakes.

EXPERIMENTAL

Reagents

All chemicals were analytical grade. Fenitrothion (99% pure) was used for preparing acetone solutions of various concentrations. Pig liver acetone powder (Sigma Chemical Co., U.S.A.) was homogenized in water (20–28°) with a mortar and pestle to give a 1% suspension, filtered through four layers of cheesecloth and used immediately as enzyme source. 1-Naphthyl acetate solution in acetone, 0.5%, and *p*-nitrobenzenediazonium fluoroborate solution in acetone, 0.4%, were prepared.

TLC plates (20 × 10 cm) coated with a 450-μm thick layer of silica gel G were prepared as reported earlier[3] and dried before use.

Thin-layer chromatography

Different concentrations of standard pesticide solutions (1–10 μl) in acetone were spotted on a dried TLC plate with a graduated glass capillary. The plate was exposed to evenly distributed bromine vapour[3] for complete oxidation of fenitrothion to fenitrooxon. The plate was removed and exposed to air for 5 min to volatilize the bromine. An acetone:hexane (1:9 v/v) solvent system was employed. After the chromatography, the plate was dried. The pig liver acetone powder suspension was uniformly sprayed over the plate, thoroughly wetting the gel. About 5–10 ml of suspension is required for a 20 × 10 cm TLC plate. The plate was kept in a moist atmosphere for 10 min, the moist atmosphere being generated as follows. A glass tank (20 × 30 × 10 cm) was fitted with a raised platform inside to carry the TLC plate. Boiling water was poured into the tank to a level below the raised platform, and the tank was closed with a lid. This generated a sufficiently moist atmosphere for enzyme incubation to occur within 5–10 min. The air temperature from the raised platform to the top of the TLC plate ranged from 45 to 35°.

The plate was then sprayed with 1-naphthyl acetate solution in acetone and was replaced in the moist atmosphere for 2 min. It was next sprayed uniformly with *p*-nitrobenzenediazonium fluoroborate in acetone. The white spots that appeared on the orange-red background were marked.

The fenitrothion (as fenitrooxon) was estimated by both the area measurement and area weight methods previously reported.[3]

Residue estimation

A litre of water uncontaminated with organophosphorus pesticides was mixed with different amounts (Table 2) of fenitrothion in 1 ml of acetone and a drop of Tween 80 (for uniform mixing). After 48 hr, the sample was transferred to a separatory funnel and 100 ml of hexane were added. The mixture was shaken vigorously for 2 min. The layers were allowed to separate and the aqueous layer was run into another separatory funnel and shaken vigorously with another 100 ml of hexane for 2 min. The aqueous layer was discarded. The combined hexane extracts were filtered through a column (150 × 24 mm) of anhydrous sodium sulphate into a Petri dish and left to evaporate in the heat of the sun. The residue extract was appropriately diluted with acetone and the fenitrothion determined as described above.

RESULTS AND DISCUSSION

The ChE inhibition zones were determined by the area measurement and area weight methods. The results (Table 1) showed that fenitrothion can be estimated at the nanogram level by this method, the minimum detectable quantity being 1 ng.

Table 1. Relationship of ChE inhibition with fenitrothion concentration as determined by area measurement method and area weight method

Fenitrothion, *ng*	Area measurement method		Area weight method*	
	Inhibition zone, mm^2	ChE inhibition, %*	Inhibition zone *mg*	ChE inhibition, %*
5	18	8 ± 0.1	4	8 ± 0.5
10	31	14 ± 0.5	7	13.5 ± 1
20	78	32 ± 1	15	29 ± 1
30	108	48 ± 1	25	48 ± 2
40	148	67 ± 1.5	33	63.5 ± 2
50	184	82 ± 2	40	77 ± 3.5

* Values are means of 6 observations ± range.

Table 2. Estimation of fenitrothion residues as fenitrooxon in fortified water samples

Fenitrothion added, *μg*	Fenitrothion recovered as fenitrooxon, *μg*	
	Area measurement method	Area weight method
5	5 ± 0.5*	5 ± 0.9
10	10 ± 0.7	10 ± 0.6
15	14 ± 0.9	15 ± 0.9
20	19 ± 0.3	19 ± 1.4
25	24 ± 1.1	24 ± 0.8

* Values are means of 6 observations ± range.

The method can be used for field analysis of fenitrothion residues in water. The water for the moist atmosphere for enzyme incubation can be boiled on a portable stove, and in hot climates the hexane can be evaporated by the heat of the sun. In cold climates the hexane can be evaporated by placing the Petri dish on a metal plate previously warmed to about 40–45°. Table 2 shows that the results for residue analysis are satisfactory.

Acknowledgements—The author is grateful to Dr. N. V. Nandakumar for his suggestions and Rallis India Ltd., Bombay for a generous supply of fenitrothion.

SYNTHESIS AND ANALYTICAL PROPERTIES OF DI(2-PYRIDYL)-*N*,*N*-DI[(8-QUINOLYL)AMINO]METHANE

R. ESCOBAR, J. M. CANO-PAVON, J. BELLANATO*, E. GALVEZ† and F. PINO

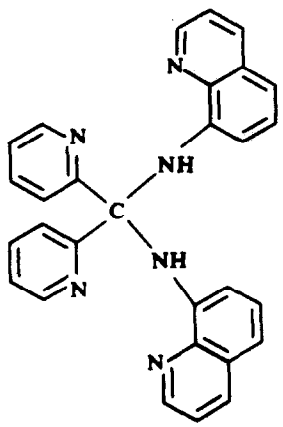
Department of Analytical Chemistry, Faculty of Chemistry, The University, Sevilla-4, Spain

(*Received* 24 *February* 1981. *Accepted* 6 *August* 1981)

Summary—The synthesis and preliminary analytical assessment of di(2-pyridyl)-*N*,*N*-di[(8-quinolyl)-amino]methane is reported. It shows some potential as a reagent for iron(II).

Schiff's bases derived from 8-aminoquinoline have been synthesized by Lions and co-workers,[1-3] and the chelates of these compounds with iron(II) and some other metal ions have been isolated. The compound 8-picolylideneaminoquinoline, formed by condensation of 8-aminoquinoline with pyridine-2-aldehyde in the form of its chelate with iron(II) has been used for the extraction of perchlorate into nitrobenzene.[4]

This paper describes a new reagent obtained by reaction of 8-aminoquinoline with di-2-pyridyl ketone in a 2:1 ratio, to yield di(2-pyridyl)-*N*,*N*-di[(8-quinolyl)amino]methane, DPQAM, and not the Schiff's base.



EXPERIMENTAL

Synthesis of DPQAM

A solution of 8-aminoquinoline (2.8 g) and di-2-pyridyl ketone (2.5 g) in ethanol (15 ml) was heated under reflux for 4 hr, and then cooled to room temperature. The yellow precipitate was collected and washed with hot ethanol, and dried at 100° for 10–12 hr (m.p. 225–227°, yield 60%). Changing the reactant ratio did not affect the synthesis.

Elemental analysis gave C 76.8%, H 4.8%, N 18.9%. $C_{29}H_{22}N_6$ requires C 76.65%, H 4.83%, N 18.52%. Formation of a Schiff's base would give $C_{20}H_{14}N_4$ which requires C 77.39%, H 4.54%, N 18.06%. The molecular weight found cryoscopically was 440 ± 40. $C_{29}H_{22}N_6$ requires 454, and $C_{20}H_{14}N_4$ 310.

The infrared spectrum of DPQAM in $CHCl_3$-*d* showed the stretching vibrations of the NH groups at 3495 and 3355 cm^{-1}, but none due to a C=N group. Bands characteristic of the quinoline ring were found at 1592, 1579, 1569, 1508, 1477, 1429, 1378, 1337, 1098, 820 and 795 cm^{-1} (in KBr). In contrast, 1-benzylideneaminoaphthalene (synthesized for comparison) showed the C=N stretching band at 1629 cm^{-1}, but no bands in the NH stretching region.

The NMR spectrum in $CHCl_3$-*d* showed two multiplets at 6.8–8.2 and 8.7–9.0 ppm, due to the heterocyclic rings, and a peak at 9.9 ppm which was attributed to the –NH– group; this peak disappeared on addition of deuterium oxide. Integration of the peaks confirmed the structure.

The mass spectrum gave molecular ions at m/e = 454 (corresponding to the parent compound), 310 (Schiff's base) and 144 (8-aminoquinoline). These results confirmed the proposed structure and partial fragmentation into the Schiff's base and 8-aminoquinoline.

Physical properties

Solutions of DPQAM in DMF, ethanol or DMF–water mixtures are stable for at least a week.

The absorption spectra of DPQAM show bathochromic shifts in acid and basic media. The reagent shows three ionization steps. Since the molecule is symmetrical and the distance between the dissociable protons is relatively great, the values of the ionization constants for corresponding groups in the two halves would be expected to lie close together, and be indistinguishable by spectrometry. The pK values of the first and second ionization steps were calculated from the variation of absorbance with pH, at different wavelengths, by the Stenstrom and Goldsmith[5] and Sommer[6] methods; the mean values found were 2.48 and 3.83. For the calculation of the third pK value, in highly basic medium, the acidity function[7] H_- was used: $pK = H_- + \log [HL]/L^-]$; when $[HL] = [L^-]$, $H_- = pK$. Values of H_- have been tabulated by Schwarzenbach and Sulzberger[8] for known concentrations of sodium hydroxide. The absorbance at 275 nm was plotted against H_-, and the inflection point calculated. The value obtained was 13.6.

Spectrophotometric study of reactions with metal ions

The reactions of 40 cations with DPQAM were tested at different pH values. The most sensitive were those of iron(II) (green colour), cobalt (II) (yellow) and nickel(II) (yellow). For the spectrophotometric study of the most interesting reactions, the samples were prepared in 25-ml standard flasks with 1–8 ppm of metal ion, 5 ml of 0.1% DPQAM solution in dimethylformamide, 5 ml of buffer solution and dilution with distilled water. The absorbance

Table 1. Characteristics of DPQAM complexes

Ion	Optimum pH	λ_{max}, nm	ϵ, $l.mole^{-1}.cm^{-1}$	M:R
Co(II)	1.0–7.5	380	8.2×10^3	1:2
Ni(II)	2.5–6.5	365	2.9×10^4	1:2
Fe(II)	3.5–6.5	685	9.4×10^3	1:2

was measured at 350–700 nm against a reagent blank. The most important results are summarized in Table 1.

DISCUSSION

From the experimental evidence the structure of DPQAM was deduced and it was concluded that the Schiff's base is not formed. However, when 1-naphthylamine reacts with benzaldehyde, the Schiff's base is formed very easily. This difference in behaviour may be attributed to the effect of the heterocyclic nitrogen atoms, resulting in formation of intramolecular hydrogen bonding between the NH groups and the N atoms of the pyridine rings, which stabilizes the structure sufficiently for this compound to remain unaltered in acid and alkaline media.

The first ($K_1 = K_2$) and second ($K_3 = K_4$) pairs of dissociation constants found must be due to the four protonated heterocyclic nitrogen atoms, so the neutral compound acts as a polyacidic base. The first pK value (2.48) may be attributed to the protonated pyridine rings. That their basicity is less than that of the dipyridyl ketone is presumably due to hydrogen bonding. The second pK value of 3.83 is attributed to the protonated nitrogen atoms of the quinoline rings, and is similar to that reported (3.56) for protonated 8-aminoquinoline.[9] The third value (13.6) is due to deprotonation of the NH-groups, and is similar to that for other compounds with the same group.[10]

The stoichiometric ratios found for the complexes of iron(II), cobalt(II) and nickel(II) show that each half of the molecule behaves independently, and this may be attributed to internal steric hindrance.

Compounds of this type have not previously been used as analytical reagents. DPQAM is a promising reagent for iron(II); the green 1:2 complex is extracted into chloroform in the presence of perchlorate or iodide; this extraction is very selective, and the partition coefficient very favourable. Although the sensitivity of the iron(II) reaction is of the same order as that of related reagents which also form green chelates, the selectivity of DPQAM is greater.[11]

POLAROGRAPHY OF AN ACIDIC DEGRADATION PRODUCT FROM CEPHALEXIN

LUIS J. NUÑEZ-VERGARA, J. A. SQUELLA and M. M. SILVA

Department of Chemical Pharmacology and Physical Chemistry, Faculty of Chemical and Pharmacological Sciences,
University of Chile, P.O. Box 233, Santiago, Chile

(*Received* 12 *September* 1980. *Revised* 16 *April* 1981. *Accepted* 6 *August* 1981)

Summary—2-Hydroxy-3-phenyl-6-methylpyrazine is identified as the product obtained by acidic degradation of cephalexin in the presence of formaldehyde. In 5*M* hydrochloric acid this product gives a well-defined reduction wave with a half-wave potential of −0.45 V *vs.* SCE. The wave is irreversible and diffusion-controlled. The diffusion current shows a linear relation with the cephalexin concentration and can be used for determination of cephalexin in plasma.

The β-lactam rings of cephalosporins and penicillins readily hydrolyse. The opening of the β-lactam ring of penicillins gives the penicilloates, but the analogous cephalosporoates are unstable and undergo further reaction. Cephalosporins with a substituted 3-methyl group undergo polarographic reduction,[1,2] but those with an unsubstituted 3-methyl group and no other reducible group do not give a peak at the dropping mercury electrode, though some of their degradation products act as depolarizers.[3,4]

In previous papers[5,6] we have reported polarographic methods for cephradine and cephalexin, based on the electroactivity of an acidic degradation product. The present paper reports on the electroactive degradation product from cephalexin obtained by acidic hydrolysis with 5.0*M* hydrochloric acid containing 1% of formaldehyde, and on a polarographic method for cephalexin in plasma.

EXPERIMENTAL

Reagents

Cephalexin (100% chromatographically pure, 99.0% activity) was obtained from Benguerel Laboratories, Santiago, Chile. All other chemicals were analytical grade.

Sørensen citrate buffer, pH 5.0, was prepared by dissolving 21 g of citric acid monohydrate in 200 ml of 1*M* sodium hydroxide and diluting to 1 litre. For preliminary work, Clark–Lubs buffers were used for pH 1–2, McIlvaine buffers for pH 2–8 and Sørensen buffers for pH 9–11.

Apparatus

The apparatus was that used in our work on flucloxacillin.[7] The operating conditions were: imposed drop-time 1 sec; scan-rate 10 mV/sec; voltage range 0.50 V; current range 5–15 μA full-scale; capillary characteristics $m^{2/3}t^{1/6} = 0.693$ mg$^{2/3}$.sec$^{1/6}$. The water-jacketed polarographic cell was kept at 25°. Solutions for polarography were deoxygenated with nitrogen which had previously been passed through a vanadium(II) scrubber.

Procedure

Cephalexin solution was hydrolysed in presence and absence of formaldehyde, at various acidities and for various times. The hydrolysed cephalexin solution was adjusted to pH 4.0 with sodium hydroxide, buffered with the pH-5.0 citrate solution, and extracted repeatedly with ethyl acetate. The combined organic extract was evaporated to dryness and the crude product was recrystallized from ethyl acetate. The product had an uncorrected m.p. of 206–208°. Analysis gave C 70.7%, H 5.5%, N 15.2%; $C_{11}H_{10}H_2O$ requires C 70.95%, H 5.41%, N 15.04%. The product had the following spectral characteristics: visible spectrum, λ_{max} (5.0*M* hydrochloric acid) 375 nm; infrared, ν (KBr disc) 2800 cm^{-1} (OH), 1650 cm^{-1} (amide), 1617, 1295, 750 and 690 cm^{-1}; NMR, δ($CDCl_3$, TMS external standard), 2.36 (3 Hs); 7.42 (4 Hm); 13.45 (1 Hs).

2-Hydroxy-3-phenyl-6-methylpyrazine was synthesized according to Barbhaiya.[8] Its elemental analysis, spectral characteristics and half-wave potential were identical with those of the degradation product, and a mixed melting point showed no depression.

For calibration 1.0–5.0-mg amounts of cephalexin were dissolved in 0.2 ml of plasma and diluted to 15 ml with 1% formaldehyde solution in 5.0*M* hydrochloric acid. For recovery tests, 2.0-mg cephalexin calibration solutions were used. These samples were hydrolysed by heating at 80° for 60 min in a constant temperature bath.

RESULTS AND DISCUSSION

The acidic hydrolysis of cephalexin in presence of formaldehyde yields a degradation product which has been isolated and identified as 2-hydroxy-3-phenyl-6-methyl pyrazine. An identical product from neutral hydrolysis of cephalexin was reported by Fogg.[9] We have obtained the same compound from the acidic hydrolysis of ampicillin.[10]

2-Hydroxy-3-phenyl-6-methylpyrazine exhibits a well-defined polarographic wave with a half-wave potential of −0.45 V *vs.* SCE in 5.0*M* hydrochloric acid. The half-wave potential is strongly dependent on pH ($\Delta E_{\frac{1}{2}}/\Delta pH = -0.068$ V, from pH 1 to pH 9).

The wave appears to be diffusion-controlled and the limiting current is proportional to the concentration of the depolarizer, as predicted by the Ilkovič equation. This linear relation can be used for determination of cephalexin in plasma. The compound, in hydrochloric acid medium, also shows a sharp absorbance maximum at 375 nm; the molar absorptivity is pH-dependent. We have used both properties to study the effect of acid concentration on the hydrolysis of cephalexin (Fig. 1). Figure 2 shows the rate of

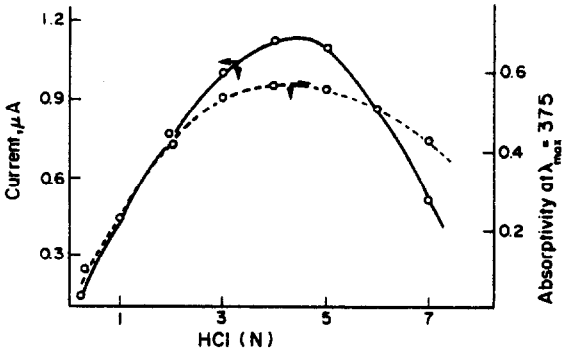

Fig. 1. Effect of acidity on diffusion current (——) and UV absorption at 375 nm (-----) of hydrolysed cephalexin.

formation of 2-hydroxy-3-phenyl-6-methylpyrazine at 60° and 80°. At 40° the reaction takes 180 min to reach completion. The hydrolysis product obtained in the absence of formaldehyde (compound A) cannot be isolated by the procedure used for the product (B) obtained in presence of formaldehyde. Product A gives two polarographic waves (at $E_{\frac{1}{2}}$ −0.50 and −0.78 V) but B gives only one wave ($E_{\frac{1}{2}}$ = −0.45 V). The identity of product A is being sought through synthesis of various substituted pyrazines.

The hydrolysis in presence of formaldehyde practically doubles the sensitivity for cephalexin.

The effect of different amounts of formaldehyde on the polarography of the pyrazine derivative is shown in Table 1: no suppressive action on the polarographic wave height was found.

There is an optimum formaldehyde concentration for the hydrolysis reaction (Table 2). This effect was observed for all the cephalexin concentrations tested (0.50–6.00 mg/ml). The use of more than 1% of formaldehyde decreases the degree of degradation of the cephalexin. Hence the recommended hydrolysis conditions are those used for the calibration. The calibration graph is linear, the equation being: $i_d(\mu A) = 1.18 \times 10^3 C - 0.032$ where C is the cephalexin concentration (mole/l.); the correlation coefficient is 0.991. The recovery for 2 mg of cephalexin was 98%, standard deviation 2% (7 replicates). The lower limit of detection was 40 μg of cephalexin per ml of plasma. This sensitivity is not adequate, because in man, after a 500-mg dose the peak antibiotic concentration is about 15 μg/ml.[11,12] The sensitivity might be improved by using differential pulse polarography, which is not available to us. Our earlier polarographic method for cephalexin was based on incomplete hydrolysis, and the method given here is better. The major advantage of the proposed method is that no extraction or deproteination is needed.

(*Received* 28 *November* 1980. *Revised* 28 *May* 1981. *Accepted* 22 *June* 1981)

Summary—A spectrophotometric investigation has been made of the red water-soluble complex of phenylbiguanide with iron(II) in cyanide medium. The complex is found to have maximum absorbance at 520 nm. Use of the extension of the Asmus method to $M_rL_mL'_n$ complexes and of Koch and Ackermann's method suggests the formula $[Fe(phenylbiguanide)(CN_4)]^{2-}$ for the red compound. Anlytical procedures for the detection of iron and cyanide are proposed.

In a previous paper on the reactivity of phenylbiguanide with metal ions, the formation of a new coloured compound with iron(II) in cyanide medium was reported.[1] Its nature and properties have now been established by means of a spectrophotometric investigation in the visible region, and analytical procedures for the determination of iron and cyanide are proposed.

The co-ordination sphere of the metal centre in Fe(II)–cyanide–ligand ternary complexes is octahedral, and the ligand often contains nitrogen as donor-atom. Most iron(II) complexes are high-spin and kinetically labile. A few ligands, such as cyanide, interact strongly with this metal centre to force spin-pairing, giving the kinetically inert configuration, where activation energies are high.

The great number of physical and chemical studies done, especially since 1970, shows the interest in these compounds. References to formation constants or analytical applications are very few, however.

EXPERIMENTAL

Reagents

Phenylbiguanide hydrochloride was prepared according to Cohn[2] and purified as described before.[1] Analysis gave C 45.0%, H 5.5%, N 32.9%, Cl 16.6%; $C_8H_{13}N_5Cl$ requires C 44.97%, H 5.66%, N 32.78%, 16.59%. All chemicals used were of analytical grade.

Procedures

These are indicated in the text.

RESULTS AND DISCUSSION

Iron(II) reacts with phenylbiguanide in cyanide medium to form a soluble red compound. The compound is also obtained, in presence of excess of phenylbiguanide, from iron(III), probably because of reduction to iron(II) by the reagent. In the presence of oxidizing or iron(III)-complexing agents, the reaction is partially or totally suppressed. In the presence of reductants, the reaction is quantitative and more rapid. There is no reaction with ferrocyanide or ferricyanide. The product is retained on an anion-exchange column (Dowex 1, OH-form), suggesting the existence of an anionic Fe(II) complex. Similar red compounds have been obtained with biguanide and ethylenedibiguanide.[3]

Iron(II) solutions containing excess of phenylbiguanide and cyanide at pH >10 exhibit a characteristic spectrum (Fig. 1) with a band due to charge transfer ($t_{2g} \rightarrow \pi^*$) from iron to phenylbiguanide; this assignment is based on the high molar absorptivity and comparison with the spectra of similar compounds.[3]

The absorption spectrum changes with pH (Fig. 2). The band at 520 nm increases with pH, while the band at 420 nm decreases. The maximum colour development is at pH 11.2–11.7; with further increase in pH the absorbance falls rapidly. At pH >11 the reproducibility of the results is poor, owing to precipitation of iron(III) hydroxide because of atmospheric oxidation.

Phenylbiguanide must be present before the iron(II) and cyanide solutions are added if the colour is to be developed without precipitation of iron(III) hydroxide. For the highest reproducibility, it is best to add the cyanide to the mixture of iron(II) and phenylbiguanide, then adjust the pH with sodium hydroxide. The maximum absorbance is reached in an hour and the colour is stable for at least 6 hr, then gradually fades; the total decomposition of the compound requires more than six months. Temperature does not much affect the absorbance and boiling for an hour is necessary for the solution to decolorize completely.

The wavelength of the absorbance maximum is independent of the ligand concentration. Large excesses of the ligands are needed, however, with the molar ratios cyanide/Fe(II) and phenylbiguanide/Fe(II) >60 and >150, respectively.

Coleman's method[4] was applied to solutions having molar ratios of phenylbiguanide/Fe(II) >0.5 and of cyanide/Fe(II) >6 [lower molar ratios could not be

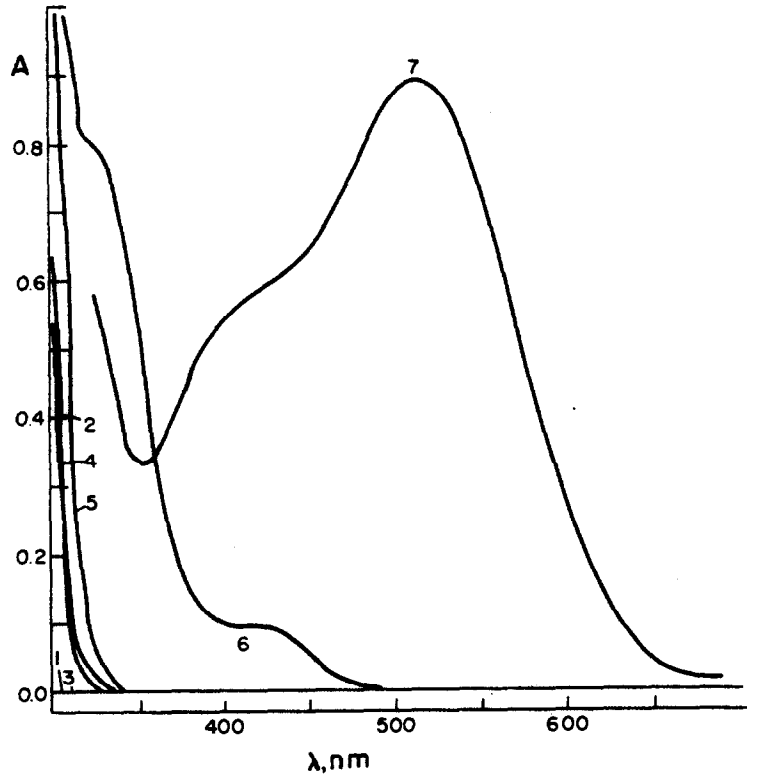

Fig. 1. Absorption spectra: Fe(II) $1 \times 10^{-3}M$, phenylbiguanide $2.5 \times 10^{-3}M$, CN^- $5 \times 10^{-3}M$; 1-cm cells. (1) Fe(II) (acid medium, $2 \times 10^{-4}M$ H_2SO_4); (2) phenylbiguanide; (3) CN^-; (4) Fe(II)–phenylbiguanide (acid medium, $2 \times 10^{-4}M$ H_2SO_4); (5) phenylbiguanide–CN^-; (6) Fe(II)–CN^-; (7) Fe(II)–phenylbiguanide–CN^-.

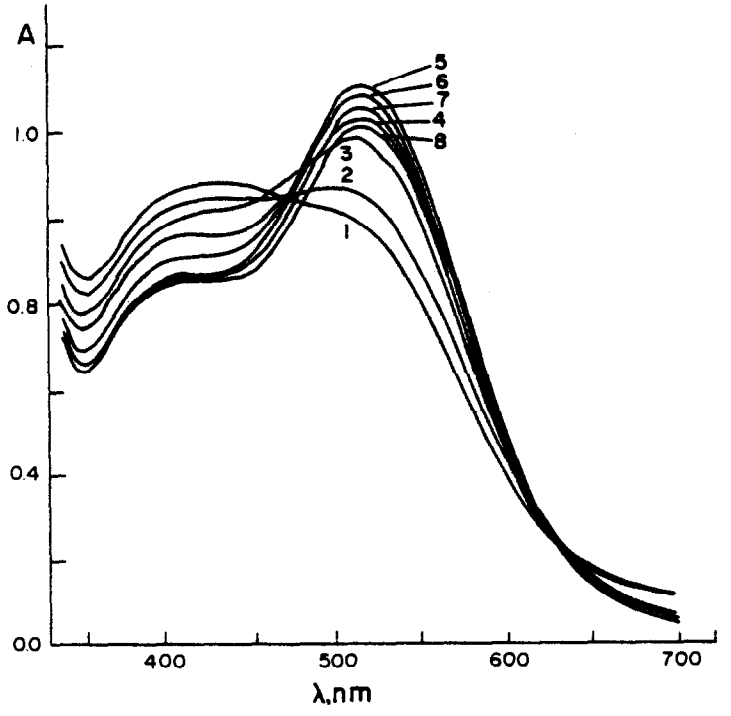

Fig. 2. Absorption spectra at various pH values [Fe(II) $1 \times 10^{-3}M$, phenylbiguanide $8 \times 10^{-3}M$, CN^- $2 \times 10^{-2}M$, 1-cm cells]. (1) 9.94; (2) 10.14; (3) 10.35; (4) 10.74; (5) 11.37; (6) 12.22; (7) 12.7; (8) 12.9.

investigated because of irreproducibility caused by formation of iron(III) hydroxide]. The results indicate that the absorbance at wavelengths longer than 480 nm is due to a single species, the red complex. The absorbance between 400 and 480 nm is also due to the red species when the solution is saturated with both ligands, but if the solution is saturated with cyanide and the molar ratio cyanide phenylbiguanide/Fe(II) is varied between 0.5 and 75 two distinct absorbing species are present. Solutions saturated with phenylbiguanide and with molar ratios cyanide/Fe(II) between 6 and 30 show the presence of three distinct absorbing species. In both cases, one of these species must be the red complex and the other(s) probably other cyanide complexes of iron.

The extension of the Asmus straight line method to $M_sL_mL'_n$ complexes[5] was applied to the absorbance at 520 nm of the solutions used for the Coleman method (Fig. 3). Linear functions were obtained that indicated 1:1:1 ratio of phenylbiguanide to cyanide to an iron(II)-complex in the red compound, but gave no information about the nature of the iron(II) complex concerned. The method due to Koch and Ackermann[6] was therefore applied to the absorbance at 520 nm of solutions at pH between 10 and 11.2 and with ionic strength 0.01M. From the general equilibrium

$$ML_{m-r}L'_{n-r'+s} + rH_aL + r'H_bL' \rightleftharpoons ML_mL'_n + sH_bL' + qH^+$$

where $H_aL = PhBH_2^+$, $H_bL' = HCN$ and $ML_mL'_n$ is the red compound, linear functions were obtained for the sets of values $r = 1$, $r' = 1$, $s = 0$, $q = 2$ and $r = 1$, $r' = 0$, $s = 0$, $q = 1$. The molar absorptivities calculated for $ML_mL'_n$ from the two functions are 1740 and 1818 l.mole^{-1}.cm^{-1}, respectively, and the value obtained from the calibration curve is 1838 l.mole^{-1}.cm^{-1}, which means that the second set of values for r, r' and q is the more probable, suggesting that uncharged phenylbiguanide is added to an iron(II)–cyanide complex to form the red compound.

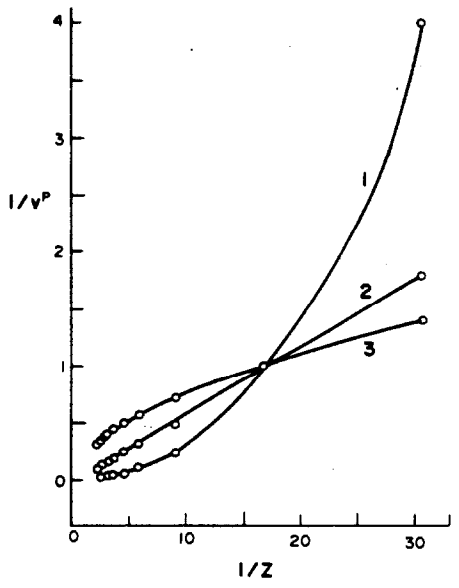

Fig. 3. Asmus method [v ml of 1.5 × 10^{-3}M Fe(II) diluted to 50 ml; concentrations of phenylbiguanide and cyanide 1 × 10^{-2}M; pH 10.6; 4-cm cells, p = (1) 2; (2) 1; (3) ½.

From the anionic nature of the complex, the neutral and bidentate character of the phenylbiguanide ligand and the tendency of iron(II) to form octahedral complexes, together with knowledge of similar compounds,[7] the formula [Fe(phenylbiguanide)$(CN)_4$]$^{2-}$ is proposed for the red compound. The precursor species $ML_{m-r}L'_{n-r'+s}$ would thus be $[Fe(CN)_4(H_2O)_2]^{2-}$, the reaction involving replacement of the two molecules of water by a molecule of phenylbiguanide; a similar reaction has been suggested with histidine as the replacement ligand.[8] That the precursor is no ferrocyanide is shown by the fact that ferrocyanide will not react with phenylbiguanide.

The development of analytical procedures based on the formation of the red complex has been studied. The detection of iron and cyanide is rapid and simple, the dilution limits being 1:8 × 10^5 and 1:2 × 10^5, respectively. Heat and alkaline conditions make the reaction instantaneous. Ag^+, Hg^{2+}, Cd^{2+}, Zn^{2+}, F^-, tartrate, SCN^-, CH_3COO^-, SO_4^{2-}, AsO_3^{3-}, AsO_4^{3-}, Cl^-, ClO_4^-, NO_3^- and NO_2^- in 100-fold molar ratio to iron do not interfere in the detection of iron at the 100-ppm level. The following species interfere at the indicated molar ratios with respect to iron: Cu^{2+} and Co^{2+}, 50; Ni^{2+} and $C_2O_4^{2-}$, 25; Au^{3+}, Mn^{2+} and $S_2O_8^{2-}$, 10; Pd^{2+} and PO_4^{3-}, 5; EDTA, CO_3^{2-} and S^{2-}, <1. F^-, tartrate, PO_4^{3-}, SCN^-, CH_3COO^-, CO_3^{2-}, SO_4^{2-}, BO_3^-, AsO_4^{3-}, Cl^-, ClO_4^- and NO_3^- in 100-fold molar ratio do not interfere in detection of cyanide at the 50-ppm level. The following species interfere at the indicated molar ratios with respect to cyanide: Mn^{2+} and AsO_3^{3-}, 75; Th^{4+}, Zr^{4+} and NO_2^-, 50; $C_2O_4^{2-}$, 40; $S_2O_8^{2-}$, 10; Cd^{2+}, Pd^{2+} and Au^{3+}, 2; Ag^+, Hg^{2+}, Cu^{2+}, Ni^{2+}, Co^{2+}, Zn^{2+}, EDTA and S^{2-}, <1.

SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF IRON(III) BY EXTRACTION OF THE MIXED-LIGAND IRON–FLUORIDE–PURPURIN COMPLEX

M. ROMAN CEBA, A. ARREBOLA RAMIREZ* and J. J. BERZAS NEVADO

Department of Analytical Chemistry, Faculty of Sciences,
University of Extremadura, Badajoz, Spain

(*Received* 1 *April* 1981 *Accepted* 30 *June* 1981)

Summary—The characteristics of the mixed-ligand iron(III)–fluoride–purpurin complex, including optimum conditions of formation and extraction into methyl isobutyl ketone are described. A procedure for determination of trace amounts of iron in fluoride medium ($\geq 0.5M$) with purpurin (1,2,4-trihydroxyanthraquinone) in methyl isobutyl ketone is given. The method is suitable for determining iron in the presence of large amounts of aluminium, cyanide, phosphate and nickel.

Most spectrophotometric methods for iron are based on complexes of iron(II) (*e.g.*, references 1–7), and comparatively few are based on iron(III) complexes.

We have developed a new iron reagent group, typified by purpurin (1,2,4-trihydroxyanthraquinone) which forms an ion-association complex with iron(III) and fluoride, that can be extracted into methyl isobutyl ketone (MIBK). The complex has a molar absorptivity of 4.6×10^4 l.mole^{-1}.cm^{-1}. The possibility of determining trace amounts of iron in the presence of large concentrations of fluoride is an attractive feature of the method.

EXPERIMENTAL

Reagents

Purpurin solution. A $4 \times 10^{-4}M$ solution was prepared by dissolving 0.1024 g of the Merck product and diluting to 1 litre with methyl isobutyl ketone. More dilute solutions were prepared from this.

Iron(III) solution. Prepared from $Fe(NO_3)_3.9H_2O$ and standardized gravimetrically. A $10^{-4}M$ solution was prepared by dilution.

Buffer. A $2.0M$ fluoride buffer prepared by dissolving 74.0 g of ammonium fluoride and enough ammonia to give pH 8.1, in 1 litre of water. This solution must be made iron-free by shaking it with successive portions of purpurin solution in MIBK until the organic phase is yellow-orange. Any purpurin left in the aqueous phase is extracted with MIBK.

All other chemicals were reagent-grade and were checked for iron contamination.

Procedure

Samples were prepared in 100-ml separatory funnels by taking 20 ml of aqueous iron(III) solution containing less than 10 μg of iron, 20 ml of pH 8.1 buffer solution ($2M$ fluoride) and 10 ml of $2 \times 10^{-4}M$ reagent solution in MIBK, and shaken vigorously for 10 min. The phases were separated and the organic phase was centrifuged. Its absorbance was then measured at 595 nm against a reagent blank similarly prepared.

RESULTS AND DISCUSSION

Absorption spectrum of the complex

Equal volumes of $8 \times 10^{-5}M$ purpurin (in MIBK) and $2 \times 10^{-5}M$ iron(III) (at pH 8.1 in $1.0M$ ammonium fluoride) were shaken together for 1 hr, and the absorption spectrum of the organic phase was measured, with MIBK as reference. Figure 1 shows the absorption spectra of the complex and the reagent. The absorption spectrum obtained in the same way but with ammonium chloride solution at pH 8.1 instead of the fluoride is practically the same as the spectrum of the purpurin solution. These facts can only be interpreted as indicating the formation of an iron(III)–fluoride–purpurin complex.

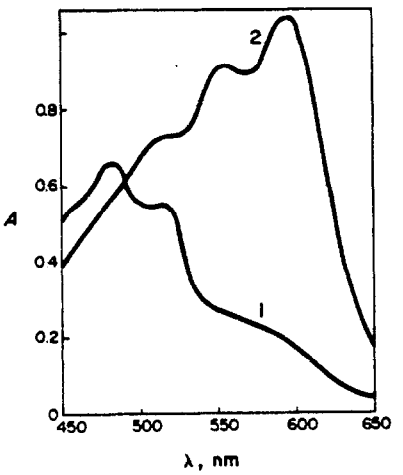

Fig. 1. Absorption spectra of purpurin in MIBK (1) and the iron(III)-fluoride-purpurin complex in MIBK (2).

* Present address: Chemistry Department, Faculty of Sciences, University of Granada, Granada, Spain.

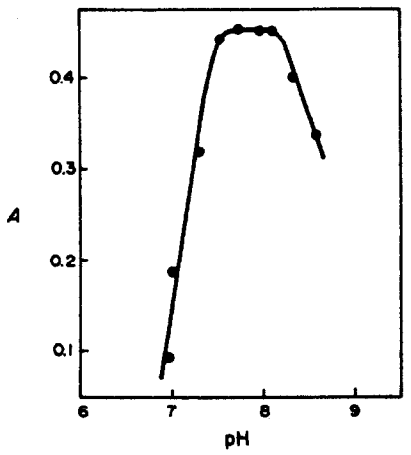

Fig. 2. Effect of pH on the formation and extraction of the mixed-ligand complex.

Effect of pH and fluoride concentration

The influence of pH was investigated for a $10^{-5}M$ iron(III) solution in $1M$ ammonium fluoride and a $2 \times 10^{-4}M$ purpurin solution in MIBK. The phase-volume ratio was 1:1 and the shaking time 30 min. Fig. 2 shows the results. The absorbance increases with pH and is maximal at pH 7.7–8.2.

The influence of fluoride concentration was investigated with $2 \times 10^{-5}M$ iron(III) and $2 \times 10^{-4}M$ purpurin at pH 8.1, obtained by addition of x ml of ammonium fluoride/ammonia buffer and $(10 - x)$ ml of ammonium chloride/ammonia buffer (both of pH 8.1) so that the ionic strength was always the same. The results are plotted in Fig. 3, which shows that the extraction of the violet complex is dependent on the fluoride concentration, becoming constant at $[F^-] \geq 0.5M$. The large concentration of fluoride necessary for complete complex formation indicates that the system would be suitable for determining very small amounts of iron in fluoride and also that rigorous control of the fluoride concentration (for $[F^-] \geq 0.5M$) is not necessary.

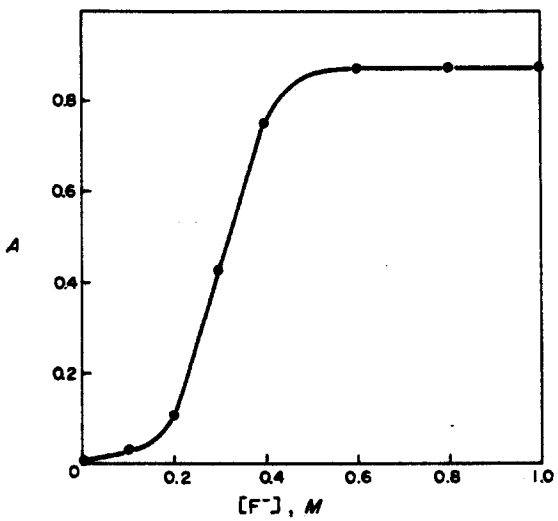

Fig. 3. Effect of fluoride concentration on the formation and extraction of the mixed-ligand complex.

Stoichiometry

The metal–purpurin ratio for the violet iron(III) complex, at pH 8.1 and phase ratio 1:1, was determined by the Job and the Yoe and Jones methods. The fluoride concentration was kept at $1.0M$. The stoichiometry was found to be 1:3 metal–purpurin by both methods.

The metal–fluoride ratio in the violet complex was determined as follows. The violet complex in MIBK was washed twice with ammonium chloride/ammonia buffer (pH 8.1) and dried with anhydrous sodium sulphate, then stripped with dilute hydrochloric acid. The purpurin remained in organic phase. The aqueous phase was made up to standard volume and the iron was determined by atomic absorption, and the fluoride spectrophotometrically by the Ce(III)–alizarin complexan method.[8] The metal–fluoride ratio was found to be 1:1. These results show that the stoichiometry of the mixed-ligand iron(III)–fluoride–purpurin complex is 1:1:3. As the complex is extractable it must be neutral, so we conclude that the third purpurin ligand is neutral and forms an adduct of the type $FeFl_2.LH$ where LH is purpurin.

Extraction constant

The extraction constant, at two different pH values, was determined by our previously published method[9] extended to cover study of mixed-ligand complexes.[10]

The results for pH 7.87 and 8.15, $2 \times 10^{-5}M$ iron(III) and $1.0M$ fluoride gave a molar absorptivity for the violet complex of 4.6×10^4 l. mole^{-1}.cm^{-1}. The extraction constant was found to be log $K_e^* = 15.11$ and 15.53 at pH 7.87 and 8.15 respectively.

If the iron(III) extraction is regarded as quantitative when the degree of extraction of the metal, α_e, is $\geq 99\%$, the expression

$$\alpha_e = \frac{[ML_3]_0}{[M]_w + [ML_3]_0} = \frac{K_e^*(C_L - 3[ML_3]_0)^3}{1 + K_e^*(C_L - 3[ML_3]_0)^3}$$

allows calculation of the maximum concentration of iron that can be extracted quantitatively for a particular analytical concentration of purpurin; *e.g.*, if $C_L = 2 \times 10^{-4}M$ up to 3 ppm of iron can be quantitatively extracted.

Spectrophotometric characteristics

The effect of phase-volume ratio was studied for the optimal conditions. The absorbance of the organic phase was practically constant for the range 1:1–4:1 aqueous phase/organic phase. We chose the 4:1 ratio as being satisfactory, and found that Beer's law is obeyed, at this phase ratio, for 0.025–0.250 ppm of iron in the aqueous phase. A shaking time of 10 min is sufficient for equilibrium to be reached.

The absorbance of the violet complex at 595 nm is constant within 1% over a period of 1 hr, and within 3% over a period of 5 hr.

Table 1. Interference of foreign ions in the determination of 0.14 ppm of iron

Ion	Tolerable concentration of foreign ion, *ppm*
Phosphate	600
Cyanide	500
Silver, beryllium, magnesium, molybdenum(VI), uranium(VI), vanadium(V), tungsten(VI)	100
Cadmium, copper(II), mercury(II) nickel, palladium, zinc	100*
Aluminium	50
Chromium(III), yttrium	25
Cerium	10
Manganese(II)	10*
Lead	6
Calcium	2
Cobalt(II)	2*
Bismuth	1
Indium	0.5
Tin(II)	0.1

* Cyanide (20 mg) added.

The standard deviation is 1.4×10^{-3} ppm for 0.14 ppm of iron(III).

Interferences

Foreign ions were added to a 0.14 ppm iron solution, and the colour was developed by the usual procedure. Cations were added up to 100 ppm concentration and anions up to 1000 ppm. The tolerance limit was taken as the concentration that did not cause more than $\pm 2\%$ change in the absorbance of the 0.14-ppm iron solution. The results are summarized in Table 1.

The interference of cadmium, cobalt(II), copper(II), mercury(II), manganese(II), nickel, palladium and zinc can be eliminated by adding 20 mg of cyanide.

ANALYTICAL DATA

A STUDY OF THE STABILITY OF ALKALINE-EARTH METAL COMPLEXES WITH FLUORIDE AND CHLORIDE IONS AT VARIOUS TEMPERATURES BY POTENTIOMETRY WITH ION-SELECTIVE ELECTRODES

VLADIMÍR MAJER
Geological Survey, Prague, Czechoslovakia
and
KAREL ŠTULÍK
Department of Analytical Chemistry, Charles University, Prague, Czechoslovakia

(*Received* 13 *April* 1981. *Accepted* 18 *August* 1981)

Summary—The complexes of the alkaline earth metals with fluoride and chloride were studied over the temperature range 15–85°. The stability constants of the MX^+ complexes were determined by potentiometry with fluoride and chloride ion-selective electrodes and the appropriate thermodynamic functions (ΔH^0_{298}, ΔS^0_{298} and ΔG^0_{298}) were calculated.

Study of the fluoride and chloride complexes of the alkaline-earth metals is especially important for geochemists, as in the theory of migration of fluoride ions in various types of sodium chloride solutions with high concentrations of sodium and alkaline earth ions, at common and elevated temperatures, the fluoride is assumed to be transported in the form of these complexes. Complexes containing fluoride and chloride ions may also play an important role in the transport of metals in hydrothermal solutions in the earth's crust, especially at higher temperatures.

The most suitable method for the determination of the stability constants of these complexes is potentiometry with ion-selective electrodes (ISEs). Both fluoride and chloride ISEs exhibit good reproducibility and potential stability, and can be used at temperatures up to about 100°.

So far, the stability constants of these complexes have been measured[1–14] at temperatures from 0 to 60°. However, this temperature interval can readily be extended up to nearly 100°. The stability constant values at temperatures higher than 100°, which are especially important in modelling geochemical transport and precipitation processes, are obtained either by extrapolation from the data obtained for lower temperatures, or by solubility measurements in autoclaves. In this way, for example, the stability constants for the MgF^+ and CaF^+ complexes were obtained[15] for temperatures of 200° and 260° ($K_{MgF^+} = 70.9 \pm 5.1$ for 200° and 268 ± 75 for 260°, and $K_{CaF^+} = 27.6 \pm 3.7$ for 200° and 43.8 ± 6.9 for 260°).

EXPERIMENTAL

Chemicals

Stock 1*M* solutions of the alkaline-earth metal nitrates (Mg, Ca, Sr) were prepared from the solid *p.a.* substances (Lachema, Czechoslovakia) and standardized by EDTA titration. Because of its low solubility, solid barium nitrate was weighed and added directly to the solutions to be measured. Stock 0.2*M* solutions of sodium chloride and fluoride were also prepared from the *p.a.* substances (Lachema, Czechoslovakia).

The ionic strength of all test solutions was adjusted with 2*M* sodium nitrate, prepared from the solid substance freed from heavy metals by ion-exchange (Dowex 50W, Na^+-form) and recrystallized. In the study of the CaF^+ complex, the ionic strength was adjusted with a solution of similarly purified potassium nitrate.

Because of the large temperature ranged used, expansion of the solutions could not be neglected and the concentrations were therefore expressed in terms of molality. The weight of water per litre of each standard solution was found and the test solutions were diluted with distilled water to contain 100 g of water. The solutions used for calibration of the ISEs, with molalities of 4×10^{-3}, 1×10^{-3}, 4×10^{-4} and 5×10^{-5}, were prepared in the same manner. The pH of all the solutions was between 5 and 6 and was not further adjusted.

The reference-electrode liquid bridge was filled with 3*M* potassium nitrate (2·5*M* for tests at 15°).

Apparatus

Radiometer equipment was used, consisting of a PHM-64 pH-meter, fluoride and chloride ISEs (F1052F

and F1012Cl, respectively), a K 401 reference electrode with a liquid bridge (precision of potential-reading, 0.1 mV), a PHM-62 pH-meter with a G 2040B glass electrode (precision of pH-reading, 0.01), a TTA 60 stirrer and an REC 61/REA 100 recorder, used for monitoring the ISE potential stabilization. The test solutions were placed in 100-ml polyethylene bottles held in a U-10 ultrathermostat (VEB Prüfgeräte Werke, GDR), and solutions with a volume of less than 10 ml were placed in a V 533 vessel with external thermostatic jacket, in which the temperature was maintained within $\pm 0.1°$ ($\pm 0.2°$ for 85°).

All calculations were done on a Hewlett-Packard HP-67 programmable calculator with our own programs (calculation of liquid-junction potential, non-linear regression, *etc.*).

Procedure

The test solutions were prepared with an ionic strength of 1*m* ($NaNO_3$), fluoride or chloride molality of $10^{-3}m$ ($10^{-4}m$ for the CaF^+ work because of the poor solubility of CaF_2) and alkaline-earth metal molality of 0.05, 0.1, 0.2 and 0.3*m*. Simultaneously, the same number of solutions containing only sodium fluoride or chloride, at the same molalities and ionic strengths, were prepared.

Before and after each series of measurements, the slope of the potential *vs.* concentration graph was checked and the ISE sensitivity determined. The ISE potential-drift was suppressed as much as possible, by measuring in immediate succession solutions containing and not containing a test metal ion and using these potentials to calculate ΔE. For each measurement, a fresh solution from the polyethylene bottle was employed.

Calculations

The stability constant of complex MX^+ is expressed by

$$\beta = \frac{[MX^+]}{[M^+][X^-]} \tag{1}$$

Under the given experimental conditions, when the total metal concentration $c_M \gg [MX^+]$, equation (1) can be rewritten in the form

$$\beta = \frac{c_x - [X^-]}{c_M[X^-]} = \frac{1}{c_M}\left\{\frac{c_x}{[X^-]} - 1\right\} \tag{2}$$

Equation (2) contains a single unknown, $[X^-]$, which can be found from the ISE calibration curve. However, because the absolute potential varies with time (in contrast to the relatively stable slope), it is better to find the ratio $c_x/[X^-]$ from two successive measurements in the absence (potential E_0) and presence (potential E_1) of the metal ion:

$$E_0 = E^0 - S \log c_x + \Delta\phi_0$$
$$E_1 = E^0 - S \log[X^-] + \Delta\phi_1 \tag{3}$$

when the E^0 value can be assumed to be constant; S is the response slope and $\Delta\phi$ is the liquid-junction potential between the test solution and the potassium nitrate solution in the liquid bridge, which can be estimated from the Henderson equation[16] (the other liquid-junction potentials also have non-zero values, but are constant). For the ratio $c_x/[X^-]$ it then holds that

$$\frac{c_X}{[X^-]} = 10^{\Delta E'/S} \tag{4}$$

where

$$\Delta E' = E_1 - E_0 + \Delta\phi_0 - \Delta\phi_1 \tag{5}$$

The resultant relationship for the stability constant of complex MX^+ is thus

$$\beta = \frac{1}{c_M}(10^{\Delta E'/S} - 1) \tag{6}$$

Random results were excluded from the results by using the *T*-test;[17] the remaining results were treated statistically and are given in Tables 1 and 2.

The temperature dependence of an equilibrium constant can be expressed by various equations, as described in any

Table 3. Dependence of the log β values on temperature in the interval 288–358 K (rounded off to two decimals after calculation)

Complex	log β
$MgCl^+$	$\log \beta = -33.14658 + 8.21289 \times 10^{-5}T^2 - 7.60913 \times 10^{-2}T + 8.49545 \ln T$
$CaCl^+$	$\log \beta = -130.00903 + 1.63105 \times 10^{-4}T^2 - 0.19682T + 30.53397 \ln T$
$SrCl^+$	$\log \beta = 241.02305 - 3.67544 \times 10^{-4}T^2 + 0.42395T - 58.78936 \ln T$
$BaCl^+$	$\log \beta = -33.02600 - 1.55733 \times 10^{-4}T^2 + 9.73845 \times 10^{-2}T + 3.05025 \ln T$
MgF^+	$\log \beta = 13.49190 - 6.01329 \times 10^{-6}T^2 + 1.78561 \times 10^{-2}T - 2.97146 \ln T$
CaF^+	$\log \beta = -60.86936 + 2.89712 \times 10^{-5}T^{-2} - 1.12161 \times 10^{-2}T + 10.81822 \ln T$
SrF^+	$\log \beta = -108.33374 + 4.31140 \times 10^{-5}T^{-2} - 3.13507 \times 10^{-2}T + 19.83241 \ln T$
BaF^+	$\log \beta = 85.42184 - 1.29908 \times 10^{-4}T^2 + 0.15601T - 21.15952 \ln T$

textbook on physical chemistry. The most advantageous form for our purposes was

$$\log \beta = a + bT^{\pm 2} + cT + d \ln T, \quad (7)$$

where the minus sign in the exponent of the second term better satisfied the dependence for the CaF^+ and SrF^+ complexes. Coefficients a, b, c and d in equation (7) can be determined by the least-squares method, by solving the normal equations for multiple regression. The regression curves for the given temperature interval, 15–85°C, are given in Table 3 and in Figs. 1 and 2. In view of the small data set and the considerable scatter of the values (especially with the chloride complexes), extrapolation toward temperatures higher than 85°C must be cautious, chiefly with the $SrCl^+$ and $BaCl^+$ complexes, with which the change in the slope of the regression curve around 80°C is probably caused by the poor precision of the last term. Linear regression was also tested but gave correlation coefficients substantially less than unity.

From log β and its temperature dependence, the values of the thermodynamic functions ΔH^0, ΔS^0 and ΔG^0 can be found for a temperature of 25° (298.15 K), namely, the standard Gibbs free energy change

$$\Delta G^0_{298} = -2.303RT \log \beta \quad (T = 298.15\,\text{K}), \quad (8)$$

the standard enthalpy change,

$$\Delta H^0_{298} = 2.303RT^2 \frac{\partial \log \beta}{\partial T} \quad (T = 298.15\,\text{K}), \quad (9)$$

where

$$\frac{\partial \log \beta}{\partial T} = \left\{2bT + c + \frac{d}{T}\right\}$$

or

$$\frac{\partial \log \beta}{\partial T} = \left\{-\frac{2b}{T^3} + c + \frac{d}{T}\right\} \quad (10)$$

and the standard entropy change

$$\Delta S^0_{298} = 2.303RT\left(\frac{\partial \log \beta}{\partial T}\right)_{298} + 2.303 \log \beta. \quad (11)$$

The calculated values are given in Table 4.

DISCUSSION

Chloride complexes

The stability of the complexes decreases in the order $Mg^{2+} > Ca^{2+} \sim Sr^{2+} > Ba^{2+}$, *i.e.*, with increasing cation radius. In view of the low values of the stability constants (the potential changes were often less than 0.5 mV), the agreement with the literature data can be considered good. The somewhat lower values compared with those of Šůcha *et al.*[9]

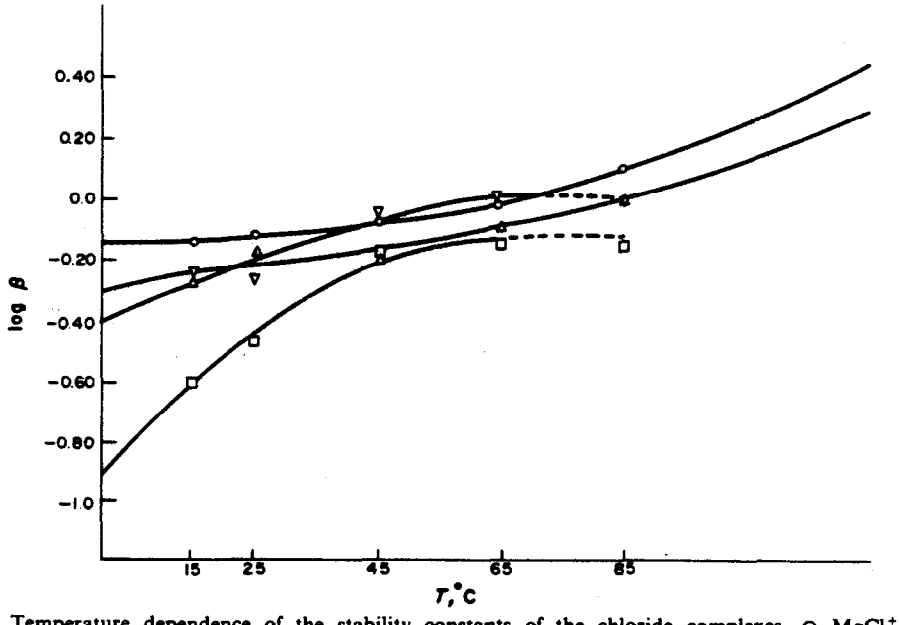

Fig. 1. Temperature dependence of the stability constants of the chloride complexes. ○ $MgCl^+$. △ $CaCl^+$, ▽ $SrCl^+$, □ $BaCl^+$.

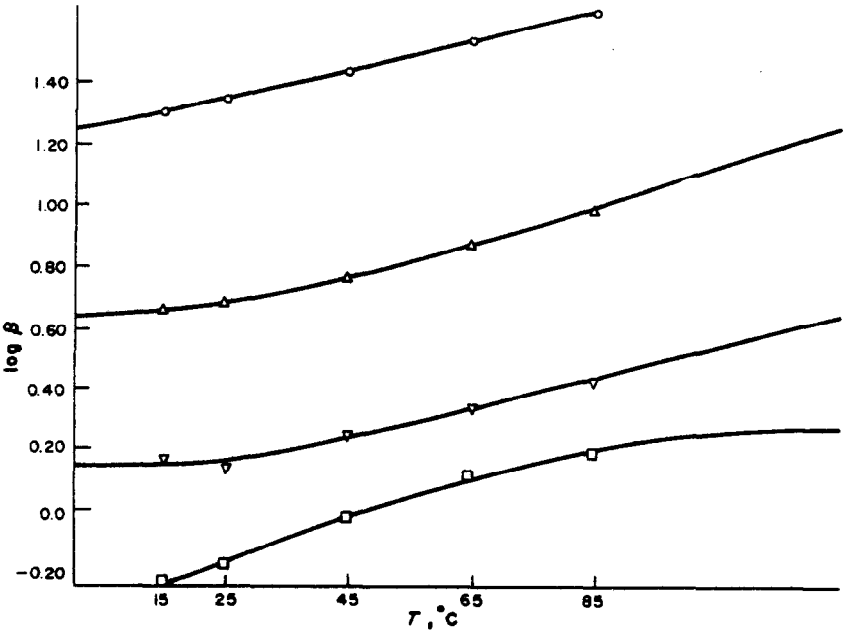

Fig. 2. Temperature dependence of the stability constants of the fluoride complexes. ○ MgF^+, △ CaF^+, ▽ SrF^+, □ BaF^+.

may be due to differences in the purity of the chemicals used.

However, the thermodynamic functions reported for the present work are different from those of Šůcha *et al.*[9] In view of the wider temperature interval studied in the present work and of the differentiation of the log β *vs.* T dependence performed here (compared with simple differences used in ref. 9) we consider the present values to be more reliable.

Fluoride complexes

The stability of the fluoride complexes depends on the cation radius analogously to that of the chloride complexes, but the dependence is more pronounced. The temperature dependence indicates a substantial increase in the stability of the MgF^+ and CaF^+ complexes with increasing temperature. The dependence can reliably be extrapolated to temperatures above 100° for all the complexes studied. The present stability constant values are somewhat higher than the average of the literature values, but are within their variance. The thermodynamic functions are also in satisfactory agreement with the literature.[1,7]

(*Received* 11 *May* 1981. *Accepted* 25 *June* 1981)

Summary—A study of the adsorption of silver ions on soda-glass, using a radiochemical technique, has been made, and the effects of time and temperature investigated. A simple kinetic treatment allows estimation of the rate constants for the adsorption and desorption processes.

The adsorption of cations on glassware is of obvious importance in analytical chemistry, particularly when solutions of low concentration are involved. The present study of the adsorption of silver ions on soda-glass follows our previous observations of silver loss, in a study of the solubility of silver chloride in methanol + water mixtures.[1] It was decided to investigate in detail the adsorption of silver from aqueous solution, and a radiochemical technique was developed, with ^{110m}Ag and an NaI(Tl) well-type crystal. The technique has been used to measure the amount of silver adsorbed per unit area of glass from a 0·5-mg/l. (0.5 ppm) silver nitrate solution, for a range of contact times, at 298 K. The concentration of 0.5 mg/l. was chosen, as being in the same range as that used in earlier studies of silver adsorption,[2–5] so that a direct comparison could be made. The effects of varying temperature and initial concentration, and of heat-treatment of the glass, were also investigated.

EXPERIMENTAL

The essential features of the technique involve the labelling of a standard silver nitrate solution with ^{110m}Ag (a β- and γ-emitter with a half-life of 253 days), to give a solution of specific activity of silver of approximately 20 μCi/mg, which is then left in contact with a glass surface for a given period of time. The amount of silver adsorbed per unit area of the surface is then determined by gamma scintillation-counting with an NaI(Tl) well-type crystal. The following procedure was adopted.

For each measurement, a 3-ml portion of the labelled standard silver nitrate solution was placed in a 10-ml soda-glass vial. The surface area of the glass in contact with the solution, calculated from the dimensions of the vial, was 8.9 cm^2. The vials were wrapped in aluminium foil to minimize exposure to light and then kept in a thermostatic water-bath for a predetermined time (the contact time). The vials were then transferred to the counting equipment, care being taken not to tilt them. After the count-rate had been measured, the solution was removed from the vial by suction through a drawn-out glass tube designed to give rapid removal with minimum disturbance of the solution. Doubly demineralized water was then added to the vial, the entire contact area being covered. The water was left in contact with the glass, without agitation, for 5 sec and then sucked out. This washing procedure was carried out ten times, and further washing did not remove significant quantities of silver from the glass. The activity of the empty vial was then counted and by a comparison of this with that of the standard solution, the amount of silver adsorbed was calculated. Correction for the decay of ^{110m}Ag was unnecessary, as the standard solution and the adsorbed silver were counted at virtually the same time.

Pretreatment of the glass vials with solvents or detergents was avoided because of the risk of modifying the surface. Before use, each vial was half-filled with doubly demineralized water, capped, and shaken gently for 15 sec, then emptied and placed upside down on absorbent paper to air-dry for 24 hr.

Analytical-reagent grade silver nitrate was used without further purification. The silver-110 m was obtained from the Radiochemical Centre, Amersham, as silver nitrate in nitric acid solution.

Further work has shown that the extent of adsorption of silver depends on the pH of the solution. In the present work the pH was monitored and was about 5.3 throughout. All labelled standard silver nitrate solutions were made up in new graduated flasks and allowed to stand for seven days before use. This allowed a correction to be made for the silver adsorbed on the graduated flask, if necessary.

RESULTS AND DISCUSSION

The technique involves washing the vial ten times with 3-ml portions of demineralized water, each wash being of 5 sec duration. The effectiveness of the washing procedure was checked by measuring the amount of silver remaining on the glass after each wash. The behaviour, for a 4-day initial contact time, is illustrated in Fig. 1. It is concluded that all the silver nitrate solution, and any "loosely" adsorbed silver is removed by the ten consecutive washes; the silver remaining after ten washes is referred to as "firmly" adsorbed silver. The dependence of the amount of this firmly adsorbed silver on contact time at 298 K is shown in Figs. 2 and 3, for an initial silver nitrate concentration of 0.5 mg/l.

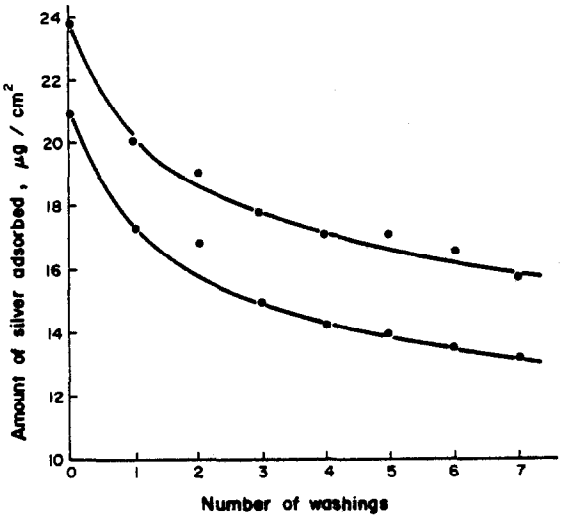

Fig. 1. Effect of successive washings on silver adsorbed after a 4-day contact time with $AgNO_3$ solution of initial concentration 0.5 mg/l., at 298 K.

Measurements were carried out in duplicate, and the difficulty in obtaining reproducible results can be gauged from the graphs. There is rapid initial adsorption in the first few minutes, followed by a much slower process which becomes almost complete after about 40 days. This may be compared with the results of West *et al.*[4] who found that maximum losses from 0.05- and 1.0-mg/l. solutions occurred during a 10–30 day period. A 4-day contact time was used for most of the present studies, for convenience, and so that the rapid initial adsorption was complete. However, the firmly adsorbed silver is not the equilibrium amount, and a much longer contact time, >40 days, is necessary to obtain this value.

The effect of increasing the initial concentration and the temperature is illustrated in Fig. 4 for a 4-day contact time. The extent of adsorption for a given concentration increases as the temperature is increased, but it is difficult to draw any further conclusions from the temperature dependence since the adsorption has not reached equilibrium after only four days. However, the extent of adsorption is clearly large enough to have serious consequences in trace analysis for silver.

The effect of heat pretreatment of the vials has also been studied. The results are presented in Table 1, and it is seen that heating in an oven at 200° for 1½ hr leads to an approximate doubling of the amount of silver adsorbed. Flaming the glass before contact results in an even larger increase. Hensley *et al.*[2] obtained a pronounced increase in adsorption with similar heat pretreatment. The mechanism of the increase is far from clear. Stress tests on the untreated vials indicated that while the outer surfaces showed a small level of residual stress, the inner surfaces were virtually stress-free.*

The present study indicates that the adsorption takes place by two processes, one occurring rapidly and reaching equilibrium at 298 K in approximately 10 min, while the other occurs relatively slowly and requires about 40 days to reach equilibrium. It seems likely that the firmly held silver is chemisorbed, although we recognize that some penetration of the glass surface, *i.e.*, absorption, may occur and that the radiochemical technique can only monitor the total silver held by the glass. Nevertheless, we may apply the following kinetic treatment to the long-term adsorption process.

*We are indebted to Dr. E. J. Hearn, City of Birmingham Polytechnic, for carrying out these tests.

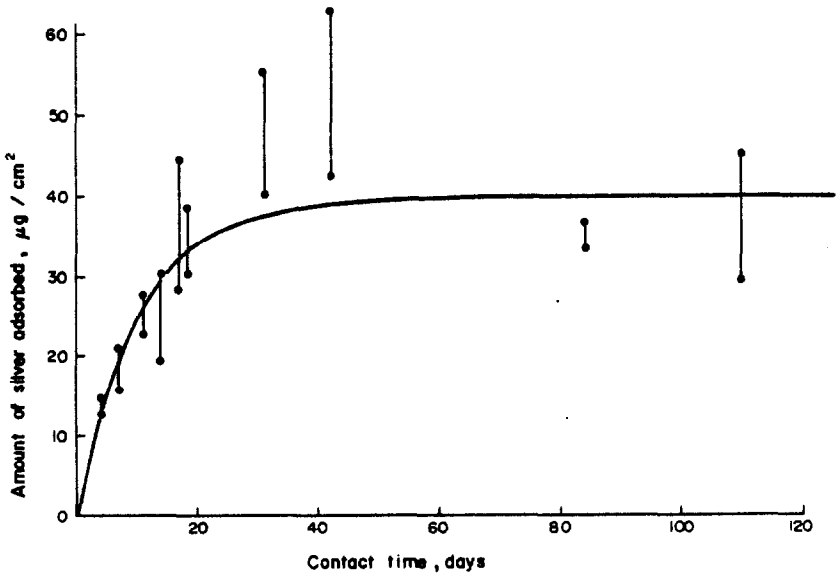

Fig. 2. Dependence of the amount of adsorbed silver on extended contact time at 298 K: initial concentration of $AgNO_3$ solution 0.5 mg/l.

Table 1. Effect of heat pretreatment of glass vials

Treatment of vial	Amount of Ag held, $\mu g/cm^3$ (4-day contact time; 298 K)	
Flamed to redness in bunsen burner	35.0	23.2
Heated in oven at 200°C for 1½ hr	23.1	25.8
No heat treatment	10.4	18.3

If we assume that the process can be described by the equilibrium

$$\text{Ag(solution)} \underset{k_2}{\overset{k_1}{\rightleftharpoons}} \text{Ag(glass surface)} \qquad (1)$$

and that the adsorption and desorption processes are first order in silver, we obtain the equation

$$\ln\left(\frac{x_{eq} - x}{x_{eq}}\right) = -(k_1 + k_2)t. \qquad (2)$$

In this equation, x is the concentration of adsorbed silver at time t, x_{eq} is the equilibrium concentration of

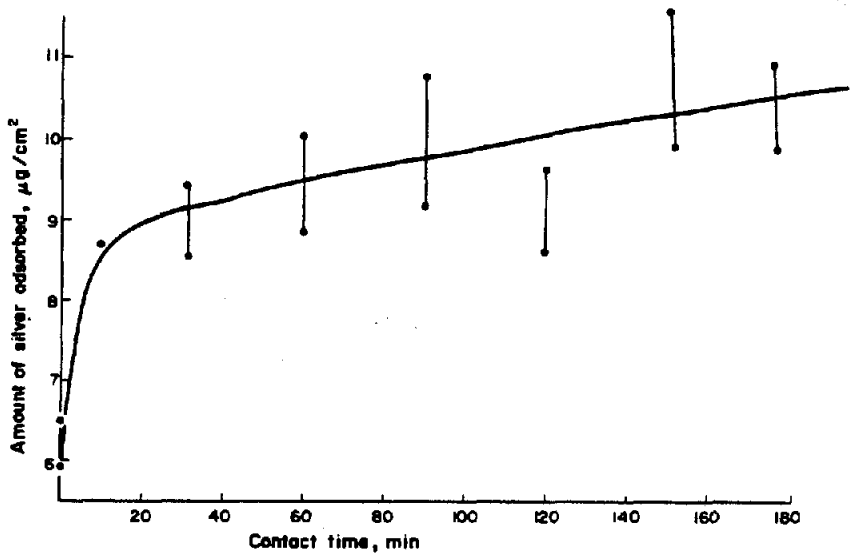

Fig. 3. Dependence of the amount of adsorbed silver on short-term contact time at 298 K: initial concentration of $AgNO_3$ solution 0.5 mg/l.

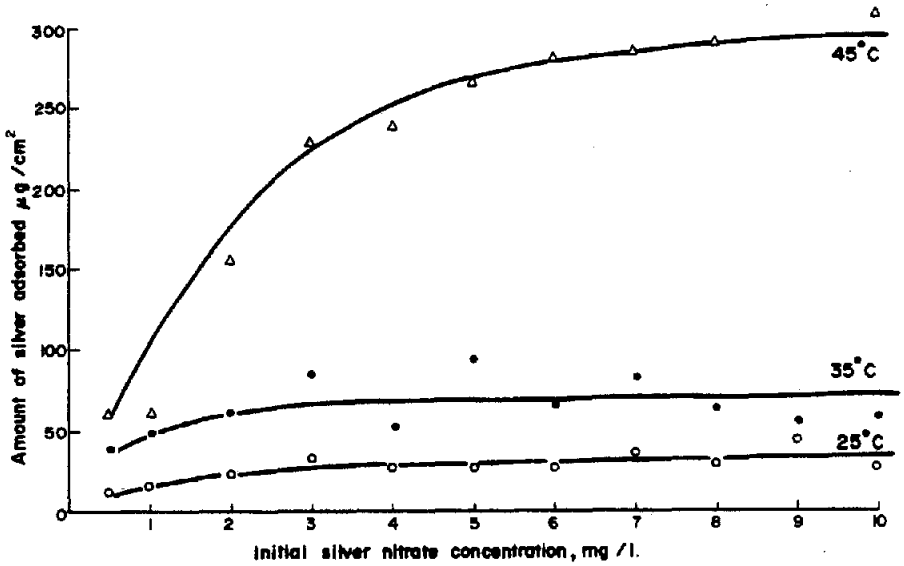

Fig. 4. Dependence of the amount of adsorbed silver on the initial concentration of $AgNO_3$, after a 4-day contact time.

adsorbed silver, and k_1 and k_2 are the rate constants for the adsorption and desorption processes. The equilibrium concentration x_{eq} may be related to the initial concentration a (converted into the same units as x, by using the known volume of solution and surface contact area), by $x_{eq} = k_1 a/(k_1 + k_2)$. From Fig. 2, we adopt the value 40×10^{-6} mg/cm^2 for x_{eq} and calculate the value 170 mg/cm^2 for a. Rearrangement of equation (2) gives

$$x = x_{eq}\{1 - \exp[-(k_1 + k_2)t]\} \quad (3)$$

and comparison with Fig. 2 yields values of 0.023 and 0.076 days^{-1} for k_1 and k_2 respectively, at 298 K. The curve in Fig. 2 is calculated from equation (3) by using these values of k_1 and k_2, and is a fair representation of the experimental data. Although the estimates of k_1 and k_2 are very approximate, it is noteworthy that k_2 is appreciably larger than k_1 and that less than a third of the silver originally in solution is transferred to the surface at equilibrium. Furthermore, if we assume that the silver is adsorbed as Ag^+, with an effective radius of 1.26 Å, we may estimate the fraction of the surface covered at equilibrium. It is estimated that the actual available surface area is greater than the measured geometric surface by a factor of at least 2.* If this factor is taken into account then the fraction of the surface covered at equilibrium for an initial concentration of 0.5 ppm is around 10% at 298 K.

As mentioned earlier, there is a strong indication that the extent of adsorption varies with the pH of the solution and further studies are in progress.

*We are indebted to Dr. B. Evans of Messrs. Pilkington Bros. Ltd, for this estimate.

ANNOTATION

THE THEORETICAL BASIS OF MERCURIMETRY IN NON-AQUEOUS SOLUTIONS

L. N. BALYATINSKAYA and A. P. KRESHKOV†

D. I. Mendeleev Institute of Chemical Technology, Moscow, USSR

(*Received* 17 *January* 1980. *Revised* 8 *January* 1981. *Accepted* 6 *July* 1981)

Summary—The methods for thermodynamic calculations of the equilibria in solutions of mercury salts and complexes are presented. The calculations of equilibrium constants in non-aqueous solvents are based on the transfer activity coefficients of mercury ions from water to the non-aqueous solvent. The dismutation and precipitation reaction constants are calculated, and the redox potentials of mercury systems are measured. Examples of analytical use of the thermodynamic functions of mercury salt solvation are given in the text.

The complexation and precipitation reactions of mercury are used for both inorganic and organic analysis; the use of non-aqueous media increases the rates of these analytical reactions.[1] However, undesirable complications such as solvolysis and dismutation can change the rates and cause errors in the results.

The basis for the use of mercury reactions in non-aqueous solvents and for prediction of the necessary analytical conditions is the thermodynamics of transfer of mercury ions from water to the non-aqueous solvent. According to IUPAC recommendations,[2] the transfer activity coefficient $\gamma_t(i)_{W\to S}$ characterizes the Gibbs free energy change $\Delta G_t(i)_{W\to S}$ for transfer of ion (i) from water (W) to non-aqueous solvent (S). The value of $\gamma_t(Hg_n^{2+})_{W\to S}$ can be calculated from the standard potentials for the corresponding systems:

$$\Delta G_t(Hg_n^{2+})_{W\to S} = RT \ln \gamma_t(Hg_n^{2+})_{W\to S} = zF({}^{W}E^0_{Hg_n^{2+}/Hg} - {}^{S}E^0_{Hg_n^{2+}/Hg}) \quad (1)$$

The redox potentials and transfer activity coefficients for mercury systems

The values of $\log \gamma_t(Hg_n^{2+})_{W\to S}$ are calculated from polarographic data (Strehlow's non-thermodynamic hypothesis[3]) and potentiometric data.[4] The redox and half-wave potentials and the transfer activity coefficients calculated from them are given in Table 1. Discrepancies between our values and those published by others will not be discussed here. They may be due, at least in part, to the use of very different solution conditions, and may also be due to traces of water (known to have strong effects in this context), but in any case the discrepancies do not affect the general sense of the discussion.

In protic solvents mercury salts are solvated more slowly than in water: this is the reason for the rapid oxymercuration reactions in alcohols and acetic acid.[5,6] In these solvents the oxidizing capacity of mercury salts increases: in acetic acid mercury(II) perchlorate quickly oxidizes the dihydroxybenzenes[7] and inorganic ions such as Fe^{2+}, Sn^{2+}, Cu^{+}, $Fe(CN)_6^{4-}$, $S_2O_3^{2-}$. In dipolar aprotic media the reducing capacity of mercury(I) salts increases.

The transfer activity coefficients of mercury ions can indicate the thermodynamic possibility of analytical reactions and allow calculation of the corresponding equilibrium constants. We will demonstrate this for some reactions of mercury.

Formation of insoluble mercury(I) salts

The solubility products of Hg_2L_2 in water and in a non-aqueous solvent are related by the equation:

$$(pK_{s_{Hg_2L_2}})^S = (pK_{s_{Hg_2L_2}})^W - \log \gamma_t(Hg_2^{2+})_{W\to S} - 2 \log \gamma_t(L^-)_{W\to S}. \quad (2)$$

The pK_s values in non-aqueous media are calculated from $\log \gamma_t(Hg_2^{2+})$ (Table 1) and $\log \gamma_t(L^-)_{W\to S}$. In most cases, although mercury ions are strongly solvated by dipolar aprotic solvents, the solubility of Hg_2L_2 is lower in these media because of the much lower dielectric constant. Some exceptions (*e.g.*, Hg_2I_2 in DMSO) are explained by the existence of weak anion solvation by hydrogen-bonding to solvent molecules. The solubility of the mercury(I) halides is levelled by their solvation in dipolar aprotic media

(Table 2). For mercurometric titration of halide ion mixtures, water is the best medium, but thiocyanate cannot be differentiated from chloride or bromide because of the small difference in pK_s and for this determination DMSO or DMF should be used. The lower limit of individual halide determinations is lower in acetonitrile (AN) medium than in other solvents.

Dismutation reactions and stability of mercury(I) solutions

The stability of the Hg(I) salts used in analytical chemistry depends on the solvolysis and dismutation reactions. The first may be avoided by keeping the pH below 2; the second takes place if the Hg(II) formed gives stable solvates with solvent molecules. For soluble and dissociated Hg(I) salts (nitrate, perchlorate) the dismutation constant K_d can be determined from the standard potentials (approximately the half-wave potentials):

$$\ln K_d = \frac{zF}{RT}(E^0_{Hg_2^{2+}/Hg} - E^0_{Hg^{2+}/Hg}). \quad (3)$$

Mercury(I) perchlorate is stable in water, less stable in alcohols, acetic acid and acetone (Table 1). In dipolar aprotic solvents [acetonitrile (AN), nitromethane (NM), dimethylsulphoxide (DMSO) and dimethylformamide (DMF)] the concentration of Hg(I) decreases continually because of the dismutation.

Redox reactions

Protic solvents enable mercury salts to be used in redox titrations: these solvents weakly solvate the mercury reagents, and are readily obtainable and easily purified. Some examples are presented in Fig. 1. The potential-jump at the end-point can be increased by addition of mercury-complexing reagents:[8] thus addition of thiocyanate or iodide increases the jumps in the titration curves for Fe^{3+} and Cr^{3+}:

$$2Fe^{3+} + Hg_2^{2+} + 8SCN^- \rightarrow 2Fe^{2+} + 2Hg(SCN)_4^{2-} \quad (4)$$

$$CrO_2^- + 3Fe(CN)_6^{3-} + 4OH^- \rightarrow CrO_4^{2-} + 3Fe(CN)_6^{4-} + 2H_2O \quad (5)$$

$$2Fe(CN)_6^{3-} + Hg_2^{2+} + 8I^- \rightarrow 2HgI_4^{2-} + 2Fe(CN)_6^{4-} \quad (6)$$

The choice of solvent for mercury reactions

The very low solvation of electrophilic reagents (mercury salts) is thermodynamically favourable for the electrophilic reactions of organic compounds with Hg(II) or cationic complexes HgL^+. This is observed for mercury salts in alcohols, acetic acid, nitromethane or propylene carbonate (PC); the HgL^+ complexes are weakly solvated in protic media.[9]

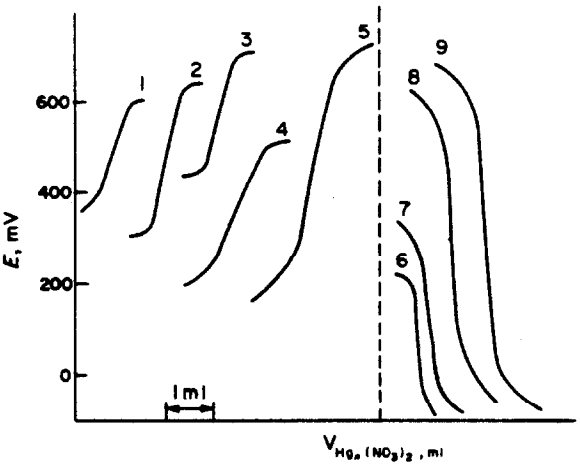

Fig. 1. The potentiometric curves for titration of inorganic salts with (1–5) $Hg(NO_3)_2$ in acetic acid and (6–9) $Hg_2(NO_3)_2$ in water: 1—$SnCl_2$, 2—$FeCl_2$, 3-CuCl, 4—$K_4[Fe(CN)_6]$, 5—$Na_2S_2O_3$, 6—$K_3[Fe(CN)_6]$, 7—$FeCl_3$, 8—$KMnO_4$, 9—$K_2Cr_2O_7$.

In contrast, dipolar aprotic solvents are better media for the reactions of anionic mercury(II) complexes.

Thus, the thermodynamic transfer function data for mercury ions and complexes allow prediction of their analytical reactions and permit the corresponding equilibrium constant calculations.

LETTER TO THE EDITOR

FLOW-INJECTION ANALYSIS AND ITS EARLY HISTORY

Sir,

Referring to the recent article by Stewart,[1] we wish to point out that we have repeatedly suggested in the past[2-4] that the term Flow-Injection Analysis be used exclusively for methods which involve the following three requirements:

(a) sample injection;
(b) controlled dispersion of the injected sample zone;
(c) reproducible timing.

Such a definition avoids any confusion such as may arise from Stewart's paper. Indeed, from Stewart's interpretation of FIA it might be wondered whether the method was not already conceived by Skeggs in 1957, because in Fig. 1 of Stewart's paper, depicting Skeggs's analyser, a section between the debubbler and the flow cell accommodates an unsegmented continuously flowing stream of liquid which alternately carries discrete samples and wash solution with the purpose of a subsequent detection of analyte. In fact Stewart's definition is so broad that it perfectly well accommodates even liquid chromatography!

The purpose of writing this comment is, however, not to create a discussion on semantics, but to draw your readers' attention to the key role of the concept of controlled dispersion of the sample zone in understanding how and why FIA works. Not until this was established and the theory behind it became outlined, was the road towards development of various FIA techniques open, and the borderline between the prehistory of FIA and its present - still early - stage of development, crossed.

ORGANIC COMPLEXING AGENTS IN ATOMIC-ABSORPTION SPECTROMETRY—A REVIEW

J. KOMÁREK and L. SOMMER
Department of Analytical Chemistry, J. E. Purkyně-University, 61137 Brno, Czechoslovakia

(*Received* 3 *February* 1981. *Accepted* 7 *August* 1981)

Summary—The influence of organic complexing agents on the determination of a particular element by atomic-absorption spectrometry (AAS) with flame or electrothermal atomization may increase the sensitivity and selectivity. The effect of the structure and properties of the organic ligand in connection with the particular atomization mechanism is discussed.

Organic analytical reagents can exhibit various effects in AAS: (*i*) the degree of atomization of elements is changed, depending on the mode and mechanism of atomization, and the efficiency of free atom formation is sometimes increased; (*ii*) the reagent may suppress or decrease interference from accompanying elements during the AAS determination of a particular analyte; (*iii*) preconcentration can be achieved by extraction of metal chelates or ion-association complexes into non-aqueous solvents, the extracts then being nebulized into flames or treated by flameless techniques. When an organic solvent is used, it also can have an effect on the AAS behaviour of a particular system.[1–9]

In general, the mechanisms by which complexing agents affect the AAS behaviour of metals are rather complicated and not yet fully understood, but it can be taken that they are mainly concerned with formation and evaporation of aerosol droplets, the thermal decomposition of the solid species, and the atomization process.

AAS IN PREMIXED FLAMES

In flames, the very fine aerosol droplets of the nebulized solution are desolvated, the resulting solid particles are thermally decomposed and the gaseous metal atoms formed may be further involved in secondary chemical reactions. The atom concentration in the flame is predominantly controlled by the concentration of the particular element in the test solution.[10] All these steps can be influenced by the presence of complexing agents, even the nebulization process being affected by resulting changes in the viscosity and surface tension of the solution. However, there is no direct relation between the stability of a metal complex in solution and the effect of the ligand on the determination of the metal by AAS. For one thing, there will always be an excess of complexing agent present, and its behaviour in the flame may also have important effects. Thus data for complex equilibria in solution, such as the stoichiometry and stability of the complexes, are of little help in predicting the behaviour of a particular complexation system in AAS.

Formation of metal atoms in flames

During the pre-atomization steps, such as the melting, volatilization and partial thermal decomposition of the solid particles, not only the oxides but also sulphides, carbides, nitrides and volatile metal complexes may be formed, these being subsequently decomposed if they are not thermally stable at the actual flame temperature. Free atoms appear by dissociation or reduction of the compounds present in the gaseous state after volatilization. The spatial distribution of free atoms in the flame (lateral flame profile) depends on the temperature and composition of the flame, and hence on the fuel: support gas ratio. The number of free analyte atoms is considerably decreased if ions or thermally stable compounds are formed or if the analyte is dispersed in some kind of non-volatile matrix which does not decompose at the flame temperature. On the other hand, the number of free atoms may be increased if readily decomposed volatile compounds are formed, or the analyte is dispersed in a volatile matrix, or high-temperature flames are used.

At flame temperatures, the compounds present in the gaseous state are generally considered to be the monoxides (although other oxides may exist in some cases) and compounds with halides, *etc.* (X) or ligands (L), which dissociate according to the equilibria

$$MO \rightleftharpoons M + O$$
$$MX_x \rightleftharpoons M + xX$$
$$M_yL_z \rightleftharpoons yM + zL$$

Organic ligands may be thermally decomposed, of course, but some of the other species may be produced in the process. The partial pressure of oxygen in the flame depends on the flame stoichiometry and controls the dissociation of the oxides.[11–14]

Reduction of oxides is the second important process leading to analyte atoms in flames and is provided by

carbon-containing radicals in the interconal zone of the flame, with production of carbon monoxide.

$$MO + C = M + CO$$

This reaction is highly exothermic since the heat of formation of carbon monoxide (1014 kJ/mole) is larger than that of most monoxides ($\leq$836 kJ/mole). Thus, carbon is able to reduce all monoxides at 2773 K.[15]

In acetylene–air flames (2550 K), CO, H and C_2-radicals provide reduction of monoxides,[16,17] but oxides with a dissociation energy $<$533 kJ/mole will be atomized at this temperature anyway. The absorbance signal of cadmium and lead is independent of the flame composition, whereas Cu, Zn, Ni, Co, In and Ga need fuel-lean flames, Fe, Ca and Mn stoichiometric flames, and Cr, Mo and Sn fuel-rich flames. The optimal flame composition between fuel-lean and fuel-rich correlates with the dissociation energy of the monoxide. A reducing atmosphere is especially suitable for elements with thermally stable oxides.[18] In the acetylene–nitrous oxide flame (2950 K) highly reducing C-, C_2-, and CH-radicals are assumed to be present.[11,19] This flame is especially used for Be, Sc, Mo, Al, Si, V, Ti, Y, Ge, Zr, W, B, Hf, Re, Tc, Nb, La, U and lanthanides, which all form stable monoxides. The red interconal reaction zone of the fuel-rich flame, which contains CN- and C_2-radicals, is most effective in this case.[20] Carbon radicals can reduce the metal monoxide to the metal or form a carbide in the solid phase as well. The absorbance signal of the element is increased if the metal or carbide formed is more volatile than the corresponding oxide (*e.g.*, Be, Al, Sc, Y, La). On the other hand, a decreased volatility in the order oxide > metal > carbide causes a decrease in the absorbance signal (*e.g.*, Mo, Ti, W, Si, V, B). Zr, Hf, Nb, Ta, and Th all give non-volatile species and their absorbance signals are not influenced by reduction in the solid state but rather by the formation of polynuclear compounds during evaporation of aqueous solutions.[21,22]

Effect of organic ligands with N, and N and O donor atoms, in flames

Aliphatic amines such as trimethylamine, diethylamine and methylamine decrease the absorbance of various elements in acetylene–air flames (*e.g.*, Fe, Ni, Co). For cobalt the absorbance is drastically lowered if a solution containing 6% triethylamine and ethanol is nebulized. A lesser effect is observed for dimethylamine and pyridine, but ethylamine or aniline has no effect. Such effects arise from insufficient dissociation of metal complexes into atoms at the particular flame temperature. In the hotter acetylene–nitrous oxide flame, the behaviour of these elements is normal and there is no effect by the amines.[23] A similar small negative effect on the absorbance signal of silver in low-temperature flames (coal gas–air) is caused by the presence of methylamine, ethylenediamine or ammonia. EDTA has no effect.[24] In contrast, the same amines increase the degree of atomization for zirconium in acetylene–nitrous oxide flames, because mononuclear complexes are formed which are more volatile and more easily atomized than the corresponding oxide. A similar effect is observed for titanium and hafnium.[25] The chelates of Cu, Ni and Pb with 8-hydroxyquinoline or salicylaldoxime produce slightly lower absorbances than the analogous chelates with cupferron, diethyldithiocarbamate or dithizone in acetylene–air flames.[26] The absorbance for calcium in the presence of 8-hydroxyquinoline or EDTA in propane–air flames (2200 K)[27,28] is lower than that for acetylene–air flames (2550 K), because the lower flame temperature is not sufficient to produce full dissociation of the calcium chelates. On the other hand, magnesium gives higher absorbance in the presence of 8-hydroxyquinoline in propane–air flames.[29] This metal chelate evidently decomposes even at moderate temperature, since most of the magnesium atoms appear close to the burner slot and their concentration rapidly decreases with distance above it. Opposite effects are also observed for titanium and molybdenum in acetylene–nitrous oxide flames, the absorbance of titanium in the presence of cupferron being double that in the presence of 8-hydroxyquinoline,[30] whereas for molybdenum the absorbance is higher in the presence of 8-hydroxyquinoline than of cupferron.[31,32] For cobalt complexes with ligands binding through both oxygen and nitrogen as donor atoms, *e.g.*, Co(III) EDTA, the distribution of free atoms in acetylene–air flames is the same as for complexes containing only oxygen donor atoms, *e.g.*, Co(III)(oxalate)$_3$.[33,34]

Effect of organic ligands with oxygen donor atoms, in flames

For titanium the yield of free atoms in acetylene–nitrous oxide flames is increased in the presence of formic, acetic, propionic and butyric acids but decreased in the presence of oxalic, citric and ascorbic acids.[30,35,36] The absorbance decrease in the presence of the last three acids probably arises from reduction in the solid phase to titanium metal or carbide which will not evaporate or decompose even at high flame temperature. The absorbance increase caused by the first four acids is due to faster evaporation of the more volatile Ti(IV) complexes in the flame, so that the slow reduction step is hindered.

It has been shown for titanium, that the presence of *o*- or *peri*-dihydroxy groups or *o*-hydroxycarboxylic groups on the aromatic nucleus, which is obligatory for stepwise formation of soluble coloured complexes in solutions, is not essential for the organic ligand to enhance the atomization process in acetylene–nitrous oxide flames. For example, 1,5-naphthalenedisulphonic acid, which does not form Ti(IV) complexes in solution, has the same effect on the behaviour in the flame[25] chromotropic acid, which forms very stable complexes of Ti(IV) in solution. What is essential, is the presence of one or more sulphonic groups in the

molecule. Thus naphthalenesulphonic acids and 5-sulphosalicylic acid have been used with success. Phenolic complexing agents without sulphonic groups have a negligible effect on the absorbance, and aliphatic ligands (*e.g.*, oxalic, ascorbic or citric acid) can decrease the atomization yield for titanium.[36] It has also been shown that a large excess of 5-sulphosalicylic acid, chromotropic acid or a number of further sulphonated aromatic derivatives increases the absorbance signal of titanium and also of molybdenum in the presence of K^+ or Na^+.[36,37] However, if the concentration of aromatic sulphonic acids is low, the absorbance for Ti and Mo in acetylene–nitrous oxide flames decreases, since the non-volatile carbide or metal is formed in the condensed phase. If a large excess of the sulphonated compounds and Na^+ or K^+ is present, sodium or potassium sulphate is formed in the solid particles in the flame and can convert the metal or carbide into the monoxide (or Mo into MoS_2). These products finally dissociate after evaporation or are reduced to atoms in the gaseous state, and the absorbance signal from the flame again increases.[36,37]

Tungsten and vanadium behave similarly in the presence of sulphonated aromatic compounds and K^+ or Na^+, but with little or no change in sensitivity. In both cases, the metallic or carbide forms are less volatile than the corresponding oxides, so their formation in the solid phase by reaction with carbon from the destroyed aromatic compound will cause a considerable decrease in signal, in the absence of large amounts of the reagent and K^+ or Na^+. However the simultaneous presence of sulphonic acid and Na^+ or K^+ enables the formation of alkali-metal sulphates at high flame temperature, which oxidize the non-volatile forms of the metals to the more volatile and more easily dissociating oxides and the full absorbance signals are restored.[38]

In general, elements can be divided into three groups with respect to the volatility of the monoxide (O), metal (M) and carbide (C) in the acetylene–nitrous oxide flame.[21] For the first group, *e.g.*, Be, Al, Sc, Y, La, the volatility increases in the order O < M < C. For the second group (*e.g.*, Mo, Ti, W, Si, V, B) the order of volatility is C < M < O, and for the third group (*e.g.*, Nb, Ta, Zr, Hf, U) all forms are non-volatile. In the presence of 5-sulphosalicylic acid, the absorbance signal of Al and Be increases by 15 and 8% respectively, because the monoxides are reduced to the more volatile metals or carbides in the solid phase by the reagent. A similar sensitivity increase is observed for calcium.[38] Formation of the less volatile metal and carbide in the flame depresses the sensitivity of AAS for the second group of elements in the presence of aromatic compounds. This interference can be removed if the metal and carbide are converted into the more volatile oxide, *e.g.*, by an alkali-metal sulphate formed as discussed above. Elements of the third group produce polynuclear species during the oxidation and reduction processes in the flame. These compounds are non-volatile and hinder the evaporation and atomization of the elements. In the presence of 5-sulphosalicylic acid, the absorbance signal of tantalum is almost completely depressed, and that of uranium decreases by 85%.[38]

The absorbance signal of calcium in the acetylene–air flame is also influenced by the presence in the nebulized solution of various ligands containing oxygen donor atoms. Citric or tartaric acid or triethanolamine will decrease the signal. The absorbance signal for manganese in an acetylene–air flame is increased slightly more by the presence of cupferron in the test solution, than of other complexing agents such as diethyldithiocarbamate, 8-hydroxyquinoline or thenoyltrifluoroacetone.[26] No effect of organic complexing agents on the copper signal from acetylene–air, propane–air or hydrogen–air flames is observed (the signal comes from the easily formed and dissociated oxide). The signal from cobalt is only slightly enhanced by cupferron, thenoyltrifluoroacetone or 8-hydroxyquinoline, but is enhanced even less in the presence of acetylacetone, *viz.* by 6% in acetylene–air or by 3% in hydrogen–air flames respectively, relative to the signal from methanolic cobalt acetate solution.[40]

Organic ligands containing carbon donor atoms, in flames

If metallocenes of Zr, Hf, Nb and Ta are nebulized, the atomization yield and sensitivity of determination are considerably increased. Refractory oxides are not formed when metallocenes containing M–C bonds decompose.[41,42] The signal for the cyclopentadiene complex of titanium (Cp_2TiCl_2) is >22 times that for an equivalent amount of the cupferron complex. Similarly, the absorbance signal for Cp_2ZrCl_2 in 0.14*M* hydrochloric acid is 5% higher than that for $ZrOCl_2$ in an acetylene–nitrous oxide flame.[43] The absorbance signal of molybdenum is lower for the binuclear sandwich complex $[MoCp(CO)_3]_2$ than for the carbonyl complex $Mo(CO)_6$ in an acetylene–air flame. This is explained by the formation of non-volatile molybdenum carbide from the binuclear species because of the shorter Mo–C bonds in the sandwich species, *i.e.*, there is a shorter distance between Mo and C in the condensed phase during evaporation.[15]

Tetramethyl-lead gives a lower absorbance signal for lead than that from lead nitrate or the 8-hydroxyquinoline chelate in a propane–air flame.[44] In contrast, the absorbance signal from CH_3HgCl is 50% larger than that from aqueous mercury(II) chloride solution in an acetylene–air flame. The same increase is produced if the mercury(II) chloride solution is made in 1:1 v/v methanol–water, but the signal for CH_3HgCl is not changed under these conditions.[45]

Organic ligands containing sulphur donor atoms, in flames

For copper and cobalt the atomization yield and the absorbance in acetylene–air flames for solutions of

the diethyldithiocarbamate and pyrrolidinedithiocarbamate do not differ from those for the complexes of organic ligands containing oxygen and nitrogen as donor atoms.[39,40] On the other hand, the absorbance signal for molybdenum is much larger for the 3,4-toluenedithiol complex than for the 8-hydroxyquinoline, cupferron and acetylacetone complexes.[32] Little attention has been paid to the effect of aromatic compounds containing chelating sulphur donor atoms on the behaviour of various elements in flames. The formation of a more volatile covalent sulphide during reductive decomposition in the flame would be interesting for the AAS determination of elements which tend to form the refractory oxide, carbide or metal in the condensed phase in flames, since it should considerably increase the sensitivity.

Summary of the effect of organic reagents in flames

The advantageous effects are as follows.

(*i*) Formation of metal species that are more volatile and more easily evaporated and dissociated than the corresponding monoxides in particular flames.

(*ii*) Atoms formed by decomposition of non-hydrated metal chelates with organic ligands are protected by the reducing atmosphere.

(*iii*) The non-selective reduction of oxides by carbon and the decomposition products of organic compounds in flames gives products in the condensed or the gaseous phase which can change the properties of a particular flame.[46]

(*iv*) The flame temperature can be increased by exothermic reactions and increased heat of combustion in the presence of organic ligands, especially aromatic and cyclic compounds.[47] The organic species burn exothermically in the flame and metal atoms are liberated more easily from the refractory oxides.

The effects are disadvantageous under the following circumstances.

(*i*) The analyte is reduced to the metal or metal carbide in the condensed phase in a particular flame if the volatility of the species decreases in the order oxide > metal > carbide.[21,22,37,38]

(*ii*) There is insufficient dissociation of the particular analyte complex at the given flame temperature.

(*iii*) If the metal chelates are not sufficiently volatile or are decomposed to species not able to dissociate in the condensed phase.

Elimination of interferences in flame AAS by use of organic ligands

The interfering elements usually hinder evaporation of the analyte or give thermally stable ternary species which do not dissociate at the particular flame temperature.

The interferences in AAS determination of the alkaline-earth elements are removed by means of various complexing agents which form chelates with the interferent or the analyte or both. 8-Hydroxyquinoline has been used to eliminate the interference of Ba,[48] Be,[49] Cr,[50] Co[51] and Fe[52] in the determination of calcium and magnesium.[27,53–59] 5-Sulphosalicylic acid behaves as a universal agent for removing interferences in the determination of Mg and Ca,[27,56] Cr, Al and Fe,[60] Ti[36] and Mo.[37] Similarly EDTA is suitable for removing interferences in the determination of Mg and Ca,[27,61–66] and Cu, Mn and Ni.[67]

Complexing agents are sometimes used together with releasing agents (an excess of a metal salt which displaces the analyte from non-volatile binary and ternary species in the condensed phase in flames), *e.g.*, 8-hydroxyquinoline + Ca^{2+} for magnesium determination, and EDTA + La^{3+}, EDTA + Sr^{2+}, or 5-sulphosalicylic acid + La^{3+} for the AAS of magnesium and calcium, especially in acetylene–air flames.[27,56–58,62,64–66]

The elimination of interferences by addition of complexing agents can be explained as due to formation of complexes with the analyte or the interferent or both, which protects the analyte from interactions with the interferent and hinders the formation of thermally stable species.[41,58] However, the stability of the chelates in solution seems not to be the decisive factor, since weak complexing agents such as glucose, sucrose, ethylene glycol, glycerol, mannitol are also effective in the AAS determination of Ca, Sr[68–70] and Mg.[66] Metals such as Ca, Mg, Al, Ti and Fe, *etc.* when bound as stable EDTA chelates at the stage at which particles are formed in the flame, are protected from the formation of non-volatile species such as $Ca_3(PO_4)_2$, $CaO.Al_2O_3$, $CaO.TiO_2$, $2CaO.Fe_2O_3$, *etc.*[47] That a fixed or nearly stoichiometric molar ratio of interferent to organic ligand is necessary for active protection of the analyte, proves the prior existence of complexes with the interferent.[27,53,56] On the other hand, the previous chelation of the analyte with the protecting agent is also probable, *e.g.*, a small concentration of 5-sulphosalicylic acid is sufficient to remove the influence of a large excess of silicate during the AAS determination of Mg and Ca.[27,56] However, if 5-sulphosalicylic acid or another aromatic is used, the reduction of the analyte or interferent complexes to the metal or carbide in the solid particles in the flame cannot be neglected. In general, the reduction of analyte and/or interferent to the metal or carbide prevents the formation of a mixed thermostable oxide and thus the organic reagent contributes to the elimination of interferences.[58,68]

Another explanation can be offered for the effect of organic reagents. The formation of metal atoms from chelates is frequently an exothermic process because of the heat of combustion of the organic species, whereas the production of metal atoms from inorganic species is almost always endothermic. Thus there could be an explosive disintegration of a droplet containing an organic species, when the organic moiety is burned in the flame. Thus, the analyte and interferent may be separately reduced to metal atoms without close contact with each other, with no thermally stable ternary species being formed.[53] This explanation, however, would mean that organic spe-

cies not containing any complexing groups would have similar effects, which does not seem to be true.

PRINCIPLES OF ELECTROTHERMAL ATOMIZATION (ETA)

The form and size of the absorbance pulse depends on the kinetics of the atomization processes and the time taken for the analyte and its atoms to be completely removed from the atomizer. As in flames, salt dehydration, decomposition and thermal dissociation and reduction of oxides take place. In contrast to flames, however, the temperature at which the various steps take place, *i.e.*, drying, salt decomposition and atomization, can be easily programmed and the form and size of the absorbance peak influenced in this way. Free atoms are produced by electrothermal atomization, especially with carbon atomizers, according to the schemes:[71,72]

$$M_xO_y(s, l) \rightleftharpoons M_xO_y(g) \rightarrow xM(g) + yO(g)$$

or

$$M_xO_y(s, l) + yC \rightarrow xM(s, l) + yCO(g)$$

$$x \downarrow\uparrow \searrow$$

$$\frac{x}{2} M_2(g) \longrightarrow xM(g)$$

V, Ca, Mg, Cd, Zn and Mn atomize through dissociation of the monoxides in the gaseous phase. For Pb, Cu, Co, Ni and Sn the oxides are reduced by graphite to metal atoms or diatomic molecules, which evaporate and dissociate in the gaseous phase. Mo, Cr and Fe behave similarly but the metal atoms are evaporated. The behaviour of elements depends on the actual temperature changes.[71,72] The atomization schemes given above were deduced from the appearance time of particular atoms and the dependence of the absorption signal on time, for various atomizer temperatures. Sometimes atomization occurs without oxide forming:

$$MX_y(s, l) = MX_y(g) \rightarrow M(g) + yX(g)$$

as happens for Fe(III), Cd and Zn halides.[72] In the ETA methods, the absorbance signal is measured during a period of rapid temperature change, and the signal depends not only on the completeness and the kinetics of evaporation, but also on the temperature at which the evaporation of analyte begins. Incomplete evaporation may arise from carbide formation by interaction of analyte with the surface of a graphite atomizer. Some elements form non-volatile thermally stable carbides even at high temperatures (3000 K), which hinders total evaporation of the element. Use of graphite tubes with their surfaces covered by pyrolytic graphite or with a carbidized surface (Ta, Nb, Zr, W, Ti, Mo carbides) prevents or diminishes the formation of carbides.[73–80] Metallic atomizers made from tungsten,[81–84] molybdenum[85] or tantalum foil[86–89] are also suitable. In this way, the sensitivity for the AAS of lanthanides, uranium and yttrium can be made two orders of magnitude better than that for atomization from graphitic surfaces.[86,90] All organic materials which decompose to carbon at elevated temperature will promote the formation of non-volatile metallic carbides and produce a decrease in the absorbance signal. Accompanying elements can considerably influence or change the mechanism of atomization of a particular analyte. The analyte atoms can interact with the interferent in the gas phase, forming non-dissociated molecules, which lowers the absorbance signal of the analyte. This especially takes place if both the analyte and the interferent evaporate simultaneously, *i.e.*, the interference is proportional to the extent of overlap of the evaporation curves of both reactants and to the bond strength between the two species in the product. The effect of the interferent can be prevented by using a precarbidized atomizer, since the evaporation intervals are then generally separated.[91–93] The analyte can also be released from the product with the interferent, if another metal is present that forms a stronger bond than the analyte with the interferent.[91]

Organic reagents in graphite atomizers

Metal chelates with different organic ligands evaporate and decompose at different temperatures. Volatilization of a chelate at a temperature lower than that of atomization produces loss of the analyte and decrease of the absorbance signal. If the species formed during decomposition of metal complexes is not an oxide, the absorbance signal will be different from that from atomization of the oxide. The elemental carbon formed during decomposition of an organic complexing agent assists in reducing the metal oxide to free gaseous atoms, but the effect will be offset if a non-volatile metal carbide is formed during the decomposition. The volatilization of metal chelates, *e.g.*, of Cu or Co, at low temperatures has not been observed to occur in the graphite atomizer. This phenomenon, however, takes place during the AAS of the metal chelates of Cu, Co, Fe(III), Mn, Ni and Zn heated in a tantalum boat in acetylene–air flames.[39,40,94] There is no influence of 8-hydroxyquinoline, dithizone, diethyldithiocarbamate, 1-pyrrolidinedithiocarbamate, cupferron or thenoyltrifluoroacetone on the absorbance signal of Zn, Cd, Ag, Pb and Cu, during atomization from a graphite filament, compared with the signal for the corresponding inorganic salts.[95] The decomposition of the Cd, Co, Cu, Fe(III), Ni and Pb chelates of pyrrolidinedithiocarbamate at 473–573 K in argon produces the metal sulphides. If oxygen is also present in the argon, a mixture of sulphides and oxides is formed and no elemental carbon appears from the organic species, as it does in pure argon.[96] The decomposition of the Ni and Cu chelates of organic ligands involving M–N, M–O and M–S bonds, such as α-furildioxime, dimethylglyoxime, cuproine, bathocuproine, acetylacetone, 8-hydroxyquinoline, dithizone, pyrrolidinedithiocarbamate,

diethyldithiocarbamate, leads to the metal, metal monoxide and metal sulphide, or a mixture of metal and metal sulphide, in an atmosphere of argon.[97] The absorbance signal for copper increases by 10% relative to that for the nitrate if its chelates with organic ligands having S-donor atoms (*e.g.*, pyrrolidinedithiocarbamate, diethyldithiocarbamate) are injected in methanolic solution into the atomizer. Even larger differences are observed if chlorinated solvents are used.[39,97] For cobalt, a 20% absorbance increase is observed (relative to results for cobalt acetate) in the presence of chelating agents containing N, S or O donor atoms, e.g., acetylacetone, thenoyltrifluoroacetone, cupferron, 8-hydroxyquinoline, 8-mercaptoquinoline, diethyldithiocarbamate, pyrrolidinedithiocarbamate or 1-(2-pyridylazo)naphthol. The increase probably arises from the additional reduction of CoO by the elemental carbon resulting from the decomposed reagent.[40] As much as a 40% increase in the absorbance signal for nickel is observed for ETA of the α-furildioxime or dimethylglyoxime chelates applied as solutions in 1:4 chloroform/methyl isobutyl ketone mixture.[97]

Similar absorbance increases (by 10 and 15% respectively) appear for copper and cadmium atomized in a graphite cup in the presence of EDTA, pyrrolidinedithiocarbamate or diethyldithiocarbamate, and there is a 250% increase for lead.[98] The enhancement effect of ascorbic acid on the absorbance signal of Pb, Cu or Ga is explained by the presence of elemental carbon after its decomposition.[99] Depression of the absorbance signals may also be caused by organic ligands, however. The absorbance of iron decreases if its 1-phenyl-1,3-butenedione chelate is analysed, especially if chlorinated solvents are used. Double peaks may appear, and the atomization is considerably slower in reaching the maximal value at 2300°C. This effect has not been observed for atomization from a tantalum surface. The presence of carbon and halogen is responsible for the occurrence of the second peak. It comes from the formation of a thermally more stable compound which needs a higher temperature for its decomposition. On a carbon surface the formation of a reactive compound is assumed, such as $C_n^+X^-.3X_2$ (where X is halogen) released from halogenated solvents at elevated temperature. This then interacts with iron(III) chloride, forming a new species $C_n^+.FeCl_4^-.3FeCl_3$. If the excess of halogen is freed from the graphite surface, it may react with the iron of the sample, producing relatively volatile iron(III) chloride. A somewhat different mechanism was indicated for the effect of halogenated solvents on the atomization of other metals.[8]

The formation of a low-volatility carbide is probably the reason for depression of the absorbance signals in particular cases such as the AAS determination of Ni and V in lubricating oils, or for Ni and V in the presence of benzoylacetone (M–O bonds), dithizone (M–S bonds) and porphyrin (M–N bonds) in the presence of heavy Conostan oil. Porphyrin gives the largest negative effect because of easy carbonitride formation.[91]

The free atom yield as well as the sensitivity of AAS determination is sometimes decreased by the presence of nitric acid. This is due to destruction of the pyrolytic surface of the graphite furnace and the simultaneous introduction of the metal into the graphitic structure. The presence of nitric acid vapour or its decomposition products at 1000 K can also cause this effect. For nickel the interference of even 2*M* nitric acid is removed if previously the chelate with dimethylglyoxime, $Ni(LH)_2$ has been formed.[100] Vanadium as VO_3^- at pH 8 does not interact with nitrate, but VO_2^+ and VO^{2+} do in acid solutions.[100] The interfering effect of chloride in the AAS determination of Pb, Cu, and Mn is removed by various organic complexing agents such as ascorbic, maleic, adipic, glutaric or tartaric acid.[91,101–104] If pure metal-ion solutions are applied in the presence of excess of chloride, metal atoms in the gaseous phase are formed by dissociation of the corresponding chloride, but non-absorbing volatile metal monochloride species are also formed, which has a depressive effect on the absorbance peak. For Mn and Cu, however, it seems that the large depressive effect of excess of chloride is due to hindrance of the atomization through oxide formation and dissociation at the particular furnace temperature. Organic acids, *e.g.*, ascorbic or oxalic acid, added to the sample solutions applied, act as a flux, preventing the dried sodium chloride crystals in the furnace from lowering the surface tension, and the improved thermal contact of matrix and furnace accelerates the pyrolysis and the decomposition of the matrix.[104]

Organic reagents in metallic atomizers

When metallic atomizers are used in AAS, the effect of elemental carbon from decomposed organic species becomes more evident, and the dissociation of oxides is the predominant mechanism during atomization. If vanadium is heated in a tungsten atomizer in the presence of thiocyanate or organic reagents, a low-volatility carbide is formed during the decomposition (charring) step at 573 K and the absorbance signal at 2473 K decreases. Because of this, the charring step was omitted in the presence of thiocyanate, *N*-benzoyl-*N*-phenylhydroxylamine, diethyldithiocarbamate or 8-hydroxyquinoline.[84] In the presence of ligands containing sulphur as donor atom, the metal sulphide is formed rather than the oxide in metallic atomizers, and this readily dissociates. Thus antimony atoms appear in the gas phase in a molybdenum microtube atomizer at lower temperature (1483 K) in the presence of thiourea than from the pure trioxide (1913 K) and the absorbance peak height is also larger in the presence of thiourea.[85]

The heats of formation, $H_f^0 = 176$ kJ/mole for the sulphide and 706 kJ/mole for antimony trioxide, correlate with this fact. Similar effects are observed for As,[105] Bi[106] and Pb.[107] For lead, the absorbance

peak maximum is usually at 1683 K but in the presence of thiourea it occurs at 1400 K (with argon at 400 ml/min and hydrogen at 100 ml/min as purge gas). The lead atoms are formed from PbS ($H_f^0 = 94$ kJ/mole) and the interference of sodium chloride in the determination of lead is prevented.[107] On the other hand, lead gives different forms of absorbance peak at different temperatures in the presence of diethyldithiocarbamate, but similar atomization profiles are obtained from various lead species in the presence of thiourea.[107] A considerably lower absorbance signal also results for tin in a molybdenum microtube atomizer in the presence of thiocyanate, thiourea or diethyldithiocarbamate in comparison with that for pure tin(IV) tetrachloride, probably because of tin sulphide formation[108] In the presence of *N*-benzoyl-*N*-phenylhydroxylamine or 8-hydroxyquinoline the atomization profiles for tin are different but the peak heights practically identical. This comes perhaps from hydrogen being premixed with the shielding argon gas. Various absorbance peak profiles result from the different thermal stabilities of tin compounds.[108]

Summary of effects of organic reagents in ETA

(*i*) Carbon resulting during pyrolysis of the organic reagent enhances the reduction of the metal monoxide to produce free atoms in the gas phase during the atomization step.

(*ii*) The character of the metal–donor atom bonds and the stability and properties of the metal complexes formed with organic reagents control the preatomization processes (formation of oxide, carbide, nitride, sulphide or volatile metal chelate).

(*iii*) The analyte may be reduced to thermally stable carbide during thermal decomposition in the presence of organic reagents.

(*iv*) Volatile metal chelates may be formed with organic reagents, and the metal species disappear before the atomization step proper.

(*v*) If a solution of a metal chelate in an organic solvent is applied, the organic solvent can interact with the graphite surface and be released at higher temperatures, and then interfere with the metal atomization (multiple peak formation).

CONCENTRATION OF TRACE METALS FROM SEA-WATER BY COMPLEXATION WITH 8-HYDROXYQUINOLINE AND ADSORPTION ON C_{18}-BONDED SILICA GEL

R. E. STURGEON*, S. S. BERMAN and S. N. WILLIE
Division of Chemistry, National Research Council of Canada, Montreal Road, Ottawa, Ontario, Canada

(*Received* 29 *June* 1981. *Accepted* 15 *September* 1981)

Summary—A reversed-phase liquid chromatographic technique based on a combination of multielement chelation by 8-hydroxyquinoline with subsequent adsorption on C_{18}-bonded silica gel is described for the concentration of Cd, Zn, Cu, Ni, Co, Mn and Fe from sea-water. Enrichment factors of 50–100 are readily obtained following elution of the absorbate with methanol to provide a matrix-free concentrate suitable for graphite-furnace atomic-absorption analysis. Quantitative recovery of these elements from near-shore samples of sea-water is demonstrated and the accuracy and precision of the technique are discussed.

Analysis of sea-water for heavy metals currently requires concentration and/or matrix separation prior to determination by most instrumental methods of analysis. A number of techniques have been successfully used for this purpose, including co-precipitation and co-crystallization,[1,2] chelation and solvent extraction,[3–6] chelating ion-exchange resins,[5,7–9] and electrolytic concentration.[10] By far the most widely used procedure is based on the formation of metal dithiocarbamate complexes and their extraction into an organic solvent.[11]

Recent studies have indicated that the true concentrations of heavy metals in open ocean water are much lower than previously thought, *e.g.*, Cd 0.2 mg/l., Cu 80 ng/l., Zn 4 ng/l.,[12] Pb 3.3 ng/l.,[13] necessitating substantial preconcentration before analysis.

Because extractions from large volumes are impractical, both from theoretical and physical considerations, there is an upper limit to the preconcentration factor which can be achieved with such single-stage separations. Again, although the application of chelating resins, such as Chelex-100,[5,8] to the analysis of sea-water permits higher concentration factors to be attained, the method is time-consuming (sample flow-rates 1–2 ml/min) and removal of significant amounts of calcium and magnesium from the resin before elution of the trace metals requires careful washing procedures.[5,14] Hence other methods must be sought.

In a preliminary report from this laboratory,[15] a method based on the formation of metal–8-hydroxyquinoline complexes and their subsequent adsorption onto C_{18}-bonded silica gel was described for the preconcentration of Cd, Zn, Cu, Pb, Ni, Mn and Fe from sea-water. Encouraged by the initial success of this approach, we report here a detailed investigation of the applicability of this method to the determination of Cd, Pb, Cu, Mn, Fe, Ni, Cr and Co in samples of near-shore sea-water.

EXPERIMENTAL

Apparatus

All atomic-absorption analyses were carried out with a Perkin–Elmer HGA-2200 heated graphite atomizer. Sample aliquots of 10 or 20 μl were delivered to the furnace with a Perkin–Elmer AS-1 autosampler and absorbance peak heights were recorded on a fast-response Speed Servo II strip-chart recorder (Esterline Corp., Indiannapolis, Ind., U.S.A.). Continuum-source background correction was used. A detailed description of the instrumentation has already been given.[5]

Figure 1 shows the preconcentration apparatus, consisting of a 1-litre polypropylene reservoir connected by a short segment of Bev-A-line IV tubing (Cole Parmer Co., Chicago, Ill.) to a borosilicate glass column in which approximately 600 mg of C_{18}-bonded silica gel (Bondapak, Porasil B, 37–75 μm, Waters Associates, Milford, MA) was supported by a coarse sintered-glass frit.

Reagents

The C_{18}-bonded silica gel was used without further purification. All acids, solvents and other reagents were purified as previously reported.[5] Subsurface samples of near-shore Atlantic sea-water (salinity 29.5‰) were collected during late autumn off the coast of Nova Scotia, filtered through a 0.45-μm membrane filter, acidified to pH 1.6 with nitric acid and stored in precleaned polypropylene bottles.

Procedure

Sample preparation was done in a clean-laboratory equipped with laminar-flow benches and fume cupboards providing a class 100 working environment.

The glass column was slurry-loaded with 600 mg of the C_{18} gel suspended in redistilled methanol. Three 10-ml

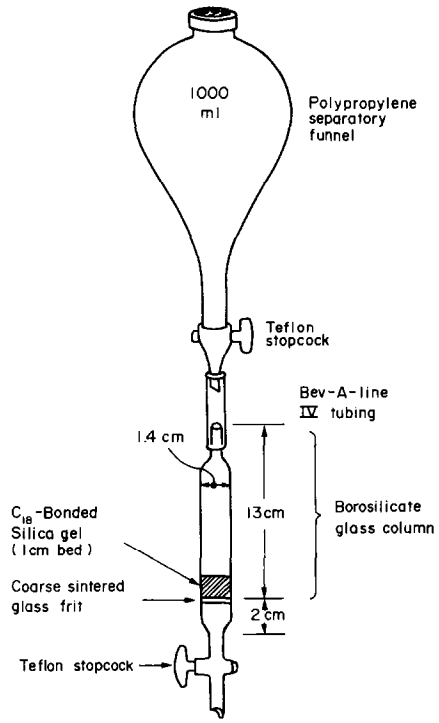

Fig. 1. Preconcentration apparatus.

portions of methanol were then passed through the bed under gravity flow to effect clean-up. Before passage of the last 200–300 μl of the methanol, distilled, demineralized water (DMW) was carefully added in small (100–200 μl) portions, thereby changing the solvent from methanol to water, in the manner of a gradient elution, without disturbing the resin bed. Following complete switch to the aqueous system, the column was washed with 5 bed-volumes of DMW and left covered with 4–5 ml of DMW.

A 500-ml sea-water sample was loaded into the reservoir and 0.5 ml of 5% purified[5] 8-hydroxyquinoline solution was added. The pH was adjusted to 8.9 with ammonia solution and the sample was drawn through the C_{18} bed with a water-aspirator, at a typical flow-rate of about 20 ml/min. Visual observation confirmed that the metal chelates were adsorbed on the top layer of the bed to form a thin green band.

Following passage of the sample, the column was washed free from sea-water with 10 ml of pH-8.9 DMW containing 50 μg of oxine per ml. The adsorbed metal chelates of 8-hydroxyquinoline were then eluted from the column with 5 ml of methanol. This eluate was either collected in a 10-ml standard flask and made up to volume with 2% v/v nitric acid or collected in a "Vycor" crucible and evaporated to dryness in the presence of 200 μl of concentrated nitric acid and 500 μl of 60% perchloric acid (this being repeated until a clear, colourless solution was obtained) and thereafter diluted to 10.0 ml with 1% v/v nitric acid. These procedures provide a theoretical concentration factor of 50.

Blanks were determined by applying the procedure to 40 ml of DMW (containing the same absolute amount of 8-hydroxyquinoline as the sample) instead of the sea-water sample.

Between runs, the column was reslurried to ensure proper packing of the bed, thoroughly flushed with methanol and changed over to the aqueous system.

The concentrates were analysed by graphite-furnace atomic-absorption, with calibration by means of solutions of appropriate metal standards in 1% v/v nitric acid as well as by the addition of metal spikes to aliquots of the concentrate in order to effect a matrix match.

RESULTS AND DISCUSSION

The method described for the preconcentration of trace metals from sea-water is essentially reversed-phase liquid column adsorption chromatography (RPLC). The application of this technique to the separation and concentration of trace amounts of heavy metals from a variety of matrices has recently been reviewed by Schwedt.[16] In RPLC, the stationary phase (in this case the C_{18} silica gel) is, by definition, less polar than the mobile phase (here, sea-water). Its effectiveness as a trace enrichment method in the present case lies in the fact that manipulation of secondary chemical equilibria in the aqueous mobile phase (formation of metal chelates) permits concentration of these hydrophobic, less polar complexes, at the head of the column. Furthermore, the weak surface attraction energies of the non-polar stationary phase promote rapid mobile-phase equilibration on the column during sample enrichment and elution, as well as gradient regeneration.[17]

Reversed-phase techniques are versatile methods for trace enrichment and have been used on several occasions to separate and/or preconcentrate heavy metals from a variety of matrices.[18–21] Applications of these techniques to sea-water analysis have been undertaken in both this laboratory[15] and, more recently, by Mills and Quinn.[22] The latter authors utilized prepacked C_{18} SEP-PAK cartridges (Waters Associates, Milford, MA) to collect both dissolved organic material and copper organometallic complexes from samples of near-shore sea-water. The use of SEP-PAK cartridges may prove very convenient for this application.

As 8-hydroxyquinoline is capable of forming insoluble metal complexes with more than 25 elements, advantage may be taken of its non-specific reactivity to complex simultaneously a number of metals present in sea-water. With suitable adjustment of pH and oxine concentration, chelation of the matrix elements (Ca and Mg) can be minimized relative to that of the transition metals.[23]

Of the elements selected for study, manganese forms the weakest complex with 8-hydroxyquinoline (log $\beta_2 = 17.5$).[24] Initial studies[15] indicated that manganese could be quantitatively recovered from sea-water at pH 8.9 with negligible recovery of calcium and magnesium.

The recommended pH range for operation of bonded-phase silica gels is 1–9.[25] Siloxane bonds are attacked by hydroxide in aqueous solution and the silica substrate must be "protected" by a high density of bonded organic phase in order to avoid dissolution. Although no deleterious effects on the performance of the columns were noted even after extended use at pH 8.9, care was taken to reslurry and repack

the bed after elution of each sample, because of the possibility of the silica dissolving under these conditions which might cause shifting and channelling of the bed.

Analytical blanks. Absolute blanks are presented in Table 1. Data are given for both the direct procedure, wherein the methanolic concentrates were directly analysed, and also following total acid decomposition of the blank eluate with dissolution of the residue in 1% v/v nitric acid. Blank values for the latter procedure are significantly higher for lead and iron, reflecting the consequences of increased sample manipulation. Furthermore, the precision of the blank determinations for acid decomposition procedures is seriously poorer than that for direct analysis of the methanolic concentrates.

Whereas reagent impurities can account for the blank values obtained for Cd, Mn, Ni, Co and Pb,[5] the C_{18}-bonded silica gel is probably the source of the high levels of Zn, Cu and Fe. Semiquantitative d.c. arc spectrographic analysis of this material revealed the presence of substantial concentrations of iron (0.06% w/w); lower concentrations of copper (0.01% w/w) and zinc (0.01% w/w) were also present. Even slight leaching of the silica substrate at high pH during each sample run could easily account for the high blank from these elements.

The low analytical blanks obtained in this study make the technique attractive for sea-water analysis. This is a significant advantage over use of activated charcoal[23] as the adsorption agent for oxine complexes and organometallic species.[22]

Recovery of spikes. The efficiency of recovery of spikes added to both DMW and sea-water samples is shown in Table 2. With the exception of cobalt, all elements of interest could be quantitatively recovered from DMW. From sea-water media, however, recovery of lead was erratic, varying from 17 to 88%. As a consequence, the technique could not be used for the determination of lead in sea-water. The reproducibility of the technique was slightly poorer for all elements when sea-water was analysed and an isolated check for chromium indicated that recovery of this element was less than 10%.

Recovery of spikes from sea-water did not vary over the range of sample flow-rates 8–35 ml/min.

Analytical results. Results for the analysis of two near-shore sea-water samples are given in Tables 3 and 4. The samples were filtered during collection and

acidified to pH 1.6 with nitric acid for storage purposes.

Each sample was analysed in triplicate following concentration (50-fold) from 500-ml portions of sea-water. As a result of the lower blanks obtained by direct analysis of the methanolic concentrates (Table 1), all analyses were completed in this manner. Calibration against metal standards in 1% nitric acid or in 1% v/v nitric acid in 50% aqueous methanol was not successful, as the presence of oxine in the solution (0.3 mg/ml in the methanolic concentrates) produced significant positive interferences (signal enhancements of up to 100%). Calibration was achieved by spiking a sample of the concentrate with the element of interest, thereby obtaining an exact matrix match (standard addition method).

Apart from the oxine, no other matrix constituents were present. Rejection of calcium and magnesium was excellent, there being less than 1 μg/ml (Ca) and approximately 20 μg/ml (Mg) in the concentrates.

In calculation of the results account was taken of the 65% recovery of cobalt. For all other elements, quantitative recovery was assumed (Table 2).

Data obtained by using the C_{18} concentration procedure are compared with "accepted" values for these samples (Tables 3 and 4). The "accepted" values were obtained by exhaustive analysis by several different techniques,[6] including isotope-dilution spark-source mass spectrometry[26] and are believed to be quite reliable.

Application of the *t*-test (at the 95% confidence level) shows no significant difference between the results obtained by the C_{18} adsorption procedure and the accepted values.

The precision of analysis averages 10% RSD (range of RSD being 4–25%) for the two samples and is generally worse for those elements for which blanks were relatively large (zinc and copper).

CONCLUSIONS

The ability of 8-hydroxyquinoline to form chelates with a large number of elements, coupled with their non-selective adsorption onto C_{18}-bonded silica gel, provides a versatile, multielement concentration technique for trace metals in sea-water.

The C_{18}-bonded gel may be reused repeatedly under the conditions cited in these experiments, thereby maintaining low operating costs. Additionally, all reagents are easily purified. The relatively fast sample processing (up to 35 ml/min) and minimum of sample manipulation permit the rapid attainment of high concentration factors,[15] contributing to its potential use as an on-site preconcentration procedure.

Blank levels ultimately determine practical detection limits, and these can potentially be lowered by synthesis of a C_{18}-bonded phase with high-purity silica gel as the substrate, and perhaps by operating the column at lower pH (to minimize hydrolysis of the silica).

RPLC with C_{18}-bonded silica gel may also prove very useful for preconcentrating trace organics from sea-water, including that portion binding trace metals, thereby permitting speciation studies. A recent study by Mills and Quinn attests to the feasibility of this application.[22]

Future application of liquid column chromatography to the concentration of trace elements from sea-water could prove more rewarding if the chelation were performed within a column bed containing immobilized 8-hydroxyquinoline. Work is in progress in this direction.

Acknowledgements—The authors thank R. Guevremont of the Atlantic Research Laboratory, National Research Council of Canada, for the sea-water samples, and V. P. Clancy for spectrographic analyses of the C_{18} gel.

ION-EXCHANGER COLORIMETRY—VIII

MICRODETERMINATION OF COPPER IN NATURAL WATERS

KAZUHISA YOSHIMURA, SATORU NIGO and TOSHIKAZU TARUTANI

Department of Chemistry, Faculty of Science, Kyushu University 33, Hakozaki, Higashiku, Fukuoka, 812 Japan

(*Received* 2 *June* 1981. *Accepted* 18 *August* 1981)

Summary—A microdetermination method for copper by ion-exchanger colorimetry has been developed. The porphyrin α,β,γ,δ-tetrakis(4-*N*-methylpyridyl)porphine was used as the colour reagent. After the complexation at pH 4.5 and 40°, the surplus ligand was converted into the protonated species by addition of sulphuric acid. The complex and the ligand were easily sorbed on the cation-exchange resin, Dowex 50W-X2-H^+ (100–200 mesh). The resin-phase absorbances of the complex species at 424 nm and of the resin background at 510 nm were used for the measurements. There were no interferences by the foreign ions expected to be present in natural waters, at up to 1000 times the concentration of copper. With a 1-litre sample the detection limit is 0.072 μg/l. It is possible to determine copper at μg/l. or lower levels in natural waters.

Porphyrins have high sensitivity for some transition metals and have been employed for their direct determination at μg/l. levels. An absorption band at about 400 nm, called the Soret band, is used for the analysis.[1,2] The molar absorptivity of the Soret band is of the order of 10^5 l.mole^{-1}.cm^{-1}. The method for determination of copper with a porphyrin which has pyridinium groups, α,β,γ,δ-tetrakis(4-*N*-methylpyridyl)porphine [T(4-MPy)P], has been reported by Ishii and Koh.[3] The complexation of T(4-MPy)P with copper(II) is accelerated remarkably by a small amount of a reducing agent such as hydroxylamine, which overcomes the general low reactivity of porphyrins with metal ions. After the complexation is complete, the spectral absorption of the ligand at the Soret band can be eliminated by addition of acid. This method has high selectivity for copper(II).

We have combined use of this highly sensitive reagent with ion-exchanger colorimetry, based on direct measurement of the resin-phase absorbance after sorption of the coloured complex,[4,5] for determination of copper(II) in natural waters at μg/l. or lower levels.

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade and demineralized water was used.

Standard copper(II) stock solution (1000 ppm). Prepared by dissolving 2.68 g of cupric chloride dihydrate in 10 ml of concentrated hydrochloric acid and diluting to 1 litre with water. The concentration was standardized by EDTA titration with PAN as indicator.

T(4-MPy)P stock solution (10^{-4}M). Prepared by dissolving 0.0319 g of T(4-MPy)P tetra-*p*-toluenesulphonate (Dojin Pharmaceutical Laboratories) in water and diluting to 250 ml. A working solution was freshly prepared by 10-fold dilution.

Dowex 50W-X2-H^+ (100–200 mesh). Conditioned, air-dried, and stored in a polyethylene container.

Apparatus

A Hitachi recording spectrophotometer (Model EPS-2U) was used for measurements of absorption spectra both in the solution and resin phases. The absorbance measurements were made with air as reference, with a Hirama single-beam spectrophotometer, Model 6B, which can measure absorbance in the range 0–2.5.

Procedure for the determination of copper

To a nearly neutral 200-ml sample containing 0.1–1.2 μg of copper were added 10 ml of 0.5% hydroxylamine hydrochloride solution, 2 ml of 5*M* acetate buffer (pH 4.5), and 4 ml of 1×10^{-5}*M* T(4-MPy)P. The solution was stood for about 5 min at 40°, then 30 ml of sulphuric acid (1 + 1) and 0.50 g of Dowex 50W-X2 resin were added. The mixture was stirred for 30 min, the coloured resin collected and the resin slurry transferred to a 1-mm quartz cell. The absorbances at 424 and 510 nm were measured.

For the determination of lower levels of copper in water, a 1-litre water sample can be used. To a nearly neutral 1-litre sample containing 0.1–1.2 μg of copper, five times the amounts of the reagents given above were added, except for the colour reagent and the resin, the amounts of which were the same as for a 200-ml sample.

When natural waters were sampled, 10 ml of concentrated hydrochloric acid were added per litre of sample immediately after filtration of the sample through a Whatman glass fibre filter, GF/D. The sample solutions were stored in polyethylene containers.

Absorbance measurements

The net absorbance of the copper(II)–T(4-MPy)P complex sorbed on the resin, at the maximum absorption wavelength (424 nm), $A_{RC(424)}$, is obtained from the equations

$$A_{RC(424)} = A_{(424)} - A_{(510)} - A_R^* \quad \text{(for sample)}$$

$$A_R^* = A_{(424)} - A_{(510)} \quad \text{(for blank)}$$

where A is the overall absorbance at the wavelength indicated by subscript and A_R^* is the difference between the resin background absorbances at 424 and 510 nm.

RESULTS AND DISCUSSION

Absorption spectra in the resin phase

T(4-MPy)P instantaneously forms a 1:1 complex with copper at pH 4.5 in the presence of hydroxylamine.[3] Once formed, the complex is very stable and is not decomposed by the addition of strong acids. At pH above 4.5, both the complex and the reagent have a charge of 4+ and show the Soret band at almost the same wavelength (426 nm). When enough sulphuric acid is added to the solution after the complex formation, the free reagent is doubly protonated to form a species with a charge of 6+ because $pKa_1 = 0.8$ and $pKa_2 = 2.06$ for the protonated species;[6] the absorption maximum of the reagent Soret band then shows a 20-nm shift to longer wavelength. We believe that the function of the hydroxylamine is to reduce the copper(II) to copper(I) which is then complexed rapidly and oxidized back to copper(II) in the complex. Cation-exchange resin can easily sorb the copper complex as well as the free ligand, because of their high positive charges. The sorbed complexes give absorption spectra similar to those for aqueous solution. As shown in Fig. 1, the separation of the Soret band of these two species in the resin phase (30 nm) is better than that for solution. The larger separation of the electronic states may be caused by interaction between these species and the resin skeleton. In the conventional solution method,[3] the decrease in absorbance of the free ligand at 446 nm is measured, because of its high sensitivity; the apparent molar absorptivity is 2.46×10^5 l.mole^{-1}.cm^{-1}. In ion-exchanger colorimetry, however, the utilization of the absorption band of the free ligand is undesirable from the point of reproducibility. The absorbance at the absorption maximum of the complex (424 nm) and that in a range where only the resin absorbs light (510 nm), are used.

Optimization of conditions

T(4-MPy)P concentration. The contribution of the absorbance of the protonated free ligand at 424 nm cannot be neglected. Excess of the reagent makes the background absorbance (A_R^*) large. The addition of 4

Table 1. Reproducibility of measurements, and detection limit

Sample volume, *ml*	Cu added, *μg*	*n*	$A_{RC(424)}$	A_R^*†	Detection limit, *μg/l.*
200	0	10		0.277 ± 0.0088	0.44
200	1	5	0.400 ± 0.014		
1000	0	5		0.301 ± 0.0056	0.072
1000	0.5	5	0.162 ± 0.0098		

† $A_R^* = A_{(424)} - A_{(510)}$ (for blank).

ml of $1 \times 10^{-5} M$ T(4-MPy)P solution is adequate for 1.2 μg of copper and 0.50 g of the resin.

pH and hydroxylamine concentration. On the basis of the results obtained by Ishii and Koh,[3] the pH of the solution was maintained at 4.5 with acetate buffer during the complex formation, and 0.5 ml of 2.5% hydroxylamine hydrochloride was added per 100 ml of sample solution.

Time for complex formation. At 40° the complex was formed completely in 2 min. Keeping at this temperature for more than 15 min lowered the absorbance of the complex because of adsorption on the vessel wall (Fig. 2).

Concentration of sulphuric acid. After the complex formation, the free ligand should be protonated by addition of sulphuric acid. With increasing amounts of sulphuric acid added to a solution containing only the ligand, the absorbance at 454 nm first increased and then (because of competition between protons and protonated ligand for sorption on the resin) decreased (Fig. 3). When sulphuric acid was added to a solution containing only the complex, the absorbance at 424 nm showed similar behaviour (Fig. 3). The addition of acid prevents adsorption of the complex on the surface of the glassware. In the standard procedure, 15 ml of sulphuric acid (1 + 1) were added per 100 ml of sample solution.

Stirring time. The effect of the stirring time on sorption of the complex species on the resin is shown in Fig. 4. The colour development was almost complete within 20 min for 200-ml water samples. As the ligand is a macromolecule (effective cross-sectional area 1 nm^2),[7] the rate of diffusion into the resin may be fairly slow. The stirring time for 200-ml water samples was fixed at 30 min.

It took longer for 1-litre water samples to complete the colour development (over 1 hr). The stirring time was fixed at 30 min with a view to more rapid determination of copper, but the calibration curve is still linear. If higher sensitivity is necessary, stirring for 60 min should be selected.

Effect of temperature. The absorbance was independent of the temperature used if this was higher than 35°. With use of temperatures lower than 35°, the absorbance was lower (for fixed stirring time), because of the lower rate of sorption of the complex on the resin (Fig. 5).

Table 2. Effects of foreign ions on the determination of copper*

Ion	Concentration, *ppm*	$A_{RC(424)}$	Relative error, %
Cu^{2+}	0.005	0.402	—
Mg^{2+}	5	0.409	+2
	50	0.395	−2
Al^{3+}	50	0.416	+3
Ca^{2+}	5	0.423	+5
	50	0.386	−4
Fe^{3+}	0.5	0.404	0
	5	0.429	+4
Mn^{2+}	0.5	0.419	+4
	5	0.387	−4
Zn^{2+}	0.5	0.402	0
	5	0.428	+6

* Sample: 200 ml. Resin: Dowex 50W-X2-H^+, 100–200 mesh, 0.50 g.

Calibration

The calibration curves were reasonably linear and could be expressed by the equations $A_{RC(424)} = 0.0800C$ for 200-ml samples, and $A_{RC(424)} = 0.313C$ for 1-litre samples in the linear ranges, where C is the concentration of copper in the sample solution, in μg/l. The sensitivity for 1-litre samples is about 4 times that for 200-ml samples, and about 80 times that for the conventional method.[3] Different lots of Dowex 50W-X2 resin gave different sensitivity and therefore the calibration equations must be checked for the reagents (and instrumentation) used.

Precision and detection limit

Precision was measured with 200-ml sample solutions containing 1.0 μg of copper, and 1-litre sample containing 0.50 μg of copper. For 5 determinations, the relative standard deviations were 3.5 and 6.0%, respectively (Table 1).

The relative detection limits, defined in the previous paper,[5] are also shown in Table 1.

Effects of foreign ions

In Table 2, the effects of various foreign ions are listed. Almost all those tested did not cause more than 5% error. The absorbance decreased when the concentration of sodium chloride was higher than 3%. The sorption of the complex species on the resin may decrease by competition between sodium ions and the sample species. When copper in sea-water is deter-

mined, the calibration curve should be prepared with solutions of the same saline concentration as the sample, or the standard-addition method should be used.

Determination of copper in sea-water and river water

The method was applied to the determination of copper in natural waters. The results are shown in Table 3. For sea-water, the calibration curve was prepared by using sample solution from which trace elements had been stripped by passage of the sample through a column of chelating resin.[8] Recovery of the added copper was almost complete. The concentration of copper found was 0.18 ± 0.03 μg/l. For the surface sea-waters in the western area of the North Pacific Ocean the average content of total soluble copper is 0.64 ± 0.21 μg/l. and more than 70% of this is bound to organic matter. These organometallic compounds are not easily decomposed when samples are stored under acidic conditions.[9,10] Hence the present method can be used for determining the concentration of soluble copper in inorganic forms in sea-water. Recovery was almost complete for the river water. The concentration of copper found was 0.49 ± 0.01 μg/l.

STUDIES ON CHELATING RESINS—I

GENERAL EQUATION FOR THE CALCULATION OF THE PROTONATION CONSTANTS OF CHELATING RESINS

Ö. SZABADKA

Department of Analytical Chemistry, University of Chemical Engineering, P.O. Box 28, Veszprém, Hungary 8201

(*Received* 21 *January* 1981. *Revised* 25 *May* 1981. *Accepted* 16 *August* 1981)

Summary—A general equation has been derived which describes the protonation equilibria of basic groups attached to an insoluble polymer matrix. The derivation is based on the application of the charge and mass-balance equations. When the relationship obtained is applied to water-soluble ligands, it reduces to the well-known Schwarzenbach equation for titration of polybasic acids.

For titration of a fully protonated N-basic acid with a strong base, the equation given by Schwarzenbach[1] can be written in the following form,† for constant ionic strength, I:

$$\sum_{j=0}^{N} (\alpha^* - N + j)\beta'_j[H^+]^j = 0 \qquad (1)$$

where

$$\alpha^* = \alpha + \frac{[H^+] - [OH^-]}{C_L}$$

$$\alpha = \frac{[\text{strong base}]}{C_L}$$

C_L is the molal total analytical concentration of all forms of the N-basic acid in the equilibrium solution, and

$$\beta'_j = \Pi K'_j$$

where K'_j is the jth protonation constant at ionic strength I:

$$K'_j = \frac{[H_jL]}{[H_{j-1}L][H^+]}$$

If L is the anion of a monobasic acid ($N = 1$) and $C_L \geqslant 10^{-3} m$, then when the pH is between 5 and 9 equation (1) reduces to:

$$(\alpha - 1) + K'\alpha[H^+] = 0 \qquad (2)$$

or

$$\log K' = \text{pH} + \log \frac{1 - \alpha}{\alpha} \qquad (3)$$

This equation does not apply, however, to polyelectrolytes or to conjugate bases fixed to insoluble matrices. When equation (3) is used for evaluation of the titration curves of such ligands, the calculated protonation constant vary significantly with the degree of titration as well as with the ionic strength of the solution.[2,3]

Several attempts have been made to extend the validity of this equation to polyelectrolyte systems. These approaches fall into two classes. Those of the first type are empirical, utilizing several arbitrary constants,[4] and the second class comprises those which are based on thermodynamic principles, such as the equation derived by Chatterjee and Marinsky,[5] which, however, only describes single-step protonation reactions.

We present here a general equation for resin protonation equilibria, which can also be applied to overlapping protonation processes.

THEORY

In our discussion the protonation will be treated as a heterogeneous chemical reaction between the components of two phases in contact: the solution phase and the resin phase.

The components of the solution phase are water molecules, protons and their counter-ions, and the electrolyte, $G^+ G^-$, used to adjust the ionic strength.

The resin phase is considered as a concentrated aqueous solution of electrolytes in which the concentrations of the components are experimentally accessible quantities.

The resin phase consists of the following components.

(1) Basic groups.
(2) Conjugate acid groups formed in the process of protonation.
(3) Counter-ions.
(4) Water molecules.

† Schwarzenbach's symbols have been replaced as follows (his symbols are given first), $m = N$, $a = \alpha$, $a^* = \alpha^*$, $Z_t = C_L$) $\bar{K}^H_{Hjz} = \beta'_j$, and his equation has been multiplied by -1. Molal concentrations are used here because the system is heterogeneous.

The resin phase can be separated from the solution phase by centrifugation.

In course of the protonation the total mass of the basic and conjugate acid groups remains the same, but their proportion as well as the quantity of the counter-ions and the water will change.

Molal concentrations will be used for components (1)–(3), the solvent medium being the water in the resin phase.

The protonation equilibria

For aqueous solutions the protonation reaction can be written as:

$$L^{n-} + H^+ = HL^{(n-1)-} \tag{4}$$

where L represents a base and HL its conjugated acid.

The protonation constant is defined as the thermodynamic equilibrium constant for this reaction where a represents activity:

$$K = \frac{a_{HL}}{a_L a_{H^+}} \tag{5}$$

According to the principles of electroneutrality an equivalent amount of counter-ions G^+ or G^- should also be present in the system, according to whether L is an anion, a neutral species or a cation, and under certain circumstances must be taken into account in the equilibria.

Protonation in a homogeneous system. When the base and the protons are present in the same phase, then equation (5) will apply irrespective of whether the base is L^-, L or L^+, since the counter-ions are not involved in the equilibrium, and simply cancel if included in the equation.

Protonation in a heterogeneous system. If the base and the protons are present in different phases, then the protonation is a heterogeneous reaction and the principles of electroneutrality apply to both phases.

Suppose the base is attached to an insoluble matrix (*e.g.*, is in a resin phase) and the protons are in the solution phase. We will denote resin-phase components by bars.

Consider first the protonation of a negatively charged base, $\overline{L}^-$, taking the counter-ions into account:

$$\overline{L}^- + \overline{G}^+ + H^+ + G^- = \overline{HL} + G^+ + G^- \tag{6}$$

The protonation constant is:

$$\overline{K}_{L^-} = \frac{\overline{a}_{HL} a_{G^+}}{\overline{a}_{L^-} \overline{a}_{G^+} a_{H^+}} \tag{7}$$

If the base is neutral, then the reaction is:

$$\overline{L} + H^+ + G^- = \overline{HL}^+ + \overline{G}^- \tag{8}$$

and the protonation constant is:

$$\overline{K}_L = \frac{\overline{a}_{HL^+} \overline{a}_{G^-}}{\overline{a}_L a_{G^-} a_{H^+}} \tag{9}$$

Finally, if the base has a positive charge:

$$\overline{L}^+ + \overline{G}^- + H^+ + G^- = \overline{HL}^{2+} + 2\overline{G}^- \tag{10}$$

and the protonation constant is

$$\overline{K}_{L^+} = \frac{\overline{a}_{HL^{2+}} \overline{a}_{G^-}}{\overline{a}_{L^+} a_{G^-} a_{H^+}} \tag{11}$$

Activity of the hydrogen ions in the resin phase

Consider the protonation process as a homogeneous reaction between the components of the resin phase:

$$\overline{L} + \overline{H}^+ = \overline{HL} \tag{12}$$

As mentioned earlier, if the protonation reaction takes place in a homogeneous system, then the counter-ions cancel in the equilibrium expression, so in this case

$$\overline{K}_L = \frac{\overline{a}_{HL}}{\overline{a}_L \overline{a}_{H^+}} \tag{13}$$

From a comparison of equations (7), (9) and (13), the activity of the protons in the resin phase can be expressed by

$$\overline{a}_{H^+} = a_{H^+} \left(\frac{\overline{a}_G}{a_G} \right)^{\pm 1} \tag{14}$$

where the sign of the exponent is positive when the counter-ion is a univalent cation, and negative when the counter-ion is a univalent anion.

Equation (14) can also be obtained if it is supposed that the protons in reaction (6) originate from the solution phase, in which case the process proceeds by transfer of protons from the solution phase into the resin phase:

$$H^+ \rightarrow \overline{H}^+$$

To preserve electroneutrality, however, this proton transfer should be accompanied by transfer of the counter-cations of the base anion, from the resin into the solution phase ($\overline{G}^+ \rightarrow \overline{G}^-$), or transfer of the counter-anions of the protons from the solution into the resin phase ($G^- \rightarrow \overline{G}^-$).

The overall processes can therefore be written as:

$$H^+ + \overline{G}^+ \rightleftharpoons \overline{H}^+ + G^+$$

$$K = \frac{\overline{a}_{H^+} \cdot a_{G^+}}{a_H \cdot \overline{a}_{G^+}}$$

and

$$H^+ + G^- \rightleftharpoons \overline{H}^+ + \overline{G}^-$$

$$K = \frac{\overline{a}_{H^+} \overline{a}_{G^-}}{a_{H^+} a_{G^-}}$$

If the standard chemical potential of the electrolyte components in the resin and the solution phases are

defined in exactly the same way, the thermodynamic equilibrium constants for both reactions above should be equal to unity, and the activity of the protons in the resin phase is then given by equation (14).

Calculation of the protonation constant for single-step protonation processes

From equations (13) and (14)

$$\log \bar{K}_L = \mathrm{pH} \pm \log \frac{a_G}{\bar{a}_G} + \log \frac{\bar{a}_{HL}}{\bar{a}_L} \qquad (15)$$

where the $\pm$ sign has the same meaning as in equation (14).

From the definition of activity, equation (15) can be written as

$$\log \bar{K}_L = \mathrm{pH} \pm \log \frac{a_G}{(G)} + \log \frac{(HL)}{(L)} + \log \frac{\bar{\gamma}_{HL}}{\bar{\gamma}_L(\bar{\gamma}_G)^{\pm 1}} \qquad (16)$$

where (L), (HL) and (G) are the concentrations in the resin in terms of mole per kg of water in the resin phase, and $\bar{\gamma}_L$, $\bar{\gamma}_{HL}$ and $\bar{\gamma}_G$ are the respective activity coefficients. These latter, experimentally non-accessible quantities, can be lumped in a $\bar{K}_\gamma$ term:

$$\bar{K}_\gamma = \frac{\bar{\gamma}_{HL}}{\bar{\gamma}_L(\bar{\gamma}_G)^{\pm 1}} \qquad (17)$$

$\bar{K}_\gamma$ can be considered as a measure of the strength of the interactions in the resin phase. The directly measurable and calculable quantities in equation (16) are the following.

(1) The pH of the equilibrium solution phase.

(2) The activity of the counter-ions in the solution phase, a_G.

(3) (G), the molality of the counter-ions in the resin phase. This term should be considered as the sum of the chemically bound and invasive amounts of the counter-ions, divided by the water content of the resin phase:

$$(G) = \frac{\bar{G}_K + \bar{G}_I}{\overline{H_2O}} \qquad (18)$$

where $\bar{G}_K$ is the amount of chemically bound counter-ions, mmole per g of dry resin; $\bar{G}_I$ is the amount of the electrolyte (in the resin phase) which has migrated from the equilibrium solution phase by the so-called electrolyte invasion process, mmole per g of dry resin, and $\overline{H_2O}$ is the water content of the resin, g per g of dry resin.

(4) The proton activity in the resin phase, $\bar{a}_H$, cannot be measured directly, nor calculated from experimentally accessible quantities, because $\bar{\gamma}_G$, the activity coefficient of the counter-ions, is not susceptible to direct measurement, but if $\bar{\gamma}_G$ is lumped into the $\bar{K}_\gamma$ term (H^+) can be redefined as a mixed proton activity in the resin phase, which can be calculated from the measurable quantities given above, as follows:

$$(H^+) = a_H \left(\frac{(G)}{a_G}\right)^{\pm 1} \qquad (19)$$

In what follows, this (H^+), defined by equation (19) will be called the calculated proton activity in the resin phase, and will also be used to express the concentration of the protons in the resin phase (as is commonly done in the treatments of complex equilibria, where $[H^+]$ is used in the sense of a_H) in the charge-balance equations.

Then $\overline{pH}$ for the resin phase can be written as:

$$\overline{pH} = \mathrm{pH} \pm \log \frac{a_G}{(G)} \qquad (20)$$

where $\mathrm{pH} = -\log a_H$.

In equations (19) and (20) the same remarks apply for the $\pm$ sign as for equation (14).

(5) (HL)/(L), the concentration ratio of the protonated and non-protonated forms in the resin phase, can be calculated from charge and mass-balance equations, as follows.

(*a*) If the base is an anion, the charge-balance equation is

$$(L^-) = \frac{\bar{G}_K^+}{\overline{H_2O}} + (H^+) - (OH^-) \qquad (21)$$

where (OH^-) is the activity of the hydroxide ions in the resin phase, calculated from the ionic product of water.

The mass-balance equation, which gives $\bar{C}_L$, the analytical concentration of the functional groups in the resin phase, is

$$\bar{C}_L = \frac{Q}{\overline{H_2O}} = (L^-) + (HL) \qquad (22)$$

where Q is the experimentally measurable capacity of the resin, mmole of functional group per g of dry resin, in uncharged (hydrogen) from.

With the help of the charge and mass-balance equations the mole fraction of the non-protonated base in the resin phase can be expressed as:

$$\bar{\alpha}^* = \frac{(L^-)}{\bar{C}_L} = \frac{\bar{G}_K^+}{Q} + \frac{(H^+) - (OH^-)}{\bar{C}_L} \qquad (23)$$

From equations (22) and (23):

$$1 - \bar{\alpha}^* = \frac{(HL)}{\bar{C}_L} \qquad (24)$$

and from equations (23) and (24) the sought-for ratio is

$$\frac{(HL)}{(L)} = \frac{1 - \bar{\alpha}^*}{\bar{\alpha}^*} \qquad (25)$$

(*b*) If the base is uncharged, then the charge and

mass-balance equations are

$$(HL^+) = \frac{\overline{G}_K^-}{\overline{H_2O}} + (OH^-) - (H^+) \quad (26)$$

$$\bar{C}_L = (L) + (HL^+) = \frac{Q}{\overline{H_2O}} \quad (27)$$

and the mole fraction of the non-protonated base is

$$\bar{\alpha}^* = \frac{(L)}{\bar{C}_L} = 1 - \frac{\overline{G}_K^-}{Q} + \frac{(H^+) - (OH^-)}{\bar{C}_L} \quad (28)$$

From equations (21)–(23) and (26)–(28) the logarithm of the protonation constant for single-step processes is

$$\log K = \overline{pH} + \log \frac{1 - \bar{\alpha}^*}{\bar{\alpha}} + \log \bar{K}_\gamma \quad (29)$$

For water-soluble monomers equation (29) reduces to equation (3), *i.e.*, the following identities exist:

$$pH = \overline{pH},$$
$$\bar{\alpha}^* = \alpha, \quad (I = \text{const.})$$
$$\bar{K}_\gamma = 1.$$

General equation for description of the protonation equilibria

For the derivation of a general equation the concepts defined by equations (17)–(19) will be used.

(*a*) Let the non-protonated base be an anion, $\overline{L}^{N-}$. The first step of protonation is

$$\overline{L}^{N-} + N\overline{G}^+ + H^+ = \overline{HL}^{(N-1)-} + (N-1)\overline{G}^+ + G^+$$

and the protonation constant

$$K'_1 = \frac{K_1}{\bar{K}_{1\gamma}} = \frac{(HL)a_{G^+}}{(L)a_H(G^+)} = \frac{(HL)}{(L)(H^+)}$$

For the second and further steps of protonation we obtain

$$K'_2 = \frac{(H_2L)}{(HL)(H^+)},$$
$$\vdots \qquad \vdots$$
$$K'_j = \frac{(H_jL)}{(H_{j-1}L)(H^+)}, \quad (j = 1, 2 \ldots N)$$

According to the principles of electroneutrality:

$$\frac{\overline{G}_K^+}{\overline{H_2O}} + (H^+) - (OH^-) = N(L^{N-}) + (N-1)(HL^{(N-1)}) + \ldots (N-j)(H_jL^{(N-j)-}) + \ldots = (L)\sum_{j=0}^{N}(N-j)\beta'_j(H^+)^j \quad (30)$$

where β'_j is the overall protonation constant:

$$\beta'_j = K'_1K'_2 \ldots K'_j$$

and, from equation (19),

$$(H^+) = a_H \frac{(G^+)}{a_{G^+}}$$

According to the mass-balance equation:

$$\bar{C}_L = \frac{Q}{\overline{H_2O}} = (L) + (HL) + \ldots + (H_NL) = (L)\sum_{j=0}^{N}\beta'_j(H^+)^j \quad (31)$$

From equations (30) and (31):

$$\bar{\alpha}^* = \frac{\overline{G}_K^+}{\overline{H_2O}} + \frac{(H^+) - (OH^-)}{\bar{C}_L} = \frac{\sum_{j=0}^{N}(N-j)\beta'_j(H^+)^j}{\sum_{j=0}^{N}\beta'_j(H^+)^j} \quad (32)$$

(*b*) If the base is not negatively charged, then again using the charge and mass-balance equations, for $(N - \bar{\alpha}^*)$ we obtain:

$$(N - \bar{\alpha}^*) = \frac{\overline{G}_K^-}{Q} - \frac{(H^+) - (OH^-)}{\bar{C}_L} = \frac{\sum_{j=0}^{N} j\beta'_j(H^+)^j}{\sum_{j=0}^{N}\beta'_j(H^+)^j} \quad (33)$$

where

$$(H^+) = a_H \frac{a_{G^-}}{(G^-)}$$

After rearrangement of (32) or (33) the general equation describing the protonation equilibria can be written as:

$$\sum_{j=0}^{N}(\bar{\alpha}^* - N + j)\beta'_j(H^+)^j = 0 \quad (34)$$

This equation applies when the fully protonated base is an N-basic acid and is titrated with a strong base.

For water-soluble monomers, equation (34) reduces to the Schwarzenbach relationship, equation (1). In this case the following identities exist:

$$(H^+) = a_H$$
$$\bar{\alpha}^* = \alpha^* \quad (I = \text{const.})$$
$$\bar{K}_\gamma = 1.$$

We reported earlier the preparation of chelating resins containing various polyethylene–polyamino

and polyethylene–polyamino–polycarboxylic acid functional groups.[6] Equation (34) has been used to calculate the protonation constants of such chelating resins.[7] In the next paper[8] further applications of the general equation will be shown.

STUDIES ON CHELATING RESINS—II

DETERMINATION OF THE PROTONATION CONSTANTS OF A CHELATING RESIN CONTAINING IMINODIACETIC ACID GROUPS

Ö. SZABADKA

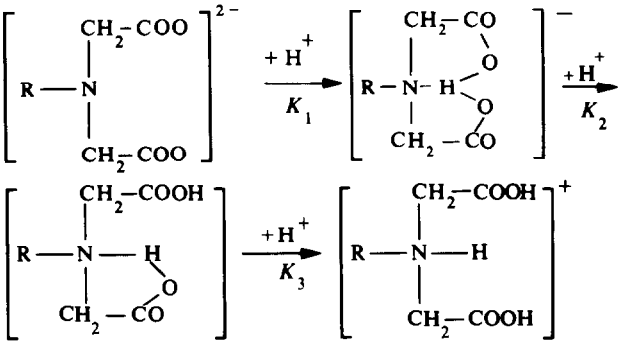
Department of Analytical Chemistry, University of Chemical Engineering, P.O. Box 28, Veszprém, Hungary

(*Received* 21 *January* 1981, *Revised* 25 *May* 1981. *Accepted* 16 *August* 1981)

Summary—A previously derived equation for the calculation of the protonation constants of immobilized ligands is used for description of the protonation equilibria of a chelating resin containing iminodiacetic acid groups. The following values were obtained for the three steps of protonation: $\log K_1 = 9.12 \pm 0.05$; $\log K_2 = 3.10 \pm 0.07$; $\log K_3 = 1.44 \pm 0.03$.

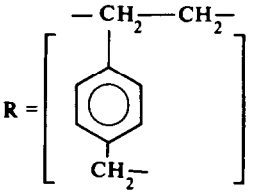
Chelating resins containing iminodiacetate groups are commercially produced in various purities by several firms under various trade names (Dowex A-1; Bio-Rad Chelex 100; Permutit S 1005). These products are widely used for the enrichment and separation of traces of heavy metals.[1,2] Few papers have been published, however, that deal with the quantitative description of the protonation equilibria.

The iminodiacetate base can be protonated in three steps according to the following scheme:



neutral, zwitterion form

where



is the resin matrix, and K_1, K_2, K_3 are the protonation constants.

Krasner and Marinsky[3] used the following equation for calculation of the second protonation constant, K_2, of the active group of Dowex A-1:

$$\log K_2 = \mathrm{pH} + \log \frac{1-\alpha}{\alpha} + \log \frac{a_M}{\bar{a}_M} + \Delta \log K \quad (1)$$

where K_2 is the thermodynamic protonation constant, pH is the equilibrium pH of the solution corresponding to a given degree of titration, α, a_M and $\bar{a}_M$ are the activities of the counter-ions in the solution and in the resin phases respectively, and $\Delta \log K$ represents a contribution originating from the difference in free energy between the negatively charged fixed base and its water-soluble analogue.

The last term was estimated according to Katchalsky's polyelectrolyte model.[4] The polyelectrolyte model can, however, be used for the description of the protonation equilibria of polyacidic bases having only one negative charge. Consequently equation (1) cannot be applied for the description of equilibria involving more than one step.

The first two protonation constants of the ligand of Dowex A-1 were calculated by Leyden and Underwood[5] by use of equation (2):

$$\log K_a = \mathrm{pH} + \log \frac{1-\alpha}{\alpha} + \log [\mathrm{Na}^+] - \log \alpha Q \quad (2)$$

Where Q is the capacity of the resin (mmole/cm^3), and [Na^+] is the concentration of the counter-ions in the solution.

The calculated values of the apparent protonation constants, K_{a1} and K_{a2} varied continuously with the degree of dissociation.

It is worthwhile emphasizing here that both the equations above and others in the literature were used mostly for the description of the protonation of bases carrying a single negative charge.

In the preceding paper[6] the following equation was derived for the description of the protonation equilibria of an N-acidic base;

$$\sum_{j=0}^{N} (\bar{\alpha}^* - N + j)\beta'_j(H^+)^j = 0 \qquad (3)$$

In equation (3) three terms need detailed explanation: (H^+), $\bar{\alpha}^*$ and β'_j. Their interpretation is given below.

The calculated proton activity in the resin phase, (H^+), can be calculated by equation (4):

$$(H^+) = [H^+]\left(\frac{(G)}{a_G}\right)^{\pm 1} \qquad (4)$$

where $[H^+]$ and a_G are the activities of the proton and the counter-ions in the solution phase, (G) is the concentration of the counter-ions in the imbibed water of the resin phase, (in mmole/g):

$$(G) = \frac{\bar{G}_K + \bar{G}_I}{\overline{H_2O}} \qquad (5)$$

$\bar{G}_K$ being the amount of chemically bound counter-ions, in mmole per g of resin, $\bar{G}_I$ is the amount of the electrolyte invading the resin phase from the solution, (mmole per g of resin), and $\overline{H_2O}$ is the water content (g) per g of resin.

The sign of the exponent in equation (4) corresponds to the sign of the charge of the counter-ion.

The real degree of titration in the resin, $\bar{\alpha}^*$, can be calculated from the amount of the chemically bound counter-ions, $\bar{G}_K$, and the capacity of the resin, Q, with allowance for the autodissociation of the water. The definition of this term depends on the type of the base to be protonated. The following three cases can be distinguished.

I. For the protonation of an anionic base (*e.g.*, a polycarboxylate anion: $\bar{L}^{k-} \xrightarrow{kH^+} \overline{LH_k}$), $\bar{\alpha}^*$ is defined as:

$$\bar{\alpha}^* = \frac{\bar{G}_K^+}{Q} + \frac{(H^+) - (OH^-)}{Q/\overline{H_2O}} \qquad (6)$$

II. For the protonation of a neutral base (*e.g.*, a polyamine: $\bar{L} \xrightarrow{lH^+} \overline{LH}^{l+}$), $\bar{\alpha}^*$ is:

$$\bar{\alpha}^* = l - \frac{\bar{G}_K^-}{Q} + \frac{(H^+) - (OH^-)}{Q/\overline{H_2O}} \qquad (7)$$

where l is the number of positive charges when the neutral base is fully protonated.

III. If the fixed ligand is an amphoteric group (*e.g.*, a polyaminopolycarboxylate: $\bar{L}^{k-} \xrightarrow{NH^+} \overline{LH}_N^{l+}$, $N = k + l$):

$$\bar{\alpha}^* = l + \frac{\bar{G}_K^+ - \bar{G}_K^-}{Q} + \frac{(H^+) - (OH^-)}{Q/\overline{H_2O}} \qquad (8)$$

In equations (6)–(8) Q always denotes the capacity of the resin in mmole/g, when the active group is in neutral form, which implies that in case I the ligand is in fully protonated form, in case II the ligand is in unprotonated form, and in case III the ligand is in zwitterion form.

Case III implies, in fact, case I and case II, so equation (8) is reduced to equation (6) in case I when $l = 0$, $N = k$, $\bar{G}_K^- = 0$ and to equation (7) in case II when $k = O$, $N = l$ and $\bar{G}_K^- = 0$.

The overall protonation constant, β'_j, at the ionic strength existing in the resin phase, is given by

$$\beta'_j = \Pi K'_j \qquad (9)$$

$$K'_j = \frac{(H_jL)}{(H_{j-1}L)(H^+)} \qquad (10)$$

From the K'-values the thermodynamic protonation constants, the K-values, can be calculated as follows:

$$K = K'\bar{K}_\gamma \qquad (11)$$

where $\bar{K}_\gamma$ is a term which contains the activity coefficients of the reaction partners in the resin phase:

$$\bar{K}_\gamma = \frac{\bar{\gamma}_{LH}}{\bar{\gamma}_L(\bar{\gamma}_G)^{\pm 1}} \qquad (12)$$

$\bar{\gamma}_{HL}$, $\bar{\gamma}_L$ and $\bar{\gamma}_G$ being the activity coefficients of the conjugated acid, $\overline{HL}$, of the base, $\bar{L}$, and of the counter-ions, G, in the resin phase. For the sign of the exponent the same applies as for equation (4).

EXPERIMENTAL

The chelating resin studied is commercially available from the firm Reanal (Budapest, Hungary) under the trade name Ligandex-I. In this resin the iminodiacetate active groups are covalently bound to the lightly cross-linked (2%) polymer framework. The sample (obtained in sodium form) was converted into the neutral zwitterion form by the procedure described earlier.[7]

The water content of the air-dry resin was determined from the weight loss on drying at 105° in an argon atmosphere. For the equilibrium study of the deprotonation and protonation of the zwitterion form of the active group, the static batch method was used. Known masses of the resin samples (~0.5 g) were weighed into 100-ml glass-stoppered flasks. The ionic strength was made 1.0 with potassium chloride.

To investigate the deprotonation, increasing amounts (0–50 ml) of 0.100M potassium hydroxide were added to the samples. The ionic strength and the 100-ml final volume

were adjusted by the addition of the calculated quantity of water and 2.0*M* potassium chloride.

For study of the protonation the procedure was identical, except that the potassium hydroxide was replaced by 1.00*M* hydrochloric acid.

The systems were left to equilibrate for 7 days at 25°. The pH of the solution phase was measured with a calibrated glass electrode. During preparation of the equilibrium systems and the pH measurement a protective argon atmosphere was used.

Determination of the water content of the resin phase

After the pH measurement the resin phase was separated from the solution by centrifuging and dried to constant weight at 105° under an argon atmosphere. The water content was calculated with reference to 1 g of the neutral dry resin.

Determination of the amount of counter-ions in the resin phase

The counter-ions are the ions of the potassium chloride used for adjustment of the ionic strength. In the first two protonation steps, when the base is anionic, the counter-ion is potassium. In the third step, when the active group is positively charged the counter-ion is chloride.

After the determination of the water content of the resin, the counter-ions originating from electrolyte invasion as well as from the chemical reaction were determined simultaneously as follows.

1. In the deprotonation experiments, the potassium ions were eluted from the resin with a known amount of 0.1*M* nitric acid and collected in a standard flask. The resin was washed free of chloride with water and the solution made up to the mark. The amount of chemically bound potassium ions was obtained by titration of the acid left in the solution, and that of the invasive potassium chloride from a Mohr chloride determination.
2. In the protonation experiments the chloride counter-ions were eluted with water into a standard flask. The amount of the chemically bound counter-ions was calculated from the results of titration of the acid, and the sum of the invasive and chemically bound chloride was obtained from the chloride content of aliquots.

The amounts (mmole) of the chemically bound and invasive counter-ions were calculated per g of dry neutral (zwitterion form) resin.

Determination of the capacity

To obtain the capacity, Q, the amount of chemically bound counter-ions was plotted against the pH of the equilibrium solution. In Fig. 1 the positive ordinate shows the amount of chemically bound potassium ions and the negative ordinate values refer to that of the chloride ions.

The active group takes up three protons in the reaction and three well-defined steps can be identified. The turnover of the potassium and chloride ions during the protonation can be estimated by drawing horizontal lines through the inflection points. In accordance with expectation the three steps in the curve are equally spaced and all give the capacity of the resin as Q = 3.0 mmole of active group per g of neutral, zwitterion form resin.

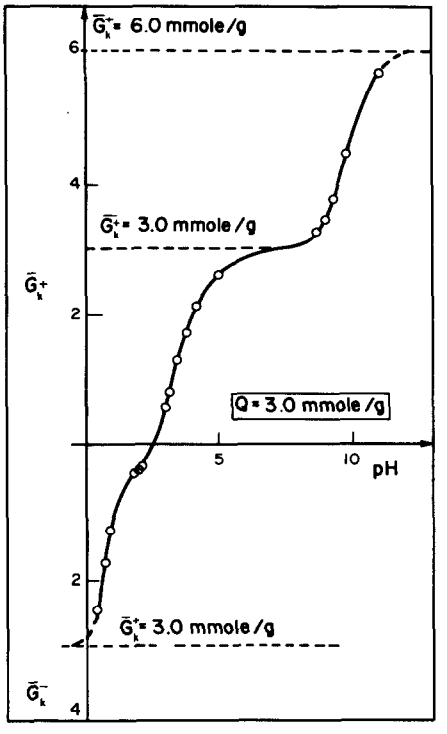


Fig. 1. The variation of the chemically bound counter-ions ($\bar{G}_K^+$ = potassium and $\bar{G}_K^-$ = chloride) as a function of the pH of the equilibrium solution. From the three horizontal inflexion lines, the capacity of the resin is Q = 3.0 mmole/g.

RESULTS AND DISCUSSION

The experimental data and some of the calculated results are given in Table 1. In the experiments 1–6 the counter-ion is chloride and in experiments 7–18 it is potassium.

Column 6 gives the molality of the counter-ions, (G), calculated from equation (5). The pH of the resin phase, $\overline{pH}$, was obtained through equation (4). The exponent is -1 in experiments 1–6 and $+1$ in experiments 7–18. Column 8 gives the real degree of titration calculated by equation (8). The last column gives the log K'-values calculated by equation (14) from each of the experiments.

In Fig. 2, the measured pH of the solution and the calculated $\overline{pH}$ of the resin are plotted against the real degree of titration, $\bar{\alpha}^*$.

When the counter-ions are positive the pH *vs.* $\bar{\alpha}^*$ curve runs above the $\overline{pH}$ *vs.* $\bar{\alpha}^*$ curve and for negative counter-ions their position is reversed. The curves intersect at the isoelectric point of the active groups, where $\bar{\alpha}^* = 1$.

As already shown, the two equations $(H^+) = [H^+]\,(G^+)/a_{G^+}$ and $(H^+) = [H^+]a_{G^-}/(G^-)$ are used for the calculation of the hydrogen-ion activity of the resin phase, for positive and negative counter-ions respectively. At the isoelectric point, of course, both equations yield the same value and give.

$$\bar{a}_{G^+}\bar{a}_{G^-} = a_{G^+}a_{G^-}$$

which is, in fact, the Donnan equation.

At the isoelectric point there is no chemically bound counter-ion in the resin phase, and the only counter-ions present are those which have migrated from the solution phase by invasion of the electrolyte (the potassium chloride). It is to be expected, there-

fore, that at this point the ionic strengths in the two equilibrium phases are equal:

$$\bar{I} = I$$

This conclusion is corroborated by Fig. 3, where the molality of the invasive electrolyte (the $\bar{G}_I/\overline{H_2O}$ ratio) is plotted against the amount of the chemically bound counter-ions (column 4 in Table 1).

With increasing amount of either chemically bound counter-ion the concentration of invasive electrolyte decreases. If the curves are extrapolated to the point where $\overline{G_K^+} = \overline{G_K^-} = 0$, then a common intercept is obtained at $(G_I) = 1.04$, which agrees with the ionic strength of the external solution. This result is also in agreement with the concept of the resin phase as a concentrated electrolyte. This concept was used at the outset of the derivation of the general equation given in Part I.[6]

Figure 4 shows the change of the water content, $\overline{H_2O}$, as a function of $\overline{pH}$ of the resin phase. From a

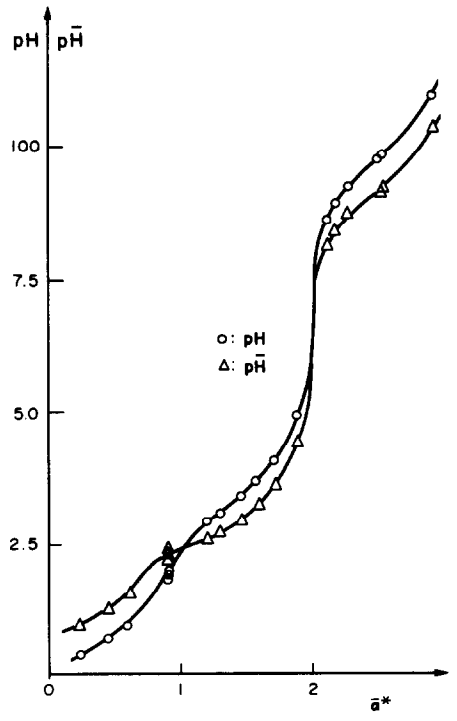

Fig. 2. Titration curves of the immobilized iminodiacetate base. ○: pH of the equilibrium solution as a function of the real degree of titration of the resin, $\bar{\alpha}^*$; △: $\overline{pH}$ of the resin phase as a function of the real degree of titration of the resin, $\bar{\alpha}^*$; [$\overline{pH} = pH \pm \log a_G/(G)$].

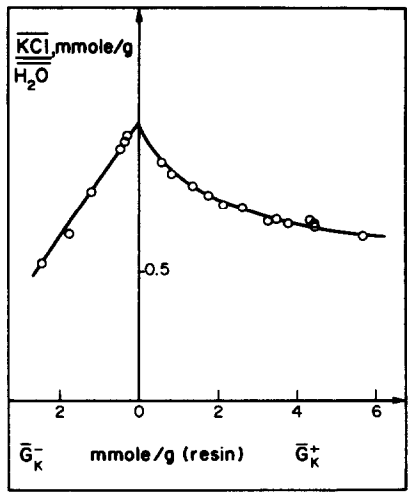

Fig. 3. The change of the invasive potassium chloride molality in the resin phase as a function of the quantity of chemically bound counter-ions; at the isoelectric point (where $\bar{G}_K^- = \bar{G}_K^+ = 0$), $\bar{I} = I$.

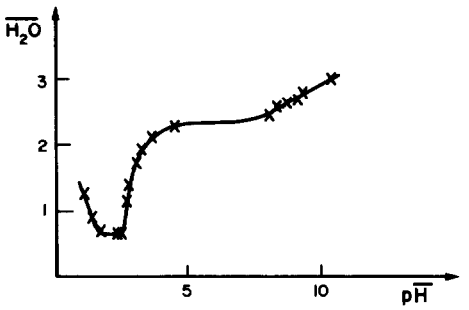

Fig. 4. Change of the water uptake of the resin, H_2O, as a function of $\overline{pH}$.

comparison of this figure with Fig. 2 it appears that the water uptake occurs in the same ranges of $\overline{pH}$ as the resin binds counter-ions chemically. This phenomenon can more directly be followed if the change of the water content is plotted as a function of the amount of the chemically bound counter-ions, as in Fig. 5.

Determination of the protonation constants

For the calculation of the log K'-values, equation (3) was applied with the corresponding data of the $\overline{pH}$ *vs.* $\bar{\alpha}^*$ function.

The summation for j in equation (3) goes from 0 to 3:

$$\bar{\alpha}^* - 3 + (\bar{\alpha}^* - 2)\beta'_1(H^+) + (\bar{\alpha}^* - 1)\beta'_2(H^+)^2 + \bar{\alpha}^*\beta'_3(H^+)^3 = 0 \qquad (13)$$

and for log K' the following values were obtained:

$$\log K'_1 = 9.12 \pm 0.05$$

$$\log K'_2 = 3.10 \pm 0.07$$

$$\log K'_3 = 1.44 \pm 0.03$$

As can be seen from Figs. 1 and 2, the consecutive steps of protonation are well separated and can be considered as individual steps, for which equation (3) takes the following simpler form:

$$\log K'_j = \overline{pH} + \log \frac{4 - \bar{\alpha}^* - j}{\bar{\alpha}^* - 3 + j} \quad (j = 1,2,3) \qquad (14)$$

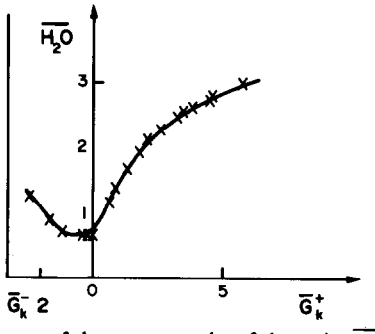

Fig. 5. Change of the water uptake of the resin, $\overline{H_2O}$, as a function of the quantity of chemically bound counter-ions.

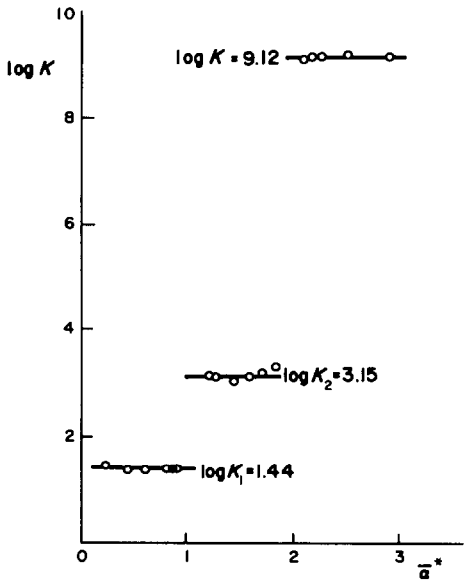

Fig. 6. Variation of the calculated log K'_j-values as a function of the real degree of titration, $\bar{\alpha}^*$.

From the corresponding $\overline{pH}$ *vs.* $\bar{\alpha}^*$ data (columns 7 and 8 in Table 1) a series of protonation constants can be calculated with equation (14) for all the three ranges of protonation (for experiments 1–6, $j = 3$; for experiments 7–12, $j = 2$; for experiments 13–18, $j = 1$). These log K'_j-values are given in column 9 of the table and are plotted as a function of $\bar{\alpha}^*$ in Fig. 6.

As can be seen from Fig. 6, the log K'_j-values are independent of the real degree of titration. The interpretation and possible extension of these results to other systems needs further consideration, however.

Acknowledgements—I should like to express my sincere gratitude and appreciation to Professor J. Inczédy who introduced me to the field of equilibrium studies. His stimulating ideas and discussions during the course of this research are gratefully acknowledged. I am indebted to A. Marton and E. Varga, with whom I had many interesting discussions during the derivation of the equation and interpretation of results, and I would like to express my extra appreciation to E. Varga for persistent help with the experimental work.

THE TOTAL EMULATION OF THE INTEL 8080 INSTRUCTION SET ON A MAINFRAME COMPUTER

D. J. LEGGETT

University of Houston Department of Chemistry, Houston, Texas 77004, U.S.A.

(*Received* 27 *April* 1981. *Revised* 8 *June* 1981. *Accepted* 8 *August* 1981)

Summary—A software system, ASSIM-8080, has been developed to permit the writing and debugging of Intel 8080 assembly-language programs with the aid of mainframe computers. ASSIM-8080 will assemble, with error checking and error diagnostics, an assembly-language program. If no errors are found in the source code, ASSIM-8080 will then simulate the execution of the assembly program. ASSIM-8080 will recognize a number of special instruction codes designed to simplify programming and debugging.

Microcomputers are becoming commonplace in the laboratory; they undertake automated control of equipment, data adjustment, report preparation and sometimes lengthy data-processing. Buchanan and Buchanan[1] have recently described a flexible and versatile microcomputer system as an aid in the development of microcomputer-controlled analytical instrumentation. Control programs for this type of instrumentation may be written directly in machine language, in assembly language, or in a high-level language. Machine-language programming is tedious, error-prone and difficult to debug. Programming with a high-level language, such as FORTRAN or PL/M, speeds software development but may lead to control programs of excessive length. Assembly-language programming, whilst it may be time-consuming, can lead to the most efficiently coded program for the specific task in hand.

A program written in assembly language still requires to be converted into machine language and debugged before being loaded permanently into the microcomputer's read-only-memory. The software system reported here is designed to permit the development and testing of assembly-language programs for the Intel 8080 microprocessor. The system, known as ASSIM-8080, is written in FORTRAN and will run on any mainframe computer. The assembly-language source program is input as data to ASSIM-8080. The output from ASSIM-8080 includes the source-code listing and descriptive error messages generated by programming faults detected in the source code. If the source code is error-free, machine-language code is generated and this is then used by ASSIM-8080 to simulate the performance of an Intel 8080 microprocessor, including data I/O. ASSIM-8080 will, if requested, display the contents of all registers after an instruction has been executed. A range of additional commands is available to simplify the task of debugging the source code. Besides providing a useful software tool for writing control programs for existing hardware, ASSIM-8080 is also suitable for use as a vehicle for teaching assembly-language programming of Intel microcomputers.

SYSTEM DESCRIPTION

ASSIM-8080 consists of four main parts. A short main program is used to define the hardware limitations of the target microcomputer. These include the size of random access memory (RAM), the size of read-only-memory (ROM), internal clock frequency and maximum run time for the simulation step. The sizes of a number of internal working tables are also established in the main program.

Once these parameters have been set, control passes to the major subroutine SIMUL8. This routine is responsible for internal initialization, the printing of diagnostic information and the control of the assembly and simulation steps, undertaken by the major routines ASEMBL and XEQTER. ASSIM-8080 has been written so that it may be used with minicomputers having a limited memory, if some minor changes are made. In this situation ASSIM-8080 would be reconfigured into two programs. The first would assemble the source code and the second would simulate the source code by using the machine language generated by the first program.

The features and capabilities of ASSIM-8080 will be discussed in the order in which ASSIM-8080 processes the source code. Details concerning the use of ASSIM-8080 are discussed in detail in the User's Manual. It is assumed that the reader is familiar with the function and meaning of the 78 instruction mnemonics used by the Intel 8080 microprocessor. The complete definition of these mnemonics may be found in an Intel publication.[2] An introductory text that explains each mnemonic with admirable clarity has been written by Leventhal.[3]

ASSEMBLY OF SOURCE CODE

Assembly of the source code is achieved by the subroutine ASEMBL. This routine examines each line

of source code to ensure that none of the Intel instruction-code rules have been violated. If an error is detected, an error message is issued and the next source line is examined. Some errors will cause compilation to cease and ASSIM-8080 will terminate at that point.

The operation of ASEMBL can be broken down into six steps. A flow chart of the process is shown in Fig. 1.

Step 1. Each line of source code is read in as a continuous string of 80 alphanumeric characters. Subroutine INPUT subdivides this string into four parts; label (characters 1–10), mnemonic (characters 11–15), operand (characters 16–25), and comment (characters 26–80).

Step 2. Once the label, mnemonic, operand and comment have been identified, each is checked for contextural legality. The mnemonic is first examined to determine whether it is an assembler or simulator directive, or a conventional instruction code. Assembler and simulator directives will be discussed in a later section. Assembler directives are examined by subroutine PSEUDO. Assembler directives and conventional instruction codes are processed by subroutine MNEMON. Macro definitions are catalogued within ASEMBL for subsequent expansion.

Step 3. The mnemonic field is checked by subroutine MNEMON. Besides the 78 Intel instruction codes, 12 simulator directives are also examined for legality by MNEMON. Simulator directives are recognized by ASSIM-8080 from their having a dollar sign ($) as the first character. The mnemonics are: $ASC; $BPN; $BPY; $DPN; $DYP; $HPN; $HPY; $MEM; $PRF; $RAM; $ROM; $STM.

Step 4. If no error has been found by subroutine MNEMON the operand field is checked by subroutine OPCHCK. The information required to be present in the operand depends upon the particular mnemonic. One of five types of data is required: (*a*) a register, (*b*) a register pair, (*c*) immediate data, (*d*) a 16-bit address, (*e*) no data. The information for (*a*)–(*d*) can be expressed as: (*i*) hexadecimal data; (*ii*) decimal data; (*iii*) octal data; (*iv*) binary data; (*v*) ASCII characters; (*vi*) a label that has been previously assigned a numeric value; (*vii*) a label to be interpreted as an address. It is the objective of OPCHCK to ensure that the operand and mnemonic are compatible. An error message will be issued if an incompatibility is found.

Step 5. Subroutine LABCHK is used to ensure that a label, if present, is used correctly. If the legal label is found it is added to the label table. The label table is used in the final step of the assembly process.

Step 6. At this point in the assembly step the line of source code is printed out together with a line number and the starting location of the hexadecimal object code associated with that line of source code. ASSIM-8080 then commences to process the next line of source code, starting at Step 1.

When the end of the source code is found, any error messages accumulated during the compilation of the source code are printed. The label, equate, and precision tables are printed out. These tables associate labels with memory locations, variable names with numeric values, and give the number of bytes for each variable, respectively. If requested by use of the appropriate assembler directive, the label and/or mnemonic cross-reference tables are also printed out. If no errors have been found, the assembled hexadecimal object code, with associated line numbers, is printed.

ASSIM-8080 is a one-and-a-half-pass assembler. This is achieved as follows. If a jump command is encountered before the destination label has been

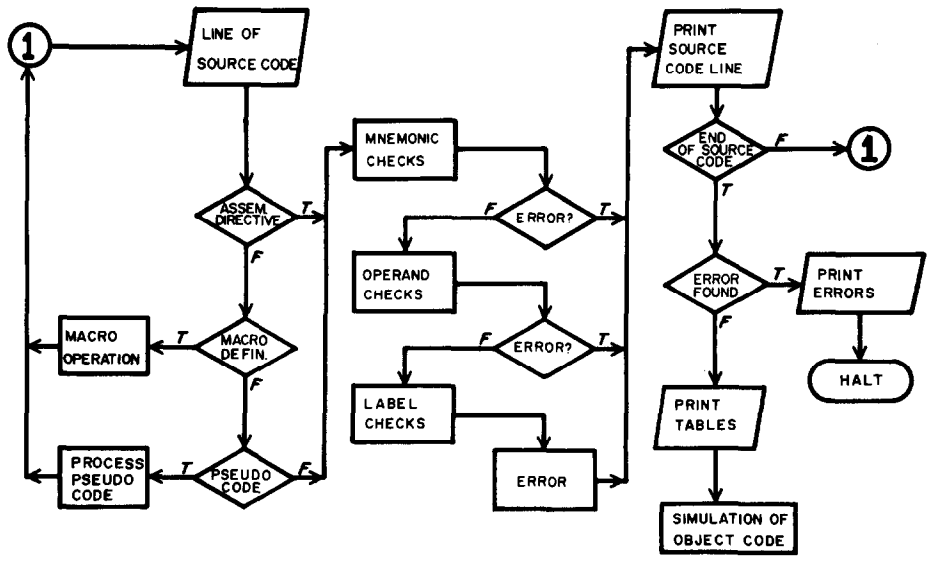

Fig. 1. Flow chart for subroutine ASEMBL, illustrating the basic steps involved in source-code error-checking.

assigned to a memory location, then that line of source code cannot be assembled immediately. A similar situation will occur for calls to subroutines. In this event a condensed version of the label, taken from the operand field, is placed in the object code. The label table contains, at the end of the assembly step, a list of the condensed label names found and their associated memory locations. The completed object code is then examined, byte by byte, for the presence of a special marker signifying that the condensed label was used rather than the absolute memory location. If the marker is found the label table is scanned for the presence of the condensed label. The associated memory location replaces the label name in the object code. This final clean-up of the object code takes less than 0.05% of the total time required.

ASSEMBLER AND SIMULATOR DIRECTIVES

Assembler and simulator directives are recognized by ASSIM-8080 but not by the Intel 8080 microprocessor. These codes have been added to the instruction set to provide the programmer with debugging aids. Assembler directives do not produce any object code. Simulator directives produce, in most instances, a two-character object code, the first character being "$".

Assembler directives

There are 17 assembler directives that are recognized by ASSIM-8080. They will be discussed as related groups.

1. *The group EQU, DB, DW, DS, ORG.* The purpose of this group of assembler directives is to equate variable names with numeric values, EQU; to place one byte, DB, or two bytes, DW, into RAM; to reserve a number of bytes of RAM and label that space with a variable name, DS; to set the start of the program in ROM or to reset the program counter, ORG. The first four codes are interrelated, and detailed explanations of their function and usage are presented in the ASSIM-8080 User's Manual. ORG must appear at least once in the source code to establish the program origin. It may also be used more than once, for example, to subdivide the first 64 ROM locations into 8-byte segments in preparation for the use of the Intel RST instruction.[4]

2. *The group FRLB, FRMN, LNLB, LNMN.* This group of codes provides cross-referencing capabilities. FRLB and FRMN give a list of the number of times each label (FRLB) has appeared in the label and operand fields, and the number of times each mnemonic (FRMN) has been used in the source code. LNLB and LNMN give the line number where a label of mnemonic, respectively, has occurred in the source code. These two assembler directives will provide this information only for a specified list of labels or mnemonics that are part of the source code. FRLB and FRMN give frequencies for all labels and mnemonics.

3. *The group MAC, ENDM.* The directive MAC, in the mnemonic field, signifies that a short section of code, known as a macro, is to be defined. The name of the macro will appear in the label field of the MAC source line. Macros are usually defined at the beginning of the source code. Subsequently, when the name of the macro appears in the mnemonic field, ASSIM-8080 places, after that line, the previously defined macro. Error checks, as outlined in steps 1–6, are then performed as each line of the macro is expanded. The principal advantage of a macro is that it permits new instruction codes to be established by the programmer; these are then used according to the rules of their definition. However, the use of a macro rather than a subroutine must be carefully weighed, since a macro generates a number of lines of code each time it is expanded whereas a subroutine reuses the same section of code each time it is called. These points are discussed further in reference 2 (introduction to Chapter 5).

The code ENDM signifies the end of the macro definition.

4. *The group LIST, NLST, PNCH, END, COMP, EXEC.* These six codes are used to control various routine operations of ASSIM-8080. LIST and NLST control the listing, or not, of all or part of the source code. END is used to signify the physical end of the source code. PNCH will cause the object code to be punched onto computer cards or, if the mainframe computer has the capability, onto paper tape. COMP and EXEC are complementary. The former will cause only the assembly of the source code to be completed. The latter causes ASSIM-8080 to simulate the 8080 microprocessor, given preassembled object code. This particular feature is useful when checking code received from software vendors, or using ASSIM-8080 as two distinct programs.

Simulator directives

There are twelve simulator directives, which will be discussed in related groups. Each directive is converted into a two-character object byte that is recognized, during the simulation step, by ASSIM-8080. They are used, in the source code, as mnemonics.

1. *The group $BPN, $BPY, $DPN, $DPY, $HPN, $HPY.* These six codes turn on, or off, the printing of the contents of each of the Intel 8080 registers, program-status word and program counter. The general form of these directives is $*x*P*y*; where *x* is either B (register contents in base 2), D (register contents in base 10), or H (register contents in base 16), and *y* is either Y (start print-out) or N (stop print-out). It is therefore possible to monitor the effect of one or more source code statements on the registers, program-status word and program counter. The default for ASSIM-8080 is that no print-out is produced during the simulation step. Once a $*x*PY has been found, the register contents are printed after each execution step until $*x*PN is encountered.

2. *The group* $MEM, $RAM, $ROM, $STM. These four directives will display various portions of memory if data exist in the memory locations. The general form is $xyM where xy is ME for all memories, RA for RAM only, RO for ROM only, and ST for the stack section of RAM. These directives produce one memory dump for each occurrence. A starting memory location, for the dump, may be specified within the operand field for each of the directives. However, if the operand field is left blank, all filled locations for the particular memory will be printed out. Together with the ability to examine selectively the contents of each microprocessor register, these four directives permit the complete monitoring of each Intel instruction step for all or part of the simulation of the source code.

3. *The directive* $ASC. When ASCII character strings are to be read into, or printed from, RAM, the characters are stored as their hexadecimal equivalents. The $ASC directive permits, during debugging of source code, the direct use of ASCII characters. $ASC invokes a conversion, within ASSIM-8080, from the character into its hexadecimal equivalent. This directive is most useful when debugging code that employs the Intel IN and/or OUT codes. When the object code is loaded into the ROM of the target machine, conversions between ASCHII and the hexadecimal equivalent are performed by the I/O device.

4. *The directive* $PRF. This directive provides a histogram of the percentage of execution time devoted to each step in the source code. This option is particularly useful when the program has to be recoded in order to reduce execution time. The histogram will indicate those areas of code for which more efficient writing could result in a significant decrease of execution time.

SIMULATION OF SOURCE CODE

Provided that there are no syntax errors or violations of the Intel instruction-code rules, the object code generated by ASEMBL is passed to subroutine XEQTER, where the operation of the 8080 microprocessor is simulated. The object code is in hexadecimal format and may include the special object-code bytes generated by one or more of the twelve simulator directives. Subroutine XEQTER examines the first character of the current object-code byte and if this character is "$" then control passes to a special section designed to process the particular simulator directive. Otherwise the object byte is assumed to be a conventional instruction code.

XEQTER is composed of a number of short sections, each related to one specific mnemonic code. The instruction byte is interpreted in the following manner. The byte, in hexadecimal, is converted into its octal equivalent, OCT. The particular value of OCT is then used to direct control to the required part of XEQTER. Figure 2 shows the first step in this process. The 8080 instruction set can be subdivided

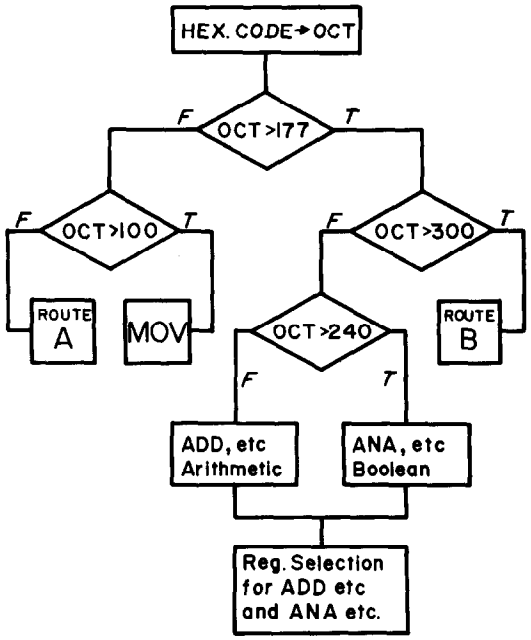

Fig. 2. Flow chart illustrating the basic algorithm for subroutine XEQTER.

into six groups. For example, if the octal equivalent of the object-code byte is between 100_8 and 177_8, then the instruction to be simulated is one of the 64 MOV instructions. Therefore, a value of OCT = 145_8 would direct control to the section of XEQTER designed to simulate MOV. It then remains to determine which two registers are involved in the particular MOV

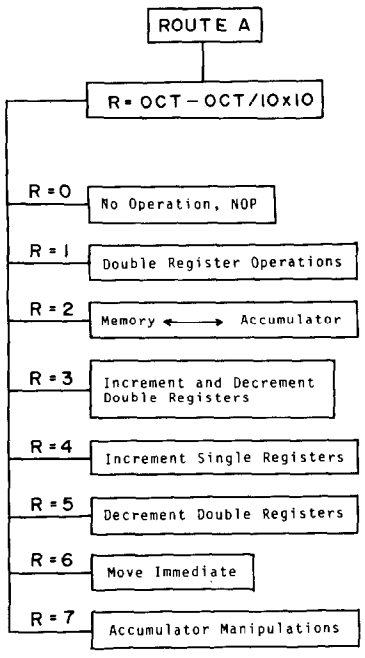

Fig. 3A. Flow chart illustrating the details of Route A (see Fig. 2).

instruction. In this particular example, since $1XX_8$ means MOV, then the second and third digits indicate which registers are involved. For OCT = 145_8 the mnemonic would have been MOV H, L. Figures 2 and 3 indicate the general method by which the value of OCT points to the simulation of the particular object-code byte.

Once the simulation of a particular instruction code has been completed, the contents of the registers are printed if $BPY, $DPY or $HPY has been set. The total number of machine cycles is updated and is used to limit the execution time of the simulation. This feature prevents the consumption of inordinate amounts of main frame computer time in the event that an endless loop is present in the source code.

OUTPUT DESCRIPTION

After this brief description of the various options of ASSM-8080 that are available to the user, it is instructive to examine a short program that has been processed by ASSIM-8080. Appendices I and II show a typical program and the output generated by ASSIM-8080. It can be seen, from Appendix I, that provided the label, mnemonic and operand are within the column constraints described earlier, there is no left-justify requirement. The source code contains a macro called WRTE. Macro construction and usage follows the normally accepted procedures.[2,3]

The output from ASSM-8080 is shown in Appendix II. Given below the header are the current constraints imposed by the target microcomputer and the maximum sizes of various key arrays within ASSM-8080.

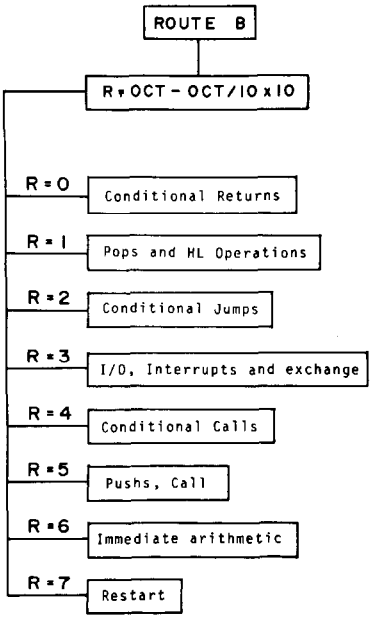

Fig. 3B. Flow chart illustrating the details of Route B (see Fig. 2).

Changes to these variables are made in the main program of ASSM-8080. Only the total available memory of the microcomputer and that portion which is ROM are specified in the main program. The actual allocations of total memory to ROM, RAM and the stack are left to the user. This is achieved through the appropriate use of the EQU assembler directive. In this example RAM starts at memory location 501_{10}, ROM starts at 16_{10} and the stack occupies the last 100 bytes of RAM. Note that the first three EQUate statements use the reserved identifiers RAMST, ROMST and STACK, respectively, to effect these memory allocations.

There follow five EQUate statements that define which particular I/O port will be used; the number of characters in the string PHRSE; and values for the multiplier and multiplicand that will be used in a simple 8-bit unsigned multiplication routine. Thirty-one bytes are reserved for the character string PHRSE, using the DS code. The character string is then defined, using the DB code. The two # signs are used by ASSM-8080 to terminate the line of output to the I/O simulator. When the character string is converted into ASCII hexadecimal codes the # signs are placed by 0D and 0A, the ASCII codes for "carriage return" and "line feed". (See RAM locations 530 and 531.) The origin for the source code is then established, using ORG. Irrespective of any other assembler directives that may be used, the first three and the last must be RAMST, ROMST, STACK EQUates and ORG, respectively. More than one origin may be established, a feature useful when dealing with restarts (RST) involved with interrupt-processing.[4]

The first line of executable code sets the stack pointer at the top of RAM, *i.e.*, location 2000_{10}. The next four lines of code indicate that the cumulative frequencies of all mnemonics (FRMN) and labels (FRLB) are to be noted; the current contents of RAM ($RAM) are to be displayed; and that a simulation time profile ($PRF) for each executable statement is needed. A listing of the macro is then provided, for reference purposes, followed, in this instance, by the actual macro calling statement. The argument list for the definition and the call need only be of the same word size. Changes in variable names are permitted.

Lines 4–11, inclusive, are the macro expansion that is assembled and simulated by ASSIM-8080. This particular example causes a character string of 31 characters to be displayed at a terminal. The macro name appears between the statement number and the ROM location counter as a reminder that this section of code is the result of a macro expansion. The assembler directive $ASC, at line 6, permits the display of the actual ASCII character during the simulation. Omission of $ASC results in the hexadecimal equivalents of each ASCII character being displayed in place of the string. It should be noted that the label PRT, in the macro definition, is renamed as PRT11 during expansion. Should WRTE be expanded a

second time the label would be renamed PRT12, thereby avoiding a repetion of the label in the same source code.

Comment statements are preceded, in the source code, by a semicolon, which is replaced by COMMENT if the complete line is a comment. However, if the comment is appended to an executable source statement the text is moved to beyond the end of the operand field.

Lines 12–27 are a straightforward 8-bit multiplication routine. In this particular example the multiplier uses register E (set to 50_{10}), the multiplicand uses register C (set to 120_{10}) and register B is the bit counter. The result is held in the double register D, E and ultimately stored in RAM location 601_{10} and 602_{10}.

The simulator directives $HPY, $DPY and $BPY, which permit the user to examine the contents of all registers in hexadecimal, decimal and binary formats, are found at lines 28, 29 and 30. Since 601D appears in the operand field of $RAM (line 33) this RAM dump starts at memory location 601_{10}.

Any errors detected during the assembly step are printed immediately following the source listing. Forty-nine messages are available that cover violations of the Intel instruction-set rules as well as improper use of assembler or simulator directives. The contents of the equate, label and precision tables are then printed, followed by a line-number-annotated object code listing. It should be noted that the simulator directives have been converted into the '$x' code. For example line 2 of the source code is $RAM which is converted into $80000. Once the source code has been completely debugged, all simulator directives must be removed and a clean object code generated before it is loaded into the target machine. The frequency table that follows the object code listing displays the number of times each mnemonic and label has appeared in the source code. A more detailed analysis of these occurrences is provided by the pseudo code LNMN and LNLB.

The simulation of the source code is now started and the contents of RAM, at line 2, are printed. Memory locations 501_{10}–531_{10} contain the hexadecimal equivalents of the ASCII string PHRSE. The string that will be printed at the terminal is displayed during the simulation, directly beneath the RAM dump. In this example the string would be output through port $2E_{16}$.

The current status of the 8080's CPU registers is then printed out in hexadecimal, decimal and binary format. The result of the multiplication, $66_{16} \times 32_{16}$, is found in RAM memory locations 601_{10} and 602_{10} and is seen to be $13EC_{16}$ ($= 5100_{10}$), as expected.

The termination of the simulation step is indicated, as shown, and followed by the execution time, in seconds, together with the number of statements executed during simulation. The execution time is calculated by assuming that the CPU is devoted entirely to the execution of the source code and therefore represents the minimum time needed for execution, at the selected clock frequency.

Since the directive $FRN was used at line 3 an execution time profile is given for the section from line 4 to the program end. As expected, most of the time is spent in writing data to the terminal.

A number of error conditions may arise during the simulation step. Notable among these are attempts to load "data" byte(s) into ROM, or access a memory location outside the available memory area. In these situations an error message is generated indicating the source-code line number where the error condition arose. Normally, although not always, simulation is terminated immediately if an error is detected.

The assembler and simulator directives used by ASSIM-8080, and their implementation, are described in detail in the user's manual.

ASSIM-8080 is written in ANSI-standard FORTRAN and has been developed and run on an IBM 370-158 and a Honeywell 66–60 computer. Memory requirements for arrays will depend upon the specific configuration of the target machine and user-declared sizes of tables.

Copies of ASSIM-8080 and the user's manual are available, on request, from the author.

TITFIT, A COMPREHENSIVE PROGRAM FOR NUMERICAL TREATMENT OF POTENTIOMETRIC DATA BY USING ANALYTICAL DERIVATIVES AND AUTOMATICALLY OPTIMIZED SUBROUTINES WITH THE NEWTON–GAUSS–MARQUARDT ALGORITHM

ANDREAS D. ZUBERBÜHLER and THOMAS A. KADEN
Institute of Inorganic Chemistry of the University, Spitalstr. 51,
CH-4056 Basel, Switzerland

(*Received* 12 *May* 1981. *Accepted* 31 *July* 1981)

Summary—TITFIT, a computer program written in HP-enhanced BASIC is able to fit potentiometric titration curves with up to 400 points by using the Newton–Gauss–Marquardt technique supplemented by the use of analytical derivatives. The program contains a part which writes an optimized subroutine as needed by the model. The program also has additional facilities such as visual interactive adjustment of parameters and a plotting subroutine for graphical presentation of the final results. Data can be entered either manually through the keyboard or automatically through an RS-232 serial interface. The performance of the program is discussed for the well studied Ni^{2+} glycine system; the results are similar to those already published in the literature.

Potentiometric titrations with a pH electrode have been widely used in the study of the stability of metal complexes with ligands having basic properties.[1] In order to obtain reliable results the collection of a large amount of data and a powerful program for the calculation are both necessary.

Data collection has been discussed in the literature and several automatic data-acquisition systems have been described.[2,3] These generally allow accumulation of the data necessary for a complete potentiometric analysis.

Several computer programs have been proposed for the evaluation of pH-titrations.[4] The use of computers in the calculation of equilibrium constants began with Sillén's LETAGROP program,[5] which is based on the "pit-mapping" technique. Later SCOGS[6] and MINIQUAD[7] appeared and are still the programs most used. SCOGS is based on the Newton–Gauss algorithm and minimizes the sum of squares of the titration-volume residuals by using the general subroutine COGSNR to calculate the concentrations of each species. MINIQUAD employs a different approach; the minimization is done on the sum of residuals of the three mass equations for total hydrogen, total metal, and total ligand. It is based on the Newton–Gauss or Newton–Raphson algorithm, together with linear optimization of the shifts.

In recent years, however, Marquardt's method,[8] which combines the steepest-descent and Newton–Gauss algorithms in a powerful way, has been introduced in DALSFEK[9] and in MARFIT.[3] The main advantage of this procedure is that it will converge to the minimum without good estimates of the initial parameters.

SCOGS, MINIQUAD and DALSFEK are programs designed for large computers, and they generally do not allow direct interaction[10] between the user and the program, which is especially important in view of the large amount of time usually needed to find the "best" model. MARFIT, on the other hand, is a smaller program written for a computer with limited memory. It allows direct interaction with the user, but it does not have all the other facilities of the large programs, for example, a new subroutine must be written for each model to be tested.

We have now written a new program which has all the facilities mentioned above. An innovation is the use of analytical derivatives combined with the Marquardt technique for finding the minimum. In addition an optimized subroutine is generated automatically by the program itself. The working of the program TITFIT will be illustrated by using data for the Ni^{2+}/glycine system which has been suggested as a test for titration and calculation methods.[11]

EXPERIMENTAL

Chemicals of analytical grade were used without further purification. Titrisol sodium hydroxide (Merck) was diluted with doubly distilled water to give a 0.4M solution. The temperature was kept constant at 25.0 ± 0.2° and the ionic strength at $\mu = 1M$ (NaCl).

The titrations were done with the automatic titrator unit described previously,[3] after calibration of the glass electrode with two buffers of pH 4 and 7. The activity coefficient γ for H^+ and the value of pK_w were determined from

Table 1. Experimental conditions for the titrations of glycine and Ni^{2+} at 25° and $\mu = 1M$ (NaCl)

c_L, M	c_M, M	c_L/c_M	Number of points n	pH range
7.0×10^{-3}	—	—	51	<11.3
1.4×10^{-2}	1.28×10^{-2}	0.914	51	<7.3
1.4×10^{-2}	6.4×10^{-3}	0.457	39	<9.9
1.4×10^{-2}	3.2×10^{-3}	0.228	36	<11.2
3.5×10^{-3}	3.2×10^{-3}	0.914	51	<8.3
3.5×10^{-3}	1.6×10^{-3}	0.457	41	<9.9
3.5×10^{-3}	8.0×10^{-4}	0.228	38	<10.8

titrations of hydrochloric acid under the same experimental conditions as for the complexation of nickel ions with glycine.

The pK_H-values of glycine were determined by titrating $7 \times 10^{-3}M$ glycine to which an excess of acid had been added. The titrations with nickel present were run at two total concentrations with different ratios of c_L/c_M (Table 1). Titrations were stopped when the pH started to drift because of incipient formation of $Ni(OH)_2$ and/or polymeric hydroxo-complexes. The maximum pH values which were used for the calculation are also given in Table 1.

The calculations were done with the aid of a Hewlett-Packard HP9835 computer equipped with a plotter (HP7225A), a serial input/output interface (HP98036A) and a Heathkit H14 printer connected through a second serial interface.

THE PROGRAM TITFIT

TITFIT is written in HP-enhanced BASIC and is a turn-key system for a Hewlett-Packard HP9835. After transcription into standard BASIC it could be run on any desk-top computer with at least 48 kbytes of memory. The program can perform eight different tasks which are shown in the flow diagram (Fig. 1).

The experimental data can be introduced either through the keyboard (task 7) or through an RS-232 serial interface (task 5) which is adapted to accept data from our data-acquisition system.[3] If other types of automatic data-collection are used, this part of the program (Subroutine Tr) must be changed. For both input modes, a new file is first created on tape and some control operations are done.

Manual input starts with an identification, then the user is asked whether the volume increment is variable, or constant, in which case only Δml need be entered. Then in a loop the values of pH and, if necessary, those of the titration volume (ml_{exp}) are typed in. The value 0 for pH indicates the end of the input.

Transfer of data through the RS-232 interface is done by setting the interface to 8-bit characters with two stop bits, no parity and 1/64 bit-rate factor. The 8-bit values are then transformed automatically into the values pH and ml_{exp}.

The dimension statement in the program is such that a total number of 400 titration points (points per curve times number of curves) can be used. For a single curve up to 100 points can be accepted.

After the titration points have been read in, the values of the constants (*e.g.*, total concentrations, known equilibrium constants) and those of the parameters (*e.g.*, unknown equilibrium constants) are entered. Constants and parameters are distinguished by an index (0 and 1, respectively) and the equilibrium constants also must have the indices m, l and h which define the species $M_mL_lH_h$.

Sometimes it is necessary to change the pH and ml_{exp} values (task 8) and to have a print-out before the data are recorded on tape. Of course the data on tape can also be retrieved (task 1).

The program can be used to plot a species distribution (task 6). To do this a set of equilibrium constants to define the model must be given, then TITFIT creates a specific subroutine (Subroutine Ohb) for calculation of the concentrations of the species, and links it to the main program. Then a further subroutine (Subroutine Plot) is called automatically to plot the species distribution (per cent *vs.* pH) over the pH range 2–12. Each species is identified by the use of a different plotting symbol and is only plotted when its concentration is >1%.

The model defined by the set of parameters can readily be changed (task 4) so that the user can see how a new model affects the species distribution.

Experimental data and calculated titration curves can be plotted to give a graphical display (task 3). The plotting subroutine does not need any special input; only the number of the curves selected for plotting in one figure need be entered. The establishment and labelling of the pH and ml_{exp} axes are done automatically. The titration points for each curve are characterized by a different symbol and the calculated curves are plotted. At the end a caption can be written on the figure. An example is shown in Fig. 2.

The main part of the program, however, is the fitting procedure (task 2). To fit the experimental points to a theoretical model given by the chosen set of complex species a subprogram must be generated to describe the model mathematically. This is done by the subroutine Wr, which writes a series of BASIC statements which together will give the subroutine Ohb. In contrast to other computer programs such as SCOGS,[6] MINIQUAD[7] and DALSFEK[9] which use general subroutines, or MARFIT[3] for which the oper-

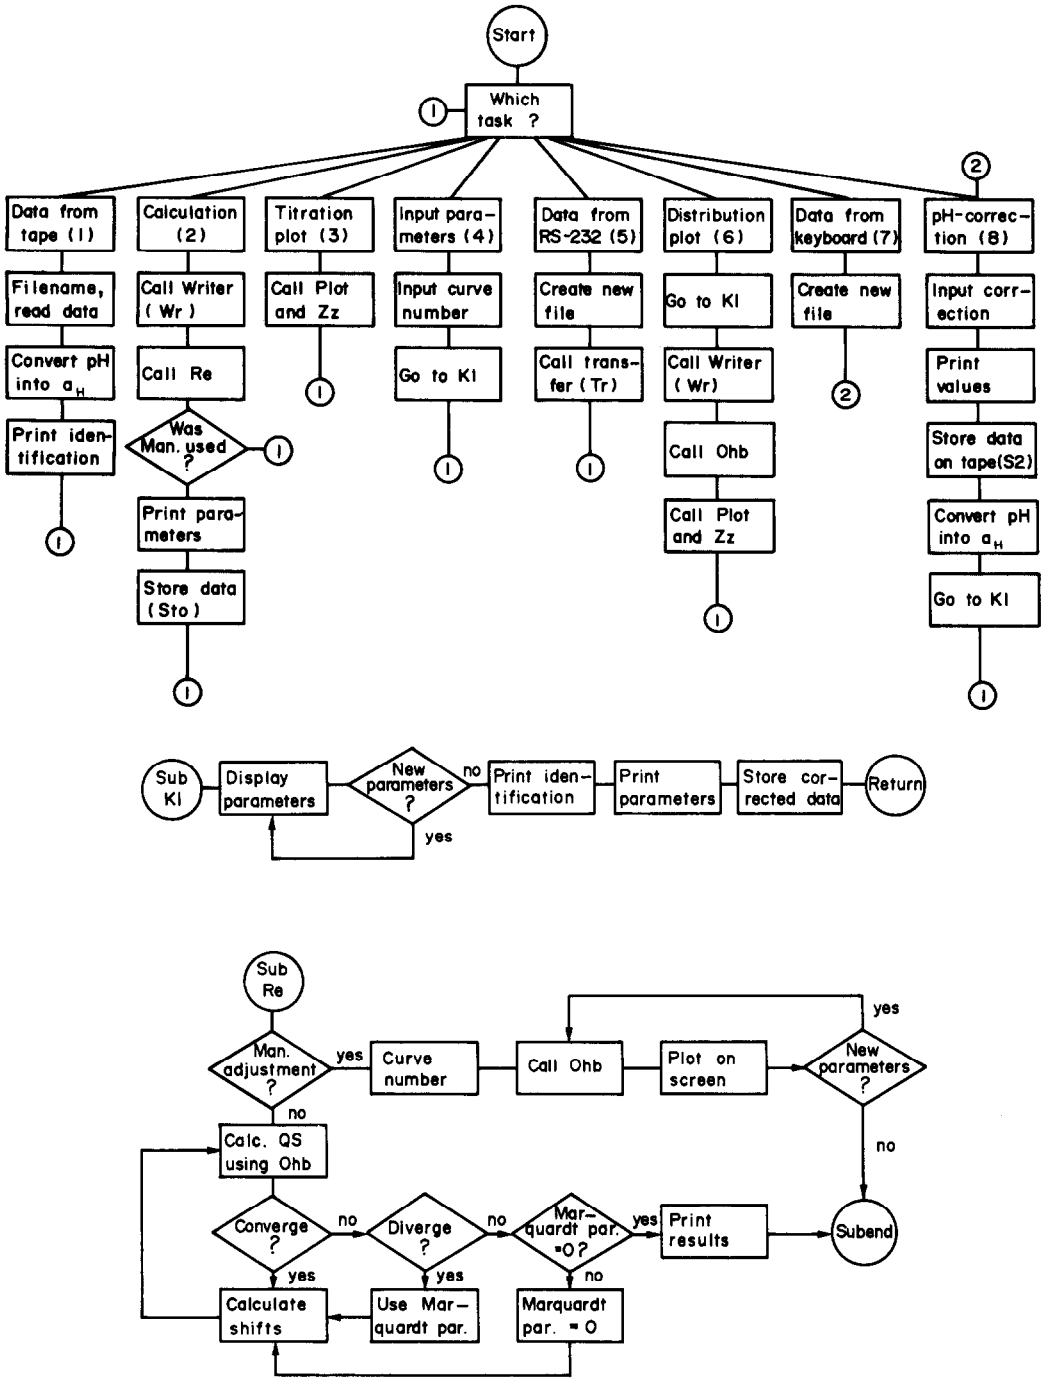

Fig. 1. Flow diagram for the program TITFIT.

ator has to write a new subroutine for each new model, subroutine Wr generates a specifically optimized subroutine for the model to be examined. The advantages are many; the user does not have to bother about the subroutine, the subroutine Ohb is much faster than a general one, and it also saves memory space, since all dimension statements are adapted to the need. All these aspects are important when a desk-top computer is used.

The subroutine Ohb first solves for the concentrations of free ligand L and free metal ion M, using a standard Newton–Raphson procedure.[14] Then the analytical derivatives $\partial \mathrm{ml}_{\mathrm{calc}}/\partial \log\ p_i$ $(i = 1, \ldots, I)$, where p_i are the I parameters to be determined, are calculated according to Nagypal *et al.*[12] In our experience use of $\partial \mathrm{ml}_{\mathrm{calc}}/\partial \log p_i$ instead of $\partial \mathrm{ml}_{\mathrm{calc}}/\partial p_i$ is more satisfactory by far since this automatically generates a Hessian[14] with diagonal elements of

roughly equal size. With the derivatives (elements of the Jacobian) the Hessian[14] (or curvature matrix[15]) is then built up.

Back in the main program the Newton–Gauss–Marquardt algorithm[8,15] is applied. The shifted parameters so obtained are used to calculate a new sum of squares QS and it is checked that convergence takes place. This is continued iteratively until the relative change in QS is less than 0.01%. In the case of divergence the Marquardt parameter is introduced. It is first set equal to the first diagonal element of the curvature matrix and is added to all diagonal elements. After each step of convergence the Marquardt parameter is reduced by a factor of 3 and in the final iteration it is set equal to zero. Once the minimum in QS is found the "best" parameters and their standard errors are printed and the values of pH, ml_{exp} and ml_{calc} are stored on tape.

TITFIT is 26 kbytes long in its original form, but will need more memory for the subroutine Ohb once this is generated and for the data (about 13 kbytes). If a computer with insufficient memory has to be used, space can be saved by deleting all the remark statements, and by linking to the main program only those subroutines which are needed in a specific task.

MATHEMATICAL BACKGROUND

For a model which consists of a set of species $M_mL_lH_h$, the equations related to the equilibrium constants β_{mlh} and to the mass balance for total metal c_M, total ligand c_L, and total hydrogen c_H are:

$$\beta_{mlh} = [M_mL_lH_h]/[M]^m[L]^l a_H^h \tag{1}$$

$$F = c_L - \sum_{mlh} l[M_mL_lH_h] \tag{2}$$

$$G = c_M - \sum_{mlh} m[M_mL_lH_h] \tag{3}$$

$$H = c_H - \left\{\sum_{mlh} h[M_mL_lH_h] + a_H/\gamma - K_w/a_H\right\} \tag{4}$$

where a_H is the measured proton activity, γ the activity coefficient for H^+ and K_w the dissociation constant of water. From these, the calculated titration volume (ml_{calc}) can be derived:

$$ml_{calc} = EQ - \frac{EQ}{n_L \cdot c_L}\left(\sum_{mlh} h.[M_mL_lH_h] + a_H/\gamma - K_w/a_H\right) + Exac \tag{5}$$

where EQ is the equivalence-point volume, Exac the volume corresponding to the excess of strong acid, and n_L the total number of protons of the ligand that can be titrated.

From equations (2) and (3) the two unknown concentrations [M] and [L], represented by M and L, can be calculated by the Newton–Raphson[14] method since $F = G = 0$. With the shifts ΔM and ΔL, calculated by using the partial derivatives $\partial F/\partial M$, $\partial F/\partial L$, $\partial G/\partial M$, and $\partial G/\partial L$ the solutions are obtained by iteration. At this point the concentrations of all species $M_mL_lH_h$ are also known and hence ml_{calc} [equation (5)] and the error square sum [equation (6)] can be calculated.

$$QS = \sum_{points} (ml_{exp} - ml_{calc})^2 \tag{6}$$

To obtain the "best" parameters the minimum of QS must be found and for the parameters p_i there are I equations of the type (7)

$$0 = \frac{\partial QS}{\partial \log p_i} = \sum_{points} \frac{\partial\, ml_{calc}}{\partial p_i} p_i \tag{7}$$

which must be solved. As parameters the unknown β_{mlh} values are taken, but also if necessary the equivalence-point volume EQ, the excess of acid Exac, the ion-product of water K_w or the activity coefficient γ. For p_i equal to EQ, Exac, K_w and γ the derivatives $\partial\, ml_{calc}/\partial p_i$ are trivial and equations (8)–(11) can be written at once.

$$\partial\, ml_{calc}/\partial \log EQ = EQ - EQ\left(\sum_{mlh} h[M_mL_lH_h] + a_H/\gamma - K_w/a_H\right)\Big/(n_L c_L) \tag{8}$$

$$\partial\, ml_{calc}/\partial \log Exac = Exac \tag{9}$$

$$\partial\, ml_{calc}/\partial \log K_w = K_w . EQ/(n_L c_L a_H) \tag{10}$$

$$\partial\, ml_{calc}/\partial \log \gamma = a_H . EQ/(n_L c_L \gamma). \tag{11}$$

However, for p_i equal to β_{mlh} the situation is a little more complicated. As discussed by Nagypal *et al.*,[12] equation (12) can be written:

$$\frac{\partial\, ml_{calc}}{\partial \log \beta_{mlh}} = -\frac{EQ}{n_L c_L}\left\{h[M_mL_lH_h] + \frac{\partial H}{\partial L}\frac{\partial L}{\partial \log \beta_{mlh}} + \frac{\partial H}{\partial M}\frac{\partial M}{\partial \log \beta_{mlh}}\right\} \tag{12}$$

$\partial H/\partial L$ and $\partial H/\partial M$ can be calculated from equation (4), whereas $\partial L/\partial \log \beta_{mlh}$ and $\partial M/\partial \log \beta_{mlh}$ are determined from the two linear equations (13) and (14):

$$0 = \frac{\partial F}{\partial \log \beta_{mlh}} = l[M_mL_lH_h] + \frac{\partial F}{\partial L}\frac{\partial L}{\partial \log \beta_{mlh}} + \frac{\partial F}{\partial M}\frac{\partial M}{\partial \log \beta_{mlh}} \tag{13}$$

$$0 = \frac{\partial G}{\partial \log \beta_{mlh}}$$

$$= m[M_m L_l H_h] + \frac{\partial G}{\partial L}\frac{\partial L}{\partial \log \beta_{mlh}} + \frac{\partial G}{\partial M}\frac{\partial M}{\partial \log \beta_{mlh}} \quad (14)$$

where $\partial F/\partial L$, $\partial F/\partial M$, $\partial G/\partial L$ and $\partial G/\partial M$ are already known from the Newton–Raphson solution for the concentrations.

Once the partial derivatives $\partial \mathrm{ml}_{\mathrm{calc}}/\partial \log p_i$ have been calculated, the Hessian matrix is directly built up and the standard Newton–Gauss–Marquardt procedure is used to compute the shifts of the parameters.

DISCUSSION

The program TITFIT was developed for use on a computer to which the operator has direct access for interaction. The program is easy to use, since it is written in blocks (subroutines and subprograms) which perform a single task and which can be assessed in any logical order. It is also possible to interrupt one task and continue with another at any moment. For the user who is not interested in writing programs or in their detailed function it can be used as a turn-key system with "black box" characteristics.

We would like to emphasize the following comparisons with the working of other programs.

(a) In contrast to other programs which minimize titration-volume differences, analytical derivatives $\partial \mathrm{ml}_{\mathrm{calc}}/\partial \log p_i$ are used for the calculation. No numerical differentiation (with all its problems of step size control and loss of significant figures) is needed in the entire program. Analytical derivatives are also used in MINIQUAD[6] but it employs a completely different approach, since it performs a least-squares fit on all three mass-balance equations (2)–(4), thus mixing independent and dependent variables.

As shown in the mathematical part, the analytical derivatives $\partial \mathrm{ml}_{\mathrm{calc}}/\partial \log p_i$ can be calculated by using the derivatives of the functions F, G and H with respect to M and L, which have been already calculated to solve for the concentrations. The advantages of the use of analytical derivatives are higher speed and better convergence.

(*b*) The program automatically writes its own optimized subroutine, including the analytical derivatives and the algorithm for building the Hessian.[14] The user need only define the complex species through their stoichiometric indices m, l and h and indicate whether a value should be refined or kept constant.

(*c*) The program has facilities which help with the choice of model and reasonable values for the parameters. Each titration curve can be displayed on the screen and the parameters can be adjusted manually. A new plot and the error square sum QS are then shown. Through visual interaction the operator can obtain a rough fit to the titration curve before the automatic refinement starts.

(*d*) At any moment the user can decide whether he wants to keep a certain value constant or whether it should be considered as a parameter and be refined. Any change requires rewriting of the subroutine, as described in (*b*).

(*e*) Like DALSFEK[9] and MARFIT[3] this program uses the Newton–Gauss–Marquardt algorithm,[8] which seems to be one of the best for a non-linear least-squares problem such as this. The Marquardt parameter is used only when divergence occurs.

(*f*) In contrast to the authors of DALSFEK[9] we think that the algorithm used here is not ideal for other types of measurements, and especially not for spectrophotometric ones. It has been shown[13] that for such data, another approach, which uses eigenvector analysis for data-reduction and elimination of the linear parameters, can greatly improve the convergence condition and decrease calculation time as well as memory requirement.

The program has been tested and used in our laboratory for more than a year with many different examples.

No difficulties have been found in fitting titration curves provided that reasonable models are chosen. In general we can fit titration curves to 0.1–0.5% of the total volume of the titrant.

RESULTS

The system Ni^{2+}/glycine was chosen for use as a model system to allow comparison of the reproducibility of techniques and calculation procedures.[11] The titration data for the free ligand were fitted with two pK_H values, taking the excess of strong acid and the equivalence-point volume as additional parameters. For 51 data points 7 sec were required for an iteration and the complete fitting was done after 3 or 4 iterations. The Ni^{2+}/glycine system was investigated by using six titration curves with a total of 256 data points. The values of the three parameters β_{110}, β_{120} and β_{130} were found after four iterations in about 10 min. This time is only slightly dependent on the number of parameters used for the fit. The best values, together with those published in the literature,[11] are given in Table 2.

Table 2. Acid dissociation constants of glycine and formation constants of the Ni^{2+}–glycine complexes at 25° and $\mu = 1M$ (NaCl)

Species m,l,h	$\log \beta_{mlh}(\sigma_{\log\beta})$†	$\log\beta_{mlh}$
0 1 1	9.653 (0.011)	9.63
0 1 2	12.083 (0.031)	12.08
1 1 0	5.638 (0.071)	5.58
1 2 0	10.391 (0.089)	10.30
1 3 0	13.922 (0.191)	13.75
pK_w	13.693 (0.02)	13.69

† Mean values and standard deviations taken from Bottari *et al.*[11]

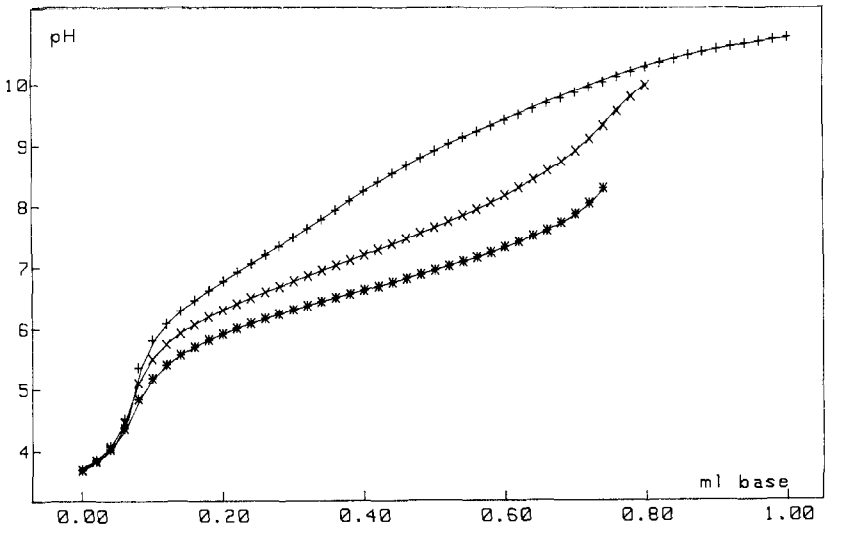

Fig. 2. Experimental and calculated titration curves for $3.5 \times 10^{-3} M$ glycine with 0.914, 0.457 and 0.228 equivalents of Cu^{2+}, plotted by the computer program TITFIT.

The values found are all well within the limits of the results obtained by the other groups and agree with the mean of the previous results within less than one standard deviation. The standard errors of our values calculated from a single set of six titration curves range from 0.002 to 0.008 and are considerably smaller than the "true" uncertainties obtained by repeating the experiments several times and by comparing results from different groups. An example of experimental and calculated curves is shown in Fig. 2.

Since one of the authors of the paper mentioned[11] proposed the presence of hydroxo-species in addition to the 1:1, 1:2 and 1:3 complexes, we also postulated the presence of Ni(gly)OH. The sum of squares decreased insignificantly from 1.766×10^{-3} to 1.765×10^{-3} and β_{11-1} was 8.6×10^{-7} with a standard error $\sigma_\beta = 3 \times 10^{-6}$, clearly indicating that the species must be rejected. We assume the hydroxo-complexes to be artefacts which are obtained only if titration points from the unstable pH region are included.

In conclusion we can say that TITFIT combines the facilities of the larger computer programs with the easy and direct access of desk-top computer systems. Direct interaction of the operator with a graphical display greatly facilitates quick testing of different models. Enhanced speed and improved numerical safety are provided by the automatic design of an optimized subprogram and the use of analytical derivatives.

Listings of TITFIT or copies on an HP200 cartridge are available from the authors upon request.

AUTOMATED SQUARE-WAVE ANODIC-STRIPPING VOLTAMMETRY WITH A FLOW-THROUGH CELL AND MATRIX EXCHANGE

E. B. BUCHANAN, JR. and D. D. SOLETA
Department of Chemistry, University of Iowa, Iowa City, IA, 52242, U.S.A.

(*Received* 16 *June* 1981. *Accepted* 31 *July* 1981)

Summary—An extremely sensitive and versatile instrument is described that performs square-wave anodic-stripping voltammetry. The instrument incorporates a flow-through cell and is capable of changing the solution matrix between the deposition and stripping steps. The working electrode is a static mercury drop electrode constructed in the authors' laboratories. The entire system is controlled by a microcomputer that allows the usual variation of the square-wave parameters, as well as setting of the initial and final scan potentials, the deposition time, the scan-rate, the instrument sensitivity and the drop size. To show the performance of the instrument, calibration graphs for Cd in the ranges 0.2–40 and 0.1–1 ng/ml are described and the reproducibility of the drop is discussed. Analysis of a NaCl sample for Cd is given as an example of application of the method.

In the last decade anodic-stripping voltammetry (ASV) has become an important electroanalytical technique, especially for trace analysis, because of its high sensitivity and specificity.[1,2] The sensitivity of ASV can be increased by increasing the deposition time: cadmium at concentrations below the ng/ml level were determined by ASV as early as 1957, but a 60-min deposition time was required.[3] The sensitivity can also be improved by increasing the rate of convection in the solution, increasing the area of the electrode or employing a more sophisticated form of voltammetry for the determination or stripping process. A number of potential–time wave-forms, such as sine-wave,[4] pulse,[5] differential pulse[6,7] and square-wave,[8] have been superimposed on a linear potential ramp for stripping purposes. Desimoni *et al.*[9] have recently shown that the specificity can be increased by coupling matrix exchange with stripping analysis.

This paper deals with an instrument that has been developed to carry out automated square-wave stripping voltammetry coupled with matrix exchange. A number of parameters which allow the analyst to achieve sensitivities in the sub-ng/ml range without the use of lengthy deposition times, *i.e.*, in less than 5 min have been investigated. By the use of a mini flow-through cell, sufficient convection is obtained during the deposition period for mechanical stirring to be unnecessary. The enhancement of sensitivity is derived from the use of square-wave voltammetry, which incorporates a square-wave combined with a staircase wave-form in the stripping stage of analysis.

EXPERIMENTAL

Apparatus

The mini flow-through cell is constructed of $\frac{1}{2}$-in. thick "Plexiglas" sheet and dowelling. It consists of two sections. The manifold control block, or first section, controls the flow of the solutions that enter the second section, the cell block, where the working, auxiliary and reference electrodes are located. The manifold control block has a $\frac{1}{16}$-in. diameter channel drilled lengthwise through its centre. This manifold has two inlets and two outlets. The first inlet is for introduction of the sample; opposite it is the sample reservoir drain, which allows draining of the sample reservoir and rinsing of the sample inlet valve. The second inlet to the manifold is used for introduction of the stripping medium into the manifold when the matrix-exchange method is used. The remaining outlet serves to connect the manifold cell block to the electrode (cell) block. The placement of these inlets and outlets is shown in Fig. 1. There are two reservoirs connected to the manifold control block. One reservoir, a 600-ml beaker with a Teflon stop-cock valve fitted on its bottom, holds the sample solution. The other reservoir, a 250-ml separatory funnel, holds the de-aerated electrolyte. Both reservoirs are connected to their respective inlets with Tygon tubing.

The cell block is also shown in Fig. 1. The cell chamber itself is a $\frac{3}{8}$-in. diameter channel $1\frac{3}{8}$ in. deep. There are two outlets and one inlet to this chamber. The inlet located at the bottom of the cell chamber is 0.020 in. in diameter, which allows the solution to flow from the manifold block at a controlled rate into the cell chamber. A $\frac{1}{16}$-in. internal

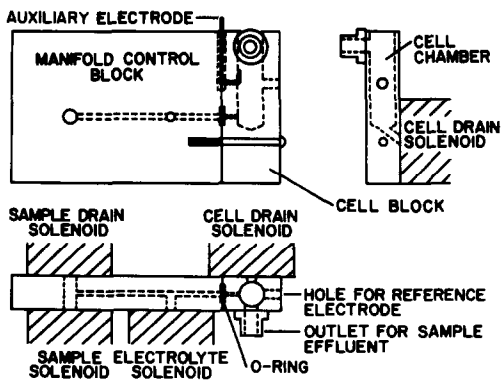

Fig. 1. Mini flow-through cell.

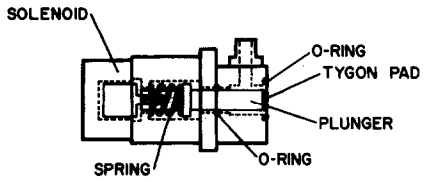

Fig. 2. Plunger assembly.

diameter O-ring is used to seal the inlet connection between the manifold and cell blocks. One outlet is located near the top of the cell chamber and is the effluent port for the solution flowing through the cell chamber during the analysis. The other outlet is at the bottom of the cell chamber and is used to drain the cell and remove used mercury from the cell chamber. Two other holes are drilled on opposite sides of the electrode block. One is for the counter-electrode (a platinum wire), and the other is for the reference electrode, a Ag/AgCl electrode employing an unfired Vycor tip as the solution/electrode interface. The two sections of the cell are held together by a bolt screwed into a hole tapped in the manifold control block.

The sample inlet, sample drain, electrolyte inlet and cell drain are controlled by plungers made from "Plexiglas" dowelling and sheet. The plungers are spring-loaded and controlled by their solenoids. When the solenoids are activated the plungers are pulled away from the corresponding valve seat on the manifold block. If the solenoids are in the non-activated state, the springs hold the plungers against the valve seats. A piece of Tygon attached to the end of the plunger makes a leak-proof seal with the seat. Figure 2 shows the plunger assembly.

The working electrode used is a static mercury drop electrode (SMDE) similar in design principle to the one described by Peterson and manufactured by E. G. & G. Princeton Applied Research Corporation.[10] In the design used in our laboratory no metal other than the platinum electrical connection comes into contact with the mercury. A "Plexiglas" plunger under the control of a solenoid regulates the flow of mercury through the glass capillary. When the solenoid is pulsed quickly and accurately, a reproducible drop is formed on the end of the glass capillary. The body of the electrode assembly is made from "Plexiglas" sheet and dowelling and is shown in Fig. 3. The drop is dislodged from the capillary by a drop-knocker of plunger–spring–solenoid design similar to that described above and shown in Fig. 4.

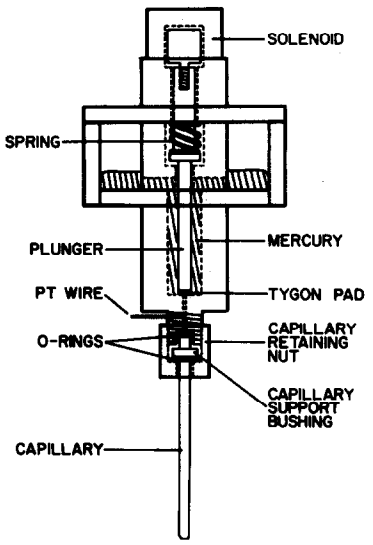

Fig. 3. Static mercury drop electrode.

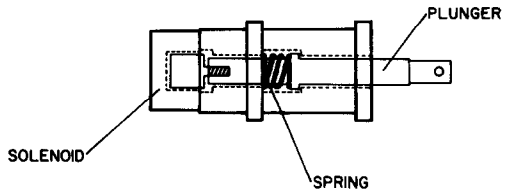

Fig. 4. Drop-knocker.

The cell potential and current signal are controlled and processed by the microcomputer-controlled square-wave polarograph designed and built by Buchanan and Sheleski.[11] The instrument applies the combined staircase voltage and square-wave signal during the stripping procedure, and monitors and processes the current flow from the cell. Table 1 lists the controllable variables applied by the square-wave polarograph.

Portions of the original software have been modified to accommodate the use of a SMDE and the stripping procedures employed with the automated flow-through cell. The main functions are retained but the use of the SMDE eliminates the need for strobe timing control. However, selection of the size of the drop formed by the SMDE is most desirable and therefore this feature was added. ASV requires the selection of deposition time and this function was also incorporated. The step duration in the staircase voltage is programmable from 1 to 65,536 msec, thus allowing the analyst to vary the scan-rate. The step height is always 5 mV. The frequency of the square-wave is selected by entering the appropriate square-wave half-period into the microcomputer. The half-period can range from 1 to 65,536 μsec, corresponding to square-wave frequencies between 8 Hz and 0.5 MHz. Square-wave amplitudes of 0, 5, 10, 25 and 50 mV are also selectable. The delay between the square-wave transition and the commencement of the current measurement is called the "transition sample delay". This parameter is adjustable from 1 μsec to the value of the square-wave half-period. The period of time over which the current signal is sampled is called the "sample aperture" and is also adjustable between 1 μsec and the square-wave half-period. The sum of these two times should not exceed the half-period of the square-wave. The deposition time can be programmed from 0 to 65,530 sec in steps of 10 sec. The initial and final potentials can cover the range ±2000 mV and are programmed in steps of 1 mV. There are four sensitivities available on the instrument. Sensitivity 1 multiplies the current produced at the working electrode by a factor of 22. Sensitivities 2, 3 and 4 provide multiplication factors of 110, 220 and 440 respectively. Four drop sizes have been made available for the SMDE. The drop size is controlled by the solenoid pulse-time when forming a drop. Drop size 1 requires the solenoid to be pulsed for 31 msec. For drop sizes 2, 3 and 4 the solenoid is pulsed for 62, 125 and 250 msec respectively. All of these parameters are constantly displayed on a cathode-ray tube (CRT) and are entered into the microcomputer from a keyboard.

A. Drop size	2

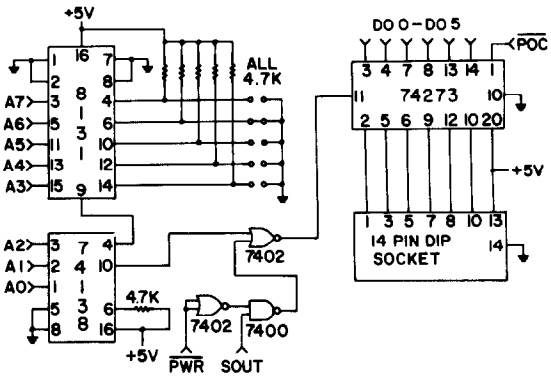

Fig. 5. Interface circuit.

Additional hardware is required for the microcomputer to manipulate the SMDE, the drop-knocker, and the solution flow through the cell during an analysis. This is accomplished through an interface board located in the microcomputer, and a manual control module connected between the interface board and the appropriate solenoids. The interface board uses the S-100 bus configuration. The circuit diagram is shown in Fig. 5. The manual control module changes the 5-V signals received from the interface board into the 24-V signals used by the solenoids. The circuit diagram of this module is shown in Fig. 6.

The sequence of events that occur during a single analysis is listed below.

1. The adjustable parameters, as shown in Table 1, are entered into the microcomputer. Comments may be entered and stored in memory.
2. The analysis is started.
3. The old drop is knocked off and a rinse drop is formed by pulsing the drop-knocker and SMDE solenoids.
4. The cell-drain solenoid plunger is activated and the cell chamber is emptied.
5. The cell-drain outlet is closed, then the electrolyte solenoid plunger is again activated and the cell is filled with electrolyte.
6. The electrolyte inlet is closed and another rinse drop is formed and knocked off.
7. An analysis drop is formed in the same manner as the rinse drop.
8. A d.c. pre-electrolysis potential of -200 mV *vs.* Ag/AgCl is applied to the cell for 40 sec to remove any oxidizable impurities from the electrode. Concurrently, the sample solenoid plunger is activated to flush the cell chamber with the sample.
9. When the pre-electrolysis period has expired, the deposition potential or initial potential is applied to the cell for the duration of the deposition time. The sample continues to flow through the cell during this period.
10. Upon completion of the deposition period the sample inlet is closed and matrix exchange is commenced by flushing the cell with the deaerated electrolyte for 40 sec. During this period the sample solution is replaced with the stripping solution. The potential applied to the cell during this period is still the d.c. deposition potential.
11. The electrolyte inlet is closed, the square-wave signal is applied to the cell and the voltage scan is started.
12. The resulting voltamperogram is recorded on a strip-chart recorder and stored digitally in the memory of the microcomputer.
13. When the final potential is reached the scan stops and the square-wave signal is terminated.
14. The instrument then waits until initialized again.

Reagents

Distilled water passed through Barnstead "Ultrapure" and "Organic Removal" cartridges was used in the preparation of all solutions. Stock solutions of cadmium and lead were prepared from reagent-grade cadmium chloride and lead carbonate. Reagent-grade ammonium chloride was used in the preparation of the stripping electrolyte. Locally purchased table salt without additives was used for preparing the sodium chloride sample solution. Oxygen was removed from the nitrogen used for deaerating the electrolyte, by bubbling the nitrogen through a chromium-(II) scrubber solution before use.

Procedure

Table 1 shows the list of operating parameters as they appear on the CRT of the instrument. The values given for each parameter are those used in all the experimentation unless otherwise noted in the text.

The pre-electrolysis potential was programmed in software to be -200 mV. The cell-chamber flush-times were also programmed in software and set at 40 sec. These parameters are not as easily changeable as those listed in Table 1, but can be varied by changing the program of the operating system.

The stripping electrolyte used for matrix exchange in all the experimentation was 0.1*M* ammonium chloride. Nitrogen was continuously bubbled through the electrolyte reservoir by means of a fritted bubbler.

Table 2. Data for 2-min deposition-time calibration graph for Cd

[Cd] *ng/ml*	Adjusted mean peak height, * *chart units*	Standard deviation, *chart units*	Relative std. devn., %	Sensitivity setting
0.2	6.3	0.2	3.2	4
0.4	13.3	0.7	5.3	4
0.6	22.1	0.5	2.3	4
0.8	31.3	1.8	5.8	4
1.0	39.5	0.4	1.0	4
4.1	178	3	1.7	3
6.2	262	4	1.5	2
8.2	354	1	0.3	1
10.3	434	14	3.2	1
14.4	608	6	1.0	1
20.6	894	14	1.6	1
30.9	1360	20	1.5	1
41.2	1790	30	1.7	1

* Adjusted to sensitivity setting of 4.

The flow-rate of solutions through the cell was measured and found to be 27 ± 1 ml/min. This value is fixed and controlled mainly by the diameter of the inlet to the cell.

Two calibration curves for cadmium were prepared. All of the sample solutions used had an ammonium chloride concentration of 0.1*M* in addition to the appropriate concentration of cadmium. A 2-min deposition time was employed in the preparation of the calibration curve. The concentrations of cadmium ranged from 0.2 to 40 ng/ml. The sensitivity setting of the instrument was varied according to the concentration of cadmium. A second calibration curve for cadmium was prepared, using a 3-min deposition time, cadmium concentrations of 0.1–1 ng/ml and a sensitivity setting of 4.

A sample of locally procured common table salt (sodium chloride without additives) was assayed for its cadmium content. A 42.1-g sample was dissolved in 1 litre of demineralized distilled water. The deposition conditions were the same as those for the second calibration curve described above. An additional sample containing a trace of added lead ions in the form of lead chloride was examined to confirm that the second peak observed was due to lead.

The peak height as a function of drop size was examined, with a 10-ng/ml Cd solution which was also 0.1*M* in ammonium chloride. A deposition time of 1 min and a sensitivity setting of 2 were employed for this study.

RESULTS AND DISCUSSION

The matrix-exchange method was used in the analysis of all solutions in this work. The change of cell solutions between deposition and stripping offers two advantages. The first is that the metal being determined can be stripped into a solution that is more favourable than the original sample solution for the oxidation of that particular metal. If several metals are being determined and their peaks overlap, the matrix-exchange method can often be used to resolve the peaks through changing the oxidation potentials by complex-formation. The second advantage accrues because only the stripping procedure requires a deaerated solution. Thus analysis time may be saved by employing a non-deaerated sample for the deposition step and then exchanging it for an already deaerated stripping electrolyte before starting the stripping procedure.

Table 3. Data for 3-min deposition-time calibration graph for Cd

[Cd] *ng/ml*	Mean peak weight, *chart units*	Standard deviation, *chart units*	Relative std. devn., %
0.1	4.2	0.1	2.4
0.2	9.3	0.8	8.6
0.4	19.1	1.4	7.3
0.6	28.5	1.2	4.2
0.8	38.9	1.0	2.6
1.0	49.0	1.2	2.4

Table 2 shows the data for the cadmium calibration graph obtained with a 2-min deposition time. All the cadmium peaks occurred at −535 mV *vs.* Ag/AgCl. The adjusted peak height takes into account the sensitivity employed and is the average obtained from three consecutive determinations on a single sample. A least-squares analysis of the data produced a line with a correlation coefficient of 0.9999 and a slope of 43.5 ± 0.1 chart units per concentration unit (ng/ml). The closeness of the correlation coefficient to unity

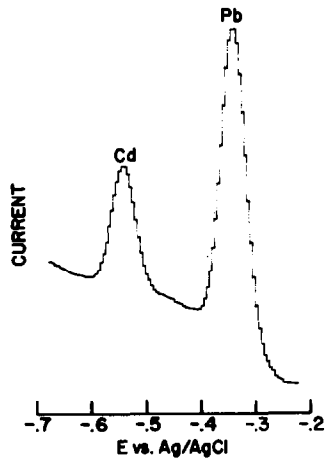

Fig. 7. Voltamperogram of a 0.72*M* NaCl solution, obtained with a 3-min deposition period.

Table 4. Drop-size comparison data

Drop size	Formation pulse time, *msec*	Mean peak height, *chart units*	Standard deviation, *chart units*	Relative std. devn., %
—	16	44	2	4.5
1	31	43.9	0.9	2.1
2	62	49.7	1.2	2.4
3	125	56.8	1.4	2.5
4	250	68	2	2.9

shows the linearity of response, and the slope indicates the sensitivity of the instrument. The mean relative standard deviation for all the data points was 2.3%.

The data for the second calibration graph are listed in Table 3. Each of the data points is a mean of 9 results taken 3 at a time on 3 separate days. The line produced by these data has a correlation coefficient of 0.9999 and a slope of 48.5 ± 0.3 chart units per concentration unit (ng/ml). The mean relative standard deviation of all the points over the 3 days was 4.6%. A comparison of the mean relative standard deviations for all the data points given in Tables 2 and 3 indicates the long-term stability of the instrument. The difference in the slopes of the two calibration graphs is indicative of the slight enhancement in sensitivity obtained by increasing the deposition time.

Figure 7 shows the voltamperogram of the table salt solution. The peak at −535 mV *vs.* Ag/AgCl is the cadmium peak and the peak at −330 mV *vs.* Ag/AgCl was identified as due to lead. The cadmium concentration in the salt solution was calculated from the second calibration graph to be 0.35 ± 0.05 ng/ml. This corresponds to 8 ± 1 ng/g in the solid sample. The magnitude of the lead content was not determined.

The cell showed no contamination problems with the cadmium and lead solutions. The cell was rinsed by filling the sample reservoir with 200 ml of distilled water and flowing it through the cell for 3 min.

Table 4 shows the results obtained in the drop-size experimentation. The peak heights are reported in chart-recorder units. Initially a drop size obtained with a 16-msec solenoid pulse was examined. The resulting peak height was the same as that obtained with a "31-msec" drop. It was concluded that this result was due to the inability of the solenoid to respond correctly to pulse times of less than 31 msec. Accordingly, the program was rewritten to make 31 msec the minimum pulse time. The increase of peak height with larger drop sizes was expected, because of the larger surface area of the drop. The reproducibility of the drop was evidenced by the mean relative standard deviation of 2.9% for the peak heights obtained for the same solution. The similarity of this value to those for the calibration graphs furthers confidence in the reproducibility of the drop sizes.

The coupling of matrix exchange with square-wave anodic-stripping voltammetry provides an analytical scheme which is capable of rapid, sensitive determinations of trace metals with minimal deposition times.

Note. Copies of the software are available from Professor Buchanan at the price of US$2.50.

RAPID-FLOW ANALYSIS USING DIFFERENTIAL PULSE POLAROGRAPHY WITH AUTOMATIC SAMPLING

P. W. ALEXANDER and H. MARPAUNG

Department of Analytical Chemistry, University of New South Wales, P.O. Box 1, Kensington, N.S.W., 2033, Australia

(*Received* 4 *March* 1981. *Accepted* 31 *July* 1981)

Summary—Differential pulse polarography is used in a rapid-flow analysis system for automated determination of lead, zinc and ascorbic acid in acetate-buffered sample solutions, without the need for sample deaeration. By use of a nitrogen-segmented buffer stream at high flow-rates, high-speed sampling at up to 180 samples/hr can be obtained at a flow-rate of 22.8 ml/min through a polarographic flow-cell fitted to the dropping mercury electrode. A linear calibration range of approx. 0.1×10^{-4}–$1.0 \times 10^{-3} M$ is found for lead, zinc and ascorbic acid, with respective detection limits of 4.0, 0.8 and $0.2 \times 10^{-6} M$, limited by the high base-line current and high noise-level. Vitamin C tablets can be routinely analysed without prior separation steps, provided the sample and wash solutions are matched in electrolyte composition. A precision of better than 1% RSD is obtained at a sampling rate of 120/hr.

Although well recognized as a sensitive and selective analytical technique,[1,2] differential pulse polarography (dpp) has been little studied as a tool for automated sample analysis in continuous-flow systems. Rapid-flow analysis has been suggested[3] as a means of improving sampling rates in continuous-flow analysis with ion-selective electrodes. There have been no reports, however, on rapid sampling systems for detecting species by direct oxidation or reduction with dpp, and this study is aimed at establishing the performance limits of dpp in automated rapid-flow analysis.

Ivaska and Smyth[4] recently reviewed the status of polarography in flow-analysis systems, and found that dpp had been little used. Alexander *et al.*[5,6] first showed that dpp could be used for fast analysis in rapid-flow systems with either a mercury-pool electrode[5] or a dropping mercury electrode (DME)[6] as the indicator electrode. Sampling rates of 60–120 samples/hr were obtained with dpp operated at fixed potentials suitable for detection of certain catalytic electrode reactions.[5,6] Additionally, it has been shown[7,8] that indirect complexometric methods can be used to advantage with dpp detection in flow systems for automated determination of various proteins at routine sampling rates of 60/hr. Tóth *et al.*[9] have discussed the possible application of other modes of polarography in flow-analysis systems, including direct and indirect (or inverse) methods.

In this study we have examined the response characteristics of the DME in a rapid-flow system for dpp detection of both reduction and oxidation electrode reactions, using lead, zinc and ascorbic acid as examples of direct electrode reactions in the categories discussed by Pungor *et al.*[9] Performance limits in fast-sampling operation have been examined, and the results compared with those obtained by using d.c. polarography. The analysis of vitamin C tablets was used as an example of fast-sampling analysis where the selectivity of dpp is used to advantage. The importance is shown of matching the composition of sample and wash solutions in order to avoid high blank readings in this type of dpp analysis.

EXPERIMENTAL

Reagents and solutions

All inorganic reagents used were analytical-reagent grade. The 0.2*M* acetate buffer (pH 4.7) was prepared by mixing equal volumes of 0.2*M* sodium acetate and 0.2*M* acetic acid. A stock 0.2% solution of Triton X-100 was used.

Lead and zinc nitrates were used without purification to prepare 0.1*M* stock solutions in water, which were then diluted with 0.2*M* acetate buffer containing 0.0002% Triton X-100 to cover the range 10^{-4}–$10^{-3} M$.

Ascorbic acid solution, 0.05*M*, was prepared in boiled-out distilled water containing EDTA (0.5 g/l.) as recommended by Strohl *et al.*[10] to stabilize the solution against chemical oxidation. A standard series in the concentration range 5.0×10^{-5}–$5.0 \times 10^{-4} M$ was prepared in boiled-out distilled water containing EDTA (0.5 g/l.) and 0.0002% Triton X-100.

Tablets analysed were commercially available pharmaceutical formulations of two different types: a vitamin C tablet (Roche) containing vitamin C (500 mg) as the only vitamin component, and a coated B-group multivitamin tablet (Altorvite, Nicholas) containing vitamins C (37.5 mg) B_1 (5.0 mg), B_2 (2.5 mg), B_6 (0.5 mg), nicotinamide (25.0 mg) and calcium pantothenate (1.0 mg) in each tablet. For analysis, sample solutions were prepared in 0.2*M* acetate buffer by dissolving single tablets of each type of boiled-out distilled water and diluting to 1000 ml after addition of 0.5 mg of EDTA, 100 ml of 2.0*M* buffer solution and 1 ml of 0.2% Triton X-100 solution. The buffered solutions were then analysed directly without prior separation. The vitamin C tablet (500 mg) solution was further diluted tenfold with the same electrolyte solution to bring the concentration into the calibration range.

Polarographic instrumentation

An EG & G/Princeton Applied Research polarograph, type 174A, was used for polarographic analysis with a matched drop-timer (PAR 174/70) and a Houston Omnigraphic strip-chart recorder, type EB5117-5-S. The electrochemical cell consisted of a dropping mercury electrode (DME), a saturated calomel electrode (SCE) and an auxiliary platinum electrode. The capillary characteristics of the DME were: mercury flow-rate 2.2 mg/sec with natural drop-life of 3.8 sec at a mercury-column height of 860 mm, when measured at a fixed potential of −0.41 V with the DME immersed in 0.2*M* acetate buffer. The electrodes were used in the flow-through cell system described below, and measurements were made at room temperature.

Automated continuous-flow system

The flow-through analysis system was similar to the one previously described[6] except that an automatic sampler was added and the flow-through cell was slightly modified. Figure 1 shows the schematic diagram of the modified system and indicates the flow-rates used for automatic sample introduction into a nitrogen-segmented buffer stream.

The automatic sampler was a Chemlab type CS40 with continuously variable control of both the sample and wash times. A 6-channel peristaltic pump (Desaga, type No. 131900) was used to pump buffer and sample solutions through the system at flow-rates varied by use of a speed controller fitted to the pump. The flow-rates given in Fig. 1 were obtained with the speed-controller set at speed 8. The stream was pumped through a single mixing coil of 2 mm internal diameter, and transmission tubing of 1 mm internal diameter.

After debubbling, the sample stream flowed through a glass flow-cap fitted to the DME with the platinum auxiliary electrode sealed in the glass inlet tube, up-stream from the DME, as described previously.[6] To improve the wash-out characteristics, however, the cell was modified by reducing the internal diameter of the flow-through channel from 2.0 to 1.0 mm, and by using a DME capillary with a small outside diameter of 4.0 mm. The resulting hold-up volume of the cell was reduced from approximately 0.5 ml to 0.1 ml. The SCE was placed in the waste solution down-stream from the DME, and the waste mercury from the DME was collected in the waste solution after being flushed out of the cell by the flowing stream, thus avoiding build-up of mercury in the flow-cell.

Procedure

The buffer solution was deaerated by continuous bubbling of nitrogen through the solution vessel. In these studies, the sample, blank and wash solutions were all made 0.2*M* in acetate (with 0.0002% Triton X-100 present) in order to match the base-line currents. For the determination of ascorbic acid, the sample, blank and wash solutions all also contained 0.5 g of EDTA per litre. A steady base-line current was initially established by pumping the buffer and wash solutions through the flow-cell, the polarographic settings (unless otherwise mentioned) being as follows: the potential was fixed at the dpp peak potential of the analyte; current range 0.2 mA; drop-timer 0.5 sec; pulse amplitude 100 mV; recorder input 2 V; recorder chart-speed 1 or 2 cm/min.

Sample solutions were loaded on the sampling tray in 10-ml cups, and the sampler was then switched on with the sampling and wash times both set for normal operation at 15 sec to give an effective sampling rate of 120 samples/hr. The wash and sample solutions were pumped into the nitrogen-segmented buffer stream and were *not* deaerated before sampling. The current at the DME was recorded continuously on the strip-chart recorder for either the dpp or the d.c. mode. When required, sampling and wash times were varied from 10 to 30 sec to give corresponding sampling rates in the range 180–60 samples/hr. The sample volumes required for analysis depended on the sampling rate used and were 4.6, 3.1, 2.3 and 1.5 ml at sampling rates of 60, 90, 120 and 180 samples/hr, respectively.

RESULTS AND DISCUSSION

The continuous-flow system shown in Fig. 1 was operated at a fixed flow-rate of 22.8 ml/min through the flow-cell. The flow-rates through the sample and buffer lines were respectively 9.2 and 11.8 ml/min with a debubbling rate of 2.2 ml/min. The high flow-rate used was found to be necessary to give rapid response

in the dpp operational mode, as previously found by Alexander and Shah.[6] The rapid response at this high flow-rate is due to the increased mass transport from the solution to the electrode surface, when the thickness of the diffusion layer is decreased. With this flow-rate fixed, we optimized the operational parameters in this system for the automated determination of lead, zinc and ascorbic acid at fixed voltage, covering maximum sampling rates, effect of oxygen, detection limits and noise levels for both dpp and d.c. operation, effect of sample matrix composition on the baseline, and an application to tablet analysis.

Choice of fixed operating potentials

Solutions of each analyte were pumped continuously through the flow-cell while voltage scans were recorded for $1 \times 10^{-3}M$ solutions of lead, zinc and ascorbic acid, in turn, to establish optimum potentials for operation in the dpp mode. The dpp peak potentials (E_p) measured are shown in Table 1. These potentials, which agree with the $E_{\frac{1}{2}}$ values reported for static d.c. measurements,[11] were then used for automatic-sampling determinations of the analytes at fixed potential. Selective determination of a single analyte should be possible without interference from other reducible or oxidizable species unless there is serious overlap of the peaks. This is an advantage over d.c. operation where species reacting at more positive potentials than the analyte may seriously interfere with current measurements at a voltage on the plateau of a d.c. cathodic wave. In the case of oxidation reactions, the interference effects are reversed and species reacting at more negative potentials than the analyte will interfere with the current measurement on the d.c. anodic wave.

Effect of sampling rate

Results for the analysis of some lead solutions are shown in Fig. 2 for a sampling rate of 120 samples/hr. At the high flow-rate of 22.8 ml/min through the flow-cell, routine operation of the automatic sampling system gave sample peak-heights reaching at least 92% of the steady-state current values. Table 2 summarizes results obtained for lead at 60, 120 and 180 samples/hr, showing the sample volume used at each sampling rate, and the precision and carry-over observed. The results indicated that sampling at rates up to 180/hr was possible with <1% carry-over between consecutive high and low samples. Precision of ±2% RSD was observed for sampling at 180/hr, *i.e.*, a 10-sec sampling time and a 10-sec wash, with sample volumes as low as 1.5 ml.

Effect of oxygen

The recording shown in Fig. 2 was obtained without deaeration of the sample or wash solutions. We found that sample peaks could be detected by deaerating the buffer and using nitrogen-segmentation in

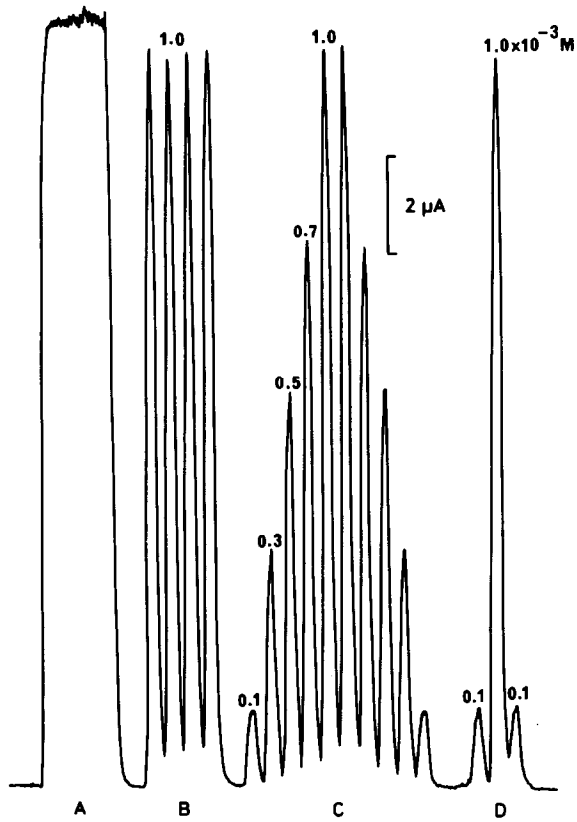

Fig. 2. Continuous recording of lead peaks at a fixed potential of −0.41 V and a rate of 120 samples/hr with 1:1 sample-to-wash ratio, using the flow-rates given in Fig. 1. (A) Steady-state reading for $1.0 \times 10^{-3}M$ lead. (B) Replicates for $1.0 \times 10^{-3}M$ lead. (C) Calibration for the concentration range $0.1–1.0 \times 10^{-3}M$. (D) Carry-over between sequential samples of 0.1, 1.0 and $0.1 \times 10^{-3}M$ lead.

Table 2. Characteristics of rapid continuous-flow determination of lead* by pulse-polarography

Sampling rate, *samples/hr*	Sample volume, *ml*	Signal, *% of steady state*	RSD,† %	Carry-over, %
60	4.6	99	0.5	nil
90	3.1	94	1.0	0.2
120	2.3	92	1.0	0.5
180	1.5	82	2.0	1.0

* Flow-rate 22.8 ml/min through the cell.
† Relative standard deviation for 5 replicates of lead solution.

the flow-system. The small amount of oxygen introduced in each sample segment was apparently not large enough to interfere with the sample peaks observed at the E_p values tested.

Base-line noise and detection limits

Table 1 shows the detection limits for lead, zinc and vitamin C, taken as twice the standard deviation of the base-line current at the operating potential. The base-line noise was found to depend on: (1) deaeration of the buffer, (2) the operating potential, (3) the flow-rate, and (4) the buffer concentration. The base-line noise for dpp operation was found to increase over the broad voltage range from approx. −0.3 to −0.9 V where oxygen is reduced at the DME. Both the sensitivity and detection limits therefore depend on base-line conditions and, since the noise levels are high in this flow-system, detection limits are not as low as those reported[12] for static dpp determination. Despite these limitations, however, many useful applications are possible.

We also operated the detector in the d.c. mode at a fixed potential (i.e., amperometric operation) on the plateau of the wave, and compared the results with the dpp data shown in Table 3 for the determination of lead. The results indicate the problems with d.c. detection at the DME, showing the high noise level on the base-line and the much lower sensitivity of the d.c. mode. The dpp mode was approximately 50 times more sensitive than the d.c. mode with the same electrode drop time of 0.5 sec and the same flow-rate through the flow-cell.

Table 3. Comparison of the detector sensitivity in the d.c. and dpp operating modes

Operating mode	Sample* concentration, *M*	Sample* current, *μA*	Operating potential, *V*
dpp	1.0×10^{-4}	1.3	−0.41
dpp noise†	nil	0.02	−0.41
d.c.	1.0×10^{-2}	2.7	−0.70
d.c. noise†	nil	0.15	−0.70

* For lead samples determined at 60/hr in 0.2*M* acetate buffer.
† Base-line noise level for 0.2*M* acetate solution.

Tablet analysis

Single tablets were selected at random from batches of vitamin C tablets, and of B-group vitamin tablets also containing vitamin C. The vitamin C content of the tablets was determined in replicate by the dpp method, and the results are summarized in Table 4. The precision of replicate analysis of each tablet was in the range 0.3–0.9% RSD, and the mean vitamin C values were within 4% of the nominal content.

Table 4. Replicate determination of vitamin C in tablets by rapid-flow analysis with dpp

	Vitamin C content, *mg**

† Calculated according to British Pharmacopoeia.[13]

The major source of error in this method was non-matching of the wash and sample blank solutions, which caused high blank values. We found it was necessary to use an acetate concentration of 0.2*M* for both wash and sample solutions in order to eliminate the blank value. This type of matching would be required for all analytical applications in this flow system operating at a fixed potential, because of the large effects which variations in electrolyte concentration have on the base-line current.

CONCLUSIONS

The system reported here performs analyses as fast as any other automated single-element method. The major advantages of dpp fixed potential are the selectivity obtainable by choice of the appropriate E_p value, and the sensitivity, in the ppm range, which is at least one order of magnitude better than that offered by the d.c. amperometric mode. Large batches of samples can be rapidly analysed for a single component with this system simply by choice of the required E_p value and appropriate blank-matching, provided that peak overlap with other sample components is insignificant as a source of interference.

(*Received* 27 *May* 1981. *Accepted* 31 *July* 1981)

Summary—From the precipitation borderline in the pM′-pC_H diagram, determined experimentally under CO_2-free conditions, the stability constants of the mononuclear species of ytterbium hydroxide have been established. The values found are log $*\beta_1 = -7.7$, log $*\beta_2 = -15.5$, log $*\beta_3 = -23.2$, log $*\beta_4 = -37.5$, log $*\beta_5 = -51.9$, log $*\beta_6 = -66.2$ and log $*K_{s0} = 18.0$. The data refer to fresh precipitates, prepared at room temperature (21.5 ± 0.2°) in sodium perchlorate medium with an ionic strength of 1. The formation of polynuclear hydroxide complexes has been considered and rejected as unlikely to occur.

The determination of the hydrolysis constants from solubility measurements has been described previously for cerium(III), samarium(III) and gadolinium(III).[1–3] In this paper our results for ytterbium(III) will be discussed. Its hydrolysis constant $*\beta_1$ and $*K_{s0}$ determined previously (Table 1)[4–11] show a fair diversity, mostly caused by differences in experimental conditions. As it is necessary to exclude carbon dioxide during the manipulations we did our experiments with Yb(III) in a large nitrogen-filled glove-box, a procedure previously applied to the other rare earths. Under these conditions reproducible results have been obtained with fresh precipitates made in a sodium perchlorate medium ($I = 1.0$). From these results, besides values for $*\beta_1$ and $*K_{s0}$, values for $*\beta_2$, $*\beta_3$, ..., $*\beta_6$ hitherto absent in the literature have been deduced. The previous papers in this series[1–3] should be consulted for more details about the theory, the possible influence of carbon dioxide and the compromise between reproducibility and non-equilibrium precipitation, for which standardization of the manipulations is necessary. The precipitation procedure has been modified slightly for practical reasons and is given below. Thereby the pC_H range has been extended into the strongly alkaline region.

EXPERIMENTAL

The ytterbium stock solutions were prepared by dissolving the metal (99.99%) in 1*M* perchloric acid. The metal was cut into small discs by spark erosion under gasoline; the discs were polished mechanically to remove carbon deposits, cleaned with acetone and dried under nitrogen. Initially the dissolution is accompanied by violent evolution of hydrogen gas, but soon the reaction slows down so that heating and stirring are eventually necessary to complete the dissolution. Ytterbium oxide is still more difficult to dissolve, even in powdered form. It was only soluble in 3*M* perchloric acid with heating. The final stock solution was made 0.1*M* in ytterbium and 1*M* in perchloric acid. Before the experiments were started, the solutions were flushed in the glove-box with nitrogen for 30 min to expel carbon dioxide.

Procedure

The stock solution of ytterbium was diluted tenfold with 1*M* perchloric acid, except for the range pYb′ < 2. Carbonate-free 50% sodium hydroxide solution was added dropwise to 200 ml of this solution until a pC_H of 1 was reached. Then the pC_H was adjusted to about 4 with (carbonate-free) 5% sodium hydroxide solution. Because of the heat of neutralization the solution had to be cooled with ice (p$C_H \simeq 4$ and 1*M* sodium perchlorate) until a temperature of about 23° was attained.

The 200 ml of ytterbium solution was divided into several portions. Each portion was adjusted to a different pC_H value from the others with 0.5% and 0.05% sodium hydroxide solution (in 1*M* sodium perchlorate). Then the series of solutions was set aside for half an hour. Next the solutions were centrifuged for about 10 min, the supernatants were removed and their pC_H values were measured accurately with an electrode system calibrated as described in the gadolinium paper.[3] Because of the alkali error and the occurrence of liquid junction potentials a glass–calomel electrode system lacks accuracy when pC_H exceeds 12.5, so in this region, the pC_H was determined by potentiometric titration. The temperature when the pC_H values were measured was 21.5 ± 0.2°.

After the pC_H determination, the solutions were acidified with perchloric acid to p$C_H \simeq 1$ and removed from the glove-box. Finally, the ytterbium was titrated photometrically with EDTA at pC_H 5.8 with Xylenol Orange as indicator ($\lambda = 575$ nm).

The precipitation procedure differed from previous ones[1–3] in that all the solutions prepared from the original 200-ml portion (p$C_H \simeq 4$) were treated separately. The pre-

cipitation procedure was repeated several times—with individual 200-ml initial portions—until the whole pC_H region 6–14.5 had been covered.

RESULTS AND CONCLUSIONS

The experimental results are shown in Fig. 1. No experiments were done at pYb′ < 1 as it was impossible to apply adequate corrections for the ionic strengths, which exceeded 1.

Above pC_H 13, the pC_H was calculated from titration results. For that purpose the molar concentration product for the autoprotolysis of water was estimated as pQ_W = 13.92 [I = 1 ($NaClO_4$), 21.5°]. This value was deduced from the literature[12–15] by applying the temperature correction $dpQ_W/dT = 0.033$[15] to the value pQ_W = 13.80 for a sodium perchlorate medium (I = 1, 25°). We also did some experiments to establish pQ_W by the titration method of Molina *et al.*[12] Contrary to their findings ($pQ_W^{2.5}$ = 13.60) we confirmed the selected value $pQ_W = 13.92 \pm 0.10$. There is a complication in using this value at high pC_H.

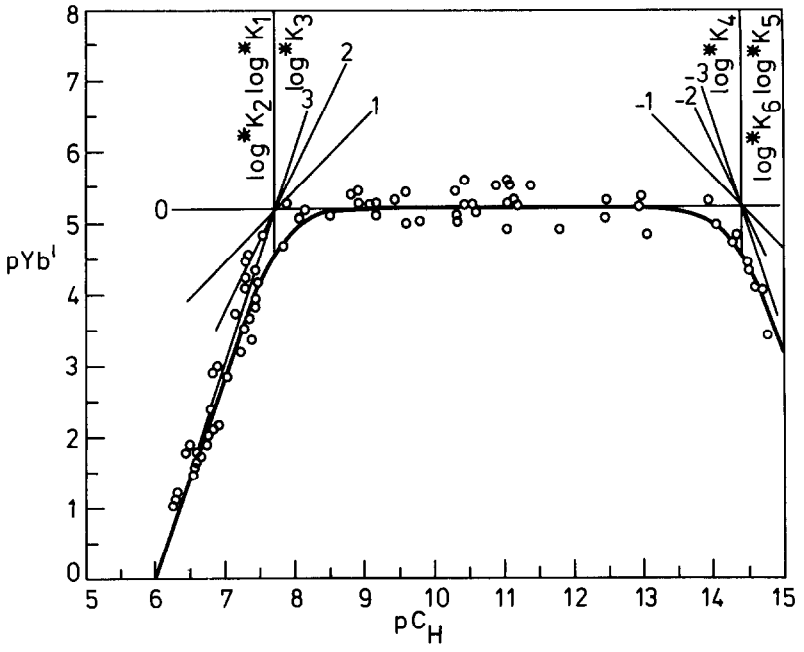

Fig. 1. The solid curve [the borderline of precipitation of $Yb(OH)_3$] was constructed with the values given in Table 3. The numbers −3, −2, −1, 0, 1, 2 and 3 near the straight lines correspond to the slopes of the straight-line segments [equations (1a)–(1g) in Table 2] approximating the exact envelope curve. The circles denote the experimental results. The vertical lines separate the regions where Yb^{3+}, $Yb(OH)_3$ and $Yb(OH)_6^{3-}$ respectively are the major species present.

Between pC_H 13 and 14, the sodium perchlorate in the medium is replaced gradually by sodium hydroxide. This slightly changes pQ_W in an unknown way.[14,15] Above pC_H 14 the ionic strength increases sharply with pC_H. This influences pQ_W to the extent of roughly 0.10 per unit of I, as we guess by comparison with other media.[14,15] It is rather speculative to compensate for this effect, and it was not done here, so conclusions from measurements above pC_H 14 should be considered with some reserve.

The borderline of the precipitation region of Yb consists of three, nearly straight parts connected by sharp bends. Regression analysis of the steep part up to pYb′ = 4.5 shows that the slope can be estimated as 2.82 ± 0.16. From theory, we know that the slope is equal to the electrical charge of the ion with the general composition $Yb_p(OH)_q^{(3p-q)+}$ that is the major ion present in the solution and in equilibrium with the precipitate. If a mixture of ions with differing charges were present in equal amounts, the precipitation borderline would show a strongly negative curvature. From the position of the experimental points (Fig. 1), it is clear that the steep part is nearly straight. Thus the solution must contain either one ion with an electrical charge of 3+ or a mixture of ions, all with the same charge, 3+. If all possible combinations with $(3p - q) = 3$ are considered, we get a series of $(p;q)$ of which the first are (1;0), (2;3), (3;6).

The occurrence, stability and structure of polynuclear hydroxides have been investigated extensively by physical chemists. A survey of the structures that have been identified reliably and confirmed experimentally has been given by Baes and Mesmer.[16] The variety is by no means as large as many investigators once thought. In accordance with this, structures such as $Yb_2(OH)_3$ and $Yb_3(OH)_6$ are rejected as unlikely to exist in major amounts. Yb^{3+} can be regarded as the main ion in solution at pC_H below 7.5.

This conclusion leads to the following set of equations for the straight-line segments which together compose the borderline of precipitation (Table 2).

If equation (1a) from Table 2 is assigned to the steep part of the borderline, the best fit to the experimental points is obtained with

$$pYb' = 3pC_H - (17.95 \pm 0.06) \quad (2)$$

Hence

$$\log {}^*K_{S0} = (17.95 \pm 0.06) \quad (3)$$

Equation (1d) can be assigned to the horizontal part of the borderline. The best fit corresponds to

$$pYb' = 5.24 \pm 0.04 \quad (4)$$

From equations (1d), (3) and (4), it follows that

$$\log {}^*\beta_3 = -23.19 \quad (5)$$

At high pC_H values ytterbium behaves amphoterically. The best fit to the experimental points in this region is obtained by assuming $Yb(OH)_6^{3-}$ to be the ion in solution. This leads to

$$pYb' = -3pC_H + (48.29 \pm 0.06) \quad (6)$$

from which follows

$$\log {}^*\beta_6 = -(66.24 \pm 0.06) \quad (7)$$

The values of ${}^*\beta_3$ and ${}^*\beta_6$ can be substituted in the general equation of the envelope curve.[3] If the terms for which no data are available are omitted, we get the equation

$$[Yb']_{max} = 10^{-3pC_H+17.95} + 10^{-5.24} + 10^{+3pC_H-48.29} \quad (8)$$

With this equation a good fit to the experimental points is obtained. From this fact the following conclusions can be drawn.

(*a*) The other straight-line segments corresponding to equations (1b), (1c), (1e) and (1f) contribute to the envelope curve either not at all or at most marginally.

(*b*) Marginal contribution of the lines (1b) and (1c) corresponds to the situation that the line segments (1a)–(1d) all intersect in one point (7.73; 5.24). As the intersecting points determine the p^*K_i values ($pC_H = p^*K_i$), this leads to $p^*K_1 = p^*K_2 = p^*K_3 = 7.73$ ($= -\frac{1}{3}\log {}^*\beta_3$). Similarly the segments corresponding to (1d)–(1g) intersect in the point (14.35; 5.24). Hence $p^*K_4 = p^*K_5 = p^*K_6 = 14.35$.

(*c*) The foregoing positions of the two groups of line segments are limiting positions. If (1b) and (1c), with slopes 2 and 1 respectively, are situated more to the right, the envelope curve is pushed away from the experimental points near the bend and this conflicts with (*a*). If they are positioned more to the left, the multiple intersection splits up into single points lying on both sides of pC_H 7.73. In any case this leads to $p^*K_1 > 7.73$. Consequently a reverse in the logical sequence of $p^*K_1 \leq p^*K_2 \leq p^*K_3$ occurs and this is fairly unlikely. Hence, the limiting position with all

Table 2. Equations for straight line segments of the precipitation borderline

Equation number	p	q	Slope $(3p - q)$	Equation
(1a)	1	0	3	$pYb' = 3pC_H - \log {}^*K_{S0}$
(1b)	1	1	2	$pYb' = 2pC_H - (\log {}^*K_{S0} + \log {}^*\beta_1)$
(1c)	1	2	1	$pYb' = pC_H - (\log {}^*K_{S0} + \log {}^*\beta_2)$
(1d)	1	3	0	$pYb' = -\log {}^*K_{S3} = -(\log {}^*K_{S0} + \log {}^*\beta_3)$
(1e)	1	4	−1	$pYb' = -pC_H - (\log {}^*K_{S0} + \log {}^*\beta_4)$
(1f)	1	5	−2	$pYb' = -2pC_H - (\log {}^*K_{S0} + \log {}^*\beta_5)$
(1g)	1	6	−3	$pYb' = -3pC_H - (\log {}^*K_{S0} + \log {}^*\beta_6)$

Table 3. Values for the constants at 21.5°C

$\log {}^*\beta_1 = -7.7$	$\log {}^*\beta_4 = -37.5$	
$\log {}^*\beta_2 = -15.5$	$\log {}^*\beta_5 = -51.9$	$\log {}^*K_{s0} = 18.0$
$\log {}^*\beta_3 = -23.2$	$\log {}^*\beta_6 = -66.2$	

segments going through one point is the most likely. Similar arguments hold for the second group of lines in the alkaline region.

When the values of $\log {}^*\beta_i$ ($i = 1, \ldots . 6$) and $\log {}^*K_{s0}$ are substituted in the general equation for the envelope curve, equation (8) is extended by four terms to become

$$[Yb']_{max} = 10^{-3pC_H+17.95} + 10^{-2pC_H+10.22} + 10^{-pC_H+2.49} + 10^{-5.24} + 10^{pC_H-19.59} + 10^{2pC_H-33.94} + 10^{3pC_H-48.29} \quad (9)$$

The added terms contribute marginally to the shape of the envelope curve. The bold curve in Fig. 1 has been constructed with this extended equation. The constants derived (Table 3) can be regarded as useful for analytical practice.

Ivanov-Emin and co-workers[17] studied the solubility of ytterbium hydroxide in strongly alkaline solution (0.01–18M). They found that the solubility reaches a maximum at an alkali concentration of 14.1M and sharply decreases at higher concentration where the solid phase sodium hexahydroxoytterbate precipitates. This also confirms the existence of $Yb(OH)_6^{3-}$ as an entity in equilibrium with solid ytterbium trihydroxide. From their results it can be concluded that p^*K_4, p^*K_5 and $p^*K_6 = 14.1 \pm 0.2$. Although their values refer to equilibrated solutions, the agreement with our results is striking.

If we assign the uncertainty in the position of the experimental points completely to pYb′, a standard deviation of 0.45 is found for the individual pYb′ values. This holds for both the steep parts and the horizontal part.

As colloidal turbidity frequently accompanied precipitate formation in the pC_H region 6–7, the influence of this phenomenon on pYb′ was studied. The colloidal turbidity disappeared after 24 hr of aging. The pC_H hardly changed (<0.05) on aging; comparison of the titration results before and after aging showed that pYb′ varied by about 0.20 in these cases. As these changes are smaller than the standard deviation for pYb′, the influence of colloid formation on the results can be neglected.

DISCUSSION

Concerning the differences between our results and those listed in Table 1, the same comment can be made as before.[1–3] Our "fresh precipitate" measurements turned out to be fairly reproducible and rather insensitive to aging for 24 hr. Concerning the errors in the constants, only those in $\log {}^*K_{s0}$, $\log {}^*\beta_3$ and $\log {}^*\beta_6$ can be deduced from the measurements (0.06, 0.07 and 0.1 respectively). As the other constants are found partly by analogy, it is a bit speculative to discuss their errors. We estimate that their uncertainty is of the same order.

Our method is not able to distinguish between species (such as Yb^{3+}, $Yb_2(OH)_3^{3+}$) that have the same electrical charge. We said before that there are good reasons to assume that Yb^{3+} is the main component in acidic solution, but this does not, however, exclude the existence of minor amounts of polycomplexes. Other experimental techniques may clarify the situation; the existence of polycomplexes has never been indicated in the literature. Also, because for stereochemical and statistical reasons[16] the formation of polycomplexes is fairly unlikely, we assume that they are not formed under the experimental conditions in our experiment.

SHORT COMMUNICATIONS

SIMPLE AND INEXPENSIVE MICROCOMPUTER-CONTROLLABLE STEPPING MOTOR AND DRIVE CIRCUIT

D. F. MARINO and J. D. INGLE, JR.†
Department of Chemistry, Oregon State University, Corvallis, Oregon 97331, U.S.A.

(*Received* 3 *August* 1981. *Accepted* 20 *September* 1981)

Summary—The construction of a simple stepper motor and drive circuit made from commercial components is described. The use of the stepper motor for a monochromator wavelength drive is discussed. The rate and direction of scan can be controlled by either a hardwired timer circuit or by a microcomputer.

Stepping motors are important components of many types of analytical instrumentation where precise mechanical positioning is required.[1] Common applications include the wavelength drive for monochromators and positioning of components (*e.g.*, a burner in flame spectrometry) mounted on translational stages. Commercial stepping-motor drive and control circuitry is available to modify existing instrumentation but is usually relatively expensive. This paper is concerned with the construction of a stepper-motor and drive circuit from commercial components at cost of less than $100 for parts.

The particular application for which the stepping-motor unit was designed is the monochromator drive for a Schoeffel (Westwood, NJ) GM100 monochromator, which is used for the excitation and emission monochromators of a molecular fluorescence spectrofluorometer.[2] The monochromator is normally provided with a synchronous-motor wavelength-drive set at one prechosen scan-rate, and a stepping-motor drive is not available from the company. A stepping-motor drive was needed to allow different scan-rates to be chosen with the scan-rate controlled either by a separate clock circuit or by a microcomputer.

It was also desired to be able to synchronize the monochromator scan-rate to the recorder-drive scan-rate so that the monochromator and recorder drive could be started simultaneously and so that one inch on the recorder chart paper corresponded to a prechosen number of nanometers. The Heath (Benton Harbor, MI) SR255B recorder employed uses a stepper-motor drive and has provision for using an external pulse train. If the external pulse train is set to 50 Hz, the switch-selectable recorder scan-rates (in./min) can be used directly.

EXPERIMENTAL

Figure 1 presents the schematic of a simple stepping-motor and drive unit based on the North American Philips Controls Corp. (Cheshire, CT) SAA1027 driver IC and K82701-P2 bidirectional stepper motor ($15 and $28, respectively).[3,4] The driver IC is designed to drive directly 4-phase stepper motors which require less than 350 mA per phase. The bidirectional stepping motor has a step angle of 7°30′ (48 steps per revolution) and a torque of about 6 oz. in. (~430 g.cm) at 100 steps/sec. The maximum step-rate is about 300 steps/sec.

Normally the set is tied high and the direction and trigger inputs control the stepper motor. A logic 1 (5-V) signal applied to the direction input is translated into a +12-V signal by IC1 (buffer) and fed into IC3 (driver) which provides for a counterclockwise rotation of the stepper. Likewise, a logic 0 (0-V) signal to the directional input will result in clockwise rotation. Upon application of a positive TTL edge (0 → 5 V, 50 nsec minimum width) at the trigger input, IC2 (one-shot) delivers a 0.23-msec logic 0 pulse to IC1, which translates the TTL pulse into a +12 → 0 V pulse for IC3 and causes the motor to step one step. IC2 is set near the minimum pulse width that IC3 will recognize. Components R1, C1, and C2 provide added noise immunity for IC3, while R2 provides bias current for the four internal NPN drivers in IC3. Diodes D1–D4 are for elimination of transients caused by switching of the motor windings. Finally, IC4, IC5, C3, D5, and T1 provide regulated +5 and +12 V power for the circuit and may be eliminated if external power supplies are available.

Figure 2 is the schematic for the controller constructed to run the stepper motor when connected to the monochromator. Master clock IC1 is adjusted with R1 and a frequency meter to provide a 400-Hz pulse train. IC2 divides this signal by 8 to provide a 50-Hz signal suitable for the external drive of the chart-recorder employed, which synchronizes the chart-recorder and stepper-drive pulses. IC3 and IC4 divide the 400-Hz master clock signal by 25 to produce a 16-Hz pulse train for IC5 and IC6. IC5 and IC6 provide a dip-switch programable divide-by-*N* network,[5] the output of which is buffered by T2. Division

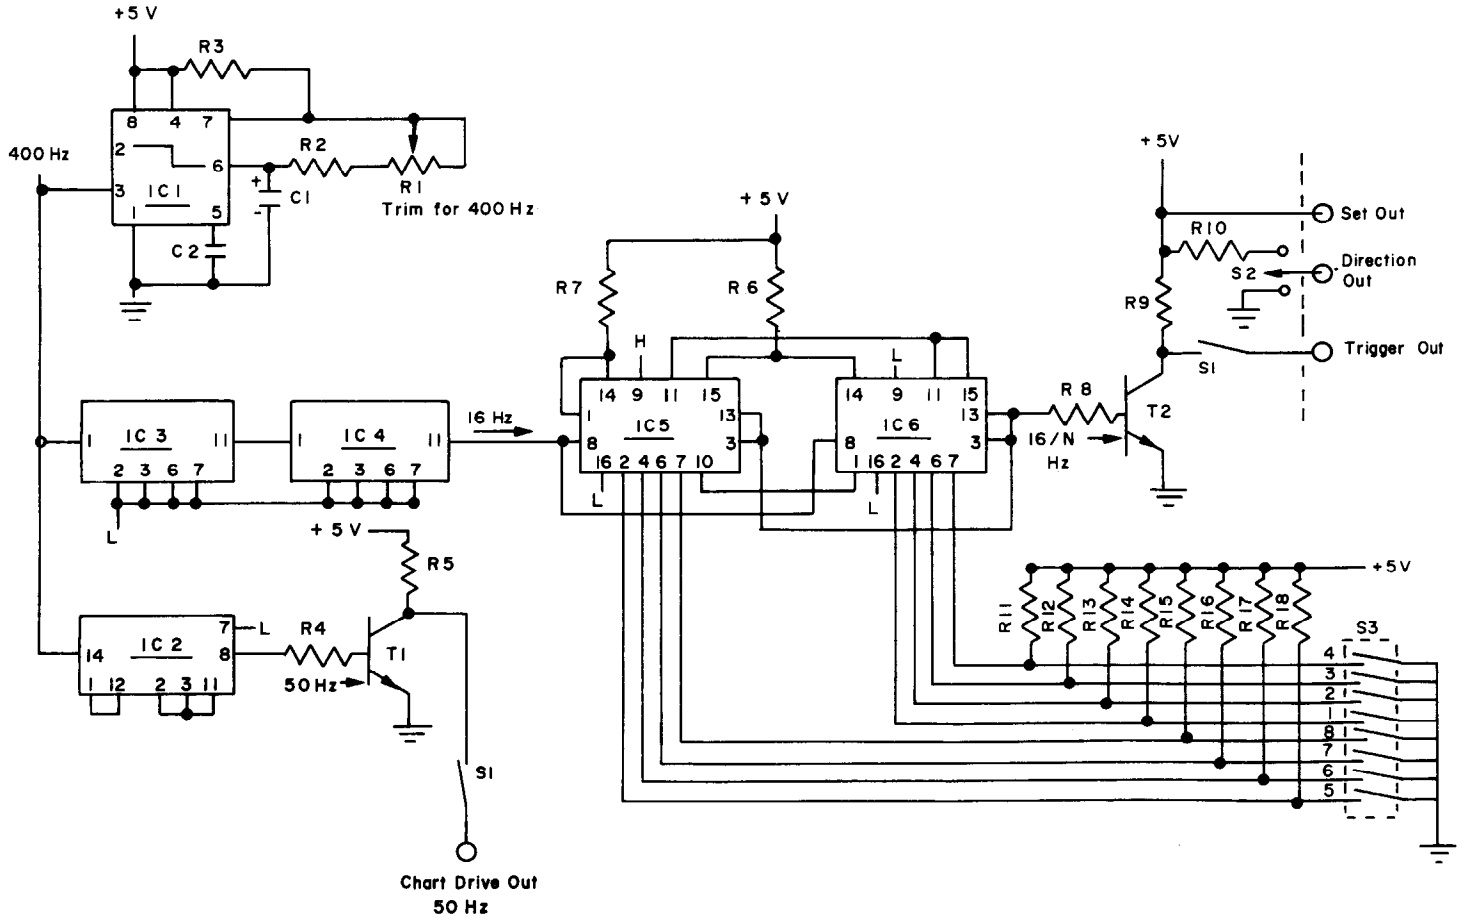

Fig. 2. Stepping-motor control circuit. IC1, 555 timer; IC2, IC3, IC4, 7490 decade counter; IC5, IC6, DM8520 modulo-*N*-divider; R1, 2 kΩ 10 turn; R2, 18 kΩ; R3, R6, R7, R9, R10, 1 kΩ; R4, R8, 10 kΩ; R5, 820 Ω; R11–R18, 1.2 kΩ; C1, 0.1 μF tant; C2, 0.01 μF cer; S1, DPST; S2, SPDT; S3, 8-pole dip switch.

by factors ranging from 2 to 255 is determined by the positions of the 8 switches in S3, allowing for output pulse trains of from 8 to 0.0627 Hz. Switch S1 allows the stepping motor and chart drive to be started simultaneously, while switch S2 allows setting of the direction of rotation of the stepping motor. The circuit is powered by a regulated +5-V, 300-mA power supply.

The shaft of the Philips stepping motor was connected to the wavelength-drive shaft of the GM100 monochromator with 1:1 gears. The worm-screw wavelength shaft of the monochromator is set up for 50 nm/revolution. With the Philips stepping motor and the control circuitry of Fig. 2, the scan-rate can be varied over the 4–500 nm/min range, with each step corresponding to 1.04 nm.

The stepping-motor drive circuit and monochromator can also be controlled directly by a KIM 1 single-board microcomputer (MOS Technology, Norristown, PA) to produce an intelligent monochromator-drive system. Only two I/O lines are needed for the direction and trigger inputs. With minimal software, the computer can duplicate the functions of the circuit in Fig. 2 except that the scan-rates and direction are keyboard-controlled. With more extensive software, the computer can be programmed to control the wavelength range scanned, to implement repetitive scanning, and to slew between wavlengths. Once the initial wavelength setting of the monochromator is keyed in, suitable software will keep track of the wavelength at any time. It is implicitly assumed that the stepper motor responds correctly to all pulses from the computer, and does not respond to any other stimulus.

Other 4-phase stepping motors (*e.g.*, with different torques or stepping angles) from Philips or other manufacturers can be used with the control circuitry described. Stepper motors with larger current requirements may be used if the four external transistors are added as shown in the inset of Fig. 1 (dashed lines) and if a larger 12-V power supply is employed.

SELECTIVE EXTRACTIVE SEPARATION OF ZINC, CADMIUM AND LEAD FROM IODIDE MEDIA WITH MESITYL OXIDE

T. PRASADA RAO and T. V. RAMAKRISHNA*
Department of Chemistry, Indian Institute of Technology, Madras-600 036, India

(*Received* 8 *June* 1981. *Accepted* 16 *August* 1981)

Summary—The extractive separation of zinc, cadmium and lead with mesityl oxide has been investigated as a function of iodide concentration and acidity. The recovery of these metals from the organic phase by back-extraction and the behaviour of other elements under the optimal conditions established for each metal ion have been examined. The method developed has been applied to the separation of these metals from rock samples before determination by spectrophotometry.

Group extraction is generally preferred for the concentration and separation of trace elements from complex matrices before determination by atomic-absorption spectrophotometry. Such an approach, however, is unsuitable when the methods employed for the determination are poorly selective. In such cases, for speed, economy and simplicity, it would be of great advantage to be able to use successive separations from a single sample with the minimum of manipulation. This paper presents such a method for the separation of zinc, cadmium and lead and its evaluation for separation of these elements from silicate rock samples.

Extraction from iodide medium was selected because little work has been done on its use for separation of these metals, the main emphasis having been on selective extraction of cadmium from zinc with solvents such as cyclohexanone or TBP,[1] aliphatic alcohols,[2] Amberlite LA-2 in xylene[3] and tribenzylamine in chloroform.[4] Zinc and cadmium can be simultaneously extracted from 1.0*M* hydriodic acid into xylene containing Aliquat 336-S-I,[5] and the zinc selectively stripped with 1*M* sodium sulphite. Methyl isopropyl ketone has been recommended for the extraction of lead from 1*M* potassium iodide.[6]

The proposed method is based on extraction of cadmium and lead into mesityl oxide from a mixture of zinc, cadmium and lead in 0.05*M* potassium iodide, followed by extraction of the zinc into mesityl oxide after the iodide concentration has been raised to >3.0*M*. The lead can be stripped quantitatively with saturated potassium iodide solution. The parameters governing the extraction and stripping equilibria have been investigated.

EXPERIMENTAL

Reagents

Standard zinc, cadmium and lead solutions (each 100 ppm), potassium iodide solutions (saturated and 0.5*M*) and 1*M* ammonia/ammonium chloride buffer (pH 10.0). Mesityl oxide for extraction.

General procedure

Transfer a portion of sample solution into a 60-ml separatory funnel. Add enough sulphuric acid and potassium iodide to make their concentrations 1*N* and 0.05*M* respectively and shake the solution for 1 min with 10 ml of mesityl oxide. Allow the phases to separate and preserve the organic phase (**I**) for the recovery of cadmium and lead. Transfer the aqueous phase containing zinc into another separatory funnel and add sufficient potassium iodide to make its concentration >3.0*M*. Extract with 10 ml of mesityl oxide and retain the organic phase (**II**) for the recovery of zinc.

Shake the organic phase (**I**) with two 5-ml portions of saturated potassium iodide solution for 5 min each to strip the lead, leaving cadmium in the organic phase (**III**). Strip zinc and cadmium from organic phases (**II**) and (**III**) respectively by shaking each with 5 ml of ammonia buffer for 5 min and washing with 5 ml of water.

Determination

Quantitatively collect the stripping (and wash) solutions in 25-ml standard flasks and proceed as follows. If the concentrations are high, use an appropriate fraction.

Zinc.[7] Add, with mixing, 2.5 ml each of 10*N* orthophosphoric acid and 5% potassium thiocyanate solution and 5 ml of 0.005% Rhodamine 6G solution, followed by 1 ml of 1% gelatin solution. Dilute to the mark with distilled water and measure the absorbance against a reagent blank in 40-mm cells at 575 nm.

Cadmium.[8] Add 2.5 ml each of citrate buffer (pH 4.0), 10% potassium iodide solution and 0.05% pyronine G solution followed by 1 ml of 1% gelatin. Dilute to the mark and measure the absorbance against a reagent blank at 575 nm in 10-mm cells.

Lead.[9] Add 2.5 ml each of ammonia buffer (pH 10.0) and $2 \times 10^{-3}M$ 4-(2-pyridylazo)resorcinol and make up to the mark. Measure the absorbance against a reagent blank in 10-mm cells at 530 nm.

Establish the concentration by reference to appropriate calibration graphs prepared from the respective standard metal solutions for 0–5 μg of zinc, 0–15 μg of cadmium and 0–125 μg of lead.

RESULTS AND DISCUSSION

Preliminary studies were made with 100 μg of zinc, cadmium or lead in 10 ml of aqueous phase and

* To whom reprint requests should be sent.

extraction into 10 ml of organic phase by shaking for 5 min. The degree of extraction was determined by establishing the unextracted metal content of the aqueous phase by atomic-absorption spectrophotometry.

The extraction of zinc, cadmium and lead as a function of potassium iodide concentration is shown in Fig. 1. For quantitative extraction of cadmium and lead, the iodide concentration should be greater than 0.01 and 0.04*M* respectively. Higher iodide concentrations do not affect the extraction of cadmium, but above 1.5*M* decrease the extraction of lead, which becomes negligible at iodide concentrations $>7.0M$. The extraction of zinc is insignificant at iodide concentrations up to 0.08*M* and becomes quantitative only when the iodide is $\geqslant 3.0M$.

Figure 2 shows the effect of acidity, varied by adding sulphuric acid or sodium hydroxide solution. Though the extraction of lead is quantitative at pH $\leqslant 5.0$, acidities greater than 0.2 and 0.5*M* respectively are needed for the extraction of zinc and cadmium.

Extraction from 0.2–3.0*M* hydrochloric acid instead of sulphuric did not affect the extraction of lead but reduced the extraction of zinc and cadmium to some extent, giving 98% extraction for zinc and 84% for cadmium from 0.4–0.5 and 0.1–0.3*M* hydrochloric acid respectively.

1,2-Dichloroethane, n-butanol, cyclohexanol, isobutyl methyl ketone (IBMK), cyclohexanone, ethyl acetate and diethyl ether were tested as extraction solvents (5 min shaking) but only IBMK and cyclohexanone proved satisfactory, and then only for cadmium. Cyclohexanone gave 96% extraction of lead and IBMK 85% for zinc. Diethyl ether and 1,2-dichloroethane were found to give very poor extraction (<1%).

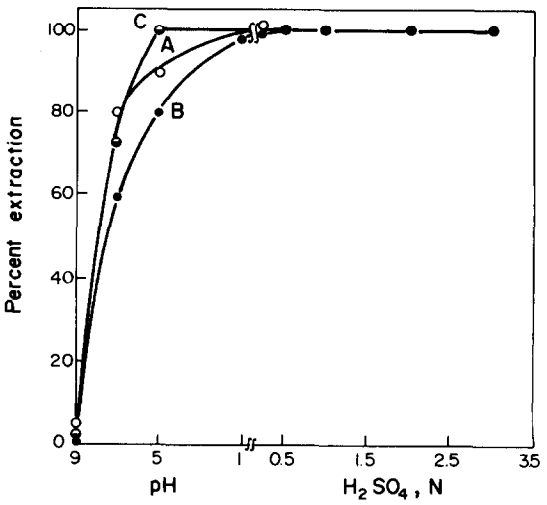

Fig. 2. Effect of H_2SO_4 or pH on extraction behaviour of A, zinc (4*M* KI); B, cadmium (0.05*M* KI); C, lead (0.05*M* KI).

Studies with mesityl oxide showed that a shaking time of 30 sec was sufficient for the quantitative extraction of zinc, cadmium and lead and that an aqueous to organic phase volume ratio of up to 10:1 was without influence on the extraction behaviour of these elements.

Ammonia buffer (pH 10.0) was found to strip both cadmium and lead quantitatively in a single step, but though water was found to strip lead quantitatively, it would also strip 65% of the cadmium. Stripping with saturated potassium iodide solution was therefore used since high concentrations of iodide prevent the extraction of lead into mesityl oxide (Fig. 1). Zinc was found to be stripped quantitatively with ammonia

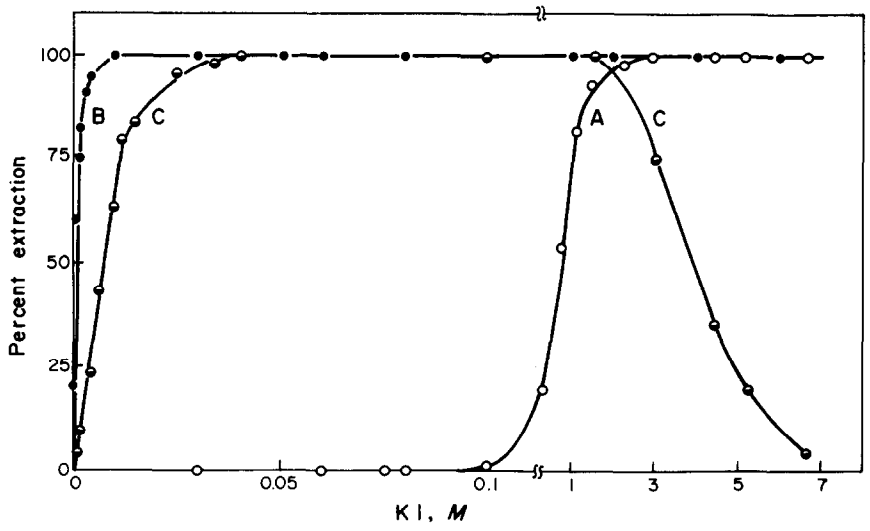

Fig. 1. Effect of potassium iodide on extraction behaviour of zinc, cadmium and lead with mesityl oxide (1*N* H_2SO_4; A, zinc; B, cadmium; C, lead).

Table 1. Results obtained by spectrophotometry for synthetic mixtures after separation by proposed method

No.	Composition (μg)	Amount found, μg		
		Zn	Cd	Pb
1	Zn(100) + Cd(100) + Pb(100)	99.6	100	101.2
2	Zn(50) + Cd(500) + Pb(20)	50.0	490	20.5
3	Zn(500) + Cd(5) + Pb(10)	496	5.2	9.6
4	Zn(5) + Cd(5) + Pb(500)	5.0	5.0	503
5*	Fe(1000) + Mn(1000) + Cu(500) + Zn(20) + Cd(20) + Pb(20)	20.8	19.6	20.5
6	Ag(500) + Co(500) + Ni(500) + Zn(10) + Cd(5) + Pb(10)	9.8	5.0	9.6
7*	Ni(500) + As(500) + Cu(500) + Zn(10) + Cd(10) + Pb(20)	10.0	10.2	20.6
8	Ca(5000) + Mg(5000) + Al(5000) + Zn(5) + Cd(5) + Pb(20)	5.0	5.2	20.0

* In the presence of 5 ml of 20% ascorbic acid solution.

buffer, but water gave incomplete stripping (85%) in a single step.

The results for extraction and stripping of each of these metals in the range 5–2000 μg, either separately or in mixtures in varying ratios with a total amount of 5 mg, showed excellent recovery for cadmium and lead over the range studied and for zinc up to 500 μg. Zinc in amounts greater than 500 μg was found to be subject to co-extraction with cadmium and lead to the extent of 2–3% from 0.05*M* potassium iodide medium, but a single wash with 10 ml of 0.05*M* potassium in 1*N* sulphuric acid would remove the co-extracted zinc without affecting the recovery of cadmium and lead.

Nature of the extracted species

The plots of log *D* *vs.* log $[I^-]$ for zinc, cadmium and lead were straight lines with slopes of 2.10, 2.08 and 2.01 respectively indicating that all three metals were extracted as MI_2 species. When the iodide concentration was greater than 1.5*M*, the plot for lead gave a slope of −4.3 indicating that formation of PbI_4^{2-} was responsible for inhibiting the extraction. However, the presence of a large excess of iodide did not affect the extraction of cadmium, although CdI_4^{2-} is known to exist. Quantitative extraction of cadmium from 1.5*M* iodide required at least 2 min of shaking, in contrast to the 30 sec required for extraction from 0.05*M* iodide, suggesting that higher iodide complexes with cadmium are formed but merely reduce the rate of extraction.

Attempts to establish the degree of solvation of the extracted species were unsuccessful, so presumably no specific solvate is formed.

Interferences

Hg(II), Bi, Sb(III), Cu(II), Tl(I), Ag, As(III), Fe(III), Co(II), Ni and Mn(II) were tested at the 100-μg level for interference. To avoid liberation of iodine, the studies on Cu(II) and Fe(III) were made after addition of ascorbic acid.

The extraction of As(III), Co(II), Fe(III), Ni and Mn(II) was found to be negligible from 0.05 and 4*M* iodide. Hg(II), Bi, Ag were quantitatively extracted and Tl(I) and Sb(III) 88% extracted from 0.05*M* iodide into mesityl oxide, and saturated potassium iodide solution gave 75% stripping of Sb(III) and complete stripping of Hg(II), Bi, Ag and Tl(I). Sb(III) could be completely stripped with ammonia buffer.

Table 2. Analysis of silicate rocks*

Sample	Metal added, μg/g			Metal found, μg/g Spectrophotometry			AAS		
	Zn	Cd	Pb	Zn	Cd	Pb	Zn	Cd	Pb
1. Basalt	—	—	—	84	7.0	438	84	7.1	440
	40	5	200	126	12.4	632	125	12.4	639
	80	10	500	163	17	940	165	17.0	945
2. Dolerite	—	—	—	107	9.8	432	105	10.0	430
	50	10	200	156	20	621	155	20.6	628
	50	20	500	156	28.8	930	155	29.2	938
3. Jasperoid	—	—	—	6.8	14.0	364	6.8	14.4	360
	4	10	100	10.6	25.0	460	10.3	25.0	462
	10	20	300	16.6	35.0	652	16.8	35.6	658

Copper could be completely extracted from 4.0*M* iodide and stripped with ammonia buffer, like zinc.

The influence of 5 mg each of Al, Ca, Mg, Fe(III), Na and K, which are usually present in rock samples, on the recovery of 20 μg each of zinc, cadmium and lead was examined. The results indicated no loss in the recovery of these metals.

Application

The method developed was applied in conjunction with spectrophotometry for the determination of zinc, cadmium and lead in synthetic mixtures, by the procedures described. Zinc was determined with Rhodamine 6G[7] and cadmium with pyronine G.[8] As the colour reaction of lead with PAR[9] was unaffected by the presence of excess of iodide, this method was used for lead. The results are shown in Table 1.

The zinc, cadmium and lead contents of three rock samples—basalt, dolerite and jasperoid—were then determined by spectrophotometry after separation by the method developed and compared with those obtained by atomic-absorption spectrophotometry.[10] The samples were opened out by repeatedly heating 0.5 g of finely ground material with sulphuric acid and hydrofluoric acid.[10] The residue was dissolved in the minimum volume of dilute hydrochloric acid needed and made up to 50 ml with water. Aliquots were treated with 2 ml of 10% ascorbic acid solution before analysis. The results, and those obtained for samples spiked with the metal ions under study, are shown in Table 2. Clearly, the proposed method works satisfactorily.

EVALUATION OF SULPHURIC ACID TREATMENT AS THE CLEAN-UP STEP FOR THE ESTIMATION OF BHC AND DDT IN FATTY AND NON-FATTY FOODS

PARM PAL SINGH and RAM PARKASH CHAWLA
Department of Entomology, Punjab Agricultural University, Ludhiana, India

(*Received* 5 *May* 1981. *Revised* 18 *August* 1981. *Accepted* 14 *September* 1981)

Summary—The potential of sulphuric acid treatment for clean-up of 10 food composites comprising 36 food items of north Indian total diet has been evaluated for the estimation of BHC and DDT residues by gas chromatography with electron-capture detection. In all cases the clean-up was satisfactory without resort to column chromatography. The chromatograms obtained were free from interference by the co-extractives. The method is simple, rapid and economical.

Adsorption column chromatography is invariably used in standard procedures for final clean-up in multiresidue analysis of organochlorine insecticides by gas chromatography with electron-capture detection (GC–EC).[1–3] Additional clean-up by passage through a Celite–sulphuric acid column[4,5] or by shaking with concentrated sulphuric acid[6] has also been suggested for eliminating interferences in the estimation of acid-stable insecticides and PCBs in fatty substrates. The direct treatment of a petroleum ether solution of butter fat with concentrated sulphuric acid in a specially designed apparatus has been used in the estimation of several organochlorine residues[7,8] and adopted for estimation of certain organochlorine insecticides in vegetable oils[9] and milk fat.[10,11] The present work extends the use of sulphuric acid as clean-up agent to non-fatty foods.

EXPERIMENTAL

Reagents

Acetone, acetonitrile and n-hexane, all redistilled in all-glass apparatus; concentrated sulphuric acid; anhydrous sodium sulphate, sodium chloride. The suitability of the reagents for residue analysis was checked by running reagent blanks.

BHC (α-, β-, γ-, δ-isomers), *p, p'*-DDD, *p, p'*-DDE and *p, p'*-DDT (all >95% purity) were obtained from the U.S. Environmental Protection Agency, and used as reference standards.

Apparatus

A Packard model No. 7624 gas chromatograph equipped with a tritium-source electron-capture detector and a 1.84 m × 2 mm glass column packed with 1.5% SP-2250 + 1.95% SP-2401 on 110–120 mesh Supelcoport. Operating temperatures were: injector 210°, column 190°, detector 200°. Nitrogen was used as carrier-gas at a flow-rate of 70 ml/min.

The extraction column[7] was made locally.

Preparation of total diet composites

Representative amounts of the constituents of each food group of the north Indian diet (Table 1) were processed (washed, peeled, baked, cooked, *etc.*) according to local practices and homogenized in a blender to obtain the composites. To avoid transfer of residues from fats and oils, boiling was used instead of frying. For foods that are eaten raw as well as cooked, half the composite was raw and the rest cooked.

Extraction and partitioning

Cereals, pulses, root vegetables and other vegetables. Composite equivalent to 50 g fresh weight was extracted with 100 ml and then 50 ml of acetonitrile by blending for 3 min each time. The combined extract was transferred to a 1-litre separatory funnel, diluted with 600 ml of 5% aqueous sodium chloride solution and partitioned with two 100-ml portions of n-hexane. The combined n-hexane layers were dried over anhydrous sodium sulphate and concentrated on a flash evaporator to about 10 ml, followed by concentration to about 5 ml by a gentle stream of nitrogen.

Fruits. Composite equivalent to 50 g fresh weight was extracted with 100 ml and then 50 ml of a 2:1 v/v acetonitrile–water mixture and further processed as for cereals *etc.*

Milk and milk products, meat and eggs and sugar, condiments, preserves, etc. Composite equivalent to 50 g fresh weight was extracted with 100 ml and then 50 ml portions of a 2:1 v/v n-hexane–acetone mixture by blending for 3 min each time. The combined extract was transferred to a 1-litre separatory funnel and washed with two 300-ml portions of 5% aqueous sodium chloride solution, then dried and concentrated as for cereals, *etc.*

Oils and fats. Three 5-g portions of composite were dissolved in separate 100, 15 and 15 ml portions of n-hexane.

Water and beverages. A 1-litre portion of composite was partitioned with two 100-ml portions of n-hexane. The combined extract was dried and concentrated as for cereals, *etc.*

Sulphuric acid clean-up

For all composites except oils and fats. The concentrated n-hexane extract was taken in a 25-ml separatory funnel and sulphuric acid was added dropwise from a Pasteur pipette till the n-hexane layer became clear. The spent sul-

Table 1. Composition of various food composites

Composites	Composition*
Cereals	Wheat flour (79) + rice (16) + bread (5)
Pulses	Rajmash (25) + black gram (25) + green gram (25) + soya beans (25)
Root vegetables	Potato (69) + onion (23) + carrot (8)
Other vegetables	Tomato (60) + cauliflower (24) + coriander leaves (6) + gourd (6) + green chillies (4)
Fruits	Mango (66) + Sapota (34)
Oils and fats	Hydrogenated vegetable oil (68) + butter fat (32)
Milk and milk products	Milk (83) + curd (16) + cheese (1)
Meat and eggs	Chicken (45) + eggs (55)
Sugar, condiments, preserves, *etc.*	Sugar (58) + salt (22) + fruit cake (4) + fennel (4) + tomato ketchup (4) + turmeric (3) + coriander (3) + chillies (2)
Water and beverages	Tap water (66) + tea infusion (26) + soft drinks (6) + coffee infusion (2)

* Numbers in brackets represent per cent of various food items (raw weight basis) in a composite. These values were based on a dietary survey.

phuric acid was discarded and the upper layer washed with 10-ml portions of distilled water till neutral.

Only 15 ml of sulphuric acid were required for complete clean-up, except for the milk and milk products, meat and eggs, and sugar, condiments, preserves, *etc.*, which required 30–40 ml.

Oils and fats composite. The Veirov and Aharonson technique[8] was used. The 100 ml of n-hexane containing 5 g of sample was taken in a glass column fitted with a stopcock, and 100 ml of sulphuric acid were added dropwise. The used sulphuric acid was occasionally discarded. The second 5-g sample (in 15 ml of n-hexane) was added to the column and again 100 ml of sulphuric acid were added dropwise. This step was repeated with the third 5-g sample. After discard of the lower phase, the n-hexane solution was washed with distilled water till acid-free, dried over anhydrous sodium sulphate and concentrated to suitable volume by flash evaporation and a gentle stream of nitrogen.

Recovery studies

All the composites except water and beverages were fortified, before extraction, with 0.016, 0.064, 0.016, 0.032, 0.02, 0.04 and 0.04 μg of α-, β-, γ-, δ-BHC, *p, p'*-DDE, *p, p'*-DDD and *p, p'*-DDT, respectively, per g. For the water and beverages composite, the fortification levels were 0.8, 3.2, 0.8, 1.6, 1, 2 and 2 μg/l. The compounds were added as a standard mixture.

Analysis

All the samples were analysed in duplicate by GC–EC, with peak-height measurement. Because of the possible presence of PCBs (which have similar retention times to some of the test compounds) in the food samples, the peaks were identified by means of the alteration in peak pattern after alkaline treatment.[12] The limit of determination was taken as the amount giving 10% of full-scale deflection, and for aldrin under the operating conditions was 0.08 μg/l. for the water and beverages composite and 0.016 μg/g for all other composites when the amounts injected for GC corresponded to 500 and 25 mg of sample respectively.

RESULTS AND DISCUSSION

Recoveries from the composites fortified with BHC isomers and *p, p'*-DDT and its derivatives ranged from 80 to 107% for all groups except milk and milk products, for which the recoveries were 74–109% (Table 2). The values for the unfortified composites are given in Table 3. The greater spread of recoveries for the milk and milk products composite may be attributed to the low level of fortification relative to the high residue values in the unfortified sample (Table 3).

Table 2. Recoveries (and range, duplicate results) of BHC and DDT residues from fortified samples of the food composites

Composites	α-BHC	β-BHC	γ-BHC	δ-BHC	*p, p'*-DDE	*p, p'*-DDD	*p, p'*-DDT

Milk and milk products, *ng/g*	84	91	49	45	24	40	41
Meat and eggs, *ng/g*	26	74	17	6	29	8	47
Sugar, condiments, preserves, *etc.*, *ng/g*	36	18	18	8	11	ND	ND
Water and beverages, *μg/l.*	0.101	ND	0.143	0.140	0.60	0.35	1.00

ND = not detectable (below limit of determination).

The clean-up method resulted in gas chromatograms free from any interference by co-extracted material. The "other vegetables" group still gave a light green colour after the sulphuric acid treatment, but there were no extraneous peaks causing interference in the GC determination.

A number of other compounds, such as aldrin, α- and γ-chlordane, heptachlor and its epoxide, hexachlorobenzene, *o,p'*-TDE and Aroclor 1254 have been reported to be stable to treatment with sulphuric acid and can be determined by this method. However, dieldrin and endrin are degraded and thus cannot be determined by this method.[7] Similarly, endosulphan A, B and sulphate have been reported to be partially degraded by this treatment.[13] Aldrin was tested at the 0.05 μg/g level in the solid composites and its recovery found to be 83–96%.

Since the sulphuric acid treatment is simple, rapid and economical, it holds promise for final clean-up, instead of with adsorbents (Florisil, alumina, silica, *etc.*), for acid-stable chlorinated hydrocarbon residues in a wide variety of fatty and non-fatty substrates. Supplementary treatment with alcoholic potassium hydroxide can be used for confirmation of the identity of insecticide residues and the presence of PCBs.[12]

QUANTITATIVE STUDY OF THE REACTION BETWEEN QUINONES AND IRON(II) IN PHOSPHORIC ACID MEDIUM

N. KRISHNA MURTY and PERI M. DAKSHINA MURTY
Department of Engineering Chemistry, Andhra University, Waltair 530 003, India

(*Received* 18 *March* 1981. *Revised* 20 *July* 1981. *Accepted* 10 *September* 1981)

Summary—A simple method is described for the determination of some quinones with ammonium iron(II) sulphate, by titration potentiometrically or with cacotheline, Methylene Blue, Methylene Green, thionine, Toluidine Blue, Azure A, Azure C or Azure-2-eosin as redox indicators. The reverse titrations can be used for estimation of iron(II). Alternatively, excess of iron (II) can be added and the iron(III) produced determined colorimetrically with thiocyanate.

Quinones can be estimated in acid solution by titration with chromium(II), tin(II), titanium(III) or vanadium(II), the quinones being reduced to the corresponding hydroquinones.[1] Iron(II) is a mild reducing agent in common acids, the conditional electrode potentials of the iron(II)–iron(III) couple being 0.71 V in 0.5*M* hydrochloric acid and 0.68 V in 1*M* sulphuric acid.[2] Headridge and Wilson[3] titrated quinones with iron(II) potentiometrically at pH 3.0 in the presence of hydrofluoric acid and ammonium fluoride. Rao and Sagi[4] reported that the formal potential of the iron(II)–iron(III) couple changed from 0.429 to 0.400 V as the phosphoric acid concentration was varied from 8.92 to 11.58*M*. In view of the hazard to the operator and damage to the glassware associated with use of hydrofluoric acid, and the inconvenience of using buffer solutions in which dissolved oxygen also reacts with the titrant and hence interferes with the determinations, it was thought worthwhile to investigate the reaction between quinones and iron(II) in phosphoric acid media. In this paper the estimation of four quinones with iron(II) by potentiometric or visual titration or by colorimetry is presented. The reverse determination, of iron(II) with quinones, is also possible, with either potentiometric or visual detection of the end-point.

EXPERIMENTAL

Reagents

Ammonium iron(II) sulphate solution, 0.01*M*, was prepared in 0.5*M* sulphuric acid and standardized with potassium dichromate.

Solutions (0.01*N*) of 2,6-dimethyl-1,4-benzoquinone, 2,3-dichloro-5,6-dicyano-1,4-benzoquinone and tetrachloro-1,2-benzoquinone were prepared in methanol, and of methyl-1,4-benzoquinone in water.

The indicator solutions were 0.1% except for cacotheline, which was 0.2%.[5]

Merck *pro analysi* syrupy phosphoric acid was used. Other reagents were analytical grade.

Apparatus

A bright platinum rod indicator electrode, a saturated calomel reference electrode, and a saturated potassium chloride salt bridge having sintered-glass ends were used for the potentiometric titrations, which were done with an atmosphere of carbon dioxide to exclude aerial oxygen.

Procedures

An aliquot of quinone solution and enough phosphoric acid to give a final concentration of 8*M* (for tetrachloro-1,2-benzoquinone, methyl-1,4-benzoquinone or 2,6-dimethyl-1,4-benzoquinone) or 10*M* for all four quinones were transferred to the titration vessel and diluted to 40 ml with water. Carbon dioxide was passed through the solution for 10 min. The quinone was then titrated with iron(II) solution. Stable potentials were obtained within 45 sec.

Iron(II) was similarly titrated potentiometrically with quinone solution, under a carbon dioxide atmosphere.

Alternatively, with a 10*M* phosphoric acid medium, 0.3 ml of cacotheline solution or 0.05 ml of Methylene Blue, Methylene Green, thionine, Toluidene Blue, Azure A, Azure C or Azure-2-eosin solution, can be added as indicator, the colour change being from yellow to pink for cacotheline, and from blue to colourless for the others. The indicator correction was 0.03 ml of 0.01*N* iron(II). The reverse titration is again possible.

For the colorimetric determination 2.0 ml of 20% potassium thiocyanate solution and 2.0 ml of 0.0075*M* iron(II) (and for methyl-1,4-benzoquinone, 5 ml of concentrated hydrochloric acid) are added to the quinone sample in a 50-ml standard flask, and the solution is diluted to the mark and mixed. The colour is measured at 520 nm or with a green filter (transmission at 500–560 nm).

RESULTS AND DISCUSSION

No potential break was observed in the titration of any of the quinones in phosphoric acid less concentrated than 4*M*. Quantitative results were obtained at acid concentrations between 6 and 12*M* although 2,3-dichloro-5,6-dicyano-1,4-benzoquinone required at least 8*M* phosphoric acid for a sharp break in potential at the equivalence point. Stable potentials were obtained throughout the titrations at all acid

12.0	598	434	517	348

concentrations. In the estimation of iron(II), stable potentials were obtained at once in phosphoric acid solutions down to 4*M*, except near the end-point, where stabilization took at least 5 min. Quantitative results and sharp potential breaks were obtained in acid concentrations from 9*M* to 12*M*.

The indicator colour transitions were all sluggish with phosphoric acid concentrations below 8*M*, but sharp in 9–12*M* phosphoric acid, for both the direct and reverse titrations.

One mole of each quinone consumed two moles of ammonium iron(II) sulphate, as would be expected.

The conditional redox potentials of the quinone/hydroquinone couples in media of varying phosphoric acid concentration were also determined. For each determination 3.0 ml of quinone solution, sufficient acid for reaction to be quantitative, and enough iron(II) solution to reduce half the quinone were taken and diluted to give the desired final acid concentration. The potential was then measured with the electrode system described. The results are presented in Table 1.

The limits of determination, and average standard deviations (given in brackets) for estimation of the four quinones are given in Table 2, and for the reverse titrations in Table 3.

The advantage of the method over the Headridge and Wilson method[3] is that the chemicals used are not hazardous, and no buffers are used. Interference by aerial and dissolved oxygen is also reduced. Titration of tetrahydroxy-1,4-benzoquinone and 9,10-phenanthraquinone was also tried but failed because the

INSTRUMENTS IN ANALYSIS—CRITICAL REVIEWS

DIFFUSE-REFLECTANCE SPECTROSCOPY IN THE INFRARED

HANS MAULHARDT and DIETMAR KUNATH*

Academy of Sciences of the GDR, Central Institute of Physical Chemistry,
DDR-1199 Berlin, German Democratic Republic

(*Received* 5 *June* 1981. *Accepted* 29 *June* 1981)

Summary—The theory, and the problems encountered in the development of diffuse-reflectance spectroscopy in the infrared region as an analytical technique, are reviewed. The introduction of Fourier-transform infrared spectrometers has eliminated the difficulty of detecting small scattered intensities, and diffuse-reflectance measurement is now a routine method. The first commercial instruments are now available.

The demands nowadays made on analytical chemistry frequently necessitate the use of modern physical instruments. The first step in solving some analytical problems is often the recording of an infrared spectrum of the substances to be studied. Most molecular compounds exhibit vibrations with frequencies comparable with those of electromagnetic waves in the infrared region. The central region of the infrared, usually defined by wavenumbers from 4000 to 400 cm^{-1} (*i.e.*, wavelengths from 2.5 to 25 μm) is called the "fingerprint region" because many functional groups of molecules are associated with characteristic absorptions in this region.

The measurement of infrared radiation encountered many problems in earlier years. The greatest of these was the detection of radiation with the very inefficient thermal detectors then available. No commercial instruments or constructional elements were then available and the problems of radiation filtering, collection and detection were dealt with individually.[1,2] Simple measurements had the status of physical experiments and were only carried out for special purposes. This situation changed in the 1930s, when continuous recording replaced point-by-point measurement. This possibility and the demands of the fast-growing chemical industry for rapid and more exact methods of analysis promoted the development of commercial instruments. The fundamental study of the interaction of electromagnetic radiation with chemical compounds left the experimental stage and when in the 1940s the first ratio-recording infrared spectrometers were built, the technique passed from the hands of experimental physicists into those of the analytical chemist and became a routine analytical method.

Later, demands for the improvement of this type of applied spectroscopy encouraged more and more new developments. The original thermocouples and bolometers were replaced by more sensitive pneumatic and semiconductor detectors and the prism monochromators were superseded by diffraction grating types. Recently the well-established alternative technique of interferometry has been applied.

At the present time infrared spectroscopy is a favoured method, because it can be applied to nearly all substances, in all states of aggregation and at any temperature.

This wide field of application is made possible by the advanced stage of instrumental development and the sophistication of measuring techniques and sample preparation. The most widely used technique is based on the measurement of transmittance of a sample and is applicable to all transparent media. Disperse media such as powders can often be made transparent by immersion in infrared-transmitting materials (salts or oils). Provided that the refractive index of the immersion medium is closer to that of the powder than to that of the surrounding air, radiation scattering is reduced. Regular reflection and attenuated total reflection (ATR) techniques are useful supporting methods for studies of bulk samples, surface and interface phenomena and thin layers. However, routine analysis now presents an increasing number of problems associated with disperse materials such as powders or fibres, where the abovementioned techniques are not applicable. There are, for example, adsorbents and catalysts which cannot be immersed in a matrix if their adsorption behaviour is to be characterized. The surface of the powder must not be disturbed by sample preparation and in any case a faster method of preparation is to be preferred. Sometimes the scattering of radiation is not greatly reduced by immersion techniques. In such cases the measurement of diffuse scattering would provide an alternative method, if the intensity of the diffusely reflected radiation could be detected quantitatively.

* To whom correspondence should be addressed.

The term "diffuse reflection" relates only to an ideally diffusing surface and there are several effects occurring when electromagnetic radiation interacts with the surface of the medium. The radiation falling onto the surface is partially reflected (diffuse and specular reflection) and is partially transmitted. The radiation penetrating the medium may be absorbed or scattered and will leave the medium in a forward or backward direction. The radiation coming from the surface in the opposite direction to that of the incident beam will thus consist of reflected and re-emitted components and the term "remission" was coined to describe it. This term is seldom used outside the German literature and so the term "diffuse reflection" is used here to describe the abovementioned phenomena.

The diffuse-reflection technique has been widely applied in the ultraviolet, visible, and near infrared spectral regions for some time. The commercial instruments and spectrometer accessories available have been described in reviews by several authors.[3–5]

The application of this technique in the infrared region is made difficult by the problem of detection of scattered infrared radiation. The thermal detectors are less sensitive than the photoelectric cells and photomultipliers used for ultraviolet and visible radiation, and are more subject to interference from ambient thermal radiation. This is often of the same order of intensity as that of the monochromatic beam which has been attenuated by scattering. This difficulty must be overcome by collecting the diffusely reflected radiation with minimal loss and directing it onto the detector, which should have a small sensitive area to minimize thermal noise. This can be achieved in two ways. The radiation source of the spectrometer is removed and replaced by the diffusely and polychromatically illuminated sample, and part of the radiation diffusely reflected into a small solid angle is analysed by the spectrometer. Alternatively, the detector may be removed and replaced by the sample. The diffusely reflected radiation from the directionally and monochromatically illuminated sample is then collected by an integrating optical element and directed onto the detector. The earlier work embodying these principles has been reviewed by Kortüm[3] and by Dunn *et al.*[6] The present article describes developments during the 12–15 years since these reviews appeared.

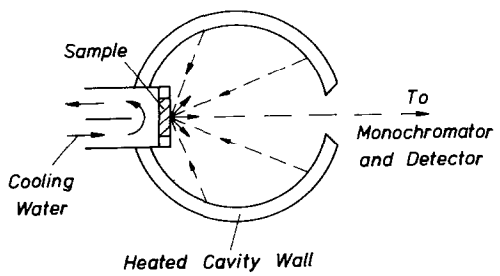

Fig. 1. "Hohlraum" type diffuse reflection cell (heated cavity).

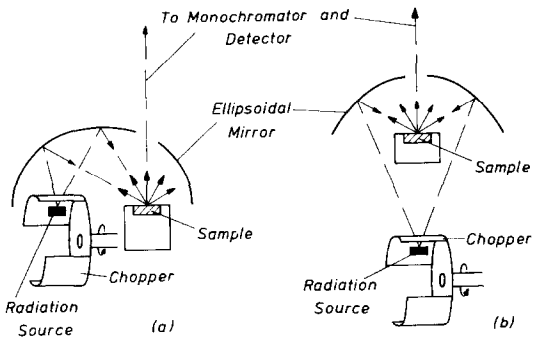

Fig. 2. Ellipsoidal mirror configurations for diffuse polychromatic sample illumination; (a) off-axis, (b) on-axis.

The first of these was realized by Gier *et al.*[7] for measurements in the mid-infrared region. The sample is placed in a heated cavity which simulates a black body (Fig. 1). Thermal radiation falls onto the sample from all directions and is diffusely reflected. The quantity of reflected radiation passing through the exit hole of the cavity may be analysed with any conventional spectrometer. This configuration has some disadvantages; samples with low thermal conductivity will be heated and changes in chemical constitution may be induced. Furthermore, thermal emission from the heated sample overlaps the reflected radiation and it is impossible to separate the two components. The spectrometer measures only a small proportion of the diffusely reflected radiation, set by the hole in the cavity and the geometry of the other optical elements, so a poor signal-to-noise ratio is obtained and long measuring times are necessary. Although some authors have reported successful applications of this method with laboratory-made cavities, and designs for commercial instruments have been developed (*e.g.*, Beckman Instruments), the method has never come into common use.

Some of the difficulties associated with this "hohlraum" type reflectometer can be overcome by illuminating the sample with an infrared radiation source and focusing with an ellipsoidal mirror in the off-axis or on-axis configuration (Fig. 2).[8,9] The radiation source is mounted at one focus of the ellipsoid and the sample is located at the second focal point where the radiation is collected by the focusing properties of the ellipsoidal mirror. The heating of the samples is reduced to 50% by chopping the incident radiation. A phase-sensitive detection system registers only the chopped radiation diffusely reflected by the sample and is insensitive to the uniform background radiation.

The second experimental arrangement, in which the sample is illuminated with monochromatic radiation, avoids all these heating problems. The same two configurations of ellipsoidal mirrors may be used, but the sample and the detector are placed at the conjugate foci (Fig. 3) as described by Kortüm and Delfs[10] and by Blevin and Brown.[11] This principle allows the diffusely reflected radiation to be measured with minimal loss. Perpendicular illumination of the sample

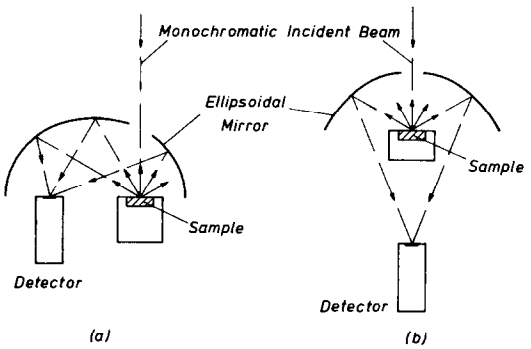

Fig. 3. Integration of the diffusely reflected monochromatic radiation over semi-infinite space with the aid of an ellipsoidal mirror, (a) off-axis, (b) on-axis.

surface serves for the separation of diffusely and specularly reflected radiation, because the latter leaves the ellipsoidal mirror through the entrance hole. The incident beam must be focused onto a small sample area, because the focusing properties of the ellipsoidal mirrors are only valid at the focal points and because the detectors have only small sensitive areas.

Brandenberg[12] and Heinisch *et al.*[13] studied these optical properties in detail for the case of the off-axis mirror and showed that there is only a small image enlargement at the second focus, caused by the rays coming from the immediate surroundings of the first focus. This configuration imposes no restrictions on the dimensions of the sample holder (*e.g.*, evacuated or temperature-controlled cells may be used), because the focal length may be chosen to suit the measurement problem before the ellipsoid is fabricated. A disadvantage of this configuration is the large solid angle of radiation incident on the detector, which will cause some loss by reflection at the surface of the detector window. This loss is lower in the on-axis configuration, but the image enlargement associated with it is very high. In the instrument described by Dunn *et al.*[14] the ratio of the illuminated areas at both focal points was 1:25. A second disadvantage is the shadow caused by the sample holder in the incident radiation flux. If it is necessary to use large

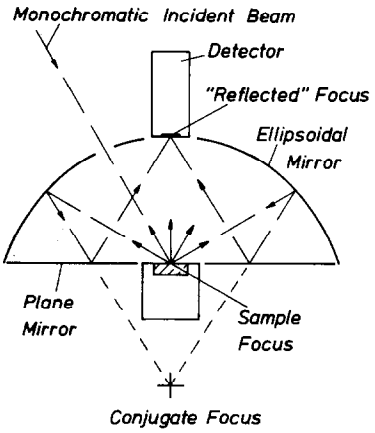

Fig. 4. On-axis ellipsoidal mirror configuration for sample holders of any dimension.

sample cells, a modification proposed by Masterson[15] can be made. A plane mirror at the sample focus and perpendicular to the main axis of an almost spherical ellipsoid ($a:b = 1.06$) reflects the rays at the detector focus through a hole in the ellipsoidal mirror on the main axis (Fig. 4).

An improvement to the off-axis type ellipsoidal mirror was made by Maulhardt *et al.*[16] who modified the ellipsoid so as to realize a true double-beam instrument, as evidenced from dispersive transmission measurements.

A disadvantage of all configurations with monochromatic sample-illumination can appear if high-temperature sample cells are used. This can cause a radiation overload of the detector, especially of semiconductor detectors. However, of the two concepts of polychromatic or monochromatic sample illumination, the second seems to be preferable, because the need for higher efficiency of radiation detection is the most outstanding problem.

It is now about 70 years since the first infrared diffuse-reflectance measurements were carried out by Royds[1] and Coblentz.[2] They used half-spheroidal mirrors instead of off-axis ellipsoids, which it was impossible to produce at that time. They placed their samples and detectors at points opposite to the centre of the sphere and as near as possible side by side to minimize the spherical aberration.

It is not surprising therefore that the detection problems in the infrared have hitherto confined successful applications of diffuse-reflection spectrometry to the ultraviolet and visible regions, for which practical integrating spheres have been designed and developed.[17] It was only after the end of World War II, when automatic recording infrared spectrometers came into common use, that the ideas of Royds and Coblentz were investigated and new concepts developed. Although today the difficulties of producing complicated ellipsoidal and paraboloidal mirrors have been overcome by using computer-controlled machinery, nearly all the early work in the infrared field was done with equipment built in the laboratory for the solution of specific problems. The development of new infrared spectrometers based on the interferometric principle and their commercial availability has radically changed the situation. The higher radiation throughput of the interferometer overcomes the detection problem. Low[18] has already measured diffuse-reflectance spectra without collection of diffusely reflected radiation. Willey[19] developed and offered a commercial spectrometer with an integrating sphere coated with diffusely reflecting gold, but its slow-scanning interferometer design was unsuccessful and the diffuse-reflectance unit was also ineffective. Fuller and Griffiths[20] and Maulhardt and Kunath[21] proposed two successful designs, combining an interferometer with an on-axis or an off-axis ellipsoidal mirror. Typical performance figures for the off-axis mirror configuration are 10% radiation efficiency (relative to the transmission intensity without the sample) and

less than 1% stray light. Only a few minutes are needed for installation of this portable instrument. Digilab Inc. (Cambridge, Mass., U.S.A.) offers the first commercially available diffuse-reflection unit for its FTS® spectrometer series, which was developed by Krishnan *et al.*[22] It is simply constructed, provides only a partial collection of diffusely reflected radiation and does not discriminate against the measurement of specularly reflected radiation. Like the development of conventional infrared spectrometers the production of these accessories has been encouraged by the requirements of analytical chemistry.

The different phenomena such as transmission, absorption, scattering and specular reflection, which affect diffuse reflection, make it difficult to obtain a quantitative estimate of optical constants, particularly the absorption coefficient, which is of paramount interest to the analytical spectroscopist. Numerous attempts have been made to derive mathematical expressions for the dependence of the diffuse reflectance on the molar absorption coefficient and sample concentration and to compare reflectance spectra with transmittance spectra (where the Beer–Lambert law applies). The theories developed fall into two classes. The basis of the first is a consideration of the interaction of the electromagnetic waves with single particles or layers of particles, the sample being considered as a "discontinuous" medium. The second group describes the scattering in terms of a "continuous" medium disregarding the effects of particles or layers of particles. Both concepts originated at about the beginning of this century. In 1899 Rayleigh[23] gave a mathematical expression for the scattering of small single particles and in 1908 Mie[24] extended it to particles of any size. Schuster[25] solved the differential equations for a continuously scattering atmosphere, in 1905. All these early treatments were carried out to provide a general description of radiative transfer through turbid media. The most commonly used theory for spectroscopic purposes is based on the continuum model of Schuster, which was rediscovered by Kubelka and Munk[26] in 1931, and in 1948 Kubelka[27] derived the formulae in the form used to the present day. The simplicity of this theory, requiring only two constants (one scattering and one absorption coefficient), promoted its widespread use. The disadvantage is that there is no exact comparison between the absorption coefficient derived from diffuse-reflectance measurements and the true absorption coefficient of the bulk material, because of the simplifications used in this theory. The "discontinuum" theories can provide more exact relationships between the optical constants of the bulk materials and those derived by reflectance measurements on powders. The phenomena of "reflection" and "refraction" of the incident radiation at the particle surface and the phenomenon of "absorption" within the particle may be considered in the form of separate processes provided that the particle size is large with respect to the wavelength of the incident radiation. This is true for normally encountered powders and wavelengths in the ultraviolet and visible regions, but not in the infrared region. Because of the necessary approximations relating to particle-size distribution and particle geometry, discrepancies appear between measured and calculated infrared reflectance values. The "discontinuum" theories are more complicated to handle because of the larger number of parameters which they take into account. The reader is referred to Hecht's comprehensive survey of the different types of theory.[28]

The theory developed by Schuster, Kubelka and Munk is the one most commonly used for studies in the infrared as well as in the ultraviolet and visible regions up to the present day, although it must be considered as only a semi-empirical method for the quantitative interpretation of diffuse-reflectance spectra. Kortüm has carefully examined the applicability of this theory to measuring techniques in all spectral regions and has pointed out its limitations. Numerous practical applications and much experience in the interpretation of reflectance spectra are summarized by Kortüm in his monograph.[3]

A problem which has not been solved up to the present time is the provision of reflectance standards which have high diffuse reflectance and no spectral absorption bands in the infrared. Such standards are necessary because diffuse-reflectance measurements carried out with the instruments described above provide no absolute reflectance data and must be related to measurements on a specimen of known reflectance. Diffusing materials such as magnesium oxide or barium sulphate are suitable "white standards" for the visible region but are not useful for the infrared. Some authors have proposed powdered sulphur as a standard but its application is restricted to the near infrared. Powders of the alkali-metal halides in the bulk form are familiar as infrared transmitting windows, and rough glass plates coated with gold or aluminium by evaporation can be used for most purposes. The alkali-metal halides have the disadvantage of being hygroscopic, while the diffusely reflecting metal coatings do not have the same radiation distribution at all solid angles, as would be the case for ideal scattering standards. This problem of reflectance standards in the infrared may be avoided by the use of alternative spectroscopic techniques, in which a reference sample assumes the function of a reflectance standard. Such a technique may have applications to a wide range of analytical problems. These include adsorbed molecules on powdered materials or fibres, material composites, mixed polymers or minerals and the quantitative analysis of molecular compounds in solids at low concentrations. Diffuse-reflectance spectrometry may be expected to become of ever-increasing importance in the non-destructive trace analysis of molecules in granular materials.

Some idea of these future possibilities for the application of the diffuse-reflectance technique in the infrared region may be gained by considering the state of development of the analogous but much

simpler technique of diffuse reflectance in the near infrared region. However, in the application of the diffuse reflectance technique in the mid infrared region there remain two severe problems. The infrared radiation reflected from the sample falls upon detectors, which have lower sensitivities and smaller sensitive areas than the photoelectric detectors used in the ultra violet, visible and near infrared regions of the spectrum and this requires increased sophistication in the spectrometer optics. In addition, there exists at the present time, no comprehensive theory, relating the absorption of the substance to its concentration.

DEVELOPMENT OF A HIGH-RESOLUTION INDUCTIVELY-COUPLED ARGON PLASMA APPARATUS FOR DERIVATIVE SPECTROMETRY AND ITS APPLICATION TO THE DETERMINATION OF HAFNIUM IN HIGH-PURITY ZIRCONIUM OXIDE

HAJIME ISHII and KATSUHIKO SATOH

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai-shi, 980 Japan

(*Received* 5 *June* 1981. *Revised* 9 *October* 1981. *Accepted* 16 *October* 1981)

Summary—A high-resolution apparatus for inductively-coupled plasma emission spectrometry (ICPES) has been developed, based on an echelle spectrometer modified for wavelength modulation with a quartz refractor plate. The selectivity of the technique is thus improved, and small amounts of hafnium in high-purity zirconium oxide can be determined directly without prior separation or preconcentration. A straight-line calibration curve passing through the origin is obtained without any correction for the interference from zirconium which exists in large excess. The detection limit for hafnium is 0.06 μg/ml, and the relative standard deviation (10 replicates) for hafnium at the 1.2 μg/ml level is about 3%.

Inductively-coupled plasma emission spectrometry (ICPES) is an excellent technique for trace determination of a number of elements. Among the requirements of ICPES, selectivity is among the most important. The emission line of the determinand often suffers spectral interference from neighbouring emission lines in the analysis of high-purity materials for trace impurities and the resolution of conventional spectrometers may be inadequate for this use of ICPES. Two approaches have been proposed for improving the resolution of the spectrometer, and hence the selectivity in ICPES. One is the use of a high-resolution echelle grating instead of a conventional grating[1,2] and the other is wavelength modulation.[3] Zander *et al.*[4] succeeded in obtaining high resolution in atomic-absorption spectrometry by using a commercially available echelle monochromator, modified for wavelength modulation, so we decided to use this approach for ICPES, using a new high-resolution spectrometer recently devised by Kihachiro Murakami of Yanaco Co., Ltd., taking our requirement into consideration, combined with a commercial ICP excitation source and a data-acquisition system. In this spectrometer, an echelle grating is mounted in a computer-controlled monochromator system and wavelength modulation is introduced. With this apparatus a well-defined second derivative spectrum can be obtained and the selectivity greatly improved. The usefulness of the method has been confirmed by its application to the direct determination of a small amount of hafnium in high-purity zirconium oxide without the need[5] for correction for the interference of zirconium.

EXPERIMENTAL

Apparatus

The individual components of the equipment are listed in Table 1. A new design of spectrometer with a modified Czerny–Turner configuration is used (commercially available from Yanaco Co., Ltd., Japan, model UOE-1). It incorporates an echelle grating (79 lines/mm) and an oscillating quartz refractor plate in the light-path behind the entrance slit (to produce wavelength modulation). The optical and electronic systems of the apparatus are shown in Figs. 1 and 2, respectively. The focal length is 0.8 m and the wavelength range 190–800 nm. The reciprocal linear dispersion and resolving power are shown in Table 2, and are about one order of magnitude better than those (8 Å/mm and 0.15 Å, respectively[6]) for a conventional Czerny-Turner spectrometer having a grating with 1200 lines/mm and a focal length of 1 m.

The wavelength modulation is done sinusoidally by a refractor plate modulator. The modulation interval can be selected in the range 0–1.0 Å by computer control. When the wavelength (λ) is modulated (by rapid scanning back and forth over a small spectral interval by the oscillating refractor plate) a signal proportional to the change in spectral intensity (I) over the interval is generated. The resulting a.c. signal amplitude is proportional to the first derivative ($dI/d\lambda$) of the intensity with respect to wavelength. If a lock-in amplifier is used to detect the a.c. component of the signal, the second harmonic (*i.e.*, twice the frequency of modulation) is proportional to the second derivative, $d^2I/d\lambda^2$. With this apparatus, the second derivative spectrum can be recorded on a chart recorder, and the original emission spectrum can also be displayed directly on a cathode-ray tube. Hence any spectral interference from neighbouring lines can be directed by monitoring the spectral profile. The wavelength can be selected automatically with a precision of 0.01 Å by computer control, with the mercury 2536.52-Å emission line as standard. Further details of the spectrometer systems will be reported elsewhere by Murakami *et al.*

Determination of hafnium

On the basis of the experimental results described below, operating conditions for the determination of hafnium were decided, as shown in Table 3.

Reagents. Stock solutions containing hafnium (1000 mg/l.) and zirconium (5000 mg/l.) were prepared from 99.9% hafnium oxide or "hafnium-free" zirconium oxide (Nippon Mining Co., Ltd.), hafnium content 6.6 μg/g, in the same

way as the sample solutions (see below). Working solutions were prepared by dilution of the stock solutions with sulphuric acid (1 + 19).

Preparation of sample solutions. Place 0.5 g or less of sample in a 50-ml beaker, and add 2.5 g of ammonium sulphate and 7 ml of concentrated sulphuric acid. Cover the beaker with a watch-glass, heat gently at first, then raise the temperature until sulphuric trioxide fumes appear, and keep at this temperature until the solution is quite clear. After cooling, dilute the solution to 100 ml (or other suitable volume) with sulphuric acid (1 + 19).

RESULTS AND DISCUSSION

Selection of spectral line for hafnium

As shown in Table 4, there are several emission lines suitable for determination of hafnium. The Hf II 2641.41-Å line is the most favourable, because it is fairly strong and is free from spectral interference by zirconium. This is well shown in Fig. 3, which shows the second derivative spectra of hafnium and zirconium near the 2641.41 Å Hf line.

Influence of modulation interval

The effect of the modulation interval on the second derivative intensity and the detection limit for hafnium was examined. The results are shown in Fig. 4, from which it is clear that enlarging the modulation interval increases the second derivative intensity and lowers the detection limit. However, if the modulation interval exceeds 0.25 Å zirconium begins to interfere because the resolution is decreased. Consequently, for determination of hafnium in the presence of a large amount of zirconium, a modulation interval of 0.25 Å is chosen as the best compromise.

†Nearest line of Zr (from M.I.T. tables).

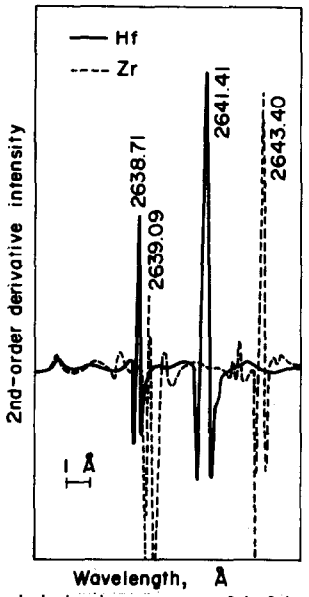

Fig. 3. Second derivative spectra of hafnium and zirconium in the vicinity of the 2641.41 Å Hf line. Hf: 20 mg/l., Zr: 3000 mg/l., slit-width: 200 μm, slit-height: 1000 μm, modulation interval: 0.25 Å.

Influence of slit width and height

With slit-widths up to 200 μm and slit-heights up to 1000 μm, the spectral resolution is good, there is no optical interference from the emission lines of zirconium, and the second derivative intensity for hafnium increases with increase in width and height of the slit, but at settings above these values the spectral resolution deteriorates and optical interference from zirconium is no longer negligible.

Influence of zirconium concentration

It can be seen from Fig. 3 that no spectral interference from emission lines of zirconium in the vicinity of the 2641.41-Å Hf line is observed even in the presence of large amounts of zirconium, because of the high resolution of the spectrometer, but high concentrations of zirconium (3 g/l.) can affect the behaviour of hafnium in the plasma, presumably by changing the population of excited hafnium atoms or ions. However, Fig. 5 shows that the zirconium concentration does not affect the second-derivative signal for hafnium if the observation height is set at 20 mm above the work coil.

Influence of acid concentration

In ICPES the acid concentration of the solution introduced into the plasma torch can affect the nebulization efficiency, so the effect of various mineral acids was examined. The results are shown in Fig. 6. The acids tested all decrease the hafnium signal; sulphuric acid has the largest effect. In spite of this, sulphuric acid is used to prepare the sample solution because the dissolution of zirconium oxide with this acid and ammonium sulphate is one of the easiest and most rapid procedures for the purpose. However, the

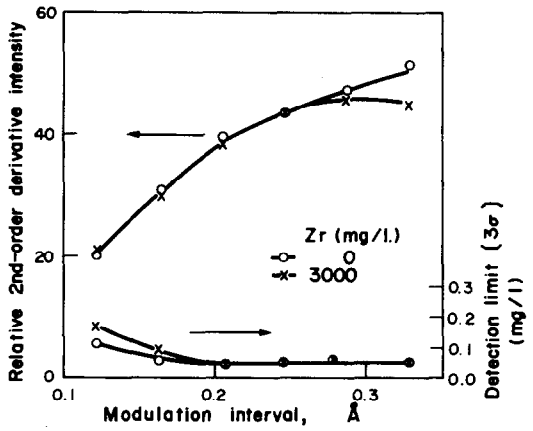

Fig. 4. Influences of modulation interval on second derivative intensity and detection limit of hafnium. Hf: 0.4 mg/l., H_2SO_4: 4*N*, $(NH_4)_2SO_4$: 2.5%.

sulphuric acid concentration of the sample solutions should match that of the standard solutions used for preparation of the calibration graph.

Influence of ammonium sulphate

Ammonium sulphate concentrations up to 4% do not affect the hafnium signal, but if the concentration exceeds 5%, solid ammonium sulphate tended to deposit on the inner wall of the quartz aerosol-injected tube.

Calibration graph, detection limit and precision

Plotting the second-derivative signal against hafnium concentration gave a straight line passing through the origin, whether zirconium was present or absent, showing that zirconium, even in large excess, did not interfere. The detection limit for hafnium, defined as the concentration giving an average net derivative signal equal to three times the standard deviation of the background noise, was found to be 0.06 μg/ml. The relative standard deviation (10 replicates) for a 1.2-μg/ml hafnium solution was ~3%.

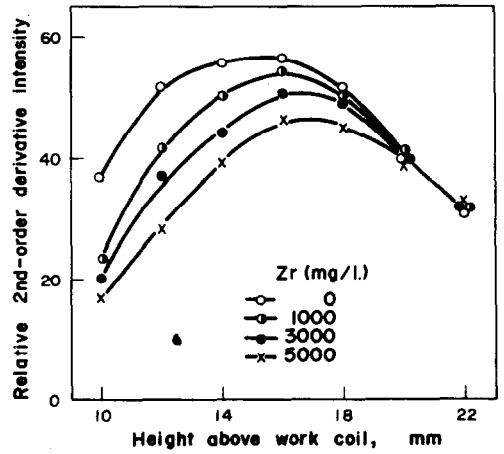

Fig. 5. Influence of observation height above work coil on second derivative intensity of hafnium. Hf: 1.2 mg/l., H_2SO_4: 4*N*, $(NH_4)_2SO_4$: 2.5%.

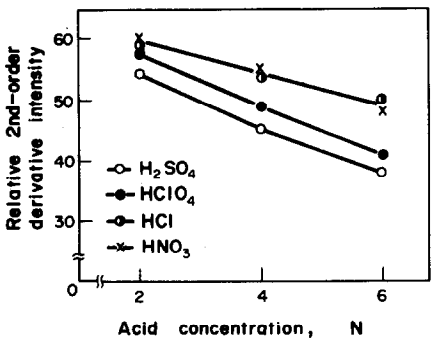

Fig. 6. Influence of mineral acid concentration on second derivative intensity of hafnium. Hf: 1.2 mg/l.

These results suggest that with this apparatus the direct determination of a small amount of hafnium in high-purity zirconium oxides, which is very difficult and almost impossible with the conventional apparatus, is feasible without prior separation, preconcentration or correction, with satisfactory precision. Further, these results indicate that such high-resolution apparatus considerably improves the selectivity in ICPES in general, and provides a very useful and powerful tool for trace element analysis, especially in a complex matrix.

Determination of hafnium in zirconium oxides

In order to confirm the high resolution and usefulness of the apparatus, hafnium present as an impurity in commercial high-purity zirconium oxides obtained from three different makers was determined with it. The results, which are summarized in Table 5 and compared with those obtained by an extraction–spectrophotometric method[8] show that the performance of the apparatus has been confirmed. In addition, it was found that the amounts of hafnium contained in these so-called "high-purity" zirconium oxides are of the order expected for zirconium oxide not subjected to purification.

Acknowledgements—The authors are most grateful to Mr Kihachiro Murakami, Yanaco Co., Ltd., for his expert advice concerning development of the high-resolution apparatus, and Mr Yasushi Nakamura, Nippon Mining Co., Ltd., for supplying almost pure zirconium oxide. This study was partly supported by a scientific research grant from the Ministtry of Education, Japan, to which our thanks are also due.

THE USE OF GLASS ELECTRODES FOR THE DETERMINATION OF FORMATION CONSTANTS—I

A DEFINITIVE METHOD FOR CALIBRATION

(*Received* 2 *July* 1981. *Accepted* 9 *October* 1981)

Summary—The computer program, MAGEC (Multiple Analysis of titration data for Glass Electrode Calibration), described can optimize simultaneously any or all of the titration parameters pertinent to the calibration of glass electrodes. In particular, the protonation constants of a ligand and the glass-electrode parameters may be determined simultaneously from a given single set of titration data. A method is described for obtaining definitive values of these parameters, involving cyclical treatment of titration data by means of MAGEC and another program such as MINIQUAD. The use of MAGEC for evaluating the performance of a glass electrode or as an analytical tool for determining, with high precision, the concentrations of acid and base solutions, is also described.

Despite three decades of extensive effort directed towards obtaining unequivocal formation constants for ligand–metal systems by glass-electrode potentiometry, there remain worrying uncertainties concerning the accurate calibration of the electrodes. Originally, glass electrodes were calibrated against buffers of specific pH but, although this approach remains valid in work where only a relative scale of acidity is required, it is unsatisfactory nowadays in metal–ligand equilibrium studies. Indeed, owing to the difficulties involved in relating pH values to hydrogen-ion activities, IUPAC has introduced an operational definition of pH.[1]

Even if a specific mathematical relationship between the *defined* pH and the hydrogen-ion activity of a buffer is assumed, difficulties remain in inferring the hydrogen-ion concentration values of a test solution, such as would be required in the determination of the protonation constants of a ligand and the formation constants of ligand–metal complexes. First, the hydrogen-ion activity coefficients are not the same in the buffer and in the test solutions, because of their different ionic compositions. Attempts to overcome this difficulty by applying various types of theoretical or empirical correction[2–9] introduce some inherent inaccuracy.[10,11] Moreover, differences in liquid-junction potential obtained with the buffer and with the test solution impose further uncertainty.[10,11]

These problems with the use of buffers in the calibration of glass electrodes are exacerbated when high concentrations of background electrolyte are used for controlling the ionic strength of the test solutions. Thus, researchers who employ potentiometric methods to measure formation constants have long used solutions of known hydrogen-ion concentration instead.[12] This is often done by titrating strong acid solutions with strong alkali and plotting the emf at each point against the corresponding values of $\log[H^+]$, where $[H^+]$ denotes the free hydrogen-ion concentration. The procedure aims to obtain a linear calibration curve for the electrode system.

There are several reasons why an ideal response is not observed in practice, however. Chiefly, it is found that unless there is a sufficient excess of acid or alkali to ensure that the solution is concentration-buffered, small errors become significant. It has, for example, been shown that the presence of glass itself causes a large deviation from linearity,[13] a fact that can probably be attributed to adsorption of hydrogen ions onto the glass surface or to dissolution of minute amounts of the glass. Another important factor is the imperfect behaviour of glass electrodes in alkaline solution: many of the types of glass used for electrode manufacture become increasingly sensitive to metal ions, especially sodium ions, above $-\log[H^+] = 11.0$.[14] The effect of hydrogen-ion concentrations on liquid-junction potentials also tends to cause some deviation at high concentrations of hydrogen ion.

Accordingly, there is a restricted range of free hydrogen-ion concentration over which strong-acid *vs.* strong-base titration data are suitable for calibration purposes. In the authors' experience, the most nearly linear response occurs in the $-\log[H^+]$ ranges 2.3–2.9 and 10.8–11.3. Data collected inside these

* To whom correspondence should be addressed.

limits with most research equipment can yield a level of precision that is adequate for the determination of formation constants for biological systems. What is less satisfactory, however, is that the critical measurements with most systems lie outside the calibration range. Thus the hydrogen-ion concentrations must be procured by extrapolation. This makes them sensitive to small errors in the analytical concentrations of the acid. Also, it is well known that the standard potential of the glass membrane varies from day to day (due to asymmetry effects) and that it is difficult to reproduce liquid-junction potentials with adequate precision. These factors can be significant even from one experiment to another.[11,14–17] *Thus internal calibrations of the electrode, performed in the test solution itself, are highly desirable.*

In principle, there are two main ways of achieving this goal. The first applies to solutions in which any strong acid added is completely dissociated and gives a correspondingly increased free hydrogen-ion concentration. It is then possible to calibrate by a series of constant additions. Alternatively, in titrations of weak acids or bases, free hydrogen-ion concentrations can be calculated at various points in the titration from the protonation constants, provided these are accurately known. Very precise calibrations can be made in this way but they are of limited use. Indeed, the object of many titrations is to measure the protonation constants. In these cases a number of parameters, including glass-electrode properties and one or more equilibrium constants, must be determined simultaneously. Straightforward solutions are very rarely available so general *optimization* techniques must be employed.

This paper describes an approach for the optimization of some or all of the parameters required for calibrating glass-electrode systems and shows how protonation constants of a ligand can, if desired, be determined simultaneously. The relevant algorithms are incorporated in a Fortran program named MAGEC (Multiple Analysis of titration data for Glass Electrode Calibration), the coding for which is available to interested readers on request.*

THEORY

Consider an electrochemical cell in which a test solution surrounding a glass electrode is in electrical contact with a reference electrode through a salt bridge. It can be represented as follows:

first reference half-cell (in glass electrode)	test solution	second reference half-cell (external)
g		l

The boundaries, g and l, respectively, indicate the glass membrane and the liquid junction at the interface between the salt bridge and the test solution. There are four contributions to the measurable potential difference between the two reference electrodes.[14–17] Two arise from the reference electrodes themselves. They will have opposite signs and will usually be of comparable magnitudes. Most importantly, their contribution will be independent of the composition of the test solution and so may be represented as a fixed combined potential, E_r. On the other hand, the potential differences generated across the boundaries of g and l will depend on the activities of all the chemical species on either side of them. If these boundary potentials are represented by E_g and E_l, the measured emf of the cell is given by the equation.

$$E_{cell} = E_r + E_l + E_g \qquad (1)$$

In the case of the liquid junction, considerable changes in the composition of the test solution are required to alter E_l significantly, so, for the time being, this will be considered as a constant. Glass electrodes, in general, are found experimentally to exhibit a Nernstian response over a wide range of concentration.[16]

Equation (1) can be rewritten as

$$E_{cell} = E_r + E_l + E_g^0 + \frac{RT}{F} \ln\{H^+\} \qquad (2)$$

where E_g^0 is the standard glass-electrode potential at unit activity of hydrogen ions, R is the universal gas constant, T is the absolute temperature, F is the Faraday constant and $\{H^+\}$ represents the hydrogen-ion activity. As long as the ionic strength of the test solution remains constant, the free hydrogen-ion activity, $\{H^+\}$, can be expressed in terms of concentration. Hence, equation (3) is obtained by putting $s = 2.303RT/F$ and collecting together all the constants (including the hydrogen-ion activity coefficient and factors arising from it) as E_{const}:

$$E_{cell} = E_{const} + s \log[H^+] \qquad (3)$$

In circumstances where strong-acid *vs.* strong-base titrations are to be used in the calibration of an electrode system (*i.e.*, in the approximate pH ranges 2.3–2.9 and 10.8–11.3), MAGEC uses a subroutine entitled CALIBT. CALIBT first analyses the data by the method of Gran.[18,19] Since the potentiometric data are transformed into a linear form, this analysis gives a good indication of glass-electrode performance and also yields an end-point that is independent of the slope and intercept used in equation (3). Furthermore, if extrapolation of the data from before the end-point produces a value significantly lower than that obtained from data after the end-point, it is possible that an alkaline titrant may have become contaminated with carbon dioxide from the atmosphere.[19] The end-point obtained from the Gran extrapolations

Fig. 1.

provides an independent check of the CALIBT optimization of the strong acid concentration referred to below.

Further processing of strong-acid *vs.* strong-base titrations is divided into three stages. To begin with, the input concentration values are used to calculate free hydrogen-ion concentrations at each point, and a linear least-squares fit is performed on the data before and after the end-point and over the entire range. This first analysis is used mainly for comparison with subsequent output. Because of the effect of relatively small errors in the concentrations of titrant and titrand, the least-squares straight line does not normally possess a Nernstian slope, so the concentration of the titrand is varied slightly until the slope from the data before the end-point becomes Nernstian. It is then possible to adjust the titrant concentration in a similar manner, but on the basis of the whole range of data. Of course, to maintain the same end-point, a corresponding change in the titrand concentration also needs to be made. In this way, very close agreements between the calculated and observed values for the emf at each point can be achieved.

A factor that critically affects the refinement of the titrant concentrations in the final stage is the value used for the dissociation constant of water, K_w. This parameter is very highly correlated with the concentration of alkali in the burette, *i.e.*, a small error in its value will cause a significant deviation in the apparent slope of the electrode response, because it is used to convert the hydroxide-ion excess into free hydrogen-ion concentrations, and so it manifests itself in the optimized alkali concentration. Another way of looking at this is that either the titrant concentration or K_w (but not both) can be determined by finding the value which yields the most ideal least-squares slope. To accommodate those situations in which K_w is uncertain, CALIBT permits the user to vary the estimate systematically. The recommended procedure for using CALIBT is illustrated in Fig. 1.

As pointed out earlier, it is often necessary to determine E_{const} and the ligand protonation constants simultaneously. In such circumstances, two further equations in addition to equation (3) are applicable. These are the mass-balance equations, (4) and (5), for the ligand and for protons.

$$T_L = [L] + \sum_p \sum_r p\beta_{pr}[L]^p[H^+]^r \qquad (4)$$

$$T_H = [H^+] + \sum_p \sum_r r\beta_{pr}[L]^p[H^+]^r. \qquad (5)$$

Here, T_L and T_H are the total concentrations of ligand and protons, respectively; [L] and $[H^+]$ are the free concentrations of ligand and protons, respectively; β_{pr} is the equilibrium constant for the general reaction,

$$pL + rH^+ \rightleftharpoons L_pH_r$$

It is clear that (3), (4) and (5) constitute only two independent equations for each titration point. T_L and T_H may be expressed in terms of the initial volume of the titrant, the volume of each added increment of titrant and K_w. E is measured at each titration point. It follows that for n titration points, there are $2n$ independent equations containing $(pr + n + 2)$ unknowns, namely, the two electrode parameters E_{const} and s, pr β-values, and n free-ligand concentrations. Thus, in principle, the $2n$ equations may be solved simultaneously to yield E_{const} and the β-values from a single set of titration data, provided that the number of titration points is sufficiently large.

The values of T_L and T_H are subject to analytical error; the value of K_w is sometimes uncertain, which imposes additional uncertainty on T_H. Thus, in a sense, T_L, T_H and K_w may be regarded as additional unknowns.

In the analysis of data obtained for the titration of monoprotic ligands, the main routine in MAGEC utilizes a number of approximation formulae, for example, the Henderson–Hasselbalch equation,

$$-\log [H^+] = -\log K_a + \log \frac{[salt]}{[acid]},$$

to solve for the free hydrogen-ion concentration at each point in the titration. Analysis of the data then

Fig. 2.

follows a similar approach to that described above for strong acids and strong bases. On the whole, however, this is not very satisfactory because it is much more difficult to know when the solution can be considered to be reasonably well buffered.

Accordingly, the main analysis applied by MAGEC to all titrations involving ligands is one of general optimization of parameter values by using an objective function based on titration volumes. The sum of squared residuals is minimized by the simplex method introduced by Nelder and Mead.[20] Any of the parameters E_{const}, s, the β-values, T_L, T_H and K_w can be flagged for refinement, so the specific procedure is left largely in the hands of the user. Usually, the requirement is to find the value for E_{const} in each of a series of titrations with the ultimate objective of determining the protonation constants of a ligand.

THE USE OF MAGEC IN PRACTICE

In our experience, the calibration of an electrode system is best carried out in the following steps.

1. Even when the calibration is needed outside the pH ranges 2.3–2.9 or 10.8–11.3, it is recommended that an initial estimate of E_{const} be obtained by applying a CALIBT analysis to the titration data for a strong acid *vs.* a strong base. An additional advantage of this step stems from the possibility of using the CALIBT analysis for checking the reliability of an individual glass electrode. Lifetimes of glass electrodes differ considerably and it is often difficult to detect the first signs of deteriorating performance. In the MAGEC analysis of strong-acid *vs.* strong-base titration data, however, the appearance of sudden and marked increases in the titration-volume residuals signals the imminent demise of the electrode. A second useful criterion of incipient electrode unreliability is a tendency for discrepancies to develop between the end-points determined by CALIBT minimization of the Nernstian response and by Gran plot.

2. The E_{const} value obtained in step 1 should be used in conjunction with data obtained for titration of a ligand (perhaps acidified with mineral acid) with a strong base, in a suitable program for refining the values of the protonation constants for the ligand. The authors favour MINIQUAD[21] for this purpose. Individual titrations (*i.e.*, either replicate titrations or titrations differing in the total concentration of ligand) should be processed together to yield global values for each protonation constant.

3. The ligand-titration data and the protonation constants from step 2 are processed by the main routine of MAGEC to yield refined E_{const} values.

4. Steps 2 and 3 are repeated cyclically until convergence to a satisfactory degree is obtained.

5. If desired, the values of E_{const} and the protonation constants may be improved further by refining the values of T_H, T_L and K_w in a series of subsequent cycles. Care must be taken, however, to ensure that the calculation is not performed with more degrees of freedom than are warranted by the accuracy of the data. If this precaution is neglected, all optimization procedures can give rise to spurious results.

The number of parameters which can be refined with safety from data with a given experimental precision depends on the particular system being investigated. Thus, it is important to ensure that the refinement includes only those parameters for which optimization leads to a sufficient improvement in the sum-of-squares function that is to be minimized.

The flow diagram of Fig. 2 illustrates steps (2)–(4).

RESULTS

An example of the calibration of a glass electrode by strong-acid vs. *strong-base titration*

A mixture of hydrochloric acid (10.00 ml, *ca.* 50m*M* and sodium chloride (20.00 ml, 212.0m*M*) was titrated with sodium hydroxide (100.0m*M*) and sodium chloride solution. The sodium chloride was used to maintain the ionic strength (*ca.* 0.15*M*) as constant as possible. The solution was maintained at 37.0 ± 0.1°.

Using only the data before the end-point (47 points)		
(*i*) electrode intercept, *mV*	362.4 ± 0.15	360.7 ± 0.04
(*ii*) electrode slope, *mV*	62.48 ± 0.07	61.53 ± 0.02
(*iii*) overall standard deviation, *mV*	1.4×10^{-1}	4.1×10^{-2}
(*iv*) number of residuals greater than 0.1 mV	26	0
Using all the buffered data (62 points)		
(*i*) electrode intercept, *mV*	360.4 ± 0.10	360.6 ± 0.05
(*ii*) electrode slope, *mV*	61.53 ± 0.02	61.50 ± 0.01
(*iii*) overall standard deviation, *mV*	5.0×10^{-1}	2.6×10^{-1}
(*iv*) number of residuals greater than 0.1 *mV*	41	15

Notes (*i*) The optimized initial acid concentration of 16.59m*M* compares with an expected value of 16.67m*M* and yields an end-point of 4.978 ml.

(*ii*) A slope of 61.50 mV corresponds to $pK_w = 13.310$. In practice, the calculation could be repeated using $pK_w = 13.305$ to obtain a better agreement with the Nernstian slope (61.54 mV).

A Gran-plot analysis for MAGEC gave end-points of 4.977 ± 0.002 and 4.97 ± 0.03 ml for the acid and alkaline pH data respectively. The CALIBT optimization analysis is summarized in Table 1.

An example of the internal calibration of a glass electrode in titration of a ligand solution

Duplicate titrations, using different electrode systems, were performed on a solution of acetic acid (20.00 ml, *ca.* 20m*M*) with 0.150*M* sodium hydroxide. A background concentration of perchlorate ions (0.150*M*) was maintained and the solution was kept at 25.0 ± 0.1°. The protonation constant and the initial concentration of the acetic acid as well as E_{const} for each electrode system were refined simultaneously by MAGEC. A Nernstian slope of 59.16 mV per log [H^+] was assumed throughout. The results are shown in Table 2.

MINIQUAD analysis of these titrations, using the electrode intercepts obtained by MAGEC and an initial value of [acetate] = 20.82 m*M*, yielded a refined pK_a value 4.523 ± 0.0004 with a sum of squared residuals of 2.3×10^{-8} and a MINIQUAD R factor of 0.0008.

pK_a	4.522	4.524
Electrode Intercept *mV*	−367.5	−379.9
[acetate], *m*M	20.83	20.81

An example of the internal calibration of a glass electrode in a student titration of ligand solution

In a fourth-year exercise, a pair of students titrated a solution of glycine (25.00 ml, 9.17m*M*) in hydrochloric acid (21.90m*M*). A background concentration of chloride ions (1.00*M*) was maintained and the solution was kept at 25.0° ± 0.1.

Table 3 indicates the progress of the MINIQUAD–MAGEC cycling refinement.

Table 3. Honours students' titration: glycine *vs.* strong base

A Nernstian slope of 59.16 mV per log $[H^+]$ was assumed throughout. The refinement, within the first run, by MAGEC of the electrode intercept to within 0.4 mV of the final value, is impressive. This is in spite of the use of approximate acid dissociation-constant values.

Table 4 shows how the magnitudes and distributions of the residuals have been improved.

DISCUSSION

The accurate experimental determination of hydrogen-ion concentrations is important in many areas of chemistry, often because the measurements provide information about other chemical species which occur in solution. Despite this, considerable differences exist in the way in which the electrode systems are calibrated.

For the determination of formation constants, many investigators still employ the pH-scale, as evidenced by the plethora of publications describing how pH measurements can be adjusted to yield values for hydrogen-ion concentration.[2–9] A standardized approach, based directly on hydrogen-ion concentrations, is clearly needed. This would facilitate both the comparison of formation-constant values and elimination of errors inherent in the use of the pH-scale. In this respect, numerical analysis of titration data, to determine parameters such as E_{const}, would appear to have many advantages.

The results presented here demonstrate the efficacy of MAGEC in the calibration of a glass-electrode system both in the strong-acid *vs.* strong-base titration range and in the hydrogen-ion concentration range where the interaction of a given ligand with protons or a metal ion is significant. A strong advantage lies in the ability of MAGEC together with MAGEC–MINIQUAD cycling to solve this problem even when the protonation constants of the ligand are not known *a priori*. Thus, E_{const} is optimized for a given titration, and any change in the liquid-junction potential is incorporated into the particular E_{const} value obtained. Small variations in the liquid-junction potential arising, for example, from poor reproducibility or concentration effects, cease to be a problem. This is a significant improvement over less general approaches such as that of Gaizer and Puskás.[22] A further marked advantage is derived from the MAGEC (CALIBT) analysis of strong-acid *vs.* strong-base data in assessing the reliability of a given glass electrode. Yet another feature of the MAGEC (CALIBT) routine lies in the analytical facility whereby the concentration of a given strong acid or strong base solution can be determined more precisely than by the Gran method.

As far as the main routine in MAGEC, as applied to ligand–proton equilibrium, is concerned, the text describes how, in principle, the parameters E_{const}, s, β-values, total concentrations of ligand and protons and K_w, can all be determined provided there are sufficient titration points. In practice, however, limitations arise, mainly from the correlation of errors between two or more of the parameters. This results from an effect in which small differences in the values of these particular parameters have similar (increasing) effects on the function to be minimized. Thus, the errors in the parameters concerned tend to compensate each other, leading to false mathematical solutions. The difficulties arising from this source may be restricted by the MAGEC–MINIQUAD cycling procedure, which provides for only one or a selected few of the parameters to be estimated by MAGEC.

While work on MAGEC has been in progress, another program with similar objectives has appeared in the literature.[23] Like MAGEC, this permits the optimization of any or all of the titration parameters. However, it does not offer the additional facilities simultaneously. Hence, the two programs partially overlap and partially complement one another.

Acknowledgements—P.W.L. and R.G.T. gratefully acknowledge generous grants from the South African C.S.I.R. and the Council of the University of Cape Town. Honours students Valerie Mizrahi, Sybella Meltzer and Pedro Monteiro, are thanked for the data used in Tables 3 and 4.

RADIOTRACER STUDIES ON ION-SELECTIVE ELECTRODE MEMBRANES CONTAINING METAL COMPLEXES OF A NONYLPHENOXYPOLY-(ETHYLENEOXY)ETHANOL IN POLY(VINYL CHLORIDE) MATRICES

B. DOYLE, G. J. MOODY and J. D. R. THOMAS

(*Received* 13 *April* 1981. *Accepted* 9 *October* 1981)

Summary—Radiotracer studies with ^{133}Ba, ^{45}Ca and ^{36}Cl are reported for PVC matrix membranes containing 2-nitrophenyl phenyl ether and the tetraphenylborate of a barium (or calcium) complex with a nonylphenoxypoly(ethyleneoxy)ethanol (NP), Antarox CO880. The results show that there is very limited permeation of radioactive barium and calcium ions through the membrane systems. However, the continued uptake (with time) of radioactive barium ions by the membranes (the uptake of calcium ion is less) suggests that in relation to selective electrode response the stabilization of ions by the NP ligand within the membrane is important in addition to the simple availability of membrane pathways for primary-ion transport through the membrane. Permselectivity to counter-ions is indicated by the non-permeation of radioactive chloride ions.

Nonylphenoxypoly(ethyleneoxy)ethanols (NPs) [$C_9H_{19}C_6H_4O(CH_2CH_2O)_nC_2H_4OH$] are non-ionic surfactants. They form complexes with metal cations,[1–3] and the tetraphenylborate (TPB) of the barium–NP complex, where $n = 29$ as in the commercial preparation Antarox CO880, functions as an ion-selective sensor for barium ions in liquid[4,5] and PVC matrix[1,2] membrane electrodes. The stoichiometry[2,3] of the ion-sensor is $Ba(CO880)_{0.4}TPB_2$.

Solvent extraction data (obtained by use of picrate as counter-ion) for the interaction of alkaline-earth cations with Antarox CO880 show that the affinity[2] of the cations for Antarox CO880 is in the order Ba > Sr > Ca > Mg. The electrode selectivity coefficients, $k^{pot}_{Ba,M}$, for PVC membrane electrodes containing the barium complex of Antarox CO880, with 2-nitrophenyl phenyl ether as solvent mediator, are in the order Sr > Ca > Mg.

The special properties of the barium–NP adduct have been attributed[4] to 12 ethyleneoxy units (EOU) complexing with Ba^{2+} to assume a tight helical conformation with a ring radius of about 1.3 Å in which the Ba^{2+} ion is held by a cage of 12 oxygen atoms (6 in each loop) through ion–dipole interaction.

With regard to possible pathways for ion transport in ionselective electrode membranes the use of radiotracers has yielded much useful information for calcium ion-selective PVC matrix membranes based on calcium dialkylphosphate sensors.[6–8] Similar techniques have now been extended to a study of the permeation of barium, calcium and chloride ions through PVC matrix membranes based on the barium and calcium complexes of Antarox CO880, the γ-emitting barium-133 ($t_{\frac{1}{2}}$ 7.2 years), β-emitting calcium-45 ($t_{\frac{1}{2}}$ 165 days) and β-emitting chlorine-36 ($t_{\frac{1}{2}}$ 3.1×10^5 years) radioisotopes being used for the purpose.

Non-ionic surfactants also elicit a potential response from such barium-sensor membranes,[9] and the effect of a solution of the non-ionic surfactant, Antarox CO880, on barium ion permeation through this sensor membrane system is also discussed.

EXPERIMENTAL

PVC-supported barium-sensitive membranes were prepared as previously described[1,10] from PVC (0.17 g) and a solution of the tetraphenylborate of the barium (or calcium) complex with Antarox CO880 (0.04 g) in 2-nitrophenyl phenyl ether (0.36 g). Additional membranes were based on other proportions of complex, Antarox CO880 and 2-nitrophenyl phenyl ether (see Table 1). Diffusion of radiotracers between two solutions separated by such membranes was followed by using the cell shown in Fig. 1. The cell was enclosed in an air thermostat maintained at 35°. The cell was charged with appropriate solutions (10 ml) on either side of the membrane and their activities were monitored by removing 20-μl (for barium-133) or 10-μl (for calcium-45 and chlorine-36) samples with a Lang–Levy auto-zero micropipette after the times shown in Table 1. Such samples were spotted onto filter paper (Whatman No. 1, 2.1 cm diameter) and the activity was counted with a Geiger–Müller mica end-window tube.

The activity of each membrane after conclusion of the experiment at the times shown in Table 1 was also monitored by (*i*) slicing off the membrane from its supporting PVC tubing, placing it on a planchette under the Geiger–Müller tube, and counting both sides in turn to determine C_{act}/C_{inact} (see results section) and (*ii*) dissolving the membrane in tetrahydrofuran (10 or 5 ml) and counting 20, 40 and 60 μl samples, spotted onto filter papers, in order to determine percentage uptake (see results section). All counts were taken for 300 sec and corrected for background (*ca.* 170 counts). Count-rates of *ca.* 8, 17 and 45 cps

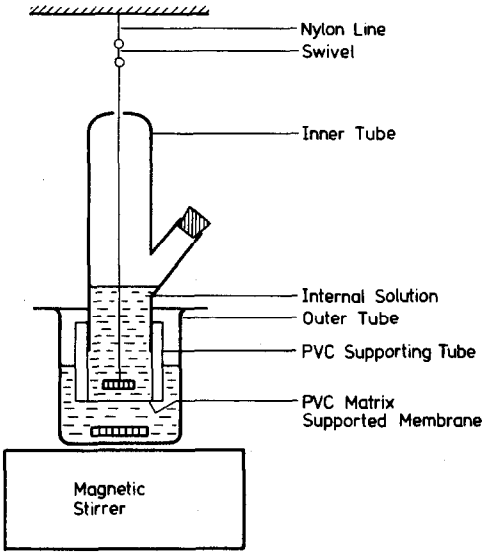

Fig. 1. Apparatus assembly for study of permeation of radiotracer ions through PVC matrix membranes by intermittent sampling of solutions.

were obtained from 10-μl samples of the barium-133, calcium-45 and chlorine-36 solutions, respectively. The half-lives of all the radiotracers were long enough for the effect of decay during the experiments to be negligible.

Barium chloride ($10^{-3}M$), calcium chloride ($10^{-3}M$) or Antarox CO880 ($10^{-2}M$) solution was placed on one side of the PVC membrane, and on the other $10^{-3}M$ barium chloride (labelled with ^{133}Ba), $10^{-3}M$ calcium chloride (labelled with ^{45}Ca) or $10^{-3}M$ barium chloride (labelled with ^{36}Cl).

The metal chloride solutions were prepared from BDH "AnalaR" grade materials. Radioactive solutions were prepared by addition of (*i*) 14 ml of $6.39 \times 10^{-5}M$ barium chloride (^{133}Ba *ca.* 0.08 mCi/ml) to 100 ml of $10^{-3}M$ barium chloride, (*ii*) 0.15 ml of $3.7 \times 10^{-2}M$ calcium chloride (^{45}Ca *ca.* 2.0 mCi/ml) to 250 ml of $10^{-3}M$ calcium chloride, (*iii*) 1.15 ml of 0.21M hydrochloric acid (^{36}Cl *ca.* 0.09 mCi/ml) to 95 ml of $10^{-3}M$ barium chloride. This ^{36}Cl-labelled solution was neutralized with barium hydroxide and the resultant solution was made up to 100 ml with distilled water. Active solutions of barium chloride (*ca.* $10^{-3}M$) were prepared by dilution of this stock solution.

RESULTS

The results presented in Table 1 refer to the permeation of barium ions (experiments 7–21, 24–30 and 33–37) or chloride ions (experiments 22, 23, 31 and 32) through PVC barium-sensitive membranes with 2-nitrophenyl phenyl ether (NPPE) solvent mediator, of barium ions through membranes containing only NPPE (experiments 4–6) and a membrane containing some free uncomplexed Antarox CO880 and NPPE (experiment 1), and of chloride ions through membranes containing Antarox CO880 and NPPE (experiments 2 and 3). The uptake of barium was also measured. The results of experiments 7–19 refer to experiments in which two barium chloride solutions were separated by a barium-sensor membrane, while those of experiments 24–32 refer to experiments in which the membrane separated barium chloride and Antarox CO880 solutions. In experiments 20 and 21 barium chloride solutions containing barium-133 were used on both sides of the membrane. Experiments 33–37 show the effect on barium-133 permeation of adding free Antarox CO880 to membranes based on barium complex plus NPPE.

Results are also presented for calcium permeation through, and uptake by, barium-sensor membranes (experiments 40 and 41), a membrane containing the calcium complex of Antarox CO880 (experiment 39) and a membrane containing only NPPE solvent mediator (experiment 38).

Since the methods involved the destruction of the membranes, fresh membranes had to be used for each experiment quoted in Table 1.

The values of C''/C' represent the ratio of counts obtained for samples taken from the radioactive solution (C') and the initially inactive solution (C''). The low ratios clearly indicate that permeation of radioactive barium, calcium and chloride ions through these membrane systems was very limited. On the other hand, the C_{act}/C_{inact} ratio represents the ratio of counts obtained from the surface of the membrane in contact with the radioactive solution (C_{act}) to counts obtained from the surface of the membrane in contact with the initially inactive counter-solution (C_{inact}) at the conclusion of each experiment.

Control membrane-counting experiments in which a number of radioactive barium chloride samples (20–100 μl) were counted (*i*) in the normal manner for PVC membranes, and (*ii*) with a barium-sensor membrane of the thickness normally used (*ca.* 0.05 cm) placed between the sample and the Geiger-Müller tube, gave values of 4.28 (s.d. 0.37), 4.17 (s.d. 0.91) and 3.89 (s.d. 0.25) for the ratio of counts obtained for three different membranes. Such values suggest that the value of C_{act}/C_{inact} for membranes in actual barium radiotracer experiments would be *ca.* 4 if all the barium radiotracer incorporated into the membrane had been concentrated at, or near, the surface of the membrane which had been in contact with the radioactive solution. The corresponding figures for the calcium-sensor membrane with radioactive calcium-45 were 34.8 (s.d. 3.7) and for barium-sensor membranes with solutions containing chlorine-36 were 2.64 (s.d. 0.18) and 2.03 (s.d. 0.21). The varying extent of the quenching of the counts from the different radioisotopes by the membranes reflects the different energies (0.384, 0.258 and 0.714 MeV for barium-133, calcium-45 and chlorine-36, respectively) and natures (β-particles for calcium-45 and chlorine-36 and γ-rays for barium-133) of the emissions from the radioisotopes.

The values of C_{act}/C_{inact} are consistent with diffusion of radioactive barium species within the barium-sensor membranes away from the radioactive solution/membrane interface with increasing contact times. No appreciable diffusion of such radioactive species occurs within membranes containing only NPPE or NPPE with Antarox CO880 (*cf.* experi-

ments 1, 4–6). If no concentration of radioactive ions occurs at or near one of the solution/membrane interfaces a value of *ca.* 1 for this ratio would indicate a homogeneous distribution of radioactive barium ions within the membrane.

In addition to providing evidence for diffusion of barium ions within the barium-sensor membranes, the experiments show that the uptake of barium ions by the membranes increases with time, *cf.* the increase in magnitude in C_{act} and C_{inact} in Table 1.

Further evidence for increased uptake of barium with time was obtained from the experiments involving dissolving the membranes in tetrahydrofuran and counting the total activity. The percentage uptake is the activity of the membrane at the end of the experiment, expressed as a percentage of the total initial activity in the radioactive solution. It provides a convenient measure of the extent of incorporation of radioactive ions by these membrane systems, and, by extrapolation, of the total number of ions of that type, assuming that no preferential incorporation of radioactive ions occurs.

Examination of Table 1, even when allowance is made for the limited reproducibility of the uptake

data on account of such factors as minor variations in membrane content and thickness, shows that over similar time scales

(*i*) the presence of Antarox CO880 as the counter-solution depressed the rate of barium-ion incorporation by the barium-sensor membranes;

(*ii*) there is no evidence for the uptake of significant amounts of barium radiotracer by membranes containing only the solvent mediator, NPPE;

(*iii*) the uptake of radioactive barium is considerably lower for a membrane containing only Antarox CO880 and NPPE than for membranes containing the barium-sensor material;

(*iv*) the presence of Antarox CO880 with complex and NPPE in the membranes leads to increased amounts of barium radiotracer appearing in the solution on the other side of the membranes;

(*v*) even over a much longer time scale the extent of incorporation of calcium-45 into membranes containing either the barium or calcium form of the Antarox CO880 complex is significantly lower than that for barium-133 ions;

(*vi*) the uptake of radioactive barium by membranes separating two active solutions (experiments 20 and 21) and an active and an inactive solution (experiment 17) after 96 hr of contact shows that incorporation of barium ions into the membranes occurs to essentially equal extents from the solutions on both sides of the membrane;

(*vii*) the results of the experiments with chlorine-36 provide no evidence for either the permeation of chloride co-ions through the membranes or for the uptake of chloride ions by these membranes.

DISCUSSION

The solvent mediator effects[1,8,11–15] and the chelation between ions and sites within the membrane, particularly when a strong affinity exists between the ions and such sites,[15–17] both strongly influence the selectivity characteristics of membranes based on liquid ion-exchangers. The results of this study strongly suggest that strong ion/membrane-site interactions are involved in the response of membrane systems based on the cation complexes of Antarox CO880.

Barium-133 and chloride-36 studies

The continued uptake of radioactive barium ions by barium-sensor membranes and the absence of evidence for the uptake of chloride ions (Table 1) confirm that these membranes possess the permeation selectivity characteristics of ion-exchanger membranes. The membrane takes up these radioactive ions, but there is no evidence for their large-scale permeation through the membrane into the inactive counter-solution (*cf.* experiments 7–19). The evidence for the entry of barium ions into the membrane from the solutions on both sides of the membranes (*cf.* experiments 20 and 21) implies that ions might accumulate within the membrane (or at least at the membrane side of the membrane–solution interface) rather than be involved in large-scale membrane pathways for primary ion transport through the membrane. Though the pattern of barium ion uptake could be due to a very slow exchange between barium ions and ion-exchanger sites within the membrane, the attainment of a maximum uptake of radioactive barium after *ca.* 2 days' contact with the barium chloride solutions and the failure of the radioactive barium ions to enter the counter-solution in appreciable amounts even after *ca.* 21 days' contact with the solutions (*cf.* experiment 19) strongly suggests the presence within the membrane of sites with a strong affinity for the incorporated barium ions.

Initial uptake of radioactive barium ions from solution, which occurs only with those membranes containing either the barium-sensor complex (experiments 7–21 and 24–30) or the free uncomplexed Antarox CO880 (experiment 1) is consistent with an interaction between barium ions in solution and surface sites on the membrane. Barium-sensor complex species and/or free uncomplexed Antarox CO880 species could act as such ion-exchange sites on the surface. Transport of incorporated barium ions away from the solution/membrane interface into the bulk of the membrane with increased contact time between the membranes and the radioactive solutions, as indicated by a general decrease in the C_{act}/C_{inact} ratio, can only occur if a network of the ion-exchanging sites exists within the membrane. In the absence of such a network and the need to preserve the electrical balance imposed by permselectivity, the incorporated barium ions would remain concentrated at or near the active solution/membrane interface (*cf.* C_{act}/C_{inact} and uptake values in experiment 1).

The reluctance of the radioactive ions to pass through the membrane and enter the bulk of the counter-solution, as happens with calcium in calcium dialkylphosphate membranes,[6,7] may be surprising in view of the seemingly ready availability of pathways for diffusion of barium ions within the membrane. However, the fact that the existence of a strong affinity between incorporated ions and sites within the membrane caused the entrapment of radioactive beryllium-7 species within membranes based on alkylphosphate indicates that permeation of radio-tracer through the membrane and into the solution on the other side is not obligatory.[7] In this respect, the maximum extent of incorporation of radioactive barium, *i.e.*, *ca.* 6%, is low in relation to the total number of ion-exchanger sites within the membrane ($\sim 1.3 \times 10^{18}$), which is approximately the same as the number of barium ions in the solutions ($\sim 6 \times 10^{18}$).

Elemental analysis[2,17] of the barium complex with Antarox CO880 indicates presence of *ca.* 5% free uncomplexed Antarox CO880. Such molecules present within the sensor membrane may act as intermediaries for the stabilization of incorporated barium

ions, but for actual uptake there must also be simultaneous co-ion permeation to preserve electrical balance, and significant permeation by chloride co-ions was not observed (experiments 22, 23, 31 and 32). However, free Antarox CO880 does seem to have a part to play, as can be seen by the small transfer of barium radiotracer to solutions on the other side of the membranes in experiments 33–37 where C''/C' exceeds the values of $\leqslant 0.01$ observed in most of the other experiments. The difficulty of coiling the Antarox CO880 into the helix postulated for the complex,[4] may well be related to the small transfer of barium radiotracer species.

Although the disappearance of the C–O–C stretching frequency bands at 1149 and 1060 cm^{-1}, the appearance of a new band at 1030 cm^{-1}, and the shift of the main band from 1115 cm^{-1} to 1085 cm^{-1} are all indicative of NP–barium complex formation,[2] infrared studies are not as discriminating as the radiotracer experiments in yielding clues to the mechanism of the barium ion transfer. Measurements indicating membrane resistances of *ca.* 0.2 MΩ also do not provide the necessary discrimination for any useful conclusions to be drawn.

The inability of membranes containing only the solvent mediator, NPPE, to incorporate radioactive barium ions to any significant extent (*cf.* experiments 4–6) also demonstrates a role for Antarox CO880, as does the concentration of barium ions incorporated at or near the active solution/membrane interface in a membrane containing only Antarox CO880 and NPPE solvent mediator.

It is clear from the data that the rate of uptake of barium radiotracer is faster when barium chloride is used in the inactive counter-solutions. The data best fit first-order kinetics, with linearization regression coefficients 0.9203 and 0.9338 for the experiments with barium chloride and Antarox CO880 respectively. The $t_{\frac{1}{2}}$ values were *ca.* 90 and 540 hr, respectively. The unsuitability of the data for satisfactory kinetic analysis is not surprising when it is considered that each datum point was obtained with a separate membrane and that minor variations in membrane composition and thickness could cause appreciable variations in the number of sites available within the membrane for interaction with the incorporated ions.

The lower rate of uptake of barium ions by the membrane when Antarox CO880 is used in the counter-solution may be related to participation of the solute Antarox CO880 with the membrane barium ion. In this respect, it is significant that the membrane system, when set up in a potentiometric electrode, responds to the ethoxylate.[9]

Calcium-45 studies

The overall electrode selectivity characteristics of these PVC-supported barium-sensor systems is related to stable complex formation with Antarox CO880 molecules within the membrane.[1,2,4] The selectivity of the membranes should, then, be due to the relative ability of barium and interferent ions to enter the membrane and to form stable complexes with membrane sites. The results of calcium-45 permeation studies with membranes containing the calcium complex (experiment 39) and the barium complex (experiment 40) with Antarox CO880 are consistent with such a view. These results show that the extent of incorporation of calcium ions is significantly less than that of barium ions. Moreover, they show that permeation of radioactive ions within the membranes occurs to a greater extent in a membrane containing the barium-sensor material (*cf.* the values of C_{act}/C_{inact} in experiments 39–41). The relative concentration of radiotracer near the active solution/membrane interface for the membrane containing the calcium complex could be due to either a strong affinity between surface ion-exchanger sites and the incorporated ions or a breakdown of the mechanism for the transfer of ions away from the membrane surface because of the greater affinity of barium ions. This study does not conclusively favour either of these possibilities but picrate solvent-extraction data for alkali and alkaline-earth metal cations show that barium forms a more stable complex with Antarox CO880 than calcium and lends support to the second alternative.[2]

CONCLUSION

These studies suggest that the response of membrane systems based on cation complexes with Antarox CO880 cannot be explained in terms of the ready availability of membrane pathways for primary ion transport through the membrane. They imply only that an important role should be assigned to the ability of the membranes to incorporate and stabilize ions by complexation. The barium/calcium selectivity behaviour of these membranes can also be explained on this basis.

(*Received* 21 *May* 1981. *Accepted* 8 *October* 1981)

Summary—A polystyrene-based macroreticular resin containing phenylalanine groups has been prepared and its analytical properties have been investigated and compared with Dowex A-1. The phenylalanine resin shows high selectivity for mercury(II) and copper(II) in the pH region 2–3. The sorption behaviour of copper has been examined in detail, with the intention of using the resin analytically. The important characteristics of the resin are fast equilibration, high selectivity and small volume change between its hydrogen form and metal forms. These enable it to be applied for the rapid concentration of trace amounts of copper in the presence of large amounts of diverse metals. It may be used for the determination of copper in sea-water and the separation of copper/cobalt and copper/nickel.

A number of chelating resins containing aminocarboxylic acid groups, (*e.g.*, ethylenediaminetetra-acetic acid,[1,2] iminodiacetic acid[3–10] sarcosine,[11] and others[12–14] have been prepared and their analytical properties investigated. Among the commercially available resins, Dowex A-1 (Chelex 100) is the most frequently employed in the concentration and/or enrichment of trace metals, including transition metals.[15–18] Although the affinity of Dowex A-1 or Chelex 100 for the metal ions is high, their selectivity is not satisfactory.[5,19,20]

It is of interest to prepare new chelating resins having specificity for a selected metal ion. The specificity or selectivity of a chelating resin is usually correlated to that of the monomeric compound corresponding to the functional group. On the basis of this idea, we have proposed use of macroreticular resins containing α-amino-acid groups which may confer greater selectivity for some metal ions than that attainable with aminopolycarboxylic acids. Schlögl and Fabitschowitz[21] have reported a glycine resin based on polystyrene, but no detailed study on its sorption of metals is available.

The present paper describes an investigation of the preparation of a macroreticular phenylalanine resin, which has essentially the same functional group as that of the glycine resin,[21] and similar metal-sorption properties. The value of the resin for the preconcentration of copper, based on its high selectivity, has been studied and compared with that of Dowex A-1.

EXPERIMENTAL

Reagents

The stock metal ion solutions were prepared by dissolving the reagent grade nitrates and chlorides in water or the matrix acids, and standardized by complexometric titration.

Preparation of phenylalanine resin

To a solution of sodium ethoxide prepared from 23.7 g of sodium and 530 ml of absolute ethanol, 246 g of diethyl acetoaminomalonate were added and the mixture was refluxed for 30 min. To chloromethylated styrene–divinylbenzene copolymer (**I**) (7.5% divinylbenzene; Cl 18.3%)[22] soaked with absolute ethanol (dry resin, 100 g), the sodium diethyl acetoaminomalonate solution prepared was added, the mixture was refluxed for 30 hr with stirring, then the product was filtered off and washed with 5 litres of water and 2 litres of methanol. The pale yellow resin (**II**) obtained was air-dried at room temperature. About 148 g (N 4.0%) of resin was obtained. This intermediate resin (140 g) was refluxed for 40 hr with 400 ml of 47% hydrobromic acid with stirring, then the resin was packed into a glass tube. The column was washed successively with 10 litres of water, 1.5 litres of 1*M* sodium hydroxide and 2 litres of 90% ethanol. The light brown resin (sodium form) obtained was air-dried at room temperature. About 130 g (N 4.5%) was obtained. The 60–100 mesh fraction of the resin was used for the metal sorption studies.

Sorption of metal ions by batch operation

Unless otherwise stated, the following method was applied. To a glass-stoppered test-tube containing 100 mg of resin, 9 ml of 1*M* acetate buffer (pH 3–7) or hydrochloric acid (pH 1.5–2.5) were added. When this mixture had been equilibrated, 1 ml of metal-ion solution was added to the

test-tube, then the mixture was shaken at room temperature for a known time. The resin was filtered off on glass-wool and the amount of metal ion remaining in the filtrate was determined complexometrically or by atomic absorption spectrophotometry (AAS).

Concentration of copper from sea-water

The surface coastal sea-water was filtered through a 0.45-μm membrane filter, and treated as follows. For determination of labile copper,[16,18] 5 litres of sample were adjusted to pH 4.0 with 1*M* acetate buffer, and for total copper, 30 ml of concentrated nitric acid were added to 2 litres of sample and this solution was boiled for 15 min, then neutralized with sodium hydroxide and adjusted to pH 4.0 with acetate buffer. The conditioned sea-water samples were passed through a resin column (phenylalanine resin 1 g, 1 × 4 cm) at a flow rate of 3 ml/min. The column was washed with 50 ml of water, and copper retained on it was then eluted with 20 ml of 2*M* nitric acid and determined by AAS.

Trace concentration of copper from the sample solutions containing large amounts of other metal ions

One litre of copper solution (10 μg/l.) containing 500 or 50 mg of various metal ions was adjusted to pH 4.0 with 1*M* acetate buffer. This solution was introduced into the resin column (1 × 4 cm) at various flow-rates with a peristaltic pump. The column was washed with 50 ml of water and then copper retained on the column was eluted with 20 ml of 2*M* nitric acid.

Separation of copper/cobalt and copper/nickel

One gram of the resin was packed into a glass tube (0.5 × 15 cm) and conditioned with 50 bed-volumes of 0.1*M* acetic acid. One ml of a solution containing the metal ions was added to the column and 50 ml of 0.1*M* acetic acid were passed through the column at a flow-rate of 1 ml/min. Copper retained on the column was eluted with 20 ml of 1*M* hydrochloric acid. Cobalt or nickel was determined in the effluent and copper in the eluate.

RESULTS AND DISCUSSION

The resin was synthesized according to Scheme 1. Spherical macroreticular styrene–divinylbenzene copolymer beads were used as starting material. After the chloromethylation, diethyl acetoaminomalonate was allowed to react with the product and then hydrolysed with hydrobromic acid in the usual way. Infrared spectra of the resins are shown in Fig. 1. In

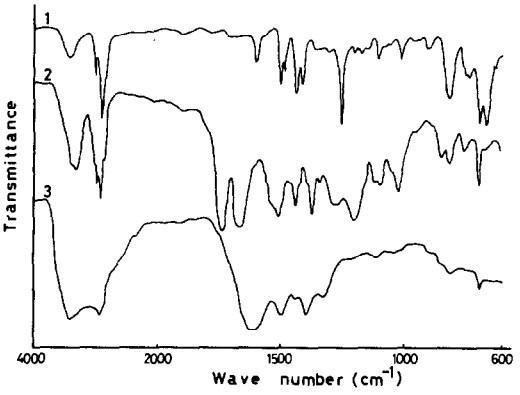

Fig. 1. Infrared spectra of resins (KBr disks). 1, Chloromethylated resin; 2, diethyl acetoaminomalonate resin; 3 phenylalanine resin.

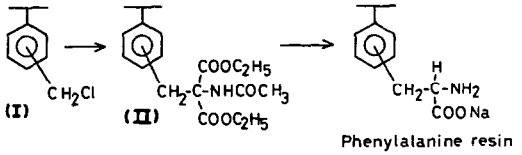

Scheme 1

the spectrum of the intermediate resin **(II)**, the absorption band at 670 cm^{-1} (ν_{C-Cl}) found in the spectrum of the chloromethylated resin **(I)** disappeared and the characteristic absorption of the carbonyl (ester) group appeared at 1740 cm^{-1}. A characteristeric feature in the spectrum of the phenylalanine resin was the presence of the bands for the carboxylate group at 1600–1660 cm^{-1} and the amino group at 3300 cm^{-1}. Resin **(I)** also shows absorption at 3300–3400 cm^{-1} due to a small amount of residual stabilizer or water, but this is rather weak and clearly different from the absorption at 3300 cm^{-1} found for the phenylalanine resin. The functional group content in the final resin (sodium form), calculated from its nitrogen content, was 3.2 mmole/g. The spectral changes and the elemental analysis support the reac-

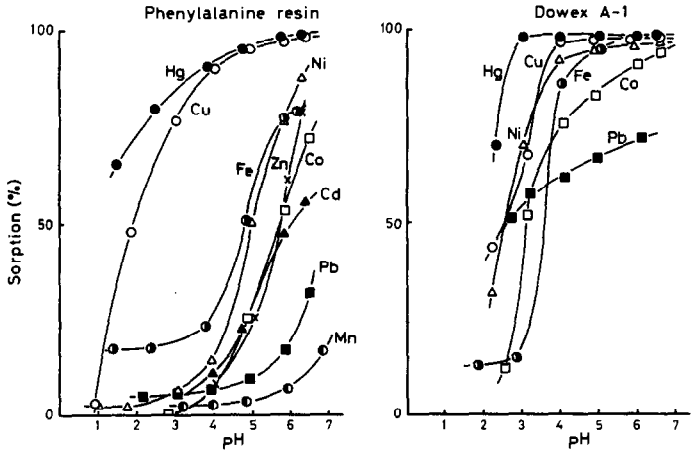

Fig. 2. Effect of pH on metal sorption with phenylalanine resin and Dowex A-1. Concentration of metal solutions 1 × 10^{-2} *M*; shaking time 24 hr.

tion scheme presented. The resin was found to be very stable on successive treatment with acid and alkaline solutions. The stability of the resin was checked by change of the hydrogen–sodium exchange capacity and the nitrogen content.

In a preliminary experiment, the sorption behaviour of some metal ions on phenylalanine resin and Dowex A-1 at different pH values was examined by the batch method, and the results are shown in Fig. 2. The phenylalanine resin shows high affinity for mercury(II) and copper(II). The selectivity for copper is particularly interesting. The maximum capacities for copper were 1.4 and 1.7 mmole/g at pH 4 and 7, respectively. The capacity at pH 7 suggests that the apparent molar ratio of copper to functional group in the resin is nearly 1:2, which corresponds to that of the copper–phenylalanine chelate.

The sorption kinetics of copper on the resin are shown in Fig. 3. Under the experimental conditions, sorption equilibrium is attained in 1 hr. In Table 1, the time required for 50% uptake of copper with phenylalanine resin and Dowex A-1 is shown. Its faster equilibration indicates the superiority of the phenylalanine resin. Table 2 shows the apparent volumes of various forms of both resins. The small difference in volume between the metal and hydrogen forms of the phenylalanine resin is important in column operation. The advantages of the resin over Dowex A-1 seem to be due to the difference in matrix as well as in functional group; the phenylalanine resin is a macroreticular resin but Dowex A-1 is a gel-type resin.

Table 1. The time required for 50% uptake of copper with phenylalanine resin and Dowex A-1

Resin	Time required for 50% uptake, *min*	
	pH 4.0	pH 7.0
Phenylalanine resin	2.4	4.3
Dowex A-1	10.0	13.2

Table 2. Relative resin volumes in different ionic forms

	Phenylalanine resin	Dowex A-1
Na^+	1.00	1.00
H^+	0.99	0.54
pH 4.0*	0.99	0.87

* $1M$ acetate buffer.

Sodium chloride, over a wide range of concentrations, does not affect the sorption of copper under the experimental conditions. This suggests use of this resin for trace concentration from sea-water samples. Copper was separated from sea-water by column operation. The concentrations of copper found in sea-water samples (*A–D*) collected at 4 points of Ariake Bay (Kumamoto, Japan) were as follows (in μg/l.): labile copper (*A*) 0.40, (*B*) 0.45, (*C*) 0.50, (*D*) 0.55; total copper (*A*) 0.66, (*B*) 0.71, (*C*) 0.80, (*D*) 0.96. These data agreed closely with those obtained with a Dowex A-1 column.

The separation of trace amounts of copper in the presence of large amounts of diverse metal ions with the phenylalanine resin column was examined. Figure 4 compares the results with those for a Dowex A-1 column. A 10-μg/l. copper solution containing 5×10^4 times as much cobalt(II) or nickel and 5×10^3 times as much iron(III) at pH 4 was introduced into the columns. The Dowex A-1 sorbed cobalt and nickel as well as copper and its colour changed to pink and blue, respectively, but there is no similar evidence of sorption of cobalt and nickel on the phenylalanine resin. With the Dowex A-1 column, recovery of copper decreased with increasing flow-rate,

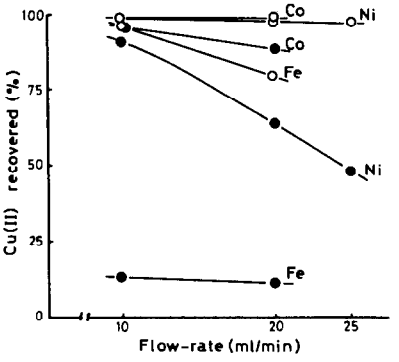

Fig. 4. Effect of flow-rate on recovery of copper in the presence of various metal ions with phenylalanine resin (—○—) and Dowex A-1 (—●—) columns. Metal concentrations, copper (10 μg/l), cobalt and nickel (500 mg/l), iron (50 mg/l).

Table 3. Separation of copper(II)/cobalt(II) and copper(II)/nickel(II) mixtures, by means of the phenylalanine resin column

Metal	Added, μg	Recovered, μg	Recovery, %
Cu	635	633	99.7
Co	5890	5798	98.4
Cu	635	635	100
Co	589	581	98.7
Cu	635	632	99.5
Ni	5870	5764	98.2
Cu	635	635	100
Ni	587	581	99.0

markedly in the presence of nickel. The presence of iron interfered strongly with the recovery of copper with Dowex A-1 column, but gave less interference on the phenylalanine resin column if the flow-rate was reduced to 10 ml/min. Thus the proposed resin is superior to Dowex A-1 for trace concentration of copper at high flow-rate.

Finally, the phenylalanine resin was applied to the separation of copper from cobalt or nickel by column operation. Cobalt and nickel are separable from copper because they are not retained on the column at pH 3 below and copper retained on the column can be eluted with 1*M* hydrochloric acid. The separation data are listed in Table 3.

(*Received* 27 *May* 1981. *Accepted* 7 *October* 1981)

Summary—A novel general-purpose interface-controller unit has been designed and applied in potentiometric analysis. The unit is operated by a personal microcomputer programmed in BASIC. The interface-controller permits direct reading of specific ion-electrodes and can activate, under program control, laboratory instruments such as motor-driven burettes. The interface-controller is expandable to 16 analogue input channels, 16 binary (logic) input lines and 16 control relays but requires only one microcomputer I/O port (a total of 9 I/O lines) to handle all operations. Analogue to digital conversion is realized by counting, with the microcomputer, the output frequency of an analogue-to-frequency converter. This inexpensive method is effective in rejecting interfering signals such as power-line interference. The system has been applied in potentiometric titration analysis for determining the apparent dissociation constants of carbonic acid in sea-water and Dead Sea brines, and for ammonia determination with a gas-sensing electrode.

It is evident that the availability of cheap microprocessors and associated devices will eventually revolutionize the analytical laboratory[1] by automation of many operational, control and computation tasks which at present are performed manually. This end could be reached by interfacing existing analytical equipment with general purpose microcomputers or by designing new microprocessor-based analytical instruments. The latter approach is pursued by a number of commercial companies.

In this paper we present the alternative approach, namely the use of a general purpose microcomputer and general purpose interface operated by a high-level language. This approach has two advantages. It allows computerization of existing instrumentation and reprogramming at any stage to meet a specific need of the user, in contrast to microprocessor instrumentation which is controlled by fixed firmware. Various systems of that type were recently described by Anderson *et al.*[2]

Martin and Freiser[3] have described a microcomputer-controlled potentiometric analysis system based on a commercial microcomputer, digital pH-millivolt meter and digital burette, operated by a high-level language (CONVERS) developed at the University of Arizona. Our study differs from that of Martin and Freiser in several respects. We use a more universal high-level language (BASIC) and have developed a novel general-purpose interface which includes a high-resolution but cheap analogue to digital conversion scheme and high-impedance buffers for direct connection of pH and ion-selective electrodes. This interface can be operated in conjunction with any microcomputer which includes one 8-bit I/O port and a control line.

In this paper we describe the interface-controller and demonstrate its application in potentiometric analysis. The range of applications of this approach seems virtually unlimited.

INTERFACE DESIGN

The interface (Fig. 1) comprises 16 analogue inputs, 16 digital I/O lines and 16 uncommitted control relays. Analogue to digital (A/D) conversion is accomplished by first applying voltage to frequency (V/F) conversion and then measuring the frequency with the microcomputer. This simple and inexpensive A/D method was chosen on the basis of the intended applications, which do not call for a high rate of sampling. The method has the distinct advantage of rejecting interfering a.c. signals.

Analogue signals are fed to the V/F converter through a 16-channel multiplexer which operates under computer control. The impedance seen at the input of the analogue multiplexer is essentially the input impedance of the V/F converter, which is about 15 MΩ. Some of the channels are buffered by a very

* To whom correspondence should be addressed.

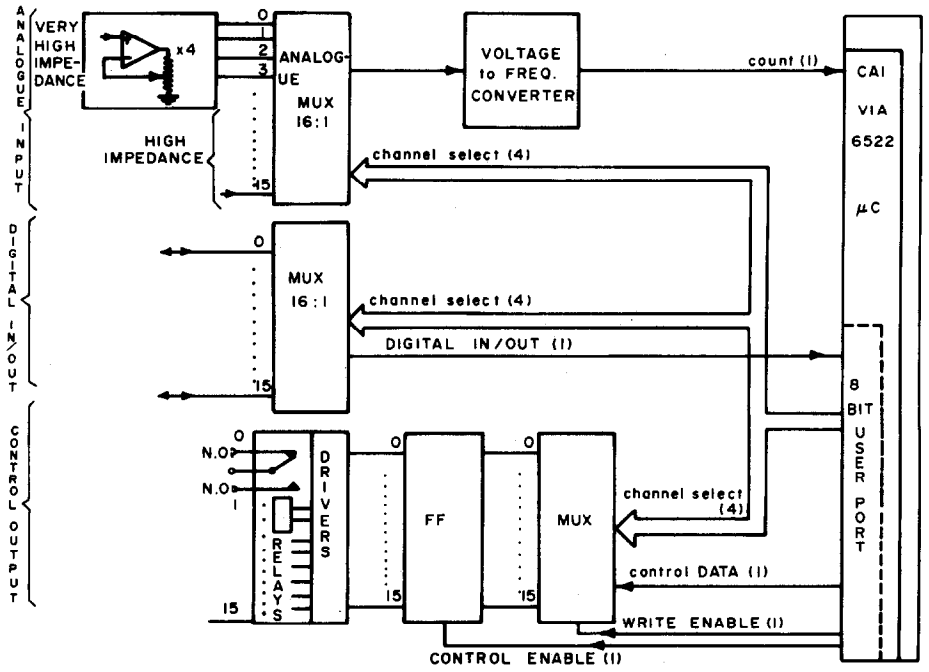

Fig. 1. Block diagram of proposed interface-controller.

high input impedance amplifier (MOSFET INPUT) to permit direct connection of pH and ion-selective electrodes. A second 16-channel multiplexer is used as a digital I/O port. Any of the lines can be a binary input or an output line. The interface-controller also includes 16 relays which are operated one at a time by the microcomputer.

Figure 1 shows a typical interconnection between the interface-controller and a microcomputer, which includes a versatile interface adaptor (VIA, type 6522). This type of interface is but one possibility, as the interface-controller is compatible with any system which has an 8-bit I/O port plus an additional binary input line for inputting the frequency signal, though it is required that any of the 8-bit lines can be programmed independently as an input or output line).

The interface-controller was built from a CMOS integrated circuit to minimize port loading and power consumption. The system used by us (Fig. 2) is, of course, just one approach of the many possible.

Figure 2a is the circuit diagram of half of the interface-controller. The complete 16 channel system is obtained by connecting two such sub-units in parallel. One half should have a break at point A of the printed circuit, and the other at point B, for proper channel decoding.

The control lines of the interface-controller are grouped as follows: PA0–PA3 (inclusive) are channel code lines. A binary combination on these lines will select one of the 16 channels of the analogue multiplexer, the digital multiplexer and one of the relay drivers. However, a relay flip-flop will be set or reset by PA4 only if line PA6 is enabled. An additional control line PA5 is used to deactivate the relays as required on turn-on or default. Digital input/out is channelled through PA7 and the output frequency of the V/F is fed to the microcomputer through line CA1.

The V/F converter (Fig. 2b) is built around a monolithic unit (RC4151 Raytheon, Inc.) and the input is buffered by a CMOS operational amplifier (CA3140, RCA). Full range is adjusted by P_1 and the offset by P_2 (Fig. 2b). In the applications considered here, the output frequency range of 0–10 kHz corresponded to an input voltage range from −500 to +500 mV. Hence, the basic sensitivity (slope) under these conditions was 10 Hz/mV.

Analogue to digital conversion

Digitization is accomplished in the system by counting the pulses of the V/F converter over a fixed period of time by a subroutine written in assembly language for maximum speed. Execution time per incoming pulse is about 100 μsec, corresponding to an upper frequency limit of 10 kHz. With a 1-sec counting window, the resolution is thus 1 part in 10^4 (*ca.* 13 bits) which is 0.1 mV. Digitization noise, estimated at ±1/2 pulse, is thus 86 db.

Besides the inherent sampling noise, the effect of integration on the signal-to-noise (S/N) ratio has to be considered. The counting technique used smooths the noise by integrating it over the counting period. Assuming a sinusoidal interfering noise of amplitude S_n, frequency ω_n and a randomly distributed phase angle ϕ_n, the total input signal S_t to the V/F is:

$$S_t = S_{in} + S_n \sin(\omega_n t + \phi_n) \quad (1)$$

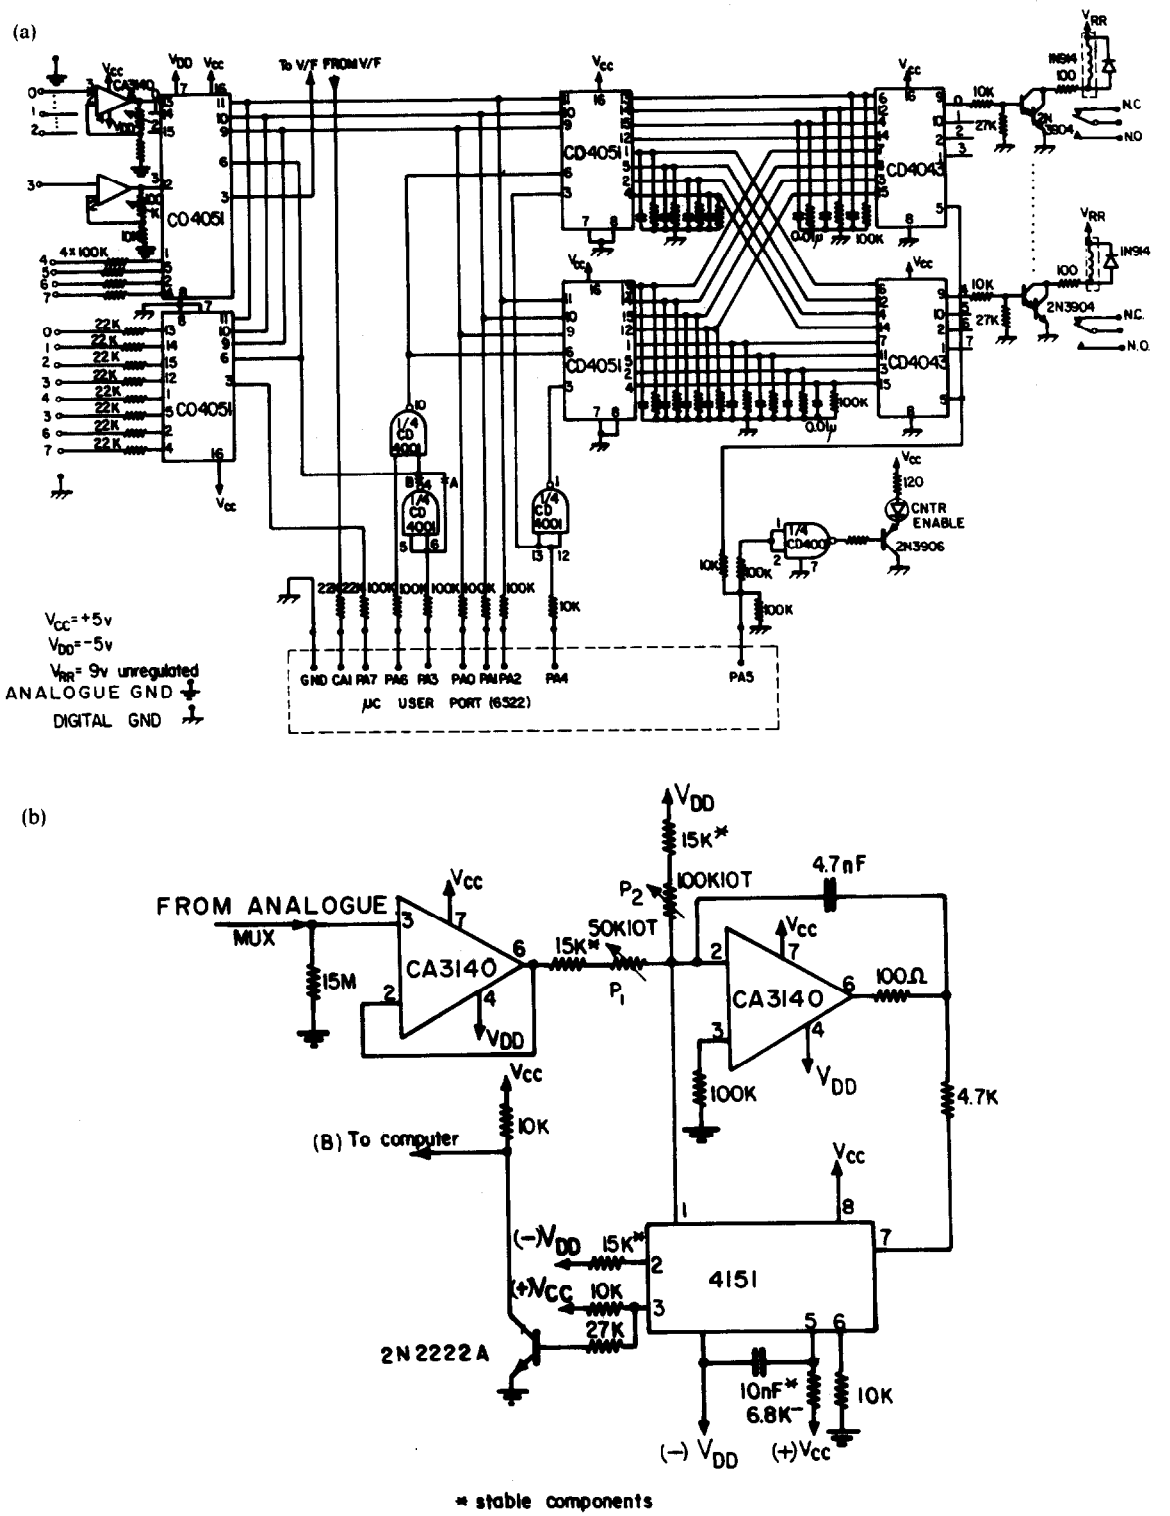

Fig. 2. Circuit diagram of interface-controller (*a*) and detailed circuit of V/F converter (*b*); 16-channel operation is obtained by using two units of type (*a*), one with a cut in the printed circuit at point A and the other with a cut at point B (shown in the 1/4 CD 4001 above PA3 in the user port).

where S_{in} is the useful input signal, which is assumed to be constant over the integration window T. Assuming linearity in the V/F conversion and neglecting sampling errors, the average total integrated (counted) signal will be

$$\bar{S}_t = \frac{1}{T}\int_0^T [S_{in} + S_n \sin(\omega_n T + \phi_n)]\,dt \qquad (2)$$

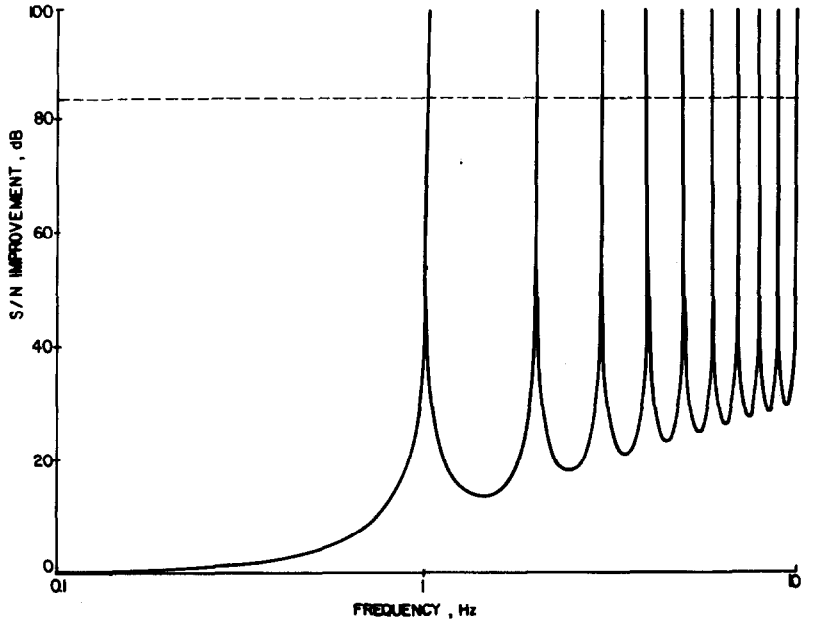

Fig. 3. S/N improvement obtained by the proposed A/D converter when the A/F frequency is counted for 1 sec. The broken line is the inherent digitization S/N (86 db) for a $1:10^4$ resolution, as used here.

$$\bar{S}_t = S_{in} + \frac{S_n}{\omega_n T}[\cos(\phi_n) - \cos(\omega_n T + \phi_n)] \quad (3)$$

The S/N ratio at the input is:

$$(S/N)_{in} = \frac{S_{in}\sqrt{2}}{S_n} \quad (4)$$

and the expected S/N ratio after integration becomes:

$$(S/N)_0 = \frac{S_{in}\omega_n T}{\sqrt{2}S_n|\sin(\omega_n T/2)|} \quad (5)$$

The improvement in S/N is thus:

$$\frac{(S/N)_0}{(S/N)_{in}} = \frac{\omega_n T}{2|\sin(\omega_n T/2)|} = \frac{\pi(T/T_n)}{|\sin(\omega_n T/2)|} \quad (6)$$

where T_n is the period of the interfering signal.

The expected improvement in S/N was calculated and plotted over the frequency range 0.1–10 Hz (Fig. 3). The broken line sets the limit of the maximum sampling error which, for a 0–10 kHz conversion range, is 86 db. The actual improvement was measured by feeding to the V/F converter a d.c. signal on which a sinusoidal signal was superimposed. It was found that the expected and actual improvement agreed very well (Fig. 4).

The effect of counting-period variation on the S/N improvement was measured by changing the counting window while corrupting the input signal with a constant interfering noise derived from the mains (50 Hz). The agreement between calculated and measured S/N improvement (Fig. 5) is good, considering the slight instability of the mains frequency and uncertainty in the counting window. The mismatch corresponds to about 0.1% variation in frequency or counting period, which is well within the tolerance of the set-up.

The ability to adjust the counting window to give optimum S/N improvement, *i.e.*, maximum rejection of an interfering noise with a given frequency, could be very useful in noisy environments. Since the mains frequency is a major interfering noise, the counting window should be adjusted for maximum rejection of this frequency. Optimum performance could be obtained by adjusting the counting window under software control to give maximum S/N improvement.

EXPERIMENTAL

Titration assembly

The titration system (Fig. 6) comprised a CBM type 2016 microcomputer (Commodore Business Machines, Inc.), the interface-controller described above, a Metrohm motor-driven burette, type E415 and a titration vessel in a thermostatic bath. The burette delivered 0.1-ml increments of titrant under program control by one relay of the interface-controller.

The sensor electrode was connected to a buffered channel of the interface controller and the reference electrode to the electrical ground of the electronics.

Electrodes

A Metrohm combination pH electrode, type EA 120, and a Broadly James NH_3 gas-sensing electrode, type 7010, were used.

Acid–base titrations

Mediterranean sea-water and Dead Sea brines were titrated with 0.5*M* hydrochloric acid. The titration was fully automatic and under microcomputer control. The titration procedure included four cycles (Fig. 7): (*a*) manual input of titration parameters; (*b*) the titration cycle; (*c*) storage of raw data; (*d*) data processing.

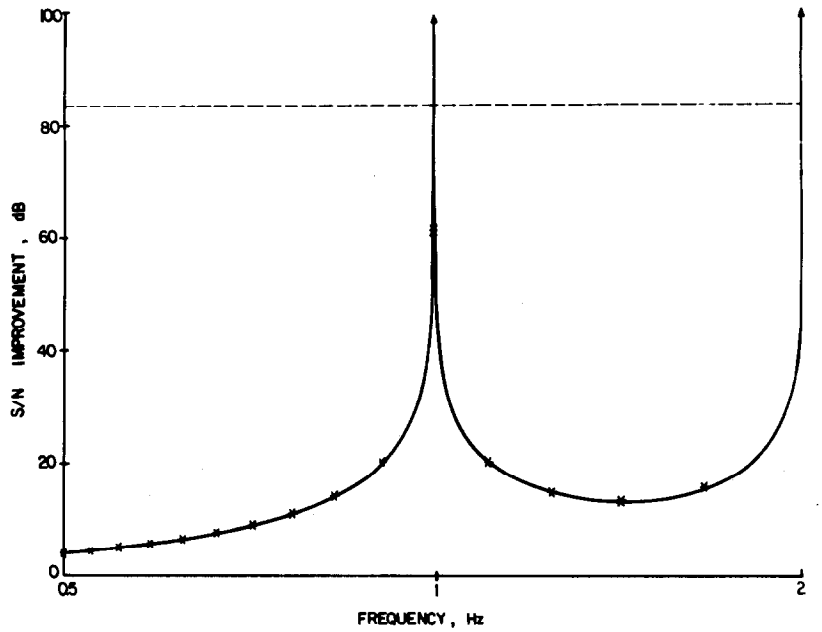

Fig. 4. Calculated (solid line) and measured (asterisks) S/N improvement in the proposed A/D converter for the frequency range 0.5–2 Hz.

Ammonia determination

The ammonia and the glass combination electrodes were connected to the interface controller through three high input impedance buffers and ground. The reference of the pH-electrode was grounded and all other lines, including the internal reference electrode of the ammonia electrode, were buffered to eliminate ground-loop problems. The pH of the solution (which had fixed ammonium chloride concentration) was adjusted manually by addition of 10*M* sodium hydroxide after addition of 2 ml of NBS standard pH-4 buffer,[4] and the outputs of the two electrodes were read by the microcomputer. These data were later used to obtain the best estimate of the constant required for calculating the total ammonia concentration from the readings of the ammonia and pH electrodes.

Computer programs

All programs, except the short subroutine for measuring the frequency of the V/F converter, were written in BASIC.

RESULTS AND DISCUSSION

Carbonate determination

The method was extensively used for studying the carbonate system in Dead Sea brines and mixtures of

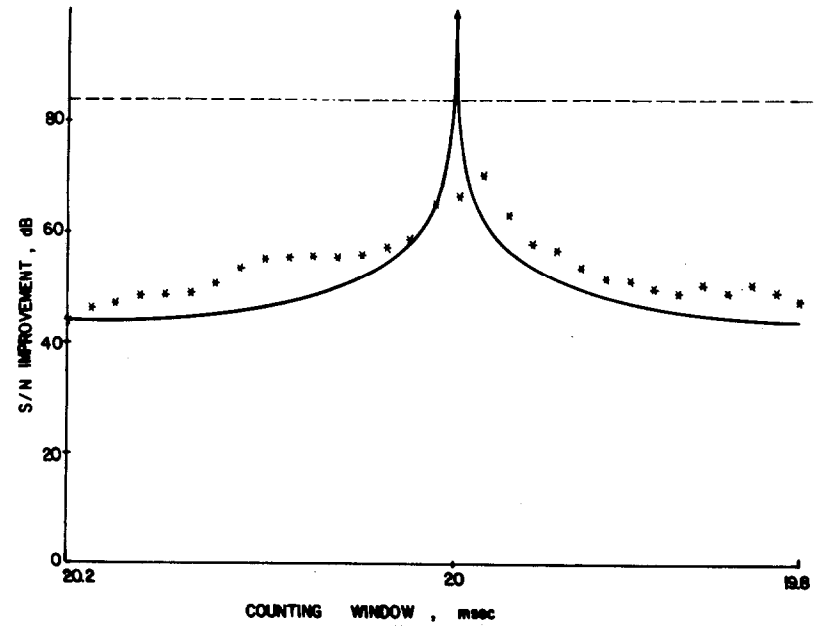

Fig. 5. S/N improvement in the proposed A/D converter as a function of counting-window width for a 50-Hz interfering signal.

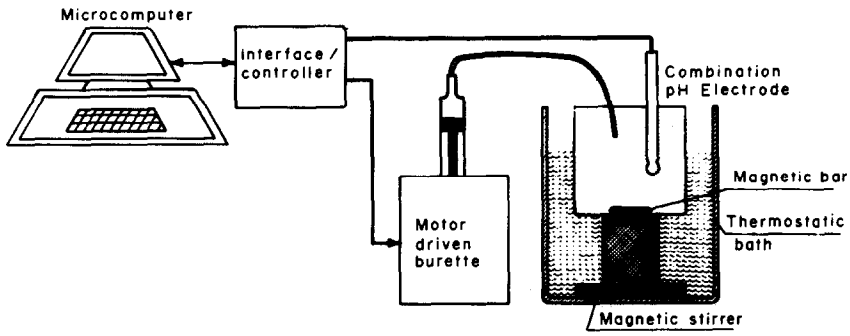

Fig. 6. Experimental system for automatic titration.

Dead Sea brines and Mediterranean sea-waters, to determine the alkalinity and first and second apparent dissociation constants of carbonic acid (K'_1 and K'_2) in the test solution. The procedure followed that described earlier by Sass and Ben-Yaakov.[5]

K'_1 and K'_2 of carbonic acid are used extensively by oceanographers[6] to describe the carbonate system in sea-water and other natural waters. The constants are defined in terms of measurable parameters:

$$K'_1 = \frac{a_{H^+}[HCO_3^-]}{[H_2CO_3]} \tag{7}$$

$$K'_2 = \frac{a_{H^+}[CO_3^{2-}]}{[H_2CO_3]} \tag{8}$$

where the brackets stand for total concentrations of the free and complexed species and a_{H^+} is the activity of the hydronium ion as determined by a glass electrode. Hence, the apparent constants are practical parameters, the use of which eliminates the need to estimate single-ion activity coefficients in complex solutions such as sea-water. However, since the constants are dependent on the ionic strength and composition of the solution, they must be determined for each case separately. They can be calculated from the pH readings during a hydrochloric acid titration. The calculation procedure[5] is basically a least-squares fit of the titration data to the model equation which describes the dependence of pH on the amount of acid added, by use of equations (1) and (2), an alkalinity mass-balance, and assumption that the total concentration of CO_2 species is constant. The alkalinity is first determined by a Gran-type titration.[5,8] The computation procedure is done by a BASIC program run after the titration is completed.

Typical titration curves obtained with the system are shown in Fig. 8. The results obtained for the sea-water ($pK'_1 = 5.95$, $pK'_2 = 9.00$ agree well with Lyman's values (5.98 and 9.06).[6]

Ammonia determination

The ammonia gas-sensing electrode responds only to NH_3 and is insensitive to the ammonium ion.[9] Since the distribution of total ammonia (ΣNH_3) between NH_3 and NH_4^+ is pH-dependent, ΣNH_3 can be directly determined by the electrode only at pH high enough for practically all the ammonia to be in the molecular form. If the ammonia and water dissociation constants

$$K_{NH_3} = \frac{[NH_4^+][OH^-]}{[NH_3]} \tag{9}$$

$$K_W = [OH^-][H^+] \tag{10}$$

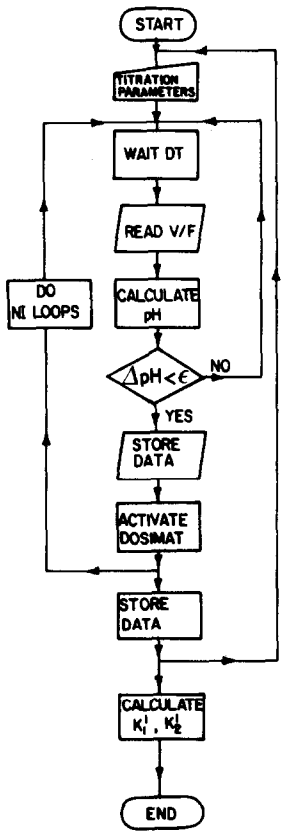

Fig. 7. Flow diagram of the titration procedure.

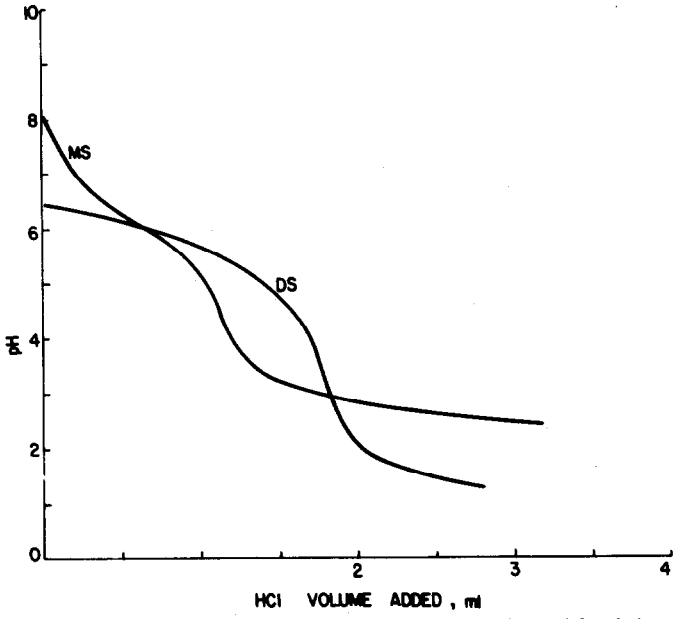

Fig. 8. Typical titration curves for Mediterranean sea-water (MS) and Dead Sea brine, obtained by the proposed system. Solutions were titrated with 0.5*M* HCl.

are known, ΣNH_3 can be calculated[10] from the readings of the ammonia and pH electrodes and the relationships

$$\sum NH_3 = [NH_3]\left\{1 + \frac{K_{NH_3}[H^+]}{K_W}\right\} \quad (11)$$

$$[NH_3] = 10^{(E^0_{NH_3} + S_{NH_3}V_{NH_3})} \quad (12)$$

$$[H^+] = 10^{(E^0_{H^+} + S_{H^+}V_{H^+})} \quad (13)$$

where E^0, S and V are the potential offset, slope and mV reading of the electrode designated by the subscript.

Direct determination of ΣNH_3 from pH and $[NH_3]$ by equation (4) is not always possible since K_{NH_3}/K_W is a function of the ionic composition of the solution and is seldom known. We have used the microcomputer system described here to calculate this constant for a given test solution by a trial and error calculation method. The procedure compares calculated ΣNH_3 values with the actual concentration for a series of guessed values for K_{NH_3}/K_W. This procedure

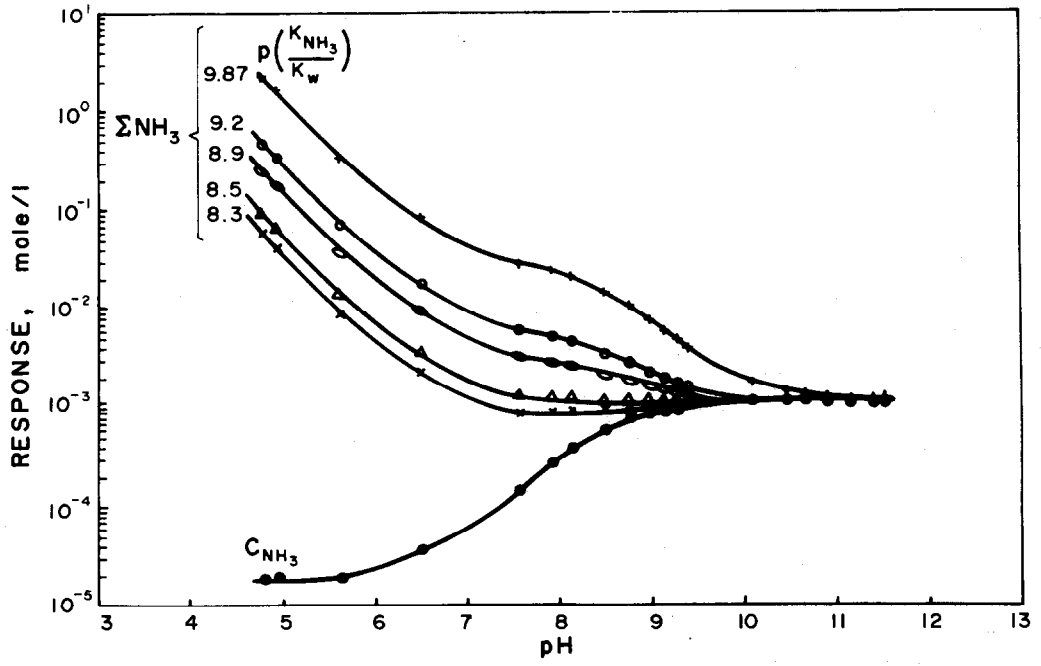

Fig. 9. Response of ammonia electrode in $10^{-3}M$ NH_4Cl at various pH values (lower curve), and calculated ΣNH_3, for various guessed values of K_{NH_3}/K_W.

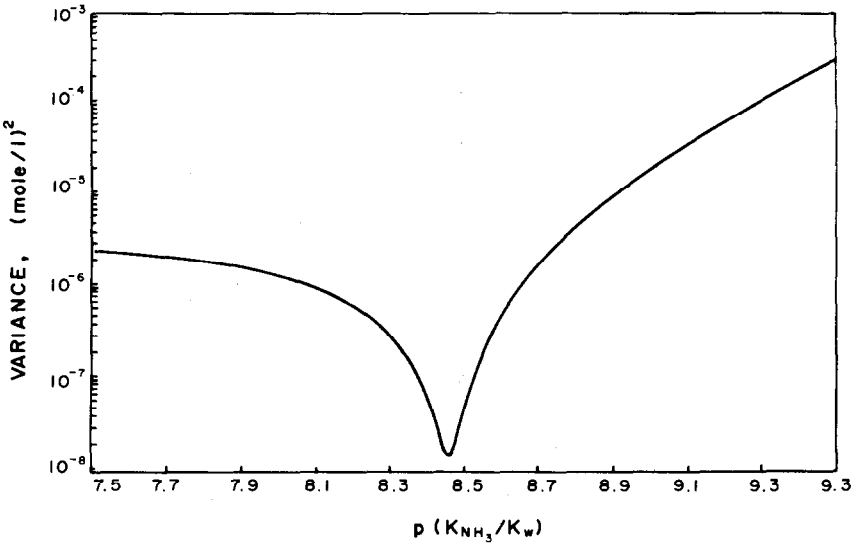

Fig. 10. Variance of the difference between calculated ΣNH_3 and known value (as measured at high pH) for various values of guessed K_{NH_3}/K_W. (For data of Fig. 9.)

is summarized graphically in Fig. 9 which depicts the original NH_3-electrode data and calculated ΣNH_3 for a number of K_{NH_3}/K_W values. The variance of the difference between the calculated values and the known concentration (as measured at high pH) was then used to find the best fit (Fig. 10). Once the constant is determined for a given solution it can be used to calculate ΣNH_3 from the reading of the electrodes at any pH provided the free ammonia concentration is not below the lower limit of linear response of the ammonia electrode. As this limit for the ammonia electrode used was about $2 \times 10^{-5}M$, ΣNH_3 at the $0.002M$ level could be determined at any pH not below 7.5 (Fig. 9).

OBSERVATIONS ON 1-PHENYL-3-METHYL-4-TRIFLUOROACETYLPYRAZOLONE-5, A PROMISING EXTRACTING AGENT

EMMANUEL CHUKWUEMEKA OKAFOR

Coordination Chemistry Research Unit, Department of Chemistry, University of Nigeria, Nsukka, Anambra State, Nigeria

(*Received* 15 *August* 1980. *Revised* 21 *September* 1981. *Accepted* 6 *October* 1981)

Summary—A simple procedure for obtaining 1-phenyl-3-methyl-4-trifluoroacetyl-pyrazolone-5 (HPMTFP), a promising metal extractant, is described. Recrystallization studies reveal that only one tautomer can be isolated, sometimes with one molecule of water of crystallization, contrary to reports that a yellow enol and a white keto tautomer can be obtained from n-hexane and aqueous ethanol respectively. The melting points and colours of some of the metal chelates of HPMTFP are tabulated and in the case of Hg(II) and Cu(II) chelates, differ from those reported by others. Solubility data for some of the metal chelates of HPMTFP are also given.

The 1-phenyl-3-methyl-4-acylpyrazolone-5 compounds, the 4-benzoyl derivative in particular, have been gaining increasing popularity for extraction of metals from acidic media,[1–15] and have been reviewed in a monograph by Zolotov and Kuzmin.[16] Recently Hasany and Qureshi employed the 4-trifluoroacetyl derivative (HPMTFP) as an extractant for some Group IB, IIB, and IIIA–VA elements[17] and obtained some encouraging results. In view of the potential of this derivative as an extractant and our general interest in this ligand and its metal complexes, we feel it necessary to clear up some confusion about some of its physical properties and those of some of its chelates. A synthesis giving very high yield of this reagent is also described.

EXPERIMENTAL

In the synthesis it was observed that the quantity and type of acid used in the acidification process affects the yield. The following procedure was found to give maximum yield.

Procedure

1-Phenyl-3-methyl-pyrazolone-5 (8.5 g) is dissolved in anhydrous pyridine (50 ml) in a 1-litre round-bottomed "Quickfit" flask. Merck pyridine (Purum grade) was found to be suitable without further purification. Next, 6.2 ml of trifluoroacetic anhydride (10 g) are added dropwise with shaking from a "Quickfit" dropping funnel, care being taken that no trifluoroacetic anhydride vapour escapes during the process. The reaction is exothermic so the flask is cooled under running water. The wine-red reaction mixture is kept at room temperature for 1 hr before being poured into 200 ml of distilled water in a 2-litre beaker. No precipitate is formed. The solution is stirred while being acidified with 3*M* hydrochloric acid (250 ml), and a pinkish-cream precipitate is obtained. This is collected on a sintered-glass funnel, washed with distilled water until the washings are colourless, and then dried in air. Yield 91%; m.p. 139–140°. The melting points of the products obtained by recrystallization from various solvents are given in Table 1.

Tautomeric forms

Jensen[1] reported that recrystallization from ethanol–water of the crude product obtained by his procedure gave 78% yield of pure product, m.p. keto tautomer 144° and enol form 132°. Hasany and Qureshi[17] reported that by Jensen's method[1] they obtained a pure product which was yellowish and had m.p. 132°. They also reported that HPMTFP exhibits keto–enol tautomerism and can be obtained in two forms, the enol being yellowish and the keto form colourless, but did not state the melting points of these tautomers. Furthermore, they depicted structure (I) for one keto form (Fig. 1) and structures (III) and (IV) for two enol forms which they claim are in "resonance". However, detailed studies carried out in our laboratories gave the results in Table 1, which do not agree with theirs. Scrutiny of the results, particularly the infrared and NMR spectroscopic data, reveals that only one tautomer is obtained throughout these studies, even though it sometimes has some molecules of water of crystallization. The result is very interesting because ordinarily for such 4-acylpyrazolones-5 as the 4-benzoyl derivative, the tautomer isolated from n-hexane (yellow form) is different from the tautomer isolated from aqueous ethanol (white form), as revealed by detailed infrared and NMR spectroscopic studies.[18] In the case of HPMTFP the tautomer isolated from carbon tetrachloride is anhydrous and assigned structure 1(IV) (Fig. 1) on the basis of conclusions arrived at during similar investigations carried out on the 4-benzoyl derivative.[18] The tautomer isolated from H_2O/MeOH (2:1 v/v) and dried over anhydrous calcium chloride in a desiccator is identical with that obtained from carbon tetrachloride, as revealed by detailed infrared and proton NMR examination.

From spectroscopic evidence both the crude product and the product recovered from n-hexane are identical and are the same tautomeric species as that obtained from both carbon tetrachloride and aqueous methanol, except that in the first of these two there is a molecule of water crystallization. The only yellow form of HPMTFP was prepared accidentally as follows.

HPMTFP [8.11 g, (0.03 mole)] was mixed with sodium triscarbonatocobaltate(III) trihydrate, $Na_3[Co(CO_3)_3].3H_2O$, (3.62 g, 0.01 mole) in 95% ethanol (120 ml), refluxed for 2 hr, cooled, and poured into excess of 3*M* hydrochloric acid. A deep yellow powder was obtained on filtration and air drying, m.p. 139–140°. Spectroscopic study

revealed this to be the same tautomeric species as the other products, with one molecule of water of crystallization.

DISCUSSION

It is obvious from these studies that only one stable tautomeric form has been isolated, and the following explanation is offered. HPMTFP may exist in four tautomeric forms as depicted below (Fig. 1).

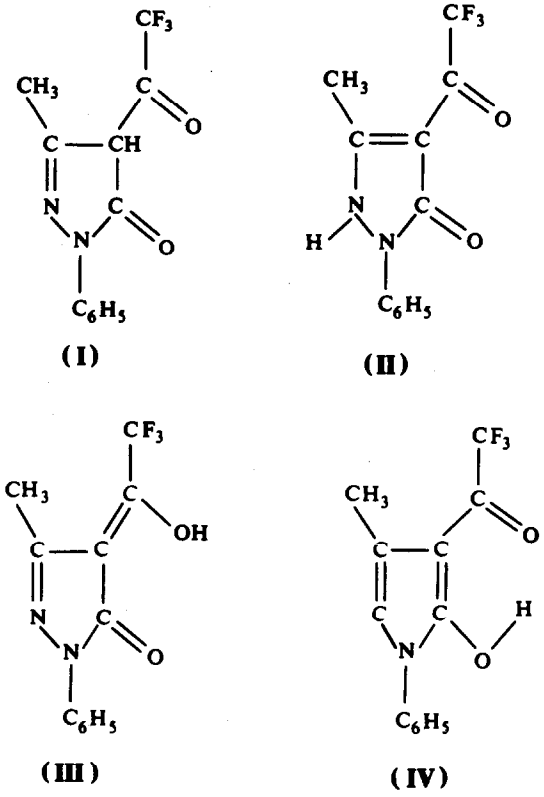

Fig. 1.

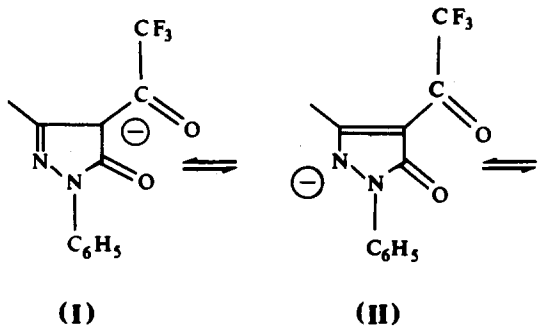
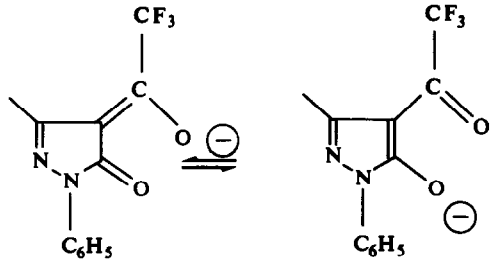
An insight into the relative stability of these forms may be gained by examining the different forms of the anion, (PMTFP)-, since the labile proton that gives rise to the tautomerism may migrate from one negative centre to another. The various resonance forms of the anion $(PMTFP)^-$ are shown below.





(III) (IV)

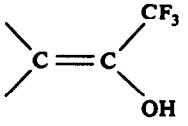
Fig. 2. Resonance forms of the anion (PMTFP).

Structure (I) (Fig. 2)

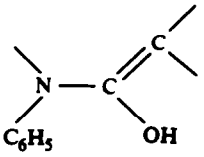
The probability of the negative charge being where located as in (I) in Fig. 2 is extremely small since several powerful electron-withdrawing groups, (C=O, –C=N– and $-CF_3$) are withdrawing negative charge from the carbon atom carrying the negative charge. Therefore this tautomer is in the least likely of the four.

Structures (II), (III), (IV) (Fig. 2)

Under suitable conditions the anions represented by (II), (III) and (IV) in Fig. 2 may plausibly be regarded as existing, and therefore the corresponding tautomers represented by (II), (III) and (IV) in Fig. 1 may be isolable. The ease of isolation of (IV) (Fig. 1) relative to that for (III) may be due to the fact that $-CF_3$ is electron-withdrawing whereas $-C_6H_5$ is electron-releasing. Therefore the hydroxyl proton in the moiety,



will be more labile than the hydroxyl proton in the moiety,



Consequently, the species represented by structure (IV) in Fig. 1 will be more stable and easier to isolate than the species (III).

Hasany and Qureshi[17] reported that they precipitated the chelates of Cu(II) and Hg(II), which were yellow to dark yellow, from buffer solutions ranging from pH 1 to 10. We have isolated and characterized some metal(II) and metal(III) chelates of HPMTFP[19] and some of the relevant data are listed in Tables 2 and 3. The metal(II) chelates were generally prepared by reacting the metal(II) acetate with HPMTFP in 95% ethanol, whereas for metal(III) chelates specific methods[19] were found desirable. The metal chelates were characterized by elemental analyses, conducti-

vity measurements, and infrared and proton NMR spectroscopy. According to our results (Table 3), the solids isolated by Hasany and Qureshi[17] were not the Hg(II) and Cu(II) chelates of HPMTFP. Our Hg(II) chelate of HPMTFP is white and not dark yellow, while the Cu(II) chelate is yellowish green and not yellow.

The selection of solvent plays an important role in establishing the optimum conditions for extraction. The solubility of the chelate is particularly important. Table 2 gives the solubility characteristics of HPMTFP and some of its metal chelates in various solvents.

Finally, it is interesting to observe that the starting material for the synthesis of HPMTFP, 1-phenyl-3-methyl-pyrazolone-5 can be regenerated from HPMTFP by boiling with a solution of sodium hydroxide in equimolar proportions, concentrating the resulting reaction mixture, and allowing the solid 1-phenyl-3-methyl-pyrazolone-5 to crystallize out.

(*Received* 10 *June* 1981. *Accepted* 5 *October* 1981)

Summary—The concentrations of Ag, Cd, Pb, Zn and Pd in sea-water have been determined by thermal-ionization isotope-dilution mass spectrometry. The concentrations found, in ng/kg, were 0.6 ± 0.4 Ag, 1.9 ± 0.4 Cd, 18 ± 8 Pb, 30 ± 8 Zn and <4 Pd. These levels are lower than some reported previously. Determination of Pd in sea-water is reported for the first time.

Although metals have been determined in sea-water for many years without apparent difficulty there is now strong evidence to suggest that much of the published data may be highly inaccurate. In the early 1970s Patterson and co-workers recognized that there were difficulties in measuring environmental lead levels. In a series of careful studies[1–5] they demonstrated that the available data were in error by orders of magnitude because of either analytical difficulties or contamination during sampling, storage or analysis. Studies of trace metal levels in sea-water by Boyle *et al.*,[6] Bruland *et al.*[7] and Bruland[8] indicate that similar difficulties may exist for cadmium and zinc. Our own studies of cadmium in river[9,10] and sea-water[11,12] also yielded lower levels than were reported elsewhere. We originally attributed this discrepancy to a particularly clean Western Australian environment, but the reason could equally well have been analytical difficulties in much of the published work.

In this paper we report the results of measurements of Ag, Cd, Pb, Zn and Pd in coastal sea-water in the Indian Ocean off Western Australia. Particular care was taken to avoid contamination during sampling, storage and analysis, and thermal-ionization isotope-dilution mass spectrometry was used for all analyses.

EXPERIMENTAL

Sampling

Water samples were collected at a location 3.3 km due west of Cape Vlaming, Rottnest Island, outside the 50-m contour. The location is approximately 20 km west of Fremantle in the Indian Ocean. The samples were collected during August and December 1980 from an aluminium work boat with a low-contamination pump constructed for the purpose. Water was transferred from a depth of 30 m to the pump through 1.2 cm bore conventional polyethylene (CPE) tubing held vertical with a stainless-steel weight. The pump operated on the principle of a simple force pump, the pumping action being achieved with an expandable Teflon bellows and two Teflon valves (inlet and outlet). All pump surfaces with which the sample came into contact were made of Teflon (PTFE). The water samples were stored in 2.5-l. high-density polyethylene (LPE) bottles, which were double sealed in LPE bags.

Reagents

Most of the sample processing and reagent preparation was done in laboratories supplied with coarsely filtered air, although laminar-flow clean-air hoods were employed for critical stages of distillation.

Quartz-distilled water (QDW). Tap water was first demineralized, then distilled in a Pyrex still. After sub-boiling distillation in a quartz still the water was stored in acid-leached LPE containers. Analysis of the water yielded 0.08 ± 0.08 ng/kg for Ag, 0.6 ± 0.4 ng/kg for Cd, 1 ± 1 ng/kg for Pb and 28 ± 10 ng/kg for Zn. Pd was not determined. Because of the possibility of contamination from handling and storage of the water these levels represent upper limits for these metals in the QDW.

Ammonia solution. A 2–3*M* solution was prepared from the analytical grade reagent with a two-bottle Teflon still.

Acetic acid. The analytical-grade reagent was distilled in a two-bottle Teflon still.

Ammonium acetate solution. Prepared by mixing appropriate quantities of acetic acid and ammonia solution to yield a solution of pH 5.0–5.5.

Hydrochloric and nitric acids. Prepared by distillation of the analytical-grade reagents, first in a quartz sub-boiling still, then in a two-bottle Teflon still. Analysis of the hydrochloric acid yielded 0.18 ± 0.06 ng/kg for Cd, 3.7 ± 0.5 ng/kg for Pb and 10 ± 3 ng/kg for Zn. Ag and Pd levels were not determined.

Ion-exchange resins. Bio-Rad 100–200 mesh AG50-X8 cation-exchange and AG1-X8 anion-exchange resins were

*Present address: Envirochem, 12 Ennis Court, Orelia 6167, WA.

stored in 4*M* and 2*M* hydrochloric acid respectively, but were cleaned and conditioned immediately before use. Bio-Rad Chelex 100, 100–200 mesh, was cleaned with dilute nitric and hydrochloric acids and stored in dilute nitric acid.

Cleaning of apparatus

The Teflon pump components were leached in dilute hydrochloric acid for 3 weeks. The CPE sampling tube was leached in dilute hydrochloric acid at 60° for the same period. The LPE sampling bottles were cleaned by successive leachings with dilute nitric and hydrochloric acids at 60° for 6 weeks. This cleaning procedure proved to be too vigorous for the LPE and one bottle became brittle and cracked during sampling; Teflon should be superior in this respect. Teflon (PTFE or FEP) laboratory ware was used, except for the ion-exchange columns (made of Vycor glass) and Pyrex conical flasks used for determination of palladium.

Isotope-dilution mass-spectrometry (IDMS)

Details of this technique have been given by Webster.[13] An accurately known amount of highly enriched stable isotope (the tracer) of the element to be determined is allowed to equilibrate with the sample. The element is then separated in a pure form and its isotopic composition measured in a mass spectrometer. From a knowledge of the isotopic composition of the tracer added and of the natural element in the sample solution, the amount of natural element present can be determined. Quantitative separation of the element is not necessary. In this study a tracer solution containing the enriched stable isotopes ^{107}Ag, ^{111}Cd, ^{204}Pb, ^{67}Zn and ^{102}Pd was prepared from materials supplied by Oak Ridge National Laboratory. The concentration of each element in this solution was determined by calibration against a gravimetrically prepared solution of the metal (Johnson and Matthey "Spec-Pure"), by the IDMS method. Before leaving the laboratory for sampling, each LPE sampling bottle was spiked with an accurately weighed amount of tracer solution. Sufficient hydrochloric acid was added to give a 0.1% solution (1 g of concentrated hydrochloric acid per kg) when the sea-water was added, to minimize loss of metals to the container surfaces. Sample bottles were protected from environmental contamination by double sealing in LPE bags. On return to the laboratory the bottles were heated to 60° under infrared lamps for at least 3 days to ensure desorption of any metal from the walls, and equilibration with the tracer.

The palladium concentrations reported were not determined by the procedures above. However, the same sampling bottles, acidification and post-sampling heating procedures were employed. Acidified 200-g samples were transferred to 250-ml Pyrex conical flasks, then tracer was added and allowed to equilibrate for 16 hr.

Chemical separations

Lead and zinc were extracted with chelating resin (Chelex 100) by procedures similar to those described by Kingston *et al.*[14]

Each 2.5-l. sample was adjusted to pH 7 with ammonia solution and then buffered to pH 5–5.5 with ammonium acetate. This enabled the samples to be transferred directly to the columns from the storage containers, and minimized the possibility of contamination. The resin was washed with ammonium acetate solution to remove calcium, magnesium and manganese, then lead and zinc were eluted with 2*M* nitric acid. The solution was evaporated to dryness and the residue treated by evaporation with *aqua regia*. This yielded a sample sufficiently pure for mass spectrometric analysis. The analytical blank was determined by processing the same quantities of reagents as used for the samples.

Silver, cadmium and palladium were extracted with anion-exchange resin (AG1-X8). This gave lower analytical blanks for these elements than could be achieved with the Chelex 100. Since the distribution coefficients for these elements on AG1 are extremely high at low hydrochloric acid concentrations, the sample solutions could be transferred directly to the columns. Following the addition of the sample the resin was washed with three 10-column-volume lots of 0.1*M* hydrochloric acid. The cadmium and silver were eluted with 6 column-volumes of 1*M* nitric acid and the eluates evaporated to dryness. Then 10 column-volumes of QDW were added to the column, and finally palladium was eluted with 5 column-volumes of 2*M* ammonia. The palladium eluate was evaporated to dryness and ammonium salts were removed by evaporating twice with a few drops of *aqua regia*. Before the palladium samples could be satisfactorily analysed they required further purification. This was achieved by passing the sample through cation-exchange resin (AG50-X8) in 0.1*M* hydrochloric acid. The silver and cadmium samples required no further processing.

Thermal-ionization mass spectrometry

The isotopic analyses were carried out in a 30.5-cm radius, 90° deflection mass spectrometer fitted with a thermal-ionization source. The ion currents were amplified with an electron multiplier and vibrating reed electrometer and the output was digitized and fed on-line to a minicomputer. The samples were loaded together with phosphoric acid and silica gel onto zone-refined rhenium ribbon single-filament assemblies. The elements were determined in three groups: (Ag, Cd), Pd and (Pb, Zn). The (Pb, Zn) group was transferred to the filament in dilute hydrochloric acid while dilute nitric acid was used for the others. The elements yielded measurable ion currents at different temperatures, so one element could be determined without loss of another. The order of appearance of the metal ions with increasing temperature was Ag, Pd, Cd, Pb, Zn. With ion currents of $>10^{-14}$ A, isotopic ratios could be measured with a precision better than 1%. The isotopic ratios measured were $^{109}Ag/^{107}Ag$, $^{112}Cd/^{111}Cd$, $^{208}Pb/^{204}Pb$, $^{66}Zn/^{67}Zn$ and $^{104}Pd/^{102}Pd$. Uncertainties introduced by the isotopic analyses made a negligible contribution to the uncertainties associated with the final element concentrations.

RESULTS AND DISCUSSION

The results of analysing sea-water for Ag, Cd, Pb, Zn and Pd are given in Table 1. The paired analyses represent determinations on 1.2-kg aliquots from the same 2.5-l. sample bottle. The 2.5-l. bottle used to determine the level of metals in the QDW was subjected to the same procedures (cleaning and pre-analysis) as the bottles containing sea-water samples. The levels found in QDW therefore represent limits of contamination acquired during the storage of samples.

Owing to the vigorous cleaning procedures employed for the polyethylene bottles, one became brittle and cracked. Analysis of sea-water samples from this bottle for silver and cadmium are shown in brackets. These values were significantly higher than those obtained from the other two bottles, indicating that contamination had occurred. Consistent results were obtained from the remaining bottles, giving 0.6 ± 0.1 ng/kg for Ag and 1.9 ± 0.4 ng/kg for Cd in sea-water.

Table 1. Levels of Ag, Cd, Pd, Pb and Zn in sea-water samples

* Sample sizes of 1.2 kg were analysed in all cases except for Pd, where 200-g samples were taken.

† Three bottles of sample were analysed in duplicate for both Ag and Cd. Two other bottles were analysed in duplicate for Pb and Zn. Another three bottles were analysed for Pd but only one in duplicate.

§ Values given in brackets were not included in mean; errors shown are 95% confidence limits.

The uniformly low blank determinations for silver indicate that contamination from the reagents and the chemical laboratory was not significant. Contamination during storage was small and within the error limits quoted. The contamination during sampling could not be assessed. Environmental contamination of samples proved to be a significant problem for lead and zinc. Two bottles of sea-water were analysed. The spread in concentration was observed to be significantly greater than that found for Ag and Cd. This was principally due to intermittent contamination problems which seemed to be marginally worse for zinc than for lead. One particularly large zinc blank was rejected (shown in brackets in Table 1). Also the analysis of the second aliquot from the second sample bottle failed when measurable ion beams could not be obtained in the mass spectrometer.

The limited data given in Table 1 for zinc are supported by some less precise measurements on smaller samples (200 g) taken from the same locality. These measurements yielded 54, 73, 16 and 98 ng/kg with an accompanying blank of 80 ± 20 ng/kg. Because one blank determination was high and analytical difficulties were experienced with the second bottle it is probably wisest to accept the lower values of 25 and 35 ng/kg in Table 1 as more accurately representing the true levels. A value of 30 ± 8 ng/kg is then obtained for zinc in sea-water. The QDW analysis gave 28 ng/kg for Zn. If a significant amount of this was from contamination during storage, the true level of Zn in sea-water may be considerably lower than 30 ng/kg.

The four determinations of lead in this study gave a value of 18 ± 8 ng/kg for sea-water. These data are also supported by less precise analyses of 200-g samples, which gave 30, 28, 1 and 7 ng/kg with an accompanying blank of 23 ± 20 ng/kg. Since the QDW analyses yielded 1 ng/kg of Pb the storage container appears to be a minor source of lead contamination.

The limited usefulness of most published lead levels for environmental samples, because of contamination, has been emphasized by Patterson and co-workers.[1–5] Chow[15] has reviewed determinations of lead in ocean water and concluded that many results in the literature are unreliable. A similar picture is emerging for zinc. Bruland *et al.*[7] and Bruland[8] have reported levels of zinc in sea-water 2–3 orders of magnitude lower than the 1–10 μg/kg levels generally reported. They attribute this to serious contamination problems in other studies. Our data support the lower values. Because of the ubiquitous nature of both lead and zinc it is not surprising that contamination is the factor limiting their accurate determination. Although from our work contamination with cadmium during sampling and analysis does not appear to be as serious a problem as it is for lead or zinc, the values we report are signficantly lower than those published previously. Florence and Batley[16] express doubts about the state of knowledge of cadmium speciation in natural waters, owing to measurement difficulties, citing analytical difficulties and contamination as the principal problems. The mass spectrometric technique employed in this study enabled <0.005 ng of cadmium to be measured accurately, hence the fluctuation of the analytical blank is the principal factor limiting the precision of these analyses. Contamination during the storage of samples could contribute up to 0.6 ng/kg if the storage containers were responsible for the cadmium found in the QDW. This would still place the level of cadmium sea-water between 1 and 2 ng/kg.

Only an upper limit of 4 ng/kg could be set for palladium in the sea-water. The low precision of these measurements was a consequence of the small volumes analysed.

An assumption made in these measurements is that the tracer becomes equilibrated with the sample. This is a reasonable expectation for dissolved species. Florence and Batley[16] have reviewed speciation of elements, including Pb, Cd, Zn and Ag, in natural waters, and find the principal species in sea-water are the chloro-complexes and carbonate for Pb, the chloro-complexes for Cd, the free metal ion, chloro-complexes and carbonato-complex for Zn, and chloro-complexes for Ag. Data for Pd are very limited, although the E_h–pH conditions for a Pd–Pt–H_2O–Cl system have been described by Fuchs and Rose.[17] Their E_h–pH diagram indicates that Pd will occur as either the metal ion or the

* Concentration in ng/l.

chloro-complex in sea-water acidified with hydrochloric acid.

Since the samples were acidified to contain 1 g of concentrated hydrochloric acid per kg, there is little risk of adsorption of these elements on the walls of the LPE storage containers, but the level of adsorption on, and dissolution from, suspended matter was not measured and is uncertain.

A comparison of the data from this study with the bulk of published data reveals a significant discrepancy for all elements, for which data could be found (*i.e.*, all except palladium). Selected published data are given in Table 2. Other data tend to be significantly higher and this is assumed to be due to contamination or analytical difficulties. The levels reported for cadmium by Boyle *et al.*[6] and Bruland[8] on samples from the Pacific Ocean are in agreement with our value of 1.9 ng/kg. Earlier measurements by Morris *et al.*[11] gave an average level of 13 ng/kg for Western Australian coastal waters. However, these samples were collected from near-shore locations where the depth of water was generally less than 2 m. Even so, some determinations gave concentrations as low as 5 ng/kg. Recent determinations by Rosman *et al.*[12] on samples taken from the seaward side of Garden Island, Western Australia, gave values as low as 2 ng/kg. Because of improvements to the sampling procedures the present results are our most reliable values. The value we report for lead compares favourably with the value of 25 ng/kg reported by Patterson *et al.*[18] for ordinary surface samples off the Californian Coast and 12–14 ng/kg reported by Schaule and Patterson[5] for near-surface samples from the Pacific Ocean. The value of 30 ± 8 ng/kg arrived at for zinc in sea-water from this study falls within the range of values found by Bruland *et al.*[7] and Bruland[8] for near-surface samples from the Pacific Ocean. These levels are approximately two orders of magnitude lower than the generally accepted levels. Confirmation of these lower levels is therefore very significant, but there remains the problem of explaining why the majority of studies appear to enhance the levels so uniformly.[16]

The value of <4 ng/kg given here for palladium may be the first reported for this element in sea-water. Because of the high level of the analytical blank compared to the level found in the water samples, we prefer to quote an upper limit for this element. The value of 0.6 ng/kg obtained for silver is significantly lower than the value of 10 ng/kg reported earlier by Robertson.[19]

The IDMS method offers significantly higher accuracy than is attainable with those methods generally used to analyse water samples. It also provides extremely high sensitivity for many elements. Mandel[20] has identified IDMS as a prime example of a definitive analytical method. Although the techniques employed by Bruland and co-workers[8,21] have adequate sensitivity for cadmium and zinc, IDMS has, in addition, high accuracy. At the levels at which many metals are present in sea-water, preconcentration is usually necessary. This will not significantly alter an isotopic ratio, hence the accuracy of IDMS is maintained. A knowledge of the chemical yield is not required and any losses at this stage will not influence the result. Hence the basic accuracy of the method is directly traceable to the gravimetrically prepared solutions used for calibration. The method is therefore ideally suited for the characterization of standard reference samples of sea-water, which are clearly needed to resolve the present uncertainties.

It should be emphasized that the method being employed in this study for isotopic analysis is thermal-ionization mass spectrometry and not spark-source mass spectrometry, as mistakenly quoted by Florence and Batley[16] in their discussion of the work by Patterson and co-workers on lead. Isotope dilution coupled with thermal-ionization mass spectrometry is a technique which has been available for some elements for more than three decades, and yet it has received very little attention from analytical chemists with the notable exception of the U.S. National Bureau of Standards (Washington, D.C.).

CONCLUSIONS

The results of the study indicate that Ag, Cd, Pb and Zn are present in sea-water at levels significantly below the currently accepted levels, confirming lower values reported in recent years by some authors. The level of Ag was found to be in the sub-ng/kg range, and a value of Pd in sea-water is reported for the first time. Evidence is accumulating which suggests that the levels of some metals in sea-water are being measured inaccurately. One serious outcome of this is that the baseline levels reported for these elements are orders of magnitude too high. To assist in resolving the discrepancies accurately characterized samples of sea-water are needed.

Acknowledgements—In particular we wish to thank Mr. G. Brown and Mr. A. Planken for their assistance with the design and construction of the sampler. Mr. C. Simpson and Mr. R. Biddescombe assisted with the sampling and Mrs. C. Green typed the manuscript. This project was funded by the Commonwealth Department of Home Affairs and Environment (Marine Assessment Programme 15) and the Australian Research Grants Committee.

DETERMINATION OF Cr, Ni, Cu, Zn AND Cd IN NIOBIUM BY RADIOCHEMICAL PROTON-ACTIVATION ANALYSIS

W. G. FAIX and V. KRIVAN

Sektion Analytik und Höchstreinigung, Universität Ulm, Oberer Eselsberg N26, D-7900 Ulm, F.R.G.

(*Received* 3 *September* 1981. *Accepted* 26 *September* 1981)

Summary—A rapid radiochemical proton-activation technique based on the utilization of short-lived indicator radionuclides ($t_{1/2}$ = 7–100 min) for the determination of Cr, Ni, Cu, Zn, and Cd in niobium is described. It involves the irradiation of the samples with 13-MeV protons, the post-irradiation decontamination of the sample surface, a rapid sample dissolution, a separation procedure based on anion-exchange from HF medium, and counting the eluate with a high-resolution gamma-spectrometer. In addition, for the determination of Ni, a specific separation procedure is proposed. For a 20-min irradiation with a beam intensity of 10 μA and a delay time of 20 min, the limits of detection are 4 ng/g for Cr, 0.5 ng/g for Ni, 60 ng/g for Cu, 0.5 μg/g for Zn and 0.2 μg/g for Cd. For Cr, Ni, and Cu, the results obtained by this technique are compared with data obtained by radiochemical neutron-activation analysis and atomic-absorption spectrometry.

Several powerful activation-analysis techniques have been developed in recent years for trace analytical characterization of niobium, enabling determination of about 30 elements,[1] but none of them is capable of detecting nickel in niobium of good or high-purity grade. Radiochemical neutron-activation analysis (NAA) involving irradiation with relatively high thermal neutron flux (8×10^{13} n.cm^{-2}.sec^{-1}) does not allow detection of nickel contents below 0.1 μg/g,[2] mainly because of the low isotopic abundance of the target nuclide ^{64}Ni (0.95%) in the natural element. Limits of detection of 2 μg/g have been reported for direct optical emission spectrography[3] and 0.3 μg/g for a spectrophotometric technique involving a specific separation of nickel.[4] These limits of detection are not low enough for application of the techniques to the determination of nickel in high-purity niobium.

In our previous work,[5] it was shown that proton-activation analysis by use of (p,n)-reactions and short-lived indicator radionuclides ($t_{1/2}$ = 20–40 min) is a very sensitive technique for the determination of nickel, and in addition of chromium and copper. However, the analysis cannot be performed instrumentally, because of strong activation of the matrix through the reaction ^{93}Nb(p,n)^{93m}Nb ($t_{1/2}$ = 6.95 hr). Consequently, radiochemical separation becomes necessary if this sensitive determination technique is to be used.

The purpose of this work was to develop a radiochemical proton-activation technique for the determination of Cr, Ni, Cu, Zn, and Cd in niobium, involving a rapid decomposition of the sample and a rapid removal of the radionuclides produced from the matrix. Although, in contrast to Ni, the elements Cr, Cu, Zn, and Cd can be determined very sensitively by radiochemical NAA,[2,6,7] the present technique can be of interest as a second complementary method offering high sensitivity.

EXPERIMENTAL

Chemicals and apparatus

All reagents used prior to irradiation were of "*suprapur*" grade. They were of "*pro analysi*" grade for post-irradiation procedures. The separations were carried out on Dowex 1X8 (200–400 mesh) strongly basic anion-exchange resin in the F^--form. The original concentrations of hydrofluoric acid and nitric acid were 40% and 65%, respectively.

The separation procedure was developed by using the radioisotopes ^{54}Mn, ^{64}Cu, ^{65}Zn, ^{72}Ga, and $^{115m/115}$Cd as tracers. In the tracer experiments, a single-channel analyser with a well-type 3 × 3 in. NaI(Tl) detector was used for counting. For γ-ray spectrometry, a Ge(Li) detector having an energy resolution of 1.9 keV FWHM for the 1.332-MeV γ-ray of ^{60}Co and an efficiency of 20% relative to a 3 × 3 in. NaI(Tl) detector and a peak-to-Compton ratio of 40:1 was used. The detector was connected to a Canberra 8180 multichannel analyser.

Samples and standards

Analyses were performed on the following niobium samples:

(a) Nb-P, Plansee, Reutte, Austria
(b) Nb-Es, Heraeus, Hanau, F.R.G.
(c) Nb-WCT, Teledyn Wah Chang, Albany, Oregon, U.S.A.
(d) Nb-R-1, Max-Planck-Institut für Metallforschung, Stuttgart, F.R.G.
(e) Nb-R-2, Max-Planck-Institut für Metallforschung, Stuttgart, F.R.G.

From the niobium samples, targets with a thickness of 0.6–1 mm were cut with a diamond saw. In order to remove possible surface contamination, the samples were etched for 10 sec in a 9:1 v/v mixture of 40% hydrofluoric acid and 65% nitric acid. Thick metal targets of pure Cr, Ni, Cu, Zn, and Cd were used for standardization. A monitor foil of pure niobium was placed on the side of the target exposed to the irradiation.

After the bombardment, the monitor foils were counted with a γ-ray spectrometer, and the relative radioactivity of ^{93m}Mo produced in the irradiation of samples and standards was taken as the basis for the quantitative evaluation. The results obtained were corrected for the difference in the depth of penetration of the protons[8] in the samples and standards.

Irradiation and post-irradiation etching

Irradiations were performed in the cyclotron of the Nuclear Research Centre at Karlsruhe. Niobium samples were irradiated in water-cooled target-holders with 13-MeV protons at a beam current of 10 μA for 10–30 min. Standards were irradiated with a beam current of 100 nA for 30 sec. In order to remove possible surface contamination after irradiation the samples were etched for 30 sec in a 9:1:5 v/v mixture of 40% hydrofluoric acid, 65% nitric acid and water, then for 10 sec in 10*M* hydrochloric acid, and finally washed with water.

Radiochemical separation procedure (Fig. 1)

The systematic studies on the anion-exchange characteristics of the elements in hydrofluoric acid medium by Faris[9] and in hydrofluoric acid and hydrofluoric/nitric acid medium by us[10] was the basis for the development of the necessary radiochemical separation procedure. After surface decontamination, the samples were dissolved in 3 ml of 7:3 v/v 40% hydrofluoric acid/65% nitric acid mixture heated initially to 80°. The acid mixture contained 100 μg of each of the inactive carriers of Mn, Cu, Zn, Ga, and In. If there was incomplete decomposition (large samples), further dropwise addition of nitric acid followed. After the dissolution, the unconsumed nitric acid was removed by dropwise addition of formic acid until there was no further generation of gas (0.2–0.5 ml). Then the solution was diluted with water to about 12 ml to give about 5*M* hydrofluoric acid concentration. The dissolution was carried out in a 20-ml polyethylene syringe which was connected by a polyethylene tube, through a tube pump, to the ion-exchange column. After dilution, the pump was started and the sample solution was brought to the column at about 6–7 ml/min. Elution was done with 2*M* hydrofluoric acid. The first 25 ml of eluate were collected in a polyethylene bottle for γ-spectrometric measurements. The polyethylene column was 10 cm in height and 0.6 cm in internal diameter and filled with the resin Dowex 1X8 (200–400 mesh), pretreated sequentially with 20 ml of 10*M* hydrochloric acid, 20 ml of water and 40 ml of 2*M* hydrofluoric acid.

On the basis of recent studies on the extractability of dithizonates from hydrofluoric acid media,[11] the indicator radionuclide for the determination of Ni, ^{60}Cu, was directly separated from the hydrofluoric acid solution after the ion-exchange by extraction with two 10-ml portions of 5×10^{-3}*M* dithizone in chloroform, and then the hydrofluoric acid solution was washed with 5 ml of chloroform. The organic phase (25 ml) was used for counting with the γ-spectrometer. Standards were measured in the solid stated for 1–5 min and the count-rates were corrected for the geometry of the 25 ml of solution.

RESULTS AND DISCUSSION

The method

Table 1 reports the relevant reactions and data for the activation of the matrix element, niobium. After a 20-min irradiation with 13-MeV protons at a beam

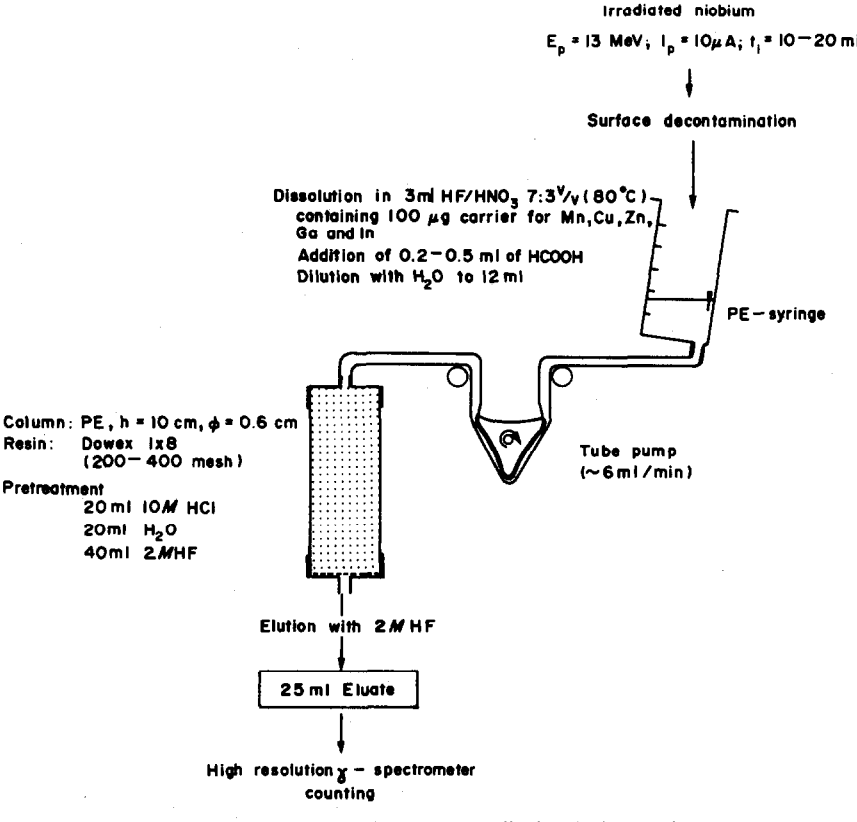

Fig. 1. Scheme of the post-irradiation radiochemical procedure.

$^{93}Nb(p,\alpha n)^{89g}Zr$	−5.6	78.4 hr	0.5110 0.9092	47.0 99.87	—

current of 10 μA, the samples give a dose-rate of 5–10 rem/hr at a distance of 10 cm, which is caused mainly by ^{93m}Mo produced from the matrix. Consequently, the samples must be processed behind appropriate lead shielding.

Data on the analytical nuclear reactions and the properties of the indicator radionuclides produced are listed in Table 2 along with primary interference reactions.[12–14]

In the determination of Cr, Ni, and Cu, the possible interferences caused by (p,pn) and (p,αn) reactions have been experimentally verified at 15 MeV,[5] and found negligible even when the content of the interfering elements is 10 times that of the element to be determined. In the determination of Zn, interference is possible from Ga and Ge, but through the reactions $^{96}Ga(p,n)^{69}Ge$ and $^{72}Ge(p,n)^{72}As$ it was proved that it could be neglected because of the extremely low content of Ga and Ge in niobium. Similarly, Sn and In can interfere in the determination of Cd, but neutron-activation analysis failed to detect these elements in the niobium samples used and the NAA detection limit is much lower[7] than that at which these elements interfere in the cadmium determination.

In trace analysis at very low levels, reliable surface decontamination can be an important factor in the accuracy. Therefore, in addition to the pre-irradiation etching and packing of the samples in clean aluminium foils for irradiation, a post-irradiation etching was performed in hydrofluoric/nitric acid mixture followed by washing in dilute hydrochloric acid. The weight loss in the post-irradiation etching is *ca.* 0.05% and is negligible.

The separation procedure described allows decontamination factors $>10^5$ to be obtained for the nuclides $^{89m,g}Zr$, ^{92m}Nb and ^{93m}Mo produced from the matrix. The chemical yields obtained for the complete post-irradiation procedure in the presence of 100 μg of carrier for each radionuclide and about 100 mg of niobium are given in Table 3. They represent the mean values and average deviations from three separate determinations.

The entire procedure, from the end of the irradiation to the start of the counting, takes on average

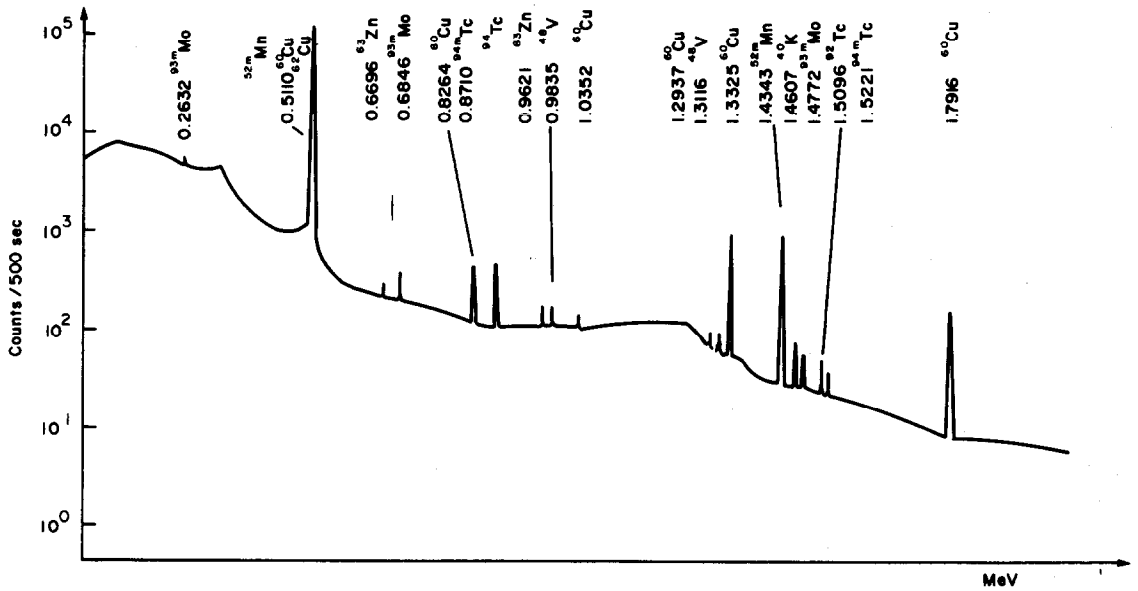

Fig. 2. γ-Ray spectrum of the eluate of a niobium sample (Nb-P) obtained by using the following experimental conditions: proton energy = 13 MeV, beam intensity = 10 μA, irradiation time = 20 min, cooling time = 18 min, counting time = 8.3 min.

Table 4. Limits of detection*

Element	Limit of detection
Cr	4 ng/g
Ni	20 ng/g
	0.5 ng/g†
Cu	60 ng/g
Zn	0.5 μg/g
Cd	0.2 μg/g

* Experimental conditions assumed; proton energy = 13 MeV; beam intensity = 10 μA; irradiation time = 20 min; cooling time = 20 min; counting time = 10 min; sample processed = Nb-R-2.
† After specific separation of Cu and using a scintillation counter; cooling time = 30 min.

about 15 min (including ~1 min transport time). The specific separation of Cu requires an additional 10 min.

In Table 4, the limits of detection are given along with the conditions under which they were obtained. The detection limit for Ni (0.5 ng/g) was obtained by counting the 1.3325-MeV γ-line of ^{60}Cu with a 3 × 3 in. NaI(Tl) detector after specific separation. This limit of detection can be improved by a factor of about 2 if the 0.511-MeV γ-line of ^{60}Cu is used for the counting. However, in counting the 0.511-MeV-line of ^{60}Cu, it must be considered that the radionuclides ^{61}Cu ($t_{1/2}$ = 3.3 hr) and ^{62}Cu ($t_{1/2}$ = 9.76 min) also contribute to formation of this peak and correct time

Analysis of niobium

The technique developed has been applied to the analysis of niobium samples of different grades of purity. The results are given in Table 5 as means of at least 3 determinations, and the corresponding average deviations. Zinc and cadmium could not be detected in any of the samples analysed, so only a limiting concentration can be given, for instance $\not< 0.5\ \mu g/g$ for Zn and $\not< 0.2\ \mu g/g$ for Cd in niobium Nb-R-2. As an example, the γ-ray spectrum of the separated fraction after ion-exchange of the niobium sample Nb-P is shown in Fig. 2.

For the determination of Cr, Ni and Cu, the accuracy of the method was checked by comparing the results with those obtained by other analytical techniques, *viz.* radiochemical neutron-activation analysis and atomic-absorption spectrometry. As can be seen from Table 6, which summarizes the results for niobium samples of different grades of purity, on the whole a satisfactory degree of accuracy could be achieved.

Acknowledgements—Grateful acknowledgement is made to Kernforschungszentrum Karlsruhe for making available the irradiation facilities free of charge. The authors thank Dr. K. Schulze, Max-Planck-Institut für Metallforschung, Stuttgart, for supplying the precious high-purity niobium samples and for valuable discussions. For discussions they also thank Dr. R. Caletka and Dr. C. S. Sastri. This project was financially supported by Bundesministerium für Forschung und Technologie, Bonn.

OXIDATION OF MICRO OR TRACE AMOUNTS OF BROMIDE TO BROMATE BY PEROXODISULPHATE BEFORE THEIR IODOMETRIC DETERMINATION BY TITRATION OR SPECTROPHOTOMETRY

ULLA LUNDSTRÖM

Department of Analytical Chemistry, University of Uppsala, P.O.B. 531, S-751 21 Uppsala, Sweden

(*Received* 15 *September* 1981. *Accepted* 25 *September* 1981)

Summary—The optimum conditions for the oxidation of bromide to bromate by peroxodisulphate at 120° as well as for the decomposition of the excess of oxidant have been determined. The predicted advantages of this oxidizing agent, *viz.* minimal blanks and destruction of small amounts of interfering organic matter and reducing substances, were confirmed. The bromate was determined iodometrically either by titration with thiosulphate or by spectrophotometry in absence of oxygen at 355 nm. The titrimetric finish applied to 0.8–8 μmole of bromide gave a mean yield of 100.0%, $s = 6$ nmole. The spectrophotometric finish applied to 0.05–0.25 μmole of bromide gave a mean yield of 98.9%, $s = 1.1$ nmole. Interfering amounts of iodide present in the sample and oxidized to iodate can be corrected for by making use of the pH-dependence of the reaction of iodide with bromate and iodate.

In the course of an investigation on the enrichment of bromide from natural waters by a selective ion-exchange procedure[1] a detailed study of the adopted method of analysis, oxidation of bromide to bromate followed by its iodometric determination, was found to be necessary. The oxidation of bromide to bromate as a preliminary to the iodometric determination of bromide has always been done with sodium hypochlorite.[2] Sodium hypochlorite solution, whether commercially obtained or prepared from reagent chemicals in the laboratory, invariably contains significant amounts of bromine accompanying chlorine in the chemicals used. The method is therefore marred by a considerable blank, which might be tolerated in micro analysis but constitutes a serious drawback in trace analysis. At this level, it is therefore necessary either to prepare a hypochlorite solution from specially purified reagents or to use an oxidant that does not contain chlorine. The present paper deals with peroxodisulphate used at 120° as oxidizing agent.[3] This oxidant should not only give a lower blank but also destroy smaller amounts of interfering organic matter and other reducing substances. The optimum conditions of the oxidation have been established for micro amounts of bromide. The iodine produced in the final step was titrated with thiosulphate, but in further studies on trace amounts it was determined spectrophotometrically as I_3^-.

PRINCIPLE OF THE METHOD

Bromide is oxidized to bromate by peroxodisulphate at the proper pH in a pressure vessel at 120°.

$$Br^- + 3S_2O_8^{2-} + 3H_2O = BrO_3^- + 6SO_4^{2-} + 6H^+$$

The excess of peroxodisulphate is destroyed by prolonged heating, through its oxidation of water:

$$S_2O_8^{2-} + H_2O = 2SO_4^{2-} + 2H^+ + \tfrac{1}{2}O_2$$

The bromate formed is allowed to react with an excess of iodide in acid solution:

$$BrO_3^- + 6I^- + 6H^+ = 3I_2 + Br^- + 3H_2O$$

Depending upon the amount, the iodine thus produced is determined by titration with thiosulphate or spectrophotometrically.

EXPERIMENTAL

Equipment

The reaction vessels were Jena Duran 50-ml or, in some special cases, 100-ml, bottles fitted with 14/15 glass stoppers. As the mouths of these bottles have a broad flange the stoppers could be kept in place by Quickfit JC 2/28 clamps, designed for spherical joints. The bottles were heated in a 5-litre "Flex-seal" pressure-cooker containing about 1 litre of water. The valve was dimensioned to give 1 atm overpressure, corresponding to 120°.

A 5-ml calibrated piston burette, graduated to 0.005 ml, was used for the titrations.

In the spectrophotometric finish the absorbance was measured with a Hitachi 101 spectrophotometer and a 1-cm quartz flow-through cell connected to a reaction funnel (Fig. 1) allowing the reaction between bromate and iodide to proceed in the absence of oxygen, under carbon dioxide.

Solutions

All solutions were made up from Merck analytical re-

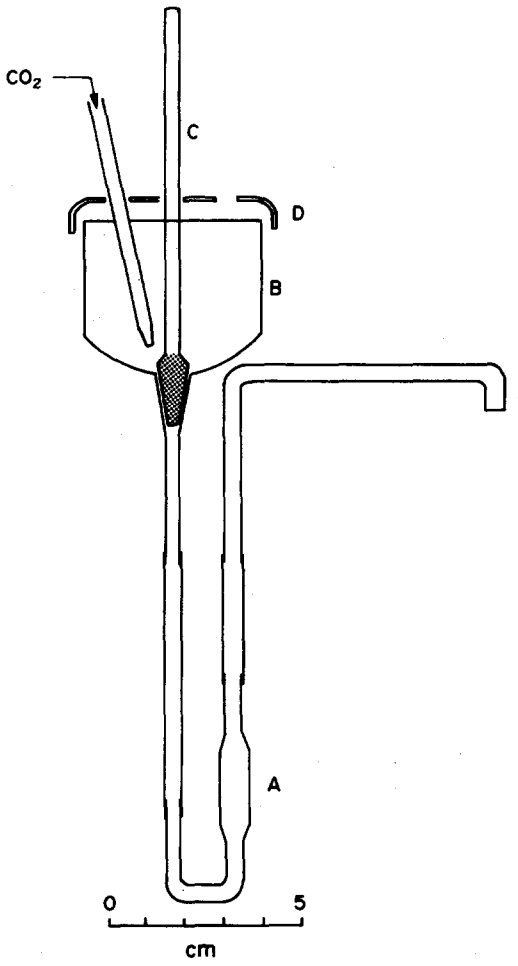

Fig. 1. Quartz cell, A, and reaction funnel, B, with stopper, C, furnished with 5/13 ground joint, and PVC cover, D. The connections are made from PVC tubing.

agents. The sodium chloride added in some cases was recrystallized from a nearly saturated solution that was acidified with hydrochloric acid and boiled after addition of hydrogen peroxide to remove traces of bromide.

Peroxo-solution": *0.100*M $K_2S_2O_8$–*0.24*M Na_2HPO_4–*0.16*M NaH_2PO_4. The decrease in peroxodisulphate concentration at room temperature due to reduction by water was determined according to Kolthoff and Carr[4] and was found to be about 1% in 16 days.

Standard bromide, bromate and iodate solutions. Prepared from potassium bromide dried at 500–600°, and potassium bromate and iodate dried at 180°.

Solutions for the titrimetric finish. These were 1*M* sodium iodide, freshly prepared, 0.2*M* sodium molybdate, 4*M* hydrochloric acid, 1.00*M* acetic acid and 1% starch solution. Standard 0.01*M* sodium thiosulphate was prepared by dilution of 0.1*M* thiosulphate before each series of experiments, and its titre was checked against a standard bromate solution in the same manner as in the actual procedure.

Solutions for the spectrophotometric finish. These must be kept free from dissolved oxygen by a continuous stream of CO_2. Enough 1.6*M* hydrochloric acid and 0.40*M* acetic acid for a series of determinations was stripped of oxygen by a stream of CO_2. The 1*M* sodium iodide used was freshly prepared for each series of determinations by dissolving the appropriate amount in water stripped of oxygen as above.

General procedure

To 10 ml of the sample solution in a 50-ml reaction bottle add 5 ml of the "peroxo solution". Stopper the bottle, apply the clamp and place it in the pressure-cooker. Heat the pot so that full pressure is attained in 7–8 min; the heating time is counted from this moment. After 20 min discontinue the heating by slowly immersing the pot in cold water until atmospheric pressure is attained. Take out the bottle and cool it in water to room temperature.

Titrimetric finish. Stir the solution in the reaction bottle for 3 min with a magnetic stirrer, under a stream of CO_2 to remove dissolved oxygen. Turn off the stream of CO_2 to avoid losses of iodine and add in order 1 ml of 1*M* sodium iodide, 3 drops of 0.2*M* sodium molybdate and 2 ml of 4*M* hydrochloric acid. Titrate with 0.01*M* thiosulphate, adding 0.5 ml of starch solution just before the end-point.

1 ml of 0.01*M* $Na_2S_2O_3$ = 10/6 μmole of Br

If iodide is present in the sample it must be corrected for by pretitration of the iodate at a higher pH. Proceed as above but substitute 2 ml of 1.00*M* acetic acid for the hydrochloric acid. Titrate the slowly forming iodine during a period of 7 min. Then add 2 ml of 4*M* hydrochloric acid and titrate the iodine produced by the bromate.

Blanks should be determined and corrected for.

Spectrophotometric finish. Transfer the solution from the reaction bottle to a 25-ml standard flask, dilute to the mark with water and mix. Fill the flow-through cell with water up to the stopper and put this in place. Pipette 10 ml of the diluted sample into the reaction funnel, place the lid on and lead a rapid stream of CO_2 through the solution for 3 min. Without turning off the CO_2 add the following oxygen-free reagent solutions in the order given: 1 ml of 1*M* sodium iodide and 2 ml of 1.6*M* hydrochloric acid. Lift the stopper, allowing the solution to replace the water in the cell, and read the absorbance 1 min after addition of the last reagent. Calibrate with a standard bromate solution (the apparent molar absorptivity for bromate is about 7.3×10^4 l.mole.cm^{-1}). Determine the blank and correct for it.

If the sample contains significant amounts of iodide a correction for this is determined with a second 10-ml portion of the diluted sample. Proceed as above but substitute 2 ml of oxygen-free 0.4*M* acetic acid for the hydrochloric acid, read the absorbance 2 min after the addition of the last reagent and apply the result as a correction.

RESULTS AND DISCUSSION

The decomposition rate of peroxodisulphate

The reaction mixture must be heated long enough to decompose the excess of peroxodisulphate, otherwise a positive error is obtained. In a similar method[3] but at pH above 12, 15 min was found to be sufficient. In the present case the final pH will be 5.8 and as the decomposition rate might be dependent on pH, some experiments were done, with various heating times; the peroxodisulphate remaining was iodometrically determined.[4] Five ml of the "peroxo solution" were diluted with 10 or 75 ml of water and heated for 5, 10, 15 and 20 min. About 10, 0.3, 0.03 and 0.00%, respectively, of the peroxidisulphate remained undecomposed, independent of the dilution. A heating time of 20 min was therefore considered as sufficient.

Influence of pH and excess of peroxodisulphate on the yield of bromate

The oxidation of bromide to bromate by peroxo-

Table 1. The effect of pH and excess of peroxodisulphate on the yield from a constant amount of bromide: each reaction mixture consisted of 5 ml of 0.01/6*M* KBr, 5 ml of a peroxodisulphate solution of varied concentration, 1 ml of 1*M* NaCl and the stated amounts of 0.4*M* buffer solutions

* No NaCl added.
† Peroxodisulphate added, μmole; % = yield at pH shown.

disulphate was found to be dependent on pH, necessitating the use of a buffer. On decomposition, 1 mole of peroxodisulphate forms 2 moles of hydrogen ion, which must be allowed for when the composition of the buffer is calculated. A lower limit for the pH is set by the oxidation of any chloride present to chlorine.

Experiments were performed, with the titrimetric finish, to study the influence of varying the pH and excess of peroxodisulphate on the yield of bromate from a constant amount of bromide. Sodium chloride was added in several cases in order to determine the critical pH for the appearance of chlorine. The results are given in Table 1. The sensitivity of the end-point detection was estimated to be ~0.01 ml of 0.01*M* thiosulphate; no blanks larger than that were detected. At the lowest excess (100%) of peroxodisulphate the yield is very dependent on pH but it is quantitative at about pH 5.5. As the excess is increased, the pH interval for quantitative yield broadens to about 4.4–6. At pH <4 chloride is oxidized to chlorine, noticeable by colour and smell, and a positive error is obtained, its magnitude depending on, among other things, how much of the chlorine remains after the treatment with CO_2 before the titration.

In further experiments, the pH and amount of bromide taken were varied, with a constant amount, 500 μmole, of peroxodisulphate in the presence of sodium chloride. The results, Table 2, show that a quantitative yield is obtained at molar ratio of $K_2S_2O_8$/KBr >4, over the pH interval 5.8–6.4. In practice this ratio should be kept much greater than 4, as the sample might contain other oxidant-consuming substances. At the theoretically adequate molar ratio of 3, a yield of about 80% was obtained, showing that the oxidation of bromide to bromate proceeds at a considerably higher rate than the autodecomposition of the peroxodisulphate. The oxidation could probably be performed in a reasonable time at only 100° but the removal of the excess of oxidant would then take at least 90 min.[3]

On the basis of these experiments the "peroxo solution" of the general procedure was given the composition 0.100*M* $K_2S_2O_8$–0.24*M* Na_2HPO_4–0.16*M* NaH_2PO_4. After heating, 5 ml of this solution will contain 0.20 mmole of Na_2HPO_4 and 1.80 mmole of NaH_2PO_4, giving a pH of about 5.8.

Applying this "peroxo solution" according to the general procedure to 9 portions of potassium bromide ranging from 5/6 to 50/6 μmole gave a mean yield of 100.0% with a standard deviation of 0.006 μmole. No blanks were observed.

Increasing the sample volume to 20 ml and keeping other conditions the same had no influence on the yield, but larger volumes, up to 40 ml, caused irreproducible yields varying between 97 and 100%.

The spectrophotometric finish

The iodine liberated may be determined spectro-

Table 2. Effect of pH and amount of bromide on the yield at constant peroxodisulphate concentration: in each case 5 ml of KBr solution of varied concentration, 5 ml of 0.100*M* $K_2S_2O_8$, 1 ml of 1*M* NaCl and the stated amounts of 0.4*M* buffer solutions were taken; with the larger amounts of bromide 0.05–0.1*M* thiosulphate was used for the titration

photometrically as the tri-iodide ion at 355 nm.[5] To avoid errors from aerial oxidation at low bromate concentrations, a special procedure had to be worked out. The sample solution as well as the reagent solutions must be deaerated with CO_2 and the reactions and measurements carried out under CO_2 as described under the general procedure. The molybdate used in the titrimetric procedure as a catalyst for the bromate–iodide reaction must be excluded, as it causes considerable absorption at 355 nm. According to Kolthoff and Hume,[6] however, no catalyst is required at sufficiently high acidity. As a high acidity also accelerates the oxidation of iodide by traces of oxygen left in the solution, the proper amount of hydrochloric acid to add was determined. Experiments performed on 0.2 *μmole* of bromate according to the spectrophotometric finish in the general procedure, the acidity and time of reaction being varied, showed that addition of the proposed 3.2 mmole of hydrogen chloride gave an absorbance (0.457) that was constant for 1–4 min if corrected for the absorbance of the blanks, which during that time increased from 0.003 to 0.007. Addition of 2.5 mmole of hydrogen chloride gave absorbance values that were constant only after 2 min, while addition of 4.5 mmole gave considerably higher blanks. Addition of 3.2 mmole of hydrogen chloride and a reaction time of 1 min were therefore decided on. The completeness of the reaction under these conditions was further confirmed by experiments in which iodate, which reacts at very low acidities, was substituted for bromate; nearly identical absorbances were obtained.

The absorptivity for 1 *μmole* of bromate in 25 ml of solution was calculated from the calibration data (Table 3). The average value was 2.250 and increased within the absorbance interval 0–0.6 by 0.9%. A similar series of determinations in which iodate was substituted for bromate gave an average value of 2.244. The apparent molar absorptivity calculated for BrO_3^- is $\sim 7.3 \times 10^4$ l.mole^{-1}.cm^{-1}.

The general procedure was then tested, with various amounts of bromide. The yield (Table 4) cal-

Table 5. The rate of the bromate and iodate reactions with iodide at varying pH: to 15 ml of a solution containing 50/6 *μmole* of bromate or iodate, 1 mmole of NaCl, 0.20 mmole of Na_2HPO_4 and 1.80 mmole of NaH_2PO_4 were added 1 ml of 1*M* NaI, 3 drops of 0.2*M* Na_2MoO_4 and the stated volumes of 1.00*M* CH_3COOH, and the iodine liberated was titrated with 0.01*M* thiosulphate during the time indicated

50/6	5/6	99.8

culated from the calibration graph for bromate was 98.9% and the mean standard deviation 0.0011 μmole. The cause of this negative error is not known. From the standard deviation of the blank a limit of detection of 0.9 nmole and a limit of determination of 3 nmole of bromine (Br) are calculated, corresponding to 0.07 and 0.24 μg respectively.

Interferences

Substances consuming significant amounts of the oxidant will interfere by causing negative errors. On the other hand, oxidizing substances initially present or produced in the reaction may react with the iodide, causing positive errors. A separation before the oxidation is therefore sometimes necessary. In the separations generally used, bromine is accompanied by iodine; this is also the case in the ion-exchange enrichment procedure mentioned earlier. A special study of iodine interference was therefore carried out.

Any iodide present is oxidized in the same way as the bromide, to form iodate, and if the subsequent reaction with iodide is carried out at a low pH, the sum of bromate and iodate will be obtained. According to Kolthoff and Hume,[6] however, the reaction rates of bromate and iodate as a function of pH differ sufficiently to allow the iodate to be separately titrated at pH 4–5 and subsequently the bromate at a much lower pH. With the titrimetric finish, experiments were performed to determine the optimal pH and reaction time under the actual conditions used. The results, Table 5, show that the end-point of the iodate titration is attained rather slowly. A titration time of 7 min at pH 3.78 (2 mmole of acetic acid added), was adopted for further experiments, as being adequate for removal of the iodate interference. It must be emphasized, however, that this is valid only for the conditions stated. Thus, if the amounts of bromate and iodate are considerably increased, the optimum pH will approach that found by Kolthoff and Hume. Experiments with 10 times larger amounts of bromate, for instance, showed that this pH was too low; at pH 3.78 and after 7 min, 3.0% of the bromate had reacted.

The correctness of the procedure adopted was confirmed by titrations of mixtures of bromate and iodate and finally of mixtures of bromide and iodide, oxidized according to the general procedure. The results in Table 6 confirm its applicability.

With the spectrophotometric finish it is hardly possible to determine iodate and bromate separately in the same aliquot. However, the correction for iodate might be determined in a second 10-ml portion of the 25 ml of diluted sample solution. Experiments to that purpose on solutions containing iodate or bromate at the same pH as adopted for the titrimetric correction for iodate, with the absorbance read 2 min after the addition of the reagents, gave quantitative recovery of the iodate added (0.05–0.25 μmole) and no interference from the same amounts of bromate. Applying this procedure to mixtures of bromate (0.05–0.25 μmole) with 0.02 μmole of iodate gave (10 determinations) recovery of the bromate that was complete to within ±1 nmole after subtraction of the correction determined for iodate. Finally the general procedure was tested on 10-ml samples containing varying amounts of potassium bromide (0.05–0.25 μmole) and 0.02 μmole of potassium iodide. From 10 determinations an average bromide recovery of 99.1% was obtained, the individual results differing from the expected values by amounts varying within the range from −2 to +1 nmole.

As mentioned in the introduction, this investigation originated from an enrichment procedure for bromide in natural waters. As the accompanying iodide content would be low, no experiments with higher amounts of iodide were performed.

Though it was not the purpose of this investigation, it was found that the results indicate that the method may also be used for the determination of iodide.

Table 7. The destruction of some organic bromine compounds: solutions calculated to contain 50/6 μmole of Br were analysed according to the general procedure

Substance	Yield of bromine, %
p-Bromobenzoic acid	99.5, 100.0
Tetrabromo-*m*-cresolsulphonphthalein	97.7, 97.9
Tetrabromophenolsulphonphthalein	98.3
Dibromothymolsulphonphthalein	98.9, 99.5

The destruction of organic matter

It is commonly assumed that dissolved organic matter is completely destroyed by heating with peroxodisulphate in alkaline medium. Some experiments were made to test whether this assumption would also be correct at the pH of the present method, at least for disruption of the carbon–bromine bond. Aqueous solutions of some organic bromine compounds were prepared and analysed according to the general procedure with the titrimetric finish. The yield obtained, Table 7, was nearly quantitative for bromobenzoic acid (B.D.H. Organic Analytical Standard), and the yield for the indicators, not guaranteed to be of 100% purity, varied between 99.8 and 97.7%. The results indicate a complete break of the carbon–bromine bond and no interference from any residual decomposition products of the organic matter. It should, however, be observed that quantitative results for organic bromine compounds may be expected only if these are water-soluble and non-volatile under the conditions used.

ASPECTS OF CHLORIDE INTERFERENCE IN ZINC DETERMINATION BY ATOMIC-ABSORPTION SPECTROSCOPY WITH ELECTROTHERMAL ATOMIZATION

LES EBDON*, ANDREW T. ELLIS† and ROBERT W. WARD*
Department of Chemistry, Sheffield City Polytechnic, Pond Street, Sheffield, England

(*Received* 28 *August* 1981. *Accepted* 22 *September* 1981)

Summary—During the determination of zinc in a polluted stream by atomic-absorption with electrothermal atomization, chloride was found to exercise a large negative interference (40%) when a carbon-filament atomizer was used, but not when a graphite-furnace atomizer was used. The effect on the filament method was confirmed and shown to be due to the formation of zinc chloride, and further complicated by interaction of this with iron. This interference could be overcome by the use of aqueous ammonia solution or silver nitrate added as matrix modifier. The absence of interference in the graphite-furnace method is attributed to the liberation of hydrogen and removal of chloride as hydrogen chloride. It is further suggested that these observations offer a basis for the exploration of apparently contradictory reports in the literature.

Considerable discrepancy exists in literature reports on interference effects in atomic-absorption spectroscopy with electrothermal atomizers. This may in part be due to different conditions of atomization and different matrices being investigated. From the variety of reports of effects observed in similar matrices and our increased understanding of atomization processes it is clear that the design of the atomizer is of great significance. Fuller[1] has reviewed the interferences that occur when electrothermal atomizers are used and concluded that they are the major problem in the practical use of these atomizers. Of these interferences the suppression of analyte signals by chloride is perhaps the best known. While this is generally thought to be due to loss of the analyte element through vaporization of molecular halide species, this generalization may be too simple to explain the effects observed for complicated matrices. In particular, when "real" samples are dealt with, the effects of concomitant cations cannot be excluded in consideration of the effects of anions.

In a study designed to determine trace levels of metals in a stream grossly polluted by storm-water overflows and industrial effluents, conflicting results were obtained for zinc when using a carbon-filament atomizer of the type first described by West and coworkers[2,3] and a commercial graphite-tube furnace of the Massmann type.[4] The results were apparently influenced by differences in the interference of chloride in the presence and absence of iron and by the different nature of the two atomizers. While considerable mention has been made of interferences in the determination of zinc by electrothermal atomization, there is a singular lack of agreement about the extent of such interferences and no systematic study of the effects of the type of atomizer.

One of the earliest reports of the application of a carbon-filament atomizer (the Varian CRA61 with a "mini-Massmann" rod) was that of Kurz *et al.*[5] who determined zinc in aqueous solutions, serum and urine. They reported no ionic interferences, no effect of a 6000-fold concentration ratio of chloride to zinc, and good recovery of zinc added to serum and urine. In the same year Clark *et al.*[6] reported that chloride gave very severe interference in zinc determinations with a carbon furnace (the Perkin–Elmer HGA 70). Complete signal suppression at a 10000-fold concentration ratio was observed, with 40% suppression at 1000-fold ratio (chloride to zinc). Further studies of interference effects when a conventional West rod was used showed that a 2000-fold molar ratio of chloride to zinc depressed the zinc absorbance by only 10%.[7] Cruz and Van Loon[8] found major suppression of the zinc signal by 1% calcium chloride when using a carbon furnace (Perkin-Elmer HGA 2000). They reported it was not possible to volatilize the zinc selectively from high-salt matrices and thus overcome the problem. Yasuda and Kakiyama[9] found zinc chloride bands in the spectra observed when a 1-mg/ml solution of zinc in 1*M* hydrochloric acid was heated in a carbon furnace (Jarrell-Ash FLA-1).

Losses of zinc from chloride solutions containing more than 1 μg of zinc per ml were attributed to volatilization of zinc chloride but below that zinc level no loss was observed and it was thought that the halide was then decomposed at these lower levels. Similar effects have been reported for carbon-filament atomizers.[10]

There have been a few reports of systematic studies of interferences in electrothermal atomizers, which are pertinent to a consideration of zinc. Depletion of the atom population by chloride formation in the vapour phase has been shown by time-resolved studies to be a potential interference mechanism,[11] for example in the lead/sodium chloride system. Using tracers ($^{65}ZnCl_2$) Maessen *et al.*[12] were able to show that the presence of aluminium nitrate promoted the more rapid atomization of zinc, but also that zinc was still being vaporized from a mini-furnace (Varian CRA-63) after atomization had apparently ceased. The need to consider together the several factors and interferents that may be encountered in practical situations has been stressed by many authors. Wegscheider and co-workers[13–15] have used statistical approaches in an attempt to do this. Their studies of cadmium[14] and lead[15] suggest that cation interferences are less severe than those from anions and that interaction between interferents may be used to eliminate interferences.

Specific studies of complex samples might be expected to exhibit evidence of some of these complicated interactions. Sea-water probably represents a typical such sample and indeed reports of the determination of zinc in sea-water do yield much information on interference effects. Campbell and Ottaway[16] found that magnesium chloride depressed the analytical signal and that iron or calcium up to 10000 μg/ml (added as nitrate or sulphate) was not effective for removing the interference. Zinc was lost if the ashing temperature was unduly high and this limited the usefulness of ammonium nitrate as matrix modifier. Standard-addition methods were used to circumvent the problems encountered. Sturgeon *et al.*[17] were able to use ammonium nitrate as matrix modifier to prevent the loss of zinc (in the ashing stage) by co-volatilization with the alkali metal chlorides in sea-water. A modified tube was also used to reduce the non-specific absorption and so permit direct determination of zinc in sea-water after selective volatilization of chloride-containing interferents.

One of the more promising approaches to understanding interferences in electrothermal atomizers is that which considers high-temperature thermochemistry. The use of conditions which promote the pyrohydrolysis of zinc chloride has been advocated as a way of countering severe depressive interferences.[18] One of the most conclusive studies of high-temperature equilibrium was by Frech and Cedergren[19,20] and concerned the determination of lead in steel. Theoretical calculations showed that it would be necessary to ash the sample in a sufficiently large amount of hydrogen to remove the chlorine from the graphite furnace, or volatile lead chlorides would be lost.[19] This was confirmed experimentally[20] and in addition it was shown that the necessary hydrogen could be formed in a tube furnace (Perkin-Elmer, HGA 72) but not in a mini-furnace of the modified West-rod type (Varian, CRA-63). The recent review by Sturgeon and Chakrabarti[21] is a useful source of suggested atomization mechanisms which can be considered thermochemically.

These various studies lead to the expectation that varying effects may be experienced in different atomizers, dependent on factors such as the size of the atomizer, the rate of heating, and concomitant elements. Much attention is now being devoted to the development of furnaces which allow atomization under isothermal conditions. A popular and simple approach has been to use graphite platforms, as first proposed by L'vov,[22] within conventional furnaces. This has been shown, for example, to reduce anion interferences in lead determination substantially,[23] confirming the identification of the factors influencing the interference.

This paper seeks to elucidate further information on the effect of chloride on zinc atomic-absorption signals following atomization from different designs of atomizer and in the presence of other concomitants likely to be encountered in monitoring water pollution.

EXPERIMENTAL

Apparatus

Two electrothermal atomizers were used. The first was a laboratory-constructed carbon-filament atomizer of the type previously described.[3] A graphite filament (2 mm diameter, 20 mm long, type WW5, Morganite Crucible Group, London) was supported by stainless-steel water-cooled electrodes. A small platform (3 mm long, 1.5 mm wide) was filed onto the filament to enable liquid samples (5 μl) to be injected reproducibly by a micropipette (Eppendorf) with disposable plastic tip. A perforated metal baffle was so placed, in the inert-gas shielding box beneath the rod, that only atoms up to 1 mm above the rod could be observed. Nitrogen (4 l./min) was used as sheathing gas. The filament was heated, by means of a step-down transformer with Variac control of the voltage (0–7 V), so that a temperature of 2200° could be reached within 5 sec with a current of approximately 100 A at 7 V. Typical operating conditions were: dry at 1.5 V for 30 sec; ash at 4.6 V for 10 sec; atomize at 6.5 V for 5 sec.

The graphite-furnace atomizer used was a Model H1475 with FA 236 power supply (Rank Hilger, Margate, Kent). The manufacturer's recommended water and gas pressure settings were used but the standard graphite tubes (54 mm long, 6 mm internal diameter) were modified by the addition of two extra holes (2 mm diameter) spaced either side of, and 3 mm from, the original central hole for the introduction of sample. The extra holes were placed to allow more efficient removal of smoke and particulates. Samples (5 μl) were introduced by the micropipette already mentioned. Typical operating conditions were: dry, power setting 07 (nominal 180°) for 35 sec; ash, power setting 05 (nominal 800°) for 20 sec; wait for 5 sec; atomize, power setting 06 (nominal 2380°) for 5 sec; cool for 30 sec. Nitrogen (2 l./min) was used as the sheathing gas with the flow

stopped during atomization, and the cooling water was supplied at 0.8 l./min.

All measurements were made with a Jarrell-Ash 82-000 series maximum versatility spectrometer with a 0.5-m focal-length Ebert grating monochromator. With two short focal-length convex lenses, light from a zinc hollow-cathode lamp (Activion, Halstead, Essex), or a hydrogen continuum hollow-cathode lamp (Activion) for background correction, was passed as a parallel beam through either atom cell firmly mounted on the optical rail of the instrument. Both the 213.9 and 307.6 nm zinc atomic lines were used. Readings were taken on a Honeywell Electronic Model 194 recorder, with a chart-speed of 2 mm/sec and a 10-mV span.

Reagents

All reagents were of analytical-reagent grade. Distilled demineralized water (DDW) was used throughout.

A 1000-μg/ml standard zinc solution was prepared by dissolving 0.2500 g of zinc metal in the minimum quantity of concentrated nitric acid, the solution being made up to 250 ml with DDW. Working standards were prepared each day by serial dilution in 0.1*M* nitric acid.

A 100-μg/ml standard chloride solution was prepared from standard hydrochloric acid and this was used for all the chloride additions.

A 100-μg/ml iron solution was prepared by dissolving 100 mg of the metal in the minimum quantity of concentrated nitric acid and diluting to 1 litre with DDW.

Procedures

These are included in the discussion section.

RESULTS AND DISCUSSION

Carbon filament atomizer

As would be expected from the volatility of zinc chloride (b.p. 732°), chloride (even at low levels) significantly depressed the zinc atomic-absorption signal when the carbon-filament atomizer was used (Fig. 1). The depressive effect increased with chloride concentration and then levelled off at about 40% depression, typical of the reported levels for carbon filaments. The curvature in the graph is characteristic of interference by compound formation. It is suggested that for a 0.1-mg/l. zinc solution, compound formation is complete when the molar ratio of chloride to zinc is 2:1, indicating that the volatile halide $ZnCl_2$ has been formed and that this is only partially dissociated into zinc and chloride atoms at the temperatures above the filament. As this is an open atom-cell the vapours rapidly disperse and cool before further reactions, other than condensation, take place. This can be taken as explaining the increased depressions observed when viewing at other than grazing incidence to the filament.

When iron(III) nitrate solution was added to 0.1-μg/ml zinc nitrate solution no interference was observed for the iron concentration range 1–5 μg/ml. However, in the presence of iron the chloride interference with the zinc signal was considerably modified. A whole family of graphs such as that presented in Fig. 2 was obtained. The levels in Fig. 2 (0.1-μg/ml zinc, 1-μg/ml chloride and 0–5-μg/ml iron) are typical of those studied. Decreasing the zinc or chloride concentration caused the curve to be shifted to the right or left respectively, but did not affect its general shape. The reasons for the initial further depression of the zinc signal are not clear, but presumably at low levels the iron has an antagonistic effect on whatever mechanism produces the dissociation of the zinc chloride, but this does not persist when the iron concentration is increased and the effect of the chloride interference is then substantially reduced. Apparently the competition from iron(III) for chloride complexation becomes significant and the zinc is freed to an increasing extent from the chloride. Further evidence

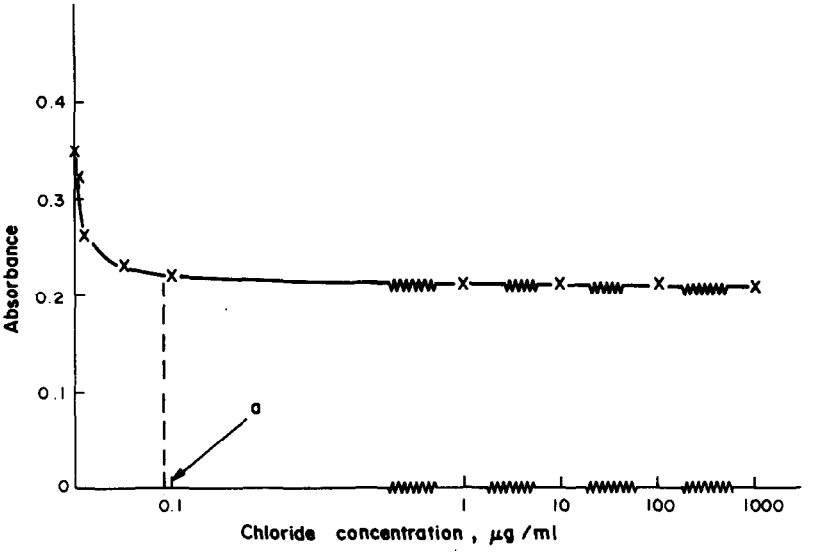

Fig. 1. Effect of chloride on the absorbance of a 0.1-μg/ml zinc solution, with a carbon-filament atomizer. The point a corresponds to a 2:1 molar ratio of chloride to zinc.

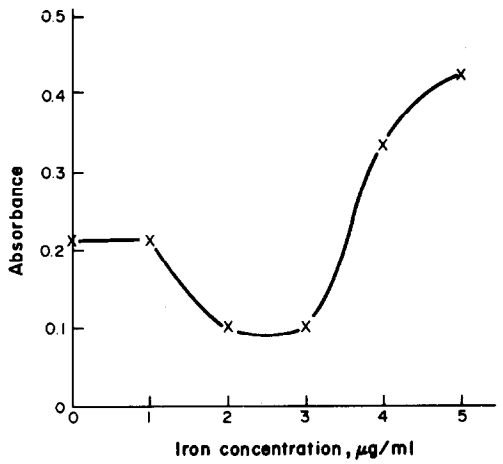

Fig. 2. Influence of iron on the interference effect from 1-μg/ml chloride on 0.1-μg/ml zinc solution, when a carbon-filament atomizer is used.

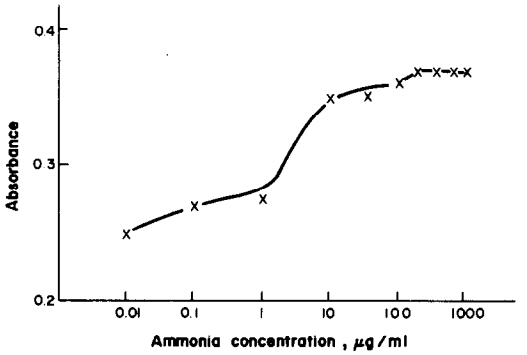

Fig. 3. Influence of ammonia solution on the interference effect from 0.1-μg/ml chloride on 0.1-μg/ml zinc solution, when a carbon-filament atomizer is used.

for this theory can be adduced from the discussion of releasing effects below. It would also appear to be consistent with recently published work[24] concerning the effect of sodium chloride on iron(III) determinations with a carbon filament. These authors added ammonia and EDTA solution to prevent premature volatilization of iron(III) chloride.

Although the effects of chloride and iron on zinc determinations with use of this atomizer can be elegantly and simply explained, this is no consolation to the practical analyst who, faced with an unknown water or steelworks effluent, will not have available sufficient evidence to correct for such complicated effects. Furthermore, standard addition, the normal resort of the practical analyst when using electrothermal atomization, is shown to be liable to error. The raising of the zinc level in the system shown in Fig. 2 would place it on a different, and not parallel, curve within the same family. Clearly it is necessary not merely to correct for this interference but to find ways of removing it.

The conventional method[25] of removing chloride interference is to add ammonium nitrate and adjust the ashing cycle so that the chloride is driven off as ammonium chloride (sublimation temperature 335°). This approach was tried by adding aqueous ammonia solution (5 μl) directly to the rod, and optimizing the ashing step so that the smoke (presumably ammonium chloride) was driven off completely without loss of zinc (10 sec at 5 V). Figure 3 shows the results of this study for 0.1 μg/ml zinc and chloride. Little effect was seen until the ammonium ion concentration was greater than the chloride concentration, and a large excess was necessary to obtain complete release. The need for a large excess might be thought to be due to the greater thermodynamic stability of the bivalent metal chloride. To test this, and to obtain further evidence about the interference mechanism, attempts were made to utilize a classical means of sequestering chloride ions, namely silver. The efficiency of silver, added as a silver nitrate solution (5 μl), to the rod can be seen from Table 1. At 20-fold w/w ratio of silver to chloride there was almost complete suppression of the interference, suggesting that the silver nitrate released the zinc from its chloride complexes. Silver can be expected to prove a useful matrix modification agent for the removal of chloride interferences in electrothermal atomization, particularly in the determination of volatile elements where there is a danger of the co-volatilization of analyte with ammonium chloride. The use of silver as matrix modifier remained effective in the presence of iron and chloride at levels typical of the stream being studied, and allowed the successful determination of zinc levels in the stream with a carbon filament atomizer.

Graphite-furnace atomizer

The interference problems encountered with the carbon-filament atomizer having been identified and overcome, an attempt was made to compare the performance of the graphite-furnace atomizer for this particular problem. The graphite furnace offered much better sensitivity than the carbon filament and great care had to be taken to avoid contamination

Table 1. Effect of adding silver ions, on the chloride interference in zinc measurements by AAS with a carbon-filament atomizer

Sample

0.1	100	10^4	4	0.33
0.1	100	10^4	5	0.33

* Added as nitrate

Table 2. Effect of chloride on absorbance at 213.9 nm from 10 pg of zinc, by AAS with a graphite-furnace atomizer

Chloride concentration, μg/l.	0	1	2	10	conc. HCl
Zinc absorbance	0.135 ± 0.003	0.143 ± 0.003	0.145 ± 0.003	0.137 ± 0.005	0.138 ± 0.003

and blanks when the 213.9-nm zinc line was used. The level of zinc in the laboratory distilled and demineralized water was found to vary between 1 and 10 μg/l. and the water was further purified by passage through two 30 × 1 cm ion-exchange columns (Zerolit 225 in acid form) to bring the zinc level below 1 μg/l. Pipette tips had to be carefully washed and regularly checked to prevent high blanks. The possibility that some of the chemical effects observed in the previous study might not be reproduced at the much lower zinc levels optimal for the furnace, and that spurious blanks, *e.g.*, from contamination by airborne talcum powder, might complicate the interpretation of results, led us to also investigate results obtained by using the far less sensitive 307.6-nm zinc line. A rapid atomization step was chosen, as this enabled the zinc to be atomized within 1 sec, before the onset of non-specific absorption effects (which occurred within 2–3 sec). As detailed above, an ashing stage was also used to minimize matrix effects.

The effect of chloride concentration on the absorbance from a 2-μg/l. zinc (as nitrate) solution (5 μl) at the 213.9-nm line was investigated and the results are reported in Table 2. The results indicate no significant depression, even for concentrated hydrochloric acid medium; if they are all assumed to come from the same population, they give a mean absorbance of 0.140 with a relative standard deviation of 3.7%, compared to a mean of 0.138 with a relative standard deviation of 3.6% for replicates of a 2-μg/l. zinc nitrate solution analysed in a comparative experiment. The only problem encountered from the concentrated acid was one of increased scatter signals and limited tube-life.

As these analyte levels were significantly lower than those used on the filament, and in view of the widespread reports that the absolute quantity of interferent is an important factor,[9,26] the level of zinc was increased and, in order to accommodate these levels, the much less sensitive 307.6-nm zinc line was used. The effect of various levels of chloride on the absorbance from a 10-μg/ml zinc solution (5 μl) is shown in Table 3. The precision of these results was poorer than that of those shown in Table 2, having a relative standard deviation of 9.5% for the solution without chloride added (mean absorbance 0.145). The addition of chloride caused no significant depression and if the results are assumed to belong to the same population, the mean is 0.145 with a relative standard deviation of 13.3%.

These results for the furnace contrast strongly with those obtained for the filament. The furnace used is of the longer and larger type and the most likely explanation would appear to be that, in the furnace, sufficient hydrogen is generated during the ashing procedure to convert the chloride present into hydrogen chloride and remove it, in a manner analogous to that proposed by Frech and Cedergren.[19,20] The size of the furnace and the ashing conditions chosen presumably allow the reaction

$$ZnCl_2(g) + H_2(g) \rightarrow Zn(s) + 2HCl(g)$$

to occur, the excess of chloride also being volatilized as hydrogen chloride. This large evolution of hydrogen cannot be expected on the exposed filament or necessarily in a smaller furnace, and any hydrogen evolved in these devices would be swept away rapidly by the flow of sheathing gas.

Additionally the higher vapour phase temperature experienced in the furnace should lead to greater dissociation of zinc chloride if it is formed in the atomization stage. Confirmation of such dissociation may be inferred from the success of work on isothermal atomization, such as that by Slavin and Manning,[23] using a platform.

CONCLUSION

The results presented suggest ways in which apparently irreconcilable reports of chloride interferences in zinc determinations by atomic-absorption spectroscopy with electrothermal atomizers may be

Table 3. Effect of chloride on absorbance at 307.6 nm from 50 ng of zinc by AAS with a graphite-furnace atomizer

Chloride concentration, μg/ml	0	1	10	16	20	50	Conc. HCl
Zinc absorbance	0.145	0.146	0.141	0.146	0.146	0.147	0.150

explained. No suppression of the zinc signal was observed when using the large furnace in this work, presumably because of the removal of chloride as hydrogen chloride. The suppression of the zinc signal by chloride when the carbon-filament atomizer was used was severe even at low levels of chloride. In practical analyses it is not advisable to assume that the method of standard additions will compensate for the presence of chloride, because there is a complex interaction of other ions with a strong affinity for chloride, such as iron(III). For the analyses in question, of grossly polluted streams or steelworks effluents, a furnace atomizer is therefore to be preferred. If it is necessary to use a filament atomizer or a minifurnace the interference effects can be satisfactorily overcome by the use of ammonia solution or silver nitrate as matrix modifiers. Phenomena such as those reported here must be considered when electrothermal atomizers are being designed or selected for purchase.

Acknowledgements—We would like to thank C. Audsley and J. Gray for some preliminary work in identifying the problem, and the Science Research Council for a grant which enabled us to purchase the graphite-furnace atomizer.

DETERMINATION OF COBALT BY PYROGALLOL CHEMILUMINESCENCE

ROBERT J. MILLER and J. D. INGLE, JR.*
Department of Chemistry, Oregon State University, Corvallis, Oregon 97331, U.S.A.

(*Received* 30 *June* 1981. *Accepted* 20 *September* 1981)

Summary—The chemiluminescence reaction involving pyrogallol in alkaline hydrogen peroxide solution is described. With reaction conditions selected for the determination of Co(II), the detection limit for Co(II) was at least two orders of magnitude below the detection limit of all other species tested. The results suggest that Ca, Mg, Mn, and Fe are the most likely interferents for environmental and biological samples. The log–log calibration graph for Co(II) is linear from a detection limit of 0.5 ng/ml up to 10 μg/ml.

In recent years, the analytical applications of chemiluminescence (CL) and bioluminescence systems have received considerable attention.[1–8] Some of the reasons for this interest are: simplicity of the instrumentation, low detection limits, large dynamic ranges, relatively short analysis times, and in some cases the possibility of chemical speciation. CL determination of metal ions has been restricted by the lack of selectivity. Therefore, masking of the interferent(s) or separation of the interferent(s) from the analyte is generally required before analysis of "real" samples.[9]

In our laboratory, we have detected trace amounts of cobalt by utilizing the cobalt(II) enhancement of the CL signal resulting from the reaction of alkaline hydrogen peroxide with pyrogallol (1,2,3-benzenetriol). The CL accompanying the reaction of pyrogallol (Pg) and alkaline hydrogen peroxide has long been known.[10,11] However, the analytical application of the system has not received much attention. A recent review on the development and present state of research on the oxidation and CL of pyrogallol is available.[12] The references cited in the review include a paper by Tomassi *et al.*,[13] who postulate that the enhancement in the CL signal by cobalt is due to the formation of a complex of cobalt(II) with a benzosemiquinone formed in the reaction. Zwierzchowska-Nowakowska[14] also studied this system with cobalt present and concluded that a diphenyl-cobalt phosphate complex was formed as an intermediate product.

Reported analytical applications utilizing this system are relatively few and include the determination of $5 \times 10^{-10} M$ horseradish peroxidase in distilled water.[15,16] Although the system has not been utilized for the determination of cobalt, Stieg and Nieman[17] reported a detection limit of 0.4 ng/ml for Co(II) with the gallic acid (3,4,5-trihydroxybenzoic acid) CL system. The gallic acid (GA) CL system, which is suspected to give similar results to the Pg CL system, has also been used to determine proteins,[18] tannins[19] and formaldehyde.[20] The CL spectrum of Pg under experimental conditions similar to those used in this paper was recently measured with an intensified diode-array detector system, but useful analytical information was not obtained.[21]

EXPERIMENTAL

Instrumentation

All measurements were obtained with a discrete sampling system which has been reported earlier[22] and with the modifications and instrumental conditions similar to those previously described.[23] The emission from the CL reaction was observed with no wavelength discrimination, all signals were registered as photo-anodic currents and a Spectrum model 1021 filter and amplifier was placed in line after the current-to-voltage converter and set for a 0.1-Hz cut-off frequency to reduce noise.

Reagents

All solutions were prepared with water from a Millipore (Milli-Q) reagent-grade water system. The pH of the samples and the hydrogen peroxide solution was adjusted by adding dilute nitric acid.

Stock 50m*M* Pg solution was prepared by dissolving reagent grade Pg in 0.01*M* nitric acid and diluting to the required volume with the same acid. Such solutions were stable at room temperature for at least two weeks (the duration of the test).

Stock 680m*M* hydrogen peroxide solution was prepared by diluting 30% reagent grade hydrogen peroxide and adjusting the pH to 4–4.5 as suggested by Montano and Ingle.[23] Stabilized peroxide gave the same results (*i.e.*, same analytical signal and detection limit) as unstabilized peroxide. The stock solution, at best, is stable for approximately two weeks. However, sometimes a larger than normal CL blank signal was observed, and then preparation of a new peroxide solution restored the blank CL signal to the normally observed blank level. However, even with a large blank signal the analytical signal for a given cobalt concentration remained constant.

Stock 0.5*M* sodium bicarbonate solution was prepared by dissolving the reagent-grade material in demineralized water and the pH was adjusted to 9.9 with reagent-grade potassium hydroxide solution just before use. The solution is stable for at least one month.

* To whom requests for reprints should be sent.

The cobalt standards and the solutions for interference studies and for cleaning glassware were made as previously described.[23] Mallinckrodt reagents were used except for the humic acid (Aldrich practical grade) and formaldehyde (Baker reagent grade) standard solutions.

Procedure

The general procedure previously described for another CL system was followed.[23] Exactly 1.0 ml of blank, analyte, or interference solution, 0.5 ml of hydrogen peroxide solution, and 0.5 ml of Pg solution are added to the sample cell with Eppendorf pipettes. With the sample cell compartment lid closed and the PMT shutter open, 0.5 ml of buffer solution is injected into the cell through a septum, with a pneumatically-driven liquid dispenser. A blank CL signal is taken as the peak signal produced by use of water acidified to the same pH as the metal test solution. The CL analytical signal is taken as the difference in the CL peak height between blank and analyte determination. Between assays the reaction cell is rinsed four times with Millipore water. Typical peak shapes for blank and Co determinations are shown in Fig. 1. The CL signal lasts for over 15 min; however, the CL signal was monitored for only the first 10 sec, as shown in Fig. 1, which was enough to ensure that the peak had been registered.

RESULTS AND DISCUSSION

The optimization criteria in order of priority were as follows: detection limit, analytical signal to background ratio (S/B), dynamic range, analysis time, and use of reagent concentrations such that small changes in concentration did not significantly affect metal and blank CL signals. In most cases, the detection limit and S/B criteria indicated identical optimal conditions. If the detection limit was fairly insensitive to changes in a variable, then the S/B became the primary criterion for optimization. All optimization was carried out with Co(II) as the analyte. The detection limit was calculated as the concentration of the analyte solution producing an analytical signal equal to twice the standard deviation of the reagent blank CL signal. The relative standard deviation in the blank signal was 4–6% and was due to both irreproducibility of the blank signal and noise in the dark current and blank CL signals.

Dependence on pH

Figure 2 shows the results of the pH-dependency data obtained with a bicarbonate buffer system adjusted with potassium hydroxide. It shows a maximum in the total signal for both the reagent blank and 10-ng/ml Co(II) solutions at a pH of 10.1, and a relatively constant detection limit over the pH range 9.0–10.0. The S/B exhibits a broad maximum over the pH range 9.5–10.0 and a pH of 9.9 was chosen for all further studies. At lower pH the CL peak is broader, which makes it more difficult to distinguish, and the analysis time is longer. Sodium bicarbonate was used as the buffer because it resulted in CL signals equivalent to those obtained with sodium hydroxide solutions of the same pH and twice as great as those

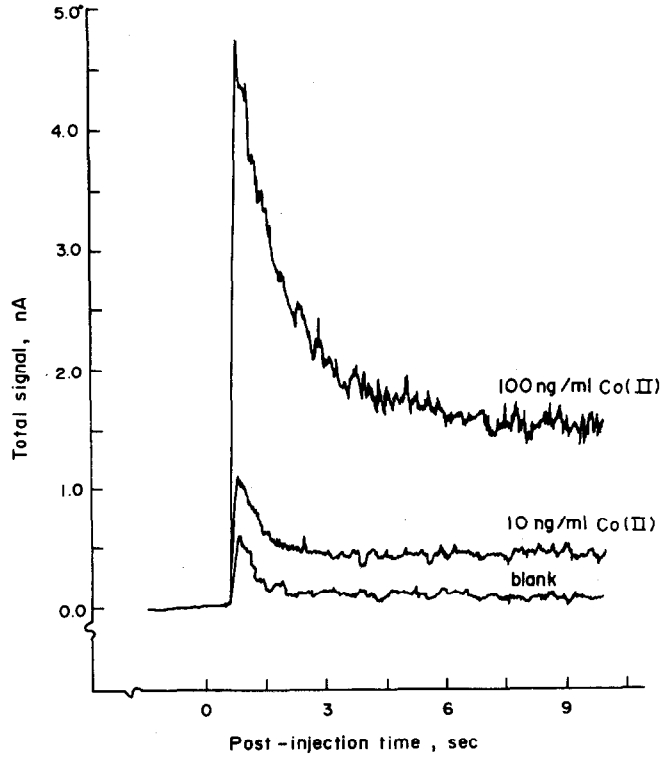

Fig. 1. Peak shapes under optimum conditions for the blank, 10, and 100 ng/ml Co(II). Cell conditions: 10m*M* Pg, 135m*M* H_2O_2, 100m*M* $NaHCO_3$ (pH 9.9), post-injection time = time elapsed after injection of the buffer.

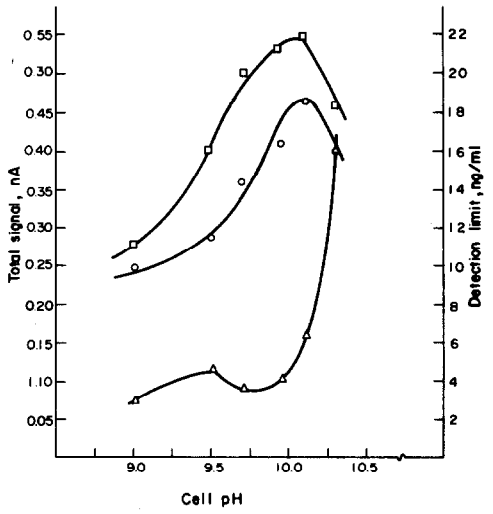

Fig. 2. Detection limit (—△—) and CL signal for 10 ng/ml Co(II) (—□—) and reagent blank (—○—) as a function of cell pH. Cell conditions: 10m*M* Pg, 156m*M* H_2O_2, 100m*M* $NaHCO_3$.

obtained with a dipotassium hydrogen phosphate buffer solution of the same pH. Since the best Co(II) detection limits were obtained if the bicarbonate concentration in the cell was 0.08*M* or higher, an initial concentration of 0.5*M* (giving 0.1*M* final concentration) was used for the rest of the studies.

Temperature

The effect of temperature in the range 18–40° was studied, and showed that no significant analytical advantage would be realized by using a temperature other than 25°, which was the temperature chosen for convenience.

Arrhenius plots for the dependence of background, 10- and 100-ng/ml Co(II) signals on temperature indicated a positive deviation from linearity. This could be due to two or more simultaneous reactions taking place or to quantum mechanical tunnelling as in electron-transfer reactions. From examination of the mechanism proposed in the literature[12,20] and our own observations of the end-products for low and high concentration of cobalt, we believe simultaneous reactions are taking place. A similar treatment of the CL signals resulting from 1- and 10-μg/ml Co(II) solutions produced linear Arrhenius plots ($r = 0.99$) and the activation energy calculated from the slope was 14 kcal/mole. Using conditions which were similar to our background reaction conditions, Slawinski[24] obtained an activation energy of 8.1 kcal/mole.

Mixing order

Montano and Ingle[23] reported that the order of mixing the reagents in the lucigenin CL system had a definite effect on the precision of the blank measurement and on the analysis time. For the Pg CL system, there are four mixing orders defined by which of the four solutions is added last. It was experimentally observed that the order of mixing the first three reagents had no significant effect on the CL signal.

The injection of the analyte or blank solution last was the only mixing order which produced an observable CL background signal prior to injection of the last solution. A 1-min delay time between mixing of the first three reagents and injection was necessary, because the CL signal derived from the mixing of Pg, peroxide and buffer decayed exponentially from a maximum which occurred in less than 1 sec to a plateau in approximately 1 min. Injection of the sample at or near the maximum gave results with relatively low precision. This mixing order was found not to be optimal, because a 50% longer analysis time was required and the precision of the measurements was dependent on the time taken to inject the analyte or blank solution.

Injection of the Pg solution last resulted in an increase in the blank signal by a factor of about four and no significant enhancement of signal with a 10-μg/ml Co(II) solution. For this reason and because the precision of the blank signal was the poorest this mixing order was abandoned.

The results obtained by injecting the peroxide or the buffer last were nearly identical. However, when peroxide was injected last the magnitude of the background or analyte signal increased with the length of time the Pg and buffer solutions were in contact before injection of the peroxide. This could be due to a higher concentration of the anionic form of Pg at the onset of the reaction or a higher concentration of an intermediate species involved in the CL reaction. In alkaline solution Pg can oxidize to various intermediate species in the absence of peroxide.[24]

The injection of the buffer last was selected as optimal because (*i*) the detection limit, S/B and analysis time were best, and (*ii*) the magnitude and precision of the CL signal were not dependent on speed of injection or delay time before the injection.

Dependence on peroxide concentration

A preliminary study indicated that the effects of the peroxide and Pg concentrations are interrelated. Therefore, approximate optimum values for both reagent concentrations were obtained by extracting S/B and detection limit information from calibration graphs for a wide range of peroxide concentrations at a number of Pg concentrations. The peroxide concentration was then reoptimized at the approximate optimum Pg concentration (10m*M*).

Figure 3 shows that the blank and analytical signals rapidly increase and the detection limit dramatically improves as the peroxide concentration is increased from 7.8 to 100m*M*, and then change more gradually at higher concentrations. A peroxide concentration of 0.14*M* was finally selected because the detection limit is still only about twice that at 1.9*M* peroxide, and the precautions which must be used when handling 9.8*M* hydrogen peroxide (1.9*M* cell

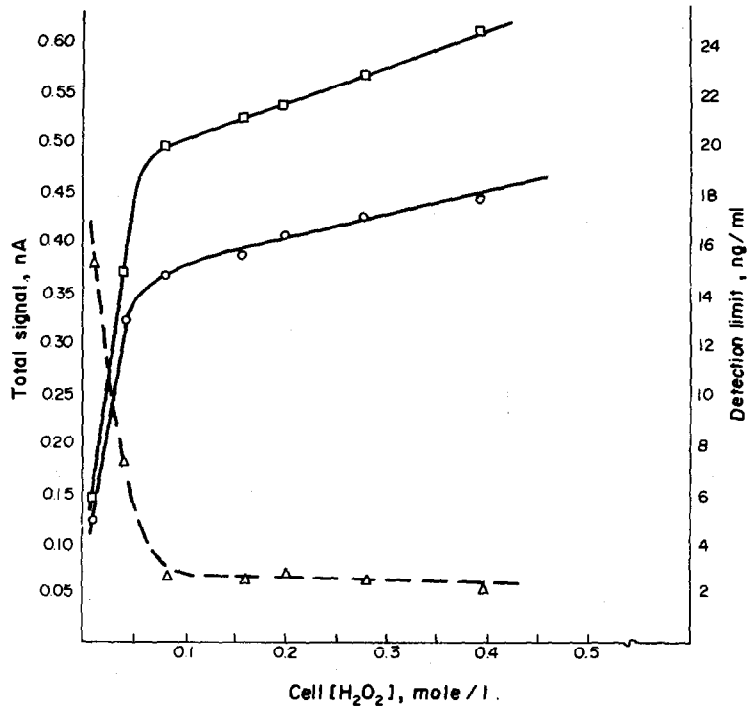

Fig. 3. Detection limit (—△—) and CL signal for 10 ng/ml Co(II) (—□—) and reagent blank (—○—) as a function of the cell H_2O_2 concentration. Cell conditions: 10m*M* Pg, 100m*M* $NaHCO_3$ (pH 9.9).

concentration) are not needed for 0.68*M* peroxide (0.14*M* cell concentration).

Dependence on Pg concentration

The effect of Pg concentration was re-examined with the selected peroxide concentration. Figure 4 shows an increase in analytical signal and decrease in detection limit as the Pg concentration increases up to 100m*M*. The increase in detection limit for Pg concentrations <5m*M* is due to a change in the peak shape when the Co(II) concentration is <30 ng/ml, resulting in a decreased S/B. There is also gradual

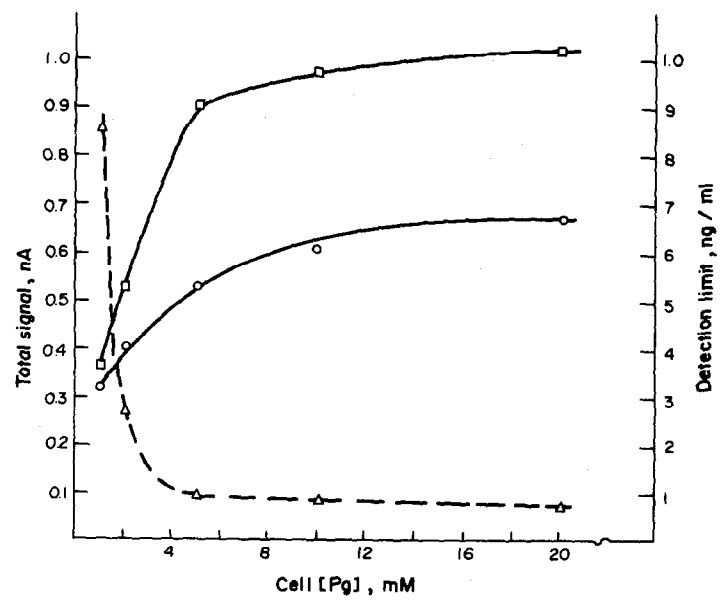

Fig. 4. Detection limit (—△—) and CL signal for 10 ng/ml Co(II) (—□—) and reagent blank (—○—) as a function of the cell Pg concentration. Cell conditions: 135m*M* H_2O_2, 100m*M* $NaHCO_3$ (pH 9.9).

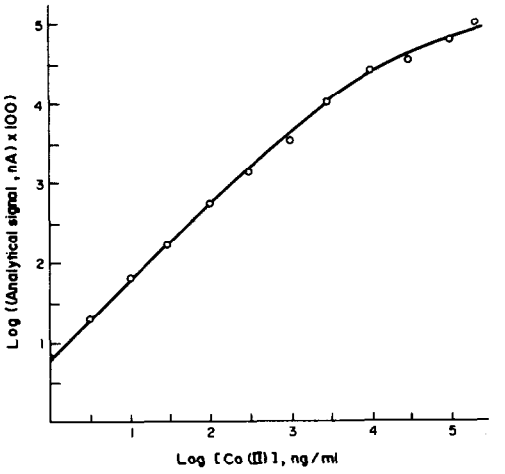

Fig. 5. Co(II) calibration curve [initial Co(II) concentrations]. Cell conditions: 10m*M* Pg, 135m*M* H_2O_2, 100m*M* $NaHCO_3$ (pH 9.9).

improvement in the detection limit as the Pg concentration is increased from 5 to 20m*M*. At Pg concentrations above 10m*M* the calibration sensitivity is lower and there is a negative deviation from linearity at lower Co(II) concentrations, which restricts the dynamic range. This deviation may have two causes: (*i*) for high cobalt concentrations a water-soluble brown polymer appears to be the principal end-product and may cause light scattering; (*ii*) examination of the Pg absorption spectrum and the CL spectrum[21] indicates that self-absorption is possible.

Calibration

Figure 5 shows a log–log calibration curve for Co(II) under the conditions determined above. The log–log plot is linear from the cobalt detection limit of 0.5 ng/ml to about 100 ng/ml, with a slope of unity, and is usable to above 10 μg/ml cobalt concentration, these concentrations being those in the sample solution. A direct plot of analytical signal *vs.* Co(II) concentration (Fig. 6a) will therefore be linear up to 100 ng/ml and is superior for this range. The slope is 0.055 nA . ml . ng^{-1}. The relative standard deviation of the signal at concentrations well above the detection limit is typically 1–2%.

Effect of dissolved oxygen

When N_2 is bubbled through the solutions (at the concentrations used for Fig. 5) to remove dissolved O_2 before initiation of the reaction, the background signal is reduced by over an order of magnitude but the net analytical signal from 10 ng/ml Co(II) does not significantly change. If O_2 is bubbled through the solutions before reaction, the blank CL signal increases by a factor of 3 and the Co(II) analytical signal increases by about 30%. If O_2 is bubbled through the solution in the absence of H_2O_2, a background CL reaction is observed with a peak at about 3 min and a peak height about 2.5 times the normal background peak. The presence of Co(II) does not affect this CL peak and no CL is observed without H_2O_2 if solutions are purged with N_2. These data indicate that dissolved O_2 is a reactant in the blank CL reaction and that the enhancement of the CL signal by Co(II) is due in part to reaction of Co(II) with H_2O_2.

Interference study

An extensive interference study was carried out and the results are summarized in Tables 1 and 2. A negative slope indicates inhibition, and a positive slope enhancement of the background CL signal by the species. The general procedure was to substitute the potentially interfering species for the cobalt solution in the standard analysis procedure, starting at the 100 μg/ml level and diluting progressively to the concentration at which the species did not interfere. The detection limit was calculated with respect to the blank reaction, as for Co(II).

All the data given represent results obtained under the optimal reaction conditions for the Co(II)-enhanced CL signal and may not be the lowest levels of the interferents that can be detected by Pg CL. For example, the detection limit for Fe(II) is listed as 2 μg/ml, but if the first three reagents are allowed to mix for 5 min before the injection of the buffer, the detection limit is lowered to approximately 34 ng/ml.

The interference effect of some species was further studied by spiking a 5-ng/ml Co(II) solution with representative interfering species from both the activator and inhibitor groups and comparing the CL signal

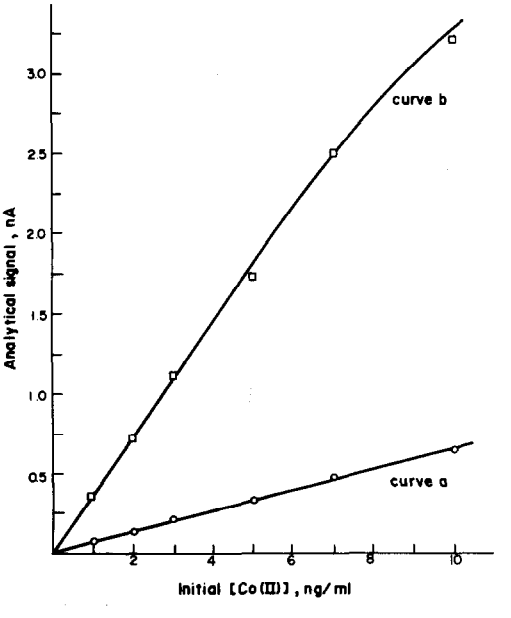

Fig. 6. Co(II) calibration curves without Ca(II) (curve a) and with 300 μg/ml Ca(II) (curve b). Cell conditions same as for Fig. 5.

with that obtained from 5 ng/ml Co(II) alone. These studies showed whether the concentration of the interferent causing significant enhancement or inhibition of the Co(II) signal was the same as the detection limit for that species in the absence of Co(II). The criterion for interference was the production of a deviation from the 5-ng/ml Co(II) standard CL signal greater than twice the standard deviation of the 5-ng/ml Co(II) signal. Of the species tested, [Mg(II), Al(III), Ca(II), Mn(II), Fe(III), Zn(II), OCl^-, CH_2O, EDTA and humic acid (HA)], all gave interference at levels within a factor of two of their detection limits, except for Al(III), Fe(III), CH_2O and EDTA, which interfered at 5, 1, 0.1 and 0.05 μg/ml, respectively, levels which are below their detection limits.

Stieg and Nieman[17] noted suppression of the cobalt signal for the GA CL system in the presence of complexing agents, and could predict the degree of suppression by calculating the concentration of uncomplexed cobalt in the solution. Similar calculations for the Pg CL system with EDTA indicated that the same behaviour was observed, but the experimentally observed Co CL signal was best approximated by calculating the free cobalt concentration from the conditional stability constant K' for the 1:1 Co–EDTA complex at a pH near 4. At pH 10, the formation of the Co–EDTA complex is quantitative ($K' \sim 10^{14}$) for $10^{-7}M$ Co(II) and EDTA, but only about a 10% suppression of the CL signal was observed. Before the injection of the buffer the pH of the solution is about 3; therefore, our data indicate that the complexation of the remaining free Co is slow relative to the time it takes for the CL peak to appear (<1 sec).

The effects of HA on the Pg CL system were studied because of the role of HA as a naturally occurring organic sequestering agent[25] and since HA is known to give CL in the presence of alkaline H_2O_2.[26] Formaldehyde was tested because Slawinska and Slaw-

inski[20] reported that formaldehyde could be detected at the $10^{-7}M$ level by the GA CL system, and Pg and GA are quite similar. The interference due to OCl^- is probably due to the CL reaction between OCl^- and H_2O_2.[27]

The apparent interference from species for which the detection limits are particularly high could be due to traces of cobalt in the chemicals used, but it would be very difficult to analyse the reagents for such low levels of cobalt.

Analysis of real samples

The interference study indicated that many species enhance or inhibit the Pg CL reaction; however, the detection limit and interference level for most species is above 1 ppm. Other than Co(II), only Cr(VI), Mn(II), Ru(III), Ag(I), Cd(II), Os(VIII), Pt(IV), and Au(III) have detection limits below 1 μg/ml.

In fresh water samples, only Ca, Mg and possibly natural complexing agents, would be potential interferences in most cases. The effect of complexing agents can be eliminated by acid digestion. In biological samples after digestion, interference can again be expected from Ca and Mg, and possibly from Fe, Zn and Mn, depending on the sample. Because the detection limit for cobalt is so much lower than for most elements, sample dilution in some cases would bring the concentration of the potential interferents to below their detection limit. Since cobalt concentrations in biological samples are typically 0.1–1 μg/ml or μg/g, the sample concentration in the final digestion solution can be as low as 0.1–1% w/w.

The applicability of the Pg CL technique was evaluated by assaying three real samples: tap water, Willamette River water, and NBS bovine liver.[28] Previous work indicated that the water samples would contain 5–15 μg/ml Ca(II), 3–5 μg/ml Mg(II) and 0.1–0.3 μg/ml Fe(III). From Tables 1 and 2, it can be seen that only calcium is a potential interferent for the determination of cobalt in the water samples. Since cobalt concentrations in natural water are usually below 10 ng/ml, and often below 1 ng/ml, dilution will not eliminate the potential calcium interference.

The calibration curve for calcium, shown in Fig. 7, indicates that the CL signal is fairly independent of the calcium concentration from 250 to 400 μg/ml. The sharp decrease in the CL signal above 400 μg/ml Ca is accompanied by the formation of a white precipitate (probably $CaCO_3$, since the buffer system will be roughly equimolar in bicarbonate and carbonate at pH ~ 10), and attendant removal of calcium from the solution. A similar effect over about the same concentration range was observed for magnesium. Addition of 1–10 ng/ml cobalt to solutions containing magnesium at concentrations in the plateau region resulted in inhibition of the Co CL signal, whereas similar treatment of calcium solutions at plateau range resulted in an enhanced Co CL signal.

The reagent blank and cobalt standards were adjusted to contain calcium at the 300-μg/ml level

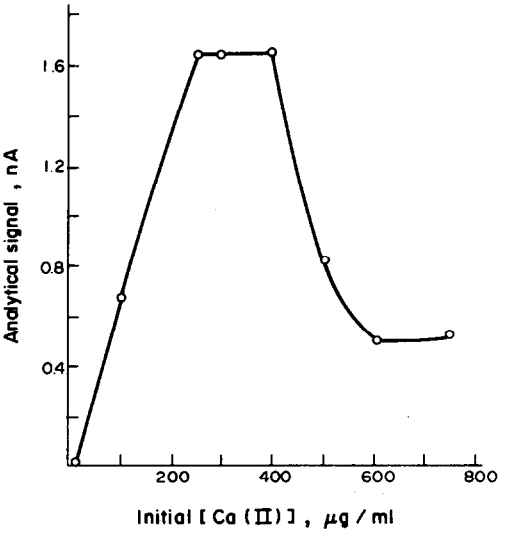

Fig. 7. Ca(II) calibration curve [initial Ca(II) concentration]. Cell conditions same as for Fig. 5.

and the cobalt calibration curve was redetermined, as shown in Fig. 6b. The curve is linear over the same region as the curve without added calcium (curve a), but the slope is significantly enhanced to 0.33 nA.ml.ng^{-1}. Hence, although the absolute standard deviation of the blank CL is greater because the mean value is increased, the detection limit remains the same owing to the increase in the calibration curve slope. However, if the samples and standards are all spiked with a 300-μg/ml calcium addition, the tolerance limit for the original calcium present is increased to 26 μg/ml, a level higher than that in most water samples. The interference levels for Mg(II), Al(III), Ca(II), Mn(II), Fe(III), OCl^-, CH_2O, EDTA and HA were tested in the presence of the 300-μg/ml calcium spike and found to be within a factor of two of the values obtained in the absence of the spike, but the interference level for Zn(II) was lowered to 1 μg/ml. Some of the HA was precipitated by the large concentration of calcium, so the supernatant solution was used for the interference study.

The results for the two water samples spiked with 300 μg/ml calcium indicated that the concentration of cobalt was below its detection limit. Standard additions of cobalt to the water samples in the 1–10 ng/ml range indicated that concentrations in this range could be determined accurately. The slope of the multiple standard addition plot was the same as the calibration slope for standard cobalt solutions.

The bovine liver sample was chosen for analysis because the matrix is well defined[28] (provisional cobalt value 0.18 μg/g). Three 0.5-g bovine liver samples were first ashed at 550° for 72 hr and then brought into solution by acid digestion with 5% v/v nitric acid. The acid-digested sample was then transferred to a 100-ml flask and the pH adjusted to 2 by the addition of 5*M* potassium hydroxide. After dilution to the mark, the sample solution was expected to

contain cobalt at the 0.9 ng/ml level, which is near the detection limit, but the Ca, Mg, Fe, and Mn concentrations were below their respective detection limits.

A cobalt concentration of 1.3 ng/ml was obtained by the multiple standard addition method with Pg CL detection. This value represents 0.26 μg/g in the original bovine liver sample, 44% greater than the expected value of 0.18 μg/g. The concentration of cobalt found from the calibration curve for the same solution was 0.8 ng/ml or 0.15 μg/g in the original sample. The iron concentration was estimated to be 415 μg/g by CL, with a 5-min wait before injection of the buffer solution. The certified iron concentration is 270 μg/g.

We attempted to confirm our results for the determination of Co in the two water samples and bovine liver sample, by neutron-activation analysis utilizing a Ge(Li) semiconductor detector after approximately 13 hr of irradiation with a flux of 3×10^{12} n.cm^{-2}.sec^{-1} from a TRIGA II reactor. Before irradiation, the water samples were preconcentrated by a factor of 20 by evaporation. The results indicated cobalt concentrations of 0.19 and 0.25 ng/ml for tap water and the Willamette River, respectively, which confirms that the concentrations were below the CL detection limit. The bovine liver sample was treated by the procedure outlined above for the Pg CL method, except that the sample solution was diluted to 5 ml so that the final concentration of cobalt in the activated sample was approximately 18 instead of 0.9 ng/ml. The results indicated a cobalt concentration of 0.28 μg/g in the original sample, which is in good agreement with the Pg CL results. A cobalt concentration of 0.25 μg/g for the bovine liver was obtained with lophine CL detection[9] and is also in good agreement with the Pg CL results.

Additional observations

The time-dependence of the Fe CL signal is only observed if Fe + H_2O_2 + Pg are all mixed together before injection of the buffer. At iron concentrations of 100 μg/ml and above, a CL signal is observed before injection of the buffer, but the CL signal is always enhanced by injection of the buffer, no matter what time delay is used.

As previously noted,[21] Mn(II) yields a unique CL response. At concentrations between 1 and 100 μg/ml, two CL peaks are observed. The first peak is observed within 0.5 sec after injection of the buffer. The second peak is observed between 30 sec and 7 min after injection of the buffer, depending on the manganese concentration. The second peak is preceded by the formation of a brown precipitate [possibly $Mn(OH)_3$ or MnO_2] and immediately before the CL emission the precipitate dissolves quickly with subsequent evolution of gas. This emission may be due to decomposition of the H_2O_2 by the $Mn(OH)_2$–MnO_2 couple.

Some of the inhibitors listed in Tables 1 and 2 are known to form complexes with Pg.[29] Thus, the inhibition may be due to an effective decrease in the free Pg concentration. However, some of the enhancers also form complexes with Pg, which suggests that more extensive research is needed to determine the nature of these complexes under the conditions of the experiments described above.

Finally, if higher concentrations of Pg and H_2O_2 are used the useful range has an upper limit of about 1 μg/ml for cobalt determination, but the detection limit could possibly be lowered by a factor of 2–4.

CONCLUSIONS

A new technique based on Pg CL has been developed for cobalt determinations in the 1–10 ng/ml range. The results indicate that the method should be useful for water samples which are not heavily polluted, and for some biological samples. For most water samples, the primary interference would be from Mg, Ca and possibly natural organic complexing agents such as humic acid. In biological samples, Fe and Mn would, in addition to Mg and Ca, be likely interferences. For a given sample, the direct applicability of the technique can be evaluated by measuring the concentration of these interfering elements by standard techniques such as flame atomic-absorption since the interference levels are above 1 μg/ml (or μg/g) except for manganese (0.04 μg/ml interference level). The calcium interference level can be raised to higher levels by spiking all standards, samples and blanks with high levels of calcium, without changing the detection limit for cobalt. Whether iron is present at a concentration high enough to cause interference can be decided by delaying the injection of the buffer for 5 min, since the signal will increase if there is interference.

As previously noted,[30] few techniques are directly applicable for determination of cobalt at concentrations below 10 ng/ml and particularly 1 ng/ml. Five different CL reagents, including Pg, provide sub-ng/ml detection limits for cobalt.[9] A rapid sample preparation procedure which removes major interfering species has recently been used for determination of cobalt by lophine CL.[9] This procedure should extend the applicability of the Pg CL to Co determinations in many types of samples.

THE CATION-CHELATION MECHANISM OF METAL-ION SORPTION BY POLYURETHANES

R. F. HAMON, A. S. KHAN and A. CHOW
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

(*Received* 7 *May* 1981. *Accepted* 11 *September* 1981)

Summary—The mechanism of sorption of ions by polyurethanes has been investigated through detailed studies of the extraction of cobalt(II) thiocyanate and the salts of several organic acids. Polyether-based polyurethanes, particularly those containing poly(ethylene oxide), were found to be distinctly superior to polyesters in the sorption of salts and performed much better than might be expected by analogy with monomeric liquid solvents. The results were judged to be inconsistent with several possible mechanisms, including adsorption, solvent extraction, weak or strong base anion-exchange, and complexation of metal anions by the polymer. A new proposal, termed the cation chelation mechanism (CCM), was advanced to account for the observations. In this view, a number of cations (including those of the alkali metals, alkaline earth metals, some transition metals, NH_4^+, RNH_3^+ and perhaps H_3O^+) may be multiply complexed (chelated) by portions of the polymer, thus facilitating the sorption of accompanying anions. As predicted by the mechanism, moderately strong and selective complexation of several cations was observed to occur with the following order of selectivity: $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+ \sim NH_4^+ < Ag^+ \sim Tl^+ < Ba^{2+} < Hg^{2+} < Pb^{2+}$. Such behaviour parallels that known for many crown and non-cyclic polyethers and is therefore identified with the polyether portions of the polymer, which are thought to adopt helical conformations surrounding the complexed cations. The cation-chelation mechanism may be widely applicable to the sorption of ions of several types by polyether-based polyurethanes, particularly when large, hydrophobic anions (such as anionic metal complexes) are accompanied by an excess of chelatable cations.

Over the past decade, polyurethanes in the form of open-cell foams, microspheres or thin films, have been applied quite successfully to the extraction of a number of organic and inorganic substances from various media. Several good reviews of the literature, mainly describing analytical applications of the polyurethanes as media for separation and preconcentration, have appeared[1,2] while another including some other facets of their use is forthcoming.[3]

In many cases, other substances such as organic solvents or greases, liquid ion-exchangers, charcoal and a host of complexing agents have been added deliberately to the polyurethane before use, in order to achieve extraction. In these instances, the chief function of the polymer (usually an open-cell foam) is simply to act as a support for the added "active" materials. However, effective extraction of both organic and inorganic substances by plain polyurethane itself has also been observed and demonstrates that the polymer is not without its own sorptive capacity. Among these reports, we have been most interested in those which describe the uptake of metal ions from solution, and particularly in the mechanism whereby this might take place.

The first and perhaps most extensive such use of plain polyurethane was reported in 1970 by Bowen[4] for Hg(II), Au(III), Fe(III), Sb(V), Tl(III), Re(III), Mo(VI) and U(VI). All of these metals except the last were said to be extracted efficiently from acidic aqueous halide solutions as anionic halo-complexes (such as $FeCl_4^-$). U(VI), on the other hand, was extracted from an aqueous nitrate medium, presumably as UO_2^{2+}. Bowen found the sorption capacities to be far too large (0.5–1.5 mole/kg) to be attributable to surface adsorption phenomena, and so deduced that a true absorption into the bulk of the polymer must be occurring. In seeking to account for this, he suggested several possible mechanisms, beginning with a type of solvent extraction. In this regard, he commented that the list of substances absorbed by polyether-based polyurethane seemed to parallel closely that of compounds extractable by diethyl ether. He also suggested that some weak-base anion-exchange sites might be expected, based on the presence of nitrogen atoms in urea and urethane polymer linkages. Alternatively, it was pointed out that polyether oxygen atoms could possibly be protonated in acid, thus requiring the sorption of accompanying anionic metal complexes to maintain electrical neutrality. Which, if any, of these mechanisms was of prime importance was not established, however.

Several workers have since expanded the original work of Bowen to provide greater detail and to include other metals as well. In particular, both Schiller and Cook[5] and Sukiman[6] have reported the extraction of gold from acidic chloride solutions, while Gesser and co-workers have described the extraction of Ga(III)[7,8] from the same medium. Although no mechanistic interpretation was offered for the Au(III)/Cl^-/H^+ system, the phenomenon of Ga(III) sorption was considered to be an ether-like solvent extraction process in which $HGaCl_4$ was apparently the species extracted. Later, in a detailed study of the Fe(III)/Cl^-/H^+ system, Gesser and co-workers[7,9] also

reported the extraction of $FeCl_3$ and $HFeCl_4$. From their results, they inferred that polyether polyurethane could be regarded as a "viscous liquid" solvent of moderate dielectric constant in which some dissociation of sorbed species was evidently possible. Similar conclusions were also reached by this group on the basis of a study of U(VI) extraction from aqueous nitrate solutions.[10] Further studies by Lo *et al.* on Sn(II) and Sn(IV),[11] and on Sb(III) and Sb(V)[12] sorption from acidic chloride solutions likewise described the process as a solid "solvent" extraction.

The extraction of several metals from thiocyanate media has also been observed. Maloney *et al.*[13,14] have reported the extraction of Co(II), Fe(III), Cd(II), Zn(II) and Pb(II), while Braun and Farag[15] have provided some additional data for Co(II) and Fe(III) only. The latter authors, concurring with several others, described these processes as "etheric solvent extraction".

Moore and Chow[16] extended the use of polyurethane to the extraction of metal ions from organic solvents, and reported the removal of Ir(IV) and Pt(IV) chlorides from acetone or ethyl acetate solutions. Contrary to some earlier interpretations, these authors commented that the results clearly could not be explained solely on the basis of an ether-like solvent extraction mechanism. As previously suggested,[4,9] the possibility of specific ion-exchange sites in the polymer was therefore considered. More extensive studies on the Co(II) thiocyanate extraction system have been undertaken by Hamon[17] and similar investigations have been made by Al-Bazi[18] for the platinum group metals (Ru, Os, Rh, Ir, Pd, Pt). The results of these studies further suggest that "ether-like" solvent extraction cannot be the sole mechanism for such systems.

From our own results as well as those of others, the concept of ether-like solvent extraction as the only mechanism of sorption for metal complexes therefore seemed unlikely. Since many of the metal species absorbed were anionic in nature and extracted with very large distribution ratios, the possibility of an anion-exchange process seemed most reasonable to us. Such a mechanism has been alluded to by several authors with reference to protonation of some sites (ether oxygen atoms or linkage nitrogen atoms). Our work,[17] however, has indicated that the presence of hydrogen ions is not necessary and we therefore sought to study the mechanism in greater detail.

EXPERIMENTAL

Apparatus

Most analytical results were obtained on a Varian model 634S spectrophotometer, a Perkin-Elmer model 306 atomic-absorption spectrophotometer and an Evans Electroselenium Ltd. flame photometer. A Baird-Atomic model 530A single-channel gamma-ray spectrometer fitted with a Harshaw well-type NaI(Tl) crystal was used for radioactivity measurements.

Infrared spectra of polyurethane and sorbed materials were obtained on a Perkin-Elmer model 337 grating instrument. Solution acidities were measured with a Fisher Accumet model 520 pH meter, with glass and saturated calomel electrodes.

Polyurethanes and aqueous solutions were equilibrated in Pyrex glass distribution cells mounted within a thermostatically controlled ($25.00 \pm 0.05°$) automatic squeezing apparatus of our own manufacture. The equipment, described elsewhere,[17] was designed to produce repetitive solution-mixing and polymer-squeezing beneath the liquid surface at a rate of 25 times per minute over extended periods of time.

Reagents

Almost all materials were of reagent grade and were used as supplied by various manufacturers, without further purification. Picric acid was standardized by potentiometric titration. The *m*-cresol was of practical grade and so was purified by distillation under reduced pressure before use. ^{60}Co tracer was obtained from New England Nuclear and kept as Co(II) chloride in $10^{-3}M$ hydrochloric acid. Gamma-ray spectrometry with a semiconductor detector and multichannel analyser were used to verify its isotopic purity.

Several types of polyurethane foam were used. One (diSPo) was the product of Scientific Products Ltd., (McGraw Park, Illinois) and was of polyester type. All other polymers used were primarily of polyether composition. Two (1338 BFG and 1338 M) were produced locally from materials supplied by Goodrich and Monsanto respectively, and were used most extensively in the investigations. Five other types used on occasion (A, B and 27CGS-44-2A, -1 and -3) were the very generous gifts of Dr. C. G. Seefried of the Union Carbide Corp. Before use, all foam materials were soaked in acid (0.1*M* nitric or 1.0*M* hydrochloric) for several hours to remove possible inorganic contaminants, and then extensively rinsed with distilled water. They were next freed from non-polymeric organic materials by Soxhlet extraction with acetone for 6 hr. The residual solvent was removed by air drying in an oven at 60° or under vacuum at room temperature. No major changes in polymer properties as a result of these treatments were observed.

General procedure

Preliminary experiments established that from 6 to 12 hr of contact between polymer and solution in the squeezing apparatus was generally sufficient to establish equilibrium. Periods of 12 or 24 hr were therefore allowed for equilibration to take place between weighed pieces of polyurethane and measured volumes of solution. At the end of this time, solution samples were withdrawn for determination of the species of interest (either cation or anion). Comparison of the equilibrium concentration (C_{eq}) of the particular species with the initial concentration (C_0) before contact with the polyurethane allowed indirect calculation of the percentage extracted (E) and the distribution ratio (D) from

$$E = \frac{100(C_0 - C_{eq})}{C_0}\,\%; \quad D = \frac{VE}{(100 - E)W}$$

where V is the volume of solution (in litres) brought to equilibrium with W kg of polymer. D thus has units of l./kg.

Sorption experiments were roughly divided into two types, based on the sort of anion employed and whether the anion or the cation was to be measured.

Anionic metal complex systems

Most experiments of this type involved cobalt thiocyanate and employed ^{60}Co tracer to measure sorption.

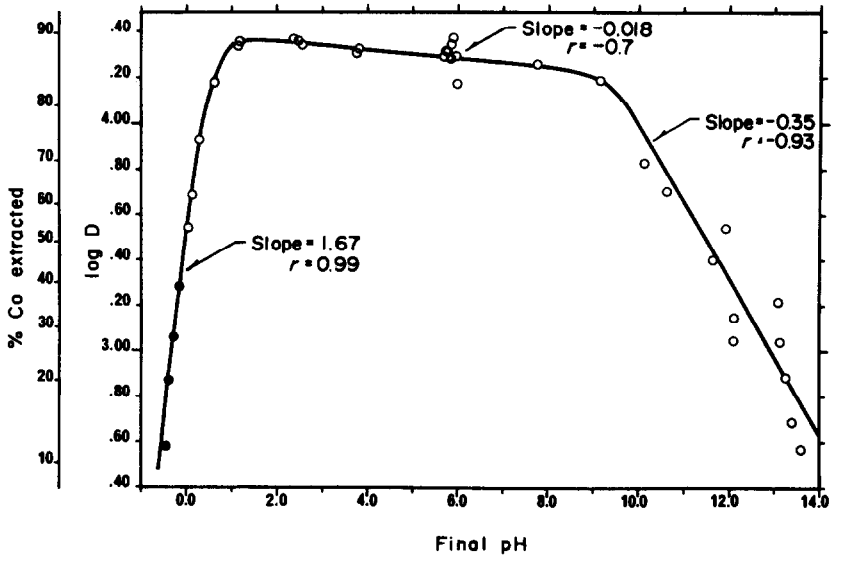

Fig. 1. Effect of pH on cobalt sorption from aqueous thiocyanate solution. Equilibrium values of pH were measured by glass electrode (open circles) or estimated by calculation (filled circles). Conditions: 0.050 g of 1338 BFG foam; 150 ml of solution $1.7 \times 10^{-6}M$ in Co(II), 0.10M in NaSCN, pH adjusted with HCl or NaOH, NaCl added to maintain 3.00M ionic strength.

In the study of dependence on acidity (Fig. 1), no buffers were used, the pH being adjusted by the addition of sodium hydroxide or hydrochloric acid of appropriate concentration, and measured before and after equilibration with 1338 BFG foam. The ionic strength and total cation concentration were adjusted to 3.0M in each case by the addition of sodium chloride in appropriate amounts.

Experiments to determine the effects of polymer type on cobalt sorption (see Table 2) were conducted similarly except that 0.1M sodium acetate/acetic acid buffer (1:1) was also added to maintain a pH near 4.7.

The influence of various cations on cobalt thiocyanate sorption was determined in two separate experiments. In the first of these (see Table 4), sorption of cobalt by 1338 M foam was measured in the presence of 2.5M concentrations of cations differing in size. Other experiments (see Table 5) were conducted with 1338 BFG foam, 0.1M acetate buffer and 0.1M concentration of different cations.

The effects of cation type on zinc thiocyanate sorption were also determined on 1338 M polyurethane foam, with 1.0M concentrations of added cations. Atomic-absorption spectrophotometry was used to determine zinc before and after equilibration.

Organic anion systems

The extraction of picrate in the presence of different cations (Fig. 2a) was investigated with $5 \times 10^{-5}M$ picrate and a 0.10M concentration of the particular cation. Samples were withdrawn after equilibration with 1338 M polyurethane foam pieces, and analysed colorimetrically for picrate. Experiments with 8-anilino-1-naphthalenesulphonate (ANS) anions instead of picrate were conducted in the same way except that 0.001M concentration of this anion and either 0.1M (Fig. 3) or 0.0225M concentrations of cation (Fig. 4) were used.

When cation extraction was measured directly (see Table 3), $10^{-4}M$ concentrations of cations with 0.025M picrate or 0.004M ANS were used, again with 1338 M foam. The initial and equilibrium cation concentrations were determined either by flame photometry (alkali metal ions) or by atomic-absorption spectrophotometry (Ag^+, Tl^+, Mg^{2+}, Ca^{2+}, Hg^{2+}, Pb^{2+}). A ^{133}Ba tracer and radiometric counting were used in the case of Ba^{2+}.

Thin film preparation and testing

Because of severe light scattering, the direct measurement of polyurethane foam spectra proved difficult. Consequently, it was necessary to prepared thin films from the foam material for observation of changes in the visible or infrared spectra, accompanying sorption of species. Thus, 0.2-ml aliquots of a solution made by dissolving 0.1 g of 1338 BFG polyurethane foam in 5 ml of *m*-cresol by refluxing at 203° were transferred to 1.5 × 3.0 cm sodium chloride plates. The *m*-cresol solvent was then removed by gentle heating under vacuum overnight. Free $-NH_2$ or $-OH$ groups in the film thus obtained were reacted for 18 hr with 0.1 g of phenyl isocyanate in 100 ml of hexane to eliminate the possibility of any complexation by such groups. The plates bearing the films were then soaked for two days in fresh hexane to remove excess of reactant, followed by evaporation of the solvent under vacuum. A film prepared in this way was soaked for 18 hr in 50 ml of saturated sodium chloride solution (to prevent dissolution of the plate) containing cobalt(II) ($8.5 \times 10^{-4}M$) and sodium thiocyanate (0.1M). Spectra of the film and sorbed species were then measured directly (Fig. 5).

RESULTS AND DISCUSSION

Possible extraction mechanisms

There are several hypotheses for the mechanism of sorption of metal ions by polyurethanes. Although we hope to identify one of these as predominant in many of the systems studied by us, others may play a role in other systems.

Surface adsorption. The concept of metal-ion adsorption at sites distributed over the polymer surface (which was assumed to be large) was one of the first to be tested and was rejected by Bowen on the basis of capacity measurements alone. Later surface-area determinations for polyurethane foam (which showed[19] a relatively small surface area of about 81 m^2/kg) as well as capacity measurements for

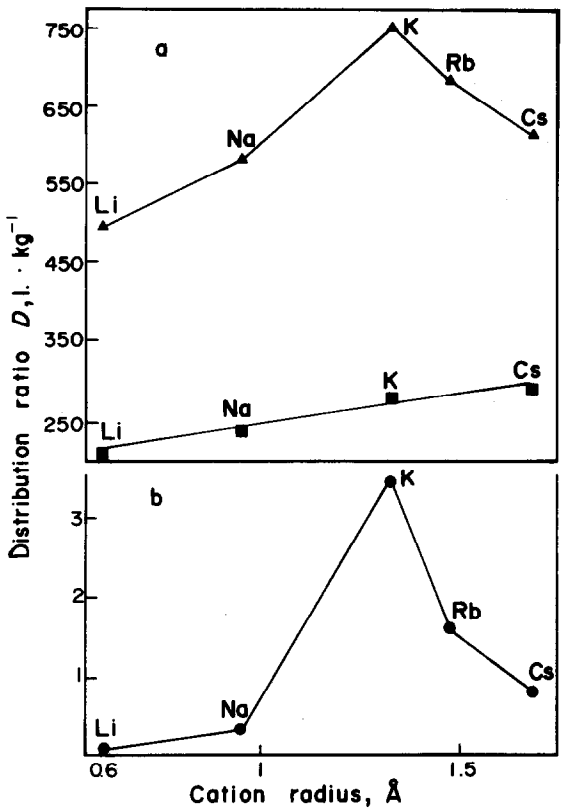

Fig. 2. (*a*) Comparison of picrate extraction from solutions containing various alkali-metal cations by polyether- and polyester-based polyurethane foams. Conditions: 0.10 g of foam; 150 ml of solution $5 \times 10^{-5}M$ in picrate and 0.10*M* in cation (added as chloride) ▲ 1338 M polyether foam, ■ diSPo polyester foam. (*b*) Extraction of $7 \times 10^{-5}M$ picrate from aqueous solution by $7 \times 10^{-5}M$ dicyclohexyl-18-crown-6 in methylene chloride; 0.10*M* cation (added as chloride); equal volumes of phases.[38]

various metal ions [including our own of 0.47 mole/kg for $Co(NCS)_4^{2-}$] have all strengthened this opinion. Furthermore, the observation that several metal species, such as $GaCl_4^-$,[8,20] $Co(NCS)_4^{2-}$,[17] $FeCl_4^-$,[20] UO_2^{2+},[20,21] are able to diffuse through intact polyurethane membranes, confirms that true absorption into the bulk of the polymer must occur.

Solvent extraction. The concept of an ether-like solvent extraction of metals was also originally suggested by Bowen[4] when he called attention to the similarity between the list of substances sorbed by polyether-based polyurethane foam and those which could be extracted by diethyl ether. Gesser *et al.*[7,9] later extended this idea to suggest that the polyether portion of the foam acted as a polymeric analogue of diethyl ether in giving "solvent extraction" of the substances tested. In this view, the long-chain portions of the polyurethane (polyether or polyester) act much as if they were the analogous liquid monomers in solvating the sorbed species, while the urethane, urea and other links joining the chains together at their ends are largely inactive in the process. This simple description is appealing and seems to have been widely accepted by most workers in the field even though it has not been rigorously tested. Such an interpretation would appear to be sufficient to account for the observed sorption of non-polar or even moderately polar compounds, but it might be expected to be inadequate when truly ionic species are involved.

Most authors have assumed that neutral complexes of the H_mMeX_n (Me = metal, X = halide or pseudohalide) or similar type are those extracted by polyurethanes. However, while this may well be the case for some elements in strongly acidic solutions, there must be doubt when sorption is observed at higher pH values. In our own studies of cobalt thiocyanate extraction, for example, we find that sorption is optimum and essentially independent of hydrogen-ion concentration over a very wide range (pH 1–9) when the solution ionic strength is maintained constant by addition of sodium chloride (see Fig. 1). If we assume that a neutral protonated species, *e.g.*, $H_2Co(NCS)_4$, is being formed and extracted by the polyurethane under these conditions, then we are forced to deduce that the conjugate anion [$Co(NCS)_4^{2-}$ in this case] is

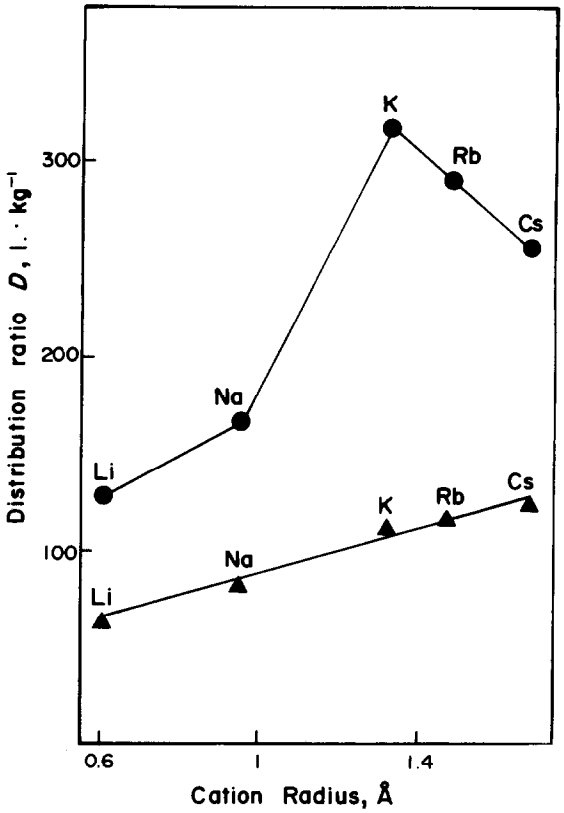

Fig. 3. Comparison of 8-anilino-1-naphthalenesulphonate (ANS^-) anion extraction from solutions containing various alkali-metal cations by polyether- and polyester-based polyurethane foams. Conditions: 0.10 g of foam; 150 ml of solution, $10^{-3}M$ in ANS^- and 0.10*M* in cation (added as chloride). ● 1338 M polyether foam, ▲ diSPo polyester foam.

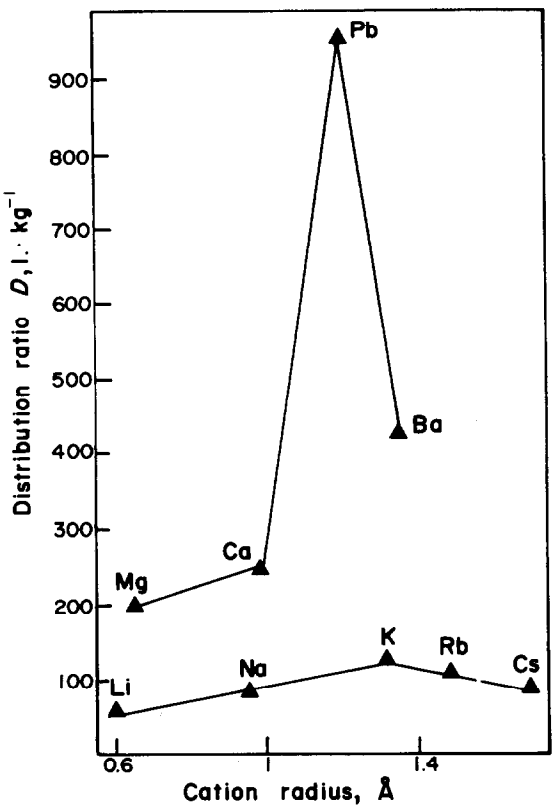

Fig. 4. Comparison of 8-anilino-1-naphthalenesulphonate (ANS^-) anion extraction from solutions containing various univalent and bivalent cations by polyether-based polyurethane foam. Conditions: 0.15 g of 1338 M foam; 90 ml of solution, 0.001*M* in ANS^- and 0.0225*M* in cation (added as chloride or nitrate).

more strongly basic than OH^-. However, basicity of this order is not at all typical of any anionic metal complexes and, moreover, we observe that extraction drops abruptly in more acidic solutions rather than increasing as might be expected. Thus, we conclude that hydrogen ions cannot be involved in the extraction of the cobalt–thiocyanate species in particular, nor of other metal complex ions, from neutral or basic solutions.

It is known that some ion-association complexes are extractable from neutral solutions, particularly when the ions involved are large and hydrophobic or only feebly hydrated. Thus, under suitable conditions, ion-association complexes of the general form $(M^{p+})_m.(MeX_n^{m-})_p$ may be formed and transferred to an organic phase (indicated by a bar) as follows:

$$mM^{p+} + pMeX_n^{m-} \rightleftharpoons \overline{(M^{p+})_m.(MeX_n^{m-})_p}$$

$$(M^{p+})_m.(MeX_n^{m-})_p \rightleftharpoons \overline{(M^{p+})_m.(MeX_n^{m-})_p}.$$

In assessing the likelihood of this type of solvent extraction phenomenon for polyurethanes, however, we must consider the following facts.

First, anion distribution ratios as high as 3×10^6 l./kg have been measured for $Co(NCS)_4^{2-}$ sorption[17] while several other anionic species, *e.g.*, $FeCl_4^-$,[9] $GaCl_4^-$,[8] $Pd(SCN)_4^{2-}$,[18] $Pt(SCN)_4^{2-}$,[18] $SnCl_4^{2-}$,[11] $SbCl_3^-$,[12] $SbCl_5^-$,[12] have all yielded values in the neighbourhood of 10^4–10^5 l./kg for aqueous solution/polyurethane systems, even when small, hydrophilic cations (H_3O^+, Na^+, NH_4^+, *etc.*) have been the only counter-ions available. Such values are much greater than the distribution ratios measured for these and similar metal complexes extracted into liquid organic solvents. The difference is especially large (several orders of magnitude) for some of the thiocyanate complexes which have been studied in our laboratories. For example, whereas *D* values in the neighbourhood of only 3 or less have been achieved for $Co(NCS)_4^{2-}$ and $Pd(SCN)_4^{2-}$ with diethyl ether,[22] values ranging from 10^5 to 10^6 l./kg have been attained with polyether-based polyurethane foam under similar conditions (see Table 1).

Moreover, Moore and Chow[16] have described the extraction of $IrCl_6^{2-}$ and $PtCl_6^{2-}$ into polyurethane foam from ethyl acetate and acetone solutions with distribution ratios ranging from 225 to 1.1×10^4 l./kg. This clearly demonstrates that if a solvent-extraction mechanism is operating polyurethane must possess some solvating characteristics which are superior not only to those of water but to those of each of these solvents as well. It is very difficult to justify treating the polymer as an analogue of diethyl

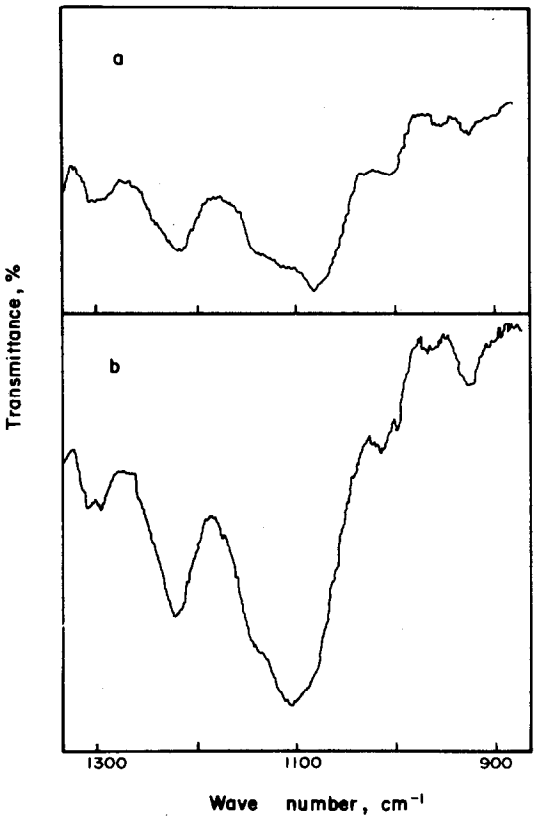

Fig. 5. Changes in the infrared spectrum of polyether-based polyurethane film on sorption of $Na_2Co(NCS)_4$ from aqueous solution (details in experimental section); (*a*) after sorption; (*b*) before sorption.

Table 1. Comparison of complex metal anion sorption by oxygen-containing organic solvents and polyether-based polyurethane foam

* D in l./kg for polyurethane foam.

ether when neither of these complex ions exhibits any appreciable solubility in that solvent. Also, since the polarity of urethane polymers has been estimated[23] from swelling measurements to be very similar to that of acetone, a distribution ratio of around 1 l./kg for $IrCl_6^{2-}$ between acetone and polyurethane would be expected, instead of the 225 l./kg found experimentally. From these anomalously high distribution ratios, it appears that factors other than simple ether-like solvent extraction apply and that some specific interactions with the polymer must exist.

Ligand addition or exchange. Since all polyurethanes contain a large number of donor atoms (N, O) (from the urethane, urea, ether or ester links), the possibility of strong interactions arising from complex formation between any of these and the extracted species must be considered. In that case, the large distribution ratios measured, particularly for some metals, would imply the existence of very strong ligands in the polymer—a situation which seems doubtful, considering the structures typical of polyurethanes. However, if complexation did take place, it would have to do so either by addition of polyurethane ligands (L) to the extracted species [*e.g.*, $Co(NCS)_4^{2-}$]:

$$Co(NCS)_4^{2-} + 2L \rightleftharpoons Co(NCS)_4L_2^{2-}$$

or by ligand exchange for those of the polyurethane:

$$Co(NCS)_4^{2-} + nL \rightleftharpoons Co(NCS)_{4-n}L_n + n\,SCN^-$$

In the first the co-ordination number of the metal must increase. A co-ordination number of five for cobalt is rare and the resulting complex would therefore most likely be hexaco-ordinate (as shown). Such a change from tetrahedral to octahedral symmetry in cobalt complexes is accompanied by a large alteration of the absorption spectrum, resulting in a colour change from blue to pink. However, the blue-green colour and the absorption spectrum definitely show the cobalt–thiocyanate species sorbed by polyurethane (foam or film) to be tetrahedral $Co(NCS)_4^{2-}$. Similarly, the colours obtained when several other metal complexes are extracted by polyurethane foam are typical of the tetrahedral species [*e.g.*, $FeCl_4^-$, $Pd(SCN)_4^{2-}$] and it is thus apparent that appreciable complexation by ligand addition cannot be common.

In the case of ligand exchange, the symmetry of the complex would change, which should also be accompanied by some alteration of the spectrum. Since no such change is observed for the cobalt–thiocyanate system and the spectrum of the sorbed complex rapidly recovered from polyurethane into several organic solvents (acetone, methyl isobutyl ketone and tetraglyme*) is again that of $Co(NCS)_4^{2-}$, metal com-

* Tetraglyme is bis[2-(2-methoxyethoxy)ethyl] ether.

plexation by ligand exchange must also be considered unlikely.

Weak or strong base anion-exchange. The possibility of polyurethane behaving as a weak-base anion-exchanger has been mentioned by several authors. This could conceivably occur by protonation of some sites in the polymer such as nitrogen-containing urea or urethane linkages, or perhaps ether linkages in polyether-based polyurethanes. According to this view, there must be some sites in the polymer phase which become protonated in the presence of acid and at which exchange of anionic metal complexes (MeX_n^{m-}) can occur as follows:

$$H^+ + A^- + \overline{\text{site}} \rightleftharpoons \overline{(H\cdot\text{site})^+} + \overline{A^-}$$

$$m\overline{A^-} + MeX_n^{m-} \rightleftharpoons mA^- + \overline{MeX_n^{m-}}$$

where species within the polymer phase are again indicated by bars and A^- (assumed, for simplicity, to be univalent) is some counter-ion for the absorbed hydrogen ions.

In the presence of high concentrations of strong acids, this mechanism may contribute significantly to the overall sorption of anionic metal complexes. However, in the absence of appreciable amounts of strong acid, it should not play a significant role. As mentioned earlier, studies on the cobalt(II)–thiocyanate system at various solution pH values (Fig. 1) demonstrate that sorption is essentially independent of hydrogen-ion concentration over a very wide range (pH 1–9) and that extraction falls rather than increases in more acidic solutions. It seems doubtful that any sites could become protonated by contact with basic (pH 9) media. Although the possibility exists that such protonation might have initially resulted from the foam cleaning procedure (which uses up to 1*M* acid), measurements of the solution pH before and after equilibrium with the polyurethane has been reached demonstrate that insufficient hydrogen ions are either released from or absorbed by the polymer under any conditions to account for the quantity of cobalt extracted. In fact, such measurements have shown that only insignificant numbers of hydrogen ions are released from the foam to solutions of pH up to 13.5. Thus, any sites which could be protonated would have to be of extremely high basicity, but the groups typical of polyurethanes (urea, urethane, allophanate, biuret, ether and ester) are all very weak bases and could not account for the observed behaviour.

The insensitivity of Co(II) sorption with respect to hydrogen ions (Fig. 1) would be more consistent with a strong-base anion-exchange mechanism in which permanent cationic sites (*e.g.*, quaternary ammonium groups) would be involved, but no such sites are typical of any polyurethanes, especially in numbers large enough to account for the high capacities for metal-ion sorption. Hence we conclude that if anion-exchange *does* occur, it necessarily takes place at sites generated by some other mechanism.

Cation-chelation mechanism (CCM). Another possible mechanism by which anionic metal complexes may be sorbed, which does not necessarily require protonation of polyurethane sites but is, nevertheless, closely related to the weak-base anion-exchange concept, is what we will call the cation chelation mechanism (CCM). According to the view which we now propose, many cations, M^{p+}, (such as Na^+, K^+, Ag^+, NH_4^+, RNH_3^+, Pb^{2+}, Ba^{2+}, and including H_3O^+) are capable of being multiply complexed by the polymer at specific sites thus giving a solid-phase (or matrix) species which can be regarded as equivalent to an ion-exchange matrix or to a solvated cation in solid solution:

$$M^{p+} + \overline{\text{site}} \rightleftharpoons \overline{(M\cdot\text{site})^{p+}}.$$

The extraction of ion-association complexes having these cations as counter-ions will then be greatly facilitated owing to the stability of the chelate. However, which anions will accompany the cations in largest numbers will be determined by a variety of factors, including the individual hydrophobic nature and charge of the anions, and perhaps their ability to interact in other ways with the polymer. Anionic metal complexes, MeX_n^{m-}, particularly those which are co-ordinatively saturated with non-hydrophilic ligands, might be expected to be well extracted.

When little or no sorption of anions other than MeX_n^{m-} occurs (either because all other available anions are nearly unextractable in nature or because an insufficient excess of cations or other anions is present), the sorption of the ion-association complex may be regarded as taking place by a solvent extraction process in which the cation happens to be more effectively solvated than usual. The extraction mechanism could be represented by:

$$mM^{p+} + pMeX_n^{m-} + m\overline{\text{site}} \rightleftharpoons m\overline{(M\cdot\text{site})^{p+}} + p\overline{MeX_n^{m-}}$$

where the chelated cation and accompanying anion are written separately but may, in fact, be associated within the polyurethane.

On the other hand, if considerable sorption of another ion-association complex containing M^{p+} and some moderately extracted anion, A^-, occurs either before or concurrently with the sorption of MeX_n^{m-}, then the latter may be more conveniently regarded as sorbed by an anion-exchange process in which it is exchanged for A^- at the positive sites that result from the chelation of M^{p+} by the polymer. The main difference between the CCM and other ion-exchange mechanisms is that electroneutrality demands that both the cation and the anion should be more or less simultaneously extracted by the polyurethane. A matrix similar to an anion-exchanger results, at which exchange of the anionic counter-ions can occur. The extraction mechanism of MeX_n^{m-} may then be

$$M^{p+} + pA^- + \overline{\text{site}} \rightleftharpoons \overline{(M\cdot\text{site})^{p+}} + pA^-$$

$$MeX_n^{m-} + mA^- \rightleftharpoons MeX_n^{m-} + mA^-$$

Table 2. Effect of polyurethane foam type on the sorption of cobalt thiocyanate

Foam	Chief polymer type	D, l./kg
diSPo	unknown polyester	6
A	60% PEO/PPO polyether copolymer 40% styrene/acrylonitrile copolymer	7.26×10^3
B	80% PEO/PPO polyether copolymer 20% styrene/acrylonitrile copolymer	8.12×10^3
1338 BFG	unknown polyether	1.68×10^4
27CGS-44-2A	0% PEO polyether 100% PPO polyether	1.05×10^3
27CGS-44-1	8% PEO polyether 92% PPO polyether	7.26×10^3
27CGS-44-3	14% PEO polyether 86% PPO polyether	2.16×10^4

Conditions: 0.050 g of foam; 150 ml of solution, $1.7 \times 10^{-6}M$ in Co(II), 0.10M in NaSCN, 2.8M in NaCl and 0.1M in 1:1 sodium acetate/acetic acid buffer.

The cation-chelation mechanism would thus resemble both solvent extraction and ion-exchange, depending, to some extent, on solution conditions. We will now demonstrate that specific interactions do exist between some part of the polyurethanes and a number of cations.

Effects of polymer type on metal sorption

To identify which portions of the polymer might be active in chelating cations, cobalt thiocyanate sorption by several types of polyurethane foam was compared. Some of the more important results are shown in Table 2.

The most striking difference in performance is that between the polyether-based foams and the polyester-based material, there being an improvement by several orders of magnitude with the former. We infer that a polyether backbone must be an important requirement for efficient metal ion sorption. This hypothesis is further substantiated by comparison of foam types A and B, there being increased sorption ability with increasing polyether content. This is in agreement with the work of others[15,24] who have recorded significant metal extraction only by polyether polyurethane foam, particularly from solutions of low acidity. This behaviour is quite different from that of monomeric solvent analogues which generally show esters to be slightly superior to ethers as metal ion extractants, and indicates the inadequacy of a simple solvent extraction mechanism. For the cobalt(II)–thiocyanate system, for instance, D values not greater than 3 have been reported[22] for extraction by diethyl ether, and $D \sim 20$–30 with butyl acetate.[25] Moreover, although the distribution ratios for this metal species are of roughly the same magnitude for either ester or polyester extractants, the very large difference in D when ethers and polyethers are used suggests that the latter must possess some special properties.

A clue to the nature of these properties is available from the results for the 27CGS-44-2A, -1 and -3 series of polymers (Table 2) which differ only in the ratio of poly(ethylene oxide), PEO, to poly(propylene oxide), PPO. The fact that stepwise replacement of PPO by PEO produces such a marked increase in extraction of cobalt thiocyanate indicates that the latter polymer is somehow much better equipped to carry out the necessary special solvation or complexation. If, as we propose, this complexation is of cations, then the difference cannot be attributed to the electron densities on the respective oxygen atoms since the mildly electron-donating character of the methyl groups in PPO would lead us to expect higher basicity (and stronger complexation) for these ligands. The fact that the opposite behaviour results suggests that steric limitations imposed by the methyl groups must outweigh any induced electronic effects and so we surmise that specific geometry plays a very important role in the process. In seeking to clarify the mechanism, we were thus prompted to investigate further some of the complexing properties of polyethers.

Complexing properties of polyethers

In the last two decades, a number of reports of polyether–metal-ion interactions have been made, particularly for the alkali metals but also involving other cations as well (*e.g.*, complexes between certain transition metals and glymes $[CH_3O(CH_2CH_2O)_nCH_3]$). Pedersen[26,27] was the first to describe the synthesis and specific complexing abilities of a number of macrocyclic ("crown") ethers. Compounds of this type having about 5–10 oxygen atoms in the ring were shown to complex a variety of metal ions within the central cavity (crown) with the strength dependent on the ratio of ion radius to cavity size, the length of hydrocarbon chain between successive oxygen atoms, and other factors. Among the alkali-metal cations, a definite order of preference was established, as $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+$, for the most extensively studied[28] crown ethers (*i.e.*, various analogues

of 18-crown-6). Such selectivity favouring members of intermediate size within a group of congeners is an important characteristic of this type of complexant in which multiple complexation (chelation) is involved.

Since then, several non-cyclic analogues of crown ethers containing similar numbers of oxygen atoms and bearing hydrophobic or complexing end-groups have also been found to complex metal ions in this fashion. The function of the end-groups in these compounds appears to be to ensure the formation of a spiral (as confirmed experimentally[29] for the complex of NaSCN with $CH_3OC_6H_5O(CH_2CH_2O)_3C_6H_5OCH_3$) which engulfs the cation completely, much like the crown ethers. Among compounds of this type, the close association of inwardly-directed polyether oxygen atoms with the cation (and not the anion) has been clearly demonstrated by X-ray crystallographic measurements[30] of Na^+ and NH_4^+ salts of $Co(NCS)_4^{2-}$ complexed by a few PEO derivatives bearing phenyl end-groups.

Later studies have revealed that even polyethers without special end-groups have cation-complexing abilities (although frequently of slightly lower effectiveness). Long-chain PEO polymers, in particular, were noted[31–33] as giving strong interactions with ions such as Na^+ and K^+,[34] and Hg(II).[35] Extension of the spiral-type configuration of oxygen atoms about a cation complexed by shorter polyethers would logically lead to a helical pattern of inwardly-directed oxygen atoms in longer chains. Pure poly(ethylene oxide) is indeed known to adopt just such a configuration in the crystalline state[36] and to retain a large part of this structure in aqueous solution.[37] On the other hand, poly(propylene oxide) does not assume a helical shape so readily[36] either in the crystalline state or in solution (evidently due to steric effects induced by the extra methyl groups). Simply on geometrical grounds, therefore, it is reasonable to assume that long-chain PEO compounds may effectively complex cations situated along the central axis of a helix whereas PPO materials would be less well disposed to behave in this manner. It also seems logical to suppose that this can occur even if the polyethers are integral parts of a larger polymer. Thus the observed structure–sorption behaviour of polyurethanes (Table 2) seems entirely consistent with the existence of cation chelation at polyether sites which are free to adopt a helical or similar configuration.

On the basis of this model of metal-ion sorption by polyurethanes, then, we may make the following general statements and predictions.

1. As with crown and other polyethers, polyurethanes will complex cations, M^{p+}, with selectivity based on size and other properties related to solvation. This selectivity will, in turn, influence the extraction of accompanying anions, because of the requirement of charge balance.

2. The nature of the anions available, A^- or MeX_n^{m-}, may likewise limit the extent to which any cation is extracted, as is the case for conventional organic solvents, ion-exchange resins and crown-ether extractants.

3. The type of polyol in the polyurethane and its freedom to assume a helical conformation within the polymer will greatly influence the degree of extraction of cations (and therefore also of anions).

To test these predictions and thus the proposed mechanism, a number of experiments were carried out.

EXPERIMENTAL TESTS OF CCM

Cation selectivity measurements

Although direct measurements of cation sorption might be preferred, the extraction of particular anions in the presence of large amounts of cations has been used most often as a measure of cation complexation. By this indirect method, Pedersen[38] has determined the selectivities of many crown ethers for cations and found the apparent order of stabilities with alkali-metal ions to be $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+$ for complexes with 18-crown-6 and its derivatives. This order is presented graphically in Fig. 2b.

Christensen *et al.*,[39] using calorimetric measurements, and other workers using different physical techniques,[28] have determined directly the stability constants of various crown ether complexes with a larger number of univalent as well as bivalent cations. The trends reported by Pedersen have thus been generally confirmed and expanded with, for example, the selectivity orders for the "A" isomer of dicyclohexyl-18-crown-6 identified as $Li^+ < Cs^+ < Na^+ < Rb^+ < K^+ < Ag^+ < Tl^+$, and $Ca^{2+} < Hg^{2+} < Sr^{2+} < Ba^{2+} < Pb^{2+}$.

In our own experiments with polyurethane foam, a maximum in the extraction of picrate or 8-anilino-1-naphthalenesulphonate (ANS^-) anions was observed for K^+ in the alkali-metal ion series and for Pb^{2+} in the bivalent cation series (see Figs 2a, 3 and 4). These maxima (and to some extent the relative orders of the

remaining elements) match the results of Christensen and others. The strong similarity between the trends observed for crown ether and polyether polyurethane extractions is considered to be strong evidence in favour of the CCM.

The extractability of a number of univalent and bivalent cations by crown ethers has also been determined directly by Takeda *et al.*[40,41] and found to follow the observed trends in anion extraction. We have likewise determined directly the extractability of several cations by polyurethane foam in the presence of picrate anions (see Table 3). The distribution ratios for Li^+, Na^+, K^+, Rb^+, Cs^+, Mg^{2+} and Ca^{2+} were all quite low [less than 5 l./kg (the limit of the analysis)] whereas several other cations had larger distribution ratios, increasing in the order $Ag^+ \sim Tl^+ < Ba^{2+} < Hg^{2+} < Pb^{2+}$. Similar trends were observed with ANS^- as the counter-anion (see Table 3) except for Ag^+ (which most likely forms a neutral complex with the anion). The higher extractability of this species also allowed us to distinguish the superior performance of K^+ amongst the alkali-metal ions. Other measurements, on the still more extractable tetraphenylborate anion, have confirmed that K^+ is extracted in preference to Cs^+ ($D = 2500$ and 1775 l./kg respectively), in contrast to the extraction of simple ion-pairs. This order of selectivity has been extended to $Na^+ < Cs^+ < K^+$ by measurements on the sorption of these alkali metal picrates from 80% aqueous methanol.

From this information we may report with some confidence the order of affinity of polyether-based polyurethane foam for various cations as $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+ \sim NH_4^+ < Ag^+ < Tl^+$ and $Ca^{2+} < Ba^{2+} < Hg^{2+} < Pb^{2+}$. It is interesting to compare this with the order of stability constants reported by Christensen *et al.*[39] for the "A" isomer of dicyclohexyl-18-crown-6, given above. With a few exceptions, the series are much the same, both showing distinct maxima for K^+ and Pb^{2+}. Such similarity in behaviour to derivatives of 18-crown-6 is perhaps not too surprising since, according to Mattice,[42] the most commonly adopted conformation of poly(ethylene oxide) chains of some length contains an 18-membered spiral. The peculiar complexing abilities of such long-chain non-cyclic polyethers have been studied by Yanagida *et al.*[43,44] by solvent extraction and NMR techniques and have been compared with those of the crown ethers.

Study of the cobalt–thiocyanate polyurethane extraction system has demonstrated that sorption of the $Co(NCS)_4^{2-}$ ion is greater from solutions containing NH_4^+ or K^+ ions than from those containing either Li^+ or Na^+. Similar results were also observed in the sorption of $Zn(NCS)_4^{2-}$ (see Table 4) in agreement with data reported by Suzuki *et al.*[45] for the extraction of this ion by several non-ionic surfactants derived from poly(ethylene oxide). As shown in Table 4, other results demonstrating the influence of cations on the extraction of anions by polyurethane foam have been offered by Al-Bazi[18] for Pd(II) thiocyanate and by Lo[11] for Sn(IV) chloride. All these observations lend support to a hypothesis of cation complexation by the polyether portions of polyurethane.

Additional support for the CCM is provided by comparisons of picrate and thiocyanatocobaltate sorption in the presence of a specific series of cations differing in their hydrophobic natures. Table 5 demonstrates that anion sorption does not follow a steady trend as cation size is increased (as might be expected on the basis of simple ion-pair extraction into an organic solvent).[46] In particular, the medium-sized Me_4N^+ cation produces lower anion extraction than do either the smaller NH_4^+ or the larger Et_4N^+ and Bu_4N^+. We interpret this as indicating that although simple ion-association complex extraction may be the predominant mechanism for larger cations, the higher sorption observed for Na^+ and NH_4^+ can only be rationalized in terms of some other phenomenon. Likewise, Table 5 shows a non-monotonic trend in anion sorption for the ammonium ion and its monoalkyl derivatives. Again, the cation of medium size, $CH_3NH_3^+$, shows the least extraction of the accompanying anion. Both observations may be

explained by the CCM, which predicts that the smaller Na^+ and NH_4^+ cations will be much better chelated by the polyether than are the larger bulky cations. Thus, high extractability of the anions results either when the cation is highly extractable by virtue of chelation or when it is sufficiently bulky to form ion-association complexes efficiently.

Anion selectivity measurements

We now discuss the implications, for anion extraction, of cation chelation by the polymer. The requirement of charge neutrality in both phases dictates that an equivalent number of anions must accompany any sorbed and chelated cations. However, experience with conventional solvent extraction and ion-exchange processes demonstrates that considerable selectivity for anions can exist. Qualitatively, the order of extractability of a small number of anions is given by the Hofmeister series (*i.e.*, $OH^- < F^- < Cl^- < Br^- < I^- < NCS^-$).[28] This order is related by most workers chiefly to the hydrophobicity of the ions, which is dictated by size, charge density, hydrogen-bonding ability and perhaps other factors. Thus ionic metal complexes which are large, have low charge densities and lack the ability to form strong hydrogen bonds with water (*i.e.*, those which do not contain F, N, O or acidic H atoms on the periphery of the complex) are expected to be highly extractable into organic media. Similar considerations should apply to the extraction of anions by polyurethanes and this is confirmed by our own observations which show that the extractability of various cations (K^+, Tl^+, Ag^+) is strongly dependent on the identities of the anions present. Among those anions for which measurement was possible, sorption of a given cation was found to increase in the order $NO_3^- <$ 2,4-dinitrophenolate$^-$ = 2,6-dinitrophenolate$^- < ClO_4^- <$ picrate$^- <$ ANS$^- < (C_6H_5)_4B^-$, matching both increasing size and polarizability of the anion. Also, amongst complex metal anions, it has often been observed that the extractability of thiocyanato complexes greatly exceeds that of the corresponding but smaller chloro complexes. The importance of anion size is further underlined by the very high extractabilities noted for the extremely large heteropolymolybdates of phosphate, silicate and arsenate.[47] Thus, we see that the sorption of ion-pairs by polyurethanes may be dependent on the identities of both cation and anion and that their extractability may be limited by that of either moiety. All of these characteristics are consistent with the CCM as proposed here.

Polymer sorption abilities

As already mentioned, the identity of the polyol portion of the polyurethane (polyether or polyester) is expected to be of prime importance in controlling the extraction of anions by cation chelation. We have already called attention to the increased sorption of $Co(NCS)_4^{2-}$ by polyether polyurethanes containing increasing proportions of poly(ethylene oxide), PEO, relative to poly(propylene oxide), PPO (see Table 2). Such differences are attributable to the greater tendency of PEO to form helical structures, compared to PPO, which is restricted by steric interactions between $-CH_3$ groups.[36]

Even more dramatic differences exist between polymers of polyether type and polyester type (see Table 2), the latter behaving in much the same fashion as a simple solvent. In terms of the proposed CCM, this is again partly attributable to the inherent inability of polyesters to become helically oriented about a central axis, owing to the geometry and limited flexibility of the ester bond. Also, to achieve the same physical properties, the number of carbon atoms between successive oxygen-containing groups must necessarily be much larger for polyesters than for polyethers used in foam production (because of the lower flexibility of the former). Such an increase in the number of carbon atoms leads both to a decrease in the density of oxygen atoms available and to a large increase in the size of any possible cage formed. The combination of these two effects will preclude the achievement of any significant cation chelation by polyester polymers and so only simple solvent-like properties will remain.

To support this interpretation, we have made a systematic comparison of the ability of polyether- and polyester-based foams to extract ANS$^-$ and picrate in the presence of the alkali metals. From Figs. 2 and 3 we see that polyester-based foam shows a slight but steady increase in anion extraction as the size of the accompanying cation increases from Li^+ to Cs^+. This is as expected on the basis of simple solvent-like ion-pair extraction.[46] By contrast, however, polyether foam is in all cases superior to the polyester material in extraction ability and displays a distinct maximum for the intermediate-sized K^+ cation. Such behaviour confirms that a definite and selective interaction exists between some cations and polyether-based polyureth-

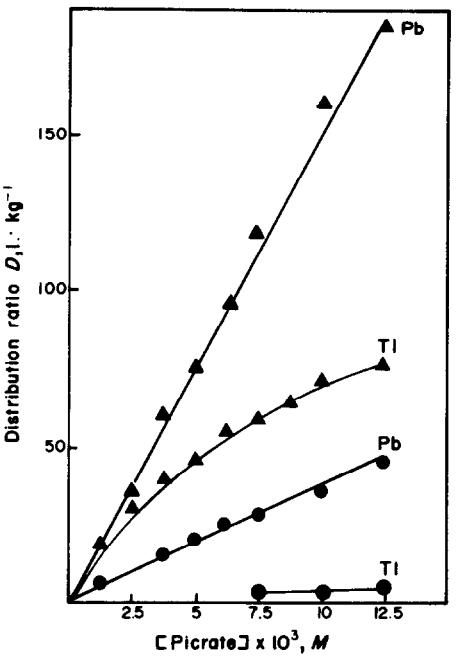

Fig. 6. Comparison of Tl^+ and Pb^{2+} extraction from aqueous picrate solutions by polyether- and polyester-based polyurethanes. Conditions: 0.4 g of foam; 100 ml of solutions $10^{-4}M$ in Tl^+ or Pb^{2+}. ● polyester foam (diSPo), ▲ polyether foam (1338 M).

ane which does not occur with the corresponding polyester polymer, as predicted by CCM.

Some further evidence is also obtained by comparing the extraction of Tl^+ and Pb^{2+} by these two types of polymer (Fig. 6). Here we see that either metal is better extracted by the polyether material over a range of picrate concentrations. This difference in behaviour is opposite to that expected on the basis of organic phase polarity since esters are more polar than ethers and we might expect this also to be true for their polymeric analogues. Such a view is supported by our own observations[47] which show that polyester foam indeed performs better than polyether foam in systems in which only simple ion-pair extraction can occur. The disparity between the expected results and those observed in Fig. 5 indicates that some specific interactions exist involving the sorbed species and polyethers, in complete agreement with the CCM.

Additional evidence in support of CCM

Further compelling evidence in support of strong polyether involvement in the extraction of ion-pairs is provided by measurement of the infrared spectrum (Fig. 5). Here we see a shift of about 30 cm^{-1} in the ether vibrational modes near 1100 cm^{-1} when Co(II) is absorbed from sodium thiocyanate solution. This change is indicative of metal–polyether interactions. However, the blue–green colour and the maximum at 615 nm and shoulder at 580 nm in the absorption spectrum both indicate that cobalt is present as the tetrahedral $Co(NCS)_4^{2-}$ ion in the polymer.[48] Moreover, the strong infrared absorption at 2055 cm^{-1} (not shown) indicates that the thiocyanate is bonded to the cobalt through the nitrogen atom.[49] Thus, it appears unlikely that cobalt atoms are involved in the interaction with the ether links. We therefore interpret this shift to be the result of sodium-ion chelation by the polymer in sorbing $(Na^+)_2Co(NCS)_4^{2-}$. Similar shifts in the infrared spectra of several other alkali and alkaline earth metal crown ether complexes have also been reported.[50]

Additional evidence for the existence of strong polyether–metal ion interactions comes from the observation that polyurethanes which are nearly saturated with cobalt(II) thiocyanate exhibit a marked increase in the polymer–glass transition temperature (*i.e.*, they fail to return to their original shape when compressed and lose much of their flexibility, to the point of becoming brittle). Such a phenomenon is not simply attributable to interchain void-filling by the sorbed species, since larger organic molecules (such as phthalates or long chain alkylamines) do not exhibit such behaviour even when present at higher concentrations. Viewed in terms of the CCM, inflexibility is easily imagined as resulting both from induced linear compression of the polyether chains in which cations are chelated along the axis, and also from electrostatic attractions between sorbed $Co(NCS)_4^{2-}$ anions and pairs of Na^+ (or, more generally, M^+) cations chelated at sites in different polymer chains (see Fig. 7). Such an arrangement of two chelated univalent cations simultaneously attracted to a single bivalent anion situated between neighbouring polymer chains constitutes a type of cross-link between them and is likely to be the largest contributing factor to polymer rigidity. Brittleness similar to this has also been observed by Moore[51] for $IrCl_6^{2-}$ and by Khan[47] for phosphomolybdate and silicomolybdate complexes, when the sorptions of univalent cations along with multivalent anions were also studied.

Although it is not our intention to reinterpret many past experiments, some other aspects of the work of Moore and Chow[16] (which records the efficient sorption by polyurethane of $IrCl_6^{2-}$ and $PtCl_6^{2-}$ from acetone and ethyl acetate solutions) are also explained by the proposed CCM. First, the existence of extraction under these conditions can be clearly seen as resulting largely from improved solvation through chelation of the cation by the polyether polymer compared to that by the organic solvent. In addition, it was previously difficult to rationalize the fact that in the capacity of polyurethane for sorption of $IrCl_6^{2-}$ from ethyl acetate is six times that from acetone. This was suggested to be the result of some unspecified interaction between the solvent and the polymer. However, physical observations of the polymer in both solvents now indicate that greater swelling (and therefore chain extension) occurs in the presence of acetone. On a molecular scale, this means reduced coiling of the polyether chains in this solvent and thus a greatly

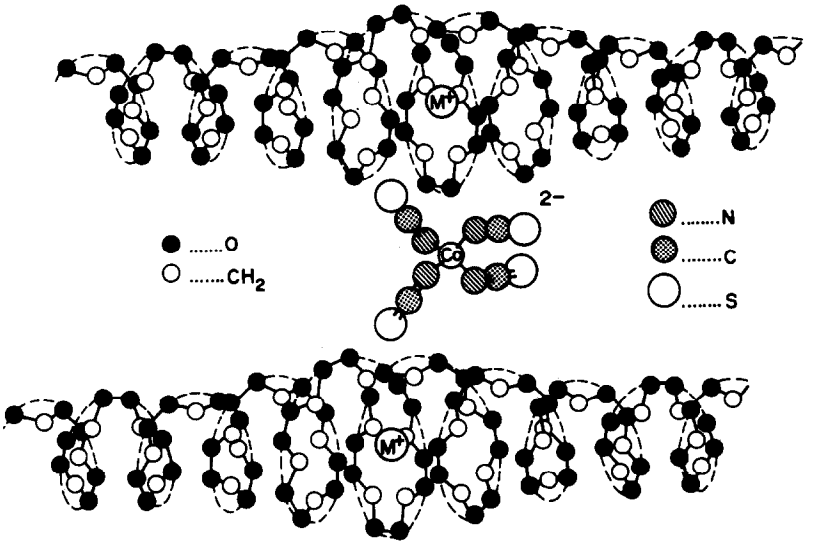

Fig. 7. Proposed helical structure (not to scale) of sorbed $M_2Co(NCS)_4$–polyether complex suggested by the cation chelation mechanism. The poly(ethylene oxide) chains have been extended beyond a length typical of polyurethane foam (~20–25 $-CH_2CH_2O-$ units) to clarify the geometry.

reduced ability to chelate cations by the proposed CCM.

Measurements of polyurethane sorption capacity for salts also appear to be consistent with the CCM hypothesis. Although a minimum of 5–10 oxygen atoms seems[27,43] to be adequate for solvating many individual cations in the case of cyclic or short-chain polyethers, the reduced freedom in an extended polymer analogue might be expected to increase this number considerably. In particular, significant disruptions would be expected to occur in any helical or other regular closed geometry of the polyether chains in the vicinity of the links (urethane, urea, *etc.*) binding them together in a polyurethane. Further losses of order in the polyether would also result from clustering of the polar linking groups into "hard" domains since bending of some polyether "soft" segments would then be necessary. Thus, considering Fig. 7, it might well be expected that in the case of many polyether chains only the central portion may be properly disposed to produce effective chelation of cations. In polyols typical of flexible polyurethane foam manufacture (molecular weight about 1000), there may be some 20–25 polyether oxygen atoms, so the undisturbed central portion might accommodate one or possibly two cations. If any further distortion of the polyether chain results from chelation of the first of these, the capacity may well be effectively limited to one cation per chain. Under these conditions, a cation capacity of roughly 1.0 mole per kg of polymer would be expected, with some variation dependent mostly on the exact polymer formulation and morphology. This is in close agreement with our own measurements[17] for $Na_2Co(NCS)_4$: 0.47 mole of Co per kg of polymer.

CONCLUSIONS

Strong interactions appear to exist between some polyurethanes and various cations. The results indicate that these occur only with polymers containing substantial polyether segments and that poly(ethylene oxide) is more effective than poly(propylene oxide) in this respect.

We note further that some selectivity of the polyether chain is demonstrated for particular cations. In the extraction of $Co(NCS)_4^{2-}$, $Zn(NCS)_4^{2-}$, picrate, ANS^- and other anions, the order of extractability follows the series $Li^+ < Na^+ < Cs^+ < Rb^+ < K^+ \sim NH_4^+ < Ag^+ \sim Tl^+ < Ba^{2+} < Pb^{2+}$. This order of cation preference is nearly identical to that of 18-crown-6 derivatives[39] and also of non-cyclic polyethers.[43] We thus believe that a helical arrangement of inwardly-directed polyether oxygen atoms forms the basis of complexation between cations and the polymer.

According to the proposed CCM, the efficient solvation of these cations then allows the facile extraction of an equivalent number of anions to take place. The most readily extracted anionic species will be those which are hydrophobic in nature, as given partly by the Hofmeister series (*i.e.*, $OH^- < F^- < Cl^- < Br^- < I^- < NCS^-$).[28] Notable among the most easily extracted species are many complex metal anions containing the more hydrophobic of these ligands, which explains the large number of metal-ion extractions observed. The high metal distribution ratios measured under conditions in which a large excess of some suitable cation is available, reflect the fact that effective solvation of the cation by the polymer is ensured by chelation and

thus the polyurethane can behave as a pseudo anion-exchanger.

Although expected to be widespread as a mechanism of ion-pair extraction by polyether-based polyurethanes, the CCM may not account for all observed extractions of metal ions or other apparently ionic species. In particular, when very large size or other steric constraint prevents complexation of the cation, simple solvent-like ion-pair extraction will be the dominant mode of sorption. Also, even though H_3O^+ may be a chelatable cation,[52] the uptake of undissociated neutral acid species, HA, rather than $H_3O^+ \cdot A^-$ ion-pairs may be very competitive for some anions in strongly acidic solutions.

Further investigation of polyurethane extraction mechanisms is continuing in our laboratory. A number of analytical and other applications are also being investigated and will be reported shortly.

SHORT COMMUNICATIONS

DETERMINATION OF THIOSEMICARBAZONES BY REACTION WITH ω-BROMOACETOPHENONE

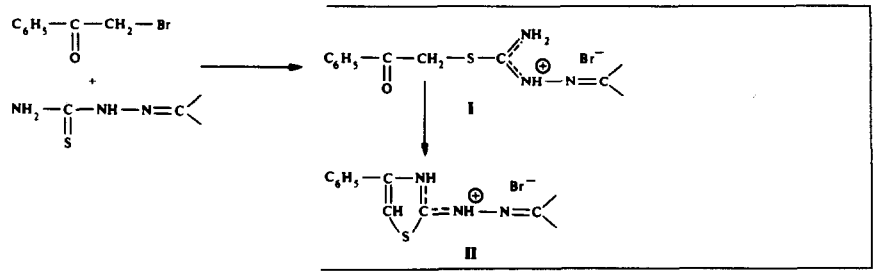
JYOTI TALEGAONKAR, SUMAN MUKHIJA and K. S. BOPARAI
School of Studies in Chemistry, Vikram University, Ujjain 456010, India

(*Received May* 1981. *Accepted* 7 *October* 1981)

Summary—Thiosemicarbazones react quantitatively with ω-bromoacetophenone in a suitable medium; hydrobromic acid thus formed is titrated alkalimetrically with Thymol Blue as indicator.

A few titrimetric methods have been developed for determination of thiosemicarbazones: mercurimetric titration with copper 4-phenylthiosemicarbazide as indicator,[1] potentiometric titration of aromatic thiosemicarbazones,[2] and amperometric titration of thiosemicarbazones of aromatic aldehydes with mercury(II).[3] Colorimetric determinations of thiosemicarbazones of aromatic aldehydes have been based on the reaction with 2,3-dichloro-1,4-naphthoquinone,[4] and 3-chloro-1,2-naphthoquinone.[5]

Thiosemicarbazones react with ω-bromoacetophenone as follows: the cyclization of I to II is facilitated by heating.[6,7]



The reaction forms the basis of a titrimetric procedure for their determination. A thiosemicarbazone is reacted with excess of ω-bromoacetophenone in a suitable medium (the reaction products generally do not have adequate solubility in ethanol, but methanol is satisfactory for the derivatives of aliphatic carbonyls, dimethylformamide for those of aromatic aldehydes and acetonitrile for those of aromatic ketones), and the hydrobromide thus formed is titrated with sodium hydroxide, with Thymol Blue as indicator. Though tested with only a selection of thiosemicarbazones, the procedure seems to be generally applicable to this type of compound. The procedure is susceptible to interference by compounds containing an –NH–CS– function and other nucleophilic species (containing hydroxy, mercapto or amino groups) which react with ω-bromoacetophenone to produce hydrobromic acid. It is simple and accurate, and uses readily available reagents.

EXPERIMENTAL

Procedure

A weighed quantity of a thiosemicarbazone, prepared and purified according to published procedures, and ω-bromoacetophenone (about 25% excess) were dissolved in 20 ml of solvent (methanol for thiosemicarbazones of aliphatic aldehydes and ketones: dimethylformamide and acetonitrile for those of aromatic aldehydes and ketones respectively) and kept for 20 min at room temperature (20–25°). Then 5 ml of 5% sodium thiosulphate solution were added to react with the excess of ω-bromoacetophenone. The solution was allowed to stand for 5 min, and then titrated with 0.1*M* sodium hydroxide, with Thymol Blue (3 drops, 0.3% solution in methanol) as indicator, to a

SEPARATION AND PRECONCENTRATION OF TRACE AMOUNTS OF SEVERAL METALS IN MAGNESIUM METAL AND NITRATE, WITH ACTIVATED CARBON AS A COLLECTOR

MASARU KIMURA* and SADAKO EGAWA

Department of Chemistry, Faculty of Science, Nara Women's University, Nara 630, Japan

(*Received* 23 *July* 1981. *Accepted* 2 *October* 1981)

Summary—A method is described for the preconcentration and determination of traces of Hg, Ag, Cu, Fe, In, Mn, Pb, and Zn present as impurities in magnesium metal (1g) and nitrate (100 g). After the metal sample has been dissolved in nitric acid (or the salt in water) and the pH adjusted to 8.1–9 (except for preconcentration of Hg, when pH 3 is used), the solution is filtered through a 2-cm paper coated with 50 mg of activated carbon. The trace metals are quantitatively adsorbed on the activated carbon and separated from the matrix. The rest of the procedure has already been described. The detection limits for the analysis of 1 g of Mg and 100 g of $Mg(NO_3)_2 \cdot 6H_2O$ are 0.03–1.3 ppm and 0.00031–0.013 ppm respectively, for all the trace metals except Hg. The limit is 0.00001_4 ppm for Hg in 100 g of $Mg(NO_3)_2 \cdot 6H_2O$. The coefficient of variation is 4–33%, depending on the trace metal.

Trace metals have been preconcentrated from magnesium metal and sulphate by means of activated carbon and dithizone.[1] However, dithizone was found unnecessary for adsorption (on activated carbon) of several trace metals in sodium perchlorate,[2] only pH adjustment being required. Even for a matrix such as zinc nitrate,[3] it was not necessary to use special agents for the adsorption of traces of Hg and Fe, which could be quantitatively adsorbed on activated carbon at a favourable pH. It seemed worth examining what sort of traces can be adsorbed on activated carbon (and at what pH), without auxiliary agents. These factors may depend on the type of matrix. Hence we started this work. Preliminary experiments showed that large amounts of chloride greatly decreased the recovery of traces of mercury so we used magnesium nitrate as the sample matrix. The highest grade of nitric acid available commercially [Super Special Grade (S.S.G.), Wako Pure Chemical Co. Ltd.] was used to dissolve magnesium powder, and the impurities in the nitric acid were determined to estimate the solvent background level. A sample of magnesium nitrate was also analysed.

EXPERIMENTAL

Reagents. Magnesium powder and magnesium nitrate of guaranteed-reagent grade were used as the test samples. Activated carbon (Merck *pro analysi*) and nitric acid (S.S.G., Wako Pure Chemical Co. Ltd.) were used without further purification. Standard solutions were the same as described previously.[2,3] The water used was prepared by distilling demineralized water from dilute alkaline permanganate in a glass still.

* Author for correspondence.

Preparation of sample solutions

$Mg(NO_3)_2 \cdot 6H_2O$ (100.0 g) was weighed out and dissolved in 200 ml of water; the pH was about 3. Magnesium powder (1.00 g) was weighed into a 100-ml beaker and dissolved by slow addition of 8.5 ml of concentrated nitric acid during about 1 hr. The solution was heated on a hot-plate at about 200° for a few hours to remove excess of nitric acid, and then transferred to a 300-ml beaker with water, and diluted to 200 ml; the pH was 2–3. Then, the pH of each solution was adjusted to 8.0–9 with 8–10 ml of 0.1*M* sodium hydroxide (G.R.). Contamination from the sodium hydroxide used was negligible.

Procedure for mercury preconcentration

The 200 ml of sample solution were filtered through a 2-cm filter paper coated with 50 mg of activated carbon. The carbon together with the filter paper was then heated at 500° for 5 min in an Automatic Mercury Evaporator, model ANA-K801 (Tokyo Photo-Electric Co. Ltd.), and measured with a flameless AAS, microgas analyser for mercury, model ANA-K80 (Tokyo Photo-Electric Co. Ltd.). The procedure is the same as reported previously.[2,3]

Procedure for other elements

The treatment of the activated carbon with adsorbed trace metals was the same as reported previously.[2,3] The concentration of the trace metals was determined on 100-μl subsamples with a Hitachi 518 Atomic Absorption Spectrometer.

Determination of impurities in the nitric acid

Separate 20, 40, 60, 80 and 100 ml portions of the concentrated S.S.G. nitric acid and 50 ml of water were evaporated to dryness in 100-ml beakers during 5–8 hr on a hot-plate at about 200°. Then 3 ml of 20% v/v nitric acid were added to each beaker and the amounts of metals in the solution were determined by AAS. No Ag, In or Pb was detected, but appreciable amounts of Cu, Fe, Mn and Zn were present; the results are given in Table 1. For each element, plots of the amount found against volume of nitric acid taken were linear, with intercepts. The intercepts were in good agreement with the values obtained from the 50 ml

* Ag, In and Pb could not be detected.

† These values are thought to be the contamination blanks, not from the water itself, but from the surrounding atmosphere during the standing time of 5–8 hr and from the beaker used.

of water and were thought to correspond to the contamination from the beakers and the surrounding atmosphere. Thus, the nitric acid (8.5 ml) used to dissolve 1 g of magnesium was shown to contain 0.06, 0.48, 0.009 and 0.24 μg of Cu, Fe, Mn and Zn, respectively, and these values were subtracted from the results obtained.

RESULTS AND DISCUSSION

Dependence of the recovery on pH of sample solution

The pH of the sample solutions was adjusted by adding nitric acid or sodium hydroxide; the amounts used contained negligible amounts of the trace metals. Plots of amounts of trace metal recovered against the amount added were linear with slopes of unit for 100% recovery, and in most cases, with intercepts on the recovery axis, arising from impurities in the activated carbon and presenting analytical blanks. The recovery as a function of sample solution pH is given in Table 2. Higher pH generally gives better recovery.

Table 2. Dependence of the recovery on pH of the sample solutions*

Trace metal	Calibration range, μg	Recovery %*, pH				
		3.0	7.1	8.1	8.3	9.0
Ag	0.1–2	0	22	81	78	82
Cd	0.1–2	0	0	0	0	49

Mg (1.00 g)	Ag	< *d.l.*	—	0.03
	Cu	8.6	5	0.2
	Fe	9.3	7	1.3
	In	< *d.l.*	—	0.4
	Mn	3.6	33	0.2
	Pb	11	8	0.4
	Zn	70	16	0.4

* C.V. = coefficient of variation, N = number of replicates, σ = standard deviation.

† In this case, 10.00 g of $Mg(NO_3)_2 \cdot 6H_2O$ was used.

At pH >9.0 the solutions were slightly turbid from precipitation of magnesium hydroxide. The partial precipitation of the matrix ion may assist the adsorption of traces on the activated carbon. On the other hand, the recovery of Hg was quantitative even in highly acidic solutions ranging in pH from 0.8 to 5.0. In preliminary experiments it was found that Hg was not recovered at all from 200 ml of solution containing 100 g of $MgCl_2 \cdot 6H_2O$ instead of $Mg(NO_3)_2 \cdot 6H_2O$, but the recovery was 88% when only 10 g of $MgCl_2 \cdot 6H_2O$ were used. This indicates that the recovery of Hg is reduced by the presence of chloride ion, presumably by formation of chloro-complexes.

Determination of mercury

When 100 g of $Mg(NO_3)_2 \cdot 6H_2O$ were dissolved in 200 ml of water, the pH was about 3, the correct range for Hg recovery. The results are given in Table 3.

Determination of Ag, Cu, Fe, In, Mn, Pb and Zn

It is seen from Table 2 that these traces were quantitatively adsorbed on the activated carbon (within experimental error) at pH > 8.1. The results obtained for the pH range 8.1–9 are also listed in Table 3.

Preconcentration coefficient

This is defined[4] as $K = (Q_t/Q_m)/(Q_t^\circ/Q_m^\circ)$ where Q_m° and Q_m are the quantities of matrix before and after preconcentration, respectively, and Q_t° and Q_t are the quantities of the trace elements in the sample and in the concentrate (*i.e.*, activated carbon in this work). When the recovery is quantitative, $K = Q_m^\circ/Q_m$. The magnesium adsorbed on the activated carbon (*i.e.*,

Q_m) was found to be 270 μg under the conditions in Table 3 [100 g of $Mg(NO_3)_2 \cdot 6H_2O$; $Q_m^\circ = 9.5$ g]. Thus, the preconcentration coefficient is 3.5×10^4. This value is thought to be satisfactorily large. In general, the matrix itself is also adsorbed on the activated carbon and the value of Q_m is dependent on the experimental conditions such as pH of the sample solutions.

(*Received* 6 *July* 1981. *Accepted* 4 *September* 1981)

Summary—Two simple and sensitive colorimetric procedures for the determination of *p*-aminophenol with 3-cyano-*N*-methoxypyridinium perchlorate are presented. One is based on reaction in methoxyethanol in presence of sodium acetate, with direct measurement at 410 nm. The reaction product obtained by this procedure has been separated and identified. The other is based on reaction in methoxyethanol in presence of chloramine-T and direct measurement at 448 nm. The method has been applied to the determination of *p*-aminophenol in pure form and as an impurity in paracetamol and paracetamol-containing tablets, with a coefficient of variation less than 2%.

Various spectrophotometric methods have been reported for the determination of *p*-aminophenol as an impurity in paracetamol, and are based on measurement of a coloured product formed through reaction with certain reagents, either before or after chromatographic separation from the paracetamol.[1–13] In many of these colour reactions[4–12] the product has not been identified. Other methods are based on non-aqueous titration with perchloric acid,[14] polarographic analysis,[15,16] HPLC with electrochemical detection,[17] and direct and indirect fluorimetric analysis.[18,19] Recently Schnekenburger *et al.*[20] used 3-cyano-*N*-methoxypyridinium perchlorate (CMPP) as a chromogenic reagent for qualitative determination of primary and secondary aromatic amines and sulphonamides in a reaction analogous with those used by Zincke,[21] König,[22] and Baumgarten.[23] All these authors have studied the hydrolysis and ring-opening of pyridinium salts by treatment with base. Salts such as 2,4-dinitrophenylpyridinium chloride,[21] *N*-cyanopyridinium bromide[22] and pyridinium sulphonic acid[23] undergo base-induced ring cleavage to form derivatives of glutaconic dialdehyde.

N-Alkoxy quaternary salts of aromatic nitrogen heterocycles are prepared from the corresponding *N*-oxides by reaction with alkylating agents.[24,25] Thus 3-cyanopyridine-*N*-oxide was synthesized according to the method of Ochiai[26] by reacting 3-cyanopyridine with hydrogen peroxide in acetic acid. The *N*-oxide was quaternized with excess of dimethyl sulphate to afford the 3-cyano-*N*-methoxypyridinium salt, which was conveniently isolated and purified as the perchlorate (CMPP).[27]

CMPP reacts with aromatic amines and sulphonamides, especially in dipolar aprotic solvents, to produce yellow solutions of 1-methoxyimino-2-cyanopentadiene derivatives. Some of these reactions require the presence of a base.[20] Accordingly, we suggest the use of CMPP as a chromogenic reagent for colorimetric determination of *p*-aminophenol. It reacts with *p*-aminophenol in presence of sodium acetate to give the intensely yellow product **I** (Scheme 1). This product, 1-methoxyimino-5-(4-hydroxyphenylamino)-2,4-pentadien-2-carbonitrile, has been synthesized and its physicochemical properties are reported. The addition of chloramine-T to a solution of **I** changes the colour from yellow to red, but the product (postulated as compound **II** in Scheme 1) is not stable enough for separation or synthesis, probably because of the quinone-imine structure.[28]

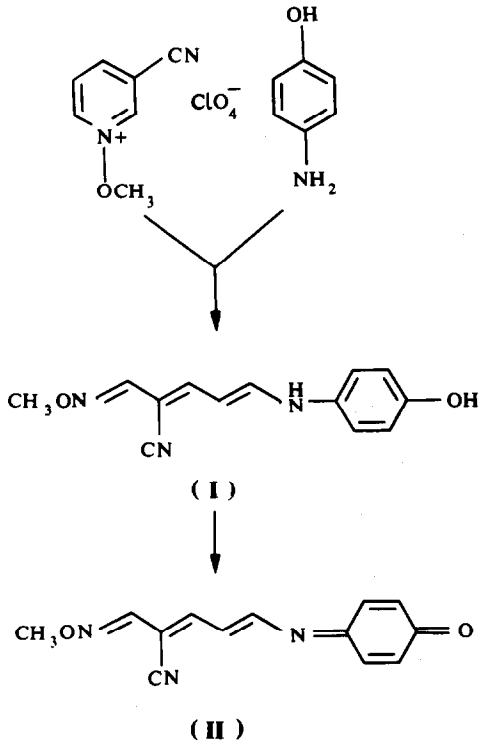
Here we use both reactions for the colorimetric determination of *p*-aminophenol either alone or in presence of paracetamol.

EXPERIMENTAL

Reagents

*3-Cyano-*N*-methoxypyridinium perchlorate (CMPP).* Dissolve 200 mg of CMPP, synthesized according to Schnekenburger and Heber[27] and recrystallized from methanol (m.p. 110°), in 100 ml of methoxyethanol. Prepare immediately before use.

Synthesis of compound I. 4-Aminophenol (1.1 mmole) and then triethylamine (5 drops) were added in one portion to a solution of 3-cyano-*N*-methoxypyridinium perchlorate (CMPP) (1 mmole) in dimethylformamide (2 ml) with vigorous stirring, and cooling in an ice-bath. The deep yellow mixture was neutralized with dilute hydrochloric acid



Scheme 1.

and then poured over crushed ice (5 g), diluted with water (5 ml), and stirred until the ice had melted. The product was filtered off, washed with distilled water, and air-dried. The crude product was purified by dissolving it in acetone (3 ml) and shaking with charcoal (500 mg). After filtration the solution was poured over crushed ice and worked up as described above (131 mg, 54% yield, m.p. 158°). TLC with chloroform–methanol (1:1) showed the product to be homogeneous; infrared (KBr) 3300, 2210, 1640 and 980 cm^{-1}; ^1H-N.M.R. (DMSO-d_6, δ[ppm]) 3.80 (s, 3H), 6.00 (t, 1H), 6.94 (m, 4H), 7.40 (d, 1H), 7.85 (t, 1H), 7.90 (s, 1H), 9.40 (s, 1H), 10.15 (d, 1H). Analysis gave C 64.1%, H 5.4%, N 17.2%; $C_{13}H_{13}N_3O_2$ (m.w. 243.26) requires C 64.19%, H 5.39%, N 17.27%.

The product was soluble in methoxyethanol, ethanol, acetone, chloroform, and dimethylformamide and sparingly soluble in water.

Chloramine T solution, 0.5% in methoxyethanol. Prepared fresh daily.

Sodium acetate solution, 0.1% in methoxyethanol.

Standard p-aminophenol solution. Prepared by dissolving 50 mg in 100 ml of methoxyethanol, and diluting a 2-ml portion to 50 ml with methoxyethanol.

Procedure A

Pipette standard *p*-aminophenol solution (0.5–2.5 ml) into 25-ml standard flasks. Add 1 ml of CMPP solution and 1 ml of sodium acetate solution. Mix and leave for 5 min. Make up to volume with methoxyethanol. Measure the absorbance in 1-cm cells against a reagent blank at 410 nm.

Procedure B

Pipette standard *p*-aminophenol solution (2–10 ml) into 25-ml standard flasks. Add 1 ml of CMPP solution and leave for 5 min. Add 1 ml of chloramine-T solution. Mix and leave for 5 min. Make up to volume with methoxyethanol. Measure the absorbance in 1-cm cells against a reagent blank at 448 nm.

Determination of p-aminophenol in paracetamol tablets

Weigh accurately 10 tablets of paracetamol and grind them in a mortar to homogeneity. Weigh a portion of the powder containing 400 ± 4 mg of paracetamol and transfer it to a 100-ml standard flask. Add 70 ml of methoxyethanol, agitate gently for 10 min, then dilute to volume with methoxyethanol. Filter through a medium-speed filter paper. Apply procedure A or B to 1 ml of the final clear solution. Calculate the amount of *p*-aminophenol from the appropriate calibration graph.

RESULTS AND DISCUSSION

Methoxyethanol, ethanol, dimethylformamide, chloroform, acetone, and dioxan were tried as solvents for the coloured products. The most suitable was methoxyethanol. The colour produced in both procedures was found to be stable in methoxyethanol for 30 min. Investigations on the effect of the concentrations of the different reagents in both procedures, with respect to maximum sensitivity, and obedience to Beer's law, led to procedures A and B above.

The yellow product (procedure A) has maximum absorption at 410 nm. No difference was found with pure synthetic I (Fig. 1). Addition of chloramine-T (procedure B) resulted in a bathochromic shift and the red colour developed showed absorption peaks at 448 and 476 nm (Fig. 1).

The colour produced in both procedures under the conditions described was found to obey Beer's law over the concentration ranges 10–60 and 40–200 μg/25 ml for procedures A and B, respectively. Five separate determinations at different concentration levels were carried out to test the reproducibility; the coefficient of variation was found to be less than 2% for both procedures. Procedure A was more sensitive (log ϵ = 4.720, 1-cm cell) than procedure B (log ϵ = 4.233 at 448 nm, 4.183 at 476 nm). Procedure B can be recommended when other amino-compounds are present that do not interfere with the measurement at 448 or 476 nm. Procedures A and B have been applied to the determination of *p*-aminophenol

† *p*-Aminophenol added in 1% ratio to paracetamol.
‡ Added in concentration range 40–160 μg per 25 ml.

added to pure paracetamol and to paracetamol tablets. Paracetamol does not interfere with either reaction and the method can be used to detect *p*-aminophenol even in the presence of a 10^5-fold amount of paracetamol. The tolerance limit for the pharmaceutical product is 1 in 2×10^4. The results obtained (Table 1) are acceptably precise and accurate for the levels concerned.

Several drugs and related compounds have been tested for interference in both procedures. Codeine, salicylamide, phenacetin, acetanilide, and phenol give no colour. Aniline, *o*-aminophenol and *m*-aminophenol give a yellow colour with CMPP. Addition of chloramine-T gives no further response with aniline or *m*-aminophenol, the colour remaining yellow, but with *o*-aminophenol the colour changes slowly to red. The negative response of the *m*-aminophenol product to addition of chloramine-T supports our assumption that *p*-quinone-imine derivatives are formed after the addition of chloramine-T to *p*-aminophenol. The method described is simple, selective, and accurate and can be extended to determination of primary and secondary amines and aminophenols.

ANALYTICAL DATA

POTENTIOMETRIC STUDY OF THE ASSOCIATION CONSTANT OF ISOTHIOCYANIC ACID

E. A. NEVES, L. ANGNES, G. O. CHIERICE and L. H. MAZO
Instituto de Química da Universidade de São Paulo, São Paulo, Cx. Postal 20780, Brazil

(*Received* 17 *February* 1981. *Revised* 18 *August* 1981. *Accepted* 2 *October* 1981)

Summary—The association constant of isothiocyanic acid, HNCS, has been determined potentiometrically and found to be 0.135 ± 0.007 and 0.168 ± 0.007 at ionic strengths ($NaClO_4$) of 2.0 and 4.0*M* respectively. The indicator electrode was $Hg(SCN)_4^{2-}$/Hg. For accuracy and precision the metal phase was used in the form of a dropping electrode. Because the association constant is so low, liquid-junction potentials would cause significant errors, since a strong acid was added to the working solutions in the procedure, and an estimate of this effect was taken into account.

Thiocyanate is a ligand of analytical importance for the determination of several metals.[1] In our studies on the uranium–thiocyanate system[2] the medium was made acidic to minimize hydrolysis. Hence it was important to know the association constant for formation of isothiocyanic acid. HNCS (which is known to be a moderately strong acid) for use in calculating the free ligand concentration. Previous values for this constant are not in complete agreement,[3–6] and were not determined at the ionic strengths used in the work reported here.

In the present work an indirect potentiometric method was used to monitor the free SCN^- concentration, from the reversible response of an $Hg(SCN)_4^{2-}$/Hg electrode, this method having previously been found to be reliable.[7] Changes in junction potential, ΔE_j were also taken into account.

EXPERIMENTAL

An Orion 801-A potentiometer coupled to a Metrohm EA 876 cell and a calomel electrode ($NaCl_{sat}$) was used in the potentiometric measurements. A dropping mercury electrode, at a constant height and with drop-time of about 5 sec, was used as indicator electrode. This kind of electrode was preferred owing to its high stability in potentiometric work.[8]

The measurements were taken when the maximum surface was attained.

The potentiometric cell used was:

Ag	$AgCl_{sat}$ $NaClO_4 + NaCl = 2.00M$ (or 4.00*M*)	$NaCl_{sat}$, Hg_2Cl_2	Hg (cell II)

The standard solution of tetrathiocyanatomercury(II) used was prepared by reacting perchloric acid with the stoichiometric amounts of mercury(II) oxide and sodium thiocyanate:

$$HgO + 2H^+ + 4SCN^- = Hg(SCN)_4^{2-} + H_2O$$

A volume of 8.00 ml of the thiocyanate test solution (composition as shown above for cell I) was placed in the cell, and the initial potential E_i was measured. Then various volumes of perchloric acid (at the same ionic strength as the test solution) were added and the corresponding potentials were measured. The maximum hydrogen-ion concentration reached was always comparable with the concentration of the thiocyanate ions.

For measurements of ΔE_j the following cell was used:

Hg	$Hg(SCN)_4^{2-} = 10.0mM$ $NaSCN + NaClO_4 = 1.97M$ (or 3.97*M*)	$NaCl_{sat}$, Hg_2Cl_2	Hg (cell I)

The ΔE_j was estimated on the basis of changes in $E^{0'}_{AgCl}$ caused by addition of perchloric acid (at the same ionic strength). All measurements were made at 25.0 ± 0.1°.

RESULTS AND DISCUSSION

The potentiometric determination

A linear relationship between E and $[SCN^-]$ was found over a wide range of free ligand concentration, for a fixed mercury(II) concentration. A virtually Nernstian response was obtained, but the slope was slightly lower than expected for the existence of only $Hg(SCN)_4^{2-}$. This is, in fact, the dominant species for

the range of ligand concentrations examined, but the small concentrations of $Hg(SCN)_3^-$ and $Hg(SCN)_2$ should also be taken into account. Thus the following Nernst equation can be applied for the potential of cell I and 25.0°, constant ionic strength (2.0 or 4.0*M*) and analytical mercury(II) concentration C_{Hg}:

$$E = E_x^{0\prime} + \frac{0.05916}{2}\log C_{Hg} - \frac{0.05916\bar{n}}{2}\log[SCN^-] \quad (1)$$

where

$$\bar{n} = \frac{2\beta_2[SCN^-]^2 + 3\beta_3[SCN^-]^3 + 4\beta_4[SCN^-]^4}{\beta_2[SCN^-]^2 + \beta_3[SCN^-]^3 + \beta_4[SCN^-]^4} \quad (2)$$

$E_x^{0\prime}$ is calculated from the measured potential E at a known C_{Hg} and free thiocyanate concentration.

The initial free thiocyanate concentration $[SCN^-]$ corresponding to the initial potential E_i would be

$$[SCN^-]_i = C_{SCN^-} - \bar{n}C_{Hg} \quad (3)$$

It was obtained by an iterative calculation starting from the estimate

$$[SCN^-] = C_{SCN^-} - 4C_{Hg} \quad (4)$$

the value of $[SCN^-]$ thus obtained being used to calculate $\bar{n}$ from equation (2) with the values $\log \beta_2 = 16.07$, $\log \beta_3 = 18.95$ and $\log \beta_4 = 20.94$, taken from the literature.[9] This value of $\bar{n}$ was then used in equation (3) to refine the estimate of $[SCN^-]_i$, and so on until a constant value for $[SCN^-]_i$ was obtained. Only one iteration was usually needed, and the value of $\bar{n}$ was not significantly affected by moderate dilution of the cell solution.

When a volume v ml of perchloric acid of concentration C_H was added to the initial V ml of cell solution, the potential shifted to E_v, corresponding to the equilibrium for the new free thiocyanate concentration $[SCN^-]_{exp}$. The following equations were then introduced into the calculations.

$$[H^+] = C_H v/(v + V) \quad (5)$$

$$[SCN^-]_v = [SCN^-]_i V/(v + V) \quad (6)$$

$$E_v + \Delta E_j = E_x^{0\prime} + \frac{0.05916}{2}\log[C_{Hg^{2+}}V/(v + V)] - \frac{0.05916\bar{n}}{2}\log[SCN^-]_{exp} \quad (7)$$

$[SCN^-]_v$ in equation (6) is the free thiocyanate concentration calculated solely from the dilution factor, without regard to other effects, and thus differs from $[SCN^-]_{exp}$. Combination of equations (1) and (7) and rearrangement gives

$$[SCN^-]_{exp} = \text{antilog}\left\{\frac{2(E_i - E_v - \Delta E_j)}{0.05916\bar{n}} + \log\frac{V}{(v + V)\bar{n}} + \log[SCN^-]_i\right\}. \quad (8)$$

In the first step of the iterative calculation no ΔE_j is considered, and $[SCN^-]_{exp}$ is calculated from equation (8) and compared with the $[SCN^-]_v$ obtained from equation (6). The difference between the two values arises because of protonation of some of the thiocyanate. An estimate of [HNCS] is thus obtained from

$$[HNCS] = [SCN^-]_i V/(v + V) - [SCN^-]_{(exp)} \quad (9)$$

and of $[H^+]_{exp}$ from

$$[H^+]_{exp} = C_H v/(v + V) - [HNCS] \quad (10)$$

The calculation is then refined by inserting

$$E_j = k[H^+]_{exp} \quad (11)$$

into equation (8) to obtain a better estimate of $[SCN^-]_{exp}$ and so on. The iterative calculations involving equations (8)–(11) take a few cycles to converge to constant values for $[H^+]_{exp}$, [HNCS] and $[SCN^-]_{exp}$. These values are then used to calculate the association constant:

$$\beta = [HNCS]/[H^+]_{exp}[SCN^-]_{exp} \quad (12)$$

for the equilibrium $H^+ + SCN^- \rightleftharpoons HNCS$.

ΔE_j measurements

Perchloric acid was added to the Ag/AgCl,Cl compartment of the cell (II for which the potential is:

$$E = E_{AgCl}^{0\prime} - 0.05916\log[Cl^-]$$

$E_{AgCl}^{0\prime}$ is held constant if sodium perchlorate of the same ionic strength is added, because the equivalent conductance of ClO_4^- is close to that of Cl^- (and also of SCN^-). If perchloric acid is added, however, $E_{AgCl}^{0\prime}$ does not remain constant, and the change to a more negative potential is interpreted as a change in junction potential, ΔE_j, caused by hydrogen ions.

The ΔE_j for addition of acid to the thiocyanate solutions was assumed to be the same as that measured for a similar addition of acid to chloride solutions of the same ionic strength, because the equivalent conductance of protons is considerably higher than that of perchlorate, thiocyanate or chloride. ΔE_j has been found to be a linear function of the acidity for both ionic strengths tested. Thus ΔE_j is directly calculated from equation (11), where k is 7.9 $mV.l.mole^{-1}$ for ionic strength 2.0*M* and 11.4 $mV.l.mole^{-1}$ for ionic strength 4.0*M*.

RESULTS

Table 1 shows the final results obtained from eight series of potentiometric measurements. Slightly smaller values were obtained if $\bar{n}$ for mercury(II) was taken as 4.00, with species other than $Hg(SCN)_4^{2-}$ being ignored. However, the ΔE_j values cannot be neglected in the measurements.

A close agreement was found with the results from potentiometric titration, 0.11, at various ionic strengths,[3] but other methods, albeit at different ionic strengths, give a spread of values from 0.01–1.6.[3–6]

Table 1. Association constant of HNCS

Ionic strength, M	C_{SCN^-}, M	β_1*	Overall averages
2.0	0.24	0.135 ± 0.0050	0.135 ± 0.007
		0.138 ± 0.0042	
	0.54	0.125 ± 0.0033	
		0.141 ± 0.0012	
4.0	0.24	0.167 ± 0.0008	0.168 ± 0.007
		0.158 ± 0.0008	
	0.54	0.175 ± 0.0033	
		0.171 ± 0.0046	

* Average ± standard deviation, obtained from 6 experiments.

Since the potentiometric method is usually more precise and reliable, we believe that the present measurements are more acceptable, since the ionic strength was held constant. The high thiocyanate concentrations used eliminate any possible effects of hyperprotonation (to H_2NCS^+) or hydrolysis to OCS and HCN. It should be added that quite inconsistent results are obtained if ΔE_j is neglected.

The SCN^- ligand can co-ordinate through sulphur (soft base) or nitrogen (hard base). Since the hydrogen ion is considered to be a "hard" acid, the dominant species formed with thiocyanate should be HNCS (isothiocyanic acid) rather than HSCN.

Summary—Twenty-two new hydrazones were synthesized for evaluation as possible colorimetric reagents for trace determinations of iron, cobalt, nickel, copper and zinc. Spectrophotometric studies revealed that several show promise as sensitive reagents, with possible utility for simultaneous determinations of two or more of the metals. Conclusions regarding geometric structures of some of the hydrazones and chelates were deduced from mole-ratio studies.

Continuing our exploration of hydrazones[1–5] in search of new chromogenic reagents for trace metal determinations, we report here the synthesis of some hydrazones of 2-, 3-, and 8-hydrazinoquinoline and the results of studies of their reactions with some first-row transition metal ions.

EXPERIMENTAL

Reagents

Preparation of hydrazones (**I–XXII**). The 2-hydrazinoquinoline[6] and 8-hydrazinoquinoline[7] were prepared as described earlier. For the preparation of 3-hydrazinoquinoline, the method of Clemo and Felton[8] was followed, except that the tin(IV) salt was decomposed with concentrated sodium hydroxide solution instead of hydrogen sulphide. To prepare the hydrazones, 8 mmole of aldehyde or ketone and hydrazinoquinoline dissolved in 25 ml of absolute ethanol and treated with 1 ml of glacial acetic acid were heated under reflux for 2 hr. The cooled solution was made alkaline with ammonia solution, and the precipitate was filtered off, dried and crystallized from the solvent indicated in Table 1.

Reagent solutions (*0.01M*). A weighed amount of each compound to be tested was dissolved in the necessary volume of ethanol containing 0.05 mole of hydrochloric acid per litre.

Other solutions. Standard solutions of metal ions, buffer solutions, and ascorbic acid were prepared by procedures already described.[1]

Chelation studies

The procedures used to determine the pH ranges over which colour formation occurred, wavelengths and molar absorptivities of maximum absorbance, conformance to Beer's law, and ligand: metal-ion ratios have been already described.[1,9,10]

RESULTS AND DISCUSSION

The hydrazones dissolved readily in strong acids to give intensely orange solutions and in ethanol (neutral) to yield yellow solutions. Those which formed coloured metal chelates did so over the pH range 2–11, with maximum colour formation generally at pH 3–10. Depending on the pH, the iron(II) chelates displayed two colours, with the transition in colour occurring between pH 5 and 6.

Hydrazones **II, III** and **V** formed the most intensely coloured chelates, the molar absorptivities and wavelengths of maximum absorbance of which are listed in Tables 2 and 3. It is notable that in all cases an aryl group at R_2 gave rise to greater absorptivities in the chelates than an H or CH_3 substituent. Compounds **II, III** and **V** merit consideration as sensitive chromogenic reagents for iron, cobalt, nickel and zinc. Simultaneous determinations of certain combinations of these metals also appear promising, and are based on the significant, though small, differences in the location and shape of the spectral band of these chelates.

None of the hydrazones derived from 3-hydrazinoquinoline (**VIII–XII**) proved effective as chromogens for the transition metal ions tested, other than copper(I). Examination of molecular models revealed that the 3-quinolyl nitrogen atom in these compounds is incapable of participating in chelation of metal ions. The models further showed that the 3-quinolyl group of a bound ligand can sterically hinder co-ordination of a second and especially the third ligand required for full octahedral chelation of the hexaco-ordinate metal ions Fe(II), Co(II), Ni(II) and Zn(II) by bidentate ligands. For the chelation of tetraco-ordinate copper(I), which forms tetrahedral complexes, no steric hindrance was evident from the models. Thus, for structural reasons, only copper(I) would be expected to yield coloured chelates with **VIII–XII**. The experimental results confirm this. The copper(I) chelates, however, proved to give only moderate absorption and therefore are not considered promising for analytical purposes.

It is possible to deduce which of the two possible stereoisomers was obtained in the synthesis of certain

XIII	2	M	2	M
XV	2	W	2	W
XVIII	3	W	†	†

* Relative strength as indicated by curvature and low degree of formation (α) in mole-ratio plots: S = strong, very little curvature; M = moderate, some curvature; W = weak, considerable curvature.

† Too weakly formed for reliable measurement.

of the hydrazones made in this study, on the basis of the ligand to metal ion ratios found for their iron(II) chelates. As described by Bell and Rose[11] and in some of our previous communications[2–5] concerning hydrazone chromogens, terdentate co-ordination may occur with one isomer of a particular hydrazone but may not be possible with the other isomer. Accordingly, if **I, II, IV, V, XIII** or **XV** were to exist in the geometric configuration depicted in Table 1, each should be capable of terdentate co-ordination to yield an iron(II) chelate with a ligand to iron ratio of 2. However, if the other isomer had been obtained instead, with the R_2 and R_3 groups interchanged, the hydrazone would be capable of bidentate but not terdentate co-ordination, and a ligand to metal ratio of 3 would be predicted for its iron(II) chelate. Inasmuch as the iron(II) chelates of **I,II,IV, V, XII** and **XV** were each found to have a ligand to iron ratio of 2, the particular stereoisomer obtained in the synthesis of each must be the one depicted in Table 1.

Hydrazones **XIII–XXII** appear to afford only marginal promise as analytical reagents. In general, the stabilities (Table 4) and molar absorptivities (Tables 2 and 3) of their chelates were appreciably less than those of the corresponding chelates of the 2-quinolyl analogues (**I–VII**). From molecular models and the results of our mole-ratio studies we conclude that the 8-quinolyl and imino nitrogen atoms of these hydrazones can co-ordinate to a metal ion to form a 6-membered chelate ring, but that this ring is strained and therefore less stable than the 5-membered chelate ring which could form if a 2-quinolyl group were at the R_1 position, and not the 8-quinolyl group. The finding that the iron(II) chelates of **XIII** and **XV** have a ligand to metal ratio of 2 indicates that the ligands are terdentate and therefore that the 8-quinolyl nitrogen atom must be co-ordinated to iron(II) in their complexes. Ligand **XVIII**, however, was found to be bidentate, with a ligand to metal ratio of 3 for its iron(II) chelate. From this we conclude that the benzoyl group neither participates nor interferes in the chelation of iron(II) by **XVIII**.

ANNOTATION

DRYING CONDITIONS FOR POTASSIUM DICHROMATE

TAKAYOSHI YOSHIMORI and KENJI KAMIJOH
Faculty of Engineering, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo, 162, Japan

(*Received* 26 *June* 1981. *Accepted* 14 *September* 1981)

Summary—The optimum conditions for drying primary-standard or SRM grade potassium dichromate have been further examined, and it has been established that if organic impurities are present in the material the drying temperature should not exceed 200°. At higher temperatures the organic matter is decomposed oxidatively by the dichromate, with a resultant error when the dichromate is used for standardization purposes.

Potassium dichromate is a particularly useful reference material for titrimetric analysis, not only because of its oxidizing power in acidic solution, but also its functions as a primary standard in acid–base work. However, in our experience and that of Knoeck and Diehl[2] the "dried" reagent is hygroscopic.

Various temperatures (from 110° to the melting point, 398°) have been recommended for the dehydration of the dichromate, and are summarized elsewhere.[3] The presence of occluded water in the crystals of the SRM 136b from the National Bureau of Standards (NBS) was observed by Knoeck and Diehl, and they found a weight loss of 0.019% on heating the reagent at 260°.[2] Sappenfield *et al.*[4] found a weight loss of 0.018% for SRM 136c heated at the same temperature. According to the specification of NBS SRM 136c, a weight loss of 0.005% may be obtained on heating at 105° and 0.01% loss on prolonged heating. Schwab and Wichers[5] earlier found 0.027 and 0.021% of water in NBS SRM 136 by a vacuum fusion–manometric method. They also found occluded water in cavities of the crystals. Svec and Conzemius[6] measured the impurities in SRM 136b by prespark mass spectroscopy, and indicated the presence of water.

For practical use for titrimetry, the SRM is usually pulverized with an agate mortar and pestle to remove occluded water, then heated at a defined temperature, cooled in a desiccator and weighed. Yoshimori and Sakaguchi[7] therefore investigated the drying conditions for potassium dichromate by coulometric microdetermination of residual water in the "dried" reagent. They showed that the water content of the dichromate decreased appreciably with heating at above 150°, and became negligibly small with heating at above 250°. Thus heating at higher than 200° was recommended.

However, it has been reported that dichromate can be decomposed to green chromium(III) oxide by high-temperature heating.[8] On the other hand, Yoshimori *et al.*[9] purified the reagent by zone melting at 400°, and obtained a very pure product, indicating stability of the reagent up to its melting point. Thus, it seems likely that production of the green oxide might be caused by reduction with some organic impurities in the sample. This problem has now been investigated both by precise coulometric assay of the dichromate and by microdetermination of carbon[10] in the reagent.

EXPERIMENTAL

The apparatus and procedure for the coulometric assay of the dichromate were fundamentally based on the work of Taylor and Marinenko[11] and have already been presented elsewhere.[9] The microdetermination of carbon has also been described[10] and is based on the principle used by Braid *et al.*[12] The dichromate sample was heated at 200° or 300° in a stream of oxygen, then the gases produced were oxidized with copper(II) oxide at 780°. The carbon dioxide thus produced was determined by titrimetry in a non-aqueous solvent.

Two reference materials (CRM-A and -B) certified by the Industrial Inspection Institute of Japan and NBS SRM 136c were tested. The first two were prepared by different producers. All samples were pulverized with an agate mortar and pestle, heated in a fan-type oven for 3 hr at each temperature, cooled for 90 min, in a desiccator containing magnesium perchlorate, and then weighed for the assay. Values of 96484.56 C/eq for the Faraday constant and 294.1844 for the molecular weight were used for the calculation.

RESULTS AND DISCUSSION

The results are shown in Table 1.

The purities found were nearly constant for all the samples heated at between 150° and 200°, though some carbon dioxide could be obtained from the

Table 1. The results of assays and the amounts of carbon by heating potassium dichromate at various temperatures

Sample (certified value)	Heating temperature, °C	No. of detns.	Purity found, % Mean	s_R	Carbon found, ppm
CRM—A (99.99%)	150	4	99.978	0.007	—
	200	6	99.976	0.015	10
	250	7	99.965	0.010	—
	300	5	99.963	0.009	30
CRM—B (99.99%)	150	4	99.981	0.001	—
	200	9	99.980	0.005	17
	250	5	99.960	0.002	—
	300	5	99.963	0.007	30
NBS SRM 136c (99.98%)	150	2	99.961	0.002	—
	200	4	99.964	0.008	5
	300	3	99.951	0.008	10

samples heated at 200°. The standard deviations for the samples heated at 200° were larger than the deviations for those dried at 150°. This indicates heterogeneous distribution of organic impurities in the samples, especially for CRM-A.

The purities found decreased significantly when the drying temperature was increased to 250°, though the decrease was only 0.01–0.02%. Residual water in the cavities of the pulverized reagent may be removed most completely by means of the phase change of the crystals at 236° (from triclinic to monoclinic) but such removal should, contrary to our results, increase the purity of the samples. However, the amounts of carbon dioxide produced by the oxidation of any organic compounds present also increased when the heating temperature was raised from 200° to 300°. These phenomena indicate that the reduction of the dichromate by organic impurities becomes significant at above 200° and could be the main cause of the decrease in purity. Since the purities for CRM-A and -B were nearly constant when they were dried at above 250°, the effect of the organic impurities evidently terminated at this temperature, and the dichromate itself did not decompose until at least 300°.

The results for the samples dried at 150° or 200° were somewhat low compared with the certified values, though the differences were less than 0.02%. They may perhaps be due to error in the current measurements for the coulometric titration, because the uncertainty of the current-measuring devices used here was about 0.01%. The contributions from uncertainty in the molecular weight of the reagent and the weights of the samples were nearly one order less than this value. The organic impurity, calculated on the basis of a 50% carbon content, would amount to not more than 0.006% in CRM-A and -B and 0.002% in NBS SRM 136c, but could easily reduce several times as much dichromate, depending on its composition.

CONCLUSION

Potassium dichromate reference material for titrimetry should be dried at between 150° and 200° after pulverization in an agate mortar and pestle, but if the dichromate is completely pure or does not contain any organic impurities, it may be dried at 200–300° and the contamination by occluded moisture thus more thoroughly avoided.

TALANTA REVIEW*

THE SPECIATION OF TRACE ELEMENTS IN WATERS

T. M. FLORENCE

Analytical Chemistry Section, Australian Atomic Energy Commission Research Establishment, Lucas Heights, NSW 2232, Australia

(*Received* 5 *June* 1981. *Accepted* 16 *October* 1981)

Summary—Speciation (determination of the different physico-chemical species formed by an element) in a water sample is necessary for an understanding of the toxicity, bioavailability, bioaccumulation and transport of a particular element. The importance of speciation measurements and the various factors leading to changes in speciation are discussed in this review. Speciation in natural waters is a difficult task, and the analytical methods available and the results obtained are critically assessed.

Speciation of an element is the determination of the individual *physico-chemical forms* of that element which together make up its total concentration in a sample. It is now well established that speciation measurements are necessary for the study of toxicity of metals for aquatic organisms and for an understanding of trace-metal transport in rivers and estuaries. Measurement of the *total* concentration of a trace element provides no information about its bioavailability or its interaction with sediments and suspended particulates.

Perhaps the most important features which distinguish metals from other toxic pollutants are that they are not biodegradable and that, once they have entered the environment, their potential toxicity is controlled to a large extent by their physico-chemical form.[1]

Some elements are essential to life. To date, iron, iodine, copper, manganese, zinc, cobalt, molybdenum, selenium, chromium, tin, vanadium, fluorine, silicon and nickel have been established as essential trace elements, and arsenic, cadmium, lead and tungsten are suspected to be essential.[2] Since life evolved in the presence of all the natural elements of the Periodic Table, it is likely that many more trace elements will be identified as essential.

For all these trace elements there exists a fairly narrow "concentration window" between the essential and toxic levels.[2] An element which is indispensable for normal body function may be highly toxic when present at higher concentrations. Some essential elements, for example selenium and vanadium, are much more toxic than some non-essential elements such as mercury and thallium.[2]

Most people are now subjected to environmental concentrations of metals much higher than those to which their forebears were exposed.[3] The body burden of lead and cadmium in modern urban man is at least 500 times that of primitive man, and is disturbingly close to the concentrations known to produce clinical toxicity.[3,4]

Variation in the speciation of trace elements can dramatically change their bioavailability or toxicity. Cobalamin (vitamin B_{12}) is the only assimilable chemical form of cobalt, and the group of chromium amino-acid complexes, known as the glucose tolerance factor, provides most of the usable chromium.[1,2] The alkyl compounds of mercury and lead are especially dangerous because they are lipid-soluble,[1] and materials such as the lead halide aerosols emitted by automobiles can enter the lungs and be absorbed directly into the blood stream.

Change in the oxidation state of an element can have a profound effect on bioavailability and toxicity. Chromium(III) is an essential element; chromium(VI) is highly toxic. Arsenic(III) is much more toxic than arsenic(V).[5–7] Significant changes in the diet may also decrease the bioavailability of trace elements; *e.g.*, high-fibre foods and soybean proteins adsorb essential elements and can cause mineral deficiencies.[8]

Most studies of the toxicity of heavy metals for fish have shown that the free (hydrated) metal ion is the most toxic form.[7] In the case of copper, hydroxy complexes are also believed to be toxic, although to a lesser extent.[9] Strong complexes, and species associated with colloidal particles, are usually assumed to be non-toxic.

The toxicity of a particular dissolved metal species towards aquatic organisms is probably related to its ability to react with a biological membrane. Transport of oxygen, sodium, potassium and chloride are affected by metal-induced morphological changes in the gill epithelia of a fish. Penetration of the membrane by a metal ion to react with cell components depends on the direct lipid-solubility of the metal species (usually only uncharged organometallic species), or the extent and rate of reaction of the metal ion

* For reprints of this review, see Publisher's announcement near the end of the issue.

Table 1. Possible physico-chemical forms of metals in natural waters

Physico-chemical form	Possible examples	Approximate diameter, *nm*
Particulate	Retained by 0.45-μm filter	>450
Simple hydrated metal ions	$Cd(H_2O)_6^{2+}$	0.8
Simple inorganic complexes	$Pb(H_2O)_4Cl_2$	1
Simple organic complexes	Cu–glycinate	1–2
Stable inorganic complexes	PbS, $ZnCO_3$	1–2
Stable organic complexes	Cu–fulvate	2–4
Adsorbed on inorganic colloids	Cu^{2+}–Fe_2O_3, Pb^{2+}–MnO_2	10–500
Adsorbed on organic colloids	Cu^{2+}–humic acid	10–500
Adsorbed on mixed organic/inorganic colloids	Cu^{2+}–humic acid/Fe_2O_3	10–500

with a membrane transport protein. Metal–protein interaction, leading to carrier-mediated transport of the metal across the membrane, will, for bivalent ions, be thermodynamically favoured when the metal is in the simplest chemical form, *e.g.*, $Cu(H_2O)_4^{2+}$, $CuCl^+$ or $Cu(OH)^+$. For tervalent ions such as Fe(III), however, the most bioavailable form may be an organic complex, because hydrolysis and polymerization could render the free ion inactive.[10] In some cases, kinetics rather than thermodynamics may dictate the biologically-active chemical species. The toxic form of aluminium appears to be $Al(OH)_2^+$, which reacts with gill mucus to hinder the transport of oxygen, potassium and sodium.[11] This species was previously shown to be the kinetically-favoured species in the reaction between aluminium(III) and a hydroxyazo compound.[12] The reaction of metal ions with biological membranes is a particularly complex process, and cannot be explained by simple[13] diffusion models.

Nature has provided fish with an effective defence against ingested heavy metals, which are eliminated through the gut and liver. This detoxification process allows fish to cope with the normal levels of heavy metals present in the food chain and sediments. The evolutionary process has not, however, equipped them to tolerate free metal ion or other reactive metal species in the water pumped through their gills. Unpolluted sea-water or fresh water contains vanishingly low concentrations of these toxic metal forms, most of the dissolved metal being adsorbed on organic or inorganic colloidal particles.[7] Man-made pollution* may add metal directly in a toxic form (*e.g.*, copper leachings from a mine) or, by lowering the pH of the water (*e.g.*, by acid rain or seepage from a mine tailings dam), may convert an inactive metal form, such as polymerized aluminium hydroxide, into a reactive toxic species, *e.g.*, $Al(OH)_2^+$.

Although the total concentrations of a dissolved metal may be similar in two water systems, the chemical forms of that metal may be quite different. Some of the possible dissolved forms of a bivalent trace metal present in a natural water are shown in Table 1. Note that, by convention, "dissolved" metal is defined as all metal species which pass through a 0.45-μm filter. Most colloidal particles will therefore be included in the dissolved fraction. "Filterable" may be a better term than "dissolved", but it is still not definitive since the pore size of the filter would also have to be stated.

There is increasing evidence[7,14–16] that iron oxide and clay particles coated with humic acid strongly adsorb heavy metal ions and control their concentrations in natural waters. It may be expected then that the predominant form of *dissolved* heavy metal will be metal adsorbed on metal–humate colloidal particles.

The concentration of many heavy metals and other elements in natural waters is often below 1 μg/l., and sometimes below 0.1 μg/l. Chemical analysis at these concentration levels is a specialized science. There are severe problems with contamination from a multitude of sources and, at the same time, serious losses of metal can occur by adsorption on the walls of sample bottles or analysis vessels. A clean-room, or at least a special room with a filtered air supply is necessary for work at the ultratrace level,[7] but even then considerable experience is needed before reliable results can be obtained. The subdivision of these very low total metal concentrations into various fractions for speciation is obviously an even more difficult task, taxing both the skill of the analytical chemist and the sensitivity of the analytical method.

* The term "anthropogenic pollution" though widely used as meaning "man-made pollution" is etymologically incorrect. The correct adjective is "anthropurgic" [Ed.].

Anodic stripping voltammetry (ASV) is the technique most commonly used for speciation of heavy metals in waters. It has high sensitivity for the common toxic heavy metals, copper, lead, cadmium and zinc (which are measured in the same analysis), and the ASV-labile metal (*i.e.*, the metal measurable by ASV at the natural pH of the water or in mildly acid conditions) may approximate to the bioavailable fraction.[7,17,18] However, for elements such as mercury, selenium and arsenic, gas chromatography or atomic-absorption spectrometry (AAS) are used, and for aluminium and iron, spectrophotometric procedures may be more suitable. Any separation or analytical procedure used in speciation measurements must be designed to minimize contamination and adsorptive losses. A direct procedure (*e.g.*, ASV-labile metal measurement) is ideal, but if a preliminary separation is needed, ion-exchange is less contamination-prone than solvent extraction.

The various physico-chemical forms of a trace element present in a water sample are not necessarily in equilibrium with one another, but even if they are, any procedure applied to the sample may disturb the equilibria and hence alter the speciation, although if the equilibrium changes are slow and the separation rapid, the disturbance may be minimal. Even the initial act of filtering the sample can affect the equilibria by changing the concentrations of dissolved O_2 and CO_2, and by removing adsorbents in the form of particulate matter. The only analytical technique which may possibly measure a particular metal species without affecting the solution equilibria is potentiometry with an ion-selective electrode (ISE). Unfortunately, ISE measurements are unreliable below $1 \times 10^{-6} M$ concentrations for most elements in natural waters, which is far too insensitive. For speciation measurements during studies on acute toxicity, however, where the total metal concentration may be much higher, ISE potentiometry can be useful.

Other analytical or separation methods, such as ASV, solvent extraction, and ultrafiltration and dialysis, will cause some metal to dissociate from metal complexes or colloidal particles as a result of the electrical potential across the electrode–solution interface (in ASV)[19] or the concentration gradient across the membrane–solution interface (in ultrafiltration and dialysis).[20] Under these circumstances, it is pointless to specify [21,22] that ASV or ultrafiltration procedures should be applied only at the natural pH of the sample, since the original solution equilibria will be disturbed by the procedure, whatever the analytical pH.[23] In any case, it is important to consider the *purpose* of the speciation measurements. If, as is frequently the case, they are needed for toxicity evaluation, then the method should provide, as far as possible, a measure of the toxic metal fraction. For ASV, the best estimate of this fraction will be obtained when the test sample conditions (pH, buffer concentration, *etc.*) and ASV conditions (rotation or stirring speed, pulse frequency, *etc.*) lead to electro-deposition of the fraction of the total metal that will dissociate at, and be transported across, the relevant biomembrane.[24] Only by coincidence would the pH for this ideal condition be identical to that of the original sample.[23]

Bioassays with algae, fish or other plants or animals may appear to provide the best speciation measurement, since they give the toxicity information directly. Bioassays, however, are lengthy and expensive, provide results on one biological species only, and demonstrate only gross effects. Chemical speciation schemes are more amenable to standardization, and can yield information on the different chemical forms present in the water. This information may help to identify a source of pollution. If the relative toxicity of these different forms is known, reliable predictions about toxicity can be made.

ADSORPTION OF TRACE METALS AND REACTION WITH NATURAL ORGANIC MATTER

Most fresh waters have a pH which is in the critical range for adsorption of heavy metals onto particles; a change of as little as 1 pH unit can cause the difference between complete adsorption or desorption (Fig. 1).[25] The high fish mortality observed[26] when the pH of some lakes is lowered as a result of acid rain may be partly due to the desorption and release of copper from lake sediments (Fig. 2).[27,28]

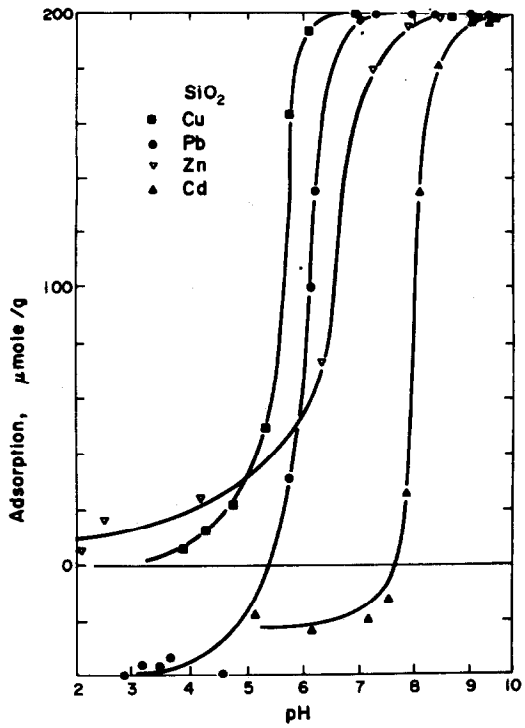

Fig. 1. Adsorption of metals on silica. The apparently negative adsorption of cadmium and lead means that adsorbed metal species are *desorbed* at these pH values, (From C. P. Huang, H. A. Elliott and R. M. Ashmead, *J. Water Pollut. Control Fed.*, 1977, **49**, 745. With permission.)

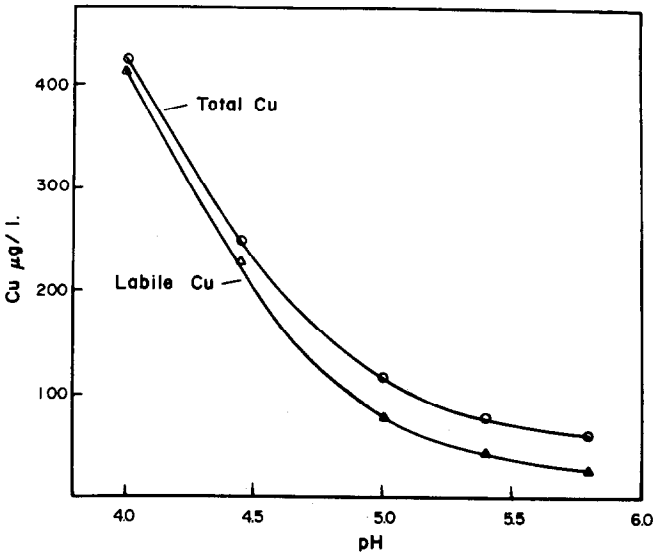

Fig. 2. Effect of pH change on the speciation of dissolved copper (measured by anodic stripping voltammetry) released from a mineralized sediment. (From P. S. Rendell, G. E. Batley and A. J. Cameron, *Environ. Sci. Tech.*, 1980, **14**, 314. With permission.)

There is little doubt that, for many heavy metals, a major fraction of the dissolved metal in fresh waters exists as species adsorbed on colloidal humic acid and colloidal particles of iron oxide coated with humic acid.[29–34] The interaction of humic material with colloidal iron oxide results in a very stable colloid, whereas uncoated iron oxide colloids are relatively unstable.[29,35] To test its ability to retain trace heavy metals, a humic acid–iron colloid with adsorbed copper and lead has been prepared, and the colloidal solution (pH 5.7) passed through a column of Chelex-100 chelating resin: no copper and only 10% of the lead was removed by the column (Batley and Florence, unpublished results). Florence[36] found that even in a low-pH river water containing little dissolved organic matter, over 50% of the copper present was associated with colloidal organic matter. In fresh waters with a high organic content, molecular complexes of heavy metals with fulvic and tannic acids may also be formed.[37–39]

In the fresh water/sea-water mixing zone of estuaries, the precipitation of high molecular-weight humic substances and hydrous oxides of iron and manganese results in the transfer of much of the dissolved heavy metals from the river water to the estuarine sediment.[40–44] The river water is thus effectively scavenged of trace heavy metals. A fraction of the most stable precipitated forms will stay in solution as colloidal particles and be transported to the oceans, along with their load of adsorbed heavy metals. The most stable colloids are likely to be iron and manganese oxides and clay particles, coated with humic material. These colloids will then carry an important part of the measured concentrations of dissolved copper, lead, cadmium and zinc in sea-water.[7,45–47] Most computer models of heavy metal speciation in sea-water have used silica as a model adsorbent.[48,49] Silica is not, however, nearly as powerful an adsorbent as a particle coated with humic acid, nor does it have the same adsorption capacity.[7,15,29]

The formation of simple, molecular organic complexes of bivalent heavy metals in sea-water is unlikely because of competition by chloride, magnesium, iron(III) and chromium(III). Even a ligand as powerful as EDTA would not complex significant amounts of copper, lead, cadmium or zinc unless present at concentrations unrealistically high for natural sea-water (Table 2).[45]

SAMPLING, FILTRATION, AND STORAGE OF WATER SAMPLES

The collection of a natural water sample, even surface water, for trace metal analysis, is fraught with dangers of contamination.[7,50–53] The risk of contamination when collecting a depth sample is at least one order of magnitude greater. Yet unless this initial step is carried out correctly, many hours of expensive chemical analysis will be wasted.

Table 2. Calculated effect of EDTA on speciation of Cu, Pd, Cd and Zn in sea-water (pH 8.1)*

	Fraction of metal as EDTA complex, %			
EDTA, *M*	Cu	Pb	Cd	Zn
2×10^{-9}	0.3	0.3	<0.1	0.2
2×10^{-8}	4.8	5.2	0.7	2.9
2×10^{-7}	35	37	6.8	24

* Fe(III) = $2 \times 10^{-9}M$, Cr(III) = $1 \times 10^{-9}M$.

The type of sampling bottle and method of cleaning must first be decided. Conventional linear-polyethylene bottles are now almost universally used for collection of surface water samples. It has been suggested, however, that Teflon is the only material which will not yield zinc to a water sample.[54] Laxen and Harrison[55] reported that soaking linear-polyethylene bottles in 1.5*M* nitric acid for 48 hr at room temperature removed all Cu, Pb, Cd and Zn leachable by synthetic and natural river water, although a simple rinse with the acid was inadequate. They found less than 0.1 μg/l. zinc contamination from a cleaned polyethylene bottle. Mart[56] and Patterson and Settle[50] recommended that polyethylene bottles be first treated with hot acid before room-temperature acid leaching, but Nürnberg *et al.*[57] claimed that this treatment could activate the surface of the polyethylene and cause losses of metal by adsorption. For fresh water samples they found it necessary to remove these activated sites by first rinsing the bottle with a solution of calcium and magnesium sulphates. Mart[56] used 1*M* hydrochloric acid for the initial hot acid cleaning, although Laxen and Harrison[55] reported that polyethylene absorbs traces of HCl, which interferes in the carbon-furnace AAS determination of some metals, and in the determination of copper by ASV.

In our laboratory we soak new polyethylene bottles in 1.5*M* reagent-grade nitric acid for a minimum of one week. The acid is emptied before the sample is collected, then the bottle is filled and emptied with the sample water at least four times before retaining a sample. Surface samples are taken over the bow of a fibreglass boat which is moving into the wind or current. Samples collected from the stern of a large power boat are invariably contaminated with copper and lead. If natural waters of similar type are being collected at intervals, the bottles are not acid-rinsed between samples, but are simply rinsed several times with the new sample. We have not observed any changes in the concentrations of Cu, Pb, Cd or Zn in sea-water or fresh waters stored at 4° over periods of weeks in bottles treated in this manner.[36,47]

The collection of depth samples is a specialized task[51] and will not be discussed here. The all-Teflon Patterson C.I.T. sampler[50] is one of the few devices available which can collect deep sea-water samples without contaminating them with metals.[58]

For speciation measurements, the water sample must not be acidifed before storage, because this would change the speciation. It should also be kept in mind, for general trace-metal analysis, that acidification of fresh water samples can cause the precipitation of humic material, which usually carries down some heavy metals. Likewise, freezing of fresh water samples is not permissible. As a water sample freezes, metal ions are continuously concentrated in the unfrozen liquid remaining in the centre of the container. Irreversible hydrolysis and polymerization of iron and other metal ions can take place at these relatively high transient concentrations, and heating with acid may be necessary to return them to solution in the thawed sample. In sea-water, the high chloride concentration may prevent hydrolysis reactions from taking place, and freezing could be an acceptable method of preservation.[47] However, storage at 4° appears to be the safest method for both fresh water and sea-water samples.[36,47]

There has been a great deal of controversy over losses of trace-metal ions to polyethylene storage bottles.[7,51] Most of the disagreement can be traced to some workers using synthetic metal solutions and others using natural waters. In general, those testing synthetic solutions found serious losses[59–62] while, with the exception of Subramanian *et al.*,[54] those using natural sea-water and fresh waters found that the losses of most metals were negligible.[36,47,55–57] This result is not surprising. Natural waters are in equilibrium with many potent adsorbents, including sediments containing iron, aluminium, manganese and silicon oxides, and humic materials. The water also contains suspended particles of these adsorbents, which have very large internal surfaces available for adsorption.[30,43] It would be most remarkable then, if a polyethylene container, which has both a relatively small surface area and weak adsorbing power, could remove any of the ionic metal (usually a minute fraction of the total metal) which is in equilibrium with the suspended particles. The colloidal particles in natural waters show little tendency to adsorb on polyethylene or even Pyrex glass.[36,63] Free metal ions, on the other hand, adsorb strongly on glass and to a lesser extent on polyethylene. Figure 3a shows the effect of pH on the adsorption of ionic Cu, Pb, Cd and Zn from distilled water onto an empty borosilicate tube containing a 1-cm thick glass-wool support. Most of the adsorption took place on the glass-wool plug. A river water sample with similar concentrations of Cu, Pb, Cd and Zn lost a negligible amount of these metal ions to the empty column. The pH at which significant metal-ion adsorption first occurs on silica can be related to the value of the first hydrolysis constant (${}^*\beta_1$); $pH = p{}^*\beta_1 - 1.5$ is a semi-empirical expression for the onset of adsorption.[7] Adsorption onto organic material can, however, occur at a much lower pH. Figure 3b shows the adsorption of metals onto a 6-cm bed of Bio-Rad SM2 resin (equivalent to Amberlite XAD-2) in the same column, but with a polyethylene frit support.

Dissolved metal in a water sample is defined by convention as metal which can pass a 0.45-μm membrane filter. The filtration step arbitrarily separates particulate metal from metal in true solution plus that associated with colloidal particles (Table 1). Open-ocean sea-water samples rarely require filtration because the concentration of particulate matter is so low, but filtration is necessary for most fresh waters. Unless filtration is done under clean-room conditions (preferably in a laminar-flow cabinet), contamination of the sample can easily occur.[7,56] The membrane

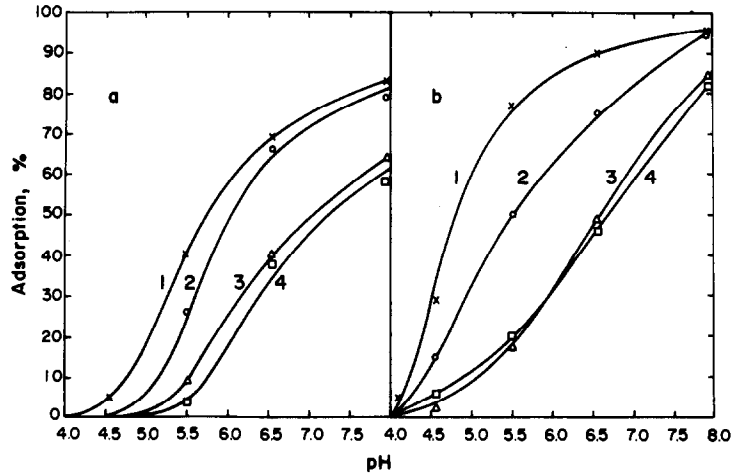

Fig. 3. Effect of pH on adsorption of (1) Cu^{2+}, (2) Pb^{2+}, (3) Zn^{2+}, (4) Cd^{2+} from distilled water; (a) empty column with 1-cm glass wool support, (b) same column, but with polyethylene frit support and filled with Bio-Rad SM2 resin.

filter must be carefully washed with acid and water before use, otherwise it can contribute both metal and organic matter to the filtrate.[64] Nuclepore membrane filters (polycarbonate) have the lowest metal content, but they block rapidly, and cellulose acetate membranes are more practical for most waters.[47,53] Polycarbonate (*e.g.*, Sartorius) filter assemblies are easier to decontaminate than glass assemblies (*e.g.*, Millipore). The filter apparatus must be cleaned with acid as carefully as the storage bottles. Pressure filtration under nitrogen is faster and less likely to result in contamination than vacuum filtration, but rupture of phytoplankton cells and contamination of the sample by their contents can occur with pressures above 0.25 atm gauge.[7]

Workers who used synthetic metal ion solutions[57,60,65] reported serious losses of several metal ions by adsorption on the membrane filter or the sintered-glass support of the Millipore filtration appartus. However, as in the case of storage containers, those using natural waters found no such losses.[35,56,57] Both river water and sea-water have been filtered through an all-glass Millipore apparatus, and the filtrate refiltered up to four times through the same filter, without any change in the Cu, Pb, Cd or Zn concentrations (Florence, unpublished results). Mart[56] found that sea-water containing as little as 15 ng of lead per kg could be filtered through a Sartorius cellulose acetate membrane without loss.

METHODS FOR THE MEASUREMENT OF TRACE-METAL SPECIATION

Trace-metal speciation in waters has been based on use of two distinctly different techniques: computer (chemical) modelling, and experimental measurement.

Computer modelling

The computer modelling approach to trace-metal speciation in waters involves the use of published stability-constant data, together with known concentrations of various ions and suspended solids in the water, to compute the equilibrium concentrations (or activities) of the various species. The rationale of chemical modelling was discussed by Jenne in the opening address to a symposium on chemical modelling held in Miami, Florida in 1978.[66] The proceedings of this symposium provide a wealth of information on the current status of the chemical modelling approach, and give details of the sophisticated computer codes now available. Gaizer[67] has also recently reviewed the computer evaluation of complex equilibria.

The main obstacle to the successful use of computer modelling of trace-metal speciation in waters is the lack of reliable thermodynamic data.[7] Just as an analysis is only as good as the sample, so a computer model is only as good as the data provided. Unfortunately, no reliable data are available for metal-ion interactions with many of the natural ligands, especially the colloidal particles present in natural waters. Indeed, even the nature and concentration of these ligands are usually unknown. In addition, there is still serious disagreement about the values for many of the simple inorganic complexes in waters.[7,66] The formation constant of the important copper species, $Cu(OH)_2$, is in dispute,[68] there is doubt about the importance of mixed-ligand complexes in sea-water,[69] and the effect of failure to correct for major ion-pair formation on the calculation of heavy-metal species concentration has been pointed out.[70] For these reasons, computer modelling results for heavy metal speciation in natural waters at present may bear little relation to reality.[7,22]

Computer modelling is a powerful technique, and will make an important contribution towards an understanding of speciation in waters once the necessary thermodynamic data are accumulated. There is an

urgent need to identify the important ligands in natural waters and to measure the relevant stability constants.

Experimental methods

The experimental determination of trace-metal speciation in natural waters is a most difficult task because of the very low concentrations of these metals. In contaminated waters, however, the analysis may be much easier because of the possibility of using ion-selective electrodes to determine the free metal-ion activity.[71] For natural waters, with presently available techniques, it is possible only to divide each metal into operational classifications or "boxes", based on the thermodynamic or kinetic behaviour of the different physico-chemical forms of the metal in the sample. Since the operations involved in measurements or separations will generally alter the original equilibria to some extent, the speciation results will be method-dependent, and it is important that full details of the analytical procedure be provided with any published speciation data.

The procedures mainly used to study trace-metal speciation in waters are anodic stripping voltammetry, ion-exchange chromatography, ultrafiltration, dialysis, and bioassay. Other analytical techniques are not as widely applicable.

Anodic stripping voltammetry. The theory and application of ASV to water analysis has been adequately reviewed.[7,57,72,73] Hanging mercury drop (HMDE) or thin mercury film (MFE) electrodes can be used. An MFE using glassy carbon as support for the mercury film provides the highest sensitivity,[57,74–76] although zinc determinations are more reproducible with an HMDE.[77] The use of a differential pulse waveform leads to lower detection limits with both types of electrodes; at a glassy carbon MFE the limit of detection for lead and cadmium is lower by a factor of about five when the differential pulse method is used instead of a simple linear voltage scan.[74] There are, however, subtle and sometimes serious problems associated with the use of differential pulse ASV for natural water analysis. Because it is a high-frequency method, the differential pulse signal is more sensitive to substances which alter the rate of the electrode reactions.[74,77] Surface-active compounds which adsorb on the mercury electrode may cause either an increase or decrease in peak height, and a shift in peak potential.[74,78–82] These effects are brought about both by natural substances such as fulvic and humic acids, and by some typical industrial pollutants, such as long-chain amines and alcohols. A more insidious phenomenon in differential pulse ASV is the production of tensammetric waves.[78] These are the result not of redox reactions, but of adsorption–desorption processes at the mercury electrode. In the past, tensammetric waves have been mistaken for metal-ion waves, and have led to the reporting of high results for Pb, Cd and Cu in sea-water. Natural organic compounds in most samples of sea-water give rise to tensammetric waves which, at pH 5, occur near the Pb and Cd waves.[83] These adsorption–desorption waves are eliminated when the sea-water is irradiated with ultraviolet light or treated with activated charcoal. They do not appear if a simple linear voltage scan is used.[83]

Another practical problem in the use of differential pulse ASV is that the test solution must have a fairly high ionic strength (0.02*M*) or consistent results are not obtained.[74] ASV measurements on river water samples without the addition of an electrolyte[21] or after buffering the solution by simply bubbling carbon dioxide through it,[22] may not be permissible.

The application of alternating current, differential pulse, and other high-frequency methods to the analysis of waters by ASV must be carefully studied for interference effects before results are reported. If it can be established that interferences are not present or can be eliminated, the higher sensitivity of the differential pulse method is a great advantage, especially for the analysis of sea-water.

Anodic stripping voltammetry is one of the very few analytical techniques that is sufficiently sensitive for direct determination of heavy metals in natural waters, and also has an intrinsic capability for speciation work. It has this ability because the amount of metal (M) deposited at the electrode during the deposition step depends, amongst other factors, on the rate of dissociation (k_{-1}) of complexed metal species (ML_n) at the electrode–solution interface;

$$ML_n \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} M + nL$$

The amount of M deposited also depends on parameters such as total metal concentration, deposition time, electrode area and temperature.[77] However, the contribution of a metal complex species to the ASV peak height (relative to that of the free metal ion) is independent of these parameters and depends only on k_{-1} and the thickness of the diffusion layer.[19] The diffusion-layer thickness decreases with increasing stirring rate, and dictates the period that the complex is "resident" at the electrode surface. The thicker the diffusion layer, the higher the contribution of a metal complex to the ASV wave height.[84–86]

These considerations have led to the widespread use in water analysis of measurement of "ASV-labile" metal, *i.e.*, the metal concentration determined by ASV at the natural pH of the water, or in mildly acid solution (acetate buffer, pH 4.7). Metal concentrations measured in this manner are usually lower than the total metal concentrations, and have been related to the metal fraction which is bioavailable.[7,17,36,87,88] Total metal can be measured by ASV after fuming the sample with nitric–perchloric acid mixture,[89] digestion with persulphate[90] or, preferably, exposure to ultraviolet irradiation.[91] It is likely that sea-water samples collected on a cruise, acidified to below pH 2, and stored for several weeks, will also yield total metal on analysis.

The ability of ASV to measure labile metal, plus its excellent sensitivity (about $10^{-10}M$[72,77]) for the four common toxic heavy metals, copper, lead, cadmium and zinc, which can be determined in the same analysis, make it a powerful tool for trace-metal speciation studies. Considerable care must be taken, however, in the intepretation of ASV measurements of labile metal since, as previously discussed, natural organic matter can have a drastic effect on the results.[23,92,93]

Ion-exchange. Ion-exchange is an attractive technique for trace-metal speciation in natural waters because separations can be carried out with little manipulation and little opportunity for contamination, a most important consideration when working with such low metal concentrations. Conventional cation- and anion-exchange resins have been used for heavy metal speciation,[7] but the iminoacetate chelating resin, Chelex-100 (Bio-Rad), has found much more application. Florence and Batley[45,94] first used this resin to separate ionic and colloidally-associated Cu, Pb, Cd and Zn in sea-water. Chelex-100 resin binds ionic metal strongly, but because it has a pore size of about 1.5 nm,[36] large molecules and colloidal particles are excluded from the resin beads and are not retained on the column. Florence[36] showed that solutions of colloidal hydrated ferric oxide and bulky organic dyes are quantitatively rejected by the resin. As reported earlier in this review (Batley and Florence, unpublished results), copper and lead adsorbed on an iron–humic acid colloid are not retained by Chelex-100. The resin therefore provides a simple, rapid, and almost contamination-free method for the separation of ionic and colloidally-associated (*i.e.*, pseudocolloid[62]) metal. This is an important function, because it is believed that these two fractions of the dissolved metal represent the main classes of toxic and non-toxic metal, respectively, in natural waters.[7]

Hart and Davies[95] used a batch equilibration technique with Chelex-100 to separate ionic metal from fresh and estuarine waters, and found this method useful for analysis of samples in the field. Figura and McDuffie[96] adopted a different approach. They used both batch and column equilibration techniques with Chelex-100 to vary the contact time of the water sample with the resin. By this method they were able to classify Cu, Pb, Cd and Zn in river water and sewage samples into the empirical groups of "very labile", "moderately labile", "slowly labile" and "inert", depending on the apparent rates of transfer to the resin. Cadmium and zinc were mainly in the very and moderately labile fractions, while significant percentages of copper and lead were classified in the slowly labile and inert fractions.

Chelex-100 resin has iminoacetate groups, which complex metals by oxygen and nitrogen bonds. This type of bonding may not, however, simulate the critical reaction between metals and biomembrane proteins, and hence may not serve as the best model for bioavailability and toxicity.[23] Passage of heavy metals across biological membranes probably occurs principally by carrier-mediated transport with metallothionein-type proteins to which the metal is complexed by sulphur (thiol) bonds.[97–101] Measurement of the metal fraction which reacts with a thiol resin may therefore be a more realistic estimate of bioavailable metal.[23] Thiol resins have been described by Phillips and Fritz[102] and Slovák *et al.*,[103] and a porous glass with bound thiol groups is available from Pierce Chemical Company, Illinois. All three thiol materials effectively remove ionic Cu, Pb, Cd and Zn from both sea-water and fresh waters (Florence and Batley, unpublished results). Results for some waters are shown in Table 3, where the effectiveness of Chelex-100 resin and the thiol porous glass are compared. It is evident that the thiol material has a somewhat lower affinity for Pb, Cd and Zn, but is much more efficient than Chelex-100 for the removal of copper. This is because of the relatively higher affinity of copper for sulphur ligands.[104] Table 4 shows that there is a much greater difference between the complexation constants of copper and the other three metals when the ligand has a sulphur donor atom, than when the ligand is iminoacetate.[105] The preference of copper for suphur ligands and their ready reduction of copper(II) to copper(I) may partly explain the very high toxicity of copper towards aquatic organisms.

Table 3. Removal of metals from sea-water and river water by Chelex-100 resin and thiol porous glass

Sample and adsorbent	Residual metal, %			
	Cu	Pb	Cd	Zn
*Sea-water,				
Chelex-100	2	<0.5	<0.5	<0.5
Thiol glass	<0.2	1.0	0.6	1.1
†River water,				
Chelex-100	75	45	18	60
Thiol glass	21	48	25	60

* Spiked with $1 \times 10^{-7}M$ Cu, Pd, Cd, Zn.
† Sewage-contaminated, unspiked.

Ultrafiltration. Ultrafiltration membranes are commercially available with apparent pore diameters from 1 to 15 nm, and can be used to separate molecular from colloidal species, or to classify colloidal particles on the basis of molecular size.[39,106] Although this appears to be a very useful technique, there are some problems. (*a*) The membranes are expensive, (*b*)

Table 4. Equilibrium constants for some metal complexes

	$\log K_1$			$-\log K_{s0}$
	EDTA	Iminodiacetic acid	Glutathione	Sulphide
Cu	18.5	10.6	14.6	49
Pb	17.7	7.5	10.6	28
Cd	16.5	5.7	10.5	28
Zn	16.5	7.1	8.3	25

The filters as supplied are contaminated with metal and soluble organic matter. Laxen and Harrison[22,107,108] reported serious adsorption of metal ions on many types of filters, but found that the Amicon PM10 filter exhibited negligible adsorption. They pretreated the filters with 0.1*M* calcium nitrate to minimize losses. Contamination or loss in ultrafiltration is especially serious, because the volume of filtrate is small, and there is a large surface-to-volume ratio. (*c*) Metal combined with large organic molecules or adsorbed on colloidal particles may be released and pass through the filter as a result of dissociation of the complex under the concentration gradient existing at the surface of the membrane filter.[20,109]

Despite these problems, ultrafiltration is certainly worthy of further study for the speciation of trace metals and trace organics,[39] particularly if correlations can be obtained between the size fractions and biological activity.

Dialysis. Beneš and co-workers have carried out much of the work on the application of dialysis to trace-metal speciation in waters.[62] Dialysis membranes commonly have pore diameters of 1–5 nm, and can effectively separate molecular and colloidal species. Like ultrafilters, dialysis membranes suffer from metal contamination, metal adsorption, and dissociation of metal complexes at the membrane surface. Dialysis, moreover, is a much slower process than ultrafiltration. Beneš[110] described an interesting semi-continuous method for monitoring dissolved ionic metal in a stream. A dialysis cell containing pure water is immersed in the stream, and ionic species diffuse into the cell, where they are removed continuously by, *e.g.*, adsorption on a suspended adsorbent. If the concentration of a dissolved species in the cell is kept very low by this method, the diffusion flow is directly proportional to the concentration of the species in the stream. This system is similar in principle to that of Hart and Davies.[111]

Bioassay. Heavy metals are toxic to a wide range of aquatic animals.[112–116] Based on the free metal-ion concentration, the order of toxicity to a marine diatom was found[116] to be

$$Hg^{2+} > Ag^{+} > Cu^{2+} > Pb^{2+} > Cd^{2+} > Zn^{2+} > Tl^{+}$$

but in the presence of different complexing agents, this order can change dramatically. Poldoski[117] found that humic acid, pyrophosphate, and aminopolycarboxylic acids reduced the uptake of cadmium by *Daphnia magna*, but that diethyldithiocarbamate increased its uptake. Rathsack and Lohs[118] found that triethanolamine increased the accumulation of copper by *Chlorella pyrenoidosa*. Ligands which increase metal accumulation and toxicity in aquatic animals probably do so by forming lipid-soluble complexes with the metals. In waters of very high organic content, the addition of low concentrations of some essential heavy metals may actually increase productivity.[119] Bivalve molluscs and other filter feeders appear to accumulate larger amounts of some metals if the metal is in particulate, rather than ionic, form.[120]

Most workers who have studied the effect of speciation on the toxicity of metals towards aquatic organisms used chemical modelling to calculate the concentrations of the different chemical species in the test tanks.[121–128] Young *et al.*[17] found that ASV-detectable copper species are the forms most toxic to shrimp zoneae, and Sunda *et al.*[129] used a cadmium ion-selective electrode to show that the toxicity of cadmium to grass shrimp is related to the free cadmium-ion activity. The modelling studies generally suggest that the most toxic forms of copper are the free cupric ion and its hydroxo complexes; carbonato complexes were found non-toxic.[122,128,130] Guy and Kean[126] suggested that the ethylenediamine and citric acid complexes of copper are also toxic to algae.

An important problem with bioassay–computer model studies of toxicity is that they cannot adequately take into consideration the effects of adsorption of the test metal on the container, the test animals and suspended particulate matter. Nor can they accurately compute the complexing of the metal by excretion products of the animal.[131]

Other methods. Ion-selective electrodes are generally too insensitive for the measurement of heavy-metal ion concentrations in natural waters. The copper ISE has been applied to sea-water,[132] but the determination is fraught with difficulties, and there are now doubts about the selectivity of the response of the electrode to cupric ion activity. The electrode may be unsuitable for use in chloride media,[133] and appears to respond to certain natural and synthetic complexing agents[134] and to hydroxo and bicarbonato complexes of copper.[135]

Gel chromatography is unsuitable for the speciation of natural waters because the relatively small sample volume and large eluent volume lead to dilution of the sample and large blank values. For sewage or polluted waters, however, gel chromatography may be an attractive method for separating metals into molecular size fractions.[136] Gas chromatography, with an atomic-absorption spectrometer as detector, is a powerful technique for the separation and determination of volatile organometallic compounds of metals such as lead, mercury and arsenic.[137]

The application of radiotracers to speciation studies is hindered by the slow equilibration of the ionic radiotracer with the non-ionic forms of the metal naturally present in the water sample. This equilibration period may be days, months or even years,[89,138,139] and underlines the danger of using standard-addition techniques in trace-metal speciation analysis.[7]

Determination of organically-bound metal

The measurement of the metal fraction which is

complexed by organic ligands, or adsorbed on organic colloidal particles, is an important requirement of any comprehensive speciation scheme. Some organometallic complexes may be directly lipid-soluble and constitute a toxicity hazard, while other organic compounds may be involved in a significant mechanism for metal transport.

Only a limited number of methods can be used for the measurement of organically-bound metal. Some rest on the premise that metals can be selectively liberated from organic complexes. The most successful techniques are ion-exchange and solvent extraction, ozone oxidation, and ultraviolet oxidation carried out at the natural pH of the sample. Oxidation in acid solution with chemicals such as persulphate and nitric or perchloric acids liberates metals from inorganic species[7,91] as well as from organic species.

Slowey *et al.*[140] used chloroform extraction to measure organically bound copper in sea-water, but chloroform is a poor choice for this analysis, because even analytical-reagent grade chloroform is badly contaminated with copper, and complete decontamination is difficult. Solvent extraction would probably not separate organic colloidal particles, which may be expected to accumulate at the liquid interface.

Ozone oxidation does not destroy all organic matter in natural waters[91] and, in any case, serious losses of lead can occur during ozone treatment, presumably as a result of the formation of lead(IV) and precipitation of PbO_2.[22]

The destruction of organic matter by ultraviolet irradiation at the natural pH of the sample has been the method most frequently used.[7,22,36,89,141,142] Florence[36] found that it could not be applied to anoxic fresh waters because oxidation of Fe(II) leads to the precipitation of hydrous ferric oxide, which carries down trace metals. Laxen and Harrison[22] and Blutstein and Smith[143] reported that brown deposits formed on the bottom of the tubes when river water samples were irradiated, and that low results for Cu, Pb, Cd and Zn were obtained after ultraviolet irradiation. This problem was not encountered by Florence,[36] but he was analysing river waters of a much lower iron content. In the speciation scheme used by Florence[36] for fresh waters, and Batley and Florence[89] and Batley and Gardner[47] for sea-water, total metal was always measured both before and after ultraviolet irradiation. No significant differences were found for any of the water samples analysed. However, when a colloidal solution of a hydrous iron(III) oxide coated with humic acid (Fe 4 mg/l.) with adsorbed Cu, Pb and Cd was irradiated, a brown precipitate and losses of the trace heavy metals to the precipitate were observed (Batley and Florence, unpublished results).

Humate-protected iron colloids may be the predominant type of colloid in many natural waters,[23,144] and humic acid appears to be essential for stability;[145] destruction of humate by ultraviolet irradiation leads to the precipitation of hydrous iron oxide. Problems[22] arising from the irradiation of fresh waters containing high concentrations of this type of colloid are a serious drawback to the general use of ultraviolet irradiation in speciation schemes, although there are apparently no difficulties with the irradiation of sea-water.

In an attempt (Florence and Batley, unpublished results) to prepare an artificial lipid membrane for measurements of solubility in lipids, Millipore prefilter cellulose discs (type AWO3) were soaked in an ethanolic solution of a mixture of cholesterol, phosphatidyl choline and phosphatidyl ethanolamine,[146] then dried. The discs were shaken with water samples to study the forms of metals which they extracted. However, serious difficulties were encountered with heavy metal impurities in the phospholipids, and adsorption of ionic metal by the membrane filter. These artificial membrane systems are too difficult to purify and too unstable for use in a routine speciation scheme. The directly lipid-soluble metal fraction is best determined by using a simple, reproducible extraction system, especially since the permeability coefficient of biomembranes is so critically dependent on the composition of the lipid bilayer, which varies from species to species.[97]

Bio-Rad Bio Beads SM2 resin (similar to Amberlite XAD-2 resin[147]) is a neutral, non-polar macroporous styrene–divinylbenzene copolymer that has a high affinity for molecules that contain both hydrophilic and hydrophobic moieties. It has a molecular-weight exclusion limit of 1.4×10^4. The material as supplied has little leachable metal impurity, is easily purified and is simple to use. A less convenient simulation model for the lipid bilayer is extraction with hexane–butanol mixtures.[146] Residual oganic solvent in the aqueous phase must be removed completely before ASV analysis, by evaporation followed by ultraviolet irradiation. Some results for the removal of organometallic complexes from water by SM2 resin and 10% tert.-butanol in hexane are shown in Table 5. Because ionic metal is strongly adsorbed by SM2 resin at pH values higher than 4.5 (Fig. 3b), the water samples were adjusted to pH 4.0 before passage through the column. This pH adjustment may, of course, alter the

Table 5. Extraction of Cu, Pb, Cd and Zn complexes from sea-water (pH 4.0) by Bio-Rad SM2 resin and hexane–10% tert.-butanol*

equilibrium concentration of complexes, so the determination with SM2 resin is, like all speciation measurements, operationally defined.

Activated charcoal has been used to extract both ionic and organically-complexed copper from sea-water,[148] but the recovery is not quantitative and the activated charcoal is difficult to purify from heavy metals.

SPECIATION RESULTS FOR SELECTED ELEMENTS

The concentrations of some metals in surface sea-water, averaged from results recently reported[7] by laboratories experienced in this area of analysis, are shown in Table 6. Some of these results are in dispute, especially those for zinc, and they will be discussed in the appropriate sections below.

Copper

Two recent comprehensive reviews have discussed the speciation of copper in natural waters.[7,149] Nriagu's two-volume compilation[149] contains a wealth of information on the chemistry, determination, speciation and toxicity of copper.

Computer modelling programs[150] suggest that the predominant inorganic forms of copper in sea-water are $Cu(OH)_2$ (40%) and $CuCO_3$ (50%), and in a typical river water, $CuCO_3$ (95%). In sea-water, up to 50% of the total copper may be associated with organic matter,[7,47,68,89] and a high percentage combined with inorganic colloidal particles.[47,151] Moore and Burton,[152] however, failed to detect any significant amounts of organically-associated copper in the eastern Atlantic Ocean. Because of the strong adsorption of copper on flocculated particles of humate-coated iron oxide during estuarine mixing,[145] it seems most likely that pseudocolloids of copper, both organic and inorganic, will be present in the oceans. In fresh water streams the percentage of organically-bound copper may be very high,[7,36,130,149,153] and in both types of waters the ASV-detectable fraction of copper (similar in amount to the toxic fraction) is usually much less than 10%.[7,9,149]

Analytical chemists should be aware that acidification of fresh water samples for preservation may lead to the precipitation of humic material, which carries down with it a considerable fraction of the copper content of the water.[145]

Lead

Computer models predict[150] that the two main inorganic species of lead in sea-water are $PbCO_3$ (83%) and $PbCl_2$ (11%), while in river water the only significant form is $PbCO_3$ (91%). It is possible, however, that basic carbonates such as $Pb_2(OH)_2CO_3$ may actually be present.[7]

Chau and Lum-Shue-Chan[87] found that in 16 out of 17 Canadian lakes studied, no lead was present in the ASV-detectable form. Beneš *et al.*[154] in a study of the Litávka River, Czechoslovakia, reported that it contained no soluble acid-exchangeable forms of lead. Lead is readily adsorbed on inorganic adsorbents, and Batley and Gardner[47] found that in sea-water 40–80% of the lead was associated with inorganic colloids.

Ionic lead spikes added to sea-water and fresh waters at the natural pH equilibrate very slowly with the lead species already present. Batley and Florence[89] found that after three days at 25°, only 20–50% of the added lead had chemically exchanged with the lead in sea-water, and Beneš *et al.*[155] showed that pseudocolloids of lead exist when the pH of fresh water is greater than 4. Harrison and Laxen[156] investigated the physico-chemical forms of lead in drinking water, and concluded that filterable lead was associated with both inorganic and organic colloidal particles. In general, lead does not show the marked preference for organic over inorganic adsorbents that copper does.[7]

Batley[157] described an *in situ* electrodeposition method for depositing labile lead in sea-water onto an atomic-absorption spectrophotometric carbon furnace tube, which was used as the working electrode. The tube was then inserted into an AAS instrument and lead determined in the usual manner. This method has the advantage of long unattended deposition times and limited opportunity for contamination.

There is evidence that tetra-alkyl-lead compounds can be formed in natural aquatic sediments.[158,159] If the presence of these organolead compounds can be confirmed, it will have serious implications for man-made lead pollution of waterways, because tetra-alkyl-lead compounds are considerably more toxic than inorganic lead salts. Settle and Patterson[160] have summarized the evidence for environmental lead toxicity in humans, and pointed out the massive increase in the lead content of the human body in modern urban man. Recent results on the lead concentration in blood from tribesman in remote areas of the Himalayas[161] and New Guinea[162] showed that

the urban populations of techologically-advanced countries have blood-lead concentrations at least a factor of five higher than those of these isolated, non-industrialized tribes.

Cadmium

In sea-water, cadmium is computed to exist as the $CdCl^+$ and $CdCl_2$ complexes (92%), while in river water the dominant forms are Cd^{2+} and $CdCO_3$, depending on pH.[150] Experimental measurement of the speciation of cadmium in sea-water[47] showed that ASV-detectable forms were predominant, while in a fresh water stream, 70–90% of the cadmium was present as the free hydrated ion or other labile complexes.[36] Batley and Gardner[47] reported that 44% of cadmium in a deep, anoxic region of an estuary existed as an non-electroactive inorganic species, possibly[150] $CdHS^+$. In general, cadmium requires a significantly higher pH than copper or lead for adsorption on organic or inorganic particles.[7]

The speciation[7] and ecological cycling[163,164] of cadmium have been reviewed recently. Bruland *et al.*[165] found that the cadmium concentration in Northeast Pacific waters increased rapidly with depth, and was correlated with phosphate and nitrate concentration at all depths. They found no evidence for colloidally-associated cadmium.

Bruland *et al.*[165] suggested that microplankton and their organic decomposition products play a dominant role in the biogeochemical cycling of cadmium. Benayoun *et al.*[166] studied the flux of cadmium through the euphausiid *Meganyctiphanes norvegica* and found that the metal was most concentrated in the viscera; faecal pellets accounted for 84% of the total cadmium flux through the euphausiid.

Zinc

Computer models[7] of sea-water suggest that inorganic zinc is divided between Zn^{2+} (27%), chloro complexes (47%) and $ZnCO_3$ (17%) whereas in a typical fresh water the main species are Zn^{2+} (50%) and $ZnCO_3$ (38%).

The speciation of zinc in natural waters has recently been reviewed by Florence[46] and Florence and Batley.[7] These reviews emphasized the current confusion about the correct value for the concentration of zinc in sea-water. Most analytical chemists who determine zinc in surface sea-water find concentrations of 1–4 μg/l.; values within this range have been reported recently by workers using a wide variety of analytical techniques, including ASV, AAS, inductively-coupled plasma emission spectrometry, isotope-dilution spark-source mass spectrometry, and neutron-activation analysis.[7,46,167] Recently, however, Bruland *et al.*[151,168] and Martin *et al.*[169] reported a classical study of zinc in the Pacific Ocean, in which they found only 8.5 ng/l. at the surface, increasing to 600ng/l. at a depth of 3 km. Bruland *et al.*[168] believed all previous results to be high as a result of contamination during sampling and analysis. Table 7 is a compilation of some recent results for the determination of zinc in sea-water by chelation extraction–carbon furnace AAS, together with the total method blanks reported by the authors.[170–175] The extremely small total blank of 2 ng/l. measured by Bruland *et al.*[151] is lower by factors of 30–435 than the blanks given by the other workers.[170–175] Since the zinc blank in the reagents used in this procedure[174] is equivalent to 1–3 ng/l. in the test sample, Bruland *et al.* must have been able to carry out the complete analytical procedure with virtually zero contamination from extraneous sources such as apparatus, atmosphere and clothing. This is a remarkable achievement considering the ubiquitous nature of zinc contamination.[46]

Accepting the accuracy of the Bruland results[168] for the location sampled, an explanation is needed for the narrow grouping of zinc results (1–4 μg/l.) for surface sea-water found by many different analysts in different countries by different techniques.[7] If all values above 10 ng/l. for surface sea-water were due to random contamination during sampling and analysis, a much wider spread of results would be expected. It is very likely that coastal sea-water sampled near sewage outfalls has an elevated zinc concentration. Since thousands of tons of zinc per year can be introduced into a coastal region from this human source,[169] the effect may be detectable at a great distance from the outfall. Martin *et al.*[169] have suggested that measurement of the zinc/silicon ratio could be

Table 7. Blanks reported for chelation/extraction/atomic-absorption spectrometric determination of zinc in surface sea-water

Source of water	Extraction system*	Total zinc, *ng/l.*	Method blank, *ng/l.*	Reference
Baltic Sea	APDC–DDDC–Freon	3000	870	170
Atlantic Ocean	APDC–MIBK	3600	620	174
Indian Ocean	APDC–DDDC–Freon	600	100	171
Atlantic Ocean	DT–chloroform	373	90	172
Gulf of Aden	APDC–DDDC–Freon	10,800	70	173
Pacific Ocean	APDC–MIBK	30	60	175
Pacific Ocean	APDC–DDDC–chloroform	10	2	151

* DT = dithizone; APDC = ammonium pyrrolidinedithiocarbamate; DDDC = diethylammonium diethyldithiocarbamate; MIBK = methyl isobutyl ketone.

used to detect man-made zinc pollution. Another possible origin of high zinc values, that would be common to workers in different countries, is contamination from polyethylene sampling bottles. Both Subramanian *et al.*[54] and Landy[176] reported that polyethylene containers slowly released zinc to water samples. Landy found that the zinc concentration of ultrapure water stored in 500-ml acid-cleaned polyethylene bottles increased from 0.02 to 1.7 μg/l. over a period of days. No increase was found for copper, lead or cadmium.

The average concentration of zinc in the oceans can be estimated from the relationship between the water–rock partition coefficients[K_Y(SW)] and electronegativity functions (Q_{YO}) of the elements.[177] From the regression line calculated by Turner *et al.*[177] for the log K_Y(SW) and Q_{YO} values of 56 elements, and the crustal rock abundance of zinc (127 μg/g),[177] a concentration of 780 ng/l. is predicted for zinc in sea-water. This result is remarkably (and perhaps fortuitously!) close to the concentration of 600 ng/l. found by Bruland *et al.*[168] at depths below 1 km.

The 60-fold decrease in zinc concentration from deep to surface sea-water is probably a result of biological activity in the euphotic zone. Algae show concentration factors (based on a sea-water value of 500 ng/l.) of 10^4–10^7 for zinc,[178] and would act as a most efficient scavenger of this metal in surface water, releasing it in deeper water as they die and decompose. Anderson *et al.*[179] have, in fact, suggested that zinc may be a limiting nutrient for the growth of coastal diatoms. The surface-water zinc concentration may depend on the phytoplankton density.

Florence and Batley[45] found that approximately 50% of the zinc in surface coastal Pacific Ocean water was ASV-detectable and extractable by Chelex-100 resin, and that only 23–59% could be extracted by ammonium pyrrolidinedithiocarbamate at pH 4.5, even though ionic zinc spikes were completely extractable at this pH. When the sea-water was acidified to pH 0.7, heated, cooled, and adjusted to pH 4.5, all the zinc could be extracted. Fukai *et al.*[180] were able to extract 13–90% of zinc from Mediterranean coastal sea-water with dithizone; the extractable zinc concentration depended on the time of the year.

Florence[36] analysed three samples of soft, unpolluted river water (pH 6.0–6.1) containing 2–6 μg/l. and found that the zinc was completely absorbed by a Chelex-100 resin column. The speciation was simple, being equally divided between ASV-detectable species and inorganic species (possibly basic carbonates) which were electrochemically inactive, but decomposed by the Chelex-100 resin. Hart and Davies,[95] however, found that in the polluted Yarra River, Australia (total Zn 65 μg/l.) only 50% of the zinc was exchangeable with Chelex-100, and Figura and McDuffie[181] reported that only 34% of the total zinc (7.4 μg/l.) in a sample of Susquehanna River water was removed by the chelating resin.

Great care must be taken with analysis for zinc at the μg/l. level. Because zinc is a component of so many materials present in the laboratory, particularly paints, talcs, rubber and human skin, and its compounds are relatively soluble, contamination of samples is a greater problem than with most other heavy metals. An efficient clean-room, or at least a laminar-flow clean hood, is essential for the determination and speciation of this element in natural waters.

Iron

Computer models[150] suggest that iron(III) exists almost entirely as $Fe(OH)_4^-$ in both sea-water and fresh waters. River water contains a high concentration of iron, which exists principally as negatively-charged iron oxide–organic matter colloids.[7,16,22,62,95,145] When sea-water and river water mix in estuaries, these colloids are neutralized and flocculated, carrying down with them most of the other heavy metals.[16,145,182,183] Some low molecular-weight colloidal particles of iron oxide stabilized with humic acid escape this estuarine scavenging and enter the ocean.[7]

Ellaway *et al.*[184] found that iron was present in the Yarra River (Australia) in mainly (>90%) non-ion-exchangeable forms, and that filterable iron decreased with increasing salinity. Mill[185] was able to recover 5–53% of the total filterable iron (7–500 μg/l.) in southwestern English rivers as a non-dialysable, macromolecular form (m.w. $>10^4$). He suggested that much of the dialysable iron was present as fulvic acid complexes. Sholkovitz[145] showed that of the bivalent metal ions, copper(II) is the most strongly adsorbed on iron–humic acid colloids.

Picard and Felbeck[186] used cation-exchange measurements to show that low concentrations of humic acid strongly influence the ability of marine sediments to react with metal ions. Their study suggests that humic acid is a transporting agent for iron and trace metals in a marine environment. Sugimura,[187] using adsorption on Amberlite XAD-2 resin, likewise obtained results which indicated that 80–90% of filterable iron in sea-water is associated with organic matter.

Thermodynamic calculations[188] show that in all oxygenated natural waters, iron(III) should be the predominant oxidation state at pH values above 6.

Chromium

Because chromates are used extensively in water treatment, and chromium(VI) has a much higher toxicity than chromium(III),[189] most interest in chromium speciation has centred on the differentiation between Cr(III) and Cr(VI).

Most methods for separating the two chromium oxidation states involve ion-exchange, although co-precipitation and liquid–liquid extraction have also been used.[7,190] The ion-exchange methods assume that Cr(VI) exists as anionic species (CrO_4^{2-} or $Cr_2O_7^{2-}$) and that Cr(III) is entirely cationic. This is,

however, a questionable assumption, since Sibley and Morgan[48] calculated that in both sea-water and fresh waters the dominant ionic form of Cr(III) is $Cr(OH)_4^-$. Yamazaki *et al.*[191] found that in the neutral pH region, Cr(III) associates with humic acid and other organic substances of pond sediment to form uncharged or negatively charged compounds. Ion-exchange resins can reduce Cr(VI); Lee[192] found it necessary to treat Dowex 50-1X with alkaline peroxide and then dichromate solution before using it to separate Cr(III) from acid pickling solutions.

Batley and Matousek[193] used a novel electrodeposition technique to measure chromium speciation in natural waters. At pH 4.7 and a deposition potential of −1.8 V *vs.* SCE, both Cr(III) and (VI) are reduced to the metal and deposited onto a graphite AAS furnace tube. At the same pH, but at a deposition potential of −0.3 V *vs.* SCE, only Cr(VI) is deposited. In sea-water (total Cr 0.25 μg/l.) and saline river water, Cr(VI) was found to be the dominant form. Cranston and Murray[194] also reported that, of the 0.17 μg/l. in Columbia River water, 98% was present as Cr(VI).

Nickel and cobalt

Computer models suggest that in both sea-water and fresh water, both nickel and cobalt exist mainly as the aquo ion and carbonato complex,[150] but there have been very few experimental speciation studies of these metals in natural waters.[7] Batley and Matousek,[195] using an electro-deposition–AAS technique, found that about 70% of both nickel and cobalt in estuarine samples was ASV-detectable at pH 4.7. Beneš and Steinnes[196] showed that in some Norwegian lakes and rivers less than 40% of the cobalt was dialysable, suggesting a high concentration of colloidal or particulate species.

Sholkovitz[145] used simulated estuarine mixing experiments, and found that 40% of riverine nickel (total 0.28 μg/l.) and only 11% of riverine cobalt (total 0.25 μg/l.) was flocculated on mixing with sea-water, whereas 95% of the iron was precipitated.

Manganese

The natural-water chemistry of manganese is dominated by non-equilibrium behaviour. The main form of Mn(II) in both sea-water and fresh waters is computed to be the free hydrated ion, although manganese(IV) oxide is expected to be the stable form in sea-water and high-pH fresh waters.[7,150] The oxidation of Mn(II) in sea-water is, however, an extremely slow process, and this kinetic effect could account for the disagreement in results reported on the speciation of manganese in natural waters.[7,197] Angino *et al.*,[198] using electron spin resonance, found that Mn(II) was present in a fresh water stream (pH 8.5), and that this ion was not in redox equilibrium with Mn(IV). They suggested that $Mn(H_2O)_6^{2+}$ is the dominant species in rivers at pH up to 6.3, while above pH 8.0 some insoluble Mn(III) species are formed. Sholkovitz[145] showed that manganese behaved very differently from iron in his simulated estuary mixing experiments; only 25–45% of the manganese flocculated, compared with 95% of the iron. Knox and Turner[197] found that, in samples from the Tamar Estuary (S.W. England), polarographically-detectable manganese varied, over a 6-month period, from <10% up to 100% of the total manganese (31–252 μg/l.). They suggested that the inactive fraction consisted of colloidally-associated manganese.

Tin

The speciation of tin in natural waters is important, not only because of the large amount of tin mining carried out, but also because of the increased use of toxic organotin compounds, such as tri-n-butyltin oxide and tri-n-butyltin acetate, in antifouling paints.[199] Craig[200] discussed the likelihood of the environmental methylation of tin, possibly through preliminary complexing of tin with cobalamin. Alkyltin compounds have been detected in several lakes and rivers,[200] but they appear to be of man-made origin. There is, as yet, no direct evidence that tin compounds can be methylated under environmental conditions.

Macchi and Pettine[201] used ASV to measure the speciation of tin in natural waters, and obtained results which suggested that at pH 8 the predominant form is $SnO(OH)_3^-$, while at lower pH values it is $SnO(OH)_2$. Florence and Farrar[202] used a preliminary separation of tin as $SnBr_4$, followed by ASV, to determine tin in sea-water and marine organisms. Coastal surface sea-water was found to contain 0.3 μg/l. as dissolved tin, with less than 0.02 μg/l. associated with particulate matter.

Mercury

About 10^4 tons of mercury are released into the atmosphere each year by the burning of fossil fuels, the smelting of sulphide ores, cement manufacture, and the heating of other materials containing mercury.[203] Other industrial operations add huge amounts of mercury to the oceans and rivers.[204]

Although mercuric ion is one of the most toxic metal ions,[7,205] methylated forms of mercury are even more toxic, and can be concentrated from water or through the food chain by virtue of their high lipid-solubility. Aquatic sediments readily oxidize metallic mercury to Hg^{2+}, and certain organisms can rapidly methylate Hg^{2+} to mono- and dimethylmercury, perhaps even in the water column above the sediment.[206] For this reason, most of the research on the speciation of mercury in natural waters has been aimed at developing methods for the differentiation of organic and inorganic mercury species.

Computer modelling results predict that mercury(II) should exist entirely as chloro complexes in sea-water, and principally as hydroxo species in river water.[7] In open ocean water the mercury con-

centration is less than 10 ng/l., but may be higher in coastal waters affected by sewage discharge.[7,204] Mercury in estuaries, lakes and rivers can vary from as low as 2 ng/l. to as high as 500 ng/l. for polluted areas.[7,204] In estuaries and fresh waters a high proportion of the dissolved mercury appears to be associated with organic matter.[204] Seritti *et al.*[207] found 0.4–9 ng/l. of "reactive" mercury, and 1–30 ng/l. of "total" mercury (*i.e.*, after oxidation of organic matter) in surface sea-water.

The separation and determination of alkylmercury compounds in natural waters is usually carried out by GLC-flameless AAS,[208] although the cold-vapour AAS technique can be used alone by varying the reducing conditions to determine phenyl- and alkylmercury compounds.[209] Goulden and Anthony[209] found that in some lake waters as much as 20% of the total mercury is present as methylmercury.

Arsenic and selenium

The concentrations of arsenic and selenium in surface sea-water are 1.5 and 0.1 μg/l., respectively.[7] Both elements commonly exist in solution in two oxidation states: As(III) and (V), and Se(IV) and (VI). In sea-water it appears that the dominant oxidation states are As(V) and Se(IV), but in river waters the other two states may be important.[7] Organic forms of arsenic and selenium are also likely to be present in all natural waters.[210] Sanders and Windom[211] found that marine phytoplankton readily assimilate arsenic(V) and incorporate some of it into the cell. Most of the As(V) is reduced, methylated, and released to solution. They calculated that 15–20% of the total dissolved arsenic in sea-water is reduced by phytoplankton during blooms on the continental shelf.

The determination of arsenic speciation by selective hydride evolution and AAS has been proposed frequently,[7,212,213] although the accuracy of the method has been questioned.[210] Howard and Arbab-Zavar[213] described a method for the selective determination of inorganic As(III) and (V) and methyl- and dimethylarsenic species by the trapping of the arsine compounds and sequential volatilization into a heated quartz atomizer tube situated in the optical path of an atomic-absorption spectrometer. There was serious interference, however, from several metals.

Recently there has been a marked increase in interest in environmental selenium chemistry because of the strong negative correlation between cancer and the selenium concentration in diet.[214] Shamberger[215] has comprehensively reviewed the distribution of selenium in the environment.

Aluminium

Until recently there was very little interest in the environmental chemistry of aluminium, the metal generally being considered relatively non-toxic under all normal conditions.[216] This situation has changed, however, with the suspicion that aluminium is the agent causing dialysis encephalopathy in patients undergoing haemodialysis with domestic water supplies high in aluminium.[217,218] Also, aluminium is implicated as a metal toxic to aquatic life [possibly as the $Al(OH)_2^+$ species[12,219]] when unbuffered lakes become acidified by acid rainfall.[11,220,221]

The concentration of dissolved aluminium in open ocean water is about 0.5 μg/l., and in fresh waters can range from 2 to 100 μg/l.[7,222] Many natural organic compounds, *e.g.*, humic and fulvic acids, can release aluminium from soils. Hydes and Liss[223] used reaction with the chromogenic reagent lumogallion to study the forms of aluminium present in estuarine and fresh waters. Their results for most rivers suggested that dissolved aluminium was present as simple ionic species or adsorbed on colloidal clay particles.

Plutonium

Plutonium is present in sea-water as a result of nuclear-weapon tests. Aston[224] used a computer model for plutonium in sea-water to predict that Pu(IV) would be hydrolysed, and adsorbed by sediments and particulate matter. Plutonium(VI) should be soluble and present as the $PuO_2CO_3OH^-$ species. These predictions are in approximate agreement with the measurements of Schell *et al.*[225] and Nelson and Lovett.[226]

MEASUREMENT OF COMPLEXING CAPACITY OF NATURAL WATERS

Heavy-metal ions added to a body of natural water are eventually incorporated into the sediment.[227] Before they deposit in the sediment they are usually adsorbed or complexed by particulate or dissolved organic compounds. This "complexing" of toxic heavy-metal ions is of vital importance to the biota, because the "complexing capacity" of the body of water determines its ability to render pollutant metals inocuous. Since copper is the most toxic of the common metal ions, the complexing capacity for Cu^{2+} is normally measured. There are several methods in common use for measuring complexing capacity, and they may give quite different results. It is important therefore, when quoting complexing capacities, to state the method used and to give all essential procedural details. Even variations in the same method (*e.g.*, change in pH or electrode rotation speed for ASV) can significantly affect the complexing capacity value found.

Hart[228] and Florence and Batley[7] have recently reviewed methods for measuring the complexing capacity of natural waters. The method most frequently used is an ASV titration, where aliquots of a standard copper(II) solution are added to the test solution, and the ASV peak height for copper is measured after a suitable equilibration period.[228,229] A typical ASV titration of coastal sea-water[229] is shown in Fig. 4. Other methods used for determining copper-complexing capacity are[7,228] ion-selective electrode potentiometry, ion-exchange on resins[230] or manganese di-

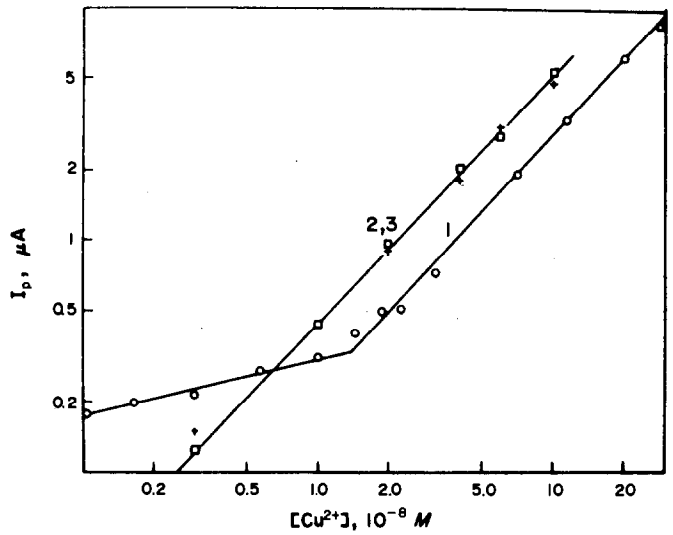

Fig. 4. ASV peak height *vs.* concentration plots for copper added to (1) sea-water, 0.015*M* acetate buffer, pH 4.8; (2) sea-water, 0.016*M* HNO_3; (3) 0.5*M* NaCl, pH 4.8. (From T. M. Florence and G. E. Batley, *J. Electroanal. Chem.*, 1977, **75**, 791. With permission.)

oxide, copper solubilization,[231] and bioassay. Copper ion-selective electrodes[232] are useful only[7,228] for detecting the end-point in the titration of a water sample with Cu^{2+}, and bioassays, while providing direct information on individual biological species,[233] are time-consuming and difficult to reproduce. Young *et al.*,[17] using larval shrimp as a test species, found good agreement between copper-complexing capacities measured by bioassay and ASV, whereas Srna *et al.*[234] reported that ASV gave values which were about half those measured by bioassay.

Some methods for determining complexing capacity also provide a simple measurement of the apparent stability constant ($^*K_1$) of the copper mixed ligand complex.[228,230,232,235,236] Values of log $^*K_1$ at pH 7 in lake or river water range[228] from 5.0 to 11.5. Sea-water and algal exudates provide stability constants within this range.[228] Hart[228] has pointed out that the commonest value of log $^*K_1$, 7.0 at pH 7, is very close to the formation constant of the copper–fulvic acid complex, and that several studies show that most of the copper-complexing ligands in fresh waters have molecular weights of 10^3–10^4.

A similar range of molecular weights has been measured for algal exudates,[131] which may dominate the complexing capacity of sea-water.[237]

The copper-complexing capacity of coastal sea-water[229] is usually in the range (1–5) × $10^{-8}M$, while rivers[228] often have values between 1 × 10^{-8} and 5 × $10^{-7}M$.

CONCLUSIONS AND RECOMMENDATIONS FOR FUTURE RESEARCH

It is inevitable that in the near future, water-quality legislation for heavy metals will include statements relating to their speciation. It may be possible to tolerate higher total concentrations of some metals as long as the labile fraction is below a certain limit. Measurement of complexing capacity may also have to be included in the water-quality criteria. In the same way, future legislation may require that the bioavailable fraction of trace elements and vitamins be measured as part of the routine analysis of foods.

Unfortunately, trace-metal speciation techniques have not yet been developed to the stage where any one method is completely acceptable for routine use. The measurement of ASV-detectable metal appears to approximate the bioavailable fraction,[17] but the term includes a wide range of techniques and procedures, and the measurement would need to be carefully defined to be internationally acceptable. The ASV technique, while almost essential for speciation analysis of saline waters, may possibly be replaced for fresh waters by equilibration with a chelating resin and measurement of the inert fraction by carbon-furnace AAS.

Potentiometric stripping analysis (PSA), developed by Jagner and co-workers,[238–240] may be more suitable than ASV for measurement of the electrochemically-active fraction of a metal. PSA is much less affected by organic matter adsorbed on the electrode than is ASV, which shows that organic matter influences the stripping, rather than the deposition step. A microprocessor-based PSA instrument has sensitivity similar to that of ASV.[240]

A trace-metal speciation scheme may be simple or complex, but it should provide the information required for the particular samples provided. If measurement of toxicity towards aquatic organisms is the purpose of the analysis, then the scheme should measure, as accurately as possible, the toxic metal fraction.[241] It should not be assumed that a chelating

resin of the Chelex-100 type is best for this purpose; thiol or other resins may be more suitable.[23] There is an urgent need for more studies of the relationship between analytical speciation schemes and direct bioassays.

A prime requirement of any speciation method is that it should require little manipulation and offer minimum opportunity for contamination. The concentrations of toxic heavy metals in natural waters are extremely low, and considerable experience is required before contamination of the sample can be consistently avoided. A laboratory must be able to demonstrate that it can routinely collect samples and measure accurately the *total* concentration of these metals in natural waters before it attempts speciation measurements. Surface sea-water from an unpolluted area is a convenient sample type to test the capability of a laboratory, because the normal concentrations of several heavy metals in sea-water are now well established (Table 6).

Computer modelling of trace-metal speciation is an attractive alternative to the difficult and tedious experimental methods. At present, however, modelling techniques are useful only for setting limits on speciation. More thermodynamic data are required on metal associations in natural waters, and the collection of these data is an urgent research need.

Humic and fulvic acids play a dominant role in trace-metal speciation in fresh waters, and probably also (through estuarine precipitation) in sea-water.[15] Humate-coated iron oxide and clay particles strongly adsorb trace heavy metals, and these "pseudocolloidal"[62,242] forms of the heavy metals are often the main dissolved species present in natural waters. More research is required to elucidate the composition, structure and behaviour of these pseudocolloids. Because of the potential toxicity of metal species which are directly lipid-soluble, improved methods for the determination of this metal fraction in natural waters should have high priority.[243–246]

Many trace-metal speciation results in the literature are undoubtedly seriously inaccurate because of contamination during collection of the sample or its subsequent analysis. This situation will continue until more laboratories establish trace-metal clean-room facilities, develop techniques for working at the ng/l. level, and train staff for this exacting area of chemical analysis.

GLASSY-CARBON AMPEROMETRIC TRANSDUCERS AS ELECTROCHEMICAL DETECTORS IN LIQUID CHROMATOGRAPHY

THE INFLUENCE OF OXYGEN

KARL BRATIN and PETER T. KISSINGER
Department of Chemistry, Purdue University, West Lafayette, Indiana 47907, U.S.A.

(*Received* 1 *April* 1981. *Revised* 27 *October* 1981. *Accepted* 1 *November* 1981)

Summary—The electrochemical behaviour of oxygen on glassy-carbon electrodes and the suitability of this electrode material for electroreduction of organic compounds have been investigated. The observed oxygen overpotential on a glassy-carbon electrode was more negative than that on an amalgamated gold electrode, thus allowing the determination of easily reducible compounds such as polynitro-aromatics and quinones without the need for exhaustive removal of dissolved oxygen. The detection limits (3σ) were about 0.2, 0.8, and 2.5 pmole for polynitro-aromatics, mononitro–aromatics and quinones, respectively. Though the glassy-carbon material has a negative-potential limit about 250 mV more positive than that for the amalgamated gold electrode, and requires a longer equilibration time before use, it is more convenient for routine use.

The marriage of liquid chromatographic and electrochemical techniques has resulted in a great many useful applications in the last ten years, primarily to easily oxidized compounds. Progress in application to reducible substances has been slower, owing to the high background currents which can result from reduction of oxygen, hydrogen ions, and transition metal ions. Several factors must be considered when selecting the electrode material for use in such reductions, the most important being the oxygen and hydrogen overpotentials. The "operating range" of an electrode material is usually limited on the negative side by the reduction of hydrogen ions and residual oxygen, both of which can be influenced by metal deposition.

Mercury is the material of choice for most electrochemical reductions because it has a very large hydrogen overpotential, as shown in Table 1. Mercury-pool electrodes are generally not suitable as electrode materials in a thin-layer amperometric detector because they suffer from vibration and edge effects due to creeping of solution between the mercury and its container. In addition, they have poor tolerance for rapid movement of the solution. Though these effects are serious at low current densities (high sensitivity), mercury-pool electrodes have been used successfully for the determination of mercapto compounds at higher current densities.[1,2] The dropping mercury electrode (DME) detector for use in liquid chromatography was introduced in 1952 by Kemula, but its use was limited to a few academic laboratories. Recent improvements in the design of the DME detector have stimulated renewed interest and several promising applications have been reported.[3–5] The combination of liquid chromatography and electroreductive techniques has recently been reviewed.[6]

Solid electrode materials such as gold, platinum, and various forms of carbon have been used extensively to study oxidation processes:[7,8] however, their utility on the reductive side has been limited, owing to their small potential range, as summarized in Table 1. These limits should be used with caution because they were abstracted from several sources, and the experimental procedures and guidelines for their determination were not uniform.

MacCrehan,[9] and co-worker,[10] and we ourselves[11–13] initially focused attention on a mercury film on a gold substrate as electrode. As shown in Table 1, amalgamated gold and silver electrodes retain most of the desirable characteristics of liquid mercury, with only a small sacrifice in the available "potential window." The low oxygen overpotential of amalgamated electrodes has led us to investigate the electrochemical behaviour of oxygen at a glassy-carbon electrode (GCE) and to evaluate the suitability of this material for electroreduction. Several applications of glassy-carbon and mercury-film electrodes to trace determinations of reducible substances are described elsewhere.[11,13]

EXPERIMENTAL

Apparatus

A conventional liquid chromatograph (LC) with temperature control and electrochemical detection (model LC-304T from Bioanalytical Systems, Purdue Research Park, West Lafayette, Indiana) was equipped with a fixed

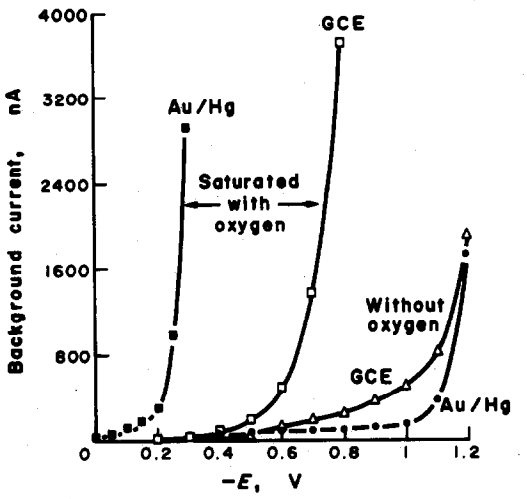

Fig. 2. Background current on a GCE (□) and Au/Hg electrode (■) without deoxygenation, and after deoxygenation with nitrogen gas on a GCE (△) and Au/Hg electrode (●) as a function of the detector potential. LC conditions: 25-cm C_8 Biophase column, 0.05*M* acetate buffer, 20% (v/v) 1-propanol, 10% (v/v) ethanol, pH 4, at 0.8 ml/min. Areas of electrodes used were 7.07 and 7.94 mm^2 for the GCE and Au/Hg electrode, respectively.

volume (20 μl) rotary sample-injection valve and an oxygen removal apparatus (Fig. 1). The LC columns were 25 cm × 4.6 mm C_{18} and C_8 5-μm Biophase.

Chemicals

Reagent grade absolute ethanol, anhydrous sodium acetate, and monochloroacetic acid were used as purchased, for the preparation of the mobile phase. Mercury was triply distilled. Picric acid (PIC), 4-nitrobenzoic acid (NBA), 3,4-dinitrobenzoic acid (DNBA), 2-chloro-3,5-dinitropyridine (CDNPY), 4-nitrophenol (NP), 4-nitroaniline (NA) and 2,4-dinitrophenol (2,4DNP) were used as purchased. 2,5-Dinitrophenol (2,5DNP) was dried under vacuum before use.

Electrode preparation and hydrodynamic voltammetry

Thin-layer mercury-film electrodes were prepared by placing triply distilled mercury on the old amalgam surface and after 2–3 min wiping the excess from the electrode surface with a piece of computer card. The potential of the electrode was initially set at −1.50 V *vs.* Ag/AgCl for "burning in" the new amalgam surface. After about 100 sec the electrode potential was lowered to a normal operating setting.

Hydrodynamic voltamperograms (HDVs) were obtained by repeated injections of standards, the potential of the thin-layer amperometric detector being changed before each injection. HDVs were plotted by using the normalized function n_{eff}, which can be derived from Faraday's law:

$$n_{eff} = \frac{Q}{FN_{inj}} = nf$$

where Q is the number of coulombs passed during the reduction process, F is the Faraday constant (9.65×10^4 coulombs/equivalent), n is the number of electrons involved in the electrochemical reaction (equivalents/mole), N_{inj} is the number of moles of analyte injected into the column and f is the fraction of injected molecules which react at the electrode surface.

RESULTS AND DISCUSSION

In our evaluation of the utility of the glassy-carbon electrode we considered hydrogen and oxygen overpotentials, reduction potentials for analytes of interest, the long term stability, and detection limits. The effect of oxygen on the magnitude of the background current is illustrated in Fig. 2. An amalgamated gold electrode exhibits detectable reduction of oxygen even at potentials around −0.1 or −0.2 V, whereas on a glassy-carbon electrode oxygen reduction occurs only at more negative potentials (about −0.5 or −0.6 V). This difference in behaviour is illustrated in Fig. 3.

Several groups have examined the electrochemical reduction of oxygen on various electrode materials.[14–16] In acidic solution, the oxygen is reduced on mercury in two 2-electron steps,

$$O_2 + 2e^- + 2H^+ \rightarrow H_2O_2 \quad (1)$$

$$H_2O_2 + 2e^- + 2H^+ \rightarrow 2H_2O \quad (2)$$

while on a glassy-carbon electrode only the first reduction process is observed and the second process is probably obscured by hydrogen evolution. A decrease in limiting current at high potentials was observed only for reduction of oxygen at the GCE; neither oxygen at the amalgamated gold electrode or picric acid at either electrode (under the conditions used for the oxygen experiment) gave a decrease. This rules out the possibility of the *iR* drop being the cause of the decrease in the limiting current.[17] A similar effect was observed by Taylor and Humffray for acidic media and a ring–disk glassy-carbon electrode.[14]

The chromatography of oxygen is very interesting. Oxygen is retained on reversed-phase columns, but its retention time (volume) is independent of the concentration of organic modifiers in the mobile phase, and is less sensitive to changes in column temperature than that of analytes which elute at about the same time as oxygen. Another distinguishing feature of oxygen chromatography is illustrated in Fig. 4. The oxygen peak is broad and badly skewed (the asymmetry

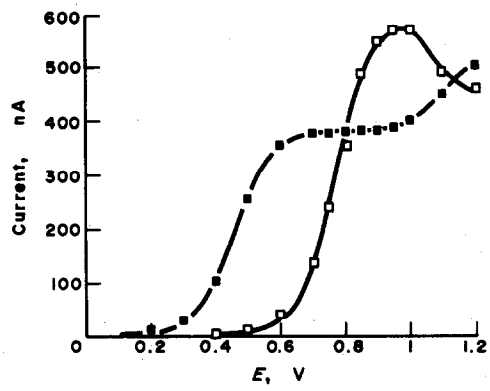

Fig. 3. Hydrodynamic voltamperograms of oxygen on a GCE (□) and Au/Hg electrode (■). LC conditions: 25-cm C_8 Biophase column, 0.1*M* acetate buffer, 20% (v/v) 1-propanol, 5% (v/v) ethanol, pH 4.8, at 1 ml/min.

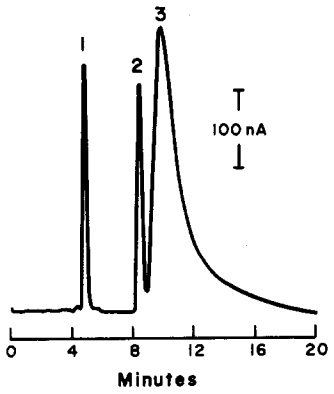

Fig. 4. A chromatogram of 170 pmole of PIC (1), 540 pmole of CDNPY (2) with injected solution saturated with oxygen (3). LC conditions: 25-cm C_8 Biophase column, 0.17*M* acetate buffer, 22% (v/v) propanol, 5% (v/v) ethanol, pH 4, at 0.8 ml/min.

factor was approximately 2.5 times larger for oxygen than for CDNPY). These factors clearly indicate that oxygen retention on the reversed-phase column is not due to the usual hydrophobic interactions, but is probably attributable to a size-exclusion mechanism. Because molecular oxygen is smaller in size than the organic analyte molecules, it is capable of penetrating smaller pores in the stationary phase.

The usefulness of the large oxygen overpotential on glassy carbon is illustrated in Fig. 5. As expected, oxygen dissolved in the injected solution does not interfere with the trace determination of easily reduced analytes (*e.g.*, picric acid, 2,4DNP), as long as the mobile phase is saturated with oxygen and the detector is operated below −0.6 V *vs.* the Ag/AgCl electrode (Fig. 5*a*, *b*). Oxygen reduction is significant at −0.6 V (manifested by high background current and increased baseline noise). Oxygen is only detected as a distinct peak when the mobile phase alone (and not the injected sample) is sparged with nitrogen (Fig. 5*c*). The lack of oxygen interference on a glassy-carbon electrode at potentials below −0.6 V simplifies the construction of the reductive electrochemical system because it eliminates the need for the oxygen-removal apparatus (Fig. 1).

Dissolved oxygen limits the available negative-potential range of the glassy-carbon detector and significantly decreases the observed detection limits for many analytes. Even though the detector response (or "sensitivity") at −0.6 V was greater than at −0.4 V (Fig. 5*a*,*b*), the detection limits under "oxygen-saturated" conditions (Fig. 5*b*) increased by a factor of 4–5 as a result of a tenfold increase in baseline noise (which is proportional to the background current). The detection limits for polynitro-aromatic compounds at −0.6 V under "oxygen-free" conditions (Fig. 5*d*) were greater by a factor of 2–3 than those at −0.4 V, and detection of less than 10 pmoles of mononitro-aromatic compounds was possible. Trace detection at potentials more positive than −0.6 V under "oxygen-saturated" conditions was not poss-

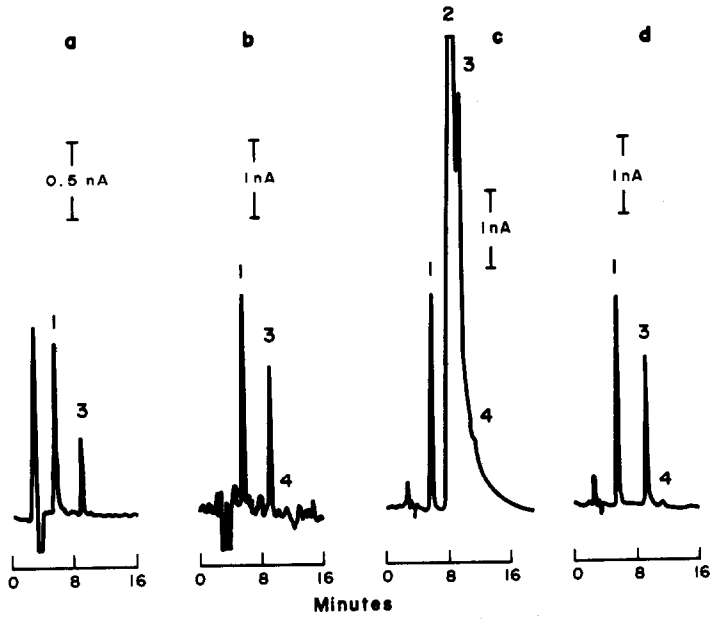

Fig. 5. The effect of dissolved oxygen (2) on the detection of 4.8 pmole of PIC (1), 9.2 pmole of 2,4DNP (3), and 28 pmole of NP (4) at GCE. (*a*) E = −0.4 V and (*b*) E = −0.6 V, both the mobile phase and injected solution being saturated with oxygen; (*c*) E = −0.6 V, the mobile phase being deoxygenated and the injected solution saturated with oxygen; (*d*) E = −0.60 V, both the mobile phase and injected solution being deoxygenated. LC conditions: 0.015*M* sodium acetate, 0.02*M* monochloroacetic acid, 0.001*M* EDTA, 17% (v/v) 1-propanol, 5% (v/v) ethanol, pH 3.5, at 1 ml/min, 25-cm column of 5-μm Biophase C_{18}.

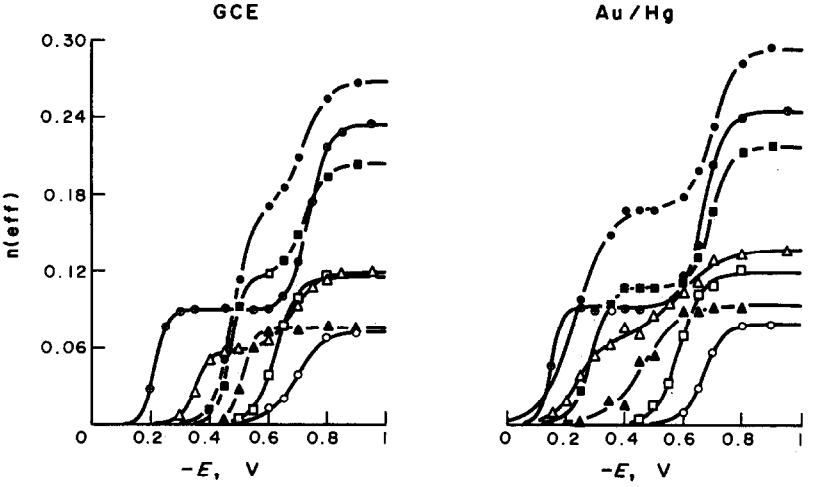

Fig. 6. Hydrodynamic voltamperograms of nitro-aromatic compounds: 160 pmole of PIC (●), 250 pmole of 2,5DNP (+), 170 pmole of 2,4DNP (■), 290 pmole of DNBA (△), 470 pmol of NBA (▲), 390 pmole of NA (□) and 650 pmole of NP (○) on a GCE and an Au/Hg electrode. LC conditions: a 25-cm Whatman Partisil PXS 5/25 ODS column; mobile phase 0.1*M* acetate, pH 4.1, 20% (v/v) 1-propanol and 5% (v/v) ethanol, and 0.9 ml/min.

ible, owing to the large background currents and associated noise.

Because of the small potential window of the GCE under "oxygen-saturated" conditions, the utility of the detector is limited to detection of analytes which contain polynitro- and nitroso-aromatic (ϕ-NO_2 and ϕ-NO), diazo, and quinone functional groups. A more negative potential limit (by about 200–400 mV) and better detection limits are achieved by deoxygenation of the mobile phase. Deoxygenation allows detection of compounds which contain a single aromatic nitro-group, aromatic *N*-oxides and thioamides.

A comparison of the redox behaviour of nitro-aromatic compounds on a glassy carbon and on an amalgamated gold electrode is illustrated in Fig. 6. The initial reduction of polynitro compounds was very sensitive to the nature of the electrode material, while the opposite was true for the reduction of mononitro compounds and secondary reduction of *meta* polynitro compounds. The detection limits on a GCE (the concentration giving a signal that is 3 times the standard deviation of the blank) for polynitro- and mononitro-aromatic compounds were about 0.15–0.25 and 0.5–1 pmole respectively. The detection limits found for quinones were higher than for nitro compounds (2.5 pmole for adriamycin) because fewer electrons are transferred in the redox reaction of quinones. These detection limits compare favourably with the detection limits obtained on an amalgamated gold electrode.[13] Lower detection limits were obtained for polynitro-aromatic compounds on the amalgamated gold electrode (by a factor of 1.5–2) if great care was used in the preparation of the amalgam surface and if the detector potential was set at the plateau of the first reduction wave.

Several groups have attempted to evaluate the reductive potential range for various electrode materials and their results are summarized in Table 1. This comparison should be used only as a qualitative guide because the criteria and the types of electrochemical techniques used in the determination of the potential ranges varied significantly among the various groups. In our experience the negative-potential limit for glassy carbon is strongly dependent on the previous history of the electrode surface and varies from one electrode to another. Often the background current at a potential between −0.8 and −1.0 V on a GCE is unstable, with an upwards drift of the order of 20–50 nA/hr, limiting the most negative useful potential to −0.8 V (for high-sensitivity measurements). On the other hand, many GCEs can be operated routinely at −1.00 V for several weeks (with only periodic surface polishing) without any significant changes in electrode sensitivity and noise (*i.e.* with invariant detection limits). A longer equilibration time of 2–3 hr is necessary if high-sensitivity measurements are to be made at glassy carbon electrodes, compared to 30–60 min for amalgamated gold electrodes. This problem can be dealt with by leaving the system on overnight at minimal mobile-phase flow (0.1–0.2 ml/min).

CONCLUSIONS

It is our experience that glassy-carbon electrodes are more reliable and easier to use than amalgamated gold electrodes for routine high-sensitivity measurements at applied potentials more positive than −0.8 V *vs.* the Ag/AgCl electrode because background current and noise levels are more reproducible. Amal-

gamated gold electrodes must be used, however, if high-sensitivity measurements (< 100 pmole) are to be made at potentials more negative than −0.8 V *vs.* the Ag/AgCl electrode. Edge effects and the spike noise common to amalgamated gold electrodes[6] are not observed with glassy-carbon electrodes. While the major drawbacks are the negative-potential limit and the longer equilibration time, glassy carbon is more convenient to use for detection of easily reduced analytes. Oxygen removal is unnecessary for trace detection of analytes on a glassy-carbon electrode at potentials less than −0.6 V *vs.* the Ag/AgCl electrode.

DETERMINATION OF THALLIUM AT SUBTRACE LEVEL IN ROCKS AND MINERALS BY COUPLING DIFFERENTIAL PULSE ANODIC-STRIPPING VOLTAMMETRY WITH SUITABLE ENRICHMENT METHODS

GILBERTO CALDERONI
Institute of Geochemistry, University of Rome, Italy

and

TOMMASO FERRI
Institute of Analytical Chemistry, University of Rome, Italy

(*Received* 30 *June* 1981. *Accepted* 1 *November* 1981)

Summary—Ten international reference samples have been analysed for thallium content by differential pulse anodic-stripping voltammetry. Two separation techniques, solvent extraction and ion-exchange, were employed to preconcentrate the thallium: the results were critically compared to establish which was the better separation technique. The values found were quite satisfactory and confirmed the wide scope for application (not yet fully investigated) of voltammetry in geochemical studies.

Despite the great increase in geochemical research during the past two decades the determination of the thallium content of geological materials is rare. Consequently there are many aspects of thallium geochemistry which have not yet been settled because they are either scarcely developed or even undefined. Most of the literature data on abundance of thallium refers to minerals and rocks of magmatic suites.[1] However, the literature provides non-conclusive information about the behaviour of thallium during magmatic differentiation, mainly because of the lack of knowledge about partitioning coefficients between most major minerals and silicate melts. Little is known about the thallium content of sedimentary rocks and natural waters[1,2] or about its chemical speciation.[3] Finally, the behaviour of thallium in metamorphic and related rocks is virtually unknown.[1]

Recently, some papers[4,5] have pointed out the possibility of using thallium as a geochemical indicator in a variety of problems of geological importance such as petrogenesis, rock–sea-water interactions and the evaluation of the degree of sulphur saturation in a silicate melt.

Unfortunately, a major constraint in the improvement of geochemical information about thallium is its very low abundance in geological materials. The abundance in the earth's crust is estimated[1] at 800 ng/g but it falls to 490 ng/g in continental rocks.[6] Consequently, thallium determination at subtrace level requires high-sensitivity analytical methods combined with dissolution and separation techniques to concentrate the element from multicomponent matrices. The analytical techniques which have sufficient sensitivity are fluorimetry, neutron activation, atomic-absorption spectrometry (AAS) and differential pulse anodic-stripping voltammetry (dpasv). Fluorimetry may suffer severe limitations due to interferences, while neutron activation requires expensive facilities and a long time for irradiation and "cooling" of the samples; comparison of AAS with dpasv, taking into account the comparable sensitivities, favours the latter technique because of its lower apparatus cost and wider measurement range.

EXPERIMENTAL

Apparatus

An Amel 472 WR multipolarograph equipped with a Hewlett–Packard 7040 A X–Y recorder was used for all the stripping voltammetric analyses. A classical three-electrode system was employed: a Metrohm E 410 as working electrode, a platinum counter-electrode and an SCE as reference. The polarographic cells were made of silica glass and all glassware was conditioned with nitric acid (1 + 1) for several days before use. During the electrolysis step the solutions were stirred with a cylindrical Teflon-coated stirring bar driven by an Amel variable-speed stirring unit. All potentials reported are referred to the SCE.

Reagents

Standard Tl(I) stock solutions, 500 mg/l., were obtained by dilution of Merck "titrisol" standard solution and also by dissolving an appropriate weight of Merck R. G. $TlNO_3$ (dried at 110°), and were stored in previously conditioned polyethylene bottles. They were further diluted to give 1 and 5 ppm working solutions. All the other chemicals were Merck "Suprapur", except the Na_2EDTA, H_2SO_3, Br_2, HBr and diethyl ether, which were Merck R. G. The resin was Bio-Rad AG1 X8, chloride form, 100–200 mesh. The columns were made of borosilicate glass, bore 0.75 cm, 15 cm long, with a porous polyethylene disc as bed support. The sulphurous acid (saturated SO_2 solution) was diluted with an equal volume of water for use. It will be referred to as "1:1 H_2SO_3" in the text.

Procedures

Sample dissolution. As all the samples were silicate or silicaceous carbonate rocks, dissolution with hydrofluoric acid and perchloric acid as described earlier,[7] was chosen. The sample weight depends on the thallium content: at least 50–100 ng of Tl should be present although less can be determined. Teflon crucibles were used, because they are cheaper than platinum, and avoid introduction of platinum into the solution.[8] The advantages of the procedure are its rapidity, the oxidation of Tl(I) to Tl(III), and the lower temperature needed for evaporation. The only disadvantage may arise in the case of high-potassium samples, because of the relatively low solubility of potassium perchlorate, but this can easily be overcome by using a low sample weight and an appropriate final dilution.

Solvent extraction. The technique used is well known[9–11] and is based on the extraction of Tl(III) into diethyl ether from hydrobromic acid medium. The sample, decomposed as above, is evaporated with 5 ml of concentrated hydrobromic acid and a few drops of bromine to guarantee complete oxidation of Tl(I). The residue is dissolved with 25 ml of 1.2*M* hydrobromic acid, transferred into a separatory funnel and shaken with an equal volume of diethyl ether (presaturated with the acid). After 30 sec of standing, the organic phase is separated and the extraction repeated. The combined organic fractions are gently evaporated and the thallium recovered is reduced with excess of sulphurous acid.

Anion-exchange separation. As an alternative to solvent extraction, $TlCl_4^-$ can be isolated with a strong anion-exchange resin. This gives a fairly good selectivity because over a certain chloride concentration range only Tl(III) and a few other trace elements (noble metals) give stable anionic chloro-complexes[12] with high distribution coefficients.[13] The sample is decomposed as before, and the residue from the evaporation is taken up in water, diluted to 100 ml and made 0.5*M* in hydrochloric acid. One drop of saturated bromine water is added and the solution is passed through the exchanger column containing a 7-cm AG1 X8 (chloride form) resin bed, at a flow-rate of 1 ml/min. The column is washed successively with 20 ml of water, 50 ml of 1*M* nitric acid and 20 ml of water, each containing 1 drop of saturated bromine water. Thallium is eluted with 50 ml of 1:1 H_2SO_3, which reduces the Tl(III) to Tl(I) (which is not retained by the resin). The eluate is evaporated to dryness.

Instrumental measurement. The residue from the eluate is dissolved in 2.5 ml of supporting electrolyte (pH-4.6 1*M* acetate buffer, 0.5*M* in Na_2EDTA) and the solution is diluted to volume in a 25-ml standard flask. A 20-ml portion is transferred to a polarographic cell and deaerated with purified nitrogen for 7 min. It is then electrolysed for 2–5 min (depending on thallium concentration) at an applied potential of −700 mV *vs.* SCE, with magnetic stirring at 600 rpm. During this phase and the subsequent scanning, nitrogen is passed over the solution. All measurements are made in the dpasv mode, at the hanging mercury drop electrode (hmde) at a sweep-rate of 20 mV/sec, pulse amplitude 40 mV. The mercury drop weight used in our work was 1.66 ± 0.66 mg for an extruded drop 1 division deep; the relative standard deviation obtained, 3.8%, agreed well with previous data[14,15] for the hmde employed.

Under these conditions the E_p value found for Tl(I) was −410 mV *vs.* SCE. The standard addition method was used for the dpasv measurements, the amount added being sufficient to increase the signal by a factor of about 2.

DISCUSSION

Sample decomposition

It is an open question whether thallium is lost by volatilization in sample decomposition, when an acidic solution is evaporated. Thallium loss was first claimed to arise from fuming mixtures of hydrochloric or hydrobromic acid with perchloric or sulphuric acid.[16] Later it was reported that thallium losses of up to 40% were found in evaporation of ^{204}Tl-labelled mixtures of hydrofluoric and sulphuric or perchloric acid.[17] However, others have reported that thallium is not lost on fuming hydrofluoric/perchloric acid[18,19] and hydrofluoric/nitric acid mixtures.[19] Our experiments with spiked samples also failed to detect loss of thallium; perhaps the discrepancy between the available data can be explained in terms of the different evaporation temperatures used. We evaporated the acidic solutions at low temperature (80–90°) in 4 × 10 cm crucibles; in addition, the double evaporation was not fully completed but continued only until incipient dryness.

Calibration

Known quantities of thallium treated by the procedures described gave a linear plot of current *vs.* amount. The working range was not investigated above 2 μg of thallium because higher amounts were not the concern of this research. Even when certified chemicals are used, it is necessary to run blanks in analysis for subtrace elements. Blank determinations were therefore run on ten times the normally required volumes of reagents and gave a result equivalent to 2.1 ± 0.7 ng of Tl for a standard (0.5–1 g) sample weight: the major contributions came from the hydrofluoric, sulphurous and perchloric acids. This blank value was used to establish the limit of detection (LOD) as 4.2 ng and the limit of quantitation (LOQ) of 9.1 ng, defined as proposed by the ACS Committee on Environmental Improvement.[20] The standard Tl(I) working solutions had high stability; checked weekly over a 3-months period against freshly-prepared corresponding solutions, they never showed a relative standard deviation higher than that arising from sampling and measuring errors (less than 5% at the <500-ng level). The choice of a suitable supporting electrolyte was not problematic; it is well known that Tl(I) gives fairly well-defined peaks in different media, hydrochloric acid[21] and pH 4.6 acetate buffer[22] being the most used. With the latter supporting electrolyte and the hmde, the E_p values for Pb(II) and Tl(I) are so close that satisfactory resolution is impossible and complexation is imperative in order to shift the lead peak. Owing to the low stability constants of many Tl(I) chelates in acidic or neutral medium in comparison with those for the Pb(II) complexes (Table 1), there is ample choice of ligand. EDTA and DCTA were first utilized by Přibil *et al.*[23–25] and later by Neeb[26] and Zieglerova *et al.*[27] Jacobsen *et al.*[28] suggested the use of DTPA, and Cignini *et al.*[29] successfully used TTHA. However, in this work a 0.1*M* acetate buffer–0.05*M* Na_2EDTA mixture was chosen as supporting electrolyte, as being the most extensively studied. The earlier workers used a lower EDTA con-

Table 1. Stability constants (log K) for some Tl(I) and Pb(II) complexes[12]

	EDTA	DCTA	EGTA	NTA	DTPA
Tl(I)	6.5	5.3	4.3	4.7	5.8
Pb(II)	18.0	19.6	14.7	11.4	18.8

centration, but in rock analysis, because of the wide variation in matrix composition, a higher concentration is required. The concentration selected was shown experimentally not to lower appreciably the peak current for Tl(I). The instrumental parameters were also experimentally chosen. In particular, the plating potential chosen was the most positive that would not affect the Tl(I) deposition and the sweep-rate represented a reasonable compromise between speed of measurement and instrumental response.

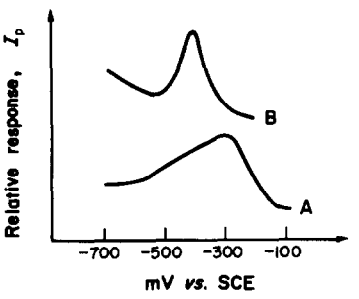

Fig. 1. (A) Signal obtained when analysing a solution containing Tl(I) recovered by solvent-extraction from a basaltic rock (Tl concentration 85 ng/g): note the matrix-dependent interference, related to the basic nature of the rock; (B) dpasv peak resulting when analysing a solution containing Tl(I) recovered by solvent-extraction from a potassium-feldspar (Tl: 50 ng/g), a typical salic mineral. The operational conditions, common to both solutions, are given in the text.

RESULTS

Solvent-extraction procedure

It was often impossible to measure the thallium recovered when the solvent-extraction procedure was used, because of an undefined Tl(I) peak. An example (a basaltic rock, Tl concentration 85 ng/g) is shown in Fig. 1A. This behaviour constantly occurred for certain samples, which all had very low thallium content. On the other hand, preliminary checks on the solvent-extraction procedure confirmed quantitative Tl recovery from synthetic solutions and from a potassium feldspar (Tl concentration 50 ng/g), with well-developed dpasv peaks (see Fig. 1B). This behaviour is due to matrix-dependent interferences. It is well known that the solvent-extraction technique used is not strictly selective, and predictions based on equilibrium constants and reagent concentrations give only a rough indication of the selectivity, because of the strong deviations introduced by the matrix. In particular Fe(III) is partly extracted even from 0.8M hydrobromic acid medium, and we have also found that micro-quantities of copper are extracted.

Table 2. Results for thallium determination (solvent-extraction procedure) in some reference samples

Although the fraction of iron extracted is low (<1.4%), the absolute amount is not negligible, because of the high iron content of femic minerals and ultrabasic and basic rocks. A literature survey showed that both copper and iron can interfere in thallium determination by dpasv, although for different reasons.[36–38] Further investigations showed that the solvent-extraction procedure was suitable for all salic minerals, acidic rocks (with normal thallium content) and for other minerals and rocks when the total iron (expressed as Fe_2O_3) did not exceed 4% and there was not less than 2 ppm of thallium. In other cases the ion-exchange separation technique must be used. Table 2 shows the results for thallium determination in some reference samples; comments on them are made in the following section.

Anion-exchange procedure

Table 3 shows the thallium concentrations found in the reference materials analysed by the anion-exchange procedure. The overall precision appears to be independent of the matrix composition and ranges from 3% (at the 700-ng/g concentration level) to 22% (at the 50-ng/g level). Table 4 compares our data with some values previously reported. It appears that there is a lack of systematic work on determination of thallium in the more generally used international reference materials, and that only in a few cases are the standard deviations or even ranges reported.

For these reasons, it being only rarely possible to estimate correctly the reliability of the few data available, "recommended values"[35] for thallium in reference materials have not yet been established. This situation is probably due to incomplete solution of the difficulties of thallium determination in geological samples at subtrace level. In estimating the accuracy of the new values obtained by both procedures it seemed more realistic to limit the comparison to the standard rocks for which the data show least scatter, such as W-1, BCR-1, GSP-1 and AGV-1, for which numerous reported values range from 102 to 115, 267 to 350, 1200 to 1535 and 270 to 560 ng/g, respectively. For these standards, the comparison demonstrates good accuracy. For the NBS standards, only one previous value was available for each and was not in agreement with ours. The thallium content of DTS-1 and PCC-1 may only be stated to be near or below the limit of detection for this method, so thallium determination in such materials will only be possible by other methods or by purifying the reagents to decrease the blank value.

* Data held to be unrealistic by the original author.

CONCLUSIONS

The dpasv technique can be successfully employed for determination of thallium in solid geological samples, even at subtrace level, with high sensitivity and low cost. However, the quality of the preliminary separation of thallium from the matrix is of the greatest importance and the results of this work show that

solvent extraction, though more attractive because less time-consuming, may only be used for salic minerals and acidic or slightly basic thallium-rich rocks; for femic minerals and ultra basic or basic rocks, the ion-exchange separation is recommended.

CORRECTION OF FORMATION CONSTANTS FOR IONIC STRENGTH, FROM ONLY ONE OR TWO DATA POINTS: AN EXAMINATION OF THE USE OF THE EXTENDED DEBYE–HÜCKEL EQUATION

PETER W. LINDER and KEVIN MURRAY

Department of Physical Chemistry, University of Cape Town, Rondebosch, 7700, South Africa

(*Received* 10 *August* 1981. *Accepted* 31 *October* 1981)

Summary—The results of an extensive examination show the extended Debye–Hückel equation to be efficacious for the use of as few as one or two formation constant values, for a given metal-complex species, for calculation of the value at a lower ionic strength. Approaches to choosing values for the constants in the extended Debye–Hückel equation are described. A statistical analysis shows the chief source of error in the resulting predicted formation constants to be uncertainties in the literature formation-constant values used as data.

We are currently engaged in a project on computer simulation of metal-ion equilibria in soil solutions. Our model requires the acquisition of numerous metal–ligand formation constants valid for an ionic strength of 0.04. Though constants are reported in the literature for many of the systems concerned, only a few correspond to this ionic strength. Indeed most of the available data are given for high ionic strengths and, moreover, at only one or two levels. There are several earlier reports[1–5] on the calculation of equilibrium constants at low ionic strengths from the values at higher ionic strengths, usually with the aid of an extended form of the Debye–Hückel equation. In these, the degree of accuracy is variable and strongly dependent on the choice of values for the constants in the equation. In this paper we examine the accuracy of an extended form of the Debye–Hückel expression [equation (1)] when applied to only one or two data points:

$$-\log\gamma_i = Az_i^2[(I)^{\frac{1}{2}}/(1 + B\mathring{a}_i(I)^{\frac{1}{2}})] + cI \qquad (1)$$

where I is the ionic strength of the solution, γ_i is the activity coefficient of ion i, z_i is the charge on ion i, A and B are constants characteristic of the solvent ($A = 0.509$; $B = 0.328$ for water at 25°)[6] and $\mathring{a}_i$ is an ionic size parameter, estimates for which have been given by Kielland.[7]

We demonstrate that for systems of interest in our soil model, equation (1) has sufficient accuracy for our purpose, with use of as few as two literature values at higher ionic strengths. We also show that the equation can still be used, though with less reliability, when a formation constant at only one ionic strength is available from the literature. In that situation, either a generally recommended value of c is used, or a value based on an educated guess.

THEORY

For a given complexation reaction between a metal ion, M^{z_M}, and a ligand, L^{z_L}

$$pM^{z_M} + qL^{z_L} \rightleftharpoons (M_pL_q)^{(pz_M + qz_L)} \qquad (2)$$

the equilibrium constants, K' and K'', at ionic strengths I' and I'' are related by

$$K'' = \Gamma''K'/\Gamma'. \qquad (3)$$

In equation (3), each Γ is a quotient, expressed generally by equation (4).

$$\Gamma = (\gamma_M)^p(\gamma_L)^q/\gamma_{M_pL_q} \qquad (4)$$

where γ is the activity coefficient of the species indicated by subscripts. These activity coefficients may be calculated from equation (1) provided that values of the constants $\mathring{a}_i$ and c are available. Kielland[7] has listed $\mathring{a}_i$ values for a wide range of ions. When $\mathring{a}_i$ values are not available, we use the following formulae:

$$\begin{aligned} &\text{for small organic ions } \mathring{a}_i = z_i + 4 \\ &\text{for inorganic ions } \mathring{a}_i = 2z_i + 2 \end{aligned} \qquad (5)$$

We also make the assumption that c has the same value for each ion in any given complexation equilibrium (2). By combining this assumption with equations (1), (3) and (4), we obtain the expression

$$\log K'' = \log K' + Af(\mathring{a}_i, (I)^{1/2}) + c(I'' - I')(1 - p - q) \qquad (6)$$

where

$$\begin{aligned} f(\mathring{a}_i, (I)^{1/2}) &= (pz_M + qz_L)^2\left(\frac{(I'')^{1/2}}{1 + B\mathring{a}_{M_pL_q}(I'')^{1/2}} - \frac{(I')^{1/2}}{1 + B\mathring{a}_{M_pL_q}(I')^{1/2}}\right) \\ &\quad - pz_M^2\left(\frac{(I'')^{1/2}}{1 + B\mathring{a}_M(I'')^{1/2}} - \frac{(I')^{1/2}}{1 + B\mathring{a}_M(I')^{1/2}}\right) \\ &\quad - qz_L^2\left(\frac{(I'')^{1/2}}{1 + B\mathring{a}_L(I'')^{1/2}} - \frac{(I')^{1/2}}{1 + B\mathring{a}_L(I')^{1/2}}\right). \end{aligned}$$

Hence the overall value of c for the system concerned may be calculated from equation (6) and used in equation (1) for predicting the formation constant at the required ionic strength of 0.04.

RESULTS AND DISCUSSION

In order to examine the approach described above, several systems were considered for which formation-constant values at several ionic strengths, including infinite dilution, were available.[8,9] These values were taken in pairs and used in equation (6) to determine the system value for c. This value was subsequently used in equation (1) and the infinite-dilution (thermodynamic) formation constant was estimated. The results are presented in Tables 1 and 2 where the literature values of the respective thermodynamic constants are given for comparison. In most cases the predicted constants are sufficiently close to the literature values to be considered satisfactory for our soil model, even when the predictions are made from ionic strengths as high as 2.0 and 3.0.

For many of the systems pertinent to our soil model, the formation constants in the literature have been determined at only one ionic strength. Thus the data used to compile Tables 1 and 2 were used in a

Table 1. Values for c and log K for $I = 0.04$, and estimates of maximum errors calculated for some inorganic complexes from pairs of log K values at different ionic strengths; all literature values are taken from reference 9

second set of tests in which the value $c = -0.10$ was used for every ion in all the systems involved. This is the general value of c recommended by Davies for 1:1 electrolytes.[10] The resulting infinite-dilution formation-constant values obtained are given in Tables 3 and 4. Though the estimated constants in Tables 3 and 4 are not, generally, quite as reliable as those in Tables 1 and 2, they are often good enough for our soil model when better values cannot be obtained. Nevertheless it is evident from a comparison with the calculated c values in Tables 1 and 2 that slightly different c values would in some cases provide greater accuracy, particularly when predictions are made from higher ionic strengths. Tables 1–4 include values of estimated maximum errors in $\log K$. These were obtained by choosing, conservatively, the following values for the maximum error in $\mathring{a}_i$.

$$\text{For } \mathring{a}_i \leqslant 5, \quad \text{error} = 1.5;$$

$$\text{for } 5 < \mathring{a}_i \leqslant 10, \quad \text{error} = 2.0;$$

$$\text{for } 10 < \mathring{a}_i \leqslant 15, \quad \text{error} = 3.0.$$

When equation (6) was used to estimate c, the error in the latter was calculated from the propagation of error formula:[11]

$$s_Q^2 = \left(\frac{\partial Q}{\partial a}\right)^2 s_a^2 + \left(\frac{\partial Q}{\partial b}\right)^2 s_b^2 + \cdots \qquad (7)$$

where $Q = f(a,b\ldots)$, is a quantity which may be calculated from several observed quantities, $a,b,\ldots$, s_Q^2 is the variance of the mean of Q, s_a^2 is the variance of the mean of a, and so forth. Otherwise an error of 0.10 was assumed for c. The errors in the $\log K$ data were assumed to be 0.05 or 0.1, depending on the implied precision in the source tables. Hence, by use of the propagation of error formula, the errors in the predicted formation constants were estimated.

To date, we have calculated nearly 150 formation constants corresponding to an ionic strength of 0.04, for our soil model, by these methods. Most of these have been estimated by the method of Tables 1 and 2, that is, by using literature constants reported for two ionic strengths. Where the literature has contained a constant for only a single ionic strength, we have either put $c = -0.10$, as in Tables 3 and 4, or if c values have been available for a set of related systems, we have guessed a similar value for the system concerned. Errors in the predicted $\log K$ values were estimated as described above for Tables 1–4.

Even though the error estimates were less conservative for the literature $\log K$ values than for the other parameters, the error analysis showed these estimates to be the major contributors to the errors in the predicted constants, for 75% of the species involved, as shown in Table 5. It must be emphasized that the relative contribution of the error in c and the literature $\log K$ values to the calculated $\log K$ increases and decreases respectively, as the difference between the ionic strengths for the known and calculated $\log K$ values increases. Nevertheless these results lend some confidence to the use of equation (1) and the approach to estimating the c parameter.

Clearly the possibility of predicting an equilibrium constant for a species which might be non-existent at the required ionic strength must be borne in mind,[12] particularly when predictions are made for a very high ionic strength from the value for a very low one, or *vice versa*. The unreliability of many published constants is also a serious problem.[12] Hence predictions must be interpreted tentatively. Nevertheless the extended Debye–Hückel expression does provide a

Table 2. Values for c and log K and estimates of maximum errors calculated for some proton equilibria from pairs of log K values at different ionic strengths; all literature values taken from 8 and 9 (Sal = salicylate^{2-}, Mal = malonate^{2-})

PHOTOCHEMICAL ANALYSIS STUDIES—III*

A FLUORIMETRIC AND ULTRAVIOLET SPECTROPHOTOMETRIC STUDY OF THE PHOTOLYSIS OF CHLOROQUINE ON SILICA-GEL THIN LAYERS, AND ITS ANALYTICAL APPLICATION

JEAN-JACQUES AARON† and JOËLLE FIDANZA

Laboratoire de Chimie Physique Organique et d'Analyse Instrumentale, Département de Chimie, Faculté des Sciences, Université de Dakar, Dakar-Fann, Sénégal

(*Received* 5 *May* 1981. *Revised* 23 *September* 1981. *Accepted* 21 *October* 1981)

Summary—The photolysis of chloroquine on silica-gel thin layers has been studied by ultraviolet spectrophotometry and fluorimetry. It has been shown that a reversible photoisomerization of chloroquine takes place and yields a fluorescent photoproduct. The effect of pH, alkali-metal halides, and the eluent system on the fluorescence intensity of chloroquine and its photoproduct was investigated. The fluorescence on silica-gel thin layers is quenched by high concentrations of sodium hydroxide; this is explained in terms of interference of sodium ions in the hydrogen-bonded adsorption of chloroquine on the silica gel. The results have been used to develop a method for determination and separation of chloroquine at the nanogram level. Linear calibration plots are obtained, covering the range between 4 and 10^4 ng.

Chloroquine is one of the antimalarial drugs most widely used in tropical regions for the prevention and treatment of malaria and other related protozoal diseases.[1] Sensitive, selective, and simple analytical techniques are needed for determining trace levels of chloroquine in human tissues, blood, urine, *etc.*, and to study its metabolism.[2]

Spot-tests have been used to detect the presence of chloroquine in urine, but their sensitivity is poor since they allow detection of only a few micrograms of the drug.[3–9] The use of ultraviolet and infrared spectrophotometric methods for determination of chloroquine suffers from spectral overlap by interfering substances in the biological sample, and from the low sensitivity.[10–13] Paper, thin-layer (TLC), and gas (GC) chromatography have mainly been applied to the identification of chloroquine and evaluation of its purity.[2] However, GC has also been used to determine chloroquine at the microgram level,[14–16] and as little as 5 ng can be detected by electron-capture detection.[17]

Fluorimetric methods have been extensively utilized for determination of chloroquine in biological media.[2,18–22] The earliest of these, because of the limitations of the instrumentation available, required photochemical conversion of the chloroquine into a more strongly fluorescent photoproduct,[18] and the procedure was very time-consuming.

Present-day spectrophotofluorimeters are sensitive enough to permit determination of the native fluorescence of chloroquine,[19–22] but require prevention of the photolysis of chloroquine. Recently, a photochemical–fluorimetric procedure was developed by Lukasiewicz and Fitzgerald.[23,24] It consisted of measuring the initial concentration of chloroquine in alkaline solution by digital integration of the decay of its native fluorescence signal or the growth of the fluorescence signal of its photochemical product. This technique is particularly sensitive, with a limit of detection of about 0.1 ng/ml (2.5 ng) of chloroquine,[23,24] but has several disadvantages, such as needing relatively expensive instrumentation and preliminary separation and purification of the chloroquine.

In a preliminary note,[25] we proposed a simple, sensitive and low-cost method for the determination and separation of chloroquine by photolysis *in situ* on a silica-gel thin layer to give a fluorescent photoproduct. Amounts of chloroquine as low as 4 ng can be measured by this method.

In the present paper, we report a detailed investigation, by ultraviolet spectrophotometry and fluorimetry, of the photolysis reaction and the effect of different parameters such as pH, alkali-metal salt concentration, and eluent system, on the analytical performance.

EXPERIMENTAL

Reagents

Aqueous solutions of chloroquine diphosphate ($C_{18}H_{26}ClN_3.2H_3PO_4$) were prepared by successive dilution of a $10^{-3}M$ stock solution.

§ Relative fluorescence intensity.

Analytical-grade absolute ethanol, 1-butanol, acetone, concentrated ammonia solution and methanol were used for the TLC eluents. Distilled water was used for solutions. Analytical-grade sodium and potassium halides were utilized.

Instrumentation

Fluorimetric measurements were performed with a Turner model 111 filter fluorimeter (with 7-60 excitation and 2-A emission filters) equipped with a Camag model 110-710 automatic TLC scanner and a Kipp & Zonen model BD-12 recorder. The sensitivity was adjusted according to the fluorescence intensity.

For the photolysis, a 200-W Osram mercury arc HBO lamp was used in an Oriel model 6137 housing and run by an Oriel model 8500 power supply.

A Beckman model 3600 spectrophotometer was used to obtain ultraviolet absorption spectra, and a Perkin–Elmer model MPF-44B spectrophotofluorimeter for determining excitation and emission fluorescence spectra.

Photochemical–fluorimetric–TLC procedure

Twenty μl of aqueous chloroquine solution were spotted on silica-gel TLC plates with a 50-μl microsyringe. The plates were developed with various solvents (see Table 1), then dried, first with a hot air current, and then in an oven. The spots were detected by their fluorescence in the 254-nm radiation from a mercury lamp.

The dried plates were placed on the Camag TLC scanner, and irradiated for a fixed time with the image of the mercury arc focused on the chloroquine spots. The fluorescence intensity of the spots was then recorded as a function of time by automatic scanning of the plates with the Turner fluorimeter.

The entire procedure, including development of the plates, required about 2 hr, but the photochemical–fluorimetric measurement took less than 10 min. It was possible to examine successively five samples on the same TLC plate.

Procedure for study of the photolysis of chloroquine

After the samples had been put on the plates, dried, and irradiated for various periods of time, the chloroquine zones were scraped from the plates, and mixed well with 4 ml of water. The clear supernatant solutions were decanted, and studied by absorption spectrophotometry and spectrofluorimetry. Initial concentrations of chloroquine during irradiation were $1.9 \times 10^{-3}M$.

RESULTS AND DISCUSSION

Investigation of the photolysis of chloroquine

The photolysis of chloroquine on silica-gel thin layers is characterized by a rapid 3–5-fold increase in the fluorescence intensity, which reaches a maximum after an irradiation time of about 30 sec, and decreases somewhat on further irradiation, to about twice the initial chloroquine signal (Fig. 1).

The absorption spectra of the chloroquine zone at different stages of the photochemical reaction are given in Fig. 2. There are two main bands, one with maxima at 330 and 343 nm, the other with maxima at 222, 237 and 257 nm. Both bands are decreased in intensity by photolysis for 1 min (the longer wavelength band more than the other), and are then increased again on further irradiation for 3 and 6 min respectively. There is no significant shift of the peak wavelength on photolysis.

The fluorescence spectra are given in Fig. 3. The emission maximum is initially at 370 nm, but shifts slightly to 379 nm after irradiation for 1 min, a new and less intense emission band appearing simultaneously at about 470 nm. This 470-nm band remains approximately constant in position and intensity on further irradiation for up to 10 min.

The only photochemical scheme for the photolysis of chloroquine so far presented referred to *alkaline solution*;[23,24] it postulated two successive photochemical steps

$$CQ + h\nu_1 \rightarrow B \qquad (1)$$

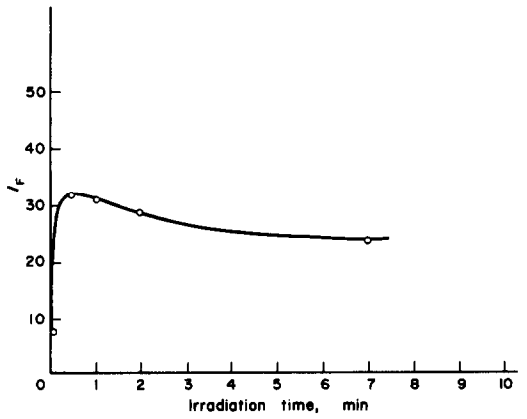

Fig. 1. Photolysis of chloroquine on silica-gel thin-layer: variation of the fluorescence signal intensity (I_F) as a function of the irradiation time. Solvent system A (Table 1). Initial chloroquine concentration 103 ppm.

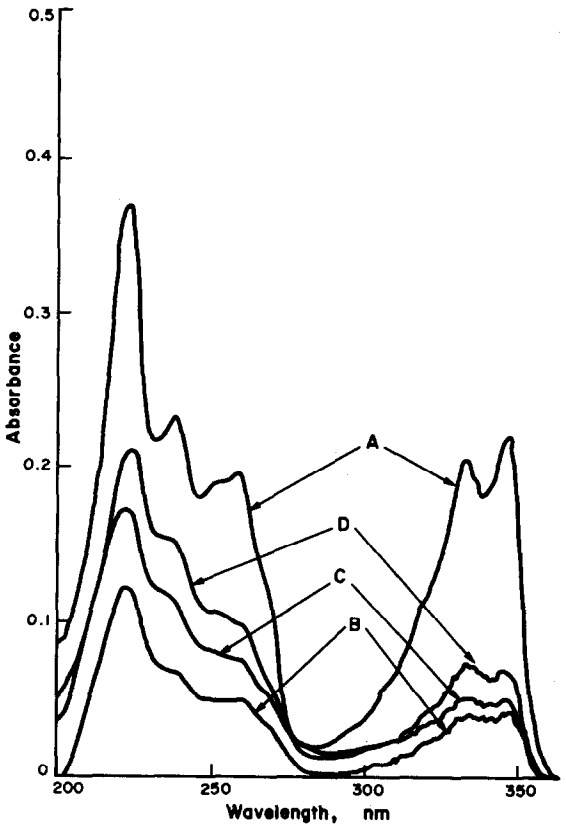

Fig. 2. Ultraviolet absorption spectra of the chloroquine zone from thin-layer chromatograms at different stages of the photochemical reaction. Chloroquine concentration 50 ppm. Photolysis time: curve A, 0; curve B, 1 min; curve C, 3 min; curve D, 6 min.

$$B + h\nu_2 \rightarrow C \qquad (2)$$

in which CQ is chloroquine, B a strongly fluorescent photoproduct and good ultraviolet absorber, and C a non-fluorescent photoproduct and poor ultraviolet absorber.

In our *solid-state photolysis* of chloroquine, the photochemical scheme seems more complicated. The rapid increase of the fluorescence intensity and the appearance of the 470-nm emission band suggest the formation of a fluorescent photoproduct B. However, the fluorescence signal decreases very slowly afterwards and then levels off, indicating that the rate of photolysis of B to C is slowed and that the reverse thermal reaction of B to chloroquine is occurring, in competition with step (2).

$$B \rightarrow CQ + \Delta H \qquad (3)$$

This interpretation is supported by the increased intensity of the ultraviolet absorption bands of chloroquine on extensive photolysis, which indicates an *increase* of its concentration, although step (1) involves a decrease.

Therefore, the primary photochemical process is probably a photoisomerization of chloroquine, a reaction which implies a limited electronic rearrangement in the molecule, and belongs to a class of aromatic heterocycle photoreactions known to be thermally reversible.[26] Step (2) implies a considerable amount of bond cleavage of the photoproduct B to give a poor ultraviolet absorber C,[23,24] the formation of which would not be evidenced in the ultraviolet spectrum because of the presence of the chloroquine yielded by step (3).

pH and salt effects on the fluorescence intensity

We have found that pH has a dramatic effect on the fluorescence intensity of chloroquine and its photoproduct; this effect is strikingly different according to whether the fluorescence measurements are made on a silica-gel thin layer or aqueous solution.

Figure 4, curve A, shows that the fluorescence intensity of chloroquine *in aqueous solution*, is practically constant for pH values between 3 and 6, but increases suddenly at around pH 8.5, and at pH 10–11 is 30 times that at pH 6. This enhancement of the fluorescence in alkaline medium is probably due to dissociation of protonated chloroquine ($pK_a = 9.94$),[2] which would give a higher fluorescence quantum yield. It also explains why earlier researchers chose a pH-10 medium for fluorimetric determination of chloroquine in aqueous solution.[2,18–22]

On the other hand, the fluorescence signal *measured on a silica-gel thin layer* is constant when the initial pH of the chloroquine solution is between 2 and 8, and decreases progressively for initial pH > 8 (Fig. 4, curve B). This behaviour can be related to quenching of the fluorescence of chloroquine adsorbed on silica gel, by the higher concentration of sodium and hydroxide ions due to the alkaline medium. It would indicate that the rate of non-radiative internal conversion of the excited singlet-state of chloroquine, and/or its rate of intersystem crossing to the triplet state, is increased relative to the rate of fluorescence emission. Recently, one of us has observed the existence of a similar quenching phenomenon of the room-temperature phosphorescence of aromatic molecules adsorbed on filter paper, in the presence of high concentrations of sodium hydroxide.[27]

There may be several causes for the quenching of the room-temperature fluorescence of chloroquine on silica gel, in the presence of sodium hydroxide. The interactions between protonated chloroquine molecules and the silica-gel matrix, which should favour the fluorescence emission, may be reduced by the dissociation of the protonated species in alkaline medium. Another, and more probable, cause may be perturbation of the silica-gel thin layer by the sodium and/or hydroxide ions, which would interfere in the adsorption of chloroquine by hydrogen-bonding to the silica-gel substrate. This would result in an increase in the probability of the non-radiative internal conversion process of the excited singlet-state chloroquine.

To decide between these interpretations, we have studied the influence of various alkali-metal halides

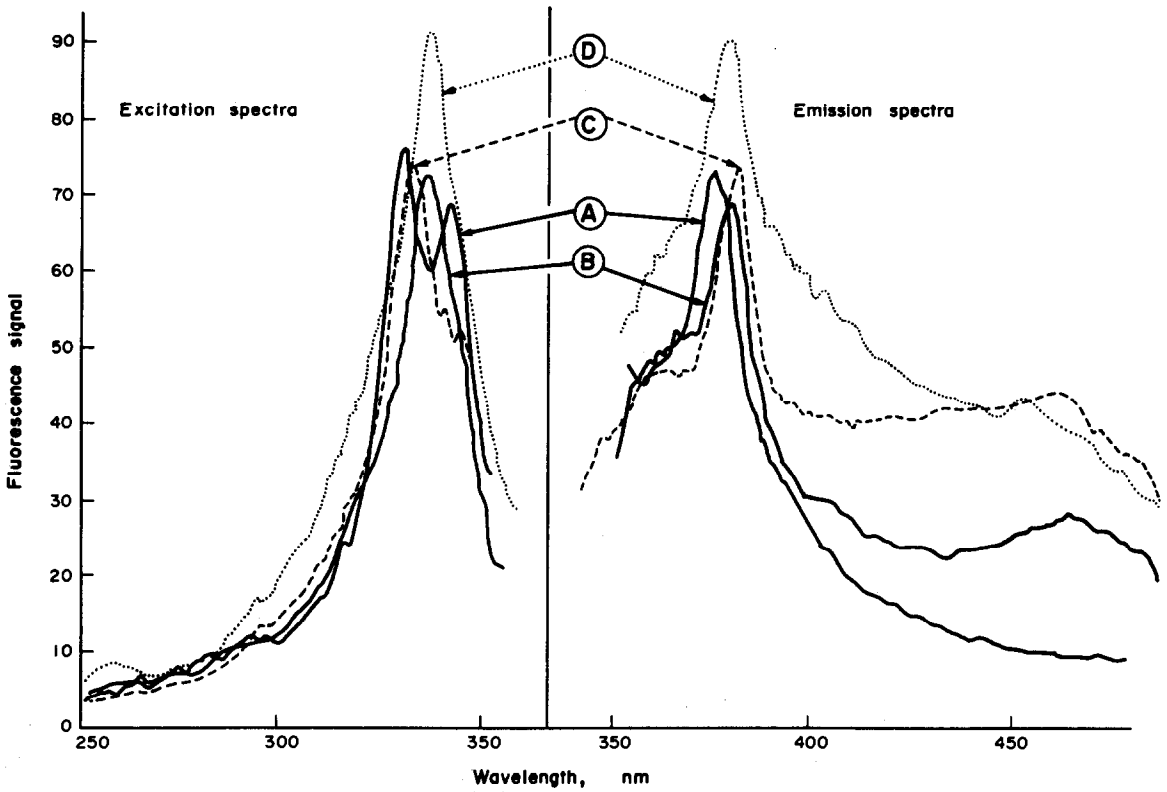

Fig. 3. Fluorescence excitation and emission spectra of the chloroquine zone from thin-layer chromatograms at different stages of the photochemical reaction. Chloroquine concentration 5 ppm. Photolysis time: curve A, 0; curve B, 1 min; curve C, 5 min; curve D, 10 min.

on the fluorescence intensity of chloroquine and its photoproduct. As can be seen in Fig. 5, the fluorescence of chloroquine and its photoproduct decreases significantly in presence of sodium fluoride, chloride or bromide at concentrations between 0.1 and 1*M*. The curves in Fig. 5 show that the quenching of the fluorescence without irradiation is practically the same for all the sodium halides tested, increasing

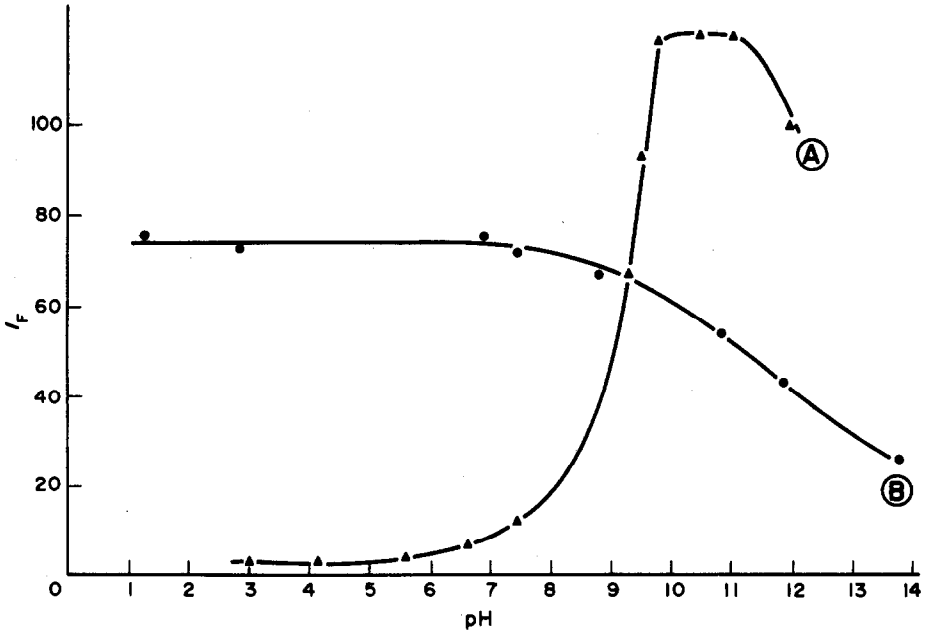

Fig. 4. Effect of pH on the fluorescence intensity (I_F) of chloroquine Curve A, fluorimetric measurement in aqueous solution (scale × 100); chloroquine concentration 10 ppm. Curve B, fluorimetric measurement on silica-gel thin-layer; chloroquine concentration 5 ppm.

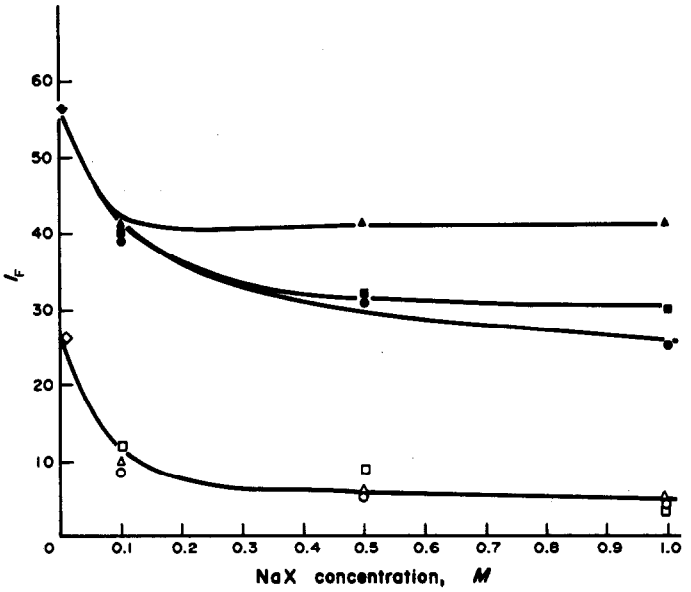

Fig. 5. Quenching effect of sodium halides on the fluorescence intensity of chloroquine and its photoproduct. ◇ ◆: water (pH-7 solution without sodium halide); ○ ●: NaF; △ ▲: NaCl; □ ■: NaBr. Open and filled symbols correspond respectively to irradiation times of 0 and 30 sec.

slightly with sodium halide concentration. The effect after 30-sec irradiation is similar, except for sodium chloride, which has less effect than the others. This suggests that the sodium ions play an important role in interfering in the hydrogen-bonding between chloroquine molecules and the silica-gel substrate. Chloride may produce a specific counter-effect.

This role of the cations is confirmed by quenching experiments performed with varying concentrations of potassium chloride and potassium bromide between 0.1 and 1.0*M*; our results show that the quenching effect due to potassium halides is about twice that of equal concentrations of the corresponding sodium halides. Therefore, the perturbation of the fluorescence by sodium halides constitutes a good model for the quenching effect of sodium hydroxide on the fluorescence intensity of chloroquine adsorbed on silica-gel thin layers.

For the maximum sensitivity of this photochemical–fluorimetric–TLC method, use of a pH-7 aqueous

solution of chloroquine, containing no sodium halides, is optimal.

Effect of the elution solvent system

We have compared the influence of four elution solvent systems of different polarity on the conditions of TLC separation of chloroquine. We summarize our results in Table 1, which shows that the R_f of chloroquine is greater in the solvent systems A and C, which have larger proportions of ethanol and butanol. Furthermore, the fluorescence intensity of chloroquine and of its photoproduct is enhanced with these two solvent systems. However, mixture A has the drawback of a higher background fluorescence signal than that of the other mixtures. Therefore, we propose system C as the best choice.

Photochemical–fluorimetric and fluorimetric calibration curves

We present in Table 2 the statistical characteristics of the calibration curves obtained under different experimental conditions, to establish the effect of irradiation time and the solvent system on the performance of the whole method. In all cases, there is a linear log–log relation between I_F (measured for an irradiation time equal to zero and 30 sec) and the initial concentration of chloroquine (Fig. 6), over about three orders of magnitude of concentration, but the slopes are not unity, indicating non-linearity for non-logarithmic calibration plots. The photochemical–fluorimetric measurements give higher sensitivity.

The correlation coefficients are close to unity, showing that the precision is satisfactory. The precision of the photochemical–fluorimetric calibration curves is greater than that of the simple fluorimetric calibration curves, except in the case of the EtOH–NH_3–H_2O system, which gives a higher background signal, and thus decreases the accuracy.

Detection limits

We also give in Table 2 the detection limits obtained under several experimental conditions. The detection limit is defined here as the amount (or concentration) of compound giving a fluorescence signal equal to three times the fluctuations of the background fluorescence signal.

The detection limits ranged between 4 and 44 ng for the photochemical–fluorimetric measurements, and between 6 and 93 ng for the fluorimetric measurements. Therefore, the detection limit for the photochemical–fluorimetric–TLC method is lower by a factor of up to about 2 than that for the fluorimetric–TLC technique.

Comparison with other analytical methods

The detection limits for chloroquine obtained by our method are close to those given by the most sensitive analytical techniques. For instance, between 5 and 10 ng of chloroquine can be detected by GC with an electron-capture detector,[17] and 2.5 ng with a digital integration photochemical–fluorimetric procedure.[23,24] The linear range and precision of our method are comparable to those of the GC and photochemical–fluorimetric techniques.

Moreover, our TLC–photochemical–fluorimetric method has the advantage of allowing quasi-simultaneous separation of chloroquine from possible impurities and determination of amounts of chloroquine ranging between 4 and 10^4 ng, whereas the classical fluorimetric techniques[18–22] and the digital integration procedure[23,24] require preliminary purification of the chloroquine.

Acknowledgement—We are grateful to Dr. F. Garnier (Laboratoire de Photochimie Solaire, C.N.R.S., Thiais, France) for the opportunity to use the spectrophotofluorimeter in his laboratory.

THE ACCURATE DETERMINATION OF BISMUTH IN LEAD CONCENTRATES AND OTHER NON-FERROUS MATERIALS BY AAS AFTER SEPARATION AND PRECONCENTRATION OF THE BISMUTH WITH MERCAPTOACETIC ACID

D. J. HOWELL and B. R. DOHNT

Analytical Laboratories, The Broken Hill Associated Smelters Pty. Ltd.,
Port Pirie, South Australia

(*Received* 25 *May* 1981. *Revised* 22 *July* 1981. *Accepted* 20 *October* 1981)

Summary—A method for determining 0.0001% and upwards of bismuth in lead, zinc or copper concentrates, metals or alloys and other smelter residues is described. Bismuth is separated from lead, iron and gangue materials with mercaptoacetic acid after reduction of the iron with hydrazine. Large quantities of tin can be removed during the dissolution. An additional separation is made for materials high in copper and/or sulphate. The separated and concentrated bismuth is determined by atomic-absorption spectrometry using the Bi line at 223.1 nm. The proposed method also allows the simultaneous separation and determination of silver.

Bismuth is a penalty impurity in lead concentrates and a quick and accurate determination in diverse materials at levels from 1 μg/g (1 ppm) upwards is important in a lead smelter. A method with high accuracy is also important in certifying primary lead standards for use in calibrating optical emission spectrometers.

Donaldson has reviewed methods for the determination of bismuth in concentrates and non-ferrous alloys and developed an iodide spectrophotometric method[1] involving separations by diethyldithiocarbamate (DDTC) and xanthate extraction, and an AAS method[2] involving DDTC extraction. These methods gave accurate results for use in the CANMET project. However, when accurate results are required in as short a time as possible, these methods take too long.

Donaldson also noted the poor sensitivity of AAS for bismuth and the numerous interferences.[1] Hence, our search for a quicker but equally accurate AAS method involved preconcentration to optimize the bismuth concentration at the measurement stage, and the elimination of interfering elements, particularly iron.

It was found that bismuth could be separated from the bulk of the lead present by precipitation with hydrogen sulphide from a 50% perchloric acid solution. In addition to bismuth, elements such as arsenic, antimony, tellurium, silver, gold, selenium and tin are also removed quantitatively. A small variable quantity of lead does precipitate, but the large bulk of the lead remains in solution.

The internal generation of hydrogen sulphide with thioacetamide was tried. It was very successful with lead alloys containing bismuth, copper, silver, arsenic, antimony *etc.*, and only a very small and constant amount of lead sulphide was precipitated with the impurity elements. However, with concentrates, the amount of lead sulphide precipitated was variable. To minimize or eliminate this variable precipitation of lead an alternative precipitant for bismuth was sought, and mercaptoacetic acid was chosen. It forms precipitates with most elements in the hydrogen sulphide group[3] in acid solution, and also reduces iron(III) to iron(II).

With solutions of the pure metals it was shown that recovery of bismuth was complete with copper as collector provided that the perchloric acid concentration did not exceed 2% v/v and the copper/bismuth ratio was at least 10. Higher acidity caused the precipitate to break up and tend to creep out of the filter paper, with a subsequent loss of bismuth.

Activated carbon was found satisfactory as the collector instead of copper, but a large amount was required: 500 mg for 5 mg of bismuth. However, the presence of copper lowered the amount of carbon required, and a combination of copper and activated carbon gave 100% recovery of bismuth from 2–15% v/v perchloric acid medium. Large amounts of copper or sulphate have an adverse effect, however, and must be separated before the mercaptoacetic acid precipitation.

EXPERIMENTAL

Reagents

Analytical-grade reagents were used throughout.

Standard bismuth solution (1 ml = 1 mg of Bi). Dissolve 0.5000 g of 99.999% pure bismuth metal and 2 g of ammonium fluoride in 50 ml of water plus 50 ml of concentrated nitric acid, and dilute to 500 ml.

Mercaptoacetic acid solution, 10% *v/v*.

Copper perchlorate solution. Dissolve 1 g of copper (Bi less than 1 ppm) in 5 ml of concentrated nitric acid and 10

ml of concentrated (72%) perchloric acid and heat to fuming. Cool. Dilute to 100 ml with water.

Activated carbon: Merck G.R. 2186.

Calibration

To each of six 150-ml beakers add 5 ml of concentrated (72%) perchloric acid. Add from a burette 0, 0.5, 1.0, 2.0, 3.0 and 4.0 ml respectively of standard bismuth solution. Heat to fuming to remove nitric acid and fluoride ion. Cool. Add 20 ml of water and 20 ml of concentrated hydrochloric acid to each and boil. Cool and dilute to volume in 100-ml standard flasks. This gives a series of bismuth standards containing, 0, 5, 10, 20, 30 and 40 mg/l.

Prepare a calibration graph of absorbance (at 223.1 nm) *vs.* bismuth content of standards; use an approximately stoichiometric air–acetylene flame. With a Varian Techtron AA6 instrument use a fuel setting of 2 and an air setting of about 6. Spray the 40-mg/l. standard and adjust the burner height so that the absorbance is about 0.6 (without scale expansion). Spray distilled water and set the zero, then adjust the gas ratio so that the zero remains constant with and without water being sprayed.

Concentrates

Weigh 2–10 g of concentrate containing 0.015–1 mg of bismuth and transfer to a 250-ml beaker. Add 5 ml of water, 5 ml of concentrated hydrochloric acid and, in proportion to sample weight, 10–20 ml of 72% perchloric acid. Heat gently on a hot-plate until the perchloric acid refluxes. Cool.

Note. Care should be taken with the dissolution. Some concentrates are difficult to dissolve and the undissolved material may react violently with the hot concentrated perchloric acid.

If the sample contains less than 50 mg of copper add 5 ml of copper perchlorate solution. Dilute to approximately 50 ml. Add a few boiling chips and 5 ml of 20% hydrazine hydrate solution. Boil. Add a further few drops of hy-

drazine hydrate solution without stirring, to check for complete reduction of iron. The precipitate should be dark green to black. The reddish brown colour of ferric hydroxide shows the need for more hydrazine hydrate to complete the iron reduction. If reduction is complete, stir to redissolve the precipitate. A pale blue solution indicates the presence of sufficient copper. Cool.

Add 5 ml of mercaptoacetic acid solution with stirring. The precipitate should be yellow. If a black precipitate is formed, either the acidity is too low or the copper content is too high (see later), and the precipitate is gelatinous and difficult to filter. Dilute to approximately 150 ml, add 0.3–0.4 g of activated carbon and stir. Filter off on a Whatman No. 2 paper and wash thoroughly with water. Discard the filtrate. Transfer the filter paper to the original beaker, add 10 ml of concentrated nitric acid, 10 ml of 72% perchloric acid, cover with a watch-glass and heat until all the carbon is destroyed. The addition of a few drops of nitric acid while the perchloric acid is refluxing will speed the removal of the carbon. When the carbon has been destroyed heat further to reduce the perchloric acid volume to 5 ml or less. Cool.

Add about 10 ml of water and 5 ml of concentrated hydrochloric acid. Boil. Cool, transfer to a 25-ml standard flask and dilute to mark with water. Mix. Determine bismuth as in the calibration procedure.

Metals and alloys

Dissolve the required mass of sample in 10–20 ml of 72% perchloric acid and 5 ml of concentrated nitric acid. Heat to fumes of perchloric acid. Cool, dilute to 50 ml with water, add copper perchlorate solution if necessary, and proceed from "Add a few boiling chips.....".

Materials high in tin

Large quantities of tin present in white metals and bearing metals, ores, *etc.* may be removed by adding hydrobromic acid during the dissolution process given for metals and alloys.

Materials high in copper and/or sulphate

Large quantities of copper (> 100 mg) present in samples of copper matte, some concentrates, ores and alloys, must be separated before the mercaptoacetic acid precipitation, and so must high sulphate contents (> 10 mg).

After dissolution and fuming is complete as in the dissolution of concentrates or metals and alloys, cool the beaker and add 50 ml of water. Add excess of ammonia and 10 g of ammonium carbonate. Dilute to 250 ml and boil. Collect the precipitate (Whatman No. 2 paper) and wash it well. Discard the filtrate. Return the filter paper to the beaker, add 5 ml of copper perchlorate solution, 20 ml of concentrated nitric acid and 20 ml of 72% perchloric acid. Cover with a watch-glass and heat to perchloric acid fumes. Cool and proceed from "Add a few boiling chips.....".

RESULTS

The method was checked by determinations on concentrates and other smelter materials with various amounts of added bismuth, and also by analysis of standard reference materials. Table 1 shows the recovery of bismuth added to various lead concentrates requiring only simple dissolution, and to smelter materials which require the carbonate separation. Table 2 shows results for standard materials.

DISCUSSION

Determination of other elements in the final analysis solutions showed complete separation from lead, zinc, iron and cadmium. Depending on the efficiency of the hydrobromic acid treatment, 50–100% of the tin and 60–80% of the antimony present are separated. Neither tin nor antimony interferes with the AAS measurements of bismuth at the levels present after this treatment.

There is no loss of bismuth in the carbonate separation; removal of copper and lead is good, and very little lead remains in the final measurement solution.

Silver is also quantitatively precipitated by mercaptoacetic acid along with bismuth and copper and thus this method may be used to determine low levels of silver in the range of materials listed in this paper. Some examples of the determination of silver are given in Table 3.

Further work on the use of this method for silver will be reported in a future paper. The results in Table 3 and recovery experiments indicate that more extensive proving of this method for silver is warranted.

The results for bismuth in the B.C.S. and NBS samples are in good agreement with the certified values. The results for the zinc–tin–copper–lead ore MP-1 are lower than the original recommended value[4] and the revised value[5,6] but in excellent agreement with that of Donaldson[1] (0.022%). Donaldson noted the possibility of bias in the recommended value.

Our value of 0.0022% for the zinc concentrate CZN-1 is lower than the recommended value but in

agreement with Donaldson's results. CZN-1 is a good "clean" concentrate and should not present any difficulties. As our figures for other more complex zinc ores, *e.g.*, MP-1, and our recovery figures for high-zinc plant samples are very satisfactory, we are confident of our result for CZN-1. In the original Canmet certification programme for CZN-1 in 1978 we obtained a mean figure of 0.00235% bismuth, by a straight AAS determination using standards accurately matched with the sample for zinc, lead and iron content.

SPECTROPHOTOFLUORIMETRIC DETERMINATION OF TERBIUM, EUROPIUM AND SAMARIUM WITH PIVALOYLTRIFLUOROACETONE AND TRI-n-OCTYLPHOSPHINE OXIDE IN MICELLAR SOLUTION OF NONA-OXYETHYLENE DODECYL ETHER

TOMITSUGU TAKETATSU

College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka, Japan 810

(*Received* 17 *September* 1981. *Accepted* 18 *October* 1981)

Summary—The fluorescence intensities of terbium, europium and samarium complexes with several β-diketone derivatives in the absence and presence of tri-n-octylphosphine oxide (TOPO) in micellar solution of nona-oxyethylene dodecyl ether (BL-9EX) were examined. The spectrophotofluorimetric determination of terbium (1.5–1500 ng/ml) has been investigated with pivaloyltrifluoroacetone (PTA) and TOPO in 0.5% micellar solution (pH 3.8–4.5) of BL-9EX. The excitation and emission wavelengths were 309 and 542 nm, respectively. Europium and samarium could be determined by a similar method.

In a previous paper, it was reported[1] that thenoyltrifluoroacetone (TTA), tri-n-octylphosphine oxide (TOPO) and their mixed complex with europium or samarium are readily soluble in aqueous solution containing polyoxyethylene iso-octylphenol (Triton X-100), and the fluorescence intensities of these complexes (which are considerably stronger than those of the corresponding mixed complexes extracted into various organic solvents) were applied for the determination of these metal ions. However, the terbium mixed complex did not give any fluorescence. Also, iron[2] and uranium[3] have been spectrophotometrically estimated with TTA and TTA–TOPO, respectively, in micellar solution of nona-oxyethylene dodecyl ether (BL-9EX).

In the present paper, the fluorescence intensities of terbium, europium and samarium complexes with several β-diketone derivatives in the absence and presence of TOPO in micellar solutions of BL-9EX are reported, and a spectrophotofluorimetric method for the determination of terbium with pivaloyltrifluoroacetone (PTA) and TOPO is described, because this mixed complex gives stronger fluorescence intensity than any other of the complexes of various β-diketone derivatives in the absence and the presence of TOPO. The determination of europium and samarium with PTA and TOPO is also described.

EXPERIMENTAL

Reagents

Standard solutions of the metal ions were prepared by dissolving the 99.9% pure oxides (for all rare earths except cerium) or the chloride (cerium and thorium) in dilute hydrochloric acid. The solutions were standardized by titration with EDTA (Xylenol Orange indicator).

Standard solutions of various β-diketone derivatives and TOPO were prepared by dissolving the reagents (Dojin Co.) in aqueous 5% w/v BL-9EX (Nikko Chemical Co.) solution. The mixed reagent solution used for the determination was $5 \times 10^{-3}M$ PTA, $5 \times 10^{-3}M$ TOPO and 5% BL-9EX.

An acetate buffer solution (pH 4.5) was prepared by adding 55 ml of 0.1*M* sodium acetate to 100 ml of 0.1*M* acetic acid.

All other chemicals used were of analytical reagent grade.

Apparatus

A Hitachi 204 spectrophotofluorimeter was used in combination with a high-pressure xenon tube and a Hitachi 200-20 automatic recording spectrophotometer.

Procedure

To a dilute hydrochloric acid solution containing 0.03–30 μg of terbium were added 2 ml of the mixed PTA–TOPO reagent solution and 2 ml of the acetate buffer solution. After adjustment to about pH 3.8–4.5 with dilute hydrochloric acid and sodium hydroxide solution, the solution was transferred to a 20-ml standard flask and made up to volume with water. The fluorescence in a 1-cm quartz cell was measured at apparent excitation and emission wavelengths of 309 and 542 nm, respectively. The procedure was also suitable for the determination of europium (0.03–30 μg) or samarium (3–30 μg) by measurement at apparent and emission wavelengths of 310 and 611 nm, respectively, for europium or 309 and 598 nm for samarium.

RESULTS AND DISCUSSION

The fluorescence intensities of the terbium, europium and samarium complexes of dipivaloylmethane

* Tb, Eu and Sm $1 \times 10^{-5}M$, β-diketone derivatives $1 \times 10^{-4}M$, BL-9EX 0.2%, pH 5.2. The reference intensities (1.00) are those of the Tb–PTA, Eu–TTA and Sm–TTA complexes in the absence of TOPO.

(DPM), trifluoroacetylacetone (TAA), hexafluoroacetylacetone (HFA), PTA, benzoyltrifluoroacetone (BFA), furoyltrifluoroacetone (FTA), TTA and heptafluorobutanoylpivaloylmethane [H(fod)] in the absence and presence of TOPO in 0.5% micellar solutions (pH 5.2) of BL-9EX are given in Table 1. From the results, the following trends can be recognized, though the values do not always represent the intensities at the optimum pH for the complexes: (*i*) most of the fluorescences are intensified by addition of TOPO; (*ii*) the europium and samarium complexes of β-diketone derivatives having R = R′ (R and R′ represent the functional groups at both ends) such as DPM and HFA do not fluoresce; (*iii*) the complexes of terbium with FTA and TTA do not fluoresce, and the TTA complex does not fluoresce even in the presence of TOPO; (*iv*) the mixed complex of terbium with PTA and TOPO gives a stronger fluorescence intensity than any of the other mixed complexes.

Fluorescence spectra

Figures 1–3 show the apparent fluorescence spectra of aqueous 0.5% BL-9EX solutions (pH 3.4) containing the terbium, europium and samarium PTA–TOPO mixed complexes for excitation wavelengths of 309, 310 and 309 nm, respectively. The emission wavelengths of prominent maxima in the spectra are 485, 542 and 582 nm for terbium, 592 and 611 nm for europium and 560, 598 and 643 nm for samarium.

As shown in Figs. 1 and 2, no emission spectra were

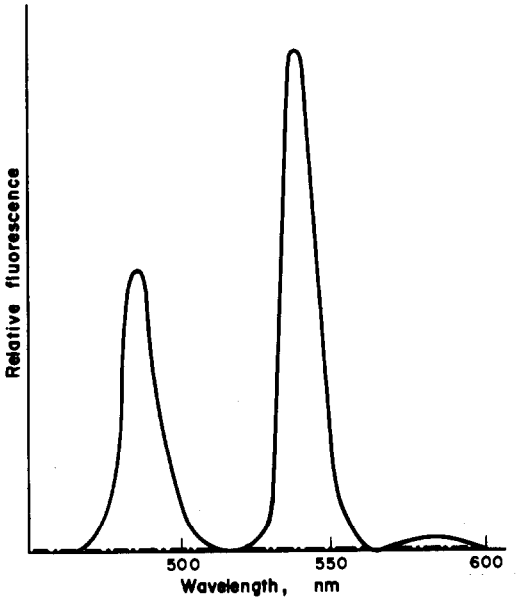

Fig. 1. Apparent fluorescence spectrum of terbium–PTA–TOPO–surfactant system. Tb^{3+} $5 \times 10^{-6}M$, PTA $5 \times 10^{-4}M$, TOPO $5 \times 10^{-4}M$, BL-9EX 0.5%, pH 3.4, fluorescence (——) and blank (— · —).

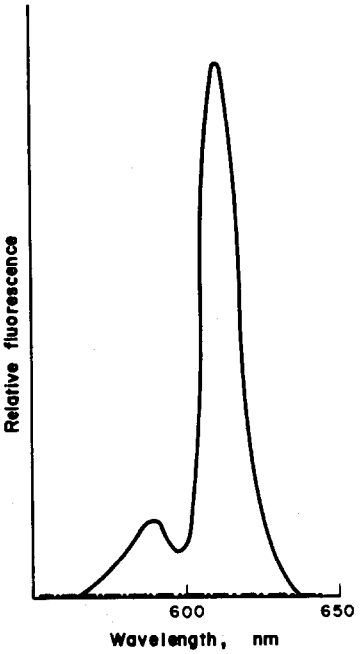

Fig. 2. Apparent fluorescence spectrum of europium–PTA–TOPO–surfactant system. Eu^{3+} $5 \times 10^{-6}M$, PTA $5 \times 10^{-4}M$, TOPO $5 \times 10^{-4}M$, BL-9EX 0.5%, pH 3.4, fluorescence (——) and blank (— — —).

found for the blank in the terbium and europium systems. On the other hand, a band was observed for the blank in the samarium system, as shown in Fig. 3. The detector sensitivity for the samarium system needs to be several hundred times that for the terbium or europium system; because the fluorescence of the samarium system is very much weaker. The band observed for the blank shifts to longer wavelength when the excitation wavelength is shifted in that direction, and this is also observed for solutions containing the surfactant only. Thus, the appearance of the band for the samarium blank system is thought to be due to

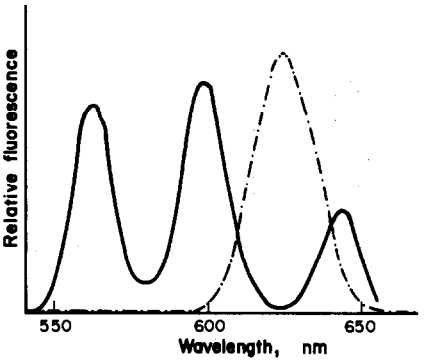

Fig. 3. Apparent fluorescence spectrum of samarium–PTA–TOPO–surfactant system. Sm^{3+} $1 \times 10^{-4}M$, PTA $5 \times 10^{-4}M$, TOPO $5 \times 10^{-4}M$, BL-9EX 0.5%, pH 3.4, fluorescence (——) and blank (— — —).

scattering of the excitation radiation by the micellar surface. However, the band gives practically no interference in the determination of samarium.

Effect of reaction variables

The variation in the fluorescence intensity at 542 nm for the terbium PTA–TOPO mixed complex was investigated as a function of pH, the intensity was constant over the pH range 3.1–4.6. The variation in intensity was also examined as a function of mole ratio of PTA to terbium (2.11×10^{-4} mmole) in the presence of a constant amount of TOPO (4.00×10^{-2} mmole) and as a function of mole ratio of TOPO to terbium in the presence of a constant amount of PTA (4.33×10^{-2} mmole). The intensities were almost constant over the mole-ratio range 100–500 for PTA:Tb and 100–1000 for TOPO:Tb. The variation in intensity was investigated as a function of the concentration of BL-9EX in the presence of excess of PTA and TOPO. Concentrations of BL-9EX in the 0.1–1.0% w/v range gave constant intensity.

(*i*) $1 \times 10^{-4}M$ TTA in carbon tetrachloride (*ii*) $1 \times 10^{-4}M$ TTA in aqueous 0.5% BL-9EX solution (*iii*) $1 \times 10^{-4}M$ PTA in carbon tetrachloride (*iv*) $1 \times 10^{-4}M$ PTA in aqueous 0.5% BL-9EX solution.

Calibration graph

The fluorescence intensity was a linear function of concentration in the range 10–1500 ng/ml for terbium and europium, and 150–1500 ng/ml for samarium.

Effects of diverse metals

The effects of scandium, other rare earths and thorium on the fluorescence intensity of terbium under the optimum conditions were investigated. With 16.8-ng/ml terbium solution, 10-fold concentrations of scandium, lanthanum, gadolinium, dysprosium, lutetium and thorium did not interfere. However, larger concentrations of these metals, especially the rare earths absorbing in the ultraviolet region, interfered. Therefore the standard-addition method was used when such metals were present. It was tested for the analysis of synthetic mixtures of rare earth and thorium oxides, and for mixed rare earth oxides obtained from xenotime. The results in Table 2 shows that the method is suitable when large amounts of the interfering metals are present.

Composition of the mixed complex

The continuous variation method was used for finding the composition of the terbium mixed complex, one ligand being added in large excess, and the mole fraction of the other (with respect to terbium) being varied. The results showed that the combining ratios of Tb:PTA and Tb:TOPO were 1:3 and 1:2, respectively, the composition of the mixed complex thus being $Tb(PTA)_3(TOPO)_2$.

Comparison with the solvent extraction method

Table 3 shows the difference between the present method and the solvent extraction method. With PTA and TOPO concentrations in carbon tetrachloride equal to those of the present method (both $5 \times 10^{-4}M$), terbium is not completely extracted. Though the degree of extraction of terbium increases with increasing concentration of PTA or TOPO, the fluorescence intensity decreases, apparently as a function of the absorption intensity of PTA in the ultraviolet region. Figure 4 shows the absorption spectra of PTA and TTA in BL-9EX solution and carbon tetrachloride. For both reagents in aqueous solution the absorption bands are at shorter wavelengths than for the reagents in the organic medium. The absorption band of PTA in the aqueous solution is especially weak. There is therefore a much lower inner filter effect from the excess of reagents when the aqueous medium is used, since the excitation wavelength used for the complexes is about 310 nm.

FLUOROMETRIC DETERMINATION OF HYDRAZINE AND AMMONIA SEPARATELY OR IN MIXTURES

NEIL D. DANIELSON* and CHRISTINE M. CONROY
Department of Chemistry, Miami University, Oxford, Ohio 45056, U.S.A.

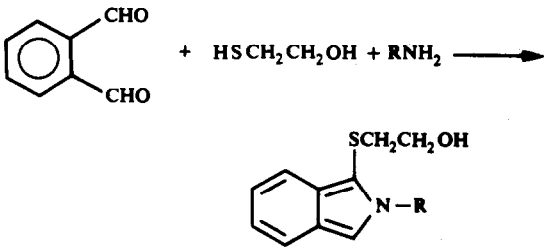
(*Received* 16 *June* 1981. *Revised* 7 *September* 1981. *Accepted* 15 *October* 1981)

Summary—Hydrazine and ammonia are often added to boiler water to inhibit corrosion. The reagents *o*-phthalaldehyde and mercaptoethanol have been found to form derivatives with hydrazine and ammonia which can be determined by fluorimetry. Because the optimum pH values for formation of the hydrazine and ammonia derivatives were different, analysis of mixtures of the two components without prior separation was possible. Simulated wet-lay-up boiler water samples containing 5–200-μg/ml levels of hydrazine and ammonia have been analysed with an average relative error of about 10%.

Hydrazine is an important industrial chemical, used as a starting material for the synthesis of polymers, blowing agents, pesticides, and pharmaceuticals.[1] Hydrazine is also commonly added to steam-boiler water to act as a reducing agent for dissolved oxygen and metal oxides. Because its reaction products are nitrogen and water, hydrazine is the reagent of choice for inhibiting corrosion or scale build-up in boilers used by electric utility companies. Generally this protective process is carried out at alkaline pH with a mixture of hydrazine and ammonia at the ppm level, under two different circumstances. One of these is the addition of ammonia and hydrazine at the 0.1–10 μg/ml level to boiler feed-water during the time the boiler is generating steam. The other is when the boiler is idle for short periods, owing to low production requirements, plant break-downs and other events, and higher concentrations (10–200 μg/ml for ammonia and 30–300 μg/ml for hydrazine) are then generally necessary, depending on the length of down-time.[2] To minimize the possibility of any boiler degradation, both additives must be determined periodically during this period of boiler idleness. In addition, the determination of hydrazine itself is of considerable importance because it is highly toxic and a suspected carcinogen.[1]

A variety of analytical methods for the determination of either hydrazine or ammonia have been developed and reviewed.[3,4] The colorimetric procedure for hydrazine after reaction with *p*-dimethylaminobenzaldehyde[5] and the potentiometric method for ammonia[6] are probably the two most widely accepted. However, methods for the determination of small quantities of hydrazine and ammonia in mixtures are quite uncommon. An oxidation-titration method using bromide[7] for the analysis of hydrazine–ammonia mixtures is simple and inexpensive, but generally was only useful down to mg quantities. Knox and McHale[8] developed a mass spectrometric method for hydrazine, ammonia, and other gases, that required expensive or specialized equipment, which limited its use.

The use of the reaction involving *o*-phthalaldehyde (OPA) and mercaptoethanol (MCE) for forming fluorescent derivatives of primary amines has proved useful for the trace determination of amino-acids,[9] peptides[10] and proteins.[11]



The product of the reaction is an *N*-substituted 1-(2-hydroxyethyl)thio isoindole, as proposed by Simons and Johnson.[12,13]

However, this reaction has not been previously applied to the determination of simple amines such as hydrazine and ammonia. We have found this method to be useful for the fluorometric determination of both hydrazine and ammonia at the ppm level. Mixtures of hydrazine and ammonia typical of boiler wet lay-up water samples can also be analysed without the need for a separation step.

EXPERIMENTAL

Reagents

Desiccated hydrazine sulphate and dried ammonium sulphate were used to prepare aqueous 500-μg/ml hydrazine and ammonium ion stock solutions, a few drops of concentrated sulphuric acid being incorporated in the ammonium ion solution. Appropriate aliquots of these stock solutions were used to prepare the sample mixtures. Stock solutions of OPA and MCE were prepared by dissolving 0.03 g of OPA in 25 ml of methanol and by diluting 0.4 ml of MCE

to 25 ml with methoxyethanol. The use of methoxyethanol instead of methanol as a solvent for MCE increased the fluorescence of the ammonia and hydrazine derivatives approximately 1.3 and 1.5 times, respectively. The various 0.1*M* buffer solutions were all prepared with sodium dihydrogen phosphate and adjusted to the desired pH with either sodium hydroxide or sulphuric acid. Each buffer solution had 2% v/v of n-butanol added as a preservative to prevent mould growth. All stock solutions were stored in the dark. All of the alcohol solvents used in the stock or buffer solutions were HPLC grade (Burdick and Jackson). Demineralized distilled water was used for all solutions.

Apparatus

An Aminco SPF-125 scanning spectrofluorimeter (American Instrument Co.) was used for all fluorescence measurements.

Procedure

The OPA and MCE stock solution (1 ml of each) were mixed with 2 ml of the desired buffer solution in a glass-stoppered 14 × 150 mm test-tube. An additional 1 ml of water was added for the assay of ammonia to maintain clarity of the solution at alkaline pH. After addition of an appropriate volume of either the hydrazine or ammonium ion stock solution with a 200-μl microburette (Gilmont, precision ± 0.2 μl), the solution was transferred to a cuvette and allowed to react in the fluorimeter cell compartment for a predetermined time before measurement. A summary of the optimum conditions is presented in Table 1.

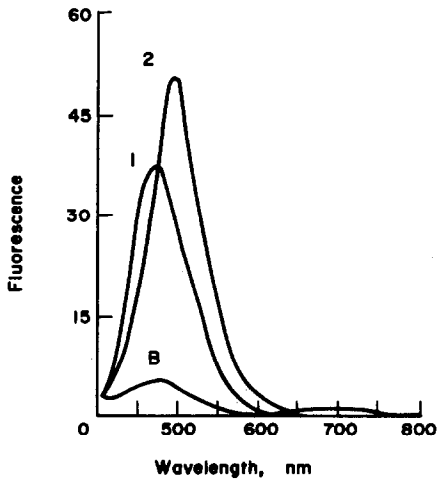

Fig. 1. Fluorescence emission spectra (uncorrected) for reactions involving OPA–MCE–ammonia (1), OPA–MCE–hydrazine (2), and the blank (OPA–MCE at pH 4, B). Excitation wavelengths, slit-widths, and other reaction conditions as in Table 1.

RESULTS AND DISCUSSION

Fluorescence of reaction products

Both the OPA–MCE–hydrazine and the OPA–MCE–ammonia reaction products had optimum excitation wavelengths at about 340 nm, consistent with those found in previous work involving primary alkyl amines.[13] The emission spectra for these reaction products as well as the blank are shown in Fig. 1. The optimum emission wavelength of 465 nm (Peak 1) for the ammonia product was also consistent with previous work.[13] The emission maximum for hydrazine occurred at slightly longer wavelength at about 495 nm (Peak 2). Only a small fluorescence signal at about 465 nm was found for the blank (Peak B). The optimum reaction times for ammonia and hydrazine were 8 and 30 min respectively. For hydrazine at about the 1-μg/ml level, the fluorescence intensity increased by approximately 8 units every 5 min until levelling off after 30 min and remained essentially constant for at least another 20 min. The hydrazine reaction took about 3 times as long if performed outside the fluorimeter cell compartment. The reaction time for ammonia was shorter, probably because of the higher pH. No fluorescence was observed for either ammonia or hydrazine when reacted with OPA in the absence of MCE. In addition, fluorescence was not observed upon reaction of hydrazine and salicylaldehyde with or without MCE present. Reaction times and fluorescence intensities observed for glycine were similar to those found for hydrazine and ammonia under the optimum conditions stated in Table 1 for each analyte. These results indicate that the fluorescent reaction product of OPA and MCE with either hydrazine or ammonia is likely to be an isoindole compound analogous to that found for other primary amines.

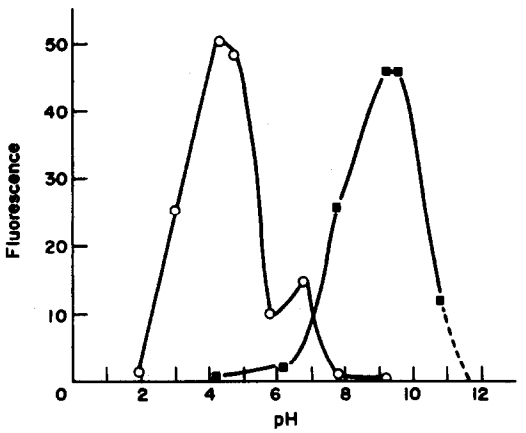

Fig. 2. Effect of pH on the fluorescence intensity of hydrazine (open circles) and ammonia (solid squares). The pH values are for the final solution, not the buffer. Other conditions as stated in Table 1.

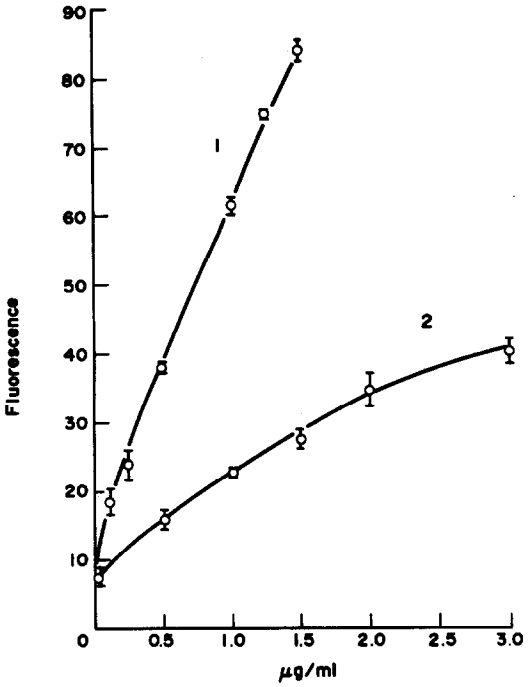

Fig. 3. Response curves for hydrazine (1) and ammonia (2). Conditions as stated in Table 1. Error bars indicate the range (n = 2 for hydrazine, n = 3 for ammonia).

Effect of pH on fluorescence

Figure 2 indicates a significant difference between the optimal pH values for the reaction of the two analytes. Maximum fluorescence for ammonia occurred when the reaction was done at pH 9–10, similarly to the reaction with amino-acids.[14] The drop in fluorescence at very high pH observed in this study was in agreement with the observation[11] that in protein analysis the background fluorescence due to ammonia could be quenched by addition of 1*M* sodium hydroxide. The optimum pH range for hydrazine was about 4–5. Essentially no fluorescence was observed for hydrazine when the reaction was done at alkaline pH. This is probably because the reaction between OPA and hydrazine at alkaline pH will produce phthalazine,[15] which is non-fluorescent. In addition, the stability of hydrazine is lower in basic solutions, owing to its greater reducing power.[1]

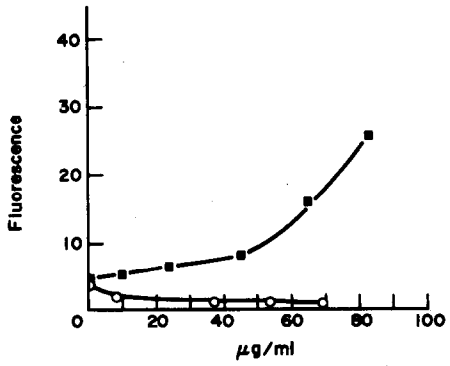

Fig. 4. Signals for of hydrazine (open circles) ammonia (solid squares), each measured under the conditions recommended for the other.

Calibration graphs

The analytical utility of the reaction was investigated by determining the response curves for hydrazine and ammonia as shown in Fig. 3. Both plots were somewhat non-linear. The fluorescence measurements were quite reproducible, as shown by an average standard deviation of ±1 fluorescence unit for both calibration curves. The detection limits for hydrazine and ammonia respectively were about 0.1 and 0.5 μg/ml. The lower sensitivity for the ammonia curve was due to the smaller slit-widths used in the measurements. The smaller slits helped to reduce the fluorescence background and minimized any interference of high concentrations of ammonia with the hydrazine determinations. Actually the molar fluorescence intensity of the ammonia derivative was about twice that of the hydrazine derivative when the same slit-width (4 mm) was used.

Interference study

The feasibility of measuring hydrazine and ammonia without serious interference was examined before mixtures were analysed. Figure 4 illustrates the results of a study in which hydrazine was measured at pH 9 under the instrumental conditions for ammonia determination and ammonia was measured at pH 4 with the instrumental settings used for hydrazine (Table 1). Because of the high pH, hydrazine produced negligible fluorescence even at high concentration. The slight quenching effect appearing at high hydrazine levels should not present a problem. Ammonia at concentrations above about 25 μg/ml could

interfere in measurement of hydrazine. However, because the sample volumes used were usually less than 0.5 ml, the dilution with reagent minimized any such interference. Interference from ammonia would only be a problem with mixtures having low hydrazine concentratration and very high ammonia content. Since the hydrazine and ammonia concentrations are generally maintained at levels below 300 μg/ml in the types of sample concerned, interference effects should not be a problem with real samples.

Hydrazine–ammonia sample mixtures

Several mixtures of hydrazine and ammonia were prepared in distilled water to simulate boiler wet-lay-up water samples. No other amines are normally found in power station water.[16] Analytical results obtained for these mixtures under the conditions in Table 1 are shown in Table 2. The average relative standard deviation was about 7% and the average relative error about 10%. These values are within the 2–10% range of precision and accuracy considered characteristic of fluorescence measurements.[17] Possible sources of interference in this method would be primary amines and/or alkylhydrazines. Primary amines would interfere with the determination of ammonia, but at low levels, would not affect the hydrazine measurement. Secondary or tertiary amines do not form fluorescent derivatives with OPA and MCE.[9] Hydrazines such as monomethylhydrazine, *asym*-dimethylhydrazine and phenylhydrazine would produce fluorescence signals when mixed with OPA and MCE in slightly acidic medium, but like hydrazine gave negligible fluorescence in alkaline media. In any case, the presence of alkylhydrazines in power-station water would be unlikely. It is expected that the method could easily be adapted for the analysis of other hydrazine–primary amine binary mixtures.

SHORT COMMUNICATIONS

DETERMINATION OF TUNGSTEN IN COMPLEX SULPHIDE ORE CONCENTRATES

V. S. SASTRI
Mineral Sciences Laboratories, CANMET, 552 Booth Street, Ottawa, Ontario, Canada

(*Received* 2 *June* 1981. *Accepted* 4 *November* 1981)

Summary—Determination of tungsten as the thiocyanato complex after separation as the α-benzoin oximate complex has been satisfactorily applied to a standard steel and a complex sulphide ore concentrate containing tungsten associated with considerable amounts of Mo, Cu, Bi, As, Pb, Zn, Fe and Sn.

Tungsten minerals that occur in sufficient abundance to be of economic significance can be divided into two groups, namely the wolframite group and the scheelite group. The three important minerals in the wolframite group are ferberite ($FeWO_4$), huebnerite ($MnWO_4$) and wolframite [(Fe, Mn)WO_4]. The tungsten minerals often occur with cassiterite, molybdenite, chalcopyrite and pyrite. This association has a high-temperature genesis.[1] The bulk sulphide concentrate used in the present study contains major amounts of sphalerite (ZnS), arsenopyrite (FeAsS) and molybdenite (MoS_2), chalcopyrite ($CuFeS_2$), galena (PbS) and quartz in intermediate amounts, and stannite (Cu_2FeSnS_4), tennantite [$(CuFe)_{12}As_4S_{13}$], bismuthinite (Bi_2S_3), pyrite (FeS_2), wolframite [(Fe, Mn)WO_4], rutile (TiO_2), cassiterite (SnO_2) and bismuth in minor amounts.

Sodium tungstate solution obtained by the decomposition of tungsten ore concentrates contains many impurities present in the original ore, and these impurities must be reduced to acceptable levels. The most frequently encountered impurities are silicon, phosphorus, arsenic and molybdenum species. Silicon species are removed by addition of aluminium and magnesium sulphates and raising the pH to 9.0–9.5. Molybdenum is precipitated as molybdenum trisulphide. Liquid ion-exchange extraction has been used to extract tungsten from sodium tungstate solution, but this method results in the co-extraction of impurities such as molybdenum, silicon, phosphorus and arsenic.

The tungsten ore concentrate used in the present study is associated with significant amounts of Mo, Cu, Bi, As, Pb, Zn, Fe, Sn and sulphide. Tungsten can be isolated from the other elements present by co-precipitation with ferric hydroxide[2] or manganese dioxide,[3] but these methods are tedious and time-consuming. Jeffery[4] isolated the element as the α-benzoin oximate complex in the course of determination of tungsten and molybdenum in silicate rocks. Cogger[5] developed a spectrophotometric method for the determination of tungsten in geological materials. A brief study has therefore been undertaken to develop a procedure for the analysis of complex tungsten ores by solvent-extraction separation of tungsten as the α-benzoin oximate complex and subsequent spectrophotometric determination, on the basis of Jeffery's and Cogger's work,[4,5] and the results obtained are reported in this paper.

EXPERIMENTAL

Dissolution of ore concentrate

Weigh a suitable amount of the ore (0.5 g) into a Teflon beaker, treat it with 10 ml of 60% perchloric acid, 10 ml of concentrated nitric acid and 10 ml of concentrated hydrofluoric acid and boil for half an hour. Evaporate to perchloric acid fumes. Add 5 ml of concentrated hydrofluoric acid, 5 ml of concentrated hydrobromic acid and 15 ml of concentrated hydrochloric acid to the residue and evaporate to perchloric acid fumes. Repeat the treatment with the three hydrohalic acids and the evaporation. Add 10 ml of concentrated hydrochloric acid and evaporate the solution to about 5 ml. Add 25 ml of concentrated hydrochloric acid, heat the contents of the beaker and then cool. Transfer the contents of the beaker into a 50-ml centrifuge tube and centrifuge at 4000 rpm for 5 min. Transfer the supernatant liquid to a 100-ml standard flask. Wash the residue with 25 ml of concentrated hydrochloric acid, centrifuge for 5 min at 4000 rpm and transfer the supernatant liquid to the 100-ml flask. Repeat the washing and transfer and finally dilute the solution in the flask to volume with 6*M* hydrochloric acid. This is solution *A*.

Transfer the residue into a zirconium crucible with water and evaporate the contents of the crucible to dryness. Fuse the residue with a minimum amount of 4:1 w/w sodium peroxide and sodium carbonate mixture. Cool, leach the solidified melt with 50 ml of water, boil for 30 min and

* Average value of four trials. The spread of the replicates was ± 0.02.

filter (Whatman No. 42 paper). Dilute the filtrate to volume in a 100-ml standard flask with distilled water. This is solution *B*.

Separation of tungsten as α-benzoin oximate

Transfer 2 ml each of solutions *A* and *B* into a 125-ml separatory funnel and add 4 ml of water followed by 27 ml of 1.5*M* hydrochloric acid. Extract the tungsten with four 10-ml portions of 0.15% α-benzoin oxime solution in chloroform. Shake the combined extracts with 20 ml of 3*M* hydrochloric acid, transfer the organic phase into a 125-ml conical flask and evaporate it to 2–3 ml. This procedure extracts tungsten as the oximate complex along with molybdenum.[4]

Spectrophotometric determination of tungsten

Add 15 ml of concentrated hydrochloric acid and 4 ml of stannous chloride solution (15% w/v in concentrated hydrochloric acid) to the tungsten oximate solution and boil the mixture gently for 5 min. Cool the solution in an ice-bath. Transfer the solution to a 125-ml separatory funnel and use two 10-ml portions of 6*M* hydrochloric acid to rinse the flask. Add 1 ml of 0.025*M* tetraphenylarsonium chloride followed by 3 ml of 2*M* potassium thiocyanate and swirl the solution. Extract the tetraphenylarsonium tungsten(V) thiocyanato complex with three 10-ml portions of chloroform, adding 0.2 ml of tetraphenylarsonium chloride solution before the second and the third extractions. Filter the organic phase (9-cm Whatman No. 42 paper), wash the filter with chloroform and make up the filtrate and washings to volume in a 25-ml standard flask. Protect the chloroform extract from direct sunlight. Measure the absorbance of the thiocyanato complex at 405 nm against chloroform, in 1-cm cells.

Prepare the calibration curve with standard sodium tungstate solution. Beer's law holds up to 50 μg of tungsten. This procedure is a modification of the one in the literature.[5]

RESULTS AND DISCUSSION

Isolation of tungsten as the oximate complex followed by extraction with chloroform has been applied in the separation of tungsten from the U.S. National Bureau of Standards sample No. 134, which contains Mn, P, S, Si, Cr, V and Mo in addition to tungsten. The results (1.87, 1.89, 1.76, 1.72, 1.77, 1.78%, mean 1.80%, s.d. 0.07%; certified value 1.82%) show that this method for separation and determination of tungsten is acceptable. The method has also been applied to tungsten ore concentrates containing significant amounts of Mo, Cu, Bi, As, Pb, Zn, Fe and Sn as sulphides, and the results obtained are given in Table 1. The method is seen to be applicable to complex ores of this kind.

It should be noted that although some molybdenum is co-extracted with tungsten, it is tolerated in the spectrophotometric determination of tungsten.[5]

SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF ANILINE BY DIAZOTIZATION, COUPLING WITH *N*-(1-NAPHTHYL)ETHYLENEDIAMINE AND EXTRACTION

GEORGE NORWITZ and PETER N. KELIHER*
Chemistry Department, Villanova University, Villanova, PA 19085, U.S.A.

(*Received* 2 *October* 1981. *Accepted* 18 *October* 1981)

Summary—A spectrophotometric procedure is proposed for the determination of trace amounts of aniline by diazotization, coupling with *N*-(1-naphthyl)ethylenediamine in sodium acetate medium, extraction of the yellow dye with chloroform, and conversion into a reddish purple dye. Two methods are available for the conversion. In the first, the chloroform extract is shaken with hydrochloric acid and the dye is converted and transferred into the aqueous phase. In the other, the chloroform extract is evaporated to dryness and the residue is dissolved in glacial acetic acid. The hydrochloric acid extraction method is the more rapid. The minimum detection limits for the two methods are 0.8 and 0.6 μg/ml respectively. Both methods show satisfactory accuracy and precision.

Aniline can be determined spectrophotometrically by diazotization, followed by coupling with *N*-(1-naphthyl)ethylenediamine (**I**) in an acidic medium to produce a reddish purple dye.[1] The method has good accuracy and precision but is not readily adaptable to the determination of traces. Brodie and Axelrod[2,3] proposed a method for the determination of traces of aniline in biological materials (blood and urine) that involves diazotization, coupling with I, and extraction. In this method the aniline is extracted from up to 5 ml of sample with isoamyl alcohol–benzene mixture and is back-extracted into 5 ml of 0.1*M* hydrochloric acid. After the usual treatment with sodium nitrite and ammonium sulphamate, 1 ml of sodium acetate solution (50%) and 0.5 ml of I solution (0.2%) are added, the sample is allowed to stand for 20 min, and 0.5 ml of 6*M* sodium hydroxide is added. The dye is extracted with 0.5 ml of isoamyl alcohol–benzene mixture, 0.3 ml of the organic layer is treated with 0.05 ml of 25% solution of trichloroacetic acid in ethylene chloride, and the absorbance of the reddish purple dye is measured at 570 nm. Brodie and Axelrod did not make a comprehensive investigation of the factors affecting the method and did not report that the colour of the dye produced by the coupling in sodium acetate medium was yellow (probably because the colour is barely perceptible with minute amounts of aniline). It is the purpose of the present paper to study these factors in the determination of traces of aniline by this method, and develop an improved method applicable to the determination of minute amounts of aniline in a large volume of solution (500 ml).

* Author to whom correspondence should be addressed.

EXPERIMENTAL

Reagents

All chemicals used were reagent grade.

Standard aniline solution No. 1 (1 ml = 10.00 mg of aniline). Dissolve 1.000 g of aniline in ethanol and dilute to volume in a 100-ml standard flask with ethanol. Prepare fresh weekly.

Standard aniline solution No. 2 (1 ml = 0.50 mg of aniline). Dilute a 5-ml aliquot of standard aniline solution No. 1 to volume in a 100-ml standard flask with water. Prepare fresh every 3 days.

Standard aniline solution No. 3 (1 ml = 2.5 μg of aniline). Dilute a 5 ml aliquot of standard aniline solution No. 2 to volume in a 1-litre standard flask with water. Prepare fresh daily.

Sodium nitrite solution (1%) and sulphamic acid solution (3%). Prepare fresh every 3 weeks.

Coupling reagent solution (0.75%). Add 0.375 g of *N*-(1-naphthyl)ethylenediamine dihydrochloride to about 45 ml of water with stirring and dilute to 50 ml. Prepare fresh every 4 days.

Preparation of calibration graphs

Hydrochloric acid method. Transfer 0.00, 1.50, 3.00, 4.00 and 5.00 ml of standard aniline solution No. 3 to 600-ml beakers and dilute to about 500 ml with water. Add 5 ml of 1*M* hydrochloric acid and 10 ml of sodium nitrite solution (1%), mix, and allow to stand for 5 min. Add 10 ml of sulphamic acid solution (3%) and allow to stand for 10 min. Add 10 g of anhydrous sodium acetate and stir to dissolve. Add 5 ml of coupling reagent solution and allow to stand for 60 min or more. Wash into a 1-litre separatory funnel, add 25 ml of chloroform, shake for about 5 sec, vent, and shake vigorously for 2 min. Transfer the chloroform layer to a dry 125-ml separatory funnel. Extract twice more with 10-ml portions of chloroform, and combine the extracts in the 125-ml separatory funnel. Add 10.0 ml of 0.2*M* hydrochloric acid (measured with a pipette) to the 125-ml separatory funnel and shake vigorously for 2 min. Drain off and discard the chloroform layer. Swirl the aqueous layer and drain off and discard about 2 ml. Drain off the remaining aqueous layer into a dry 50-ml beaker. Measure the absorbance at 555 nm against water, deduct

the blank, and plot absorbance against μg of aniline per 500 ml of solution.

Acetic acid method. Transfer 0.00, 1.00, 2.00, 3.00 and 3.50 ml of standard aniline solution No. 3 to 600-ml beakers and proceed as described in the hydrochloric acid method to the point at which the yellow dye has been extracted with chloroform, but combine the three chloroform extracts in 50-ml beakers. Place the beakers on a steam-bath and evaporate to dryness, but do not heat much further. Add 5.0 ml of glacial acid to each by pipette, swirl to dissolve the residues, and cover the beakers with watch-glasses. Let cool, then measure the absorbance at 555 nm against glacial acetic acid, deduct the blank, and plot absorbance against μg of aniline per 500 ml of solution.

Procedure

Transfer 500 ml of the sample (or a suitable smaller portion diluted to about 500 ml) to a 600-ml beaker. This volume should contain not more than 12 μg of aniline if the hydrochloric acid method is to be used, or 9 μg for the acetic acid method. Proceed as described for the calibration graphs.

RESULTS AND DISCUSSION

Formation of the yellow dye

The yellow dye was studied by diazotizing aniline in hydrochloric acid medium, treating with sulphamic acid, adding sodium acetate and coupling reagent, and measuring the absorbance at 468 nm (the wavelength of maximum absorbance). The effect of the amount of sodium acetate was investigated with 200-μg portions of aniline (4.00 ml of a tenfold dilution of aniline solution No. 2). The solutions were diluted to about 80 ml in 100-ml standard flasks and let stand for 5 min after addition of 1.0 ml of 1*M* hydrochloric acid and 1.0 ml of 1% sodium nitrite solution to each; then 2 ml of 3% sulphamic acid solution were added and the solutions were allowed to stand for 10 min. Various amounts of sodium acetate and 1.0 ml of 0.75% reagent solution were added, the solutions were diluted to the mark, and the absorbances measured at 468 nm. The results obtained (Table 1) show that the intensity of the yellow colour and the time required for its development are related to the amount of sodium acetate added. With 10 g of sodium acetate per 100 ml (which produced a pH of 6.7), the colour developed fully in 10 min. However, the use of this amount of sodium acetate seems wasteful, so the use of 2 g (which produces a pH of 5.9) and the measurement of the yellow colour after 30 min is recommended. A calibration graph prepared with 0–5 ml of the 50-μg/ml aniline solution and 2 g of sodium acetate per 100 ml was found to obey Beer's law. The method is about half as sensitive (on the basis of mg of aniline per ml) as the conventional method in which the reddish purple colour is produced by coupling in hydrochloric or sulphuric acid medium.

The yellow colour was also developed by use of a sodium hydroxide or a sodium acetate–sodium hydroxide medium, but the results were not as satisfactory as with the sodium acetate medium. The yellow dye, when present in moderately high concentrations, had a tendency to be adsorbed on glass, hence it was necessary to rinse all glassware, including the spectrophotometer cells, with 6*M* hydrochloric acid after each determination. The hydrochloric acid washings were yellow after the rinsings. The results in Table 1 on the effect of time on the absorbance would seem to indicate that the dye is adsorbed essentially as a monomolecular layer.

Extraction of the yellow dye

It was found that the yellow dye, unlike the reddish purple dye, was readily extracted into chloroform or other water-immiscible solvents and that the sensitivity of the method could be considerably increased by this means. For quantitative recovery of the very small amounts of aniline involved it was necessary for the solution to stand for 60 min before the extraction, so that the dye complex could be fully developed. The yellow colour in the aqueous solutions, however, was barely perceptible for the low concentrations of aniline used. A calibration graph for the extraction procedure was prepared by transferring 4.00, 8.00, 10.00

Table 1. Effect of sodium acetate on the development of the yellow dye (0.20 mg of aniline and dilution to 100 ml)

		Absorbance after different time intervals

* Added as 20% solution.

and 12.00 ml of standard aniline solution No. 3 (1 ml = 2.5 μg of aniline) to 600-ml beakers, diluting to about 500 ml, treating with 5 ml of 1*M* hydrochloric acid, 10 ml of 1% sodium nitrite solution, and 10 ml of 3% sulphamic acid solution. Then 10 g of sodium acetate and 5 ml of 0.75% reagent solution were added and the solutions were allowed to stand for 60 min. Three extractions with 15-ml portions of chloroform were performed and the combined extracts were evaporated to a volume of about 5 ml. The solutions were then diluted with chloroform to volume in 10-ml standard flasks, and the absorbances measured at 442 nm (the wavelength of maximum absorbance). Beer's law was obeyed.

Conversion of the yellow dye into the reddish purple dye

Two methods were investigated for converting the yellow dye into the more sensitive and distinctive reddish purple product. The first involved shaking the chloroform extract with 10.0 ml of dilute hydrochloric acid to make the conversion and transfer the dye to the aqueous layer. The absorbance of the aqueous layer was then measured at 555 nm (the wavelength of maximum absorbance). The acid concentration was optimized by applying the procedure to 4.00-ml portions of standard aniline solution No. 3, with use of various hydrochloric acid concentrations. The absorbances obtained were: 0.005*M* HCl, 0.40; 0.02*M*, 0.47; 0.05*M*, 0.50; 0.1*M*, 0.51; 0.2*M*, 0.51; 0.5*M*, 0.51; 1.0*M*, 0.51. A concentration of 0.20*M* was selected. The optimum acidity for this conversion and transfer is much the same as that for developing the reddish purple dye directly in the aqueous solution (0.10–1.0*M* as reported earlier[1]), but the reddish purple colour develops immediately in the conversion method and requires 75 min in the direct method. The colour is stable for several hours.

The second method involved evaporation of the chloroform extract to dryness on a steam-bath and dissolution of the residue in 5.0 ml of glacial acetic acid. As with the hydrochloric acid extraction method, the absorbance was measured at 555 nm (the wavelength of maximum absorbance). The heating on the steam-bath must not be prolonged much past the point of dryness being reached, otherwise somewhat lower results may be obtained, probably because of slight decomposition or oxidation. It is not thought that the yellow dye is volatile, since on evaporation of chloroform extracts just to dryness, and standing the beakers uncovered for 1 week, complete recovery was still obtained.

In the acetic acid method the development of the colour is also immediate. The colour is stable for 4 hr and then slightly increases in intensity, owing to appreciable volatilization of the acetic acid.

Some experiments were conducted on conversion of the yellow dye into the reddish purple form by evaporation of the chloroform extract to dryness, dissolution of the residue in a measured amount of chloroform and addition of a measured amount of glacial acetic acid. For complete conversion it was necessary that the ratio of acetic acid to chloroform be at least 5:1. The results obtained by using this method were not as satisfactory as those with acetic acid alone.

Table 2. Recovery of aniline by the hydrochloric acid extraction and acetic acid methods

Aniline added, μg/500 ml	Aniline found, μg/500 ml: HCl extraction method	Aniline found, μg/500 ml: Acetic acid method
2.5	2.5	2.4
	2.3	2.3
	2.5	2.6
	Mean 2.43	Mean 2.43
5.0	5.2	5.0
	5.0	4.9
	5.2	5.2
	Mean 5.13	Mean 5.03
7.5	7.5	7.4
	7.5	7.4
	7.6	7.6
	Mean 7.53	Mean 7.47
10.0	10.0	
	10.2	
	10.0	
	Mean 10.07	

The hydrochloric acid extraction method is faster than the acetic acid method. On the basis of mg of aniline per 500 ml of solution, the hydrochloric acid extraction method is about 0.7 times as sensitive as the acetic acid method and about 2.4 times as sensitive as the chloroform extraction method involving the measurement of the yellow colour. Taking an absorbance of 0.02 as the minimum absorbance that can be determined, the minimum detection limits for the hydrochloric acid extraction method and acetic acid method are 0.4 and 0.3 μg per 500 ml, respectively. It is to be noted that the reddish purple colour obtained in glacial acetic acid has a somewhat greater intensity than the reddish purple colour obtained in dilute hydrochloric acid (on the basis of μg of aniline per ml of solution of which the absorbance is measured). To test the precision of the two methods, portions of standard aniline solution No. 3 were added to 500 ml of distilled water and the samples carried through the recommended procedures. The results (Table 2) indicate that both methods have satisfactory accuracy and precision.

(*Received* 7 *April* 1981. *Revised* 21 *September* 1981. *Accepted* 1 *October* 1981)

Summary—A spectrophotometric method using 0.5*M* hydrochloric acid in methanol as solvent, has been used for the determination of 2-amino-3H-phenoxazin-3-one [APZ], occurring as a coloured impurity in *o*-aminophenol [OAP]. This impurity dissolves in the acid medium, giving a stable red solution which complies with Beer's law. The method can be applied to the determination of APZ in technical samples of OAP.

o-Aminophenol (OAP) can be manufactured by catalytic reduction of *o*-nitrophenol. It is a key intermediate in the synthesis of heterocyclic systems such as benzoxazoles, phenoxamines and oxyquinolines. It is used in the dye industry for the manufacture of azo and sulphur dyes, in the photographic industry as a developer, and as an intermediate for the manufacture of the insecticide "phosalone", which is *S*-[6-chloro-2,3-dihydro-2-oxobenzoxazol-3-yl]methyl *O,O*-diethyl phosphorodithioate. *o*-Aminophenol is unstable to air and light, undergoing oxidation readily to brown or black substances (phenoxazones). We have isolated and characterized 2-amino-3H-phenoxazin-3-one (APZ) (I) as a coloured impurity in OAP samples prepared by catalytic hydrogenation of *o*-nitrophenol in methanol.[1] In the manufacture of phosalone, estimation of this impurity in OAP is important since its presence may give rise to undesirable intermediates in the subsequent steps of the process, and these may affect the quality of the phosalone.

Some pure aminophenoxazin-3-ones, including APZ, have been determined by titration with tin(II) chloride solution.[2] Some substituted phenoxazin-3-ones have been determined by coulometric titration with titanium(III), with potentiometric indication of the end-point.[3] However, both these methods are for assay of these compounds as major or sole components of the sample. No method has been reported for determination of APZ in OAP, though a polarographic method has been given for determination of APZ produced by photolysis of OAP.[4]

This communication describes a spectrophotometric method for this determination.

EXPERIMENTAL

Instrument

A Zeiss "Specord" double-beam spectrophotometer with 1-cm quartz cells was used for all absorbance measurements.

Reagents and solutions

2-Amino-3H-phenoxazin-3-one (APZ). An authentic sample was prepared by oxidation of (OAP) with *p*-benzoquinone.[5]

APZ stock solutions. (*A*) About 10 mg of APZ accurately weighed, and dissolved in and diluted to 1 litre with concentrated hydrochloric acid. (*B*) About 10 mg of APZ accurately weighed, dissolved and diluted to 100 ml with 0.5*M* hydrochloric acid in methanol.

Calibration solutions. Two sets of calibration solutions were prepared by making appropriate dilutions of the APZ stock solutions to cover the ranges 2.5–10.0 μg/ml for *A* and 2.3–12.0 μg/ml for *B*.

Procedures

Concentrated hydrochloric acid medium. An appropriate amount of OAP, depending on the APZ content as indicated below, was accurately weighed into a conical flask (with ground-glass stopper) and 20 ml of concentrated hydrochloric acid were added. The solution was stirred for 15 min on a magnetic stirrer. If dissolution was incomplete, the mixture was allowed to stand for 4 hr, during which the hydrochloride of APZ went into solution and undissolved OAP hydrochloride settled out. The supernatant liquid was removed and its absorbance at 485 nm was measured, with concentrated hydrochloric acid as reference. Samples that dissolve completely can be measured at once.

APZ content, %	0.01	0.05	0.1	0.4	0.6	0.8
OAP, *g*	1.0	0.4	0.2	0.05	0.025	0.020

Methanolic hydrochloric acid medium. Between 50 and 2000 mg of OAP, depending on the APZ content, was accurately weighed, dissolved and diluted to the mark in a 50-ml standard flask with 0.5*M* hydrochloric acid in methanol. The absorbance of the solution was then measured at 465 nm against a solvent blank.

The amounts of APZ in the samples are calculated by using the calibration equations.

RESULTS

Pure OAP dissolved in either medium does not absorb light in the visible region. The absorption spectra of OAP containing APZ, for both media, are shown

Table 1. Spectrophotometric characteristics of APZ

Medium	λ_{max}, nm	Beer's law limits, μg/ml	Molar absorptivity, $l.mole^{-1}.cm^{-1}$	Calibration equation*
Conc. HCl	480–510	2.5–10.0	1.52×10^4	$A_{485} = 1.52 \times 10^4 C - 0.003$
0.5*M* HCl in MeOH	463–472	2.3–12.0	1.38×10^4	$A_{465} = 1.38 \times 10^4 C + 0.006$

* A is the absorbance at the prescribed wavelength and C is the molar concentration of APZ solution. The coefficients must be determined with the instrument used.

in Fig. 1. The spectrophotometric characteristics of APZ in both media are given in Table 1.

Determination of APZ in laboratory made mixtures

The validity of the calibration equations was tested by determining the amount of APZ in laboratory-made mixtures prepared by taking a fixed amount of OAP (0.400 g) in concentrated hydrochloric acid (about 10 ml) or 0.5*M* hydrochloric acid in methanol (about 30 ml), adding the desired volume of appropriate APZ solution and making up to 20 or 50 ml with the solvent medium used. The absorbances of the solutions were measured against the solvent blanks at 485 and 465 nm respectively as outlined in procedures A and B. The results are presented in Table 2.

Validification tests using standard addition method and technical OAP samples

These tests were performed on a fixed quantity of technical sample (as shown in Table 3) on the same lines as for laboratory-made mixtures. The results obtained are presented in Table 3.

Repeatability

Concentrated hydrochloric acid medium. In a test of repeatability, six OAP samples (each weighing 1000 ± 3 mg) containing 0.208 mg of APZ and six OAP samples (each weighing 400 ± 1 mg) containing 0.083 mg of APZ were taken. The absorbances were measured at 485 nm as described before. The standard deviation of absorbance was calculated for each set and the results are presented in Table 4.

Hydrochloric acid (0.5M) in methanol medium. The repeatability of the method was tested in a similar manner by recording the absorbances at 465 nm of two OAP samples. Their respective weights, APZ content, mean of six determinations and standard deviations are recorded in Table 4.

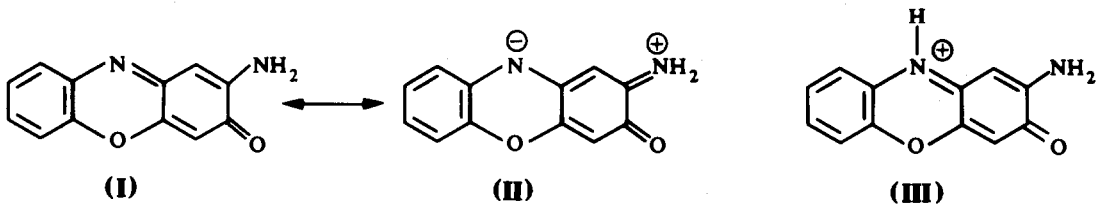

Fig. 2.

DISCUSSION

APZ can be represented by **I** and **II** (Fig. 2) as contributing canonical forms. APZ in methanol shows only one wavelength maximum in the visible region, in the range 430–434 nm. This undergoes a bathochromic shift by about 33 nm in 0.5*M* hydrochloric acid in methanol medium (λ_{max} 463–472 nm) and by about 55 nm in concentrated hydrochloric acid (λ_{max} 485–510 nm). The basicity of the amino group in APZ is so slight[6] that the first proton preferentially adds to a free electron-pair of the ring nitrogen atom (**III**). The positive charge on the ring nitrogen atom may be delocalized to give canonical forms contributing to the bathochromic shift and the colour of the protonated APZ.

The molar absorptivity of APZ in methanol is substantially higher (2.51×10^4 l.mole^{-1}.cm^{-1}) than that in concentrated hydrochloric acid (1.52×10^4 l.mole^{-1}.cm^{-1}). It was expected, therefore, that the spectrophotometric determination of APZ in methanol might serve as a quicker and more sensitive method for the determination of APZ in OAP samples. It was, however, found that under the influence of atmospheric oxygen and light, OAP undergoes rapid oxidation to APZ. A 10-g/l. solution of OAP in methanol changes its absorbance at 432 nm from the initial value of 0.20 (pale straw) to 2.38 (yellow) within 15 min. It has been reported[7] that OAP is oxidized initially to *o*-quinoneimine, which further reacts with a molecule of OAP to produce APZ. The *o*-quinoneimine is fairly stable only at temperatures below 0° in solvents such as diethyl ether, toluene, chloroform, acetone and acetonitrile, but not in methanol and ethanol.[8] However, it was found that solutions of OAP in its hydrochloride form, as in concentrated hydrochloric acid and 0.5*M* hydrochloric acid in methanol media, were quite stable with respect to APZ formation for a long period of time.

The spectrophotometric method of estimation of APZ in OAP with 0.5*M* hydrochloric acid in methanol as the medium has the distinct advantages of rapidity, better repeatability and complete dissolution even at higher concentrations of OAP. In comparison, the method using aqueous concentrated hydrochloric acid, although more sensitive, is less rapid owing to incomplete dissolution at higher concentrations of OAP, when a settling time of 4 hr has to be allowed for the undissolved OAP hydrochloride.

Acknowledgements—We wish to thank Dr. C. I. Jose for useful discussions, and Mr. M. J. Thakar for recording spectra.

A PHOTOCHEMICAL REDOX METHOD FOR THE ESTIMATION OF THALLIUM(III)

S. R. SAGI, G. S. PRAKASA RAJU, K. APPA RAO and M. S. PRASADA RAO

Inorganic Chemistry Laboratories, Andhra University, Waltair, India

(*Received* 1 *September* 1981. *Accepted* 3 *November* 1981)

Summary—A convenient photochemical redox method for the estimation of thallium(III) by reduction with oxalic acid followed by oxidation of thallium(I) with potassium bromate has been developed. The reduction is carried out in the presence of small concentrations of chloride and bromide as catalysts.

Oxalic acid has long been used in the photochemical reduction of metal ions, such as iron(III),[1–5] cobalt(III)[6,7] and manganese(III).[8] It is well known that thallium salts are also photosensitive.[9] Moreover, it has been observed that during the formation of oxaloto complexes of thallium(III), some of the thallium(III) is always reduced to thallium(I).[10]

The reduction of thallium(III) to thallium(I) with oxalic acid at elevated temperatures and subsequent titration of the thallium(I) with cerium(IV) sulphate has been described by Sagi and Ramana.[11] In this method the titration has to be done at 90°, a blank correction is needed, and thallium(III) is estimated by an indirect procedure involving titration of surplus oxalate after oxalate reduction of thallium(III).

Since thallium salts are photosensitive and oxalate is a photochemical reducing agent, it seemed likely that the photochemical reduction of thallium(III) with oxalic acid would be possible. Hence a critical study has been made of this reaction and a convenient photochemical method developed for estimation of thallium(III).

EXPERIMENTAL

Reagents

Thallium(III) hydroxide was prepared as reported earlier[11] and dissolved in suitable amounts of perchloric or sulphuric acid. The thallium content was estimated iodometrically[12] and verified by other methods.[11,13]

All other reagents were of analytical-reagent grade.

Procedure

The photochemical reductions were carried out by exposing the solutions in colourless glass containers to either bright sunlight or the light from a high-pressure mercury vapour daylight lamp.

RESULTS AND DISCUSSION

Effect of light on the redox reaction between thallium(III) and oxalic acid

Perchloric and sulphuric acid media were used, but not nitric acid medium, since nitric acid oxidizes organic material in the presence of light.[14] Dilute perchloric acid forms no known complexes with thallium(III) and hence the medium effects are minimal in this acid, which was therefore investigated first.

It was found that the reduction of thallium(III) with oxalic acid in perchloric acid is complete in about 3 hr at room temperature under direct light from the mercury vapour lamp. In diffused daylight in the laboratory the complete reduction of thallium(III) takes about 24 hr, but in the dark, thallium(III) is still detectable in the solution even after 15 days.

Effect of halides on the photochemical reduction

Chloride and bromide are reported to catalyse the reduction of thallium(III) with organic reagents,[15] so their effect on the photochemical reduction was examined.

A separate study showed that oxalic acid does not interfere in the bromate titration of thallium(I)[16–18] so this titration was used for monitoring the progress of the photochemical reduction.

The effect of varying amounts of chloride, bromide, oxalate and hydrogen ion is given in Tables 1–3. The total volume of solution was 75 ml, containing 0.12 mmole of thallium(III). The perchloric acid concentration was 0.5*M* and the amount of oxalic acid present 0.24 mmole except when these reagents were the variables.

The results in Table 1 indicate that (1) chloride at relatively low concentration catalyses the reaction, (2) the optimal chloride concentration is double that of the thallium(III), and (3) high chloride concentrations inhibit the reduction. Bromide has a similar but more efficient catalytic effect, and the optimal concentration is half that of the thallium(III).

Fluoride up to 0.1*M* concentration was found to have no catalytic effect, and sulphate was found to retard the reaction.

Brubaker and Andrade[19] reported that in perchloric acid medium reduction of thallium(III) with oxalic acid proceeds at a rate comparable to or faster than that of the thallium(I)–thallium(III) exchange reaction. Chloride and bromide at low concentrations

Table 1. Effect of chloride and bromide

Table 3. Effect of oxalic acid concentration

Oxalic acid, *mmole*	Time for complete reduction, *min*		
	in absence of catalyst	in presence of 0.24 mmole of chloride	in presence of 0.06 mmole of bromide
0.10	no complete reduction	no complete reduction	no complete reduction
0.15	not reduced completely even after 4 hr	12	2.5
0.20	180	10	2
0.40	120	8	1.5
0.80	90	6	1
1.60	60	5	1

reduce the exchange rate,[20] especially when their concentrations are twice and half that of the thallium(III) respectively, whereas higher concentrations considerably enhance the exchange rate. It is also reported[21] that sulphate increases the exchange rate.

Our results show that the rate of photochemical oxidation of oxalate by thallium(III) is greatest under the conditions for minimal rate of the exchange reaction. This indicates that there are two competing reactions: (1) electron transfer from thallium(I) to thallium(III), and (2) electron transfer from oxalate to thallium(III), the rate of one being at its maximum when the rate of the other is at its minimum.

Table 2 shows that the rate of reduction decreases with increase in hydrogen-ion concentration whether the chloride or bromide is present or not. Variation of the oxalic acid concentration in the presence of chloride and bromide at twice and half the concentration of thallium(III) respectively (Table 3) shows that the reduction is rapid enough at an oxalic acid concentration equal to that of the thallium(III), and that higher concentrations increase the rate comparatively slightly.

The effect of the light intensity on the reduction was studied by varying the distance between the lamp and reaction mixture, with and without halide ions present. The reduction rate decreases with decrease in the light intensity.

Table 2. Effect of hydrogen ion concentration

$[H^+]$, *M*	Time for complete reduction, *min*		
	in absence of catalyst	in presence of 0.24 mmole of chloride	in presence of 0.002 mmole of bromide
0.10	80	10	20
0.20	120	11	22
0.40	180	12	24
0.60	270	15	25
1.00	360	30	30

The light from the mercury lamp was also passed through a blue, green or red filter made out of acrylic plastic. The reaction was found to be fast under the blue light, whereas it was very slow, even in the presence of catalyst, under green or red light. The reaction was much faster when unfiltered light was used, owing to the higher intensity of the unfiltered light.

Recommended procedure for determination of thallium(III)

To 50 ml of 0.25*M* sulphuric acid in a 200-ml beaker add 0.1–0.25 mmole of thallium(III) and 0.2 mmole of oxalic acid. Stir the solution continuously, add 0.05–0.1 mmole of bromide, and expose to light from a high-pressure mercury vapour lamp for 15 min. Add 15 ml Conc. HCl to 0.1 ml of 0.1% Methyl Orange solution, heat to 60°C and titrate with 0.05*N* potassium bromate (1.392 g/l.) until the indicator is destroyed.

Application to mixtures of thallium(I) and (III)

First estimate thallium(I) directly by potassium bromate titration. Take a second sample and reduce the thallium(III) as described above. Titrate to find the total thallium and subtract the amount of thallium(I) already found. Typical results are given in Table 4.

Interferences

Cadmium, zinc, ammonium and potassium ions do not interfere. Copper(II) does not interfere if its con-

Table 4. Estimation of thallium

Thallium(I), *mmole*		Thallium(III), *mmole*	
Taken	Found	Taken	Found
0.0244	0.0244	0.2000	0.2000
0.0610	0.0608	0.1333	0.1335
0.0976	0.0976	0.0888	0.8889
0.1220	0.1222	0.0444	0.0449
0.1464	0.1459	0.0222	0.0220

centration is below 0.02*M* but at higher concentrations its colour masks the colour change at the end-point. Nitrate at below 0.03*M* concentration does not interfere, but large quantities of chloride and bromide inhibit the reduction. Iron(III) interferes.

DETERMINATION OF SOME DITHIOCARBAMATES BY CATALYTIC THERMOMETRIC TITRATION

NOBUTOSHI KIBA, YASUO SAWADA* and MOTOHISA FURUSAWA

Department of Chemistry, Faculty of Engineering, Yamanashi University, Kofu-shi, 400, Japan

(*Received* 16 *April* 1981. *Revised* 1 *October* 1981. *Accepted* 26 *October* 1981)

Summary—The determination of dithiocarbamates by catalytic thermometric titration is described. The dithiocarbamates can be determined in the range 0.5–20 μmole with relative errors of about 5%.

Many methods for the determination of dithiocarbamates, which have been used as fungicides, vulcanization accelerators and analytical reagents, have been proposed.[1,2] Dithiocarbamates are smoothly decomposed by hot dilute mineral acids to yield carbon disulphide and the amine. The carbon disulphide generated can be collected and determined iodimetrically or colorimetrically.[3,4] Clarke *et al.*[3] proposed a method in which the CS_2 is collected in alcoholic potassium hydroxide and determined iodimetrically. The method is suited for macro determinations.

It is well known that the reaction of primary and secondary amines with carbon disulphide affords dithiocarbamic acids.[5] The dithiocarbamic acids are weak acids and can be titrated with a strong base. This principle has been utilized for the determination of amines.[6] Catalytic thermometric titrimetry is suitable for determination of small amounts of weak acids in non-aqueous solution;[7] for example, phenols, thiols, barbituric acids and the acidity of petroleum can be determined by using a hydroxide-catalysed acetone-condensation reaction as indicator.[8–11]

In this communication, a method is described in which a dithiocarbamate is decomposed by treatment with acid[4] and the carbon disulphide evolved is collected in a solution of ethylenediamine in propan-2-ol. The dithiocarbamic acid formed is titrated with potassium hydroxide solution in the presence of acetone as thermometric indicator.

EXPERIMENTAL

Apparatus

A twin-cell thermometric titrator (TOA Electric, TMT-3A) was used. It has been described in detail.[12] The titration vessels were 30-ml Dewar flasks. The apparatus used to decompose the dithiocarbamates and collect the carbon disulphide was similar to that described by Cullen.[13]

Reagents

The absorption solution was 0.5*M* ethylenediamine in propan-2-ol. Carbon disulphide stock solution (0.05*M*) was made by dissolving carbon disulphide in propan-2-ol, standardized by the xanthate method of Hofman-Bang and Szybalski[14] and then stored in a refrigerator at 0°. Dilute standard carbon disulphide solutions were prepared by diluting the freshly standardized stock solution for each measurement. Zinc dimethyldithiocarbamate, zinc and copper diethyldithiocarbamates, zinc and nickel di-n-butyldithiocarbamates, zinc dibenzyldithiocarbamate were prepared from carbon disulphide and the corresponding amine.[15] The products were recrystallized twice from acetone and dried *in vacuo* at room temperature for 40 hr, then analysed iodometrically by the method of Clarke *et al.*[3] Dithiocarbamate solutions were prepared in propan-2-ol for each measurement. Potassium hydroxide solutions (0.1 and 1.0*M*) were prepared in dry propan-2-ol and standardized with benzoic acid. All reagents were of analytical reagent grade.

Procedure

A sample of dithiocarbamate equivalent to 1–40 μmole of carbon disulphide was introduced into a dry flask. The first trap contained 20 ml of 0.1*M* sodium hydroxide and the second trap, containing 10 ml of absorption solution, was kept at 25 ± 4°. The sample was refluxed with 200 ml of 2*M* hydrochloric acid containing 2 g of $SnCl_2 2H_2O$. The carbon disulphide evolved was swept through the traps with a stream of nitrogen at a flow-rate of 20 ml/min. After 15 min the contents of the second trap were transferred, with 5 ml of acetone for rinsing, to the titration vessel. The second titration vessel was charged with an equal volume of reference solution (propan-2-ol:acetone, 2:3 v/v). One g of molecular sieve 3A pellets was introduced into each vessel. The cover with its attached thermistors, stirrers and burette tips was fitted and the stirrers were started. One burette was filled, with standard potassium hydroxide solution and the other with propan-2-ol. When the thermistor-bridge recorder showed a steady trace, the synchronous burette-motor was started to perform the titration. The recorder full-scale sensitivity was 50 mV and the rate of titrant addition was 0.05 ml/min. Blank tests were performed to determine the blanks from the reagents themselves. Calibration was done with standard benzoic acid solutions.

RESULTS AND DISCUSSION

The results obtained for the six dithiocarbamates

Table 1. Determination of dithiocarbamates

Compound	Taken, μmole	Found, μmole	Recovery, %	C.V., % (n = 5)
Zinc dimethyldithiocarbamate	0.52	0.50	96	5
	15.6	15.6	100	2
Zinc diethyldithiocarbamate	0.58	0.56	98	4
	11.6	11.5	99	3
Copper diethyldithiocarbamate	0.55	0.53	96	5
	11.0	11.0	100	3
Zinc dibutyldithiocarbamate	0.60	0.58	97	4
	6.00	5.98	98	3
Nickel dibutyldithiocarbamate	0.55	0.54	98	4
	16.5	16.5	100	2
Zinc dibenzyldithiocarbamate	0.50	0.50	100	4
	5.03	5.00	100	3

are summarized in Table 1. In each case, the dithiocarbamate was added as a dilute solution to the digestion flask, various concentrations being used. The volume of titrant used was a linear function of amount of dithiocarbamate taken, in the range 0.5–20 μmole. Recovery of smaller amounts of dithiocarbamates ($\sim 10^{-7}$ mole) is rather low, probably because of decomposition of the dithiocarbamates in very dilute solution, as pointed out by Clarke *et al.*[3] The upper limit occurs because the reaction of ethylenediamine and carbon disulphide is not very rapid. The unreacted carbon disulphide is lost by being swept out by the nitrogen stream. Several dithiocarbamate mixtures were analysed for total dithiocarbamate by this method. Results are shown in Table 2. The recoveries of zinc dimethyldithiocarbamate and zinc diethyldithiocarbamate residues on apples are shown in Table 3.

The reactivities of primary and secondary amines such as ethylenediamine, n-propylamine, di-n-propylamine, di-isopropylamine, n-butylamine, isobutylamine, di-n-butylamine, n-heptylamine, n-octylamine, di-n-butylamine, 1,2-propyldiamine, monoethanolamine, 3-amino-1-propanol and morpholine were studied at 20–30°. Ethylenediamine reacted quantitatively with carbon disulphide within 15 min under the conditions studied. By reacting ethylenediamine with carbon disulphide in various ratios, it was found that molar ratios of amine to carbon disulphide above 30 gave quantitative results. For n-propylamine, n-butylamine and di-n-propylamine, the reaction was complete after 45 min at 30° or 60 min at 25°. For other amines, the reaction yielded low results under all conditions. Ethylenediamine solution (0.5*M*) was therefore used as absorbing solution at 25°. Titrations in an atmosphere of nitrogen were capable of greater precision than those in air. Under these conditions, 0.8–60 μmole of carbon disulphide could be determined with a coefficient of variation ($n = 5$) less than 1%. The effect of the flow-rate of nitrogen on the trapping of carbon disulphide was investigated. At nitrogen flow-rates above 50 ml/min or less than 3 ml/min, the trapping of 40 μmole of carbon disulphide was incomplete. At higher flow-rates, the vigorous bubbling causes loss, and at lower rates the dense carbon disulphide gas is incompletely transferred. A nitrogen flow-rate of 20 ml/min was chosen. The use of air instead of nitrogen as carrier-gas

Table 2. Determination of mixtures of dithiocarbamates

Mixture	Total taken, μmole	Total found, μmole	Recovery, %	C.V., % (n = 5)
Zinc dimethyldithiocarbamate and diethyldithiocarbamate	11.06	10.9	98	2
Zinc dibutyldithiocarbamate and nickel dibutyldithiocarbamate	11.55	11.5	99	2

Table 3. Recovery of dithiocarbamates from apples (100 g)

Compound	Added, μmole	Found, μmole	Recovery, %	C.V., % (n = 5)
Zinc dimethyldithiocarbamate	1.13	1.09	97	8
	2.26	2.19	98	5
Zinc diethyldithiocarbamate	1.52	1.47	97	8
	3.04	2.95	97	5

caused poor recovery because of aerial oxidation of the dithiocarbamate formed in the absorption solution, to a thiuram disulphide.

The conditions for the decomposition were investigated. The decomposition was complete in 10 min in hydrochloric acid at concentrations above 2*M* and containing 1% w/w stannous chloride. At an acid concentration of 0.5*M*, the reaction took about 30 min. The stannous chloride concentration could be varied from 0.5 to 3% without affecting the yield of carbon disulphide. A 2*M* hydrochloric acid/1% w/w stannous chloride solution and reflux time of 15 min were chosen. The formation of hydrogen sulphide during the decomposition was measured by determining the sulphide in the first trap (0.1*M* sodium hydroxide) by the Methylene Blue method.[16] A maximum of 0.2% of the available sulphur was evolved as hydrogen sulphide for all the dithiocarbamates tested. However, with manganese and zinc ethylenebisdithiocarbamates, 9–14% of the available sulphur was evolved as hydrogen sulphide, and some as carbonyl sulphide (identified by gas chromatography).

The end-point temperature change was not very sharp in the presence of water, even at concentrations as low as 0.1%. The influence of water could be avoided by adding a molecular sieve (in pellet form) to the titrand. The presence of up to 1 g of molecular sieve did not interfere mechanically or chemically with the titration. Gaseous acidic substances such as hydrogen sulphide, which are generated in the course of the acid decomposition, were completely removed by using 0.1*M* sodium hydroxide solution (20 ml) in the first trap.

OPTICAL EMISSION SPECTROSCOPY WITH A MICROWAVE-INDUCED PLASMA IN A SEALED MICROTUBE

DAVID W. HOLMAN* and THOMAS J. VICKERS†
Department of Chemistry, Florida State University, Tallahassee, FL 32306, U.S.A.

(*Received* 17 *February* 1981. *Accepted* 20 *October* 1981)

Summary—A microwave system is used to induce a plasma inside a sealed microtube containing a sample or standard, and the emission from the analyte is measured. The detection limits are about 4 ng for S, Cl and Br, and 100 ng for Cd and Sn, in ~30-μl samples. Both gaseous and liquid samples can be analysed.

Most arrangements for analytical atomic spectroscopy make use of a flow system in which the residence time of the sample in the region of measurement is short. This necessitates continuous delivery of sample from a relatively large sample reservoir, as in conventional sprayed-sample systems for flame and plasma spectroscopy, or measurement of short-lifed transient signals, as in furnace atomic-absorption spectroscopy. The first approach has the disadvantage of requiring relatively large quantities of sample. The second approach requires fast response (broad bandwidth) measurement systems, with a consequent increase in the noise associated with the measurement. This report describes the results of an effort to overcome the limitations of flow systems by making use of the atomic emission from a microwave-induced plasma in an enclosed-sample system.

EXPERIMENTAL

Apparatus

The experimental facilities are described in Fig. 1 and Table 1.

Preparation of sample tubes. Sample tubes were prepared from 1-mm bore, 3-mm outside diameter quartz tubing on a vacuum line, the major components of which are shown in Fig. 2. The tubing was cleaned by soaking in nitric/sulphuric acid cleaning solution for 24 hr and flaming with a hydrogen–oxygen torch with helium flowing through the tube. An approximately 60-cm length of the tubing was blown onto the quartz side of a graded seal on a 10/30 Pyrex joint to permit attachment to the vacuum line at V5. Different procedures were used for gaseous and liquid samples.

Gaseous samples. The cleaned quartz tube was cut into four equal lengths, one remaining attached to the 10/30 joint. The open end of the attached tube was then fused shut. The tube was connected to the vacuum line at V5, evacuated and heated to a white glow with the torch. When the tube had cooled, helium was admitted to a pressure of 25 mmHg, stopcock V1 was opened and the system was evacuated to a pressure of about 10^{-4} mmHg.

Sample, which had previously been degassed by repeated freeze–pump–thaw cycles, was admitted to the system

through V4 to a pressure of about 0.2 mmHg. With V4 closed and V1 opened, the system pressure was then adjusted to the value calculated by the operator to be suitable for the intended measurement. With V1 and V2 closed, V3 was then opened to adjust the pressure of helium to the desired value (approximately 50 mmHg). A magnetically driven stirring bar in the expansion flask provided thorough mixing of the sample with the helium. Sample was admitted to the sample tube by opening V5. After a 1-min equilibration time, V5 was closed, and the sample tube was fused shut and cut from the graded seal. This provided a sample tube with a total length of about 14 cm. This tube was then sealed in the middle, cooled, and then sealed again in the middle of each of the halves to provide 4 sample tubes, each about 3 cm long, with an internal volume of about 30 μl. The amount of sample in the tube was calculated from the pressure and volumes of the vacuum system and sample tubes. Ideal gas behaviour was assumed. The volume of the vacuum system was measured by a manometric method, and that of the sample tubes was estimated from their length and bore. Additional samples were then prepared by the same procedure after sealing the remaining lengths of tubing, in turn, to the 10/30 joint.

Liquid samples. Small bulbs, each about 0.2 cm in internal diameter and 0.3 cm long, were blown every 5 cm in the 60-cm length of tube attached to the 10/30 joint. The end was sealed, the tube was attached to the vacuum system at V5, evacuated and heated to a white glow. After cooling, the tube was removed from V5, and the end was reopened.

One μl of the sample solution was placed in the lowest bulb with a micropipette. The sample was frozen in liquid nitrogen and the end of the tube was again sealed. The tube assembly was then re-attached to the vacuum system, and the sample was freeze-dried. After adjustment of the helium pressure to the desired value (about 20 mmHg), the sample tube was sealed about 1.5 cm above the bulb and cut from the tube assembly. Additional samples were prepared by filling the other bulbs in succession by the same procedure.

Measurements

The cavity was operated with the cylindrical axis vertical. Samples were mounted on the cylindrical axis at the centre of the cavity, and the radiation was viewed through an opening in the wall of the cylinder, as indicated in Fig. 1.

For gaseous samples the plasma was initiated (with a Tesla coil) at 8 W forward power, and the sample spectrum was excited at 60 W forward power. For solution residue samples the plasma was initiated at 2 W forward power, and the sample was excited at 30 W forward power. The tuning was adjusted to maintain reverse power at 2 W or less. The lower initiation power for residue samples was made possible by the lower helium pressure in the residue sample tubes. Maximum power for residue samples was

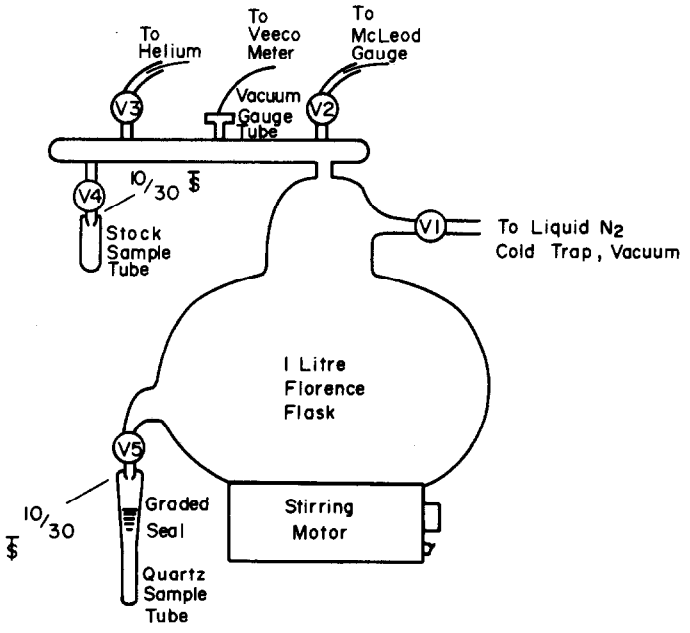

Fig. 2. Arrangement of vacuum system.

Table 2. Analysis lines and limits of detection

Analyte	Wavelength, *nm*	Detection limit, *ng*
S(II)	545.4	0.33
Cl(II)	479.5	0.54
Br(II)	470.5	0.53
Cd(I)	228.8	0.01
Sn(I)	286.3	0.18

limited to 30 W because the thinner wall produced in blowing the bulbs fused at higher power settings.

Data were acquired under computer control. Readings of the amplified photomultiplier signal were taken at 50-msec intervals, following initiation, to a maximum of 512 points. The first 29 points were taken as a background reading at the low microwave-power setting. A computer-actuated relay stepped the microwave power to the measurement value for the balance of the readings.

The data were displayed on an oscilloscope and the limits of signal integration were chosen by the operator. The integral of emission signal *vs.* time, normalized to the least sensitivie amplifier setting, and the amplifier settings used, were then printed on the teletype.

RESULTS AND DISCUSSION

Preliminary studies

Line emission from the analyte appeared quickly upon initiation of the plasma in a sample tube, increased rapidly, and then decayed rapidly. At the power level used for gaseous samples, the intensity of the emission due to analyte decayed to the level of background emission in approximately 15 sec. Decay of the signal was less rapid for lower power settings.

The reasons for this somewhat disappointing result are not known. By some process the analyte material was irreversibly removed from the plasma region. Van Montfort *et al.*[1–5] reported similar variations with time of the signal intensities in their studies, although signal decay was much less rapid with the larger sample tubes used in their studies. They were able to modify the temporal behaviour by addition of various excitation buffers. We did not examine this possibility in our studies.

The atomic emission due to helium (measured at 388.86 nm) increased with time throughout the observation period (the longest period studied was 18 min).

Calibration graphs and limits of detection

Results with the sealed-tube microwave-plasma excitation system were obtained for S, Cl and Br, introduced as gaseous samples, and for Cd and Sn, as solution residues. S, Cl and Br were introduced as CS_2, CH_2Cl_2 and C_2H_5Br, respectively. Cd and Sn were introduced as aqueous solutions of the metal chlorides.

Lines of the singly ionized element were found to be the most sensitive for S, Cl and Br. Atomic lines were most sensitive for Cd and Sn. The lines used for measurement are listed in Table 2.

The calibration graphs appeared linear up to the highest weight investigated: approximately 4 ng for S, Cl and Br, and 100 ng for Cd and Sn. Relative standard deviations for points on the analytical curves were typically 10% (3 measurements) at weights more than 10 times the detection limit. The limit of detection was taken as the amount producing a blank-corrected signal three times the standard deviation of the blank. Limits of detection are listed in Table 2. These results are preliminary in nature, and considerable improvement in limits of detection seems possible.

CONCLUSIONS

This study has demonstrated the feasibility of analytical emission spectroscopy with a microwave-induced plasma in a closed microvolume sample tube. Although the analyte signal varies with time, it lasts long enough to be measured with electronic systems with suitable time-constants.

In common with most microscale techniques, the sample handling requires considerable skill and care. Approaches for preparaing gaseous and liquid samples and standards have been developed. Liquid samples can probably be handled more conveniently by techniques such as furnace atomic-absorption spectroscopy, at least for the determination of metals, but the sealed-tube microwave-plasma technique offers promise for the determination of volatiles in air and other samples when combined with any of several trapping schemes, such as the Tenax GC approach described by Zlatkis *et al.*[6–9]

ANALYTICAL DATA

HEAVY-ATOM ENHANCEMENT AND ANALYTICAL FIGURES OF MERIT FOR LOW-TEMPERATURE PHOSPHORIMETRY IN THE RED REGION FOR SEVERAL POLYNUCLEAR AROMATIC HYDROCARBONS

E. L. INMAN, JR., A. JURGENSEN and J. D. WINEFORDNER*
Department of Chemistry, University of Florida, Gainesville, FL 32611, U.S.A.

(*Received* 3 *September* 1981. *Accepted* 15 *October* 1981)

Summary—Analytical figures of merit for the low-temperature (77 K) phosphorescence of 22 polynuclear aromatic hydrocarbons are presented. Also, heavy-atom enhancement factors have been obtained for these compounds with an n-heptane solvent with iodoethane and dimethylmercury as sources of external heavy atoms, and with a 3:1 v/v ethanol/water solvent with potassium iodide, silver nitrate, thallium acetate, and lead acetate as heavy-atom sources. Effects of these heavy atoms on the phosphorescence signals vary markedly, depending on the compound of interest.

The use of luminescence methods for the determination of polynuclear aromatic hydrocarbons (PAHs) is widespread. Room-temperature (298 K) fluorescence offers excellent sensitivity for these compounds, but because of the relatively broad-band nature of fluorescence spectra, the spectral selectivity is severely limited. One possible solution to this problem of selectivity is to cool the sample to the temperature of liquid nitrogen or helium and use Shpol'skii solvents and/or fluorescence line-narrowing methods.[1-3] Phosphorescence gives greater spectral selectivity and provides an excellent means for PAH determination. Both room-temperature (298 K) and low-temperature (77 K) phosphorescence have been used for PAH determination.[4-6]

The use of heavy atoms to enhance the phosphorescence intensity of organic compounds is common, and extensive effort has been made to explain this phenomenon.[7,8] Significant enhancement of room-temperature phosphorescence by thallium, silver, lead, iodide, and mercury has been reported.[9,10] These external heavy atoms have also been used in low-temperature phosphorescence.[11-14] LueYen-Bower and Winefordner[10] have reported a trend in the heavy-atom enhancement of room-temperature phosphorescence of several PAHs.

This paper presents the low-temperature phosphorescence figures of merit and heavy-atom enhancement factors for 22 PAHs that phosphoresce in the red region (>580 nm). These compounds are often omitted in phosphorescence data owing to instrumental limitations in the red region. A non-polar solvent, n-heptane, and a polar solvent, 3:1 v/v ethanol/water, were used, with the heavy atoms most commonly reported in the literature—silver, thallium, lead, iodide, and mercury.

EXPERIMENTAL

Instrumentation

Figure 1 shows a block diagram of the system used. A complete list of the equipment and its manufacturers is given in Table 1. A 150-W Eimac lamp, operated at 12 A, was used as the excitation source. The exciting light was focused onto the entrance slit of a JY H-10 monochromator. The radiant flux from the monochromator was then focused into the centre of a standard Aminco sample-cell compartment by an $f/4$ quartz lens. The phosphorescence was observed at 90° to the incident excitation beam and focused with an $f/4$ quartz lens into a Spex 1670 Minimate monochromator with a grating blazed at 1000 nm. Since weak phosphorescence intensities were expected for some of the PAHs, a red-sensitive 1P28 photomultiplier tube operated at −1000 V was used. This photomultiplier tube allowed phosphorescence radiation at wavelengths shorter than ~1000 nm to be detected. Phosphorescence intensity readings were taken from a laboratory-constructed nanoammeter, with a 1-sec time constant.[15] The output of the nanoammeter was fed to a strip-chart recorder for continuous monitoring of the signal and for recording excitation and emission spectra.

The sample compartment for the system had a circular opening at the top to accommodate a Dewar flask with a quartz optical window. The Dewar flask was held in place with a phenolic plastic ring slip-fitted to the compartment opening. A cylindrical cover was fitted over the Dewar and slip-fitted to the lower portion of the sample compartment. The precision-bore Spectrosil quartz sample tubes, 30 cm long, 3 mm outer diameter, 1 mm inner diameter (Thermal American Fused Quartz Co., Montville, NJ 07045) were sealed at one end and fitted into Teflon cylinders with

* To whom correspondence should be addressed.

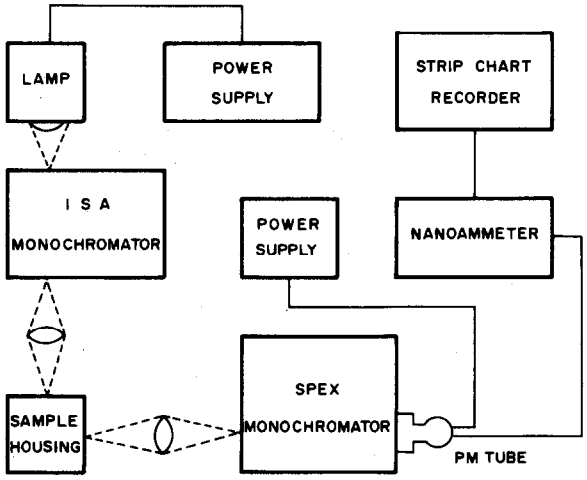

Fig. 1. Conventional red-region luminescence detection scheme.

Teflon tape. The sample tube was held rigidly in place by the Teflon cylinder and immersed in liquid nitrogen in the Dewar to attain a temperature of 77 K. To avoid frost from forming on the optical tip of the Dewar, a gentle stream of nitrogen gas was flushed into the lower section of the sample-cell compartment. A black felt cover was placed loosely over the top of the sample tube during analysis to minimize interference from room light.

Reagents

All chemicals used, and their sources, are listed in Table 2. Unless otherwise indicated, all chemicals were reagent grade or better and used as supplied. Iodoethane was purified by passage through activated alumina in a dark room and was stored over copper away from room light.

Procedure

The excitation and emission monochromators were calibrated with a low-pressure mercury lamp. Detailed phosphorescence excitation and emission spectra were obtained for each PAH in n-heptane, with a 4-nm spectral bandpass and a concentration 10–100 times the detection limit (0.1–10 μg/ml), in the linear portion of the calibration graphs. It was assumed that the peak intensity wavelengths were approximately the same as those observed when polar solvents are used. All intensity-maximum wavelengths were uncorrected for instrumental response. The sample cell was filled with about 25 μl of solution by means of a 2-ml syringe with a 12-in. long 17-gauge stainless-steel needle. The volume illuminated was about 10 μl.

Analytical calibration graphs were prepared by examination of serial dilutions of a stock 100-μg/ml solution. Detection limits were calculated from those concentrations which fell on the linear portion of the calibration graphs at the maximum excitation and emission wavelengths.

Enhancement factors are defined as ratio of the phosphorescence intensity with heavy atom present to that without heavy atom, after correction for the blank. For each measurement, a standard solution in the 0.1–1.0 μg/ml range was prepared in the particular solvent/heavy-atom combination. A 10-μg/ml solution was used for anthracene. Each phosphorescence signal was obtained at the wavelength maximum selected from the previously obtained spectra.

RESULTS AND DISCUSSION

Tables 3 and 4 contain the phosphorescence analytical figures of merit for PAHs in the red region, in n-heptane and ethanol/water media respectively. The limits of detection for most of the compounds are below 100 ng/ml and the average relative standard deviation is 6%. The detection limits for several of the PAHs are compared to those previously reported[14,16] for the conventional spectral region. From the wavelengths listed, some results in the early reports appear to be in error.

For most PAHs the concentration range for linear response covers four orders of magnitude. The relative standard deviations range from 5 to 10% and agree with those routinely obtained by low-temperature phosphorimetry.

The heavy-atom enhancement factors for n-heptane and 3:1 v/v ethanol/water solutions of PAH are reported in Tables 5 and 6 respectively. For alkane solutions, the sample cell was plunged into liquid nitrogen in the Dewar flask and frozen rapidly to minimize segregation of solute and solvent molecules. Aggregates exhibit much lower emission yields than isolated molecules.[17] A measurement was then taken when the signal intensity had become constant (in <30 sec). The Dewar flask was refilled after every three measurements, and the liquid nitrogen was completely replaced if flakes of ice were seen accumulating in the optical tip of the Dewar flask. For ethanol/water solutions, the sample cell was lowered slowly into the liquid nitrogen over a period of 1 min to obtain clear, frozen glasses with no cracks. If the rate of freezing was increased, severe cracks in the glass arose, lowering the phosphorescence intensity and the precision. St. John and Winefordner[18] and Hollifield and Winefordner[19] have discussed such problems

¶ Reference 16.

arising from use of solvents at 77 K. The measurement was taken immediately after the sample had been completely lowered into the Dewar. Any red shifts in wavelength maxima (caused by the heavy atoms or difference in solvents) were slight. A 40-nm spectral bandpass was therefore used, centred at the wavelength maximum obtained for anlyte solutions without heavy atoms, thus compensating for any slight shift in the wavelength maximum as a result of presence of the heavy atom.

1,2:3,4-Dibenzopyrene, 1,2:4,5-dibenzopyrene, 3,4:8,9-dibenzopyrene, and 3,4:9,10-dibenzopyrene were available in only limited quantities, so were examined only in n-heptane solution. Attempts to acquire more material commercially were unsuccessful.

The relative intensities of phosphorescence peaks may change dramatically in the presence of an external heavy atom, and a relatively weak peak may become the most intense. For example, the phosphorescence of the (0, 0) peak of triphenylene or coronene is very weak in EPA as well as in crystalline matrices, but very intense in solvents containing heavy atoms.[20] Consequently, the enhancement factors reported are not necessarily the largest values obtainable for these compounds. The heavy-atom enhancement factors indicate the increase or decrease in phosphorescence observed at the wavelength maxima of analyte solutions without heavy atoms present. The concentration of the heavy atom was limited by its solubility in the solvents used. As previously reported, iodoethane,[13,14] dimethylmercury,[11] silver[11,12] and iodide[11,12] give the largest enhancement factors. Although lead and thallium(I) give large enhancement factors when used for phosphorescence work on paper,[22] they give only small enhancement effects for frozen solutions. The use of the external heavy atom is an experimentally simple means of increasing the signal levels.[16] Unfortunately, heavy atoms can also increase the background signal to the same or even a greater extent, resulting in poorer limits of detection. Therefore, the experimenter must evaluate the enhancement factor, the detection limit, the precision, and the linear response range for each analyte to determine whether the benefits justify the high cost and/or risk from the toxic effects of the heavy atoms.

COMPORTEMENT ELECTROCHIMIQUE DES THIOCYANOSULFATES

Y. AUGER, G. DELESALLE, J. C. FISCHER et M. WARTEL

Laboratoire de Chimie Minérale I, Université des Sciences et Techniques de Lille, B.P. 36, 59655 Villeneuve d'Ascq, France

(*Reçu le* 7 *Mai* 1981. *Accepté le* 18 *Octobre* 1981)

Résumé—Dans le cadre d'une étude systématique des propriétés sulfonantes des complexes du type SO_3B, nous nous sommes interessés aux thiocyanosulfates KSO_3SCN et NH_4SO_3SCN. Nous avons établi, par conductimétrie, que ces sels sont dissociés et que le solvant choisi, le sulfolane, solvate peu les espèces et possède un caractère aprotonique marqué. Par potentiométrie, nous avons pu déterminer la constante K de l'équilibre $MSO_3SCN \rightleftharpoons MSCN + SO_3$ en étudiant le couple électrochimique $Ag + SO_3SCN^- \rightleftharpoons AgSCN + SO_3 + e^-$. Les valeurs trouvées pour les sels d'ammonium et de potassium sont respectivement $K = 10^{-11,5 \pm 0,45}$ et $10^{-9,7 \pm 0,7}$. Les thiocyanosulfates apparaissent comme des agents de sulfonation moins faibles que les chlorosulfates. L'ion SCN^- est donc une base plus faible que Cl^- vis à vis de SO_3 dans le sulfolane.

Nous avons proposé récemment[1] un classement dans le sulfolane (TMS) de la basicité de différents solvants vis à vis de l'anhydride sulfurique, en étudiant l'équilibre:

$$TMS + SO_3 \cdot Sv \rightleftharpoons SO_3 \cdot TMS + Sv$$

Afin d'établir un classement plus complet du pouvoir sulfonant de complexes du type SO_3B dans le sulfolane, nous nous sommes intéressés aux complexants minéraux et en particulier au cas où la base B est SCN^-. Bien que la synthèse des thiocyanosulfates MSO_3SCN soit connue depuis quelques années,[2] aucune référence n'a pu être trouvée dans la bibliographie concernant le comportement physicochimique de ces composés.

La détermination de la constante K de l'équilibre

$$MSO_3SCN \rightleftharpoons MSCN + SO_3$$

nécessite la connaissance du degré de dissociation ionique, de MSO_3SCN et $MSCN$ et celle de la constante de dissociation de l'ion SO_3SCN^- en SO_3 et SCN^-. Nous avons donc tout d'abord réalisé l'étude conductimétrique des sels (M = NH_4,K) puis étudié la dissociation de l'ion SO_3SCN^- par voltampérométrie à l'électrode d'argent.

PARTIE EXPERIMENTALE

La purification du sulfolane a été décrite précédemment[3] ainsi que la préparation des thiocyanosulfates d'ammonium et de potassium.[2]

Les courbes intensité–potentiel en régime stationnaire sont tracées à 30° ± 0,1° à l'aide d'un ensemble voltampérométrique Tacussel. La vitesse de l'électrode indicatrice d'argent est de 10 t/sec. La vitesse de balayage des potentiels est de 5 mV/sec.

Les mesures potentiométriques ont été réalisées à l'aide d'un millivoltmètre Tacussel Isis 20000 suivi d'un enregistreur permettant d'apprécier la stabilité des potentiels. L'électrode de référence est constituée par la demi-pile $Ag/AgClO_4$ 0,1M.

La potentiel de demi-vague du système ferrocène–ferricinium est pris comme origine de l'échelle des potentiels.

Les conductances sont mesurées à l'aide d'un conductimètre Tacussel CD 75N. La fréquence de polarisation choisie est de 1000 Hz.

RESULTATS ET DISCUSSIONS

Etude conductimétrique

Toutes les expériences ont été réalisées avec les concentrations inférieures à $10^{-2}M$. Les résultats sont traités par la méthode préconisée par Fuoss *et al.*[4]

Les équations utilisées sont:

$$\Lambda = \Lambda_0 - S(C\gamma)^{1/2} + E'C\gamma \log 6E_1'C\gamma + LC\gamma - K_A Cf^2\gamma \quad (A)$$

si l'électrolyte est associé (constante d'association $K_A > 10$) ou

$$\Lambda = \Lambda_0 - SC^{1/2} + E'C \log 6E_1'C + (L - A\Lambda_0)C \quad (B)$$

si l'électrolyte est dissocié. Dans ces équations, les différents symboles ont leur signification habituelle, $S = \alpha\Lambda_0 + \beta$, $E = E_1'\Lambda_0 - E_2'$, et les différentes constantes α, β, E_1' et E_2' calculées à partir des équations de Fuoss *et al.*[4] ont respectivement pour valeur dans le sulfolane 0,5439, 6,996, 1,300 et 2,443. Les paramètres Λ_0 et K_A ont été déterminés par la méthode des moindres carrés.[4]

Les données expérimentales sont analysées par ordinateur IRIS 80. Leur traitement à l'aide de l'équation (A) établit que seul NH_4SCN peut être considéré comme associé ($K_A = 65$). Par contre les constantes d'association K_A des autres électrolytes étant très faibles, ces composés ont été considérés comme dissociés[4] et les résultats ont été traités à l'aide de l'équation (B). Les valeurs trouvées sont consignées dans le tableau 1.

Nous constatons que les différences entre les

Tableau 1.

	Λ_0	σ	K_A
NH_4SCN	14,45	0,04	65
KSCN	13,62	0,01	
KSO_3SCN	8,94	0,01	
NH_4SO_3SCN	9,72	0,004	

valeurs des conductivités limites des thiocyanates de potassium et d'ammonium d'une part, et celles des thiocyanosulfates correspondants d'autre part, sont voisines (respectivement $\Delta\Lambda_0 = 0,83$ et 0,78). Par ailleurs, la valeur trouvée pour Λ_0^{KSCN} est en bon accord avec celle donnée dans le même solvant par Della Monica *et al.*[5] (13,63).

Les conductivités ioniques limites $\lambda_0^{\pm}$ ont pu être déterminées à partir de celle que nous avons récemment établie[6] pour K^+ (Tableau 2). Les rayons ioniques des cations K^+ et NH_4^+ dans le sulfolane ont pu être estimés à partir de la loi de Stokes et des corrections proposées par Robinson et Stokes.[9] Les nombres de solvation (n) trouvés pour ces cations sont très petits, ce que confirme le très faible pouvoir solvatant du sulfolane (Tableau 2).

Etude électrochimique

A l'image de l'ion chlorosulfate dont nous avons étudié le comportement dans le sulfolane,[3] l'ion SO_3SCN^- doit se dissocier dans le solvant selon

$$SO_3SCN^- \rightleftharpoons SO_3 + SCN^- \qquad (I)$$

L'électrode d'argent étant indicatrice de l'ion SCN^- dans ce solvant, il fallait, pour calculer la constante $K_{SO_3SCN}^{SO_3}$ de l'équilibre (I), montrer que cette électrode était également indicatrice de l'ion SO_3SCN^-. L'étude du couple oxydo-réducteur

$$Ag + SO_3SCN^- \rightleftharpoons AgSCN + SO_3 + e^- \qquad (II)$$

a donc été entreprise.

La tracé des courbes voltampérométriques des solutions de SO_3SCN^- en présence d'électrolyte indifférent [$(C_2H_5)_4NClO_4$, $10^{-1}M$] met en évidence la présence de vagues d'oxydation reproductibles. La proximité du mur d'oxydation de l'argent rend difficile l'évaluation du courant limite de diffusion, comme le montre la Fig. 1. On peut remarquer cependant que ce courant est proportionnel à la concentration en thiocyanosulfate et que la potentiel de demi-vague en est indépendant.

Une coulométrie, faite pendant l'électrolyse d'une solution de KSO_3SCN dans le sulfolane avec une

anode d'argent, montre que la réaction électrochimique fournit un électron par molécule de thiocyanosulfate.

Si l'on admet, par analogie avec le chlorodisulfate, que le thiocyanodisulfate—s'il existe—est entièrement dissocié dans le sulfolane en SO_3 et SO_3SCN^-, ces résultats permettent d'établir que la réaction d'oxydation de l'argent s'effectue bien selon (II).

Dans ces conditions, le potentiel pris par l'électrode d'argent est

$$E = E_1^0 + 0,06 \log \frac{(SO_3)}{(SO_3SCN^-)} \qquad (III)$$

avec

$$E_1^0 = E_{Ag/Ag^+}^0 + 0,06 \log \frac{K_s}{K_{SO_3SCN^-}^{SO_3}} \qquad (IV)$$

K_s étant le produit de solubilité de AgSCN.

Détermination de K_s

Les travaux de Della Monica *et al.*[10] sur différents complexes de l'argent dans le sulfolane et ceux de Parker et Alexander[11] établissent comme valeur du produit de solubilité de AgSCN dans le sulfolane à 30° respectivement $pK_s = 16,3$ et $14,5 \pm 0,3$.

Ces valeurs étant trop distinctes, nous avons redéterminé K_s dans le solvant purifié selon Pierens *et al.*,[3] par dosage potentiométrique d'une solution de KSCN par $AgClO_4$.

Le traitement mathématique des courbes potentiométriques conduit au produit de solubilité de AgSCN ($K_s = 10^{-14,8 \pm 0,2}$) et aux constantes de dissociation de $Ag(SCN)_2^-$ en AgSCN et SCN^- ($K_1 = 10^{-0,1 \pm 0,2}$) et de $Ag(SCN)_2^-$ en Ag^+ et SCN^- ($K_2 = 10^{-14,9 \pm 0,4}$).

La valeur de K_1 montre que le complexe $Ag(SCN)_2^-$ est peu stable, ce qui est en accord d'une part avec l'apparition du précipité de AgSCN avant la demi équivalence lors du dosage du thiocyanate par l'ion

argent, et d'autre part avec une inégalité des courants de diffusion correspondants aux deux vagues obtenues lors de l'étude voltampérométrique de l'oxydation de l'argent en présence de thiocyanate de potassium.

La valeur trouvée pour K_s est proche de celle proposée par Parker *et al.* bien que ceux-ci n'aient jamais signalé l'existence du complexe $Ag(SCN)_2^-$.

K_s et K_2 ont été comparées aux valeurs obtenues dans d'autres solvants.[12,13] A l'aide des coefficients de solvatation de Ag^+ déterminés par Badoz-lambling et Bardin[13] à partir de l'hypothèse de Strehlow dans différents solvants aprotoniques, nous avons pu calculer les coefficients de transfert du solvant de référence (0) au solvant (S) des ions SCN^- et $Ag(SCN)_2^-$. On peut en effet établir aisément que:

$$\log {}^{0\rightarrow S}\gamma(SCN^-) = (pK_s^S - pK_s^0) - \log {}^{0\rightarrow S}\gamma(Ag^+)$$

et

$$\log {}^{0\rightarrow S}\gamma[Ag(SCN)_2^-] = 2\log {}^{0\rightarrow S}\gamma(SCN^-) + \log {}^{0\rightarrow S}\gamma(Ag^+) + \log K_2^s - \log K_2^0.$$

Nous avons choisi, parmi les solvants dipolaires aprotoniques usuels, le nitrométhane (NM) comme solvant de référence pour ses propriétés complexantes très faibles vis à vis de Ag^+.[13]

Les valeurs de

$$\log {}^{NM\rightarrow S}\gamma$$

regroupées dans le tableau 3, sont en général voisines de zero, confirmant ainsi que ces solvants aprotoniques possèdent, comme le nitrométhane, un très faible pouvoir solvatant vis à vis des anions Cl^-, SCN^- et $Ag(SCN)_2^-$. On constate également que pour ces solvants de constantes diélectriques semblables (excepté le carbonate de propylène) les variations de solvatation diminuent quand la taille de l'anion augmente: $[Cl^- < SCN^- < Ag(SCN)_2^-]$.

$$\text{Pour } Cl^- = 0 < \log {}^{NM\rightarrow S}\gamma < 3{,}3$$

$$\text{Pour } SCN^- = -0{,}8 < \log {}^{NM\rightarrow S}\gamma < 1{,}9$$

$$\text{Pour } Ag(SCN)_2^- = -1{,}7 < \log {}^{NM\rightarrow S}\gamma < 1.$$

La différence

$$\log {}^{0\rightarrow S}\gamma(Cl) - \log {}^{0\rightarrow S}\gamma(AgCl_2^-)$$

a été choisie par Badoz-Lambling et Bardin[13] comme critère d'aprotonicité des solvants. Un calcul analogue fait à l'aide des valeurs trouvées pour les ions SCN^- et $Ag(SCN)_2^-$ confirme le classement obtenu[13] (exception faite pour le DMSO) (Tableau 3). Nous remarquons que seul le nitrométhane et le carbonate de propylène sont des solvants de caractère aprotonique plus faible que le sulfolane. Le nitrométhane ne pouvant être utilisé (les solutions concentrées de SO_3 y sont peu stables), le carbonate de propylène et le sulfolane restent donc les solvants les mieux adaptés à notre étude. Cependant, au vu de l'expérience acquise ces dernières années dans notre laboratoire, il nous a paru plus judicieux d'utiliser le sulfolane.

Constante de dissociation de l'ion SO_3SCN^- dans le sulfolane

La réaction

$$SO_3 + SCN^- \rightarrow SO_3SCN^-$$

est réalisée par addition du thiocyanate de potassium

Tableau 3.

(a) $K_2 = \frac{(Ag^+)(SCN^-)^2}{[Ag(SCN)_2^-]}$; (b) Ref. 13; (c) Ref. 15; (d) Ref. 16; (e) Ref. 17; (f) Ref. 18.

à une solution de SO_3 dans le sulfolane en milieu $(C_2H_5)_4NClO_4$ 0,1*M* et suivie par potentiométrie à l'électrode d'argent.

L'étude conductimétrique ayant établi que KSCN et KSO_3SCN étaient dissociés, le traitement mathématique des courbes potentiométriques obtenues (Fig. 2) à partir des relations (III) et (IV) donne pour constante de dissociation de l'ion SO_3SCN^-:

$$K^{SO_3}_{SO_3SCN^-} = 10^{-11,5 \pm 0,45}$$

La valeur de cette constante, plus élevée que celle du produit de solubilité de AgSCN, montre que le thiocyanosulfate d'argent ne peut être préparé dans le sulfolane. De plus, l'écart relativement faible entre $K^{SO_3}_{SO_3SCN^-}$ et K_s^{AgSCN} ($\Delta pK = 3,3$) justifie que l'oxydation de l'argent en présence de SO_3SCN^- (Fig. 1) ait lieu à des potentiels proches de l'oxydation de l'argent seul.

Ce faible écart ne permet pas le dosage simple d'une solution de thiocyanosulfate dans le sulfolane par l'ion Ag^+, ce que nous avons pu constater expérimentalement.

Le pouvoir sulfonant d'un thiocyanosulfate est mesuré par la constante de l'équilibre:

$$MSO_3SCN \rightleftharpoons SO_3 + MSCN$$

Dans le cas où les deux sels sont dissociés (sels de potassium), la constante pour KSO_3SCN est aussi celle de l'équilibre:

$$SO_3SCN^- \rightleftharpoons SO_3 + SCN^-$$

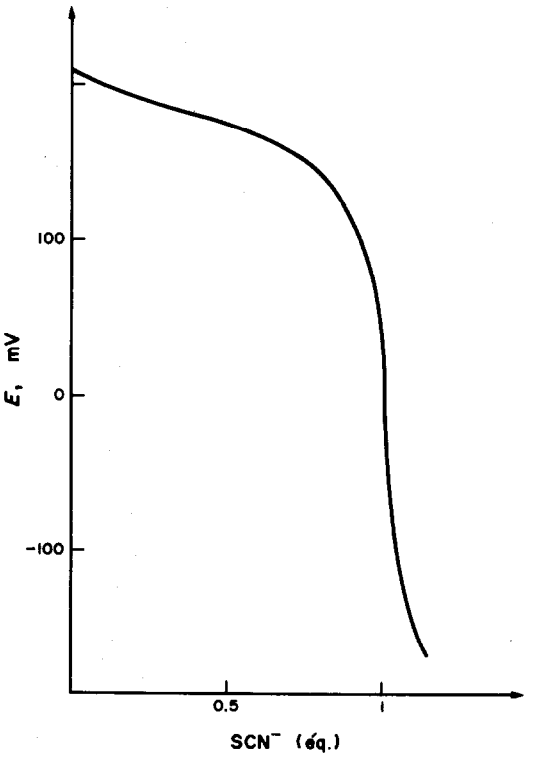

Fig. 2. Dosage potentiométrique d'une solution de SO_3 dans le sulfolane par KSCN.

soit

$$K^{SO_3}_{SO_3SCN^-} = 10^{-11,5 \pm 0,45}$$

Si M = NH_4, le thiocyanosulfate est dissocié à la différence du thiocyanate correspondant. Le pouvoir sulfonant qui peut alors s'exprimer par

$$K^{SO_3}_{NH_4^+SO_3SCN^-} = \frac{K^{SO_3}_{SO_3SCN^-}}{K^{D}_{NH_4SCN}} = 10^{-9,7 \pm 0,7}$$

augmente donc avec la stabilité du thiocyanate ($K^{D}_{NH_4SCN}$ = constante de dissociation ionique de NH_4SCN).

Notons que, dans le cas où aucun des deux sels n'est dissocié, la pouvoir sulfonant dépend du rapport des constantes de dissociation ionique $K^{D}_{MSO_3SCN}/K^{D}_{MSCN}$.

CONCLUSION

L'ion thiocyanosulfate apparaît être dans le sulfolane un agent de sulfonation faible mais plus fort que l'ion SO_3Cl^- ($K = 10^{-14,3}$) dont nous avions précédemment étudié la dissociation.[3] La différence entre le pK de dissociation de ces deux ions est en accord avec la plus faible stabilité thermique du thiocyanosulfate.[14] Elle montre que, *vis-à-vis* de l'acide SO_3, l'ion SCN^- est une base plus faible que Cl^- dans le sulfolane. Ce résultat est en accord avec les conclusions de Bréant *et al.*[19] qui constatent que SCN^- est une base plus faible que Cl^- *vis-à-vis* de l'acide H^+ dans des solvants dipolaires aprotoniques tels que le NM_2P et le DMF. Une étude plus générale du comportement de différentes bases *vis-à-vis* de l'acide de Lewis SO_3 dans le sulfolane devrait nous permettre d'établir un classement de la force d'autres agents sulfonants minéraux.

Summary—In a systematic study of the sulphonating properties of SO_3B complexes, we have paid attention to the thiocyanosulphates KSO_3SCN and NH_4SO_3SCN. We have shown conductimetrically that these salts are dissociated and that the ionic solvation is weak in the chosen solvent—sulpholane—which is strongly aprotic in character. We have determined potentiometrically the equilibrium constant K of the reaction $MSO_3SCN \rightleftharpoons MSCN + SO_3$, by means of the electrochemical couple $Ag + SO_3SCN^- \rightleftharpoons AgSCN + SO_3 + e^-$. The values found for the ammonium and potassium salts are $K = 10^{-11.5 \pm 0.45}$ and $10^{-9.7 \pm 0.7}$ respectively. Thiocyanosulphates appear to be stronger than chlorosulphates as sulphonating agents. Therefore SCN^- is a weaker base than Cl^- in sulpholane medium.

ANNOTATION

A COMPARATIVE STUDY OF THE APPLICATION OF THE METHOD OF LEAST-SQUARES IN THE POTENTIOMETRIC DETERMINATION OF PROTONATION CONSTANTS

M. CELIA GARCIA, G. RAMIS and C. MONGAY
Department of Analytical Chemistry, Faculty of Chemistry, University of Valencia, Valencia, Spain

(*Received* 13 *May* 1981. *Accepted* 5 *October* 1981)

Summary—Methods of simple and multiple linear regression applied to the potentiometric determination of protonation constants of diprotic and triprotic acids are studied critically. The best way of fitting the data, according to the order of magnitude of the constants, is established. The conclusions are checked by calculating the protonation constants of succinic and citric acids.

The potentiometric determination of the protonation constants of an acid—base system may utilize graphical or analytical methods. Graphical methods[1–4] have been criticised because of their lack of accuracy, but they may assist detection of incorrect points, which is usually not possible by using only analytical methods of calculation. Analytical methods, on the other hand, are quicker and more accurate and precise. They include the unweighted least-squares procedure, which requires only a simple calculation program, and has the advantage over other analytical methods that it can be done with programmable pocket calculators.

In recent years high-speed computers have been widely used for calculation of constants.[5–8] The computer programs often include weighting factors, and are relatively sophisticated.

If the successive protonation constants of an acid differ greatly in magnitude, they can be treated separately, but when they are close, simultaneous fitting of the data is necessary. This is the case discussed here. For diprotic acids, among the various methods described, the linear least-squares procedure has been widely used, because of its precision and ease and speed of application.

For triprotic acids, the available analytical methods are much more laborious, so graphical curve-fitting methods are usually recommended.[9] Here, the least-squares method has been considered as not entirely satisfactory by some authors.[10]

In the present work the extension of the least-squares method to triprotic acids is studied with the aid of an HP 67 calculator. The conditions of its applicability to diprotic and triprotic acids are examined in parallel, and examples are shown for acids for which the successive logarithmic constants differ by unity. Systems with larger and smaller differences are also tested, with analogous results.

Potentiometric determination of protonation constants involves two well-differentiated steps: first, measurement of the experimental points to get the set of values $(\bar{n}, h)$ and secondly, an appropriate treatment of the data to obtain the constants. In this paper, hypothetical acids with known constants are assumed in order to be able to discuss not only the precision, but also the accuracy of the method. The theoretical titration curves of these acids are calculated, then "experimental" titration curves based on these are simulated by adding Gaussian errors to the volumes of reagent and the values of pH.

Finally, the conclusions are applied to the determination of the protonation constants of two real systems, and the results are compared with others in the literature.

THEORETICAL TITRATIONS

For an n-protic acid, H_nA, titrated with a strong base, the titration curve is given by:

$$v = V \frac{\left(\frac{K_w}{h} - h\right) + \frac{\Sigma(n-i)\beta_i h^i}{\Sigma\beta_i h^i} C_A}{C_v - \left(\frac{K_w}{h} - h\right)} \quad (1)$$

where h is $[H^+]$, V is the volume of acid of concentration C_A, v is the volume of strong base of concentration C_v, and β_i is the ith overall protonation constant of the system, with $\beta_0 = 1$ by definition.

Values for the protonation constants of a hypothetical acid are selected and 40 "theoretical" points along its exact titration curve $v = f(\mathrm{pH})$ are calculated, giving values to the parameters V, C_A and C_v. From this "exact" curve, 15 simulated "experimental" titration curves are obtained as follows. Each "theoretical" point is transformed into an "experimental" one by addition of a Gaussian error generated with the aid of a table of Tippett numbers,[11] which gives random deviates in units of standard deviation. To make use of this table, standard deviations of 0.01 ml in the volume of titrant and of 0.001 in pH are assumed. These values are about the lowest expected for the techniques most commonly used in the determination of stability constants. They illustrate the gradual differences, not only in precision but also in accuracy, found for the different methods of linear fitting discussed here.

For the diprotic acids the values $V = 40$ ml, $C_A = 5 \times 10^{-3}M$ and $C_v = 4 \times 10^{-2}M$ are assumed, except for the titration of the very weak acid with $\log K_1 = 12$ and $\log K_2 = 11$, for which C_v was taken as $0.1M$.

For the triprotic acids the values $V = 30$ ml, $C_A = 5 \times 10^{-3}M$ and $C_v = 5 \times 10^{-2}M$ were used, except for the titration of the acid with $\log K_1 = 12.5$, $\log K_2 = 11.5$ and $\log K_3 = 10.5$ for which C_v was $0.15M$.

TREATMENT OF THE DATA

(a) Diprotic acids

The expression

$$\bar{n} = \frac{\beta_1 h + 2\beta_2 h^2}{1 + \beta_1 h + \beta_2 h^2} \tag{2}$$

may be written in the form:

$$Y = a_0 + a_1 X \tag{3}$$

where X and Y are functions of $\bar{n}$ and h, and the parameters a_0 and a_1 are directly related to β_1 and β_2. In this way, equation (3) may lead to the three forms shown in Table 1.[9]

For each of the 40 experimental points (v, pH) a pair of values ($\bar{n}$, h) is obtained. Only points with $\bar{n}$ values given by $0.1 \leqslant \bar{n} \leqslant 0.9$ and $1.1 \leqslant \bar{n} \leqslant 1.9$ are used, because of the sensitivity of the values of X and Y to slight experimental errors in $\bar{n}$ in the other ranges. For this reason, the number of useful points, N, is reduced to about 36 in each titration.

Each of the three equations in Table 1 is fitted by the least-squares method, by using the usual equations:

$$\sum Y = a_0 N + a_1 \sum X$$
$$\sum XY = a_0 \sum X + a_1 \sum X^2 \tag{4}$$

leading to three regression lines of Y on X, from which the constants K_1 and K_2 are estimated. In the same way, three regression lines of X on Y are fitted, leading to other values for the constants.

This procedure is followed in the 15 titrations for each acid. The mean values and standard deviations of $\log K_1$ and $\log K_2$ are given in Table 2. Standard deviations (s) are given with two significant figures.

(b) Triprotic acids

In the same way the expression

$$\bar{n} = \frac{\beta_1 h + 2\beta_2 h^2 + 3\beta_3 h^3}{1 + \beta_1 h + \beta_2 h^2 + \beta_3 h^3} \tag{5}$$

may be written as the equation of a plane

$$Z = a_0 + a_1 X + a_2 Y \tag{6}$$

where X, Y and Z are functions of $\bar{n}$ and h, and the parameters a_0, a_1 and a_2 are functions of the constants β_1, β_2 and β_3 as shown in Table 3.

For the same reason as above, only the values $0.1 \leqslant \bar{n} \leqslant 0.9$, $1.1 \leqslant \bar{n} \leqslant 1.9$ and $2.1 \leqslant \bar{n} \leqslant 2.9$ are used, reducing the number of useful data, N, to about 33 in each titration.

Each of the four planes in Table 3 is fitted by the least-squares treatment by solving the system of equations

$$\sum Z = a_0 N + a_1 \sum X + a_2 \sum Y$$
$$\sum XZ = a_0 \sum X + a_1 \sum X^2 + a_2 \sum XY$$
$$\sum YZ = a_0 \sum Y + a_1 \sum XY + a_2 \sum Y^2 \tag{7}$$

to obtain four regression planes of Z on X and Y. From each plane the values of the constants K_1, K_2 and K_3 are calculated. Similarly the regression planes of Y on X and Z, and of X on Y and Z are obtained.

The mean values and standard deviations obtained from the 15 simulated titrations are shown in Table 4.

Table 1.

Straight line	Equation	Y	X
I	$\beta_1 X + \beta_2 Y = 1$	$h^2 \dfrac{(2 - \bar{n})}{\bar{n}}$	$h \dfrac{(1 - \bar{n})}{\bar{n}}$
II	$\dfrac{1}{\beta_1} X + \dfrac{\beta_2}{\beta_1} Y = 1$	$h \dfrac{(\bar{n} - 2)}{(1 - \bar{n})}$	$\dfrac{\bar{n}}{(1 - \bar{n})h}$
III	$\dfrac{1}{\beta_2} X + \dfrac{\beta_1}{\beta_2} Y = 1$	$\dfrac{\bar{n} - 1}{(2 - \bar{n})h}$	$\dfrac{\bar{n}}{(2 - \bar{n})h^2}$

DISCUSSION

As stated previously, the values for the standard deviations of the pH and volume are at the lower limit of those normally observed. This allows better observation of the gradual differences in precision and accuracy. In practice, the deviations are often a little bigger, leading to more dispersed values than the ones shown in Tables 2 and 4.

In these tables, it can be seen that for equal deviations of pH and volume, slightly better precision is

obtained in the determination of the constants of diprotic acids than for triprotic acids. It is also clear that the four methods of fitting for triprotic acids lead to much larger differences in precision and accuracy than do the three methods for diprotic acids. The different methods of fitting would lead to the same set of constants if the experimental data were not subject to errors.

From Table 2 it can be seen that, for diprotic acids with pK-values of about 3.5–11.5, the values of X and Y are interchangeable, leading to negligible differences in the values of the constants and standard deviations.

For strong acids, the regression of Y on X appears to lead to results with similar standard deviations but less accurate mean values. This is also true for triprotic acids, where the greater differences show that the regression of Z on X and Y is clearly the least accurate.

Generally, straight line II was found to give better precision and accuracy than lines I and III. Some authors have distrusted this equation,[12] but others have accepted it.[13]

For strong acids, the results from straight line I are nearer to those from straight line II than those of straight line III are. For these acids, evaluation of K_1 is more accurate and precise than that of K_2 with both lines I and II. For strong bases, the results from straight line III are close to those of the straight line II, but straight line I gives poor agreement.

For the triprotic acids (Table 4) results from plane I are not very useful, and they become worse for weaker acids, eventually resulting in interchanged

Table 3.

Plane	Equation	Z	Y	X
I	$\beta_1 X + \beta_2 Y + \beta_3 Z = 1$	$h^3 \frac{(3-\bar{n})}{\bar{n}}$	$h^2 \frac{(2-\bar{n})}{\bar{n}}$	$h \frac{(1-\bar{n})}{\bar{n}}$
II	$\frac{1}{\beta_1} X + \frac{\beta_2}{\beta_1} Y + \frac{\beta_3}{\beta_1} Z = 1$	$h^2 \frac{(\bar{n}-3)}{(1-\bar{n})}$	$h \frac{(\bar{n}-2)}{(1-\bar{n})}$	$\frac{\bar{n}}{(1-\bar{n})h}$

values of the constants (log K_1 log K_2 *etc.*). Plane IV also does not give valid results for all acids. K_1 is always obtained with a slightly better precision than K_2 and K_3, which may become interchanged (log K_2 < log K_3).

Plane II leads to good results for all acids, but for the strongest acids, K_3 is less precise, and K_1 is the best constant. For medium-strength acids, this plane leads to acceptable values of all three constants. As the acid strength decreases, K_3 is determined with better precision (but plane III gives better precision for weak acids).

Plane III gives good results for weak and medium-strength acids (comparable to those of plane II for the latter). For strong acids, the results are not very good.

Results were also obtained for acids with greater and smaller differences between their protonation constants, and similar conclusions were reached.

CONCLUSIONS

For diprotic acids, least-squares fitting by means of straight line II is to be preferred. For strong acids, it is better to use the regression of X on Y. For other acids, both regressions should be performed, and the results with smaller dispersion, or the mean value, if both regressions have a similar precision, accepted.

For triprotic acids, the data should be fitted by means of plane II or III for strong and weak acids, respectively. For strong acids, the regression of Z on X and Y should not be used. For other acids, the three possible regressions should be calculated, and the one with the smallest dispersion, or the mean value of those with the smallest dispersion, accepted.

EXPERIMENTAL

Titrations were done at 20° with the aid of a Radiometer PHM 84, (resolution 0.001 pH unit) and a combination glass electrode, Radiometer GK2401 C, standardized against 0.05*M* potassium hydrogen phthalate (pH 4.001) and 0.025*M* potassium dihydrogen phosphate/0.025*M* disodium hydrogen phosphate (pH 6.874). The ionic strength was adjusted to 0.10*M* by addition of an appropriate amount of sodium perchlorate. All the reagents were of analytical grade.

(*a*) *Succinic acid.* Five titrations were done of 50 ml of $1.656 \times 10^{-3}M$ disodium succinate with 0.0212*M* hydrochloric acid. The mean values of the constants and standard deviations obtained by means of straight line II are shown in Table 5, where they are also compared with some literature constants obtained in similar conditions. Both regressions (X on Y and Y on X) were used because their standard deviations were of the same order of magnitude.

(*b*) *Citric acid.* Five titrations of 50 ml of $1.025 \times 10^{-3}M$ trisodium citrate were done with 0.0190*M* hydrochloric acid. The mean values of the constants and standard deviations calculated by means of plane II are shown in Table 6, where some values from the literature are also given. The three fitting possibilities were used.

LETTER TO THE EDITOR

THE ANALYTICAL METHOD OF CALCULATING THE DERIVATIVES OF EQUILIBRIUM CONCENTRATIONS

Sir,

In connection with the letter from Bugaevsky and Nikishina[1] on the analytical method of calculating the derivatives of equilibrium concentrations we would like to state that we were not aware of the publications of Bugaevsky and co-workers when we wrote our paper. That was our fault. However, we deliberately avoided the term "new" in our paper, because the rules for the derivation of implicit function systems have been known for more than a hundred years and can be found in any textbook on mathematical analysis. The question of priority implied by Bugaevsky and Nikishina therefore seems rather academic. We think it unfortunate that the technique seems to be unknown by most of the people working on solution equilibria, although the scientists working on the fundamental aspects of equilibrium systems have been using this method for decades. The most recent advances can be found in a review by Smith.[2]

We hope that these letters - in accordance with our original intention - will draw the attention of people working in the field of solution equilibria to the possibility of calculating the derivatives analytically.

USE OF ELECTROSTATIC PRECONCENTRATION AT HIGH SALT CONCENTRATIONS

P. A. MICHALIK and R. STEPHENS

Trace Analysis Research Centre, Department of Chemistry, Dalhousie University, Halifax, Nova Scotia, Canada

(*Received* 2 *October* 1981. *Accepted* 28 *December* 1981)

Summary—Apparatus is described for the electrostatic preconcentration of aerosol particles with a collector trough electrode from samples containing large amounts of matrix salts. A cooling and filtration cycle is used to precipitate and separate the matrix salts, and prevent saturation of the collector solution. The system has been applied to the preconcentration of sea-water species before analysis by flame atomic-absorption spectroscopy.

Electrostatic collection has been used successfully for the concentration of species in air[1,2] and water[3,4] samples. In the latter case the procedure requires initial conversion of the solution into an aerosol, which is then desolvated and collected either on a wire[3] or in a trough[4] electrode. In practice the trough electrode is the more convenient, as the concentrated sample is obtained as a solution and is therefore immediately available for analysis, but the collector solution rapidly becomes saturated if the original sample solution contains high concentrations of matrix salts. After this point is reached aerosol particles are still collected, but as a solid layer on the bottom of the trough rather than in solution. It is found that any analyte contained in such undissolved particles remains *in situ*, rather than being released to the solution. Hence the preconcentration process ceases to be useful at this point.

This limitation restricts the applicability of electrostatic preconcentration, at least when a liquid collector is used. Thus, for example, the preconcentration of sea-water trace species is rendered impracticable, which is a pity because the low trace element concentrations and availability of large samples make this an obvious application. The present work was carried out to determine whether the trough collector could be modified to overcome this problem and used for preconcentration of sea-water.

EXPERIMENTAL

Apparatus

The equipment has already been described.[4] The trap was modified as below.

For preconcentration of trace species in samples which contain large amounts of matrix salts, the latter must be precipitated at some point in the apparatus other than the electrostatic collector. The system used for this is shown in Fig. 1. The collection medium (water) is lifted above the collector by a peristaltic pump, then passed through a 1-ml reservoir into a filter funnel (7 cm diameter; Whatman No. 1 paper), and allowed to enter the collector trough through a drip feed. A second drip feed carries water from the other end of the collector trough back to the pump inlet. The drip feed arrangement was adopted to provide electrical isolation between the high voltage on the collec-

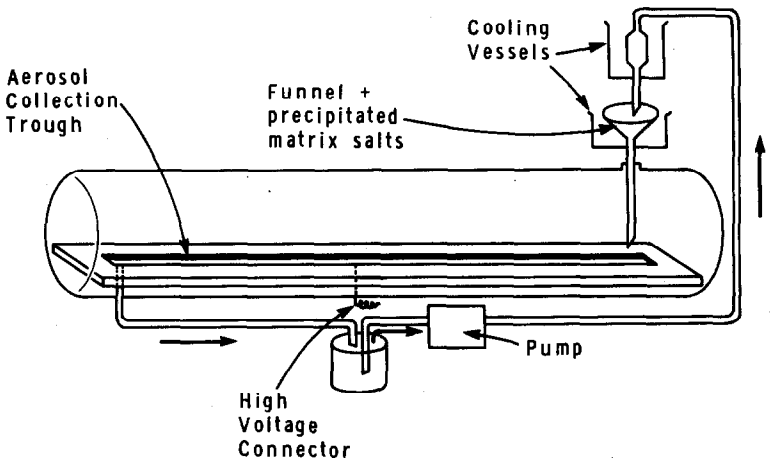

Fig. 1. The apparatus.

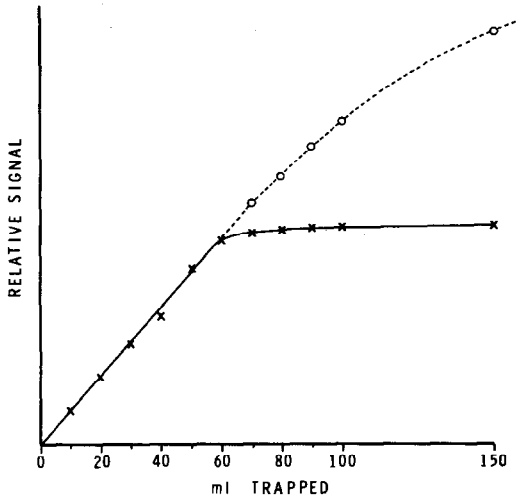

Fig. 2. Response from the collector solution *vs.* amount of sample solution which was concentrated. Open circles and crosses represent points obtained with and without use of the filtration system.

tor and the rest of the apparatus, which was grounded. The volume of solution required to fill this modified collector was 8 ml, eight times the volume used in the original trap. To minimize the amount of sample solution required to achieve a given concentration factor with this increased collector volume, it was decided to increase the efficiency of aerosol generation. This was done by preheating the air supply to the pneumatic nebulizer to 90°, which gave about 25% conversion of solution into aerosol at an uptake rate of 4.5 ml/min.

During operation, the filter funnel and reservoir are surrounded by a plastic jacket containing an ice–salt freezing mixture. During trapping, sample aerosol dissolves in the collector solution as usual, increasing its salt content. However, the cooled solution in the reservoir and funnel reaches saturation before the solution in the electrode trough. Thus the matrix salts crystallize and are retained in the funnel. After leaving the funnel the filtrate warms up sufficiently to dissolve more trapped aerosol particles. This cycle can be repeated almost indefinitely, eventually providing a solution of the concentrated trace components (together with a high loading of dissolved matrix material) for analysis, and a filter funnel in which the bulk of the matrix salts is retained as solid crystals. Any water held in these crystals is drawn from the reservoir above the funnel (Fig. 1).

This process relies on the matrix material crystallizing as the pure salt, leaving trace constituents in solution. If equilibrium is established between the salt and the solution with which it is in contact then the extent to which preconcentration is realized depends on the distribution coefficient of the material of interest between the solid and liquid phases, *i.e.*, upon its chemical potential in the two media. In practice the usual processes of occlusion, adsorption *etc.* will tend to increase the analyte concentration in the solid phase to above the equilibrium level. Therefore all these processes are expected to combine to cause reduction in the efficiency of preconcentration once collection of the matrix salts begins.

The correct rates of heating and cooling required for crystallization to proceed in the manner described were established by varying the flow-rate of the pump. A flow-rate of 2 ml/min was found to be satisfactory. The exact value does not appear to be critical.

Procedure

The procedure adopted with the present system was similar to that described previously.[4] That is, the trapping system was set up and the nebulizer allowed to aspirate a given volume of sample solution. As before, the latter process could run automatically and unattended.

To carry out an analysis the trap was initially calibrated with a known concentration of analyte in a salt solution of appropriate composition. This gave the trapping efficiency of the device (*i.e.*, the ratio of amount of analyte retained in the trap solution to the total amount entering the trap). The collector solution was analysed by the standard-addition method. Background correction was applied to all atomic-absorption readings.

It was found necessary to reduce trapping voltages to about 10–12 kV. At higher voltages the liquid in the collector tended to creep over the edges of the trough: in addition, significant liquid loss occurred in the trap because of aerosol generation. This phenomenon has been described by Mavrodineanu and Boiteux.[5] However, it was not observed in the previous work, even at trapping voltages up to 20 kV, possibly because a slightly wider collector trough was used.

RESULTS AND DISCUSSION

The effectiveness of the cooling system in removing unwanted matrix salts was tested by trapping solutions containing 1 μg of lead and 100 mg of sodium chloride per ml, with and without the cooling system in operation. The concentration of lead in the collector solution was measured as a function of the volume of sample solution aspirated. Results are given in Fig. 2, and show that the cooling system gives greater analyte preconcentration than the previous arrangement does. Salt crystals were seen to collect in the filter funnel as expected.

Measurement of trapping efficiency

Trapping efficiencies were generally determined from atomic-absorption measurements and suitably prepared calibration graphs rather than by the procedure described originally.[3,4] Figure 3(*a*) shows the calibration graph for cadmium obtained by plotting response *vs.* concentration, no trapping being used. Figure 3(*b*) shows the corresponding graph obtained

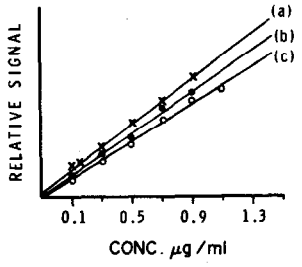

Fig. 3. (*a*) Calibration curve for Cd^{2+}, obtained by aspirating increasing concentrations into the flame without use of the trap. (*b*) Calibration curve for Cd^{2+}, obtained by preconcentrating volumes of 0–80 ml into 8 ml of collector solution. Sample solution was 0.1-μg/ml Cd^{2+} in distilled water. (*c*) Results of (*b*) repeated for 0.1-μg/ml Cd^{2+} in 3% NaCl solution.

Table 1. Trapping efficiencies for various elements in distilled water and sodium chloride media

	Trapping efficiency from calibration, %		Trapping efficiency by signal reduction, %	
Element	Distilled water	30 g/l. NaCl	Distilled water	30 g/l. NaCl
Cd	81	76	79	77
Cr	78	73	75	73
Cu	93	93	75	77
Pb	79	74	80	78
Zn	78	75	82	77

for volumes from 0 to 80 ml of 0.1 μg/ml cadmium solution with trapping into the 8 ml collector volume without the cooling system. Figure 3(*c*) is the graph for 0–80 ml of 30 g/l. sodium chloride solution containing 0.1 μg of cadmium per ml, with the cooling system in operation. It is assumed that if the device were 100% efficient all three graphs in Fig. 3 would coincide. Thus the trapping efficiency is given by the ratio of the signal on graph (*b*) or (*c*) to that from curve (*a*).

This procedure is more convenient than the original version because it simultaneously takes into account the inability of the electrostatic field to trap all the available aerosol particles, analyte loss due to retention in the filter system, and any dependence these effects may have on analyte concentration.

Table 1 gives the trapping efficiencies for various elements, measured by this procedure. They are essentially the same except for copper. They also appear to be only slightly reduced by the sodium chloride matrix. Table 1 also shows the trapping efficiencies determined separately by the original procedure, *i.e.*, by aspirating a standard solution of known, high concentration and measuring the signal reduction when the trapping voltage was applied. The difference between the two sets of values (*i.e.*, between the amount of material which is trapped and that which reappears in solution) provides a straightforward way of measuring the total amount of analyte irreversibly trapped and held by the system. It is assumed that the bulk of this unrecovered material is retained by the crystallized salts in the filter. Table 1 shows this amount was small in these experiments.

The trapping efficiencies given for copper in columns 1 and 2 of Table 1 are obviously high and inconsistent with the values in columns 3 and 4. The most likely explanation for these results is contamination of the collector solution. In fact contamination by copper is difficult to avoid with the present apparatus because of the various electrical components located around the trap.

Analysis of sea-water

After the apparatus had been tested with sodium chloride, the experiments were repeated with magnesium chloride as the matrix salt, but the results were not satisfactory. The magnesium chloride, solution in the cooling system and collector trough merely became supersaturated, with no precipitation. This caused the trap to cease functioning, because trapped aerosol particles failed to dissolve in the collector (the effect observed in the original liquid collector in the presence of high salt concentrations[4]). Therefore it was decided to proceed directly to examination of preconcentration of sea-water, to find out whether matrix salt(s) would be precipitated or whether supersaturation of the collector solution would render the process inoperative.

Sea-water was obtained from a supply pumped into the building from an adjacent inlet. Samples were acidified by addition of 1 ml of concentrated hydrochloric acid per litre immediately on collection, to give a final solution pH of about 2.0. The acid was prepared immediately before use by dissolving hydrogen chloride in demineralized distilled water.

It was found that the trap behaved towards these samples in the same way as it did to solutions of sodium chloride. The precipitated salts collected in the filter, trapped material dissolved continuously in the collector, and the concentration process could be continued almost indefinitely. Analysis of the precipitated material collected after some minutes of operation showed it to consist of a mixture of sodium chloride and magnesium chloride. It was concluded that sodium chloride probably precipitated first, and that the crystals thus formed acted as nuclei for the crystallization of other salts and thereby prevented supersaturation from occurring.

Standard-addition measurements were then made on the sea-water to test the reproducibility and trapping efficiency of the system. The behaviour of the trap was found to be indistinguishable from that already described for sodium chloride. These results gave some confidence in the ability of the system to effect a reliable concentration of the trace elements in sea-water. Accordingly, analyses were done for Cd, Cu, Cr, Pb and Zn to test the system. Each sample was divided into three immediately before analysis. The first part was preconcentrated and analysed by using the trap, followed by flame AAS, as described above for sodium chloride solutions. The other two parts were analysed directly by graphite-furnace AAS

Table 2. Comparison of concentrations found in sea-water ($\mu g/l.$)

Element	Trap/flame AAS	Anodic stripping	Graphite furnace
Cd	3.2	2.1	2.5
Cr	3.2	—	2.6
Cu	11	2.6	2.3
Pb	2.4	1.7	8.0
Zn	8.7	—	11

and by anodic-stripping voltametry for comparison. Results are given in Table 2.

Overall, the concentrations in Table 2 appear rather high, but are felt to be correct, the reason being that the source of the sea-water lay in the city and the water was piped and stored before use. The copper value obtained by use of the trap is particularly high, but as already mentioned, this is probably due to contamination from the apparatus. The other results are felt to be reasonably consistent, given the complex nature of the sample matrix,[6–8] though the high value obtained for lead by the graphite-furnace method may be noted. The reason for this apparent anomaly is under investigation.

CONCLUSIONS

The results show that it is feasible to use electrostatic preconcentration with a liquid collector for solutions which contain macroscopic quantities of matrix salts. The modified apparatus used here retains the advantages of automatic operation and an inherently low risk of contamination which characterized the original system. The cooling process used to force crystallization and separation of the salts probably occurs fast enough to cause retention of analyte by the filter system in amounts greater than those corresponding to equilibrium. Despite this, use of the cooling system reduced the trapping efficiency by only $\sim 5\%$, an encouraging sign of the potential tolerance of the system for variations in matrix composition.

Despite the success of the device with sea-water the use of a saturation and precipitation cycle to remove matrix salt(s) probably has less ability to remove matrix interferences than was apparent here. In particular, the results with magnesium chloride show that supersaturation can occur in practice. This effect is easy to recognize, however, since the trap completely ceases to operate. It also appears to be simple to cure, by addition of some nucleating species to the system. The results suggest that sodium chloride is effective for this purpose. However, it seems likely that, in addition to such obvious effects, some less apparent interferences can be expected, for instance through co-precipition, which might simply alter trapping efficiency to a greater or lesser extent. The occurrence, severity and possible remedies for such effects have not yet been investigated.

The consistency of the results found for sea-water shows that the trap is capable of functioning satisfactorily in the presence of a complicated matrix, and also demonstrates a useful and practical application of the device. It is thought likely that other types of sample containing high salt loadings could be treated with similar success, provided that the behaviour of the sample matrix in the collector system were investigated first.

(*Received* 19 *October*, 1981. *Accepted* 26 *December* 1981)

Summary—Distribution coefficients and capacities have been determined for many different organic compounds on a new molecular sieve called silicalite, which does not adsorb water but does adsorb small organic molecules with diameters up to 6 Å, from both liquid and gaseous streams. The characteristics of silicalite have been examined closely and new applications for it are briefly described.

Four years ago the Linde Division of Union Carbide developed a new molecular sieve[1] called silicalite, possessing a feature unique amongst all other natural and synthetic molecular sieves. Generally, molecular sieves are strongly hydrophilic and can be used to sorb water from organic solvents and from gas streams. However, silicalite is hydrophobic and can instead sorb different organic molecules from aqueous solutions and from gas streams.

Silicalite is a polymorph of silica, with a rather unusual crystal structure. It has a tetrahedral framework with a large fraction of 5-membered rings composed of silicon–oxygen tetrahedra. The material has intersecting channels defined by rings of 10 oxygen ions (Fig. 1). A mixture containing silica, hydroxide ions and alkylammonium cations, is crystallized hydrothermally in a closed system, resulting in a silica clathrate around each alkylammonium ion. This material is then calcined in air to produce the open-pore structure called silicalite. The channels are 6 Å in diameter and the total pore volume is about 33%.[2] The alkylammonium cations, which have hydroxide counterions to maintain charge balance, are driven off during the heating process. Crystalline silicalite produced in this way is in the form of particles of approximately 5–20 μm breadth. This material is referred to in this paper as unbonded silicalite. Aluminosilicate clays are used as binders to form larger particles.

Silicalite is very stable to heat: it will degrade only at temperatures higher than 1100°. It is stable in most solvents, but slowly decomposes in basic solutions. Silicalite is fairly brittle: breakage of the silicalite particles can sometimes occur during excessive shaking.

* This work was supported by the U.S. Environmental Protection Agency under Contract No. 68-03-2974 and was performed in the Ames Laboratory which is operated by the U.S. Department of Energy under Contract No. W-7405-eng-82.

The most important property of silicalite is that it will sorb non-polar and polar organic compounds, even some which are completely miscible with water, such as ethanol. For sorption, the diameter of the molecules must not exceed 6 Å. However, water itself is not adsorbed, because water molecules associate into clusters of 10–12 molecules with a total diameter larger than 6 Å.[2] Silicalite will sorb small molecules from liquid, vapour and gas streams.

The use of silicalite for removal of ethanol from fermented beer has been studied.[3,4] A sorption process for the production of ethanol is potentially more attractive than a distillation process because of the possible lower capital investment and energy cost. The sorbed ethanol can be removed from the silicalite column by increasing the temperature or the pressure. Another application of silicalite is the removal of chloroform from drinking water.[5]

In this work, an extensive study of the characteristics of silicalite and its applications was undertaken. Distribution coefficients and capacities for a wide variety of compounds were determined. The effects of the binder and temperature on the performance of silica-

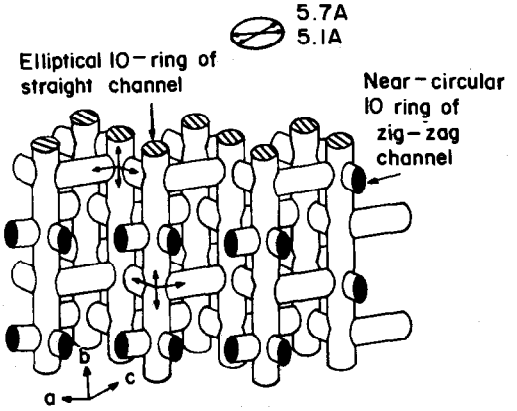

Fig. 1. Pore structure of silicalite (by courtesy of *Nature*).

lite have been investigated. The results suggest many new uses for the material.

EXPERIMENTAL

Apparatus

A Gow Mac 550 gas chromatograph with thermal conductivity detector was used for the gas-phase distribution studies. Short copper columns were used (4 mm bore, 19–20 cm length), filled with different types of silicalite. High-purity helium was used as carrier-gas. For the liquid-phase distribution studies, a Tracor 550 gas chromatograph with flame-ionization detector was used. A Tenax column (80–100 mesh) was used as the stationary phase with nitrogen as the carrier-gas.

Solutions and sorbents

All solutions for the liquid-phase distribution studies were made up in water that had been distilled and demineralized. The standard solutions were 100 ppm v/v. The chemicals were used as received, and had purities of at least 97%, with the exception of phenol (89%), 1-chlorododecane, chloroacetaldehyde (45%) and dichloroacetonitrile (90%). The gases had a purity of at least 99%, with the exception of carbonyl sulphide (97.5%).

Two types of silicalite (Linde Division, Union Carbide) were used as the sorbent: pure non-bonded silicalite (S 115) with a particle size of 5–20 μm, and bonded silicalite (LZ 115) with a particle size of up to 1 mm. Before use the silicalite was cleaned by heating in a porcelain crucible for at least 10 hr at 750° in a muffle furnace. The bonded silicalite was crushed and sieved to obtain different mesh sizes.

Measurements and calculations

Gas-phase distributions were calculated by measuring the retention time of pure compounds under isothermal conditions. The distribution data are expressed as distribution coefficients:

$$D_g = \frac{\text{(retention time} \times \text{flow-rate)} - \text{dead volume}}{\text{g of silicalite}}$$

The dead volume was determined from the retention time of 2,2,4-trimethylpentane, which is not retained by silicalite.

Liquid-phase distribution data were obtained by shaking a known amount of silicalite with 10.00 ml of standard solution for 1 hr. After the silicalite had settled, 2 μl of solution were injected into the gas chromatograph. The peak heights obtained were compared to those for corresponding standard solutions. From this ratio the distribution coefficients were calculated and expressed as

$$D_g = \frac{\text{amount retained/g of silicalite}}{\text{amount in solution/ml water}}.$$

The distribution coefficients of acids were determined by titration of 5.00 ml of equilibrated solution with standard sodium hydroxide solution, with phenolphthalein as indicator.

Capacities of silicalite for gases were measured by passing the gases through a column filled with bonded silicalite. The columns were weighed periodically until no further weight increase was detected.

The capacity for liquids was determined from breakthrough curves. Solutions (0.1% v/v) were pumped through a column (25 cm × 4 mm bore) filled with bonded silicalite. The effluent was monitored continuously with a Tracor 970A variable-wavelength ultraviolet detector. The wavelength was selected as appropriate for the compound being studied. The capacities for ethanol and chloroform were measured by fraction collection and gas chromatographic analysis. The columns used here were 31 cm long and 6 mm in bore and were filled with 4.70 g of granular (1 mm) silicalite.

RESULTS AND DISCUSSION

Two series of measurements were made to characterize silicalite, involving the determination of distribution coefficients for many compounds in both gas and liquid phases and the recording of breakthrough curves from which capacities were calculated. The results are presented in Tables 1–5.

Distribution coefficients of compounds in the gas phase

Values of the gas–solid distribution coefficients are given in Tables 1 and 2. Both gases and liquids were studied. Some compounds reached equilibrium in the gas–solid distribution very slowly, resulting in very broad peaks. For these compounds the distribution coefficient is given to only one significant figure.

The pore size is the most characteristic property of silicalite. Molecules with a diameter larger than 6 Å are sorbed very slowly or not at all. Molecules smaller than this are very strongly sorbed and give high distribution coefficients. Compare, for example, the D_g values of trimethylpentane and 2-methylpentane on non-bonded silicalite (0 and 90 respectively). However, for very small molecules, such as formaldehyde or oxygen, the distribution coefficients are lower, because while these smaller molecules fit easily into the pores of silicalite they can also easily move out again.

Within a homologous series a maximum distribution coefficient seems to exist at a certain carbon number. This effect is to be expected. Molecules should be linear to fit into the silicalite pores, so for a given molecule to be sorbed the energy needed to straighten the chain should be less than the energy of sorption by silicalite. The longer the molecule, the more energy it will take to straighten it and the lower the distribution coefficient will be.

Branching in a molecule results in a larger effective diameter of the molecule: when this diameter exceeds 6 Å the molecule will not be sorbed by silicalite. Comparison of the distribution coefficients of pentane, 2-methylpentane and 2,2,4-trimethylpentane shows this clearly (50, 90, 0 respectively).

Temperature effect

The effect of a change in temperature on the distribution coefficients of liquids is very large (see Table 1). Methanol, for example, has a D_g of 27 at 250°, 61 at 200° and 110 at 150°, methyl formate has a D_g of 41 at 250° and 88 at 200° (on non-bonded silicalite). This can be used to advantage in desorbing compounds from silicalite to clean it for future use. In general, molecules are sorbed more strongly at lower temperatures and are more easily desorbed at higher temperatures.

Small gas molecules interact very little with silicalite at any temperature, with the exception of sulphur dioxide, carbon dioxide, ethane, ethylene, acetylene and propane. The low sensitivity of the thermal conductivity detector at large retention times prevented the measurement of distribution coefficients for most liquids at temperatures of 150° and below.

Effects of the binder

Since pure silicalite has a very small particle size (5–20 μm), a binder is added so that particle sizes of up to 1 mm diameter can be obtained. The binder used contains alumina, making the product more hydrophilic than the pure silicalite. The effects of this binder can be seen from the data in Table 2. The more polar compounds have a higher affinity for the bonded silicalite, which is explained by the fact that the binder is polar. Conversely, bonded silicalite sorbs non-polar compounds less than non-bonded silicalite does, perhaps because of a repulsion between the hydrophilic binder and the hydrophobic compounds.

Distribution coefficients of compounds in the liquid phase

The liquid–solid phase distribution coefficients in Table 3 show that most of the compounds tested are taken up well by silicalite. Even compounds which are

completely miscible in water, such as ethanol and acetic acid, are still sorbed by silicalite. Equilibrium is reached rapidly in these sorption processes, as indicated by measurements of concentrations in the aqueous solutions as a function of time. No noticeable difference was found in the degree of sorption attained after equilibration times of 1 min and 1 hr.

The existence of a maximum D_g for a homologous series is seen in the aldehyde series: pentanal is most strongly sorbed, with the highest D_g value of 2800. Both shorter and longer-chain aldehydes have smaller distribution coefficients. The effect of molecular diameter (as opposed to length) can be seen in a comparison of the distribution coefficients of acetaldehyde and 2-chloroacetaldehyde, 575 and 23 respectively. Noteworthy is the high distribution coefficient of dichloroacetonitrile, a compound which is receiving considerable attention because of its potential car-

cinogenic danger. Possibly, silicalite could be used to isolate and concentrate this compound from natural waters.

Capacity

Measurements of the uptake of compounds from the gas phase have shown that silicalite has a very large capacity for many gases (see Table 4). The amount of gas sorbed is so much larger than the pore volume of silicalite (0.19 ml/g) that the gas must be sorbed with its molecules in contact, *i.e.*, in virtually a condensed state.[2]

It is interesting to note that the capacity is higher for the larger gas molecules: sulphur dioxide 67 ml/g, propane 39 ml/g, butane 38 ml/g, in comparison with oxygen and nitrogen, both 8 ml/g.

From the liquid phase, breakthrough capacities of up to 15% have been found (see Table 5). For phenol, propanal, pentanal and acetonitrile, breakthrough was so slow that the 50% breakthrough point could not be determined. Brief experiments were done to determine the influence of sodium chloride, humic acid and the surfactant Zonyl FSP on the capacity for ethanol. Addition of sodium chloride slightly increases the capacity for ethanol, for which 50% breakthrough was reached at a capacity of 15.1% from water and 15.8% from 1% sodium chloride solution. Addition of 0.1% v/v Zonyl FSP surfactant increased the capacity to 16.7%, while addition of 8.0 mg of humic acid per 100 ml of aqueous ethanol increased the capacity to 15.7%. The molecules of both Zonyl FSP and humic acid are too large to be sorbed by the silicalite.

Possible applications

The unique characteristics of silicalite suggest several valuable uses in analytical chemistry. The ability of silicalite to retain small organic molecules should be useful in the concentration–extraction of C_1–C_{10} aldehydes, acrylonitrile and dichloroacetonitrile from dilute aqueous samples, especially since synthetic polymer resins used to sorb organic molecules from aqueous solutions are not effective in removing those compounds that are highly miscible with water.[6,7]

The compounds retained on silicalite can be recovered by thermal desorption.[8,9] The ability of silicalite to sorb small gas molecules preferentially should also be useful. Gases could be purified by removal of their low molecular-weight impurities. Sulphur dioxide, which is very strongly retained, could possibly be removed from stack gases: the excellent temperature stability and inertness of silicalite are attractive attributes for this application.[10]

A POROUS-JET FLOW-THROUGH ELECTRODE

JOSEPH WANG* and HOWARD D. DEWALD
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

(*Received* 1 *September* 1981. *Accepted* 14 *December* 1981)

Summary—An electrochemical flow detector, based on a jet of solution directed at a thin porous carbon electrode, is described, along with its electrochemical characteristics and analytical applications. The electrode has a volume of 19 μl and surface area of 1.26 cm². The detector exhibits better sensitivity and detectability than a wall-jet detector. Dopamine and ferrocyanide were used as test systems to give detection limits at nanomolar concentration levels. Applications indicated include continuous-flow analysis (utilizing stopped-flow voltammetry) and flow-injection analysis.

With the growing interest in hydrodynamic voltammetry as a sensitive analytical tool, efforts are being made toward developing working electrodes of better properties. Flow-through solid electrodes based on various configurations have been introduced in recent years.[1] The most popular cells (which are also commercially available) are those in which the solution flows through a thin-layer channel,[2] through an open tubular electrode,[3] or onto a wall-jet electrode.[4] The wall-jet detector in particular offers the advantages of very high sensitivity, extremely small dead volume and freedom from surface adsorption.[5,6] In addition to these cells, various flow-through porous electrodes are being employed, aimed mainly at improving detector response by increasing the electrode surface area. The porous electrode material (*e.g.*, carbon, platinum or silver particles) is usually packed in cylindrical columns, which have relatively large (0.1–5 ml) dead volumes. This presents a drawback for use as a detector in monitoring chromatographic column effluents, where a low dead-volume flow-cell is required in order to maintain the separation achieved by the column.

In this article we describe the behaviour and use of a very thin porous carbon disk electrode under a jet-flow of solution. Such an electrode is a hybrid between the wall-jet electrode and a porous carbon electrode. It combines the small volume and effective mass-transport that characterize the wall-jet electrode with the large surface area of a porous electrode. The sensitivity and detectability are thus made better than those of the wall-jet electrode. The porous disk is made of reticulated vitreous carbon (RVC), a material possessing many electrochemical and hydrodynamic advantages.[7] RVC has been exploited recently as an effective working electrode in a variety of flowing systems.[8–10] The electrodes employed in these studies had volumes of about 0.1–2 ml. Although the present electrode has a volume of only 19 μl it has a substantial surface area of 1.26 cm.[2] Cell design and operation are simple. Its characteristics and advantages are elucidated in this paper.

EXPERIMENTAL

Apparatus

A schematic diagram of the cell is shown in Fig. 1. The body consists of two 1.25-in. diameter "Plexiglas" blocks, the upper block 0.75-in. thick and the lower one 0.69-in. thick. The two blocks are held together with three stainless-steel bolts (not shown). A solution inlet (A) (0.34-mm diameter) is drilled in the upper block. An RVC disk (C) (2 × 3-S type, 0.55-cm diameter, 0.083-cm thick, 100 pores per inch, Fluorocarbon Co., Anaheim, Cal.) is placed exactly opposite the solution inlet. Electrical contact to the RVC is made through the face of a glassy carbon rod (2.5-mm diameter) which is bonded with conducting epoxy cement to a copper wire (F) that leads to the outside of the lower block. Bolting the two blocks together exerts pressure on the RVC disk and five Teflon washers (E) (each

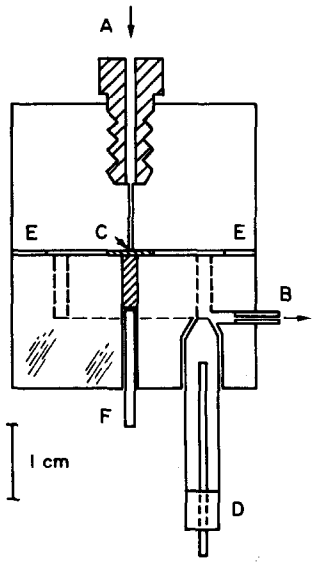

Fig. 1. Flow-through cell assembly. A, Sample solution inlet; B, Sample solution outlet; C, RVC disk; D, reference electrode; E, Teflon spacers; F, lead to working electrode.

0.005 in. thick, 1.0 cm i.d., 1.6 cm o.d.) separating the blocks. To maintain uniform flow in all directions an annular cavity (0.7 cm i.d., 0.9 cm o.d., 0.8 cm deep) is machined in the lower block (dashed line). The solution leaving the working electrode flows through the cavity, and is discarded through Tygon tubing (1/32-in. bore, 1/32-in. wall) sealed with epoxy cement into a hole drilled in the lower block (B). The Ag/AgCl reference electrode (D) was introduced into the outflow solution through an appropriate well drilled in the lower block. A rubber O-ring (not shown) forms a seal round the reference electrode. The cell construction permits easy and fast replacement of the working electrode.

The sample solution is placed in a 250-ml Nalgene beaker. Solution flows from the beaker to the cell by gravity, through 0.5-mm bore Teflon tubing and a tube-end fitting (a hydraulic head of about a foot permits flow-rates up to 3 ml/min). The flow-rates are calibrated and checked volumetrically. All our measurements are made with a Sargent-Welch Model 3001 Polarograph.

Reagents

The chemicals and reagents used have been described in detail previously.[11]

Procedure

Small air-bubbles were removed from the fresh RVC disk by pumping demineralized water up and down rapidly with a syringe located at the solution outlet. The fresh surface was activated by applying potentials of +0.9 and −0.9 V alternately, allowing 1.5 hr at each potential, over a period of 6 hr.

Daily electrode pretreatment consisted of applying potentials of +0.9 and −0.9 V alternately over a period of 10 min, allowing 2 min at each potential and ending with application of the positive potential. Following pretreatment, the desired working potential on the plateau was applied. The transient currents were allowed to decay until a steady state was reached. Following this, measurements were made on the background solution and the analyte solution. All data were corrected for background. Stopped-flow working was obtained by turning on and off a stopcock inserted between the solution reservoir and the cell. Stopped-flow voltamperograms were taken pointwise by making 100-mV changes in the applied potential and waiting for about 20 sec before applying the flow pulse.

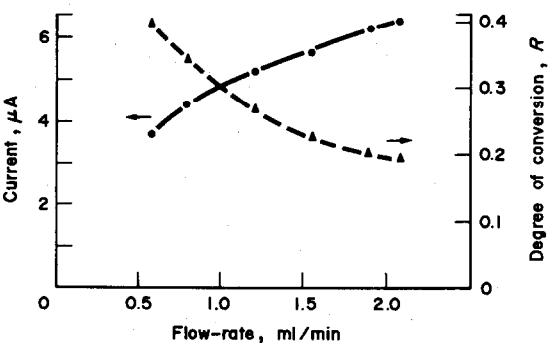

Fig. 2. Dependence of the limiting current and degree of conversion on flow-rate: 10 μ*M* $K_4Fe(CN)_6$ in 0.1*M* phosphate buffer (pH 7.4); applied potential +0.90 V.

The flow-injection measurements were performed by alternating (with a three-way stopcock) between the carrier solution (the supporting electrolyte) and the sample solution. Details are given in the following section.

RESULTS AND DISCUSSION

Mass transport

The dependence of the limiting current and of the degree of conversion (*R*) on the flow-rate is shown in Fig. 2. *R* is the fraction of electroactive species electrolysed while the solution is passing through the electrode. A log–log plot of current against flow-rate (not shown) is linear, with a slope of 0.42. *R* Values ranging from 0.32 to 0.73 for have been reported for different lengths of RVC column.[9] *R* depends on the residence time of an element of solution in the RVC electrode, so decreasing the flow-rate provides larger conversion efficiency. For the flow-rates used in this study *R* increases from 0.19 at 2.08 ml/min to 0.40 at 0.58 ml/min. At these flow-rates the calculated residence times of the solution in the electrode volume are 0.57 and 2.06 sec, respectively. The slope of the

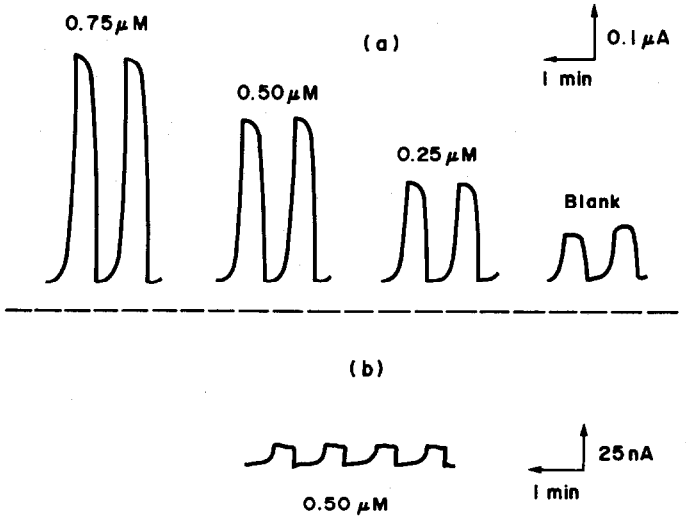

Fig. 3. Stopped-flow response at the submicromolar concentration level. (*a*) Porous-jet electrode. (*b*) Wall-jet electrode (distance between the nozzle tip and the electrode surface, 0.25 mm). Conditions: flow-rates 1.2 ml/min (on) for 20 sec, and 0 ml/min (off) for 30 sec; applied potential. +0.85 V.

log–log current *vs.* flow-rate plot for intermediate efficiency electrolysis detectors depends upon the flow regime and the degree of conversion.[12] Different electrode dimensions (and hence different degrees of conversion) will therefore result in different values of the slope.

While the mass-transport equation has not been solved exactly, for the analytical purposes for which the cell was designed the limiting current I_l can be described in the following empirical form, as was suggested for other intermediate efficiency electrolysis detectors:[12,13]

$$I_l = fC_0V^m \quad (1)$$

where f and m are experimental parameters (that may change with the degree of conversion), C_0 is the bulk concentration of the electroactive species, and V is the solution flow-rate.

Stopped-flow voltammetry

Analytical advantages may be gained when the high analytical currents at solid electrodes are combined with sensitive techniques that discriminate against the high background current. Stopped-flow modulation voltammetry has been shown to be effective in discriminating against most components of the background currents at flow-through solid electrodes.[14] Figure 3(*a*) illustrates the sensitivity and detectability obtained at the porous jet electrode by employing this modulation procedure. It is a reproduction of a chart-record for ferrocyanide at submicromolar concentration levels. The blank stopped-flow current corresponds to a concentration around 0.22 μM. The noise level is around 2 nA, corresponding to a limit of detection of about 4nM (for a signal equal to the noise). Similar values have been reported for large-volume RVC electrodes.[9,10] The stopped-flow response times are about 12 sec (on) and 20 sec (off). Rapid stopped-flow procedures, without achievement of the "off" current steady-state are under investigation. The two recorder peaks shown in Fig. 3(*a*) for 0.5μM ferrocyanide are part of a series of ten successive stopped-flow measurements, which were made for measuring the precision. The average stopped-flow current difference found was 224 nA with a range of 216–229 nA. The relative standard deviation over the complete series was 1.0%.

Figure 3(*b*) shows a stopped-flow response for 0.5μM ferrocyanide, obtained at the wall-jet electrode (using the same cell body with the RVC disk and 3 of the 5 Teflon spacers removed and the disk face of the glassy carbon contact serving as the working electrode); the other experimental conditions being the same as for Fig. 3(*a*). The wall-jet stopped-flow current (11 nA) was significantly lower than that observed for the same concentration level at the porous-jet electrode (224 nA). The noise was about 1 nA. A detection limit of about 45 nM is thus obtainable with the wall-jet electrode (for a signal equal to the noise), about 11 times that for the porous jet electrode. The improved sensitivity and detectability with the porous-jet electrode are the result of combining effective mass-transport with large surface area. The surface area of the planar wall-jet electrode is 0.049 cm^2 as compared to 1.26 cm^2 for the RVC disk (a planar disk with similar area to the RVC would require a diameter of 1.27 cm). The high linear flow-rate of the solution streaming out of the inlet nozzle is maintained inside the thin channels of the RVC. Detectors operating in the intermediate range of electrolytic efficiency (20–40%) thus provide better sensitivity than low-yield amperometric detectors, while still maintaining small dead-volumes in comparison to the electrode volumes required to achieve complete conversion.

Quantitative evaluation of the cell is based on the linear correlation between the analytical current (*i.e.*, current amplitude in the case of stopped-flow measurements) and the analyte concentration. Six concentration increments from 2.5 to 15μM ferrocyanide yielded a highly linear plot [conditions: flow-rate (on) 1.2 ml/min; pulsing time, 40 sec; applied potential, +0.9 V]. Least-squares analysis of the calibration data yielded a slope of 0.57 μA.l. μmole^{-1} (correlation coefficient 0.998). A slightly higher sensitivity (0.7 μA.l. μmole^{-1}) was reported for a larger RVC disk of 3.8 cm^2 area, indicating that the present design promotes higher efficiency of mass-transport.

Current *vs.* potential curves provide important information for the identification of compounds in flowing streams. Figure 4 shows a stopped-flow hydrodynamic voltamperogram for the oxidation of 10 μM dopamine, along with the residual current. The curve shows a well-defined wave and plateau region. The stopped-flow half-wave potential is +0.24 V, with $E_{3/4} - E_{1/4}$ equal to 135 mV. The background stopped-flow current is very low, less than 1% of the analyte stopped-flow current. The sensitivity is 2.3 μA.l. μmole^{-1}.

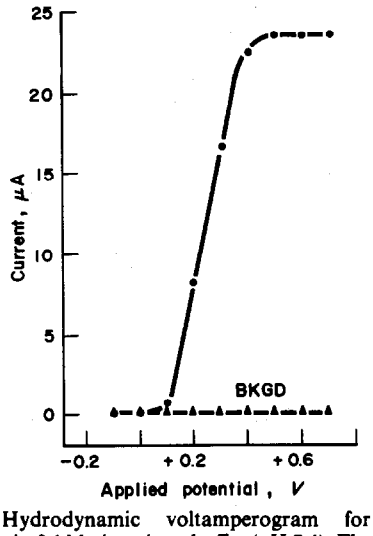

Fig. 4. Hydrodynamic voltamperogram for 10 μM dopamine in 0.1M phosphate buffer (pH 7.4). Flow-rates: 0 ml/min for 90 sec (off); 1.2 ml/min for 40 sec (on).

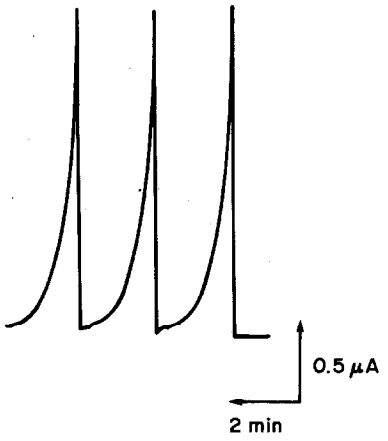

Fig. 5. Repetitive injections of 5.5 μM ferrocyanide solution. Sample flow, 15 sec; carrier (0.1 M phosphate buffer) flow, 105 sec. Flow-rate 1.3 ml/min. Sample size 0.325 ml, containing 0.75 μg of ferrocyanide. Applied potential, +0.85 V.

Flow-injection analysis

The porous-jet electrode can be used as a useful detector for flow-injection analysis. Figure 5 is a typical recording of the detection peaks for 5.5μM ferrocyanide in phosphate buffer solution (corresponding to 0.75 μg in the injection volume used). The time between sample injections was 105 sec, and the sampling rate 30 per hour. A higher sampling rate may be obtainable by use of much faster flow-rates.[10] A detection limit near 40 nM ferrocyanide (5 ng) is expected.

A detection limit of 0.7 ng of ferrocyanide was reported for flow-injection analysis at a much larger (surface area 125 cm^2) RVC electrode, utilizing higher flow-rates.[10] The three peaks shown in Fig. 5 are part of a series of eight repetitive injections for which a relative standard deviation of 3% was calculated.

Future studies will include evaluation of a porous ring–disk jet electrode, and of rapid stopped-flow scanning potential voltammetry.

TRACE METAL ANALYSIS BY ANODIC-STRIPPING VOLTAMMETRY

EFFECT OF SURFACE-ACTIVE SUBSTANCES

PAUL SAGBERG and WALTER LUND

Department of Chemistry, University of Oslo, Box 1033 Blindern, Oslo 3, Norway

(*Received* 20 *July* 1981. *Revised* 30 *November* 1981. *Accepted* 14 *December* 1981)

Summary—The presence of cationic, anionic, and neutral surfactants and humic substances is shown to affect the peak heights of copper, lead and cadmium in synthetic sea-water analysed by differential pulse anodic-stripping voltammetry. At surfactant concentrations below 0.1 mg/l. the effect is insignificant, but at higher concentrations the peak heights usually decrease, although for copper an increase in the peak height was also observed. The peak heights do not depend to any great extent on the pH of the solution, except in alkaline solution and in the presence of humic substances. Adsorption and complex formation may account for the observed dependences.

The environmental impact of many trace metals present in natural waters depends strongly on the chemical form of the metals; increasing attention is therefore focused on analytical methods which can be used for metal speciation studies. Owing to their non-destructive nature and the ability in certain cases to discriminate between different types of species in solution, electroanalytical techniques appear to be particularly suitable for such studies. Because the concentration of trace metals in samples of environmental interest is frequently in the μg/l.–ng/l. range, the most sensitive technique, *i.e.*, anodic-stripping voltammetry (ASV) will often be the method of choice. Unfortunately, for real samples there is usually no simple relationship between the height and potential of a given stripping peak and the chemical form of the corresponding electroactive metal. For instance, the presence of surface-active substances may have a marked effect on the voltammetric response, owing to the adsorption of such compounds at the electrode surface.[1] Therefore, information about the effects of different surfactants is of importance for adequate use of ASV in metal speciation studies.

This paper describes the effects of synthetic surfactants and naturally-occurring humic substances on the ASV response of synthetic sea-water samples spiked with copper, lead and cadmium. Because the effect of a surfactant may depend on its ionic charge,[2] cationic, neutral and anionic surfactants were studied. Further, the effect of pH was studied in detail, because this is an important parameter in ASV measurements, and in addition the adsorption characteristics of surfactants may depend on pH.

EXPERIMENTAL

Apparatus

A Princeton Applied Research 174A Polarographic Analyzer and a Radiometer Servograph REC51/REA112 recorder were used. The different steps in the stripping voltammetric procedure were controlled by a home-made timer unit. A Beckman Rotating Unit, consisting of a variable speed drive (188501) and a rotating body (188551) was used with a three-edged Teflon rod for stirring.

The electrolysis cell was a Metrohm EA880-20T vessel with a thermostatic jacket, through which water at 25.0° was circulated. The working electrode was a Metrohm E410 hanging mercury drop; only capillaries with a small diameter of the mercury reservoir (2.5–2.7 mm) were used.[3] The reference electrode was either a Metrohm EA427 Ag/AgCl electrode, or a silver wire coated with silver chloride and placed inside a Luggin capillary. A platinum spiral served as counter-electrode; the wire was placed inside an open glass tube to ensure a fixed position of the electrode in the cell.

All glass equipment, particularly the electrolysis cell and the mercury drop capillary, was thoroughly cleaned before each new series of measurements. The cell and capillary were treated with dimethyldichlorosilane at regular intervals.

Reagents and solutions

The metal solutions were prepared from analytical grade salts and acidified to pH 2 with perchloric acid; solutions with a concentration below $10^{-4}M$ were prepared just before use. All acids and the sodium hydroxide used were of Suprapur quality (Merck). The water was demineralized and distilled. Solutions (1%) of the following surfactants were prepared: sodium dodecyl sulphate (M.W. 288.38), dodecylamine (M.W. 185.36), and octylphenoxypolyethoxyethanol (Triton X-100, M.W. 646.87). The dodecylamine solution was heated to 90° and shaken before use, and the dodecyl sulphate solution was heated to 30°. The "humic acid" concentrate was prepared by 20-fold concentration of a fresh-water sample from Hellerudmyra, Bærum, Norway in a rotary evaporator at 35°. The water sample, which was particularly rich in humic substances, contained[4] 23 mg of organic carbon per litre.

The synthetic sea-water was prepared from analytical-grade salts as specified in Table 1. The salts were dissolved in 25 litres of distilled water and stored in a thoroughly cleaned polyethylene container. The solution was spiked with 21.25 ml of a stock solution of copper, lead and cadmium (each $10^{-4}M$), and acidified to pH 2.3 with hydro-

chloric acid to prevent bacterial growth. The addition of acid resulted in a loss of hydrogen carbonate from the solution. The variation in voltammetric response with pH was studied by adding hydrochloric acid and sodium hydroxide to the sample.

Instrumental parameters

The following parameters were used for recording the differential pulse anodic-stripping voltamperograms: diameter of mercury drop 0.8 mm, deposition time 3 min, deposition potential −0.9 V *vs.* Ag/AgCl, stirring rate 20 rps, rest period 30 sec, scan-rate 5 mV/sec, modulation amplitude 50 mV, and pulse repetition time 0.5 sec. Before analysis, the solution was deaerated with nitrogen for 20 min.

RESULTS AND DISCUSSION

Effect of pH

A differential pulse anodic-stripping voltamperogram of the synthetic sea-water with metal spikes is shown in Fig. 1. As expected for chloride media, a lower and broader peak is observed for copper than for lead and cadmium.

In Figs. 2, 3 and 4, the variation in peak height with pH is shown for the three metals, in presence of the surfactants. The broken lines indicate that the measurements were poorly reproducible, or that the peak almost merged with the mercury wave. In the figures, SS refers to the pure spiked synthetic sea-water, whereas HUMIC SUB, DDS, DDA and TRITON indicate the addition of humic substances, sodium dodecyl sulphate (anionic), dodecylamine (cationic), and Triton X-100 (non-ionic), respectively. The concentration of the surfactants was 10 mg/l., corresponding to 15–54μM concentrations of the different surfactants (depending on molecular weight), while that of the humic substances was 4% (1 ml of humic acid concentrate per 25 ml), *i.e.*, organic carbon 18 mg/l. From the curves in Figs. 2, 3 and 4, it can be seen that the presence of surfactants alters the peak

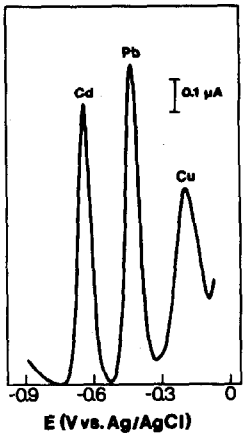

Fig. 1. Differential pulse anodic-stripping voltamperogram of synthetic sea-water spiked with copper, lead and cadmium, at pH 2.3. Total concentrations: 133nM Cu, 96nM Pb and 91nM Cd; these concentrations are the sums of the 85nM spike for each metal and the concentration in the synthetic sea-water (Cu 48nM, Pb 11nM, Cd 6nM).

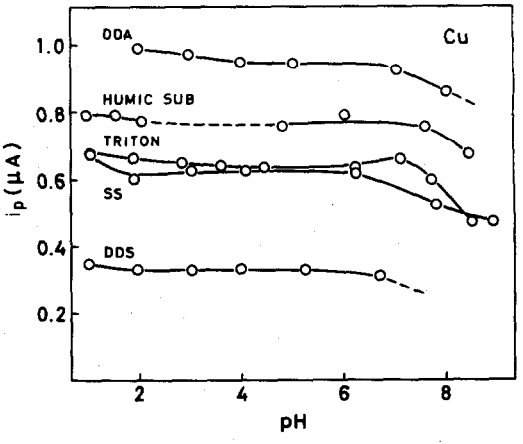

Fig. 2. Variation in the peak height of copper in synthetic sea-water as a function of pH, in absence and presence of surfactants and humic substances.

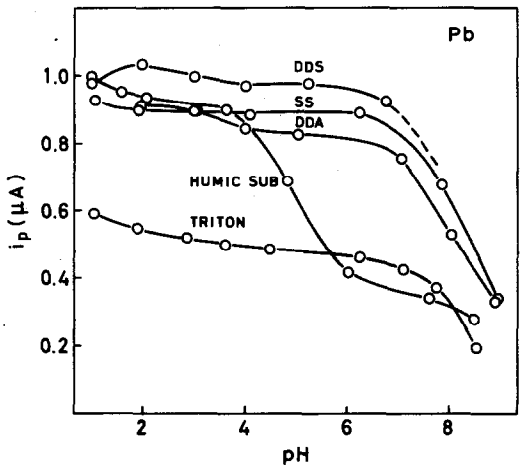

Fig. 3. Variation in the peak height of lead in synthetic sea-water as a function of pH, in absence and presence of surfactants and humic substances.

heights for the three metals. However, the peak heights do not vary to any great extent with pH in the acidic region, in contrast to results obtained by Brezonik *et al.*[1] The general pattern exhibited by the synthetic sea-water sample (SS) is also followed when the surfactants are present. For lead, and to a minor degree for copper, the peak heights decrease in alkaline solution, probably because of formation of hydroxo-complexes of these metals. The formation of carbonate complexes was disregarded, because carbonate was lost during the acidification of the synthetic sea-water. The less pronounced decrease for copper relative to lead is probably due to reduction of copper hydroxide. The decrease in peak heights was accompanied by a cathodic shift in the peak potentials, which indicates complex formation.

With humic substances present in the sample, more pronounced effects of pH were observed. For lead (Fig. 3), a decrease in peak height was seen in the pH region from 3.6 to 8.4. It was accompanied by a marked (74 mV) cathodic shift in the peak potential, indicating complex formation. For cadmium (Fig. 4), the peak height decreased as the solution was made more acidic. This decrease is not easily explained. Although a small anodic shift in the peak potential implied adsorption,[1] a well-defined stripping–polarographic curve[5] (peak height recorded as a function of deposition potential) was obtained at pH 2.3, indicating the absence of adsorption effects.

Effect of surfactant concentration

The variation in peak height with the concentration of surface-active substances (SAS) at pH 2.3 is illustrated in Figs. 5, 6 and 7 for copper, lead and cadmium, respectively. From the curves it can be seen that the change in peak heights was insignificant for concentrations of surfactant below 0.1 mg/l. Higher concentrations of dodecyl sulphate and Triton X-100 led to decreased peak heights, except for copper in presence of Triton X-100. For the highest concentrations of dodecyl sulphate, the peak heights tended to return to their original values. For dodecylamine, the peak heights remained unaffected, except for copper, where the peak increased. The absence of a peak-depression effect for dodecylamine may indicate that the electrode reactions involved negatively charged metal chloro-complexes, because these should be less affected by positively charged surfactants like dodecylamine than by anionic and non-ionic surfactants.[2]

A marked decrease in peak height was usually accompanied by a small (30–50 mV) shift in the peak potential in the anodic direction, indicating adsorption effects. For Triton X-100, the stripping–polarographic curves were ill-defined for all three metals, indicating strong adsorption. No "limiting current" plateau was observed on these curves. The same was noticed for cadmium in presence of sodium dodecyl

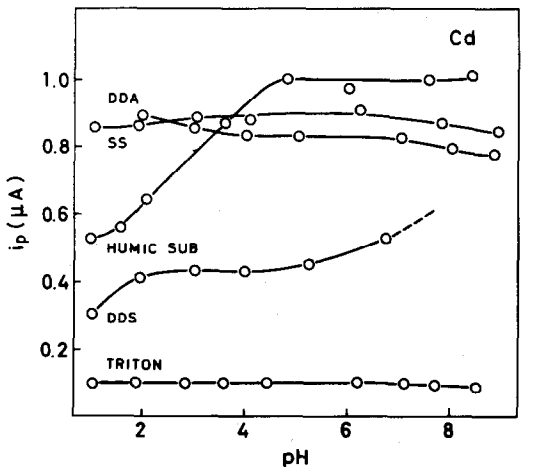

Fig. 4. Variation in the peak height of cadmium in synthetic sea-water as a function of pH, in absence and presence of surfactants and humic substances.

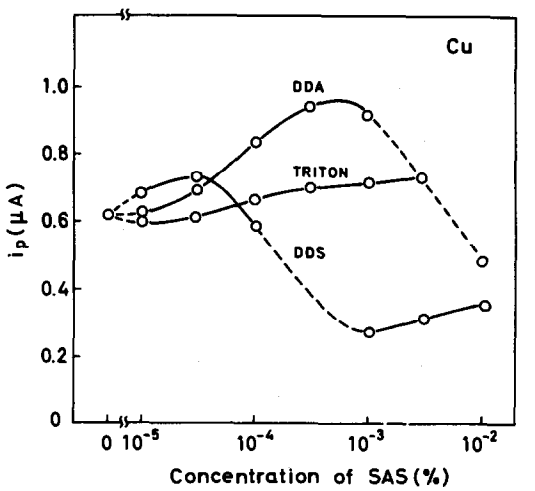

Fig. 5. Variation in the peak height of copper, as a function of surfactant concentration.

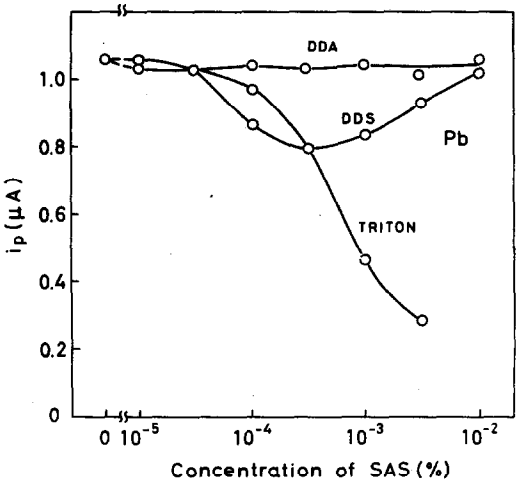

Fig. 6. Variation in the peak height of lead as a function of surfactant concentration.

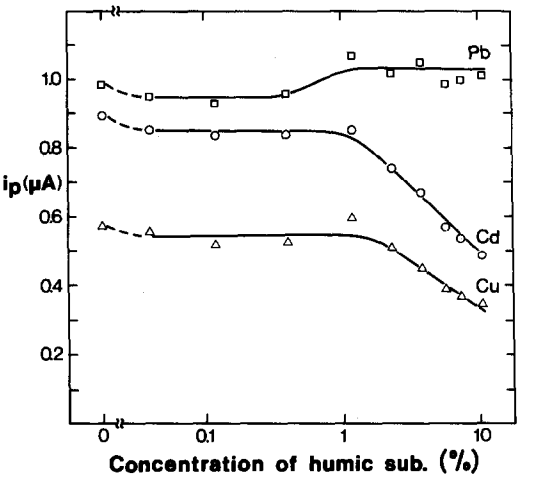

Fig. 8. Variation in the peak heights of copper, lead and cadmium as a function of the concentration of humic substances.

sulphate. The other curves resembled normal polarographic waves.

The variation in peak height with concentration of humic substances is shown in Fig. 8. The peak heights were corrected for the metal content of the humic acid concentrate. The concentration is given in terms of the "humic acid concentrate". Thus, a 1% solution contained 4.6 mg of organic carbon per litre. From Fig. 8 it can be seen that the peak heights were unaffected by low concentrations of humic substances, whereas at high concentrations the peak heights decreased for copper and cadmium, but not for lead. Only minor changes were noted for the peak potentials. The results differ from those of Ernst *et al.*,[6] who observed more pronounced changes in the height and potential of the peaks with concentration of humic acid. However, their experiments were carried out at pH 6.8, which may account for the differences.

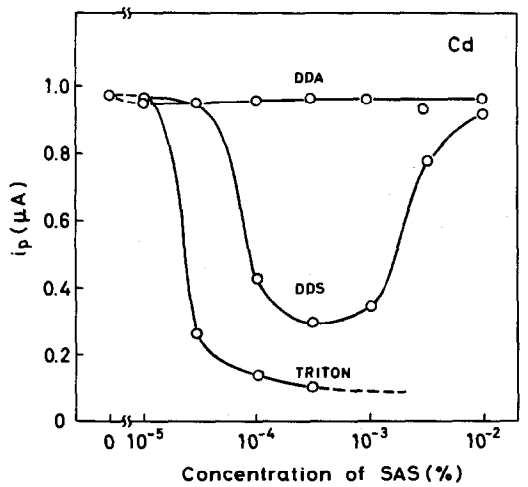

Fig. 7. Variation in the peak height of cadmium as a function of surfactant concentration.

Finally, the peak heights were recorded as a function of the metal concentration, in presence of the surfactants. Linear relationships were invariably obtained, implying that the metals can be determined quantitatively when surfactants are present, provided that the standard addition technique is used.

Conclusion

The adsorption of surfactants may lead to decreased peak heights in differential pulse anodic-stripping voltammetry. However, the effect may be reversed at high concentrations of surfactant. Further, not all surfactants exhibit a depression effect, so no general trend can be established.

The peak heights obtained in presence of a surfactant are not much affected by pH changes in the acidic region, in agreement with the general pattern observed for pure synthetic sea-water. Consequently, if a marked increase in the peak heights is observed upon acidification of a neutral water sample, this may indicate that metals are released from particles or complexes in solution, even if surfactants are present in the sample.

Acknowledgement—We would like to thank Dr. E. T. Gjessing, Norwegian Institute for Water Research, for providing the humic acid concentrate.

ATOMIC-ABSORPTION SPECTROMETRIC DETERMINATION OF METALS AND SILICON IN TAR-SANDS FLY-ASH

C. O. GOMEZ-BUENO, G. L. REMPEL* and D. R. SPINK
Department of Chemical Engineering, University of Waterloo, Waterloo, Ontario, Canada

(*Received* 9 *April* 1980. *Revised* 1 *December* 1981. *Accepted* 14 *December* 1981)

Summary—Atomic-absorption spectrometric methods are described for the determination of metals and silicon in a fly-ash which is produced during oil recovery from Alberta tar sands. The techniques of standard additions and matrix matching are compared. An experimental design for the detection, estimation and correction of interference effects arising in the determination of specific elements in the fly-ash is presented.

During the recovery of oil from the Athabasca tar sands, a boiler ash containing appreciable amounts of metals such as vanadium, nickel, titanium, iron and aluminium, as well as silicon, is collected in the boiler hoppers and cyclones of the steam-generation plants fired with petroleum coke. Thus, as well as being a petroleum resource, the tar sands are also a source of vanadium and possibly other metals, provided that efficient metal recovery processes can be developed.[1,2] Although there have been a number of recent reports on analytical methods for the chemical characterization of fly-ash emitted from coal-fired power plants,[3–5] a reliable method for the chemical characterization of the fly-ash obtained from tar sands has not yet been reported, though it is needed for metal recovery studies and for evaluation of the potential health hazards of tar-sands fly-ash. In this paper we present results which help define a reliable analytical method, based on atomic-absorption spectrometry (AAS), for such fly-ash analyses.

EXPERIMENTAL

Fly-ash sample preparation and AAS analyses

The petroleum coke fly-ash used in this investigation was provided by Great Canadian Oil Sands Ltd. (GCOS). Carbon-free fly-ash was obtained by heating the samples (as received from GCOS) at *ca.* 500° in air until all the carbonaceous fraction had been burned off. The loss in weight on ignition corresponded to 58.3% in the fly-ash.[6]

The analysis of the carbon-free fly-ash is based on an acid-digestion bomb method previously reported for the decomposition and subsequent AAS analysis of coal ash[5,7]

The carbon-free fly-ash (0.100 g) was digested with 3 ml of concentrated hydrofluoric acid and 1 ml of *aqua regia* in a 25-ml Teflon-lined Parr pressure bomb at 150° for *ca.* 45 min, then cooled to room temperature. Next, 3.8 g of boric acid were added to the solution and the whole was made up to volume in a 100-ml standard flask with demineralized water. A 10-ml aliquot was then diluted to 100 ml with dimineralized water and used for the AAS analysis, done with a double-beam Pye Unicam SP 1900 AA spectrophotometer equipped with a Pye-Unicam SP 1960 deuterium lamp background-corrector. Calibration graphs for the elements determined were obtained by use of commercially available AAS standard solutions (BDH). The accuracy of the entire analytical procedure was checked by analysis of a weighed amount of silicon standard reference material (NBS-SRM 640), an error of 0.2% being found.

Preparation of matrix-matching solution

Matrix-matching solutions containing elements present in the fly-ash were prepared from the AAS standard solutions and the reagents used in the digestion.

RESULTS AND DISCUSSION

Optimization of operating conditions

Besides the routine atomic-absorption spectrometer adjustments, the two parameters to be optimized are the fuel/oxidant flow-ratio and the burner height.[8] Metals such as vanadium which form stable oxides in the flame require a hot fuel-rich (reducing) acetylene–nitrous oxide flame. The height of the optical path in the flame is important because the temperature and composition profiles of the flame also affect the element–oxide equilibrium.

Both these parameters were optimized by continuously aspirating a suitable analyte solution into the flame and adjusting the burner height and flow-rates to maximize the signal. Figure 1 shows a typical result for silicon, titanium and aluminium. The best conditions found experimentally are summarized in Table 1 and were used in all the subsequent AAS analyses. Despite the inherent specificity of the AAS technique, under certain conditions spectral, physical and chemical interferences may arise.[8] Possible interference effects in the AAS analyses in the present study were therefore investigated.

Detection of matrix interference effects

For fairly complex samples, the method of Hansen and Hall[9] for detecting matrix interference effects should provide good results. The matrix interference effect is found by comparing the analyte absorption

* To whom correspondence should be addressed.

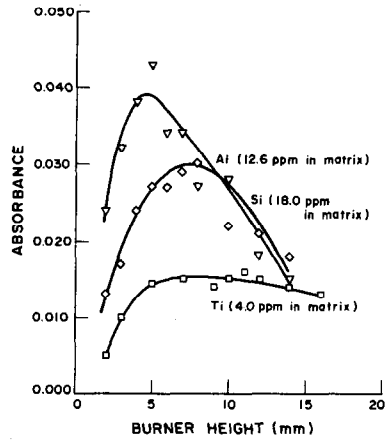

Fig. 1. Variation of absorbance of Al, Si and Ti with burner height. Other conditions as in Table 1.

signal for the series water, matrix blank, matrix + analyte, analyte + water. The results obtained are shown in Table 2.

Another method for interference detection in AAS is the graphical one proposed by Schrenk[10] in which the unknown solution is prepared at three analyte concentration levels (*e.g.*, *A*, 2*A*, 3*A*). If there is no interference, a plot of analyte signal *vs.* concentration should be linear and pass through the origin; an intercept is taken as an indication of some type of interference. The results obtained with this test are included in Table 2.

Standard-addition and matrix-matching techniques

The standard-addition technique[8,11] gave the results also provided in Table 2.

Matrix-matching solutions containing the elements listed in Table 2 were prepared so that they contained the elements (other than the analyte) at the levels indicated by the standard-addition results. This was done by using appropriate amounts of the AAS standard solutions and addition of the digestion reagents to simulate the bomb conditions used for the fly-ash dissolution. This mixture is referred to as the matrix blank. Calibration standards of given analytes in the matrix blank were prepared and when these standards were analysed by AAS, plots like those shown in Figs. 2–4 were obtained. These plots were subsequently used to determine the concentration of specific elements present in the fly-ash. The values so obtained, shown in the last column of Table 2, are the average of five replicates and have the 95% confidence interval limits shown.

The calibration graphs shown in Figs. 2–4 not only provide a value of a given analyte concentration but also provide a check for interference effects. It is readily seen from Figs. 3 and 4 that the plots for Al, Si and Ti have intercepts; thus some type of interference is expected for these elements.[10] This is in agreement with the Hansen interference-test results shown in columns 2–6 of Table 2.

In the case of iron, while the Hansen test indicates that there may be some interference, the intercept test does not. Further tests with solutions having a con-

stant concentration of iron and varied concentrations of the other elements (over ranges close to the levels in the matrix) did not reveal any interference effects in the iron determination. No interferences were noticed for V and Ni at the concentration levels used in this work.

Comparison of the values in the last two columns in Table 2 shows that the standard-addition method gives results, in most cases, which agree reasonably well with the matrix-matching results (*i.e.*, the values

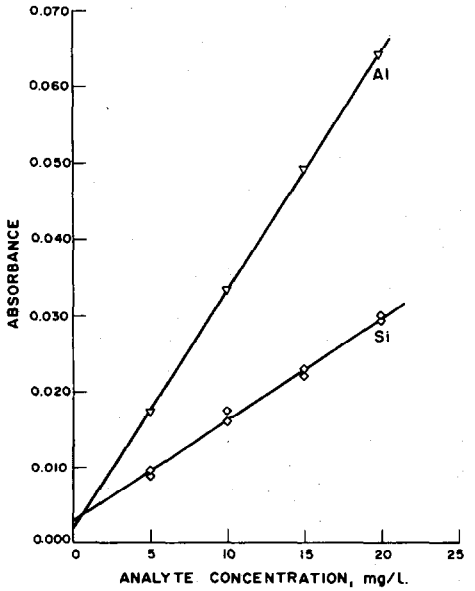

Fig. 3. Calibration curves for aluminium and silicon; analyte in matrix.

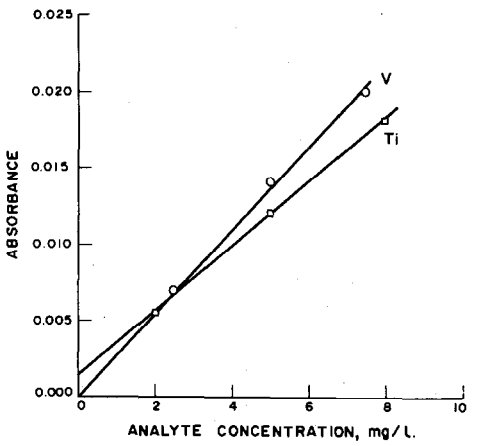

Fig. 4. Calibration curve for titanium and vanadium; analyte in matrix.

given by the matrix-matching technique are expected to provide the best estimate of the fly-ash composition[12]). The method of standard additions gives good results only in the absence of additive types of interference such as light-scattering or the effect of analyte present as impurity in the reagents.[8,11] Light-scattering interference can be overcome by using a deuterium-lamp background corrector;[12,13] this device is most effective at wavelengths shorter than 300 nm. If a calibration curve such as those shown in Figs. 2–4 passes through the origin, it is unlikely that light is scattered in the flame. It was found that the background correction for either aluminium or silicon was negligible, which suggested that the standard-addition technique should provide reasonably good values if no other source of interference is present.

When the slope of the calibration curve is enhanced (or depressed) by other matrix elements, error can arise if the calibration is done by use of pure solutions of the analyte. Such a type of error can be corrected for by the use of the standard-addition technique or by use of matrix-matched standards. Such an error appears to arise in this work for aluminium, titanium and silicon, as can be seen from Figs. 3 and 4. In order to gain a better understanding of the nature of the signal enhancement for these elements, the analyte signals from a series of synthetic solutions with varying Al, Ti and Si concentrations, with all other elements held at constant concentration (Table 3). A linear least-squares statistical analysis obtained by using a BMD 9K computer package[14] resulted in equations (1)–(3) as the ones giving the best fit to the observed data.

$$Abs_{Ti} = 0.00303\ [Ti] + 0.0000613\ [Al] \quad (1)$$

$$Abs_{Si} = 0.00191\ [Si] + 0.00119\ [Ti] \quad (2)$$

$$Abs_{Al} = 0.00469\ [Al] + 0.000267\ [Ti] \quad (3)$$

where Abs_E = absorbance of element E and [E] is the concentration of E (mg/l.). The statistical analysis

	c	14	12	3	0.032	0.059	0.010, 0.010
	d	14	12	3	0.031	0.059, 0.059	0.010

* Each solution also contains 2.65 ppm V, 1.20 ppm Ni, 5.50 ppm Fe, together with the bomb reagents (0.3 ml of concentrated hydrofluoric acid, 0.1 ml of *aqua regia* and 0.38 g of boric acid per 10 ml of solution).

appeared to indicate a small interelement effect between Si and Al in the silicon and aluminium determinations, but this contributed less than 5% to the observed signal and was ignored. Thus according to these equations the Ti signal is enhanced by Al, the Si signal is enhanced by Ti and the Al signal is enhanced by the presence of Ti. The first of these interferences has been previously reported[15] and so has the enhancement of the Al signal by Si (and *vice versa*).[16]

Equations (1)–(3) are of the form $y = ax + b$ when the interfering element concentration is constant. These types of curve are depicted in Figs 3 and 4; as mentioned previously, the intercept is associated with the interfering effect. Equations (1)–(3) and the concentrations of the several elements present in the fly ash, as given in Table 2 (last column) allow an estimate to be made of the errror incurred if no matrix-matching technique is used. A summary of the errors introduced by interferences in the analyte determination is given in Table 4. The errors are larger for titanium and silicon than for aluminium.

Comparison of atomic-absorption and classical analyses

In order to verify the validity of the matrix-matching technique in the atomic-absorption spectrophotometric determination of metals in fly-ash, a series of different fly-ash samples was also analysed by classical methods. The classical methods used were first checked on artificial matrices of known composition prepared from commercially available AAS standard solutions, with addition of digestion reagents to simulate the bomb-reagent conditions used for the fly-ash dissolution (see experimental section). References for the classical methods used for the fly-ash analyses are noted in Table 5 which provides a complete summary of the atomic-absorption and classical method results for four different fly-ash samples. The results of the two methods compare favourably and suggest that the atomic-absorption method can be used with a fair degree of confidence for fly-ash analyses.

A RAPID PROCEDURE FOR THE SIMULTANEOUS DETERMINATION OF ZIRCONIUM AND HAFNIUM IN HIGH-TEMPERATURE ALLOYS BY MEANS OF A SPECTROPHOTOMETRIC MASKING APPROACH

THOMAS R. DULSKI
Carpenter Technology Corp., Reading, PA 19603, U.S.A.

(*Received* 2 *October* 1981. *Accepted* 8 *December* 1981)

Summary—Data are presented for a refined spectrophotometric procedure for the simultaneous determination of zirconium and hafnium based on the combined effects of hydrogen peroxide, sodium sulphate, and excess of zirconium ion on the hafnium and zirconium complexes with Xylenol Orange in 0.2*M* perchloric acid. Isolation procedures for the hafnium/zirconium content of complex high-temperature alloys which result in an ionic substrate compatible with the spectrophotometric masking method were devised.

Certain high-temperature alloys which are under development for jet turbine applications in aircraft for the late eighties and nineties incorporate both zirconium and hafnium. Routine procedures for the determination of zirconium and hafnium in these matrices usually involve some form of spectrographic approach (optical emission calibrated with synthetically prepared solution standards, or X-ray fluorescence with direct calculation from fundamental parameters). Chemical determinations are characteristically lengthy and tedious and, therefore, are seldom used except to establish calibration standards for spectrographic work or for referee work requiring a high degree of reliability. For this purpose, our laboratory has employed a modified version of the anion-exchange procedures of Machlan and Hague[1,2] as part of a larger separation scheme which requires at least 15 working days to complete.

The works published by Cheng[3–6] on the Xylenol Orange complexes of zirconium and hafnium pointed the way toward a spectrophotometric method which promised to be significantly faster than any devised up to that time, but quantitative data remained elusive and the complex matrices of high-temperature alloy samples presented special problems. Challis[7] expanded part of the work of Cheng into a practical simultaneous determination for nickel-base alloys which employed calibration and measurement at three precisely-adjusted acidity levels. This method requires that the zirconium and hafnium levels in the sample do not exceed 0.2% and that the matrix alloy be free from tungsten, niobium and tantalum. Kiciak and Gontarz[8] recently described the equilibria at work in the method of Challis.

However, the compositions of the powder-metallurgy alloys, AF115 and MERL 76, to list two examples, exceed the conditions for application of the Challis procedure, and in addition, the method is still too slow for our requirements. As a result, a series of studies was conducted, based on another aspect of Cheng's work—the effect of hydrogen peroxide and sodium sulphate on the Xylenol Orange complexes. It was found that with suitably adjusted conditions, aqueous mixtures of zirconium and hafnium could be accurately determined by a spectrophotometric masking technique. A separation scheme based on *p*-bromomandelic acid and ammonia separations was then applied to dissolved high-temperature alloy samples to isolate the zirconium and hafnium in a way which permitted the application of the new method.

EXPERIMENTAL

Reagents

Hafnium stock solution (1000 μg/ml). High-purity hafnium oxychloride ($HfOCl_2 \cdot 8H_2O$ 2.2943 g) was dissolved in 2*M* hydrochloric acid and diluted to 1 litre with the same acid.

Zirconium stock solution (1000 μg/ml). High-purity zirconium oxychloride ($ZrOCl_2 \cdot 8H_2O$ 3.5326 g) was dissolved in 2*M* hydrochloric acid and diluted to 1 litre with the same acid.

Zirconium working solution (100 μg/ml). An aliquot of zirconium stock solution was diluted with water (prepared fresh weekly).

Aluminium solution (5 mg/ml). High-purity aluminium rod (5.0000 g) was dissolved in 100 ml of concentrated hydrochloric acid and 25 ml of concentrated nitric acid. The cooled solution was diluted to 1 litre with water.

Xylenol Orange solution (1×10^{-3}M). Xylenol Orange (0.0761 g) was dissolved in water and diluted to 100 ml with water.

Sodium sulphate solution (1M). Anhydrous sodium sulphate (142.0 g) was dissolved in 800 ml of water with stirring and gentle heating. The cooled solution was diluted to 1 litre with water.

Perchloric acid (5M). Prepared from concentrated perchloric acid in 500-ml quantities.

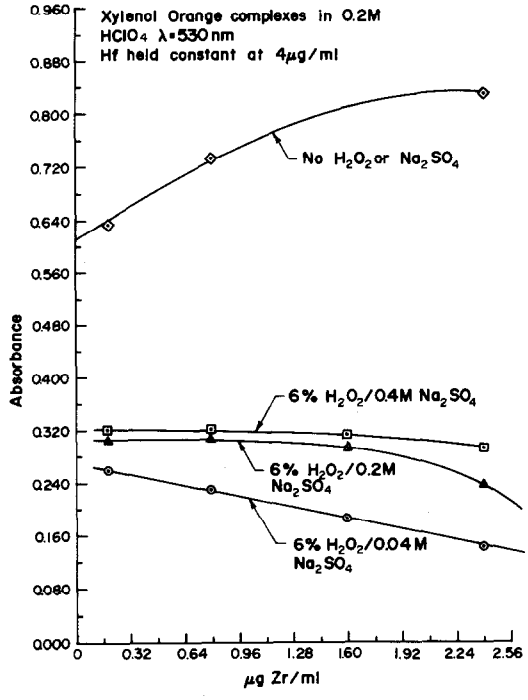

Fig. 1. Effects of hydrogen peroxide and sodium sulphate on Xylenol Orange complexes; mixtures of zirconium and hafnium.

Work with pure solutions

Cheng's studies[6] on the effect of hydrogen peroxide and sodium sulphate on the absorbance of mixtures of the zirconium and hafnium complexes with Xylenol Orange in 0.2*M* perchloric acid were repeated. In this study, the hafnium concentration was held at 4 μg/ml, while the zirconium concentration was varied between 0 and 2.4 μg/ml. Figure 1 shows the absorbance response of zirconium under four sets of conditions. In the absence of hydrogen peroxide and sodium sulphate, the apparent hafnium response increases with increasing zirconium concentration. When the same set of mixtures is examined in the presence of 6% hydrogen peroxide/0.04*M* sodium sulphate, the apparent hafnium response *decreases* with increasing zirconium concentration. Increasing the sulphate concentration produces a moderation of this effect until, with the combination of 6% hydrogen peroxide/0.04*M* sodium sulphate, the apparent hafnium response is nearly independent of zirconium concentration. Similar results were obtained by Cheng[6] who theorized that the hydrogen peroxide masks the zirconium complex completely and the hafnium complex slightly; sulphate "demasks" the hafnium complex, but only when the zirconium-complex is also present. The results in Fig. 1 give further support to this view.

Next, a series of hafnium calibration curves was prepared under the "optimized" conditions from Fig. 1 (6% hydrogen peroxide/0.4*M* sodium sulphate) with various fixed levels of zirconium. Despite the results depicted in Fig. 1, a definite effect on the hafnium calibration curve was noted for various levels of zirconium, with the greatest effect occurring between 0 and 0.8 μg of zirconium per ml. When single-element hafnium and zirconium curves were generated with use of the 6% hydrogen peroxide/0.4*M* sodium sulphate reagent (Fig. 2), the zirconium response became practically independent of zirconium concentration at around the 3–4 μg/ml level. The hafnium curve was observed to rise steeply under these conditions. On the basis of these data, it was decided to incorporate a fixed addition of zirconium (4 μg/ml) in a masking procedure for hafnium determination. The zirconium addition is intended to provide a uniform zirconium-complex background, independent of the zirconium content of the sample, against which to measure the hafnium response. This approach is analogous to the "swamping" technique used in flame photometry for overcoming interference (from anions forming thermally stable species with the analyte cation) by addition of the threshold amount of interferent to all samples and standards.

The effectiveness of this approach was verified by preparing a series of synthetic mixtures and analysing them as "unknowns." Values obtained for hafnium in the range 80–90 μg in the presence of 5–15 μg of zirconium were within 1% of the amount taken.

It remained to devise a way to extract a zirconium value from the chemistry of the Xylenol Orange complexes. It was established that in the absence of hydrogen peroxide and sodium sulphate, the complexes of hafnium and zirconium show nearly identical molar absorptivities in 0.2*M* perchloric acid, as well as a large range of linear response. The hafnium value obtained by the masking procedure, therefore, subtracted from the sum of hafnium and zirconium determined in a second run without the masking agents, was used to obtain a value for zirconium.

The method can be summarized as follows.

(1) Three calibration curves are prepared:

(*a*) Hf 0–6 μg/ml with 6% H_2O_2, 0.4*M* Na_2SO_4, 4 μg/ml Zr, 0.2*M* $HClO_4$, 8×10^{-5}*M* Xylenol Orange;

(*b*) Hf 0–6 μg/ml with 0.2*M* $HClO_4$, 8×10^{-5}*M* Xylenol Orange;

(*c*) Zr 0–2 μg/ml with 0.2*M* $HClO_4$, 8×10^{-5}*M* Xylenol Orange.

(2) The "unknowns" are analysed twice:

(*a*) once with 6% H_2O_2, 0.4*M* Na_2SO_4, 4 μg/ml Zr, 0.2*M* $HClO_4$, 8×10^{-5}*M* Xylenol Orange;

(*b*) once with 0.2*M* $HClO_4$, 8×10^{-5}*M* Xylenol Orange.

(3) The hafnium concentration of the "unknown" is derived from curve 1(*a*) and the absorbance obtained in 2(*a*).

(4) A "correction absorbance" is read from curve 1(*b*) using the hafnium concentration just obtained.

(5) The "correction absorbance" is subtracted from the absorbance obtained in 2(*b*) to derive the zirconium absorbance.

(6) The zirconium concentration of the "unknown" is derived from curve 1(*c*) and the zirconium absorbance.

Table 1 shows the results obtained for a series of synthetic mixtures of pure solutions by using this approach.

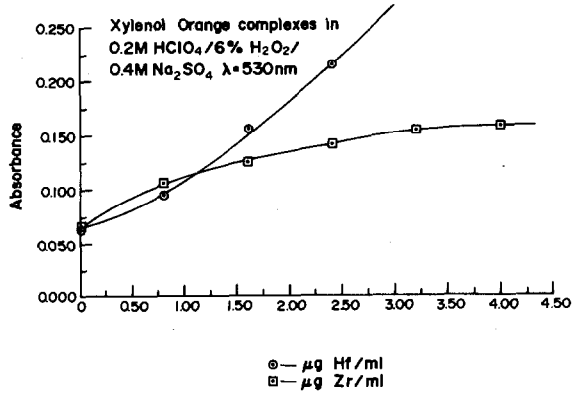

Fig. 2. Calibration curves for hafnium-only and zirconium-only, using the optimized concentrations of hydrogen peroxide and sodium sulphate.

Work with alloys

Application of the procedure to complex high-temperature alloys presents numerous difficulties: the corrosion resistance of the alloys, the tendency of certain matrix components to hydrolyse, and the very specific solution composition required by the new method. Both acid digestion and fusion/leach techniques have been developed which are effective in dissolving these alloys, but attempts to apply the masking approach directly fail owing to interference from the sample matrix. Complexing agents such as EDTA and citrate are ineffective in surmounting the interference.

Numerous separation schemes for isolation of the hafnium and zirconium from the alloy matrix were therefore investigated, including solvent extraction, mercury cathode electrolysis, and sodium hydroxide precipitation schemes. The most useful approach was found to be precipitation first with *p*-bromomandelic acid and then with ammonia.

Procedure

The method was developed specifically for iron and nickel-base alloys containing hafnium in the range 0.25–1.25% and zirconium in the range 0.05–0.30%. It is also applicable to alloys with 0.25–1.25% hafnium but no zirconium. Chromium, cobalt, molybdenum, aluminium, titanium, niobium and tungsten in the amounts normally encountered in high-temperature alloys do not interfere.

Isolation of zirconium and hafnium. Portions (0.2000 or 0.3000 g) of an appropriate matrix alloy are weighed into each of seven 125-ml Erlenmeyer flasks. (Note: if the samples to be analysed contain large amounts of hydrolysable elements such as titanium, niobium, molybdenum or tungsten, the matrix alloy is chosen to match the samples closely. Use of a master alloy containing no hafnium and zirconium is ideal; otherwise, pure iron or pure nickel can be used). The same weight of the samples is taken and 75 ml of concentrated hydrochloric acid are added to each flask. The flasks are covered with watch-glasses and allowed to stand on a warm hot-plate overnight or until the alloys have dissolved. The matrix alloy solutions are spiked with pure zirconium and hafnium solutions as follows:

Flask	μg of Hf	μg of Zr
1	—	—
2	500 or 1000	—
3	1000 or 1500	—
4	2000	—
5	—	100 or 150
6	—	300
7	—	600

The exact choice of spike-size depends on the concentrations of zirconium and hafnium expected in the samples, the sample and matrix weights taken, and the sensitivity of the given batches of reagents.

The solution volumes are reduced to about 30 ml by very gentle boiling and the flasks are cooled to approximately 40°C. Then 20 ml of concentrated perchloric acid and 20 ml of water are added to each. Next, 0.5 g of *p*-bromomandelic acid is added to each and the flasks are heated in a boiling water-bath for 20 min, then allowed to stand at room temperature overnight. The solutions are filtered through a hardened, fine-porosity filter paper (Whatman No. 542) containing a small amount of filter-paper pulp. The residues are washed thoroughly with water and the filters are transferred back to the original flasks. The organic material is destroyed by heating the filters with 50 ml of concentrated nitric acid and 10 ml of concentrated perchloric acid, over medium heat at first, then at higher temperature. Additional nitric acid is cautiously added, as necessary, *to ensure an excess at all times* (as evidenced by the evolution of dark brown fumes) until all organic matter has been destroyed. Then samples which are white or clear and evolving white fumes are heated for 1 min more, and cooled to room temperature. Next, 50 ml of water and 6 ml of aluminium solution (Al 5 mg/ml) and 30 ml of concentrated ammonia solution are added to each flask and the solutions are boiled gently for 1 min, then allowed to stand overnight. The precipitates are filtered off on glass fibre filters of medium porosity (Reeve Angel No. 934AH) folded and used like filter papers. The residues are washed five times with 1% v/v ammonia solution. The original flasks are placed under the funnels and 15.0 ml of 5*M* perchloric acid are transferred into each funnel by pipette. Next, approximately 25 ml of boiling water are added to each funnel. When the funnels have drained, 100-ml standard flasks are placed under the funnels and the solutions in the 125-ml Erlenmeyer flasks are poured through the corresponding filters in such a manner that the inner surfaces of the Erlenmeyers are wetted. The Erlenmeyer flasks are then returned to below the funnels and the solutions in the standard flasks are poured through the filters. The solutions are recycled in this way five times, then, with the 100-ml standard flasks under the funnels, the Erlenmeyer flasks and the filters are washed thoroughly with plain water. The solutions are diluted to the mark and mixed. If the solutions appear cloudy at this point they are filtered through a 0.22-μm filter (Millipore No. GSWP 04700) under suction, into a dry flask, then transferred to a dry storage flask without rinsing.

Colour development and spectrophotometry. Two sets of standard flasks are arranged—one set of 25-ml capacity and one set of 50-ml capacity. The 50-ml flasks are dried in an oven before use. Then a pipette is used to transfer a 7.0-ml portion of a sample into a 25-ml flask and a second into a 50-ml flask, for each sample in form.

To the 50-ml flasks the following reagents are added by pipette, in the sequence stated: 1500 μl of 5*M* perchloric acid; 1000 μl of zirconium working solution (Zr 100 μg/ml); 5.0 ml of 30% hydrogen peroxide; 10.0 ml of 1*M* sodium sulphate; 2.0 ml of $1 \times 10^{-3}M$ Xylenol Orange. The solutions are swirled to mix them thoroughly, *but not diluted.* After 30 min the absorbances are measured at 530 nm in 1.0-cm cells, with water as reference. To the 25-ml flasks 3.0 ml of 5*M* perchloric acid and 2.0 ml of $1 \times 10^{-3}M$ Xylenol Orange are added by pipette. The solutions are diluted to the mark and mixed thoroughly. After 30 min the absorbances are measured at 530 nm in 1.0-cm cells with water as reference.

Calculation of results. The absorbances obtained from the hafnium calibration solutions in the 50-ml standard flasks are corrected for the blank and plotted *vs.* hafnium concentration. The corrected absorbances for the "unknown" samples in the 50-ml standard flasks are translated into hafnium content by means of this plot.

The absorbances of the hafnium calibration solutions in the 25-ml standard flasks are corrected for the blank and plotted *vs.* hafnium concentration. The corresponding

"absorbance corrections" for the "unknown" samples are found from the hafnium contents and this curve, and then subtracted from the blank-corrected absorbances of the "unknown" samples in the 25-ml standard flasks. The difference is the absorbance for the zirconium in the "unknown" samples.

The absorbances of the zirconium calibration solutions in the 25-ml standard flasks are corrected for the blank and plotted *vs.* zirconium concentration. The "zirconium absorbances" calculated as above are then translated into zirconium content by means of the calibration plot.

RESULTS

Table 2 lists the nominal compositions of several alloy types to which the new method was applied. Table 3 lists the results obtained for hafnium and zirconium on samples of Astroloy matrix (no hafnium or zirconium) and AF115 Master Alloy (contains all the components of AF115 except hafnium and zirconium) which were spiked with known amounts of hafnium and zirconium before analysis. The hafnium level was chosen to simulate the specification level in AF115, and the zirconium was varied between 0.05 and 0.30% to check its effect on the hafnium determination (note: the zirconium range for AF115 is 0.05–0.07%). A real but slight effect was noted at 0.30% zirconium, a small positive error being produced in the hafnium results. This effect is shown to be negligible at the zirconium levels encountered in AF115 alloy.

While no primary standard materials are available which are certified for hafnium at these levels, the National Bureau of Standards SRMs 361–364 are certified for zirconium at levels which are determinable by the new method. These iron-base low-alloy standards were spiked with hafnium at the 1% level to simulate the analytical problem for which the method was designed. The results are shown in Table 4.

Table 5 shows the results from several different hafnium/zirconium-bearing high-temperature alloys, and also the results obtained by other techniques. The agreement is considered good in view of the speed of the new procedure relative to that of the modified Machlan and Hague procedure.

DISCUSSION

The new masking procedure for the simultaneous spectrophotometric determination of zirconium and hafnium has been designed for the range of these elements that occurs in some specific alloys which cannot be analysed by the method of Challis[7] (see Tables 2 and 5). Other ranges of these two elements can be determined by appropriate modification of sample weights and aliquot volumes but probably only within certain limits. Beyond these limits some modification of the chemistry would be required to achieve equivalent accuracy and precision. On the other hand, the robustness of the method is reflected in the results obtained for alloys with a difficult matrix, such as AF115.

The final form of the procedure specifies dissolution of the alloy in warm concentrated hydrochloric acid—a process which could require as long as a day, but has the advantage of minimizing the hydrolysis of elements such as titanium, niobium, molybdenum and tungsten. *p*-Bromomandelic acid is then used for selective precipitation of zirconium plus hafnium. Acid-insoluble material, if any, is retained with the precipitate and both are treated with nitric acid and fumed with perchloric acid. For the alloys investigated, this treatment proved adequate, though in other cases, where very refractory zirconium and hafnium inclusions are present in the alloy, a fusion step might be required. Next, an ammonia separation, with an aluminium carrier, removes traces of nickel, cobalt, molybdenum and tungsten and allows preparation of a sample solution with a precise perchloric acid concentration.

Trace amounts of components of the alloy matrix may survive these separations—notably niobium and titanium, which may precipitate before filtration of the *p*-bromomandelates. Any niobium dissolved in the final sample could interfere with the determination by producing a colour of its own, but its effect is minimized by the use of a precise concentration of perchloric acid.[9] Titanium interferes by forming a faint colour due to the peroxo-complex, but a suitable blank takes care of this effect. Precipitates of niobium and titanium interfere by their turbidity. When this occurs, a blank is usually not adequate for compensation and filtration of all samples is required.

The procedure described is believed to be the most rapid way to determine zirconium and hafnium in high-temperature alloys chemically (five samples have been analysed in as little as three days). The accuracy and precision have been shown to be adequate for the concentration ranges and the alloy matrices which were studied.

Summary—Solution equilibria are calculated from the system of equations expressing the mass balance and the law of mass action. The solution of these equations usually requires the use of complicated iterative procedures. It is shown in the present paper, that for mononuclear complex formation, the whole system can be represented by a single diagram exhibiting all of the important chemical information, including solubility equilibria. The data necessary for the construction of the diagrams can be calculated directly without iterative procedures.

Mononuclear stepwise complex equilibrium systems are most frequently represented by formation and distribution curves. It is well known that these functions depend only on the free ligand concentration.[1–4]

$$\bar{n} = \frac{T_L - [L]}{T_M} = \frac{\sum_0^N i\beta_i[L]^i}{\sum_0^N \beta_i[L]^i} \quad (1)$$

$$\alpha_i = \frac{[ML_i]}{T_M} = \frac{\beta_i[L]^i}{\sum_0^N \beta_i[L]^i} \quad (2)$$

where

$\bar{n}$ = average number of bound ligands (formation curve);
$\beta_i = [ML_i]/([M]\,[L]^i)$ = formation product of the ith species; $\beta_i = K_1K_2 \ldots K_i$, the product of the successive formation constants; $\beta_0 = K_0 = 1$ by definition; $K_i = [ML_i]/([ML_{i-1}][L])$;
N = maximum number of ligands;
$[L]$ = free ligand concentration;
T_L, T_M = total concentrations of the ligand and the metal ion, respectively;
α_i = partial mole fraction of the ith species (distribution curve).

The behaviour of the concentration distribution functions in this simple case is well known. The partial mole fraction of free metal ion ($i = 0$) decreases monotonically, while that of the complex containing the maximum number of ligands (ML_N, $i = N > \bar{n}$) increases monotonically with increasing free ligand concentration. Each of the distribution curves of the intermediate complexes (ML_i, $0 < i < N$) exhibits one maximum $[d(\ln\alpha_i)/d(\ln[L]) = 0]$ at the appropriate integral point of the formation curve.

The behaviour of the concentration distribution functions is much more complicated in three- and multicomponent systems. The distribution curves may then exhibit more than one extremum, as discussed by us earlier.[5,6]

CALCULATION AND USE OF EXTENDED DIAGRAMS

For mononuclear stepwise complex formation, distribution curves are very informative and useful; if the free ligand concentration is known, the distribution of the complexes is directly seen.

However, these curves are not very useful in practical situations, and particularly in analytical chemical practice, because generally only the total concentration of each component is known.

$$T_M = \sum_0^N [ML_i] = [M]\sum_0^N \beta_i[L]^i \quad (3)$$

$$T_L = [L] + [M]\sum_0^N i\beta_i[L]^i = [L] + \bar{n}T_M \quad (4)$$

If it is desired to calculate the species distribution at particular total concentrations, then first these nonlinear equations must be solved by an appropriate iteration procedure for [L] and [M]; only then may the distribution be calculated. If the concentration distribution is to be shown as a function of the total concentration, the iterative calculation must be

repeated several times. Therefore, from a practical point of view, it would be better if the distribution curves could be expressed as a function of the total concentrations.

It is shown in this paper that it is possible to relate the distribution of the complexes to the *total* concentration, by an appropriate extension of the $\bar{n},\alpha_i = f([L])$ curves.

The total concentrations of the components unambiguously determine the free ligand concentration. At the same time, at a constant ratio of the total concentrations, $q = T_L/T_M$, T_M may be expressed explicitly as a function of the free ligand concentration from equations (3) and (4):

$$T_M = \frac{[L]}{q - \bar{n}} = \frac{\sum_0^N \beta_i [L]^{i+1}}{\sum_0^N (q - i)\beta_i [L]^i} \qquad (5)$$

Values for the function $T_M = f([L])$ can be calculated directly with a simple programmable calculator, without iterative procedures. A useful diagram can then be obtained if the $\bar{n},\alpha_i = f(\log[L])$ and $\log T_M = f(\log[L])$ functions are drawn with a common

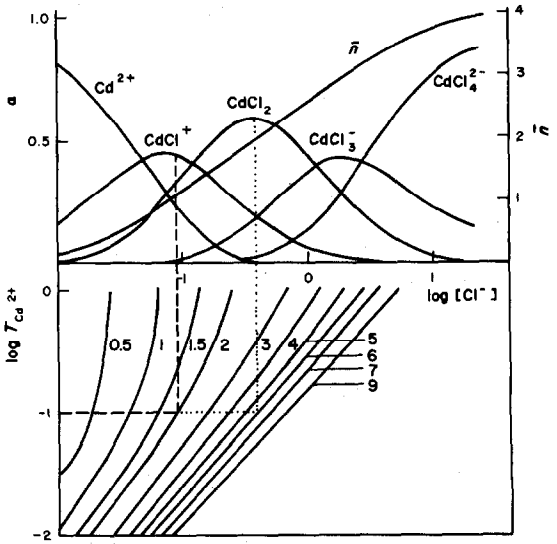

Fig. 1. Extended distribution diagram for the Cd^{2+}–Cl^- system. Upper part: formation curve and distribution of the complexes. Lower part: log $T_{Cd^{2+}}$ as a function of log[Cl^-] at different total concentration ratios. The numbers on the lines are the $T_{Cl^-}/T_{Cd^{2+}}$ values. For interpretation of the dashed and dotted lines, see text. Log $\beta_1 = 1.32$, log $\beta_2 = 2.22$, log $\beta_3 = 2.13$, log $\beta_4 = 1.68$. Medium 4.5*M* $NaClO_4$, $T = 298$ K.[11]

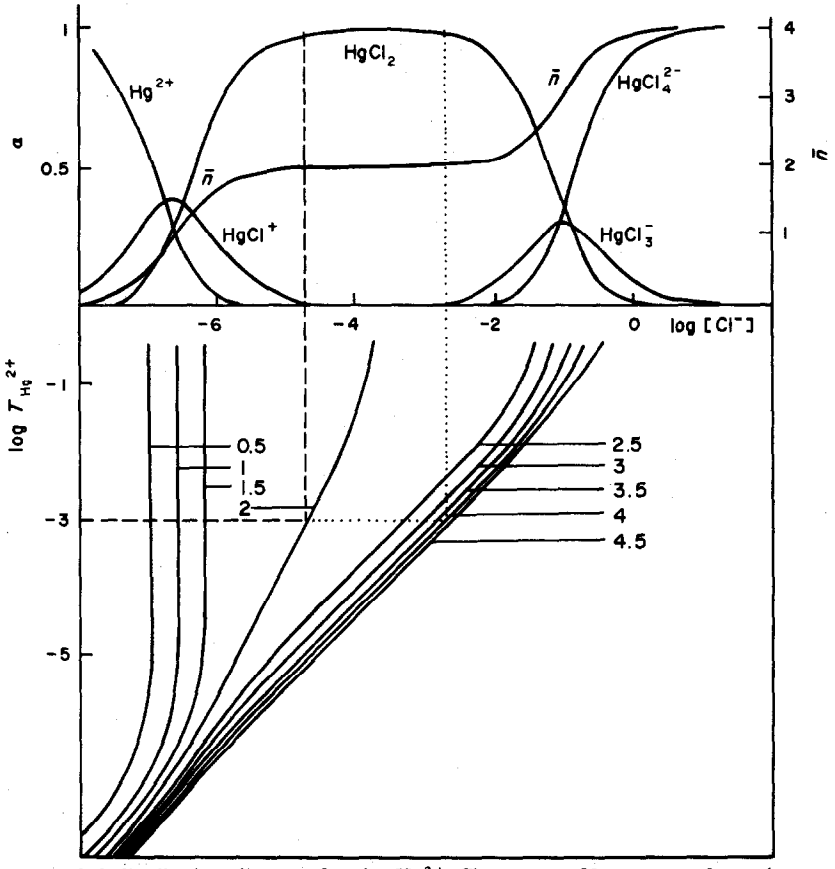

Fig. 2. Extended distribution diagram for the Hg^{2+}–Cl^- system. Upper part: formation curve and distribution of the complexes. Lower part: log $T_{Hg^{2+}}$ as a function of log[Cl^-] at different total concentration ratios. The numbers on the lines are the $T_{Cl^-}/T_{Hg^{2+}}$ values. For interpretation of the dashed and dotted lines, see text. Log $\beta_1 = 6.76$, log $\beta_2 = 13.24$, log $\beta_3 = 14.19$, log $\beta_4 = 15.24$. Medium 0.5*M* $NaClO_4$, $T = 298$ K.[12]

horizontal log[L] axis. Curves for a range of q values are drawn as illustrated in Fig. 1.

Figure 1 shows the extended distribution curves for the Cd^{2+}–Cl^- system. The upper part consists of the usual formation and distribution curves, while the lower part shows the function $\log T_{Cd^{2+}} = f(\log[Cl^-])$ at different $T_{Cl^-}/T_{Cd^{2+}}$ ratios. The thick line represents a solution of $CdCl_2$. The curves show the nature of the relationship between total and free ligand concentration. The amount of curvature towards the y-axis is indicative of the extent of complex formation. It can be directly read from the curves that, for example, in 0.1M cadmium chloride solution the dominant species are $CdCl^+$ (44%), $CdCl_2$ (31%) and free cadmium ion (23%) (see dashed line). If it is desired to prepare a solution in which the partial mole fraction of $CdCl_2$ is at its maximum, then ~0.4M potassium chloride should be added to 0.1M cadmium chloride (see dotted line).

The complexes formed in the Cd^{2+}–Cl^- system are relatively weak. Figure 2 shows the extended distribution curves for the Hg^{2+}–Cl^- system, in which strong $HgCl^+$ and $HgCl_2$ complexes are formed.

It is apparent from Fig. 2 that if either $HgCl_2$ or K_2HgCl_4 is dissolved at $10^{-3}M$ concentration in aqueous solution, $HgCl_2$ is the dominant species. It is seen moreover, that when $T_{Cl^-}/T_{Hg^{2+}} < 4$ the lines on the lower part of the figure approach asymptotically a certain log[Cl^-] value. The asymptotically vertical lines show that complex formation is practically complete; further increase in total concentrations (at constant $T_{Cl^-}/T_{Hg^{2+}}$) has no influence on the distribution of the complexes. The essential completeness of complex formation means that $\bar{n} \approx T_{Cl^-}/T_{Hg^{2+}}$ if $T_{Cl^-}/T_{Hg^{2+}} < 4$ and $\bar{n} = 4$ if $T_{Cl^-}/T_{Hg^{2+}} \geqslant 4$. Thus the log[$Cl^-$] value asymptotically reached is the one which belongs to the $\bar{n} = T_{Cl^-}/T_{Hg^{2+}}$ point of the formation curve. It has a definite value only if $\bar{n} < 4$, so asymptotically vertical lines represent the system for solutions in which $T_{Cl^-}/T_{Hg^{2+}} < 4$. If $T_{Cl^-}/T_{Hg^{2+}} > 4$, then log[Cl^-] increases monotonically as $T_{Hg^{2+}}$ increases.

These diagrams are much more informative and useful for practical purposes than the distribution curves alone. Two restrictions on their use, however, should be mentioned.

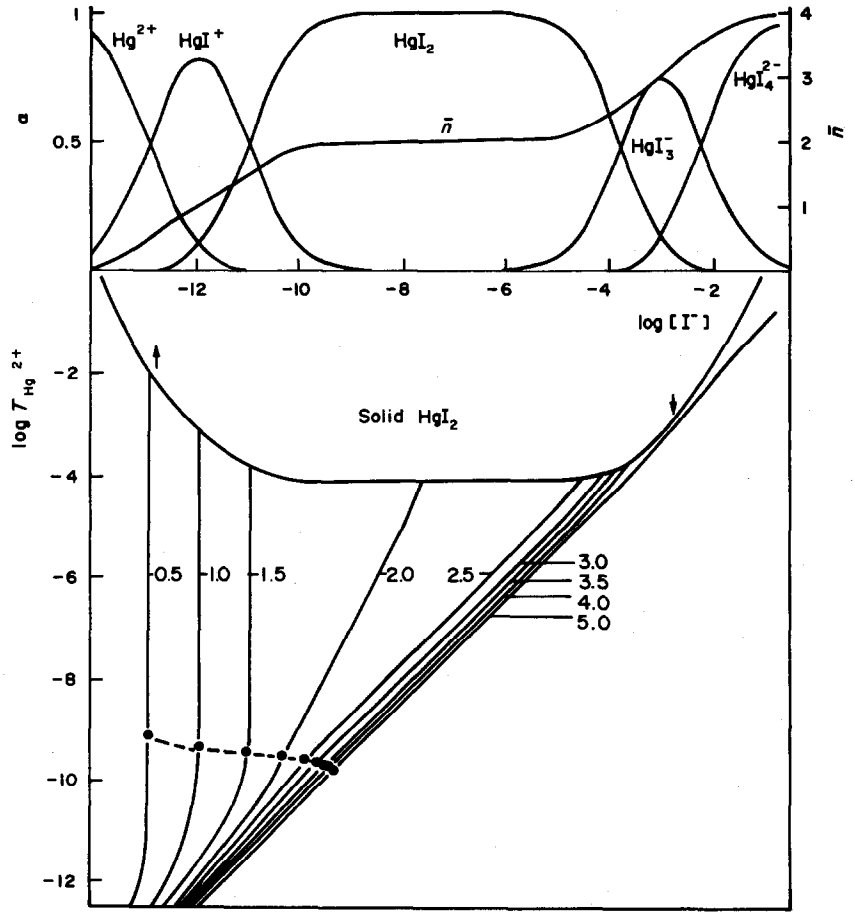

Fig. 3. Extended distribution diagram for the Hg^{2+}–I^- system. Upper part: formation curve and distribution of the complexes. Lower part: log $T_{Hg^{2+}}$ as a function of log [I^-] at different total concentration ratios, and the solubility curve. The numbers on the lines are the $T_{I^-}/T_{Hg^{2+}}$ values. Log β_1 = 12.87, log β_2 = 23.82, log β_3 = 27.60, log β_4 = 29.83, log K_s = −27.95. Medium 0.5M $NaClO_4$, T = 298 K.[13]

The β_i values used to calculate the curves are valid for a given standard state, ionic strength and temperature. The curves may be used reliably only under the same conditions. The change in total concentration along the curves causes a corresponding change in ionic strength, so the curves may be used only in a concentration range which is far less than the concentration of the background electrolyte. The requirement of keeping a constant standard state along the curves also means that the diagram can be used correctly only if dilution is done with the background electrolyte. Obviously the standard state cannot be kept constant during evaporation of the solvent, *i.e.*, if the solution is concentrated.

The other problem connected with the use of the curves is the solubility limit of the neutral complex. It is known, however, that solubility is also an unambiguous function of free ligand concentration only:[7]

$$S = \sum_{0}^{N} K_s \beta_i [\mathrm{L}]^{i-\nu} \qquad (6)$$

where

ν = the number of ligands in the neutral (sparingly soluble) complex;

$K_s = [\mathrm{M}][\mathrm{L}]^{\nu}$ = solubility product of the neutral ML_ν species.

Figure 3 shows the formation, distribution, solubility and total concentration curves for the Hg^{2+}–I^- system.

It is seen from this figure that mercuric iodide is precipitated even from $10^{-3}M$ K_2HgI_4 solution, but one equivalent of potassium iodide in excess is enough to prevent the precipitation. The individual points marked in the lower part are those that would be calculated for the solubility from the solubility product without taking into account the effect of the complex formation. The deviation of the real solubility curve from these points nicely illustrates how misleading the usual textbook-type calculation of solubility from the solubility product can be. This has already been dealt with in detail earlier.[8–10] The points marked by arrows represent the precipitation and dissolution of mercuric iodide when Hg^{2+} is added to $5 \times 10^{-3}M$ potassium iodide. At $T_{Hg^{2+}} < 10^{-3}M$, no precipitate is formed; precipitation begins at $T_{Hg^{2+}} \approx 1.2 \times 10^{-3}M$, but the precipitate dissolves if excess of mercury(II) is present ($T_{Hg^{2+}} > 10^{-2}M$).

Figure 4 shows the diagram for sparingly soluble lead iodide. It can be seen directly that lead iodide dissolves only in a very large excess of iodide. The $T_{I^-}/T_{Pb^{2+}} \approx 500$–$5000$ ratios are especially interesting, because the lines in this range may intercept the solid phase at two points. This means that if, for example, a clear solution for which $[KI] = 3M$ and $T_{Pb^{2+}} = 0.005M$ is diluted, then lead iodide first precipitates and then redissolves on further dilution.

It should be stressed that the precipitation of lead iodide on dilution differs in principle from the precipitation of hydrolysed species, which frequently occurs on dilution. In the latter case, the concentration of the reacting species (OH^-) increases on dilution, but in the Pb^{2+}–I^- system, the concentration of the reacting species (I^-) decreases. The precipitate is formed because lead iodide is formed by dissociation of PbI_4^{2-}

$$PbI_4^{2-} \rightleftharpoons PbI_2 + 2I^-$$

which is favoured by dilution.

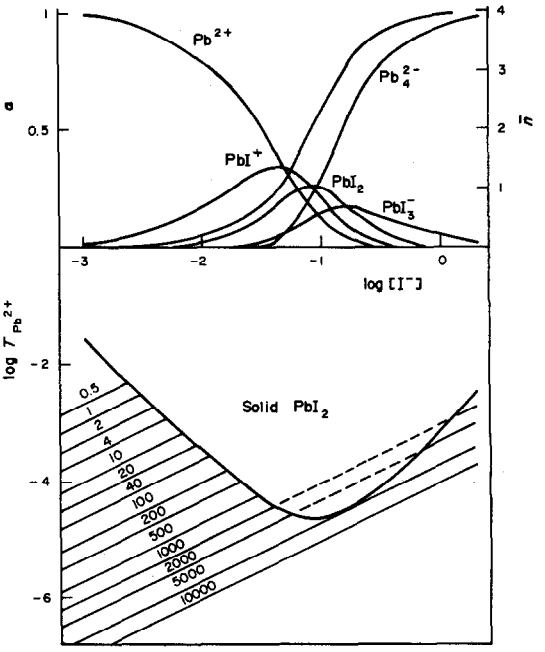

Fig. 4. Extended distribution diagram for the Pb^{2+}–I^- system. Upper part: formation curve and distribution of the complexes. Lower part: log $T_{Pb^{2+}}$ as a function of log[I^-] at different total concentration ratios. The numbers on the lines are the $T_{I^-}/T_{Pb^{2+}}$ values. log $\beta_1 = 1.30$, log $\beta_2 = 2.38$, log $\beta_3 = 3.14$, log $\beta_4 = 4.43$, log $K_s = -7.605$. Medium $2M$ $NaClO_4$, $T = 298$ K.[14]

In connection with the solubility curves some further points may be mentioned. One is that the minimum of the solubility curve is always found at $\bar{n} = \nu$ (*i.e.*, at $\bar{n} = 2$ for the cases considered).[2,3,7]

Another concerns the point at which the curve log $T_M = f(\log[L])$ is tangential to the solubility curve. This saturated solution has the interesting property that both dilution and concentration remove the saturated state. It is characterized by $T_M = S$ and $dT_M/d[L] = dS/d[L]$. Thus

$$\frac{dS}{dT_M} = \frac{dS}{d[L]} \cdot \frac{d[L]}{dT_M} = \sum_{0}^{N} K_s(i-\nu) \times \beta_i [L]^{i-\nu-1} \frac{d[L]}{dT_M} = 1 \qquad (7)$$

Taking into account that $qT_M - [L] = \bar{n}T_M$ along the curves log $T_M = f(\log[L])$, $d[L]/dT_M$ may be expressed as

$$\frac{d[L]}{dT_M} = q - \bar{n} \qquad (8)$$

Substituting this into equation (7) and multiplying both sides by $[M][L]^{\nu+1} = K_s[L] = K_s(q - \bar{n})S$, followed by simplifying gives:

$$\sum_0^N [M]i\beta_i[L]^i - \nu \sum_0^N [M]\beta_i[L]^i = S \qquad (9)$$

The sums on the left-hand side are $T_L - [L] = \bar{n}S$ and $T_M = S$. Substitution and rearrangement lead to the simple expression

$$\bar{n} = \nu + 1 \qquad (10)$$

Thus, the point of contact is at the maximum for formation of the first anionic complex $ML_{\nu+1}$. This further implicitly means that interception of the solid phase area, *i.e.*, precipitate formation by dilution, may be expected only if $N \geq \nu + 2$.

Exactly similar extended distribution diagrams can be drawn to represent acid–base systems. For the three-component proton–metal–ligand systems the extended diagrams may only be drawn in the form of two-dimensional cross-section of the full three-dimensional distribution diagram. The same applies for mixed-ligand complex formation involving two different ligands.

(*Received* 21 *March* 1981. *Revised* 18 *November* 1981. *Accepted* 30 *November* 1981)

Summary—A kinetic study of the photochemical reaction of Azur B and EDTA (in the absence of oxygen) has been made in connection with development of a new kinetic method for iodide. The reaction is first-order with respect to the dye, EDTA and absorbed light-intensity. The rate of photoreduction is strongly pH-dependent, and maximal at about pH 6.8. The photoreduction involves a long-lived excited state of the dye and is dramatically retarded by small amounts of iodide. A tentative mechanism is proposed, and the experimental conditions have been optimized. The variable time method appear to be the most suitable. A detection limit of 1.0 μg/ml and a coefficient of variation of about 3% can be achieved. Chloride and bromide do not interfere at levels below 100-fold mole ratio to iodide. Metal ions do not interfere if enough excess of EDTA is used. Coloured species may interfere at high concentration (filter effect).

Light-induced oxidations of aminopolycarboxylic acids by certain dyes belonging to the groups of thiazines, oxazines and phenazines have been repeatedly studied[1–4] and are the basis for several analytical determinations.[5–8] Surprisingly, EDTA shows reducing character in such photochemical processes, whereas its oxidation under normal circumstances requires the use of powerful oxidizing agents in hot and strongly acid media.

The overall light-induced reactions of EDTA with the dyes of the above-mentioned groups are irreversible and lead to the dye in its leuco form and to various oxidation products.[9–11] The mechanism of such photochemical reactions is complex and has been reported[12–15] as taking place through a series of collisions between the dye in its triplet state and specific forms of the aminopolycarboxylate anion.

This paper reports studies on the photochemical reaction of 3-dimethylamine-7-methylaminephenothiazonium chloride (Azur B) and EDTA. It has been found that the reaction is strongly inhibited by even small amounts of iodide. We have based a new method for determination of traces of iodide on this reaction.

EXPERIMENTAL

Reagents

Analytical-reagent grade chemicals and demineralized distilled water were used throughout. Aqueous Azur B solutions were prepared from the Merck product, purified by the method of Bonneau *et al.*[16] and standardized with standard sodium dithionite solution. EDTA and iodide solutions were made from the required amounts of the compounds. Buffer solutions were prepared by mixing a solution which was 0.1*M* in phosphoric, acetic and boric acids with appropriate amounts of 1*M* sodium hydroxide, and checked with a Radiometer PHM-63 pH-meter.

Apparatus

In the photolysis device the light from the lamp was passed through a small water-cooled chamber arranged so that several neutral density filters could be used to give different light intensities. Two lamps were used as sources, a low-pressure sodium lamp (Osram, 220 V, 90 W) and a halogen lamp (Sylvania, 24 V, 150 W). The emission spectra of the lamps were obtained with a Beckman DK2A spectrophotometer. The bleaching of Azur B was followed with a photometric titration unit (EEL-Unigalvo 200), a 607 filter being used. The incident intensity, I_0, was measured with a thionine–EDTA actinometer.[17]

Procedure

To the reaction cell of the photometric titration unit, add 5 ml of $10^{-4}M$ Azur B, 2 ml of 0.1*M* EDTA, 3 ml of pH-4.6 buffer and enough standard potassium iodide solution to give a final iodide concentration between 1 and 25 ppm. Dilute with demineralized distilled water to 25 ml. Deoxygenate the solution by bubbling pure nitrogen (99.99%) through it for 20 min. Switch on the halogen lamp and measure the time needed for the absorbance to be reduced to a tenth of its initial value.

Calibration graphs are constructed by plotting the iodide concentrations *vs.* t_x/t_0, where t_x is the time required for photoreduction of the sample, and t_0 the time required for an iodide-free sample. The illumination intensity chosen should give a value of about 100 sec for t_0.

Iodide in samples is determined in the same way. The reagent concentrations and light intensity must be kept constant throughout a series of measurements.

RESULTS AND DISCUSSION

When a solution containing Azur B and EDTA is illuminated at suitable pH and in the absence of oxygen, photoreduction of the dye occurs, and the blue colour disappears, but this only takes place at a fair rate when a sufficiently intense light source is used.

$$\text{Azur B}_{ox} + \text{EDTA} \rightarrow \text{Azur B}_{red} + \text{EDTA oxidation products} \quad (1)$$

A sodium lamp was used as excitation source for studying the photochemical reaction; its emission band fell within the Azur B absorption range (Fig. 1).

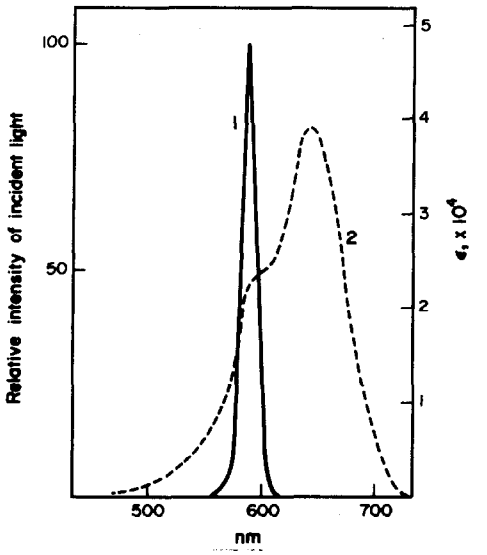

Fig. 1. Curve 1: spectral intensity of the light source. Curve 2: absorption spectrum of Azur B.

Figure 2 shows the absorption spectrum of the dye before photoreduction and the spectra obtained after reoxidation with oxygen or hydrogen peroxide. The three spectra coincide, showing that the Azur B does not undergo demethylation or irreversible breakdown during the photochemical reaction.

Stoichiometry

The stoichiometry was determined by adding excess of EDTA, at various pH values, photolysing until the dye was completely decolorized, and titrating the surplus EDTA with zinc solution or adding excess of zinc and measuring the surplus polarographically. The molar ratio found was 2:1 Azur B:EDTA.

Reagent concentrations

The initial-rate and integration techniques were used for determination of the order of reaction with respect to Azur B. The dye concentration should not exceed $3 \times 10^{-5}M$, to avoid any aggregation.[18] For the integration method the diffusion current corresponding to reduction of Azur B_{ox} on a mercury drop electrode (at *ca.* −0.5 *vs.* S.C.E.) was used. In the initial-rate method, a fixed amount of chromium(VI) was added, which reoxidized the Azur B_{red} in a fast reaction. The time needed to reduce all the chromium(VI) was dependent on the Azur B concentration (for fixed light-intensity). The results of both methods (Fig. 3 and Table 1) show a first-order dependence on Azur B concentration.

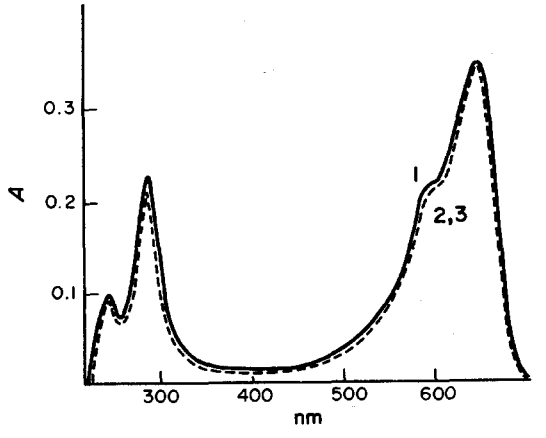

Fig. 2. Absorption spectra for $10^{-5}M$ Azur B/$10^{-2}M$ EDTA/acetate buffer (pH 5.5). Curve 1: Before the photochemical process. Curves 2 and 3: After the photochemical process and reoxidation with oxygen and hydrogen peroxide, respectively.

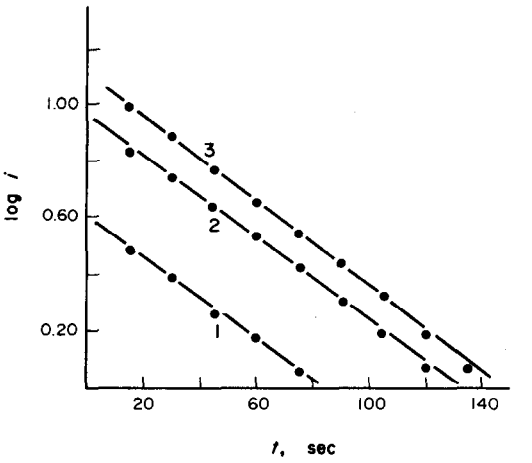

Fig. 3. Plots of logarithm of current *vs.* time. EDTA $4 \times 10^{-2}M$, acetate buffer pH 5.5; $T = 25°C$. Curve 1: Azur B $2 \times 10^{-6}M$. Curve 2: Azur B $4 \times 10^{-6}M$. Curve 3: Azur B $6 \times 10^{-6}M$.

The overall reaction order was also determined by the integration method polarographically. The results in Table 2 show an overall reaction order of 2, so the reaction is also first-order with respect to EDTA.

Effect of pH

Figure 4 shows that the reduction rate is highest at pH 6.8 and this was found to hold for all EDTA concentrations tested.

Effect of temperature

Table 3 lists the decolorization times for identical samples at different temperatures, showing that the rate increases with temperature.

Table 1. Values of the experimental pseudo first-order constant for different initial Azur B concentrations

[Azur B], μM	K, min^{-1}
9.0	3.3
8.0	3.0
7.5	3.2
7.0	3.4
6.5	3.6
6.0	3.1
5.5	3.3
5.0	3.2

[EDTA] = 0.02M; Cr(VI) = 5 μeq; acetate buffer pH 5.5; $T = 25°C$.

Table 2. Values of the experimental overall second-order constant

Photolysis time, t, *sec*	Current, *nA*	[Azur B_{red}], μM	K, $l.mole^{-1}.min^{-1}$

X = [Azur B_{red}]; $K = \frac{1}{t(a-b)} \ln \frac{b(a-X)}{a(b-X)}$.

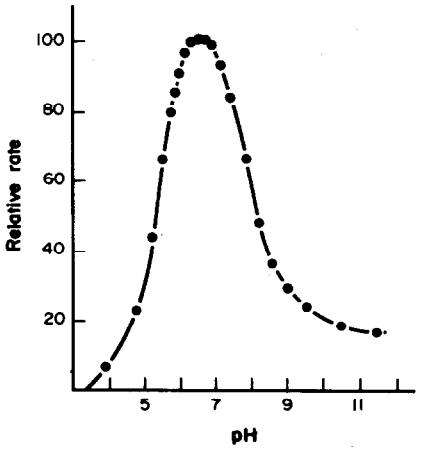

Fig. 4. Rate of photoreduction as a function of pH.

Influence of light-intensity and quantum yield

The rate of the photochemical reaction follows the general equation:

$$V = -\frac{dc}{dt} = KI_a^n \tag{2}$$

in which n denotes the reaction order with respect to the absorbed light-intensity I_a (expressed in Einstein.l^{-1}.sec^{-1}), c being the molarity of the absorbing species, and K a proportionality constant.

We have used the Fornier and Faure method[19] to determine n directly from the kinetic curves. From the Lambert-Beer law, equation (2) can be written:

$$V = -\frac{dc}{dt} = KI_0^n(1 - e^{-2.3\epsilon lc})^n \tag{3}$$

in which I_0 is the incident intensity, and ϵ the molar absorptivity of Azur B. The integrated equation is:

$$-\int_{c_0}^{c} \frac{dc}{(1 - e^{-2.3\epsilon lc})^n} = KI_0^n \int_0^t dt \tag{4}$$

From the values of ϵlc at various times, the values of the integral as a function of time can be plotted for different n values (*e.g.*, $\frac{1}{2}$, 1, $\frac{3}{2}$, 2, $\frac{5}{2}$). The straight line satisfying equation (4) gives the value of n.

Since the light-source is not monochromatic, a mean molar absorptivity has to be obtained by integrating over the waveband of the photolysis radiation used:

$$\bar{\epsilon} = \frac{\int_{\lambda_1}^{\lambda_2} \epsilon_\lambda I_\lambda^0 \, d\lambda}{\int_{\lambda_1}^{\lambda_2} I_\lambda^0 \, d\lambda} \tag{5}$$

in which ϵ_λ and I_λ^0 are the molar absorptivity and incident intensity at wavelength λ. The ϵ curve cannot be expressed analytically so a numerical integration has to be performed on the data in Fig. 1. We have found an $\bar{\epsilon}$ value of 2.20×10^4 $l.mole^{-1}.cm^{-1}$ for the range 555–600 nm.

The decolorization of Azur B by EDTA in the absence of oxygen and at different I_0 values was monitored polarographically by measurement of the dye reduction current. Equation (4) shows that the rate of the photochemical reaction is a linear function of the light-intensity:

$$K = \frac{-dc/dt}{I_a} \tag{6}$$

so K is the same as the quantum yield Φ since it represents the number of molecules transformed by each photon in a given time. Table 4 shows the quantum yield at three pH values and for different concentrations of EDTA.

Reaction mechanism

From the above, we can say that the photochemical reaction of Azur B and EDTA in the absence of oxygen takes place through a series of collisions between EDTA molecules and the dye molecules in an excited state. The strong influence of pH on the reaction rate (Fig. 4) can be explained by assuming that the only reacting species—as happens with other aminopolycarboxylic acids and dyes[1,5–8]—are the ionic forms of EDTA having at least one non-protonated nitrogen atom, and Azur B in its excited triplet state.

The photoreactive state of the dye is probably the triplet[1–4] since EDTA in low concentration does not quench the dye fluorescence although it is oxidized by

Table 3. Effect of temperature on photochemical process

Temperature, °C	20	25	30	35	40	45	50

[EDTA] = $1.6 \times 10^{-2} M$, [Azur B] = $4.0 \times 10^{-6} M$; acetate buffer pH 5.5.

Table 4. Values of the overall quantum yield (Azur B $10^{-5}M$)

[EDTA], M	Yield pH 7.25	pH 9.0	pH 10.0
0.040	4.16×10^{-2}	3.96×10^{-2}	3.10×10^{-2}
0.020	4.10×10^{-2}	3.71×10^{-2}	3.00×10^{-2}
0.010	4.04×10^{-2}	3.15×10^{-2}	2.95×10^{-2}

the activated dye. Further, small amounts of *p*-phenylenediamine or iodide do not quench the dye fluorescence either, but both substances dramatically retard the photoreduction of Azur B by EDTA. Obviously this is due to an energy-transfer process between the dye in the triplet state—which has a relatively long life—and the inhibitor.

According to our experimental results, we can assume the following kinetic scheme.

	Process	*Rate*
1.	Azur $B(S_0) + h\nu \longrightarrow$ Azur $B(S_1)$	K
2.	Azur $B(S_1) \longrightarrow$ Azur $B(S_0)$	$K_{ic}[S_1]$
3.	Azur $B(S_1) \longrightarrow$ Azur $B(T_1)$	$K_{isc}[S_1]$
4.	Azur $B(T_1) \longrightarrow$ Azur $B(S_0)$	$K'_{isc}[T_1]$
5.	Azur $B(T_1)$ + EDTA $\longrightarrow$ products	$K_r[T_1][EDTA]$
6.	Azur $B(T_1) + I^-(S_0) \longrightarrow$ Azur $B(S_0) + I^-(T_1)$	$K_e[T_1][I^-]$
7.	Azur $B(S_1) \longrightarrow$ Azur $B(S_0) + h\nu_f$	$K_f[S_1]$
8.	Azur $B(T_1) \longrightarrow$ Azur $B(S_0) + h\nu_p$	$K_p[T_1]$

where the quantities S_0, S_1 and T_1 are the ground and excited singlet states and the triplet state respectively, and the subscripts ic, isc, r, e, f and p mean internal conversion, intersystem crossing, reduction, excitation, fluorescence and phosphorence respectively.

Iodide determination

Taking into account the proposed kinetic scheme and applying the steady-state hypothesis for the concentration of Azur B in the triplet state, we have

$$[T_1] = \frac{K_{isc}[S_1]}{K_p + K'_{isc} + K_r[EDTA] + K_e[I^-]} \quad (7)$$

The rate of conversion of the dye into its leuco form is controlled by the rate of the chemical reaction step. This is equal to $K_r[T_1][EDTA]$ and so the expression for the quantum yield for the consumption of Azur B is:

$$\phi = \frac{K_r[T_1][EDTA]}{K} \quad (8)$$

Substituting for $[T_1]$ from equation (7) and rearranging gives:

$$\frac{1}{\phi} = \frac{K}{K_{isc}[S_1]}\left(1 + \frac{K_d}{K_r[EDTA]} + \frac{K_e[I^-]}{K_r[EDTA]}\right) \quad (9)$$

where K_d is equal to $K_p + K'_{isc}$. If the possibility of a reverse intersystem crossing ($T_1 \rightarrow S_1$, non-radiative) is considered, K_d will contain an additional constant, K''_{isc}, for this process, but this transition is regarded as unlikely.

In the absence of iodide, equation (9) reduces to:

$$\frac{1}{\phi^0} = \frac{K}{K_{isc}[S_1]}\left(1 + \frac{K_d}{K_r[EDTA]}\right) \quad (10)$$

where ϕ^0 is the quantum yield for the consumption of Azur B_{ox} in the absence of quencher. Dividing (9) by (10) we obtain:

$$\frac{\phi^0}{\phi} = 1 + \frac{K_e[I^-]}{K_d + K_r[EDTA]} \quad (11)$$

For measurements made with a fixed light intensity, with and without iodide, we have:

$$\frac{V^0}{V_x} = \frac{\phi^0}{\phi} = 1 + \frac{K_e[I^-]}{K_d + K_r[EDTA]} \quad (12)$$

V_x and V^0 being the reaction rates with and without iodide.

Operating with a large excess of reducing agent so that its concentration can be deemed constant, we have:

$$\frac{V^0}{V_x} = 1 + K[I^-] \quad (13)$$

This equation allows us to determine iodide by measuring the rate of the photochemical process in its presence and absence. The reaction conditions need to be optimized, as follows.

Figure 5 shows the inhibition of the photochemical reaction as a function of pH. The pH range 4–5 gives a high degree of inhibition, coupled with a moderate rate for the photoreduction (Fig. 4). The system needs careful buffering, however.

The decolorization time decreases with increasing EDTA concentration, but there is no further decrease for concentration ratios of EDTA to Azur B greater than 200.

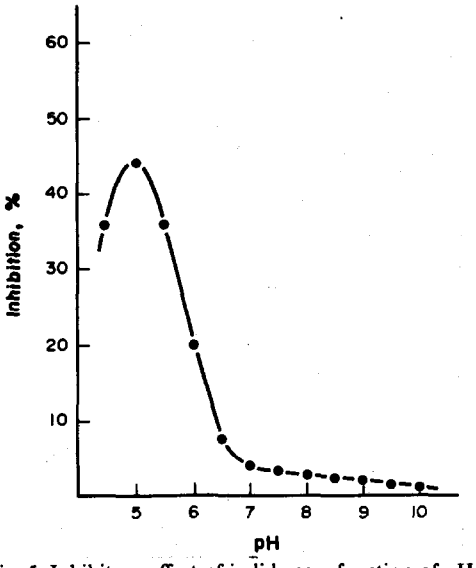

Fig. 5. Inhibitory effect of iodide as a function of pH.

Influence of iodide concentration

Equation (13) shows that iodide can be determined by means of the rate of reduction of Azur B by EDTA if the variables of the photochemical process are controlled.

We decided to use the variable time method, measuring the time required for the sample to reach a preselected absorbance (one tenth of the initial value).

To keep the process simple we used a white-light source (a halogen lamp). It gave the same results as a low-pressure sodium lamp. The method is reasonably precise under the conditions described, the maximum deviation being 3%. The limit of detection is 1.0 μg/ml. For lower levels of iodide the error increases since the decolorization time of the test sample is too close to that of the control sample. On the other hand, for iodide concentrations above 25 ppm the decolorization time is too long, and it is advisable to dilute the sample.

Interferences

Chloride and bromide do not interfere when present in up to 100-fold molar ratio to iodide. This precludes use of the method for analysing chlorides and bromides for traces of iodide.

If metal ions forming stable EDTA complexes are present, a preliminary titration with EDTA is required so that enough can be added to the test sample to fix the metal ions as chelates and leave a sufficient amount of free EDTA.

Table 5.

Sample	Iodide found, % Azur B/EDTA	Starch–iodine
I	0.024	0.022
II	0.032	0.030
III	0.034	0.035
IV	0.041	0.042

Table 6.

Salt \ Salt concentration	Iodide found, 0.02*M*	0.05*M*	0.2*M*
Na_2SO_4	4.0	4.1	3.9
K_2SO_4	4.1	4.2	3.8
KNO_3	4.0	4.3	4.1
KH_2PO_4	4.2	4.2	4.1

Coloured solutes will interfere if present in concentrations high enough to reduce the intensity of the radiation incident on the Azur B, and should be removed beforehand.

Applications

We have applied the method to determination of iodide in potassium sulphate, using 0.1–0.5 g of sample dissolved in a little doubly distilled water, and applying the procedure already given. The iodide was also determined by the starch–iodide method. The results are shown in Table 5.

The method was also applied to solutions of reagent-grade salts, containing 4.0 μg of iodide per ml. The results (average of three determinations are given in Table 6.

Finally a photographic solution containing sodium carbonate (10 g/l.), sodium sulphate (100 g/l.), potassium bromide (0.5 g/l.) and potassium iodide (0.01 g/l.) was analysed after acidification and heating to remove SO_2. The result (10.0 μg/ml) was in excellent agreement with the nominal content and also with the result obtained by the starch–iodine method (9.95 μg/ml).

FLAME ATOMIC-ABSORPTION DETERMINATION OF BERYLLIUM AFTER EXTRACTION FROM NH_4SCN MEDIUM WITH TRIOCTYLAMINE IN MIBK

J. R. CASTILLO, M. A. BELARRA, M. DOMINGUEZ and J. AZNÁREZ

Department of Analytical Chemistry, Science Faculty, University of Zaragoza, Zaragoza, Spain

(*Received* 21 *April* 1981. *Revised* 19 *November* 1981. *Accepted* 25 *November* 1981)

Summary—A study has been made of the experimental conditions, errors, sensitivity, limits of detection and linear response range in the determination of beryllium by AAS in a nitrous oxide–acetylene flame, with aqueous or aqueous organic solutions or MIBK solutions containing the ion-pair $[Be(SCN)_4^{2-}][(R_3NH)_2^{2+}]$. The interference of Al, Mg, Ti, V, Fe, Ca, Mn, Na, K, SiO_3^{2-}, PO_4^{3-}, Cl^-, SO_4^{2-}, F^-, ClO_4^-, $H_2BO_3^-$ and SCN^- has been studied, and methods established for eliminating that of titanium, aluminium, fluoride and silicon.

The development of electronic and nuclear technology during the last two decades has resulted in beryllium becoming an important constituent of several materials (computer components, X-ray tube windows, *etc.*). The incidence of beryllium as an environmental pollutant ("berylliosis" or Fabroni's disease) has meant intensified study of methods for analytical control in the ng/ml range.[1]

Atomic-absorption spectrophotometry (AAS) with low-temperature flames (such as air–acetylene) is reported to give 1% absorption for a 300 μg/ml beryllium solution.[2] Use of a fuel-rich oxygen–acetylene flame gives 1% absorption with a 0.2-μg/ml ethanolic solution of beryllium.[3] A highly reducing nitrous oxide–acetylene flame gives the same response with a 0.02 μg/ml solution,[4] with a linear response range of 0.03–4 μg/ml.[5]

The effect of low concentrations of miscible organic solvents on AAS determination of beryllium in the air–acetylene flame has been reported,[6] and the effect of alcohols, ketones and glycols on AAS determination of beryllium in the nitrous oxide–acetylene flame has been also described.[7] Ramakrishna *et al.*[8] claimed improved sensitivity with use of a 10% aqueous solution of diethylene glycol diethyl ether, and studied the interference of several substances at low concentrations (up to 0.1 mg/ml). The effect of high concentrations of various metal ions (up to 10 mg/ml) has been described by Fleet *et al.*[9]

The main interfering elements suppressing the AAS signal of beryllium are aluminium and silicon. These elements form non-volatile compounds with the beryllium, which therefore cannot be effectively atomized even in the nitrous oxide–acetylene flame. Ramakrishna *et al.*[8] used addition of fluoride to eliminate the depressive effect of aluminium. Fleet *et al.*[9] recommended the addition of 8-hydroxyquinoline for this purpose, and Nakahara *et al.*[7] used diethylene glycol monobutyl ether. All these procedures give a satisfactory result up to about 4 mg of aluminium per ml.

Alternatively extraction has been used to isolate beryllium prior to its flame or flameless atomic-absorption determination either directly in the organic phase or after stripping. These methods are generally based on the extraction of acetylacetone complex into xylene,[10] benzene[11] or chloroform.[12–14] Methyl isobutyl ketone (MIBK) has also been used for extracting the acetylacetone complex, for determination by flameless AAS[15] or direct nebulization into the nitrous oxide–acetylene flame.[16,17]

The use of liquid ion-exchangers, especially ammonium quaternary salts, as extracting agents from thiocyanate or other medium is receiving increased attention for isolating beryllium. Tri-n-octylamine and tri-iso-octylamine,[18,19] 1-(3-ethylpentyl)-4-ethyloctylamine sulphate,[20,21] and tricaprylmethylammonium chloride in oxalic acid medium[22,23] have all been used to extract beryllium into n-hexane and toluene. Novoselova *et al.*[18] used MIBK as the solvent, and worked out suitable pH values for separation of binary mixtures of beryllium with Al, Mg, Zn or Mn.

The present work is intended to be both a contribution to the study of the AAS determination of beryllium in the nitrous oxide–acetylene flame, when added in mixtures of miscible organic solvents, and to the determination of interference effects of those species which frequently accompany beryllium in samples. A study was made of the extraction of beryllium from ammonium thiocyanate medium with trioctylamine–MIBK solution, and AAS determination by direct nebulization of the organic phase, with a view to eliminating interference and increasing the preconcentration and the nebulization and atomization efficiency.

EXPERIMENTAL

Apparatus

A Pye Unicam SP-9 spectrophotometer was used with a Westinghouse beryllium hollow-cathode lamp and a single-slot burner (50 mm path-length). The working wavelength was 234.86 nm.

Reagents

Stock beryllium solution (1000 μg/ml) was prepared by dissolving beryllium oxide (analytical grade) in 2*M* sodium hydroxide and immediately acidifying with 3*M* hydrochloric acid. Working solutions were obtained by suitable dilution of the stock solution just before use.

Stock solutions of interfering elements were obtained from pure chemicals, as follows: Al^{3+} from Al metal, Mg^{2+} from $Mg(NO_3)_2$, Ti^{4+} from TiO_2, V(V) from NH_4VO_3, Fe^{3+} from electrolytic Fe, Ca^{2+} from $CaCO_3$, Mn^{2+} from $Mn(NO_3)_2$, Na^+ from NaCl, K^+ from KCl, SiO_3^{2-} from Na_2SiO_3, PO_4^{3-} from Na_2HPO_4, Cl^- from KCl, SO_4^{2-} from K_2SO_4, F^- from NaF, ClO_4^- from $NaClO_4$, $H_2BO_3^-$ from H_3BO_3, SCN^- from NH_4SCN.

The remainder of the reagents used, $La(NO_3)_3$, trioctylamine, MIBK, acetone and ethanol were analytical grade.

Procedures

These are implicit in the text below.

RESULTS AND DISCUSSION

Atomic-absorption determination of beryllium in different media

A study was made of the conditions, errors, sensitivity, limit of detection and interval of linear response, for AAS analysis of aqueous, aqueous acetone, and aqueous alcohol media, and for an MIBK solution of triocytylamine, used for extracting beryllium from ammonium thiocyanate medium. Results are shown in Table 1.

From the results obtained, the optimum flame composition, slit-width and lamp current do not vary appreciably for the different media used, mainly because a strongly reducing flame was used. However, the height of observation in the flame is more critical and has to be adjusted to suit the solvent medium used. The standard deviation and the errors were larger than those generally obtained in AAS. The error of 2.6% for the water–acetone (20:80) medium was due to the increase in background noise both for the base line and the signal maximum. The sensitivity obtained in aqueous medium (0.033 μg/ml for 1% absorption) was the same as found by other authors, and improved as a function of increase in concentration of miscible organic solvent, becoming maximal for water–acetone (20:80) and for the MIBK–trioctylamine system. With this last system the sensitivity could be improved still further (to 0.001 μg/ml for 1% absorption) by using a 1:10 volume ratio of organic phase to aqueous phase, the sensitivity becoming comparable to that obtained by electrothermal atomization in a graphite furnace.

The use of organic solvents miscible with water did not improve the limit of detection, however, because of the increased background noise level. On the other

hand, the MIBK system gave a much better limit of detection (0.004 μg/ml) because of the physical characteristics of the MIBK. The MIBK system also gave a wider range of linear response (0.02–3.0 μg/ml), the upper limit being restricted by the read-out scale, a saturation signal being obtained for higher concentrations, even without scale expansion.

Since the optimum composition of the flame is about the same for all the media used, the increased sensitivity obtained with the MIBK system must be attributed not to higher flame temperature but to (*a*) improvement of the nebulization efficiency due to the effect of the lower density, viscosity and surface tension of the solution, and (*b*) to an increased atomization efficiency due to the fast production of ground-state beryllium from the easily combustible matrix.

Interferences

The effect of Al^{3+}, Mg^{2+}, Ti^{4+}, V(V), Ca^{2+}, Fe^{3+}, Mn^{2+}, K^+, Na^+, silicate, phosphate, chloride, sulphate, fluoride, perchlorate, boric acid and thiocyanate was studied, with a beryllium concentration of 2 μg/ml and an interferent concentration of 50–1000 μg/ml.

Of the cationic species tested, only Al^{3+} and Ti^{4+} produced a strong depression of the atomic-absorption signal of beryllium, the effect setting in at a concentration below 50 μg/ml (Table 2). None of the other cations tested interfered at levels below 200 μg/ml.

When Fleet *et al.*[9] studied the effect of a 4000-μg/ml titanium solution in hydrofluoric acid medium, they found an increase of only 1.0% in the atomic-absorption signal of beryllium. This may be because the medium was hydrofluoric acid, which eliminates the interference by formation of hexafluorotitanate, but in our case the medium is sulphuric acid and the titanium interference starts at a concentration below 50 μg/ml and is total at 300 μg/ml. Ramakrishna *et al.*[8] found that at ratios of up to 100:1 to beryllium, only palladium and silicon interfered, depressing the beryllium signal by about 29 and 8%, respectively.

The interference of aluminium and titanium can be removed by adding lanthanum, which does not affect the atomic-absorption of beryllium. Addition of increasing amounts of lanthanum to a 1000-μg/ml aluminium or titanium solution containing beryllium at the 2-μg/ml level showed that at La:Al and La:Ti ratios of 10:8 and 15:8, respectively, the absorbance was the same as for pure beryllium solution over the range 0.03–3.0 μg/ml beryllium concentration.

None of the anionic species tested gave interference, except silicate and fluoride (Table 2). Amos and Willis[4] reported no interference from 2.5*N* sulphuric acid and that a slight enhancement was produced by phosphoric acid. Fleet *et al.*[9] found a 5–7% enhancement by 10-mg/ml sulphuric acid solution, but no interference from hydrochloric, hydrofluoric, nitric or phosphoric acid. Conflicting results for interference effects are reported in several investigations in this field, including the present study. This may be due to differences in the concentration range and the efficiency of the nebulizers or burners used. We have found that there is no interference if the sample solution nebulized is 6*M* sodium hydroxide containing beryllium at the 2-μg/ml level and silicate or fluoride at 1000 μg/ml.

Although the addition of lanthanum or use of the 6*M* sodium hydroxide medium avoids the interference from aluminium and titanium or silicate and fluoride, respectively, neither increases the sensitivity, and this may be necessary for analysis of samples of very low beryllium content. For this reason we examined the preconcentration system with trioctylamine and thiocyanate.

Extraction system

The extraction of beryllium from ammonium thiocyanate medium with trioctylamine (TOA) in MIBK was used by Novoselova *et al.*[18] to separate binary mixtures of beryllium with Al, Mg, Zn, or Mn, but this system has not been used for atomic-absorption determination of beryllium.

Table 2. Interferences in flame AAS determination of beryllium (2 μg/ml)

Concentration of interfering ion, *ppm*	Be absorbance

1.90	1.87	−2
2.50	2.53	+1

* As 0.04, B 0.24, Se 0.02, V 0.06 μg/ml in the synthetic samples.
† Average value of ten determinations.

According to our results, the optimum pH of extraction with 3% TOA in MIBK from 0.3*M* thiocyanate medium is 2.60–3.15, higher than that reported by Novoselova *et al.* With a 10:1 aqueous phase:organic phase volume ratio and shaking for at least 4 min, the recovery in a single extraction is at least 98.5%, for the beryllium range 0.2–3.0 μg/ml in the aqueous phase. When the sensitivity permitted it, the beryllium left in the aqueous phase was determined by flame AAS; otherwise, it was determined spectrophotometrically with quinalizarin. The AAS characteristics for beryllium determination in MIBK medium are shown in Table 1.

Aluminium, titanium, silicon and fluoride up to 1000 μg/ml were found not to interfere.

The American Public Health Association[24] recommends determination of beryllium in natural or sewage water by atomic-absorption in the nitrous oxide–acetylene flame with direct nebulization if the beryllium concentration is higher than 0.03 μg/ml, or by spectrophotometric measurement of the aluminium complex at 515 nm. The beryllium contents of such samples are seldom higher than 0.03 μg/ml.

Beryllium was determined in synthetic samples of the composition used by the American Public Health Association,[24] by the extraction and AAS method described. The results given in Table 3 show that the maximum relative standard deviation was 2% and relative error −6%, the average error being 3%.

EVALUATION OF NMR SPECTROSCOPY FOR THE QUANTITATIVE CHARACTERIZATION OF UREA–FORMALDEHYDE RESINS

R. TAYLOR, R. J. PRAGNELL, J. V. MCLAREN and C. E. SNAPE
Coal Research Establishment, Stoke Orchard, Cheltenham, Glos. GL52 4RZ, England

(*Received* 3 *August* 1981. *Revised* 13 *October* 1981. *Accepted* 22 *November* 1981)

Summary—A comparative evaluation has been made of both proton and ^{13}C nuclear magnetic resonance techniques in the quantitative characterization of commercial urea–formaldehyde resins. There is good agreement between data derived from ^{13}C NMR spectra and from ^{1}H high-field continuous wave, or low-field (Fourier transform) NMR spectra. Low-field continuous wave proton spectra exhibit inferior resolution and provide inaccurate quantitative data. Combination of ^{13}C and proton NMR with nitrogen analysis gives a quantitative characterization technique for these resins.

Despite the development of many new polymeric materials, interest has continued in well-established thermosetting condensation resins. Knowledge of one type of resin, urea–formaldehyde (U-F), has increased considerably with the advent of new instrumental techniques of analysis. In recent years the traditional methods of elemental analysis[1] and formaldehyde analyses[2] have been supplemented by infrared spectroscopy,[3] chromatographic methods[4–7] and NMR spectroscopy[5,8–13]

This paper evaluates methods of obtaining quantitative data on commercial U-F resins by use of both ^{1}H and ^{13}C NMR spectroscopy. The conditions required to obtain accurate and reproducible data are studied and the interpretation of such data is discussed.

EXPERIMENTAL

Aerolite UL-333, a liquid U-F resin manufactured by Ciba-Geigy Ltd., was used in this study. To obviate interference from the water present, a thin film of the sample was dried to a solid in a vacuum desiccator at 20°. All spectra were recorded at 25°.

^{1}H NMR

Continuous wave spectra were recorded, using relatively concentrated solutions (200 mg/ml), at 60 MHz (Hitachi Perkin–Elmer R24B) and 220 MHz (Hitach Perkin–Elmer R34). Pulsed (Fourier transform) spectra were obtained on more dilute solutions (40 mg/ml) at 80 MHz (Bruker WP80-WG). In each case the solvent employed was deuterated dimethylsulphoxide (DMSO-*d6*). The chemical shift was expressed in ppm relative to a tetramethylsilane (TMS) internal standard. Quantitative analysis was based on the intensity of each signal given by the integrator. In each case the integral was adjusted to the nearest 0.5%.

^{13}C NMR

These spectra were also recorded on the Bruker WP80-WG spectrometer. Gated decoupling (3-sec delay following acquisition) was employed and chromium acetylacetonate (0.02*M*) was added to the solution to obtain reliable quantitative data.[14]

Low concentrations of non-interacting paramagnetic species, such as chromium acetylacetonate, reduce thermal relaxation times (t_1) to about 0.15 sec,[15] and nuclear Overhauser enhancements (NOE) by the same factor (gated decoupling then removes the residual NOEs); 90°-pulses (duration 6.5 μsec) were employed since relaxation times were shortened sufficiently to ensure complete relaxation between pulses (~3–5 sec). The sweep width was 9000 Hz and 8000 data points were collected, so the acquisition period was 0.45 sec. The chemical shift was measured relative to TMS, and the quantitative information, based on the intensity of each band, was expressed to the nearest 0.5%.

RESULTS AND DISCUSSION

^{1}H NMR

The ^{1}H NMR spectrum of the U-F resin recorded at 60 MHz is shown in Fig. 1. The signal assignment is based on that given earlier by Chiavarini *et al.*,[10] Kambanis and Vasishth,[8] and Duclairoir and Brial.[9] The spectrum exhibits a methoxyl signal, at 2.8–3.4 ppm, and a shoulder on the –CONH– resonance, at 7.5–9.0 ppm, neither of which has previously been reported. The methoxyl signal arises because of the use of methanol-stabilized formalin in the preparation of the resin; methanol was presumably absent from the resins studied by the earlier authors.[8–10]

Resolution is improved at 220 MHz (Fig. 2). The peaks corresponding to –OH and $-NH_2$ are well resolved and the shoulder on the –CONH– signal appears as a distinct, though very broad, peak. In addition, the breadth of the $-CH_2-$ signal at 60 MHz (dotted lines in Fig. 1) is greatly reduced at 220 MHz. All these factors result in a more accurate integration profile (Table 1). At 60 MHz the width of the $-CH_2-$ band results in an underestimation of the intensity of that signal and a corresponding overestimation of the $-NH_2$, –OH and $-OCH_3$ intensities. The higher resolution at 220 MHz of the $-NH_2$ and –OH signals improves the accuracy of the intensity calculations for both peaks.

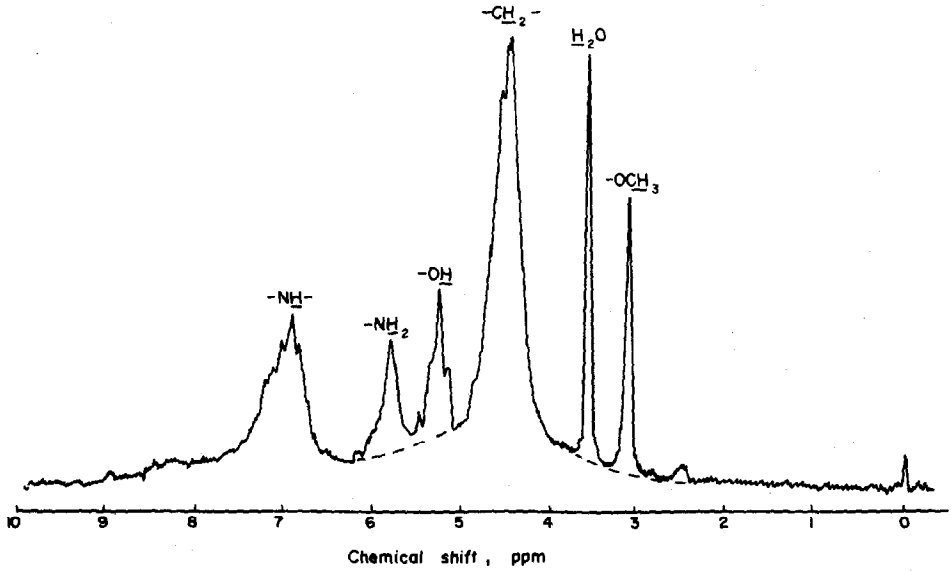

Fig. 1. 60-MHz proton NMR spectrum of a U-F resin.

In an attempt to obtain a reasonable spectrum at low field, a pulsed (FT) spectrum at 80 MHz was recorded, for a much more dilute solution of the U-F resin. The spectrum obtained (Fig. 3), although not as clearly resolved as that at 220 MHz, is superior to that obtained at 60 MHz. Integration of this spectrum (Table 1) clearly shows the improvement the Fourier transform technique makes for the low-field data, producing good agreement with results obtained at 220 MHz.

Finally, the addition of excess of deuterium oxide to the sample solution results in the replacement of all exchangeable protons, with a corresponding disappearance of the –OH, $-NH_2$ and –NH signals, includ-

Table 1. Hydrogen distribution of a U-F resin measured by ^1H NMR techniques

Functional group	Chemical shift, *ppm*	Percentage of total hydrogen		
		60 MHz	220 MHz	80 MHz (FT)
Shoulder	7.5–9.0	5.5	3.0	3.5
Monosubstituted amide (–NH–)	6.5–7.5	21.0	23.0	22.0
Non-substituted amide ($-NH_2-$)	5.5–6.5	11.0	6.5	7.0
Hydroxyl (–OH)	5.1–5.5	11.5	8.5	10.0
Methylene ($-CH_2-$)	4.0–5.1	44.0	54.0	52.5
Methoxyl ($-OCH_3$)	2.8–3.4	7.0	5.0	5.0

ing the shoulder on the latter. The shoulder would seem, therefore, to be attributable to –NH protons.

^{13}C NMR

The chemical-shift range of the methylene resonances is much larger in ^{13}C NMR than in ^1H NMR, making it possible to obtain more detailed information on the resin structure. The ^{13}C spectrum obtained with the U-F sample is shown in Fig. 4. The resonances have been assigned according to Slonim *et al.*[12] and Tomita *et al.*[13] The carbon distribution obtained from the spectrum is given in Table 2. Two points of caution must be borne in mind when assessing the intensity of the ^{13}C signals. First, care must be taken when estimating the size of the $-CONHCH_2NHCO-$ signal because of the very close proximity of the solvent resonance bands. Secondly, the presence of any uron derivatives will produce an error in the estimation of the $-N(CH_2)CH_2OCH_2-$ and $-NHCH_2OCH_3$ signals, owing to overlap of resonances. The presence of a carbonyl peak at 153.5 ppm, as observed with the resin investigated, indicates the presence of uron species.

Quantitative results

Chiavarini *et al.* all invoked some means of quantitative measurement in their early ^{1}H NMR studies. Of these, the last approach[10] was the most comprehensive, combining the information gained from the spectrum with that obtained by nitrogen and formaldehyde analyses to obtain quantitative data on a large number of functional groups present in U-F resins.

The Chiavarini formulae were therefore applied to our information obtained from the three types of proton spectra. In order to obtain the full range of data it

* Total urea concentration = 1.02 mole/100 g, total formaldehyde concentration = 1.74 mole/100 g, oxidizable formaldehyde concentration = 1.02 mole/100 g.

was necessary to determine the total nitrogen content (Kjeldahl method), the total formaldehyde concentration (acid hydrolysis)[16] and the oxidizable formaldehyde concentration (alkaline peroxide).[17] The free formaldehyde content, estimated by the sulphite method,[18] was found to be negligible in the dried sample.

The calculated functional group concentrations are given in Table 3. They show clearly the large errors that exist in the 60-MHz data, owing to the overlap of signals. However, within the limits of accuracy of the method (approx. 0.1 mole/100 g), the information derived at 220 MHz and 80 MHz (FT) shows good agreement.

By using the total urea concentration, and assuming all the carbonyl species are derived from urea, a similar range of functional group concentrations can be derived from the ^{13}C NMR data (assuming an accuracy of 0.1 mole/100 g) (Table 2).

Good agreement is achieved between the ^1H [220 MHz or 80 MHz (FT)] and the ^{13}C data. The only instance where a serious discrepancy exists is when the Chiavarini formulae are used to calculate the concentrations of the different types of oxymethylene formaldehyde. Here, due to the nature of the calculation, any slight errors made in integrating the spectrum become greatly magnified. These groups produce well-defined signals in an area of the ^{13}C spectrum well-removed from any interfering solvent resonances, and thus should provide relatively accurate information, even when the presence of uron species is taken into account (Table 4).

CONCLUSIONS

Derivation of accurate quantitative data for U-F resins from 60-MHz ^1H NMR spectra is not possible. Such information can be obtained from high-field spectra (220 MHz) or, alternatively from low-field (Fourier transform) spectra for dilute solutions. Accurate quantitative data can also be obtained from ^{13}C NMR spectra, provided that care is taken in interpreting the intensities of the signals. Agreement between the two sets of data is good, but errors have been found when deriving oxymethylene formaldehyde data from the ^1H NMR spectrum by using previously proposed formulae. Comparison of the ^{13}C NMR results with those obtained by classical

THE EFFECT OF POLYETHYLENE OXIDE MOLECULAR WEIGHT ON DETERMINATION OF ITS CONCENTRATION IN AQUEOUS SOLUTIONS

J. NUYSINK and L. K. KOOPAL*

Laboratory for Physical and Colloid Chemistry, Agricultural University,
De Dreijen 6, 6703 BC Wageningen, The Netherlands

(*Received* 3 *September* 1981. *Accepted* 14 *November* 1981)

Summary—The influence of the molecular weight of polyethylene oxide (PEO) on the results from several methods for determining its concentration in aqueous solutions has been investigated. Modified versions of the complexation reactions of PEO with molybdophosphoric acid and with tetraiodobismuthate give results that are independent of molecular-weight effects for the range *ca.* 400–10^6. The reaction with $KBiI_4$ is the less accurate. Oxidative digestion is also independent of molecular-weight, but impurities easily obscure the measurements. Other methods studied included interferometry, viscometry, and complexation with tannic acid. Interferometry and the reaction with tannic acid were only independent of molecular-weight for M > 4000. With viscometry very poor results were obtained.

Polyethylene glycols (PEG) and polyethylene oxides (PEO) find many applications[1] and are well suited for model studies on adsorption[2–6] and flocculation.[7,8] The general formula of a polyethylene oxide or a polyethylene glycol segment is —CH_2CH_2O—. The lower molecular-weight members of the series (up to about M = 2×10^4) are generally known as PEGs, the higher molecular-weight members as PEOs or polyoxyethylenes. In this paper we will use the term polyethylene oxide as a general name.

The use of PEO in model studies demands accurate and simple methods for determining the solution concentration of PEO. Several such methods exist,[3–6,9,10] especially for the lower molecular-weight series (PEGs). Little attention has been paid to the high molecular-weight PEOs[11] and to the effect of the PEO molecular weight on the determination. The latter aspect is of particular importance for polymer adsorption studies, because from a polydisperse polymer sample the higher molecular-weight species will be preferentially adsorbed.[12] As a result, the average molecular weight of the polymer remaining in solution will no longer be known. To avoid systematic errors in such a case, a method is required for determining PEO concentration that will be practically unaffected by the molecular weight of the PEO.

The objective of this study was to examine the PEO determination methods with regard to dependence on the molecular weight and to develop methods which can also be used for adsorption studies.

Existing methods

Determinations of PEO in aqueous solution can be divided into two broad classes.

(1) Methods in which a PEO solution property is measured directly, for instance interferometry,[4] viscometry,[5] or oxidative digestion.[6] In general such methods can be applied only to *pure* PEO solutions.

(2) Methods based on the ability of PEO to form precipitates with large anions in the presence of cations such as Ba^{2+}.[9,13] The following anionic reagents have been used: molybdophosphoric acid,[14,15] silicotungstic acid,[14,16] cobaltothiocyanate,[17] potassium ferrocyanide,[18] sodium tetraphenylborate (NaTPB),[10,19–21] potassium tetraiodobismuthate(III),[22] and tannic acid.[11,13] After precipitation the complex is separated from the solution and analysed. In the case of tannic acid the turbidity of the tannic acid–PEO solution is measured. Except for the reaction with tannic acid, PEOs of relatively low molecular weights have been used.

For the methods mentioned under (1), no quantitative information is available with regard to molecular weight effects. In the case of viscometry, the PEO determination is expected to be molecular-weight dependent, because the viscosity of a polymer solution is related to the molecular weight of the polymer.[25] In the case of interferometry and oxidative digestion, the nature of the segments is much more important than the length of the polymer chain. Therefore, molecular-weight effects should vanish as soon as end-group effects become negligible.

The precipitation or complexation of PEO with reagents as indicated under (2) is mostly explained by assuming that PEO forms quarternary oxonium derivatives. Two such "oxonium" groups, formed for approximately every 6 ethylene oxide units, are involved in the binding of a reagent anion.[13] For example, in the well-studied case of NaTPB in the presence of $BaCl_2$,[10,20,23] approximately 11 ethylene oxide units combine with 2 TPB ions and 1 Ba^{2+} ion. It has been suggested that this ratio is determined by the steric conformation of the PEO chain in the reagent solution.[13,23] Owing to the large number of ethylene oxide units involved in the binding mechanism, the

* To whom all correspondence should be addressed.

reaction does not proceed with PEOs of very short chain length. For PEO chains of intermediate length, the steric conformation of the complex is still substantially dependent upon molecular weight. Consequently, most PEO determinations based on the analysis of the precipitated complex will be molecular-weight dependent when PEOs of "low" molecular weight are used. Such a dependence is clearly established for the reaction of PEO with NaTPB[10] and cobaltothiocyanate[24] and it is indicated in the case of the reaction with silicotungstic acid.[14]

In a preliminary investigation we found that the reactions with $KBiI_4$ and molybdophosphoric acid were only slightly dependent on the value of M. For the reaction of PEO of large M with tannic acid it has been reported[11] that the presence of PEOs of low molecular weight caused erroneous results.

In conclusion, we may say that little quantitative information is available on the molecular-weight dependence of the various PEO concentration determination methods. Therefore, the effect of molecular weight on the following methods was studied: interferometry, viscometry, oxidative digestion, complexation with tannic acid, precipitation with $KBiI_4$ and with molybdophosphoric acid. In the last two cases the supernatant solution was analysed instead of the precipitate. This simplified the procedure and enhanced the chance of obtaining a method not affected by the PEO molecular weight.

EXPERIMENTAL

Reagents

Polyethylene oxides. These were commercial products (Union Carbide Corporation), trademarked "Carbowax" for the lower molecular-weight members ($200 < M_n < 2 \times 10^4$) and "Polyox" for the higher molecular-weight series ($10^5 < M_w < 4 \times 10^6$). M_n is the number average molecular weight and M_w the weight average molecular weight. The "Carbowax" samples will be denoted as PEO followed by their approximate M_n, *e.g.*, PEO 600, PEO 6000; the "Polyox" types as PEO plus their approximate M_w, *viz.* PEO 100,000, PEO 600,000, *etc.* All samples were used without further purification, except for prolonged drying over phosphorus pentoxide in a vacuum desiccator.

Solutions of the PEO samples were prepared by sifting the polymer into about one-half to two-thirds of the required amount of water (at the boiling point) with mild stirring, then removing the heat source and, with continuous stirring, cooling the solution with some water at about 20°, and finally cooling the solution and transferring it to a standard flask and making up to volume with water. This procedure prevents the particles from agglomerating and facilitates the dissolution.[1]

Tannic acid solution. Made by dissolving 0.200 g of tannic acid, dried for 2 hr at 105° and 29.2 g of sodium chloride in 1 litre of water.

Bürger's reagent. Dragendorff reagent was made by dissolving 1.70 g of basic bismuth(III) nitrate ($BiO.NO_3.H_2O$) in 20 ml of glacial acetic acid and diluting to 100 ml with water, then mixing with a solution of 40 g of potassium iodide in 100 ml of water, adding 200 ml of glacial acetic acid, and making up to volume in a 1-litre standard flask. Then 100 ml of the Dragendorff reagent were combined with 50 ml of water in which 18.8 g of barium chloride dihydrate had been dissolved. The mixed reagent keeps for about two weeks in a brown bottle. It should be discarded when it turns brown.

Molybdophosphoric acid reagent. Made by dissolving 0.50 g of $H_3Mo_{10}PO_{32}.24H_2O$, 0.50 g of barium chloride dihydrate and about 1.5 ml of concentrated hydrochloric acid in 250 ml of water.

Potassium dichromate solution. Made by diluting one ampoule of Baker Chemicals "0.1*N* $K_2Cr_2O_7$" concentrate and 8 ml of concentrated sulphuric acid to 1 litre with water, to give an acidic 0.1000*N* dichromate solution.

Mohr's salt solution. Made by dissolving 39–40 g of $FeSO_4(NH_4)_2SO_4.6H_2O$ and 8 ml of concentrated sulphuric acid in 1 litre of water, and standardized with the potassium dichromate solution.

Apparatus

Interferometer (Carl Zeiss, Jena), having a double glass cell of matched 2-cm path-length, in a thermostatic water-bath.

Viscometer (Viscomatic MS, type 53000, Fica) having electronic timing (±0.01 sec) and Ubbelohde capillaries. The dilution vessel and capillaries were temperature-controlled to within 0.005° with a thermostatic water-bath.

Spectrometer (Beckman model 3600), double-beam, digital reading, equipped with a temperature-controlled dual cell holder; wavelength range 190–900 nm.

Turbidity meter (Unicam SP 1800 spectrometer), double-beam, equipped with a temperature-controlled cell-holder. The sample was placed in the secondary sample position, *i.e.*, close to the detector, in order to obtain the best accuracy.

Procedures

Interferometry and viscometry. These methods are based on the increase in refractive index or viscosity, respectively, with increasing polymer concentration. Measurements on PEO test solutions are made at constant temperature, with water as reference.

Oxidative digestion. The oxidation of PEO with dichromate is described by the equation

$$5Cr_2O_7^{2-} + 40H^+ + 3[-(C_2H_4O)-] \rightarrow 10Cr^{3+} + 6CO_2 + 26H_2O.$$

An excess of dichromate is added and the surplus back-titrated with iron(II). The amount of PEO originally present can be calculated from the mass balance as $4.4(V_C N_C - V_M N_M)$ mg, where V_C ml of dichromate (normality N_C) and V_M ml of Mohr's salt solution (normality N_M) are used. Pipette 5 ml of dichromate solution into a beaker, add b ml of PEO test solution containing about 1.5 mg of PEO, and heat for 2 hr at 90°, allowing enough evaporation to obtain a dichromate concentration high enough to oxidize the polymer completely, but without evaporation to dryness. Cool, dilute carefully, and titrate potentiometrically with the Mohr's salt solution.

Molybdophosphoric acid method. Shaffer and Critchfield[14] have described an analysis in which PEO is precipitated with phosphomolybdic acid, collected, dried and weighed. Stevenson[15] modified this procedure and measured the absorbance of a solution of the precipitate in concentrated sulphuric acid, at 520 nm. Concentrations down to 1 mg/l. could be detected. In the present study a method has been developed in which the difference in the molybdophosphoric acid concentration before and after the reaction with PEO is used as a measure of the PEO content. Pipette 2 ml of molybdophosphoric acid reagent solution into a dry centrifuge tube, add 2 ml of PEO solution (10–300 mg/l.). Shake gently, store the tube for 15 min at 20°, and centrifuge. Pipette 1 ml of the supernatant solution into a 50-ml standard flask and make up to

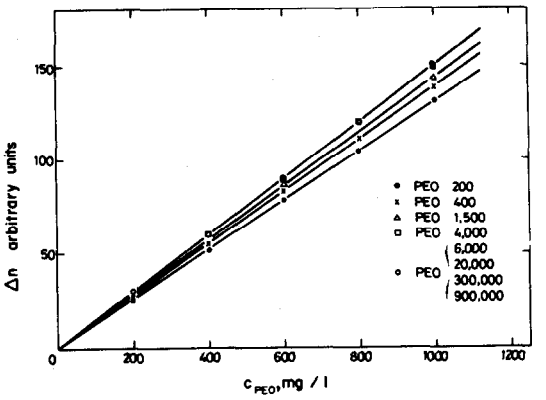

Fig. 1. Interferometry. The difference in refractive index between blank and test solution, Δn, *vs.* PEO concentration, c_{PEO}. The PEOs studied are indicated.

volume with water. Measure the absorbance at 216 nm in a 1-cm quartz cuvette against water, at 20°, directly after the cuvette has been placed in the spectrometer. The original polymer concentration, c_{PEO}, is found from the difference in absorbance between a blank and the test solution, by means of a calibration graph. The blank solution is made in the same way as the test solution but with 2 ml of water instead of the PEO solution.

Tetraiodobismuthate method. Bürger[22] precipitated PEO with $KBiI_4$ in a narrow-ended centrifuge tube and used the depth of the deposit as a measure of the PEO content. We have tried this method but could not obtain accurate results, so we have modified the procedure, determining the change in the $KBiI_4$ concentration caused by the reaction with PEO.

The effect of time, temperature and exposure to light on the absorbance of the $KBiI_4$ solution were explicit variables.

Dissolve 26.7 g of potassium iodide and 145 ml of glacial acetic acid in 1 litre of water (same concentrations as in Bürger's reagent). Store this solution in the dark. Pipette 2 ml of PEO solution (c_{PEO} 5–300 mg/l.) and 1 ml of Bürger's reagent into a dry centrifuge tube. Mix the solution carefully and store the tubes for 30 min in the dark at 20°. Centrifuge, and pipette 1 ml of the supernatant solution into a brown 50-ml standard flask containing 25 ml of the iodide/glacial acetic acid solution and make up to volume with this solution. Measure the absorbance at 337 nm in a quartz cuvette against water at 20°, directly after placing the cuvette in the spectrometer. Run a blank in the same way (with 2 ml of water instead of the sample). The PEO concentration is found from the difference in absorbance between the blank and the test solution, by means of a calibration plot.

Turbidimetry with tannic acid. Essentially the method given by Attia and Rubio[11] was followed, but the turbidity was measured with a spectrometer instead of a nephelometer. The turbidity or absorbance of a suspension depends on the number and size of the particles present. In the case of the PEO–tannic acid precipitate both the number of particles and the size are functions not only of the polymer concentration, but also of the composition of the reagent solution, the way of mixing reagent and polymer, and the temperature. To develop a standard procedure, a series of experiments has been carried out in which the concentrations of tannic acid and sodium chloride, the temperature and the measurement wavelength were varied. The molecular-weight effect was studied with the established standard procedure.

Put about 15 ml of the standard tannic acid solution into a 25-ml standard flask, add 5 ml of PEO solution (c_{PEO} 2–150 mg/l.) and make up to volume with the tannic acid solution. Mix by turning the flask upside down 10 times. Store the mixture for 1 hr in the dark at 20° and measure the absorbance of the suspension at 600 nm against water in a 1-cm cuvette.

N.B. The absorbance, A, of the suspension in a 1-cm cell is directly related to the turbidity, τ, by $A = 0.434\ \tau$, with τ in cm^{-1}.

RESULTS AND DISCUSSION

Interferometry

A typical set of curves, showing the difference in refractive index between a PEO solution and water as a function of c_{PEO} for various PEOs differing in molecular weight, is shown in Fig. 1. Apparently the difference depends on molecular weight up to at least $M_n = 1500$, and this is due to the influence of the end-groups of the PEO chain.

For $4000 \leqslant M \leqslant 9 \times 10^5$ no molecular-weight effect could be detected. The sensitivity of the method, however, is rather poor. The lower detection limit is about 100 mg/l. In the presence of salt (at constant concentration) a still lower sensitivity is observed. Hence the method is only suitable and independent of molecular weight for pure PEO solutions of sufficiently large c_{PEO} and M_{PEO}.

Viscometry

The results obtained by viscometry are shown in Fig. 2, where the relative increase in flow-time is plotted *vs.* c_{PEO} for various PEOs in aqueous or salt solutions. From Fig. 2 it follows that the determination is limited to PEOs with $M > 6000$. The sensitivity of the method is very poor except for PEO 4×10^6. The molecular-weight dependence is strong and in qualitative agreement with the Mark–Houwink–Sakurada and Flory–Fox relations[25] which give the dependence of the intrinsic viscosity on M. It is also shown that both the type and concentration of salt present in the

solution can affect the determination. In conclusion, viscometry is a very poor method for determination of PEO concentration.

Oxidative digestion

Results are shown in Fig. 3. It follows that the oxidative digestion is a reasonably accurate method for PEO determination, and is independent of molecular weight. In principle, even very small PEO concentrations can be determined, but in that case a relatively large volume of solution is required and attention has to be paid to the nearly complete evaporation of the solution, or quantitative oxidation of the PEO is not attained. Moreover, other oxidizable compounds must be absent. In adsorption studies it should be remembered that any adsorbed polymer or oxidizable adsorbent still present in the supernatant solution because of incomplete sedimentation will also be determined by this method.

Molybdophosphoric acid method

The absorption spectra of the reagent solution before and after the reaction with PEO are plotted in Fig. 4; all exhibit a well-defined peak at 216 nm, indicating that only free reagent is present in the solution. Comparison of the curves for different PEOs shows that the effect of molecular weight is relatively small, except for PEO 200. The molybdophosphoric acid solution obeys Beer's law up to a concentration of 40 mg/l. The molar absorptivity is 7.5×10^4 $l.mole^{-1}.cm^{-1}$. Prolonged exposure of the reagent to ultraviolet light decreases the absorbance.

The standard PEO determination given in the experimental section is based on these findings. A maximum molybdophosphoric acid concentration of 20 mg/l. is used in order to keep the absorbance below 0.8, which enhances the accuracy of the method. To diminish the influence of ultraviolet light, water is used as a reference. The difference (ΔA_{216}) in the absorbance at 216 nm of the reagent solution before and after the reaction with PEO, is a measure of the PEO content.

In Fig. 5, ΔA_{216} is shown as a function of c_{PEO} for several PEOs differing in molecular weight. A linear relation is found, which is practically independent of molecular weight if $M \geqslant 400$. For PEOs with $M \geqslant 10^5$, the calibration curve has a slightly lower slope than for the lower molecular weights, but up to $c_{PEO} = 150$ mg/l. the differences between the different PEOs are within the experimental error. In the case of PEO 200 the reaction between polymer and reagent solution is incomplete, but it is still possible to determine the PEO concentration with the present method. It can be concluded that a rather simple and attractive new method has been developed.

The calibration curve allows us to calculate the average number of ethylene oxide units (EOUs) involved in the binding with a molybdophosphoric acid unit. An 80-mg/l. PEO solution decreases the

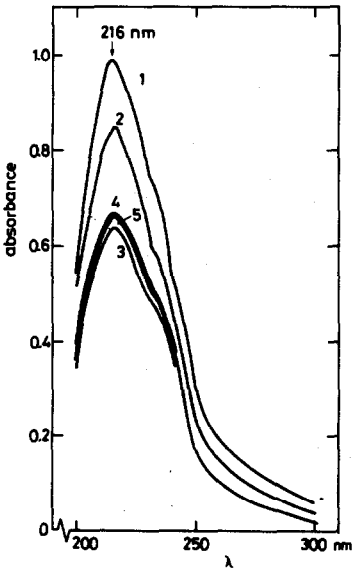

Fig. 4. Absorption spectra of the molybdophosphoric acid reagent before and after the reaction with PEO; 1, blank; 2, PEO 200; 3, PEO 400; 4, PEO 6,000; 5, PEO 600,000.

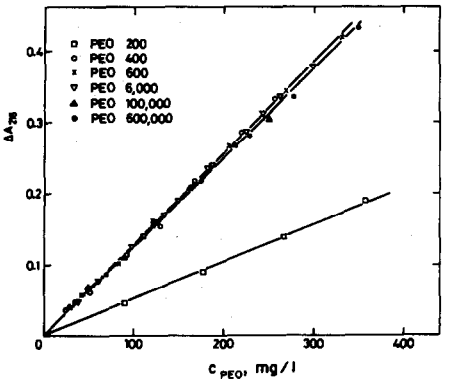

Fig. 5. ΔA_{216} (1-cm cuvette) of the molybdophosphoric acid reagent as a function of PEO concentration.

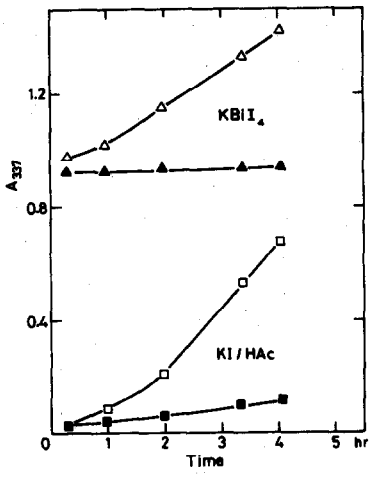

Fig. 6. Effect of time and light on the A_{337} of tetraiodobismuthate solution and a KI/acetic acid solution. Open symbols: solutions exposed to light; closed symbols: solutions kept in the dark.

absorbance by 0.1. This corresponds to a decrease in the original molybdophosphoric acid concentration of 262 mg/l. Hence, 1 molybdophosphoric acid unit reacts with about 14 EOUs or about 4 Mo atoms with 6 EOUs. Apparently, the reaction mechanism of PEO with a large unit such as molybdophosphoric acid is more complicated than that of the reaction with NaTPB.

Tetraiodobismuthate method

This method is essentially very similar to that with molybdophosphoric acid. The tetraiodobismuthate(III) anion in sulphuric acid solution exhibits absorbance maxima at 337 and 465 nm.[26] In Bürger's reagent, acetic acid is used instead of sulphuric acid. We therefore measured the absorbance of the BiI_4^- complex in the iodide/acetic acid solution. The absorption maxima are again found at 337 and 465 nm, and Beer's law is obeyed up to Bi concentrations of 10 mg/l. The molar absorptivity is 3.14×10^4 $l.mole^{-1}.cm^{-1}$.

Owing to the potassium iodide present, the reagent solution is rather sensitive to light. This can be seen from Fig. 6, where the absorbances of Bürger's reagent and a comparable iodide/acetic acid solution are shown as a function of time and exposure to light. Water was used as reference. The strong increase in absorbance in the presence of light is due to the formation of iodine. To minimize this reaction, all iodide/acetic acid solutions should be kept in the dark, brown glassware should be used, and spectrometer readings made directly after the cuvettes have been filled. Provided that these precautions are taken, the effect of temperature on the absorbance is small.

In Fig. 7 the difference in absorbance at 337 nm, ΔA_{337}, of the reagent solution before and after the reaction with PEO is shown as a function of the PEO concentration for a number of PEO samples differing in molecular weight. Except for PEO 200, all the PEO samples gave (within experimental error) the same calibration curve irrespective of the PEO molecular weight. Apparently in this case also the reaction of PEO 200 with the reagent solution is incomplete.

However, the scatter of points around the calibration curve is rather large. Probably this is connected with the presence of iodide and the fact that the precipitation reaction is reproducible only within a few per cent. Above $c_{PEO} \simeq 350$ mg/l. the slope of the calibration curve decreases strongly and the method becomes increasingly inaccurate.

All in all, the tetraiodobismuthate method gives a reasonably accurate PEO determination, the error being within about ± 10 mg/l. in the concentration range 10–350 mg/l.

From Fig. 7 it can be calculated that for low c_{PEO} 1.33 mg of PEO reacts with 1.23 mg of bismuth, indicating that about 7 EOUs are involved in the binding with one tetraiodobismuthate ion. This is somewhat larger than the quoted EOU/reagent anion ratio of 6. The discrepancy may be due to the iodide concen-

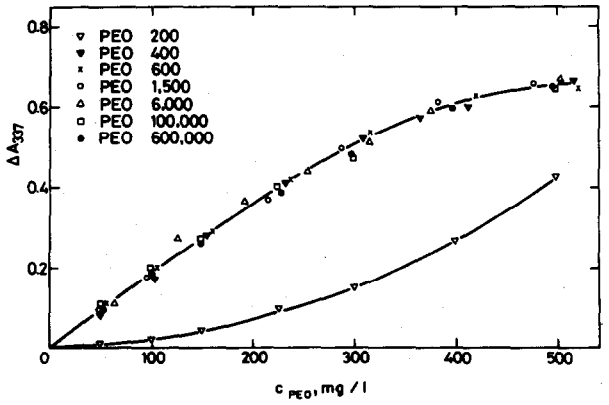

Fig. 7. ΔA_{337} for tetraiodobismuthate as a function of PEO concentration.

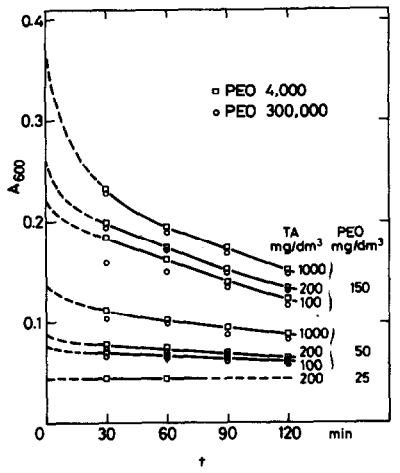

Fig. 8. The absorbance at 600 nm of tannic acid (TA)/PEO solutions as a function of time, for PEO 4,000 and PEO 300,000.

tration being limited to minimize the experimental error. In the present case, the ratio KI/Bi in the test solution is about 10^3 whereas Lisicki and Boltz[26] indicate that this ratio should be $\geq 10^4$ in order to ensure attainment of maximum absorptivity at 337 nm.

Turbidimetry with tannic acid

In the reaction of PEO with tannic acid (TA) the size and number of particles formed depend on the extent of the reaction. Hence, the turbidity of such a suspension is a function of time. This is shown in Fig. 8 where the absorbance at 600 nm, A_{600}, measured in a 1-cm cuvette, is plotted *vs.* incubation time, *t*. A_{600} is directly proportional to the turbidity (expressed in cm^{-1}).

With increasing PEO concentration an increase in the time effect is observed. Probably only the values of A_{600} extrapolated to $t = 0$ would show a linear proportionality between A_{600} and c_{PEO}. However, in practice this situation can never be attained. An increase in the tannic acid concentration also increases the time effect. At a wavelength of 400 nm instead of 600 nm, the observed time effects strongly increase.

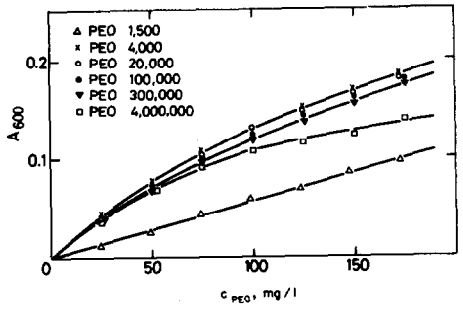

Fig. 9. The absorbance at 600 nm of tannic acid/PEO test solutions as a function of PEO concentration.

The trends mentioned are about the same for PEO 4000 and PEO 300,000, except for TA concentrations of 100 mg/l. and large PEO concentrations. In other words, the effect of molecular weight is small.

Decreasing the sodium chloride concentration from 0.5*M* to 0.1*M* lowers A_{600}. However, at low PEO and TA concentrations the time effects are similar to those shown in Fig. 8.

Temperature differences of $\pm 5°$ have only a minor effect on A_{600} and this effect is practically independent of the TA concentration.

We conclude that measurements should be made at 600 nm, a TA concentration of 200 mg/l. and an incubation time of at least 30 min. Once the time is selected, only small deviations from it are allowed, otherwise serious systematic errors occur, especially at PEO concentrations larger than 50 mg/l.

In Fig. 9 the absorbance, A_{600}, measured under standard conditions, is plotted *vs.* c_{PEO} for a series of PEO samples. As expected on the basis of the results shown in Fig. 8, the calibration plots are curved. However, for $100 < c_{PEO} < 170$ mg/l. an approximately linear relationship is found.

The reagent apparently did not react at all with PEO 600, and only very little with PEO 1500. For $M \geq 4000$ the reaction develops well, but there is still some effect of molecular weight. For very large M ($>10^6$) and large c_{PEO} (>100 mg/l.) the method becomes inaccurate. In general, the method is reasonably sensitive and accurate in the molecular weight range of 4000–10^6.

CONCLUSIONS

For the determination of PEO in aqueous solution three methods are available which are practically unaffected by the PEO molecular weight and can be used over a large PEO molecular-weight range. These three methods are oxidative digestion, precipitation with molybdophosphoric acid, and precipitation with tetraiodobismuthate. The last two methods are modifications of previously suggested procedures.

In general the precipitation reaction with molybdophosphoric acid is preferable to the other two. Oxidative digestion of PEO is very sensitive to the presence of other oxidizable compounds, and the precipitation of PEO with tetraiodobismuthate is somewhat less accurate than that with molybdophosphoric acid.

For PEOs of relatively large molecular weight, the complexation reaction with tannic acid can also be used.

(*Received* 23 *July* 1981. *Accepted* 13 *November* 1981)

Summary—A new chelate-forming resin bearing mercapto and azo groups was prepared from a common anion-exchange resin by treatment with azothiopyrine disulphonic acid (ATPS). ATPS resin was very stable and highly effective for the collection of mercury(II) by the batch and column methods. In the column method, the amount of mercury(II) in solution could be reduced to below 0.5 μg/l. The mercury(II) adsorbed could be eluted with thiourea solution, and the resin could be used repeatedly.

We have presented some chelate-forming resins of a new type, prepared simply by the modification of common ion-exchange resins with the proper chelating agents.[1–3] Some of them were found to be stable even in 1.0*M* sodium chloride medium and effective for the collection of heavy metal ions. The usefulness of these resins is attributed to the triple function of the chelating agents, namely ion-exchange, chelate-formation and physical adsorption on the ion-exchange resin.

A chelate-forming resin, prepared from a common anion-exchange resin by treatment with azothiopyrine disulphonic acid [disodium 4,4′-(4-diazenediyl-5-mercapto-3-methyl-1,2-diazacyclopenta-2,4-dien-1-yl)dibenzenesulphonate, abbreviated to ATPS hereafter], has been reported briefly as being effective for the adsorption of mercury(II).[2] This paper gives full details of the adsorption and recovery of mercury(II) ion with this resin (ATPS resin), together with those for copper(II) and cadmium. The synthesis and some properties of ATPS, the first example of a chelating agent bearing mercapto and azo groups, were reported previously.[4]

EXPERIMENTAL

Materials

Azothiopyrine disulphonic acid (ATPS, Fig. 1) prepared as reported previously[4] was used. The solutions of mercury(II), cadmium and copper(II) were prepared from the nitrates. Amberlite IRA-400 (8% divinylbenzene) in the chloride form, 100–200 mesh, was the anion-exchange resin used. All other reagents were of analytical-grade.

Preparation of ATPS resin

The anion-exchange resin was added to the solution of ATPS and the mixture was shaken at 30° until the supernatant liquid became colourless. The resin was filtered off, washed with water and methanol, air-dried, and stored in a refrigerator.

Determination of exchange capacity for mercury(II)

The resin, 200 mg, loaded with various amount of ATPS (0.10, 0.20, 0.40 and 0.60 mmole per g of resin) was shaken with a small excess of mercury(II). The amount of mercury(II) left in solution was determined at regular time intervals.

Determination of metal ion

Mercury(II) was determined by cold-vapour atomic-absorption spectrometry with a Shimadzu atomic-absorption/flame-emission spectrophotometer AA-630-01 equipped with a reduction/aeration apparatus. Copper and cadmium were also determined by atomic-absorption spectrometry.

Adsorption of metal ion by batch operation

Procedure A. To 1 ml of 1000 or 100-mg/l metal ion solution and 99 ml of 0.1*M* acetate buffer, 200 mg of ATPS-loaded resin (0.2 mmole/g) were added. The pH of the solution was adjusted to below 3.6 with 0.1*M* nitric acid. The mixture was shaken for about 12 hr, and the resin was then filtered off on a fritted-glass funnel. An appropriate volume of filtrate was used for determination of the metal ions.

Procedure B. To 1 ml of 1000-mg/l mercury(II), copper(II) and cadmium solution, 10 ml of 5*M* sodium chloride, 87 ml of 0.1*M* acetate buffer and 200 mg of ATPS-

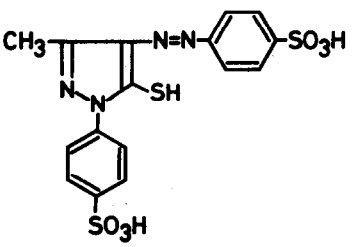

Fig. 1. ATPS.

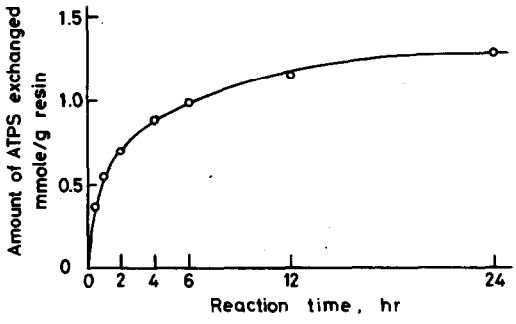

Fig. 2. Adsorption of ATPS on the anion-exchange resin.

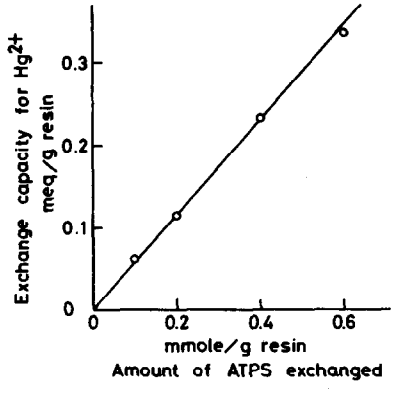

Fig. 3. Exchange capacity for mercury(II).

loaded resin (0.2 and 0.5 mmole/g) were added. Adjustment of pH, shaking of the solution and determination of the metal ions were carried out as in procedure A.

Elution of mercury(II) in column operation

In glass columns (1 cm diameter) 0.5-g amounts of ATPS resin (loading 0.2 mmole/g) which had adsorbed 1000 μg of mercury(II) were packed, to a height of 1.3 cm. The columns were eluted individually with 20 ml of 10*M* hydrochloric acid, 10*M* perchloric acid, 5, 8, 10 and 12*M* nitric acid, 10% thiourea solution, 10% thiourea solution in 0.1*M* hydrochloric acid, and 5, 7, 8 and 10% thiourea solutions in 0.1*M* perchloric acid.

Adsorption and recovery of mercury(II) ion by column operation

Columns (diameter 1.0 cm) were packed with ATPS-resin (loading, column I 0.1 mmole/g; column II 0.2 mmole/g) to a height of 10.0 cm. After the columns had been washed with 200 ml of distilled demineralized water, 50-mg/l mercury(II) solution in 0.1*M* nitric acid was passed through the column at a flow-rate of 1.5 ml/min. The resin was washed with distilled demineralized water and then the amount of mercury(II) in the eluate was determined. Mercury(II) adsorbed on the ATPS-resin in column II was eluted with 10% thiourea solution in 0.1*M* perchloric acid at a flow-rate of 1.0 ml/min, and then the column was washed with 100 ml of 0.1*M* nitric acid and 200 ml of pure water, and the amount of mercury(II) in the eluate was determined. After recovery of the mercury(II), 50-mg/l mercury(II) solution in 0.1*M* nitric acid was again passed through column II, and the amount of mercury(II) in the eluate determined.

RESULTS AND DISCUSSION

We reported earlier that the mono and disulphonic acids of azothiopyrine[4] had been obtained and that they were stable to air oxidation even in as strongly an acidic solution as 10*M* hydrochloric acid. The disulphonate was used in the present study, because of its greater solubility. As shown in Fig. 2, the exchange-capacity of the anion-exchange resin for ATPS was 1.3 mmole/g of resin. Loading with 50% of the capacity required 2 hr. The resin loaded with ATPS (0.2 mmole/g), which took 20 min to prepare, was mainly used in this study. Azothiopyrine was found to be scarcely adsorbed on the anion-exchange resin in 50% methanol. The large exchange-capacity of the resin for ATPS is attributed to an ion-exchange reaction between ATPS and the resin. The binding capacity for mercury(II) on ATPS resins (loading 0.1–0.6 mmole/g) is shown in Fig. 3. The time required for 50% uptake of mercury(II) is less than 10 min. The binding capacity for mercury(II) increases linearly with increase in the amount of ATPS loaded, and the binding ratio of mercury(II) to ATPS on the resin is about 1:2.

The adsorption behaviour of mercury(II), copper (II) and cadmium on ATPS resin as a function of pH is shown in Fig. 4 (procedure A). The adsorption of copper(II) and cadmium increases with pH. The metal ions are adsorbed more effectively at lower concentrations. Adsorption of mercury(II) is complete, the log K_d value being 6.9 in the pH range 1–7. The K_d value for a metal ion is given by the ratio (mmoles

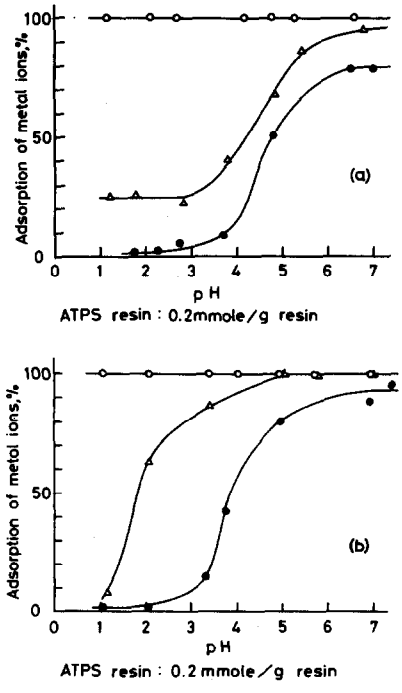

Fig. 4. Adsorption of metal ions by batch operation: ○ mercury(II); △ copper(II); ● cadmium(II). Initial concentration of metal ion: (a) 10 mg/l, (b) 1 mg/l.

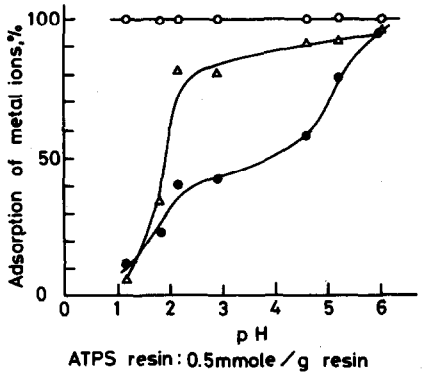

Fig. 5. Adsorption of mercury(II), copper(II) and cadmium(II) from 0.5*M* NaCl by batch operation: ○ mercury(II); △ copper(II); ● cadmium(II). Initial concentration of metal ions 10 mg/l.

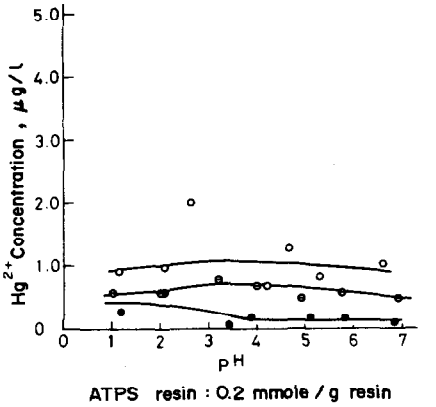

Fig. 6. Concentration of mercury(II) left in the aqueous phase. Initial concentration (mg/l) of mercury(II): ○ 10; ⊖ 1; ● 0.1.

sorbed per g of resin)/(mmoles left per ml of solution). The high K_d value for mercury(II) on ATPS resin indicates that the combination of mercapto and azo groups is extremely favourable for chelate-formation with mercury(II). In fact, the stability constant of the azothiopyrine–mercury(II) chelate[5] has been found to be as high as that of the dithizone–mercury(II) chelate.

To find whether ATPS resin would be suitable for the collection of mercury(II) from estuarine and sea-water, the influence of foreign ions was examined by use of procedure B. The resin, loaded with 0.2 mmole of ATPS per g, was found to sorb 99.6% of mercury(II) added, 71% of copper(II) and 53% of cadmium(II) at pH 6. The incomplete uptake of mercury(II) was due to insufficient loading of the resin with reagent, and the concentration of mercury(II) remaining in solution was reduced to less than 5 µg/l at pH 6 when the resin was loaded with 0.5 mmole of ATPS per g. The uptake of copper(II) and cadmium(II) was much lower than that of mercury(II) in the pH range 1–6, as shown in Fig. 5. Furthermore, these findings indicate that ATPS resin is stable even in the presence of 0.5*M* sodium chloride, and the resin can be applied effectively at pH 1 to the collection of mercury(II) from estuarine and sea-water containing copper(II) and cadmium(II). The strong fixation of ATPS on the resin is attributed to physical interaction between ATPS and the ion-exchange resin. The chelate-forming resins[3] prepared from some chelating agents which bear ion-exchange groups but are not adsorbed physically on the ion-exchange resin have been found to be unstable in the presence of chloride ion.

The amounts of mercury(II) left in the aqueous phase at various pH values were determined and the results are shown in Fig. 6. An initial mercury(II) concentration of 10 mg/l was reduced to below 2 µg/l by shaking with ATPS resin for 4 hr, indicating almost complete sorption of the mercury(II) on the resin. Initial mercury(II) concentrations of 1 or 0.1 mg/l were reduced to less than 1 µg/l.

The commercially available chelating resins for selective collection of mercury(II) cannot be regenerated and ignition is necessary for recovery of the mercury.[6] However, in the case of ATPS resin, there are two possibilities for elution of mercury(II):

$$\text{I}\quad (\text{resin–reagent–metal ion}) \xrightarrow{\text{eluent}} (\text{resin}) + \text{reagent} + \text{metal ion}$$

$$\text{II}\quad (\text{resin–reagent–metal ion}) \xrightarrow{\text{eluent}} (\text{resin–reagent}) + \text{metal ion}$$

where the species in brackets are in the solid state. As shown in Table 1, mercury(II) was completely eluted with 8*M* nitric acid by method I and the anion-exchange resin was regenerated. In method II the mercury(II) was eluted completely with a 10% solution of thiourea in 0.1*M* perchloric acid, and the ATPS resin recovered.

Table 1. Desorption of mercury(II) from ATPS resin by various eluting agents

Eluent	Recovery of mercury(II), %
6*M* HNO_3	78
8*M* HNO_3	100
10*M* HNO_3	100
12*M* HNO_3	100
10*M* $HClO_4$	18
10*M* HCl	21
5% thiourea in 0.1*M* $HClO_4$	0
7% thiourea in 0.1*M* $HClO_4$	93
8% thiourea in 0.1*M* $HClO_4$	96
10% thiourea in 0.1*M* $HClO_4$	100
10% thiourea in 0.1*M* HCl	0
10% thiourea in aqueous solution	0

Sorption conditions (batch operation): ATPS resin (0.2 mmole/g) 0.5 g; mercury(II) 1000 µg in 50 ml of 0.02*M* HNO_3; shaken for 6 hr at 30°C.

Desorption conditions (column operation): ATPS resin (1000 µg Hg sorbed) 0.5 g; column 10 × 13 mm; elution rate 1 ml/min; 20 ml of eluent.

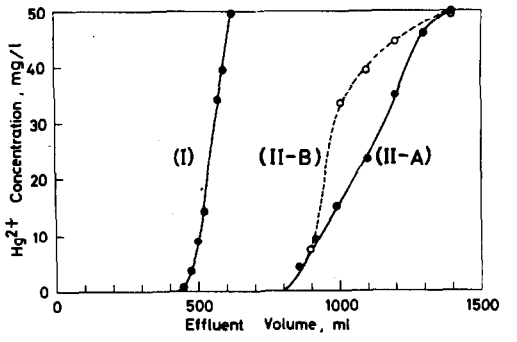

Fig. 7. Break-through curves for mercury(II). Column 1.0 × 100 mm. ATPS loading on the resin (mmole/g) (I) ●——● 0.1; (II-A) ●——● 0.2; (II-B) O---O 0.2 (resin regenerated with 10% thiourea in 0.1M $HClO_4$). Flow-rate (ml/min) (I), (II-A) 1.5; (II-B) 1.0. Concentration of mercury(II) in the sample solution: 50 mg/l in 0.1*M* nitric acid.

The removal of mercury(II) ion from 0.1*M* nitric acid medium was investigated by the column method. The break-through curve for mercury(II) is shown in Fig. 7. The concentration of mercury(II) in the effluent from column I was below 0.5 μg/l up to the break-through point. No mercury(II) was detected in the effluent from column(II), although the break-through curves varied slightly with flow-rate. At a flow-rate of 1–2 ml/min, the sorption of mercury(II) from 0.1*M* nitric acid was efficient.

In Japan, the concentration of mercury(II) in waste-water is severely controlled by law to be less than 5 μg/l. The results presented here indicate the practical applicability of ATPS resin for the final stage of waste-water treatment, after the general procedure for removal of metal ions. The volume of solution that can be treated with an ATPS resin column is doubled if the amount of ATPS loaded is doubled, in agreement with the batch operation results (Fig. 3). As shown in Fig. 7, ATPS resin regenerated with 10% thiourea solution in 0.1*M* perchloric acid can still reduce the mercury(II) concentration to below 5 μg/l although the capacity decreases slightly with repeated use.

A distinct colour change, from red to yellow, was observed on sorption of mercury(II), unlike the case for other thiol-containing chelating resins. The colour change corresponds to the spectral change of ATPS solution in chelate-formation with mercury(II), the bands at 398 and 465 nm shifting to 338 nm and 425 nm.[4]

ATPS resin was found to be stable and to hold its sorption ability for mercury(II) for at least 6 months when stored in a refrigerator. The ATPS on the resin is as stable towards air oxidation as ATPS in solution.

In conclusion, ATPS resin is regarded as a valuable sorbent for the treatment of waste-water containing mercury(II) and to have advantageous features for the preconcentration of some metal ions in trace analysis.

EXTRACTION OF PALLADIUM THIOCYANATE WITH POLYURETHANE FOAM

SARGON J. AL-BAZI and ARTHUR CHOW
Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

(*Received* 3 *August* 1981. *Accepted* 9 *November* 1981)

Summary—Conditions for the extraction of the thiocyanate complex of palladium by polyether-type polyurethane foam are reported. Distribution ratios of more than 10^6 with a capacity of about 0.8 mole per kg of foam were obtained. The palladium could be rapidly recovered from the foam with high efficiency by use of ammonia solution. The efficiency of palladium extraction depends on how well the cation associated with the complex fits into the polyether segment of the polyurethane foam.

The use of polyurethane foam in the separation of metals from aqueous solutions was first demonstrated by Bowen.[1] The high distribution coefficients obtained[2] and the ease of handling of the system have aroused considerable interest in using polyurethane foam for the extraction and separation of inorganic and organic species from aqueous solutions.[3–5]

The use of thiocyanate as a complexing reagent has served as a basis for the liquid-liquid extraction of a number of metals,[6] and of palladium into ethyl acetate.[7]

Recently, some attention has been devoted to the extraction of metal thiocyanate complexes onto unloaded and loaded polyurethane foam. The extraction of cobalt,[8] and of cobalt, iron, zinc and cadmium,[9] as well as the preconcentration and separation of rhodium and iridium thiocyanates[10] from aqueous solutions with polyurethane foam has been reported.

Chow and co-workers recently studied the mechanism of the extraction of alkali metals as picrates[11] and cobalt as thiocyanate[8] by polyurethane foam and concluded that the foam acts as a long acyclic polyether chain. Thus the extraction of the anion is a consequence of the complexation of a cation in the cavity of the chain, and the efficiency of extraction depends on how well the cation fits.

The purpose of the present work was to study the mechanism of extraction of palladium as a thiocyanate complex from aqueous solutions, with polyether-type polyurethane foam, and to find the optimum conditions for use of this method for preconcentration of palladium.

EXPERIMENTAL

Apparatus

A model 306 Perkin–Elmer atomic-absorption spectrometer was used for palladium determination, a Fisher Accumet model 520 for pH measurements and a Varian 634 UV-visible spectrometer for absorbance measurements.

Reagents

A stock 1000 μg/ml palladium concentration solution was prepared from palladium chloride in 0.1*M* hydrochloric acid. All other chemicals used were of analytical reagent grade. The water was doubly distilled and demineralized. Commercial polyether-type polyurethane foam sheets were obtained locally and cut into small cubes of approximately 1.0 g each. These foam cubes were soaked in 1*M* hydrochloric acid for 24 hr with occasional squeezing, washed several times with distilled water until acid-free, extracted with acetone in a Soxhlet apparatus for 12 hr and finally air-dried.

Procedure

An aliquot of the stock solution of palladium chloride was put into a 100-ml standard flask with the desired amount of thiocyanate and hydrochloric acid and made up to volume with distilled water. The acid was added after dilution of the thiocyanate solution, to minimize the decomposition of thiocyanate caused by direct contact with concentrated acid.[12]

The extraction was done by placing 95 ml of the sample solution (palladium 13.3 μg/ml) in a 250-ml glass cell containing about 0.05 g of foam. The foam was squeezed by means of a glass plunger in order to bring fresh solution into contact with the foam. The plunger was operated with a multiple automatic apparatus[8] consisting of an eccentric cam turned by a heavy-duty motor to give a 5-cm stroke at a rate of 24/min. The extraction was done at 25.0 ± 0.05°.

The percentage extraction of the metal (E) was calculated by measuring the concentration before and after extraction.

$$E = \frac{(\text{metal})_{\text{initial}} - (\text{metal})_{\text{final}}}{(\text{metal})_{\text{initial}}} \times 100$$

The distribution coefficient (D) for the extraction process was calculated from the ratio of the concentration of the metal in the foam to the concentration of the metal left in solution at equilibrium.

$$D = \frac{\%\ \text{metal on foam}}{\text{wt. of foam (g)}} \times \frac{\text{vol. of solution (ml)}}{\%\ \text{metal left in solution}}$$

RESULTS AND DISCUSSION

The rate of extraction of palladium thiocyanate was studied by varying the time of contact between the foam and 13.3-μg/ml palladium solution from 5 min

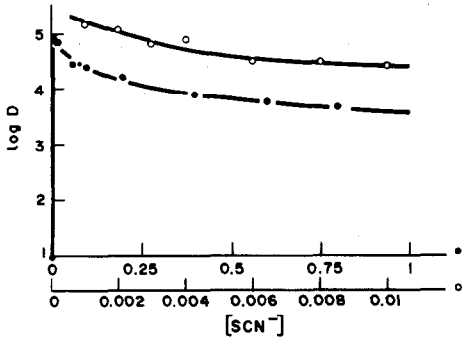

Fig. 1. Effect of thiocyanate concentration on the extraction of palladium: initial palladium concentration 13.3 μg/ml; hydrochloric acid concentration 0.8*M*; volume of solution 145 ml; weight of foam 0.05 g; time for extraction 24 hr.

to 27 hr, with thiocyanate and hydrochloric acid concentrations of 0.5 and 0.4*M*, respectively. The percentage of palladium extracted increased sharply with extraction time up to 15 min, and then more slowly up to 1 hr, after which it remained almost constant; hence a minimum of 1 hr extraction was used in further studies.

The effect of thiocyanate on the extraction of palladium is shown in Fig. 1. The results indicate a very rapid increase in extraction from 0.3% at zero thiocyanate concentration to a maximum at 0.001*M* thiocyanate, with which 98% of the palladium was extracted. Higher concentrations of thiocyanate decreased the extraction somewhat, which may be attributed to the increased influence of thiocyanic acid and 5-amino-1,2,4-dithiazole-3-thione (which forms as a result of thiocyanic acid trimerization[13]) on the extractibility of palladium thiocyanate.

The ultraviolet-region spectra of the solutions before extraction showed an absorption band at 308 nm, which is consistent with $Pd(SCN)_4^{2-}$.[14] Further, with thiocyanate concentrations above 0.1*M*, the appearance of a band at 292 nm indicated the formation of 5-amino-1,2,4-dithiazole-3-thione, the concentration of which paralleled the thiocyanate concentration.

The effect of the thiocyanate on the extraction of palladium was also studied in the presence of 2*M* potassium chloride. The results (Table 1) indicate that the extraction of palladium thiocyanate increased sharply with thiocyanate concentration up to 0.002*M*, and decreased slightly at $[SCN^-] > 0.06M$. The decrease in the extraction of palladium thiocyanate may be attributed to competitive extraction of potassium thiocyanate, which may be expected to be somewhat extractable. As in the previous experiments, the spectra of the solutions before extraction indicated the formation of $Pd(SCN)_4^{2-}$ in amounts increasing with thiocyanate concentration up to 0.06*M*, beyond which the extent of formation became constant. However, these spectra also showed that 5-amino-1,2,4-dithiazole-3-thione was not formed under these conditions, thus accounting for some of the increased palladium extraction at high thiocyanate concentrations.

* Initial palladium concentration 13.3 μg/ml; pH = 2.7; potassium chloride concentration 2*M*; volume of solution 95 ml; weight of foam 0.05 g; time for extraction 20 hr.
† Not determinable.

The effect of hydrochloric acid on the extraction of palladium from 0.006*M* thiocyanate medium was studied. As the hydrochloric acid concentration of the solutions was varied from 2×10^{-3} to 1.0*M*, the palladium extraction increased from 57% (log *D* = 3.59) at 0.002*M* acid to 84% (log *D* = 4.19) at 0.08*M* acid, beyond which it increased slowly to 96% (log *D* = 4.83). The spectra of these solutions before extraction showed that the amount of $Pd(SCN)_4^{2-}$ formed is not altered by the acid concentration, so the influence of the hydrochloric acid must be on the distribution of the palladium complex between foam and solution.

The effect of pH of the aqueous phase on the extraction efficiency of polyurethane foam for palladium thiocyanate in the presence and absence of 2*M* potassium chloride was studied. The pH was varied from 2.15 to 10.69 by addition of lithium hydroxide or hydrochloric acid. The results given in Fig. 2 show that in the absence of potassium chloride the extrac-

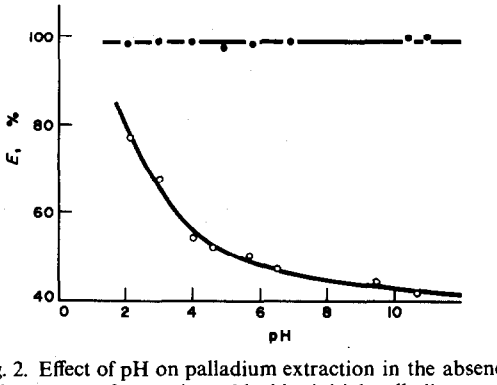

Fig. 2. Effect of pH on palladium extraction in the absence and presence of potassium chloride: initial palladium concentration 13.3 μg/ml; thiocyanate concentration 0.006*M*; volume of solution 95 ml; weight of foam 0.05 g; time for extraction 20 hr; (○) in the absence of potassium chloride; (●) in the presence of 2*M* potassium chloride.

tion of palladium decreases considerably as the pH is raised. The spectra of these solutions before extraction indicated that the $Pd(SCN)_4^{2-}$ absorption peaks were not changed in either intensity or shape by change in pH. Therefore, the decrease in extraction of palladium with increasing pH must be attributed not to the formation of palladium hydroxide but rather to change in the distribution of palladium thiocyanate between the foam and the solution.

The extraction of palladium thiocyanate from solutions containing 2*M* potassium chloride was found to be very high and independent of the pH (Fig. 2). The spectra of these solutions before extraction indicated that the concentration of $Pd(SCN)_4^{2-}$ formed is almost independent of pH and is identical to that observed in the absence of potassium chloride. Thus the presence of potassium chloride must have some effect on the distribution of palladium thiocyanate between the foam and the solution and not on formation of the complex. The presence of potassium chloride broadens the range of pH over which extraction of palladium thiocyanate is quantitative.

Under the optimum conditions for the extraction of palladium thiocyanate from solutions containing only hydrochloric acid and from those containing potassium chloride at high pH, the capacity of polyether-type polyurethane foam was studied for palladium concentrations from 10 to 300 μg/ml. The hydrochloric acid and potassium chloride concentrations were kept constant at 0.5*M*. The pH of the potassium chloride media was fixed at about 6 by addition of lithium hydroxide or hydrochloric acid. The thiocyanate concentration was varied from 6.4×10^{-3} to $5.6 \times 10^{-2}M$, according to the palladium concentration. This was done to minimize interference by potassium thiocyanate or thiocyanic acid, in order to obtain clearer information on the mechanism by which palladium thiocyanate is extracted. The spectra of the solutions indicated that the amount of $Pd(SCN)_4^{2-}$ formed was the same for both sets of experiments. The foam capacity for extraction of palladium was also about the same, about 0.8 mole/kg. Thus the polyether-type polyurethane foam is highly efficient for the preconcentration of palladium from either medium, and since the foam capacity is almost the same the extraction mechanism of the palladium thiocyanate may be the same.

The effect of ammonia on the extraction of palladium from 0.5*M* potassium chloride/0.006*M* thiocyanate medium was also studied. The pH was adjusted to about 6 with potassium hydroxide or hydrochloric acid. Ammonia solution was then added to give a total concentration of 0.01–0.1*M*, which produced a final pH of 10.54–11.14. The extraction of palladium was very low under these conditions, varying from 0 to 3%. The extraction of palladium from in 0.5*M* ammonium chloride/0.006*M* thiocyanate media was studied, the pH before extraction being varied from 4.01 to 8.27 by the addition of ammonia solution or hydrochloric acid. The extraction of palladium

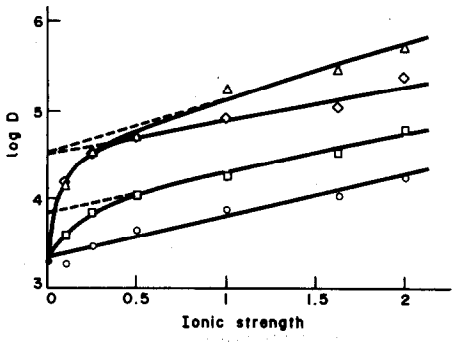

Fig. 3. Effect of ionic strength on the extraction of palladium; initial palladium concentration 13.3 μg/ml; thiocyanate concentration 0.006*M*; (●) H_2O, (○) Li^+, (□) Na^+, (◇) K^+, (△) NH_4^+; pH ~ 6, except for NH_4^+, where pH was ~4; volume of solution 95 ml; weight of foam 0.05 g; time for extraction 20 hr.

dropped from 96% at pH 4.01 to 75% at 6.25 and to zero at 7.41. The spectra before extraction for solutions containing ammonium chloride indicated that the absorbance peak at 308 nm for $Pd(SCN)_4^{2-}$ decreased with increasing pH and reached zero at pH 7.41. The same results were obtained for the 0.5*M* potassium chloride solutions, for which the absorbance at 308 nm was zero even at 0.01*M* ammonia concentration. The decrease in the extraction of palladium may thus be due to the formation of $Pd(NH_3)_4^{2+}$, which is not extractable. Therefore, the addition of ammonia solution or the adjustment of pH may be used for recovery of palladium from the foam. Qualitative studies indicate that palladium can be recovered from the foam with high efficiency.

The ionic-strength effect of various chlorides on the extraction of palladium thiocyanate by polyurethane foam was studied with lithium, sodium, potassium and ammonium chlorides. The pH of the solutions before extraction was adjusted to about 6 with lithium hydroxide or hydrochloric acid except for those containing ammonium chloride, where the pH was adjusted to around 4 to prevent the formation of $Pd(NH_3)_4^{2+}$. The results shown in Fig. 3 indicate that the effect of added salt concentration on the extraction of palladium thiocyanate was virtually independent of the nature of the salt at concentrations above about 0.5*M* (indicating a salting-out effect in this concentration range), but gave very different behaviour at lower concentrations, where the cation chelation mechanism[11] clearly predominates when potassium or ammonium salts are added. The spectra of these solutions indicated that the absorbance of the $Pd(SCN)_4^{2-}$ was the same for all the solutions before extraction, so the differences in the salt effects on the extraction are due to differences in the distribution of palladium thiocyanate between the foam and the solution rather than in formation of the complex. Furthermore, Fig. 3 shows that the extraction efficiency increases in the following order of the cations added: $Li^+ < Na^+ < K^+ \leqslant NH_4^+$. The ion-dipole interaction of ammonium ions with the oxygen sites of

† pH ~ 4.0.

polyurethane foam may be considered as contributing to the extraction of $Pd(SCN)_4^{2-}$ being higher in the presence of ammonium chloride than of potassium chloride at concentrations above about 0.5*M*. The linear portions of the curves in Fig. 3 were extrapolated to zero concentration of the salt, and the intercept for lithium chloride was the only one which coincided with the value obtained for the extraction of $Pd(SCN)_4^{2-}$ from a 0.006*M* thiocyanate solution at pH 6 with no added salt. Table 2 shows a direct relationship between the ionic diameter of the cation and the extraction of $Pd(SCN)_4^{2-}$ relative to that with no added salt.

The effect of the different cations on the extraction of $Pd(SCN)_4^{2-}$ as shown in Fig. 4 is $Li^+ < Na^+ < K^+ \leqslant NH_4^+ > Rb^+ > Cs^+$, the ions being arranged in order of increasing diameter. This indicates that the efficiency of polyether-type polyurethane foam for the extraction of palladium thiocyanate, as a function of ionic diameter of the cation, passes through a maximum. This suggests that there are factors involved, besides the ability of the cation to form ion-pairs with $Pd(SCN)_4^{2-}$, which cause the extraction to decrease with increasing cation diameter. If it is assumed that polyether-type polyurethane foam acts as long acyclic polyethylene chains[8] and that the extraction of the anion is through a cation chelation mechanism,[11] the extraction of $Pd(SCN)_4^{2-}$ would be expected to increase with increasing ionic diameter for Li^+, Na^+, K^+ and NH_4^+ and to decrease for Rb^+ and Cs^+.

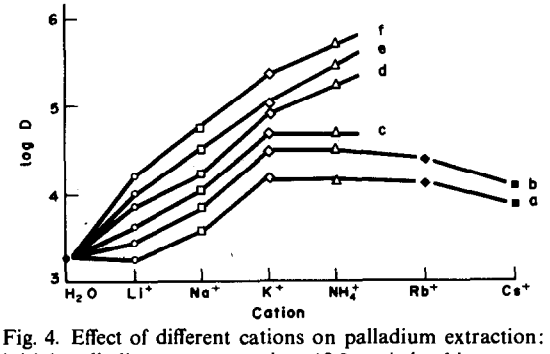

Fig. 4. Effect of different cations on palladium extraction: initial palladium concentration 13.3 μg/ml; thiocyanate concentration 0.006*M*; salt concentration: a 0.1*M*, b 0.25*M*, c 0.5*M*, d 1.0*M*, e 1.5*M*, f 2*M*; (●) H_3O^+, (○) Li^+, (□) Na^+, (◇) K^+, (△) NH_4^+, (◆) Rb, (■) Cs; pH ~ 6, except for NH_4^+ where pH was ~4; volume of solution 95 ml; weight of foam 0.05 g; time for extraction 20 hr.

Since H_3O^+ has an ionic diameter close to that of K^+ and NH_4^+, in other words, close to the cavity size of the foam, $Pd(SCN)_4^{2-}$ is highly extractable from acidic aqueous solutions. This also explains why the foam capacity for the extraction of palladium thiocyanate was almost the same whether 0.5*M* hydrochloric acid or potassium chloride was used, and also why the extraction of palladium thiocyanate decreases with increasing pH of the acid medium, whereas it is independent of pH in the presence of potassium chloride. It was also noted that the rate of extraction of $Pd(SCN)_4^{2-}$ is higher from hydrochloric acid than from potassium chloride medium. This can be explained by the fact that H_3O^+ is held in the cavity through ion–dipole interaction as well as hydrogen-bonding, whereas K^+ is held only by ion–dipole interaction.

Conclusions

Polyether-type polyurethane foam is highly efficient for the preconcentration of palladium from thiocyanate solutions containing only hydrochloric acid, and from those containing potassium chloride at high pH. The extraction is explicable in terms of the cation chelation mechanism.

BENZYL 2-PYRIDYL KETONE 2-PYRIDYLHYDRAZONE AS REAGENT FOR THE FLUORIMETRIC DETERMINATION OF ZINC AT ng/ml LEVELS

F. GARCIA-SANCHEZ, A. NAVAS and J. J. LASERNA
Department of Analytical Chemistry, Faculty of Sciences, University of Malaga, Spain

(*Received* 17 *March* 1981. *Revised* 14 *September* 1981. *Accepted* 8 *October* 1981)

Summary—A sensitive fluorimetric method for the determination of zinc, based on the formation of a fluorescent chelate with benzyl 2-pyridyl ketone 2-pyridylhydrazone is described. In darkness, the fluorescence develops rapidly and remains stable for 1 hr. The detection limit is 15 ng/ml. The effect of reaction variables, and methods of removing interferences, are discussed.

Heterocyclic hydrazones with the reaction group —N=C—NH—N=C—C=N— generally interact in alkaline medium with hexaco-ordinate bivalent metal ions to form neutral 2:1 ligand:metal chelates, the secondary-amine hydrogen atom in this grouping often being important in determining the structure and behaviour of the complexes.[1,2] The determination of metal ions with such reagents is often improved by employing an extraction procedure, or an aqueous ethanol medium to keep the chelate in solution.

Benzyl 2-pyridyl ketone 2-pyridylhydrazone (BPKPH) has been reported[3] as a highly sensitive and relatively interference-free reagent for the fluorimetric determination of gallium. The fluorescence system formed by zinc(II) and this ligand is reported here. A few elements interfere but this can be prevented by appropriate conditioning of the solution. The method is suitable for determination of zinc in the presence of cadmium, gallium and indium, metals that are often produced from the same mineral source.

EXPERIMENTAL

Reagents

BPKPH, $5 \times 10^{-4}M$ solution. Prepared daily, in absolute ethanol.

Zinc solution. A 0.1*M* stock solution prepared from $ZnSO_4.7H_2O$ in 0.5*M* sulphuric acid and standardized by EDTA titration. Solutions of lower concentration were made by dilution with demineralized water.

Sodium hydroxide, 0.15M solution. Freshly prepared.

Apparatus

A Perkin–Elmer spectrofluorimeter, model MPF-43A, equipped with an Osram XBO 150-W xenon lamp, excitation and emission grating monochromators, 1 × 1-cm quartz cells, R-508 photomultiplier and a Perkin–Elmer 023 recorder. A set of fluorescence polymer samples (Perkin–Elmer) was used to adjust (daily) the spectrofluorimeter to compensate for changes in source intensity.

Procedure

Place 1 ml of 0.15*M* sodium hydroxide and 1 ml of $5 \times 10^{-4}M$ BPKPH in a 50-ml standard flask. Add an aliquot of the sample solution (pH > 3) containing 0.75–3.25 μg of zinc and dilute to volume with demineralized water. Store in the dark until measurement of the fluorescence intensity at 550 nm with excitation at 469 nm; apply a correction for a reagent blank.

RESULTS

Fluorescence spectra

Figure 1 shows the fluorescence excitation and emission spectra of the reagent and its complex with zinc at pH 11.3. Band maxima are found at 469 and 550 nm for excitation and emission, respectively. As shown, a remarkable increase in fluorescence intensity is caused by the chelation.

Effect of reaction variables

For 2% ethanol solutions, it was found that the chelate formation was complete at pH 11 and that the fluorescence intensity remained constant at pH up to at least 13 (Fig. 2). The pH can be adjusted to the desired range by addition of 1 ml of 0.15*M* sodium hydroxide. This is advantageous because potential interference of buffer ions is avoided.

The effect of solvent composition is shown in Fig. 3. The fluorescence intensity is maximal in 2% ethanol medium, but light seriously affects the time necessary for full fluorescence development. This problem is overcome by storing the solutions in darkness until they are measured, and by employing a very narrow excitation slit (3 nm for the recommended procedure). Under these conditions the fluorescence remains stable for 60 min, then slowly diminishes (Fig. 4). There is no temperature effect over the range 5–50.

The maximum fluorescence intensity is attained when the BPKPH concentration in the solution is $1 \times 10^{-5}M$, above which it decreases gradually. Hence 1 ml of $5 \times 10^{-4}M$ BPKPH is used in a final volume of 50 ml.

Using the optimum experimental conditions, it was established that the order of reagent addition is im-

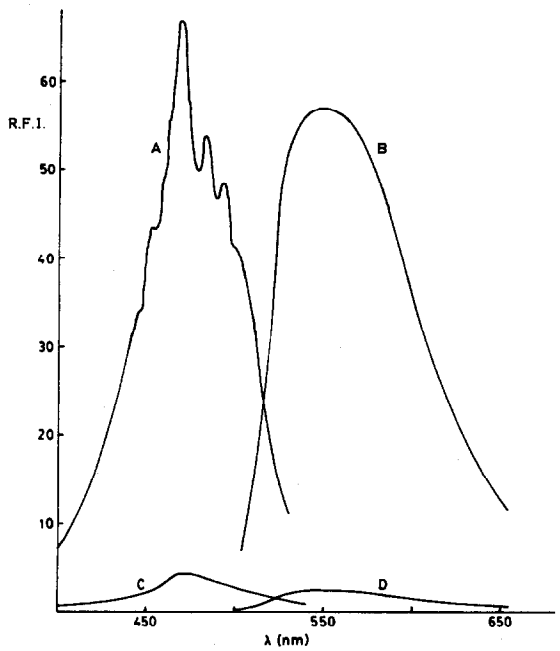

Fig. 1. Uncorrected (A, C) excitation and (B, D) emission spectra of (A, B) complex and (C, D) free ligand, at pH 11.3. [Zn] = $5 \times 10^{-6}M$, [BPKPH] = $1 \times 10^{-5}M$.

portant. The fluorescence intensity is maximal when the complex is formed in alkaline medium. Optimum results are obtained when sodium hydroxide, BPKPH, zinc and water are mixed in that order.

Calibration

The calibration graph obtained by the recommended method is linear up to 65 ng/ml, with a practical limit of detection of 15 ng/ml (defined as the zinc concentration yielding a signal-to-noise ratio of 2:1). For a series of 11 measurements on a 39-ng/ml zinc solution, a relative error of 2.4% and a relative standard deviation of 3.6% were obtained.

Interference studies

The effect of various ions on the determination of

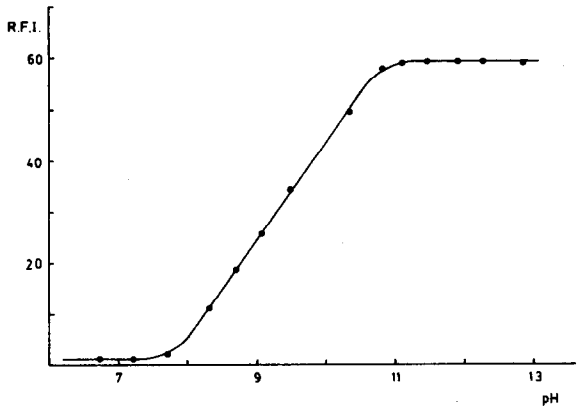

Fig. 2. Effect of pH on the formation of the zinc–BPKPH chelate. [Zn] = $1 \times 10^{-5}M$, [BPKPH] = $1 \times 10^{-5}M$.

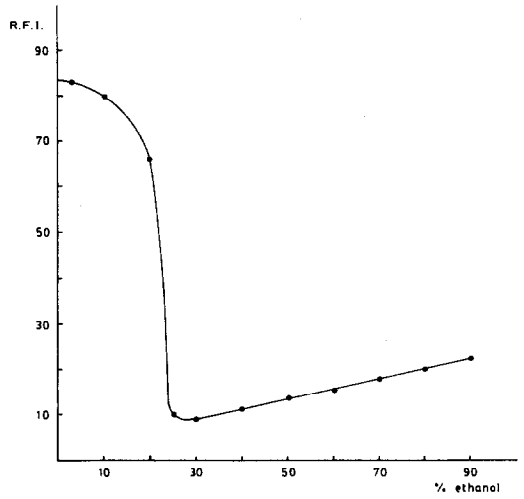

Fig. 3. Influence of solvent composition on the fluorescence intensity of the BPKPH–Zn chelate. [Zn] = $5 \times 10^{-6}M$, [BPKPH] = $1 \times 10^{-5}M$.

zinc at the 39-ng/ml level was investigated by first testing a 100-fold w/w ratio of interferent to zinc, and (if interference occurred) reducing the ratio progressively until interference ceased. Higher ratios were not tested, and the non-interference of fluoride in the aluminium bronze analysis implies that the tolerance level for fluoride is well above the 100-fold w/w level. The interference levels found were 4 ppm for Be^{2+} and F^-, 2 ppm for Tl^+, 1 ppm for PO_4^{3-}, 0.4 ppm for BrO_3^-, 0.2 ppm for Mn^{2+}, Fe^{2+}, Ni^{2+}, Cu^{2+}, Ga^{3+}, Tl^{3+}, Cr^{3+}, Ti^{4+}, CN^- and $C_2O_4^{2-}$, 0.08 ppm for Ca^{2+}, Al^{3+}, In^{3+}, Sc^{3+}, As(V) and V(V), and 0.04 ppm of Mg^{2+}. However, Co^{2+}, Fe^{3+} and EDTA are tolerated only at the 0.02 ppm level, and Cd^{2+} (positive interference) at 0.01 ppm. Figure 5 shows the effects produced by some of these ions.

The interference of cadmium (up to 40 ng/ml) can be eliminated by masking with a fourfold molar ratio of cyanide (2 ml of 5-μg/ml potassium cyanide solution). Cobalt up to 40 ng/ml can be masked by addition of 1 ml of 0.1*M* ammonia solution, followed by 1 ml of 0.2*N* hydrogen peroxide. Iron(III) up to 200 ng/ml can be masked with 0.5 ml of 0.01*M* fluoride. The results of analysis of several synthetic samples and an aluminium bronze are presented in Table 2. The aluminium bronze was dissolved in hot nitric acid, the solution was evaporated to dryness and the residue taken up in demineralized water; this solution was made alkaline with 2*M* sodium hydroxide to precipitate interfering elements. The precipitate was filtered off and washed and the filtrate was made up to standard volume. Then an aliquot was treated with 2 ml of 0.1*M* sodium fluoride and analysed spectrofluorimetrically.

Stoichiometry

The ratio of zinc to BPKPH in the complex was established as 1:2 by both the molar-ratio and conti-

Table 2. Determination of zinc in different samples

Sample	Zn taken, *ng/ml*	Zn found, *ng/ml*
Zn + Fe(III) (200 ng/ml)[a]	39.0	41.4
Zn + Fe(III) (80 ng/ml)[a]	39.0	39.5
Zn + Co (II) (40 ng/ml)[b]	39.0	39.0
Zn + Cd (II) (40 ng/ml)[c]	39.0	39.5
Zn + Fe(III) (200 ng/ml)[a] + Co(II) (40 ng/ml)[b] + Cd(II) (40 ng/ml)[c]	39.0	40.2
Aluminium bronze[d]	40.0	39.0(= 0.92%)[e]
	60.0	58.2(= 0.91%)[e]

[a] In presence of 0.5 ml of $10^{-2}M$ fluoride solution.
[b] In presence of 1 ml of 0.1M ammonia solution and 1 ml of 0.2N hydrogen peroxide.
[c] In presence of 2 ml of 2.5-μg/ml potassium cyanide solution.
[d] Nominal composition: 0.94% Zn; 85.90% Cu; 2.67% Fe; 0.27% Mn; 1.16% Ni; 8.80% Al.
[e] Average of three determinations.

nuous-variation methods. The complex is readily extractable into solvents such as carbon tetrachloride, cyclohexane, n-hexane and benzene.

DISCUSSION

It has been stated that ferroin-type compounds with the —N=C—NH—N=C—C=N— grouping act as terdentate planar chelating agents. This is in accord with our results and some other conclusions can also be drawn.

The well-structured excitation spectrum is indicative of a planar structure for the ground state of the fluorophore, but a partial loss in planarity presumably accompanies the excitation process as indicated by the lack of resolution in the emission spectrum.[4] This occurs for both 2 and 80% ethanolic medium although there are marked differences in the spectral parameters for solutions of the complex in the two media, except for the molar absorptivity (Table 1). The similarity in the latter parameter is further evidence of planarity of the complex in both solvents, with no effect from changes in polarity or hydrogen-bonding ability of the medium. There is, however, one site in the molecule that plays an important role in the chelating behaviour of these compounds, namely the secondary-amine nitrogen atom. It is well known[5-9] that in alkaline medium these ligands act in the anionic form as one or other of the resonance structures after loss of the imine hydrogen atom, this being favoured by the chelation process.[10] On the basis of aromaticity energy arguments, however, neither of the chelates derived from structures **I** and **II** is preferred. In these circumstances,[2] the fluorescence intensity will be lower than that for chelates in which the —N=C— form is energetically favoured. That is the case for these chelates in 80% ethanol medium at pH 8.0.[11] On this basis, the abrupt increase in fluorescence intensity when the ethanol content is decreased (Fig. 3) suggests that the —N=C— form is then energetically favoured. Some evidence of this is found in the low-lying excited state of the complex in aqueous medium (Table 1). If for this type of ligand a charge-transfer process promotes the *n*-electron pair from the imine nitrogen atom towards the heterocyclic nitrogen atom upon excitation,[12] (see scheme above), then irrespective of the effect of this on the chelation process, the preferred form will be that for which the solvent most hinders displacement of the *n*-electron pair towards the site of co-ordination. In fact, chelation is more effectively achieved with structure **I** than structure **II** in water, a strong hydrogen-bonding donor solvent, which stabilizes the —N=C— form.

The results of the present investigation show that BPKPH is a suitable reagent for the fluorimetric determination of zinc. According to the structure of the ligand and the co-ordination number index of zinc ion, a neutral complex is formed. This is in agreement with the easy extraction of the chelate by low polarity solvents. Consequently, the low upper limit of the calibration graph is presumably a consequence of the insolubility of the chelate in water.

DETERMINATION OF ARSENIC IN POLLUTED WATERS BY DIFFERENTIAL PULSE ANODIC-STRIPPING VOLTAMMETRY

P. C. LEUNG, K. S. SUBRAMANIAN and J. C. MÉRANGER

Environmental Health Centre, Health Protection Branch, National Health and Welfare, Ottawa, Ontario, Canada

(*Received* 2 *September* 1981. *Revised* 3 *November* 1981. *Accepted* 26 *November* 1981)

Summary—Experimental parameters affecting the analytical response of arsenic in differential pulse anodic-stripping voltammetry (DPASV) have been examined. DPASV offers higher sensitivity than linear-scan anodic-stripping voltammetry for similar analysis times. Both techniques have been applied to the NBS Standard Reference Water (SRM 1643) and some polluted water samples. The results on polluted waters compared favourably with those obtained by graphite-furnace atomic-absorption spectroscopy.

The direct determination of arsenic in natural waters by anodic-stripping voltammetry (ASV) generally suffers from interferences from co-existing species such as copper and iron.[1] These interferences were overcome by Davis *et al.*[2] by use of a reduction–distillation sample treatment coupled with a high-speed ASV method. This approach was adapted recently for a charge-transfer analyser in the linear-scan ASV (LSASV) mode.[3] The advantages of differential pulse ASV (DPASV) over the more conventional LSASV are well recognized,[4–6] although the slow stripping process of DPASV has hindered its wide application in routine analysis. In this study, the various experimental parameters affecting the sensitivity of arsenic determination by DPASV were examined. The DPASV results were compared with those obtained by LSASV with similar analysis times. Both techniques were applied to some natural and synthetic water samples. Some of the results were also compared with those obtained by graphite-furnace atomic-absorption spectroscopy (GFAAS).

EXPERIMENTAL

Reagents

Aqueous As(III) stock solutions, 10 and 0.1 mg/ml, were prepared from "Ultrapure" As_2O_3 (Ventron Alfa). A 1-μg/ml aqueous As(III) working standard solution was prepared fresh daily by dilution of the 0.1-mg/ml stock solution. A certified atomic-absorption arsenic standard (1 mg/ml, Fisher) was used to prepare arsenic standards of lower concentrations used in the GFAAS measurements. A 10% copper(I) chloride solution in concentrated hydrochloric acid was prepared according to Davis *et al.*[2] Nitrogen gas ("Zero Oxygen", max. 0.5 ppm O_2) was supplied by Union Carbide Canada Ltd. Distilled demineralized water was obtained from a Corning AG-11 water purification apparatus. All other reagents used were of analytical reagent grade or better.

Apparatus

All electroanalytical measurements were made with an ESA 3040 charge-transfer analyser (CTA) equipped with a Heath-Schlumberger SR-207 X–Y recorder. The functional features of the CTA have been described in detail elsewhere.[3,7] The electrochemical cell was an ESA 3600-01 with a three-electrode system: a pyrolytic tubular graphite working electrode with a gold film plated on the 2-cm^2 active inner surface; a platinum wire counter-electrode in 0.05*M* hydrazine hydrochloride solution and a silver/silver chloride reference electrode in saturated sodium chloride solution. Both the reference and counter-electrodes were isolated from the sample solution by porous Vycor plugs supplied by ESA. The porosity of the plug is unknown. Effective stirring was accomplished by a top-mounted propeller.

The distillation apparatus used to separate the As(III) from the original sample is a modified version of the one used by Davis *et al.*[2] To minimize contamination and facilitate rapid changing of apparatus between distillations, a Quickfit B-10 ground-glass joint was used instead of the original tight-fitting rubber septum to connect the nitrogen line to the distillation apparatus. To eliminate variations in the flow-rate of the nitrogen carrier-gas, regulator-equipped flowmeters (Brooks Instruments Sho-Rate 150) were used to monitor the gas flow through each set-up throughout the distillation process.

A Perkin–Elmer 603 atomic-absorption spectrophotometer equipped with a Perkin–Elmer HGA-2100 graphite furnace, a deuterium-arc background corrector, and an arsenic electrodeless discharge lamp (EDL) was used for the electrothermal atomic-absorption measurement of arsenic. The nitrogen purge-gas flow was interrupted during atomization.

Procedure

Transfer a portion of the water sample (5 ml for an arsenic level of 1–50 ng/ml) into a 25-ml test-tube placed in a thermostatically controlled metal block. For higher

Table 1. Instrumental parameters for DPASV and LSASV

Instrument parameters	DPASV	LSASV
Scan-rate, *mV/sec*	5	100

resting	30	60
Final potential, *mV*	+300	+550
Total analysis time, *sec*	250	247

arsenic concentrations dilute the sample to an arsenic concentration between 20 and 50 ng/ml. Add 2 ml of a 24:24:1 mixture of nitric, perchloric and sulphuric acids to each sample. Reduce the initial sample volume to less than 1 ml at 100° to avoid losing any liquid through bumping, then continue the evaporation, to near dryness, at 200°.

Separation of the arsenic from the digested sample follows essentially a previously described reduction–distillation procedure[2,3] and is therefore not described here in detail. Using the glass reduction–distillation apparatus discussed earlier, reduce the As(V) in the digested sample with 1% copper(I) chloride solution in concentrated hydrochloric acid and simultaneously distil the $AsCl_3$ liberated, collecting it in 4 ml of distilled-demineralized water in an ASV analysis test-tube. After 16 min of distillation at a nitrogen flow-rate of 140 ml/min, add concentrated hydrochloric acid to give a total volume of 5 ml in the analysis tube. Determine the arsenic levels in the resulting solution, using the instrumental parameters listed in Tables 1 and 2. Record the stripping voltammograms on the X–Y chart recorder and also note the digital read-out of the instrument at the base and at the tip of the peak. Find the peak heights either by direct measurement on the strip chart or by calculation from the recorded digital read-outs. Obtain the concentration of total arsenic in the samples by the method of standard addition.

The atomic-absorption determination uses a direct graphite-furnace method with nickel matrix-modification. Dilute a known volume of the sample with concentrated nitric acid, 10% nickel nitrate solution and distilled-demineralized water so that the final concentrations are 1% acid, 0.05% nickel and ~20 ng/ml arsenic. Inject a 10-μl aliquot of this solution into a pyrolytically coated graphite tube with an Eppendorf pipette fitted with a precleaned[8] polypropylene tip. Initiate the sequential "dry", "char", "atomize" (100°/40 sec–900°/30 sec–2500°/7 sec) programme. Read off the peak absorbance at 193.7 nm after an integration time of 8 sec. Average five replicate measurements for each test solution. Calculate the amount of total arsenic in the sample by interpolation from the linear working curves prepared by using aqueous arsenic standards in 1% nitric acid and 0.05% nickel medium.

RESULTS AND DISCUSSION

Figures 1–5 show the variation of arsenic ASV response as a function of scan-rate, pulse frequency, pulse amplitude, deposition potential and deposition time. Since the scan-rate, pulse frequency and pulse

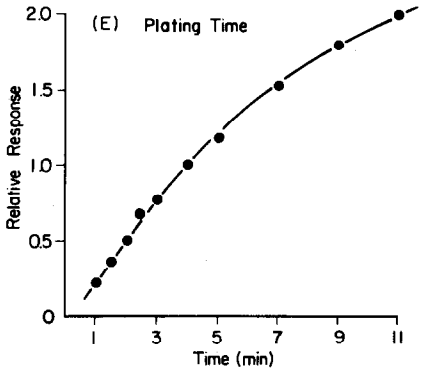

Fig. 5. Effect of plating time on the DPASV response to As(III) (as in Fig. 1).

amplitude were interactive in the ASV response, the optimum value of each parameter was also confirmed by systematically varying the other two. To obtain the highest sensitivity possible for a given analysis time, the optimum for each parameter except deposition time was chosen as the value giving the largest stripping current without peak broadening or sloping of the baseline. Higher sensitivity, if required, could be achieved by increasing the plating time within reasonable limits (Fig. 5).

Davis *et al.*[2] have made a detailed study of the experimental conditions (*e.g.*, distillation time and effect of hydrochloric acid concentration) affecting the analytical signal for arsenic. Our observations are in agreement with theirs.

Table 3 summarizes the detection limit, linear range and precision for arsenic by LSASV, DPASV and the nickel matrix-modification of GFAAS. The detection limit is defined as 3 times the standard deviation of the blank. It is apparent that DPASV gave the lowest detection limit.

Table 3. Analytical performance parameters

Parameter	DPASV	LSASV	Ni-GFAAS
Detection limit*, *ng/ml*	0.15	1.0	1.5
Linear range, *ng/ml*	0–100	0–500	0–60
Precision†, CV, %			
5 × dl	1.5	4.5	17
10 × dl	1.0	2.7	9
50 × dl	1.2	2.9	—

* Detection limit = 3 × standard deviation of blank.
† At 95% confidence interval at 5, 10 and 50 times the detection limit (dl) for arsenic, 20 replicate measurements.

Table 4. Recovery of arsenic by DPASV and LSASV (all concentrations in ng/ml)

Sample	Spiked or certified value	LSASV	DPASV
As standard in demineralized water	3.0	3.2	3.0
	10	9.9	9.6
	20	21.3	19.2
	40	36.7	40.2
NBS Standard Water 1643	77	79	78

The working calibration curves for LSASV and DPASV were obtained under the conditions listed in Tables 1 and 2. For the range 5–500 ng of arsenic, the plot of DPAS peak-heights (Y) *vs.* arsenic concentration (X, ng/ml) can be represented by the equation $Y = 3.77X + 4.2$. The correlation coefficient is 1.000. Similarly the equation for the calibration plot of the linear-scan mode can be represented by $Y = 0.83X + 4.0$ over the arsenic concentration range 2–100 ng/ml with a correlation coefficient of 0.998.

The precision, expressed as the coefficient of variation at the 95% confidence interval, was obtained at five, ten and fifty times the limit of detection for each technique. Twenty measurements were made at each concentration. Considering the levels involved, the precision is quite satisfactory.

To determine the accuracy of the ASV methods, the complete procedure was applied to several synthetic standards and the NBS Reference Material 1643 (Trace Elements in Water). The arsenic recoveries determined by DPASV and LSASV are summarized in Table 4. Very good agreement is found between the results of the two methods and the spiked or certified values.

To confirm the accuracy of the DPASV method and investigate its application to polluted waters, the arsenic contents of some environmental samples were determined by DPASV and also by GFAAS with nickel matrix-modification. The results in Table 5

Table 5. Concentration of total arsenic in some polluted water samples by electrochemical and atomic-absorption techniques (all concentrations in ng/ml)

Sample	LSASV	DPASV	GFAAS (with nickel)
ENL 1		114	115
ENL 2		94	100
ENL 3		558	550
ENL 4		433	440
ENL 5		696	645
RG	227	229	210
LG	8.06×10^3	7.71×10^3	7.50×10^3

show good correlation between the two techniques. Thus no interference was encountered in the samples analysed by DPASV when the proposed method was used in combination with the arsenic separation procedure developed by Davis *et al.*[2]

Acknowledgements—The authors express their sincere gratitude to Eldorado Nuclear Ltd., Ottawa, Canada, for providing some of the polluted water samples, and to the Ontario Ministry of Environment, Canada, for assisting with the collection of the other samples.

DETERMINATION OF INDIUM BY HYDRIDE GENERATION AND ATOMIC-ABSORPTION SPECTROMETRY

I. S. BUSHEINA and J. B. HEADRIDGE
Department of Chemistry, The University, Sheffield, England

(*Received* 14 *October* 1981. *Accepted* 1 *November* 1981)

Summary—Conditions are presented for the determination of indium by atomic-absorption spectrometry following hydride generation. Indium hydride produced by addition of sodium borohydride to a solution of indium in 3*M* hydrochloric acid is flushed with argon into an electrically heated silica tube. The mass of indium giving 1% absorption is 0.3 μg.

Hydride generation coupled with atomic-absorption spectrometry is a most useful technique for the determination of elements in the middle and towards the bottom of Groups IV, V and VI of the Periodic Table, namely germanium, tin, lead, arsenic, antimony, bismuth, selenium and tellurium.[1,2] During an attempt to extend the method to neighbouring elements, it was found that indium can be determined by atomic-absorption spectroscopy after generation of indium hydride from aqueous solution. The appropriate conditions are now presented.

EXPERIMENTAL

Apparatus and reagents

The hydride was generated in a cylindrical tube of 22 mm internal diameter, sealed with a flat bottom and fitted with a detachable top. Its total capacity was 70 ml. It was constructed with a side-arm fitted with a "Suba-seal" through which sodium borohydride solution could be injected. The inlet tube for argon was centrally situated and terminated 10 mm from the bottom of the tube, *i.e.*, just above the surface of the liquid during the generation of hydride. The exit tube for argon was situated at the top of the vessel and contained a plug of glass wool to prevent any spray being carried forward. The vessel is like a Drechsel bottle with a side-arm for injection of solutions. The exit tube was connected to a silica tube (8 mm bore × 17.5 cm long) with a short length of PVC tubing. The silica tube was heated electrically and positioned within a Perkin–Elmer 300S atomic-absorption spectrometer fitted with an indium hollow-cathode lamp. The resonance line at 303.9 nm was employed.

Standard indium solution (*1 mg/ml*). Dissolve 0.1 g of indium metal in about 54 ml of hydrochloric acid (1 + 1) with warming. Dilute the solution to volume in a 100-ml standard flask to produce a solution 3*M* in hydrochloric acid.

Sodium borohydride solution, 2%. Prepared freshly each day. The solution was not stabilized with sodium hydroxide, because the acid concentration is an important factor in the hydride generation.

Preparation of the calibration graph

Into the dry generating vessel through which argon is flowing at 2 l./min, inject 20 μl of standard indium solution, onto the flat bottom. Then inject 2 ml of sodium borohydride solution. Measure the absorbance of the exit argon gas within the silica tube at 1200°. Repeat the measurements for 40, 60, 80 and 100 μl volumes of indium solution. Construct a calibration graph of peak height or peak area *vs.* mass of indium.

RESULTS AND DISCUSSION

Useful indium signals were obtained at silica-tube temperatures above 700°, with an optimum temperature range of 950–1250°. The optimum flow-rate of argon was 2 l./min. The optimum hydrochloric acid concentration of the indium solution for hydride generation was 3*M* for area measurements, but well-shaped peaks were produced within the acid concentration range 2–6*M*.

When larger volumes (0.5–5 ml) of 3*M* hydrochloric acid containing 20–100 μg of indium were injected into the generating vessel, followed by sodium borohydride, much smaller absorbances were obtained and success in obtaining useful absorbances required the injection of volumes of indium solution smaller than or equal to 100 μl.

With peak height measurements the calibration graph for 20–100 μg of indium was slightly convex but that of peak area *vs.* mass was a straight line through the origin. The mass of indium giving 1% absorption was 0.3 μg and for peak area (absorbance × time in seconds) measurements the slope of the calibration graph was 0.033 sec/μg of indium. Compared with atomic-absorption spectrometric methods involving hydride generation for germanium, tin, arsenic, antimony, bismuth, selenium and tellurium,[1,2] the method for indium has poor sensitivity. However, the characteristic mass for indium by hydride generation is not appreciably greater than that for lead.[1,2] It may be possible to improve upon the sensitivity by a detailed study of generating conditions.

Previous information on the existence of indium hydride is scanty and the compound does not appear

to have been well characterized.[3,4] Not all the indium(III) is converted into indium hydride, because, in all cases, a black precipitate (presumably of metallic indium) was also produced on addition of sodium borohydride. The signal was definitely due to atomic absorption and not molecular absorption because no absorbance signal resulted when the indium hollow-cathode lamp was replaced by a hydrogen lamp.

With the reported reciprocal sensitivity of 0.3 μg of indium for 1% absorption, the method involving hydride production has little to commend it in comparison with nebulizing an indium solution into an air–acetylene flame, for which the characteristic concentration is 0.5 μg/ml.[5] Pulse nebulization of 100 μl of indium solution into a flame should produce a greater absorbance than the hydride method with a similar volume of solution[6] but any future improvement in the hydride method will make it more competitive with methods involving nebulization into flames.

(*Received* 17 *July* 1981. *Accepted* 21 *October* 1981)

Summary—A platinum electrode, a Radelkis OP-C-7111D graphite electrode and a laboratory-prepared silicone-rubber-based membrane graphite electrode were used in potentiometric titrations of reducing substances with bromine in acetic acid. In determinations of hydroquinone, 2-methylhydroquinone, 2-chlorohydroquinone and ascorbic acid, the Radelkis electrode showed the greatest sensitivity. The advantage of the laboratory-prepared membrane graphite electrode lay in its rapid attainment of stable potential values. Titrations were improved by addition of potassium acetate to the solutions analysed. The effects of water and acetic anhydride on the results were also investigated.

According to the literature, electrodes prepared from pyrolytic graphite,[1] glassy carbon,[2] carbon fibre,[3] and by Růžička's method[4] are all suitable for end-point detection in potentiometric titrations in aqueous media. Pungor and Szepesváry have prepared silicone-rubber-based graphite electrodes of low porosity, and used them, after pretreatment with suitable oxidizing agents, as indicator electrodes in potentiometric titrations of acids and bases in water and acetone.[6,7] Since various other components can be incorporated in the membrane, making possible the preparation of electrodes having particular properties, a study has been made of the mechanism of their function in acid–base titrations.[8]

The aim of the present work was to investigate use of silicone-rubber-based membrane graphite electrodes for potentiometric titrations of reducing substances with bromine in acetic acid. The bromine reagent is used extensively as a titrant,[9–17] and conditions have been found for anodic generation of bromine in acetic acid with high current-efficiency.[18,19]

EXPERIMENTAL

Apparatus

Potentials were measured with a Radiometer PHM 26 instrument. The electrodes used were:

(1) a platinum electrode, area 6 cm^2;
(2) a Radelkis OP-C-7111D graphite electrode (C_R);
(3) a silicone-rubber-based membrane graphite electrode (C_M) made from a membrane[5] cemented to one end of a glass tube (0.5 cm bore) containing mercury for electrical contact;
(4) a mercury–mercury(I) acetate reference electrode.

Reagents and solutions

All reagents used were of analytical grade. Anhydrous acetic acid was prepared by distillation of Merck glacial acetic acid; the fraction boiling at 117.5–118° was collected. The potassium acetate was dried for 6–8 hr at 120° before use. Other reagents were used without purification. The bromine solution (0.05*M*) was prepared by dissolving 2.60 ml of Merck bromine in 1 litre of acetic acid in a dark bottle, and standardized daily by biamperometric titration[20] of a standard arsenic(III) solution.

Solutions of hydroquinone, 2-methylhydroquinone, 2-chlorohydroquinone (all 0.05*M*) and ascorbic acid (0.005*M*) in glacial acetic acid were prepared from accurately weighed amounts of the substances. Arsenic(III) chloride and antimony(III) chloride solutions in the same solvent were standardized by coulometric titration with anodically generated bromine in aqueous solution.[21,22] More dilute standard solutions were prepared by exact dilution of these solutions.

Procedure

A measured volume of the solution to be titrated was added to 15–20 ml of glacial acetic acid in a 50-ml flat-bottomed vessel and the required amount of 1*M* potassium acetate was added. The solution was stirred with a magnetic stirrer, and standard bromine solution was added from a 10-ml burette made of dark glass, the tip being immersed in the solution during the titration.

RESULTS AND DISCUSSION

All performance characteristics of the electrodes are given in Table 1 and all titration results in Table 2.

The titration of hydroquinone in acetic acid was investigated first. The absence of a pronounced potential jump at the end-point made this determination difficult, but addition of potassium acetate to give a concentration of 0.07*M* made the potential increase at the end-point large enough. A similar effect was observed in titrations of the other reductants, so all further determinations were done in 0.2*M* potassium acetate (in glacial acetic acid).

In titration of the hydroquinones, the potentials stabilized most slowly at the platinum electrode, and fastest at the membrane graphite electrode (almost immediately, except near the end-point, where stabilization took 2–3 min). Table 1 shows that the Radelkis electrode gave the best performance for these titrations.

The rather larger potential changes for the 2-methylhydroquinone system suggested that smaller amounts might be titrated successfully with more dilute titrant, but the curves obtained were too flat, and the results had low accuracy and reproducibility.

The platinum and Radelkis electrodes gave practically the same electrode potential but the membrane graphite electrode gave a much lower potential for the substituted hydroquinones (Fig. 1), and this might be due to a matrix effect or the way in which the graphite was incorporated into the membrane.[6] The hydroquinones were oxidized to the corresponding quin-

Table 2. Results of potentiometric titrations obtained by using a platinum electrode (Pt), a "Radelkis" graphite electrode (C_R), and a silicone-rubber-based membrane graphite electrode (C_M), and a mercury–mercury(I) acetate reference electrode

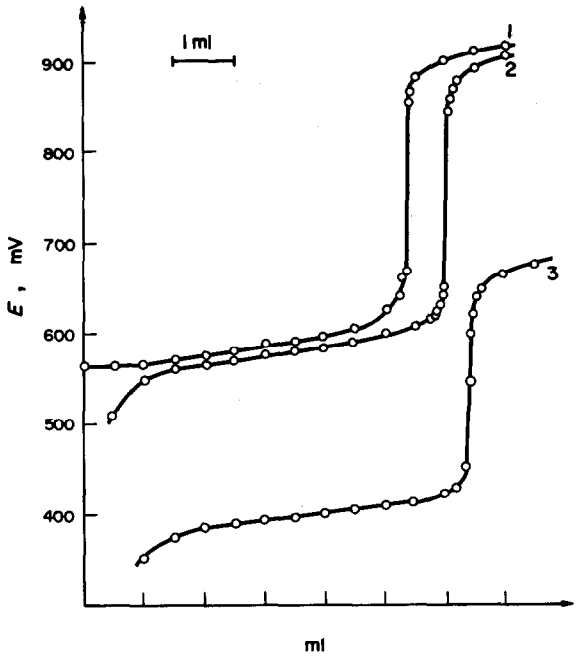

Fig. 1. Potentiometric titrations of 2-chlorohydroquinone with bromine in acetic acid, with (1) a platinum electrode, (2), a Radelkis graphite electrode and (3), a silicone-rubber-based membrane graphite electrode.

ones in a 2-electron reaction, and the titrations were quantitative (Table 2).

In the study of ascorbic acid, the solubility in acetic acid was examined first and found to be 0.005*M* maximum at room temperature. At higher temperatures, the solubility is increased, but the titration results are low by up to 9%. The response times and sensitivities of the three electrodes followed the same pattern as for the hydroquinone titrations (Table 1). The results obtained were about 2.5% low, but reproducible (Table 2).

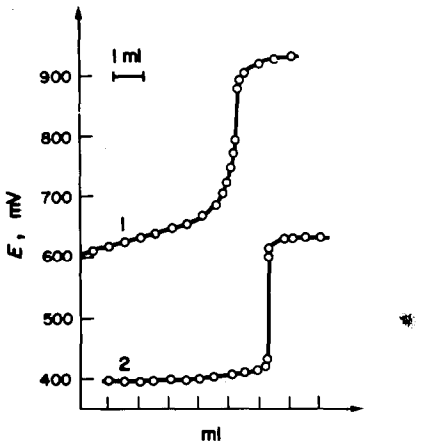

Fig. 2. Potentiometric titrations of antimony(III) with bromine in acetic acid, in the presence of (1) a platinum electrode and (2) a silicone-rubber-based graphite electrode.

The determination of arsenic(III) was also improved by addition of potassium acetate, but with 0.05*M* potassium acetate and $>10^{-3}M$ arsenic(III) a precipitate formed. Potential stabilization was very slow until the precipitate had dissolved (which was just before the end-point). The sensitivity of the electrodes is given in Table 1, and the results were accurate and reproducible (Table 2).

The addition of a small amount of iodine (reported to catalyse this reaction) does not improve the determination; the titration curves are flat, and the results low. Back-titration also gives unsatisfactory results, presumably because of the volatility of bromine, although the potential stabilizes quickly until the end-point is reached, but very slowly after it.

In titration of antimony(III), the total change of potential at the platinum electrode is equal to that obtained with arsenic(III), but the potential jump at the end-point is significantly lower (Table 1). Figure 2 shows that the membrane graphite electrode gives a better end-point than the platinum electrode.

Titration of pyrocatechol, resorcinol, acid hydrazides, mercury(I), thallium(I) and titanium(III) was also attempted but only titration of the acid hydrazides gave distinct end-points.

The presence of up to 30% water has no effect on the determination of arsenic(III) or antimony(III), but 5% of water makes the 2-methylhydroquinone results about 6% too high. The presence of water makes stabilization of the potential faster, but does not affect the total change in potential.

The presence of acetic anhydride makes it impossible to determine substances that react with it. Up to 5% of it in the solution makes the results high by up to about 3% and larger amounts result in disappearance of the potential jump at the end-point.

ALKALIMETRIC DETERMINATION OF AMOXYCILLIN TRIHYDRATE IN NON-AQUEOUS MEDIUM

JYOTI TALEGAONKAR and K. S. BOPARAI
School of Studies in Chemistry, Vikram University, Ujjain, 456 010 India

(*Received* 27 *August* 1981. *Accepted* 24 *November* 1981)

Summary—A simple method for determination of amoxycillin by non-aqueous titration in dimethylformamide medium is described. The relative standard deviation is 0.3%.

Amoxycillin can be determined by fluorimetric assay[1] of the highly fluorescent product formed by the reaction of a blood or urine sample with formaldehyde (but it should be done without delay since the samples are not stable); colorimetry[2] based on the blue colour produced by heating with phosphomolybdic acid; spectrophotometric measurement[3] of the degradation product formed by heating with citric acid–disodium hydrogen phosphate buffer in presence of copper(II); mercurimetric titration[4] of the corresponding penicilloic acid, which is highly dependent on the speed of titration, temperature and the initial sample concentration; and by high-pressure liquid chromatography.[5]

Alkalimetric determination of amoxycillin in aqueous medium gives erratic results, though it has been reported to be successful in 80% aqueous acetone, with potentiometric indication.[6] It has now been observed that its solution in dimethylformamide can be titrated with sodium methoxide, with 2-nitroaniline as indicator; benzene–methanol (4 + 1) is unsuitable as the solvent owing to inadequate solubility of the amoxycillin trihydrate. Thymol Blue gives a diffused end-point. One mole of amoxycillin trihydrate reacts with two moles of methoxide. The procedure is precise and accurate, as is evident from the statistical analysis, and has the advantage of not requiring any sophisticated equipment. It seems to be worthy of recommendation.

Table 1. Determination of amoxycillin trihydrate*

Taken, *mg*	Found, *mg*	Apparent purity, %†
45.6	45.6	100.0
48.8	48.7	99.8
54.0	53.8	99.6
58.2	58.0	99.7
64.2	64.2	100.0
66.2	66.3	100.2
72.0	72.1	100.1
77.6	77.7	100.1
82.4	82.0	99.5
95.6	95.9	100.3

* From Amoxylin capsules, Biddle Sawyer Pvt. Ltd., Bombay; average purity found by potentiometric titration[6] 99.7%; standard deviation, 0.3%.

† Mean 99.9%, standard deviation 0.3%.

Procedure

A weighed quantity of amoxycillin trihydrate is dissolved in 25 ml of dimethylformamide, by warming. 2-Nitroaniline (2 drops, 1% solution in benzene) is introduced followed by titration with *ca.* 0.1*M* sodium methoxide[7] solution in benzene–methanol (4 + 1), standardized against benzoic acid,[8] to a distinct orange–red colour. A blank is run and deducted (typically 0.15 ml).

Applicability

The method is applicable to determination of amoxycillin trihydrate in commercial samples, mostly available in the form of capsules.[9] Typical results are shown in Table 1.

EXTRACTION OF VANADIUM(V) CHELATES WITH *N*-BENZOHYDROXAMIC ACID (BHA) AND AMMONIUM THIOCYANATE AND ITS APPLICATION IN STEEL AND ROCK ANALYSES

S. P. BAG, A. B. CHATTERJEE, A. K. CHAKRABARTI and P. R. CHAKRABORTY

Department of Chemistry, Jadavpur University, Calcutta 700032, India

(*Received* 17 *August* 1979. *Revised* 16 *October* 1981. *Accepted* 24 *November* 1981)

Summary—A mixed-ligand complex of vanadium(V) with *N*-benzohydroxamic acid and thiocyanate formed at various acidities can be extracted into methyl isobutyl ketone, and used for photometric determination of trace amounts of vanadium in materials such as alloy steels and rocks. The absorption maximum of the violet mixed-ligand complex is at 535 nm. The values for the simple complex are 505 nm and molar absorptivity 7.4×10^3 l.mole^{-1}.cm^{-1}.

N-Benzohydroxamic acid (BHA) reacts with vanadium(V) over a wide range of pH, and several authors[1–5] have studied the effect of different media on the reaction. The studies on the complexes in 1:1 water–ethanol and 1-hexanol are open to question as alcoholic solvents have detrimental effects on vanadium colour systems. Here we report on the methyl isobutyl ketone (MIBK) extraction of the BHA–vanadium complexes, including a mixed-ligand thiocyanate complex. These photometric methods developed for determination of traces of vanadium in alloy steels and rocks have advantages over others,[6–11] and are simple, rapid, accurate and reproducible. The composition and the extraction and stability constants of the complexes have been determined by the absorptiometric method.[12–14]

EXPERIMENTAL

Reagents

*BHA solutions (0.036*M *and 0.073*M). The reagent (m.p. 125–128°) was prepared in the usual way; 0.5% and 1.0% reagent solutions in methyl isobutyl ketone were used for the "simple" and "mixed-ligand" extractions, respectively.

Ammonium vanadate solution. Prepared by dissolving ammonium metavanadate in doubly distilled water containing a little ammonia, and standardized by complexometric titration[15] and photometrically with *N*-benzoylphenylhydroxamic acid.[16] The solution was diluted to 100 μg/ml.

*Ammonium thiocyanate solution (0.26*M). Prepared in doubly distilled water and standardized by Volhard's method.[15] A 2% solution was used and diluted as necessary.

Exactly 0.1*M* hydrochloric acid was obtained by diluting stock standard 6*M* acid. A standard buffer of pH 4.0 was prepared from 0.2*M* acetic acid and 0.2*M* sodium acetate. All other chemicals used were of general or analytical reagent grade and the solvents were purified.

Procedure A

To an aliquot of vanadium(V) solution (up to 100 μg/ml) in a 100-ml separatory funnel add 5 ml of 0.5% BHA solution and either 2 ml of the pH-4 buffer or enough 6*M* hydrochloric acid to give a final 1.5*M* concentration, and in either case dilute to 10 ml with water.

Extract the yellow-brown (pH 4) or wine-red (1.5*M* acid) vanadium complex by shaking for 5 min with 10 ml of methyl isobutyl ketone. Separate the organic layer and extract again with 5 ml of solvent. Combine the extracts, transfer to a 25-ml standard flask and make up to volume with the solvent.

Measure the absorbance against a solvent blank at 460 nm (yellow-brown complex) or 505 nm (wine-red complex).

Procedure B

To an aliquot of vanadium(V) solution (up to 100 μg/ml) in a 100-ml separatory funnel add 5 ml of 1% BHA solution and enough 6*M* hydrochloric acid to give an acidity of 1.5*M* after dilution to 10 ml. Shake with 10 ml of methyl isobutyl ketone for 2 min, then add 5 ml of 2% ammonium thiocyanate solution and shake again for 7 min more. Separate the violet extract and transfer it to a 50-ml beaker containing anhydrous sodium sulphate. Repeat the extraction with two 5-ml portions of solvent. Transfer the combined extract to a 25-ml standard flask and make up to the mark. Measure the absorbance against a solvent blank at 535 nm.

Procedure for steel analysis

Dissolve 0.5 g of steel in 20 ml of sulphuric acid (1 + 1) in a beaker on a hot-plate. Add 5 ml of concentrated nitric acid and evaporate to strong fumes of sulphur trioxide. Cool, add 50 ml of water, boil, filter with a Whatman No. 42 paper and wash the residue several times with hot dilute sulphuric acid and finally with hot water. Cool the filtrate and washings, transfer to a 250-ml standard flask, make up to the mark and mix.

To 5 ml of this solution add 0.1% potassium permanganate solution till a pink colour persists. Add this mixture to hot 15% sodium hydroxide solution in excess and boil. Filter off the precipitate and redissolve it in dilute hydrochloric acid. Reprecipitate the hydroxides as above and filter. Combine the filtrates and evaporate to low bulk. Cool, add 15 mg of sodium fluoride, and determine the vanadium content by either procedure *A* (1.5*M* acidity) or *B*. Measure the absorbance at 505 or 535 nm as appropriate.

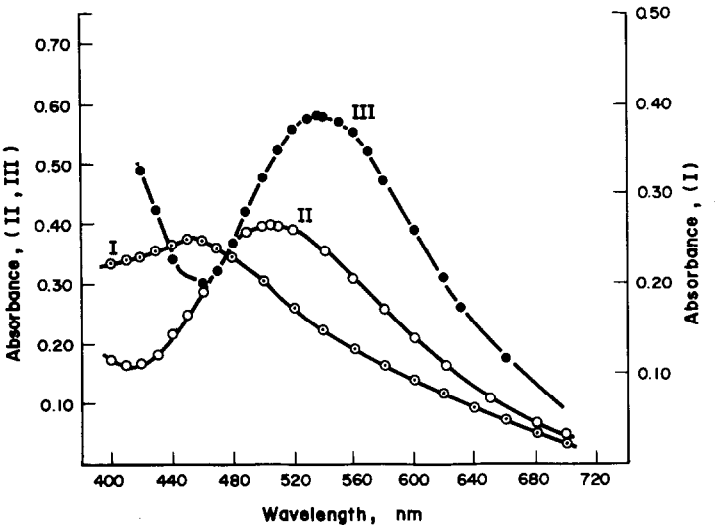

Fig. 1. The absorption spectrum of binary and ternary complex of vanadium(V) in methyl isobutyl ketone. Vanadium(V) 4 μg/ml, reagent (N-BHA) 0.0073*M* (I, II) and 0.0146*M* (III), thiocyanate 0.0866*M* (III), I: ⊙ V(V)–BHA chelate at pH 4.0; II: ○ V(V)–BHA chelate, 1.5*M* HCl; III: ● V(V)–BHA–SCN^- chelate, 1.5*M* HCl.

Procedure for rock analysis

Fuse 0.5 g of finely powdered sample (200-mesh) with 9 g of potassium bisulphate and a few drops of sulphuric acid in a silica crucible to a clear melt. Cool the mass and leach it with sulphuric acid (1 + 9). Boil and oxidize the solution with a few drops of nitric acid and then precipitate iron and titanium as hydroxides with an excess of 15% sodium hydroxide solution. Free any adsorbed vanadium from the hydroxide precipitate by double precipitation. Combine the filtrates and evaporate to about 50 ml. Transfer the solution to a 100-ml standard flask and make up to volume with water.

Take appropriate aliquots of the solution and determine the vanadium content by procedure *A* or *B*, adding 15 mg of fluoride as masking agent for any traces of iron and titanium in the solution.

RESULTS AND DISCUSSION

Absorption spectra

The yellow-brown complex forms quantitatively with vanadium(V) and reagent at pH 2.2–5.6 and has a flat absorbance maximum at 455–465 nm; it is very stable. The reagent also reacts quantitatively with vanadium(V) in 1–3*M* hydrochloric acid to form a wine-red complex [with a chloride ion attached to the sixth co-ordination position of the vanadium(V)] having an absorbance maximum at 505 nm.

The mixed-ligand complex (violet) formed in 0.75–2.1*M* hydrochloric acid (procedure *B*) has an absorbance maximum at 535 nm. A solvent reference solution can be used, as the reagent does not absorb at these wavelengths. The spectra of the complexes are shown in Fig. 1. The absorbance remains constant for at least 24 hr.

Effect of BHA

The absorbances for the yellow-brown and wine-red complexes remain constant when at least 5 ml of 0.5% reagent solution are used. When 5 ml of 2% thiocyanate solution are added, 1.5 ml of 1.0% BHA solution will be sufficient for full colour development. A large excess has no adverse effect if the order of addition is maintained. Hence, 5 ml of 1% BHA solution should be used.

Effect of thiocyanate

One ml of 2% thiocyanate solution is sufficient for complete formation of the mixed-ligand complex. A large excess has no adverse effect, so 5 ml are used.

Optical properties

The several complexes obey Beer's law in the range 1–6 ppm vanadium (in the solution measured) at 460 nm, 0.2–12.5 ppm at 505 nm, and 0.4–12 ppm at 535 nm. The optimum ranges (Ringbom plots)[17] are 1.5–6, 0.4–12.5 and 1–8 ppm, and the molar absorptivities are 0.31×10^4, 0.50×10^4 and 0.74×10^4 $l.mole^{-1}.cm^{-1}$, respectively.

Interferences

Interference studies were made for only the 1.5*M* acid systems, the tolerance limit being the amount causing a deviation of more than 0.005 in the absorbance (Table 1).

Composition, extraction and stability constants

The metal:BHA ratio in the wine-red complex was found to be 1:2 by the continuous variation, mole-ratio and slope-ratio methods. The extraction constant, K_{MR}, was found from a plot of log $A(A_{max} - A)$ *vs.* log $(HR)_0$ to be $10^{6.55}$.

The formation constants were evaluated by two photometric methods[18,19] and though the stepwise

* Fluoride used as masking agent.
N.I. No interference—interference removed by double precipitation.

constants were inconsistent (log $k_1 = 2.02$, log $k_2 = 4.32$ by Leden's method; log $k_1 = 2.84$, log $k_2 = 3.55$ by Yatsimirskii's method), the log β_2 values (6.34 by Leden's method, 6.39 by Yatsimirskii's method, 6.55 by an absorptiometric method, 6.52 by the Harvey and Manning method) agreed quite well.

By the same methods the metal:BHA ratio in the mixed-ligand complex was also found to be 1:2 when excess of thiocyanate was used. The metal:SCN^- ratio was similarly found to be 1:1 for the mixed-ligand complex. Thus, the composition of the mixed-ligand complex is 1:2:1.

Determination of vanadium in steel and rock

The extractive photometric methods were found excellent because of their high selectivity. They are rapid, simple and accurate when fluoride is used to mask more than a 20-fold ratio of the interfering ions [Fe(III) and Ti(IV)] to vanadium. Moreover, the mixed-ligand method has greater selectivity for the analysis of alloy steels and ilmenites. The two ilmenites were collected from Tamil Nadu and IOL, Calcutta, India and finely ground (200-mesh) for analysis directly after separation. The samples were also analysed spectroscopically and found to contain 0.1 and 0.15% vanadium, respectively.

Results of the analyses of a standard steel (BAS 64b) and the two ilmenites by procedures A and B were 1.96 and 1.97% (certified value 1.99%), 0.08 and 0.09% (certified value 0.1%) and 0.14 and 0.14% (certified value 0.15%), respectively.

(*Received* 16 *March* 1981. *Revised* 6 *November* 1981. *Accepted* 19 *November* 1981)

Summary—A method has been developed for the rapid determination of substances by use of solid-phase reagents and a luminescence indicator reaction coupled with photographic detection of the light. The viability of the assay has been demonstrated for glucose estimations. The method uses small sample sizes (5–20 μl) and shows good sensitivity, *e.g.*, detection of glucose down to 28 nmole.

The major advantage offered by photographic film as a detection system in luminescence is that of simplicity, a permanent visual record being obtained without the use of complex ancillary equipment. Obviously this advantage remained relatively unappealing while photographic emulsions required conventional "wet" development, but the advent of the Polaroid "Land" system[1] and related systems of "instant" development, produced an attractive alternative. An arrangement which may make best use of such a detection system is the use of thin layers of dried or otherwise immobilized reagents, aligned so as to produce light following the application of a liquid sample and in close contact with a photographic emulsion for detection purposes.

Analytical systems employing solid-phase reagents either in the form of thin films[2] or impregnated layers[3] have been described by several groups of workers. Two different types of detection system are used to monitor such solid-phase reactions, namely reflectance spectrophotometry and conductance. As yet, the combination of solid-phase reagents with a luminescent indicator reaction and photographic detection has not been described. Luminescent indicator reactions have several advantages over conventional colorimetric or spectrophotometric reactions: they are rapid, and extremely sensitive, and they may be coupled to a wide range of analyses.[4]

The objective of this study was to explore the feasibility of a luminescent analytical system employing solid-phase reagents and photographic detection of light. Initially, a simple chemiluminescent reaction between lucigenin and hydrogen peroxide was used to compare the detection of light by photographic film and by a photomultiplier tube. An assay for glucose based on the chemiluminescent reaction of luminol with enzymatically produced hydrogen peroxide was then chosen as a model, and the reaction sequence is shown below.

$$\text{Glucose} + O_2 \xrightarrow{\text{Glucose oxidase}} \text{Products} + H_2O_2$$

$$H_2O_2 + \text{luminol} \xrightarrow{\text{Peroxidase}} \text{Products} + \text{light}$$

EXPERIMENTAL

Reagents

Luminol (5-amino-2,3-dihydrophthalazine-1,4-dione) and lucigenin (*bis*-*N*-methylacridinium nitrate) were obtained from the Aldrich Chemical Co. The monosodium salt of luminol was prepared by recrystallization from hot 1*M* sodium hydroxide, followed by recrystallization twice from water. Glucose oxidase (Type II; product no. G 6125) and peroxidase (crude; RZ approximately 0.3; product No. P8000) were obtained from the Sigma London Chemical Co. All other reagents were of analytical grade where possible.

Analytical system

Luminescent reactions were carried out in disposable plastic tubes (44 × 11 mm diameter) in a "Tufnol" mask (Fig. 1). The mask together with the tubes was placed in intimate contact with a Polaroid Land film holder No. 44-46 (Polaroid Ltd.) containing either Polaroid Type 47

(ASA 3000) or Type 410 (ASA 10000) black and white print film. Light produced by the reactants passed downwards to the emulsion in close contact with the base of the tubes, producing, in effect, a "contact print". The mask was necessary to prevent a "halo" effect as a result of light escaping from the sides as well as the base of the tubes. No account was taken in these experiments of the relative colour sensitivities of these films.

Calibration procedure

Dilutions (1 in 1000, 2 in 1000, 3 in 1000 and 4 in 1000) of a hydrogen peroxide solution (50% v/v; 1.47*M*) were prepared and 10 μl of each of these dilute solutions were added to the disposable plastic tubes. In addition, tubes were set up with 10 μl of distilled water as blanks and all tubes were placed in the "Tufnol" mask. In a darkened room the shutter covering the film was removed and the "Tufnol" mask containing the tubes was placed in the film holder so that it covered the sensitive area. Still in the dark, a mixture of lucigenin (20 μl of a 0.2m*M* solution in water) and sodium hydroxide (1 ml of 0.1*M* solution) was injected into the tubes with a powered syringe unit.[5] The film was then exposed to the light produced by the reaction in the tubes, for 0.25, 0.5, 1.0, 2.0, 3.0 and 4.0 min.

In order to compare these results directly with those obtained by using a photomultiplier tube as a detector, identical reactions were carried out in a prototype luminometer[6] and the peak light output was recorded.

Reagent discs

Luminol-impregnated "Visking" dialysis tubing (Jennings Co., Nottingham, U.K.) was prepared by soaking lengths of tubing (type 18/32) in luminol solution (2m*M* in 1*M* potassium hydroxide) for 1 hr. Excess of luminol solution was removed by blotting with filter paper and the tubing was dried overnight at room temperature.

Enzyme discs were prepared by soaking "Millipore" filters (type AP 2502500) in glucose oxidase/peroxidase solution (glucose oxidase 22 mg/ml, *i.e.*, 400 U/ml; peroxidase 1.3 g/l., 120 U/ml) in phosphate buffer (0.1*M*, pH 7.0) for 1 hr. Finally the discs were dried overnight at room temperature.

Assay of glucose with solid-phase reagents

Disposable plastic tubes in which 2-mm diameter holes had been drilled to prevent the formation of air-locks were loaded with a disc of luminol-impregnated "Visking" tubing and a disc of enzyme-impregnated filter material. The discs were held in position by O-rings (Fig. 1).

For calibration or analysis, 5–20 μl of 5.6m*M* glucose solution in distilled water was added to tubes positioned in the "Tufnol" mask and the reaction was allowed to proceed for 5 min. Then, in a darkened room, the mask was placed in the film holder and the luminescent reaction was initiated by the addition of 200 μl of distilled water, which flushed the mixture onto the luminol-impregnated "Visking" tubing. After exposure of the film (Type 410) for 1 min, the mask was removed and the film was developed. Identical reactions were carried out in a prototype luminometer to measure the light output.

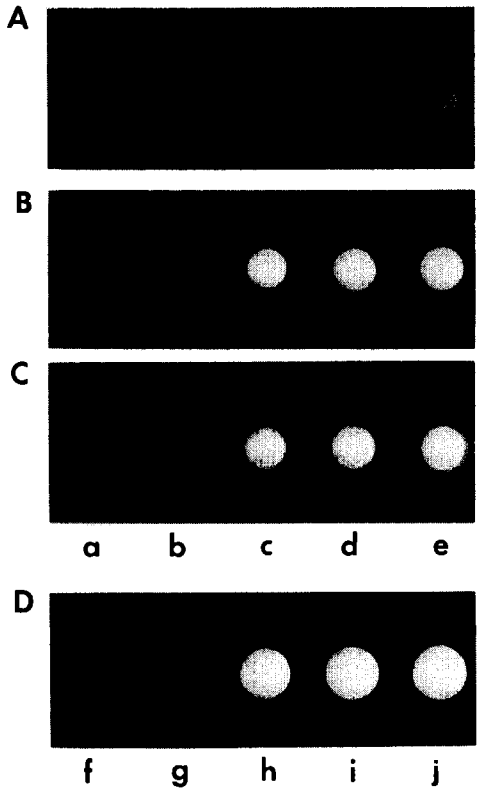

Fig. 2. Photographic film response to various chemiluminescent reactions. A, Response of Polaroid type 47 film to chemiluminescence reaction of lucigenin and different concentrations of hydrogen peroxide, exposure time 1 min; B, as for A except exposure time was 2 min; C, as for A except Polaroid type 410 film and an exposure time of 30 sec were used. Hydrogen peroxide added (μmole: a = 0, b = 14.7, c = 29.4, d = 44.1, e = 58.8. D, Response of Polaroid type 410 film to solid-phase chemiluminescent assay for glucose, exposure time 1 min. Volume of 5.6m*M* glucose added: f = 0 μl, g = 5 μl (28 nmole), h = 10 μl (56 nmole), i = 15 μl (84 nmole), j = 20 μl (112 nmole).

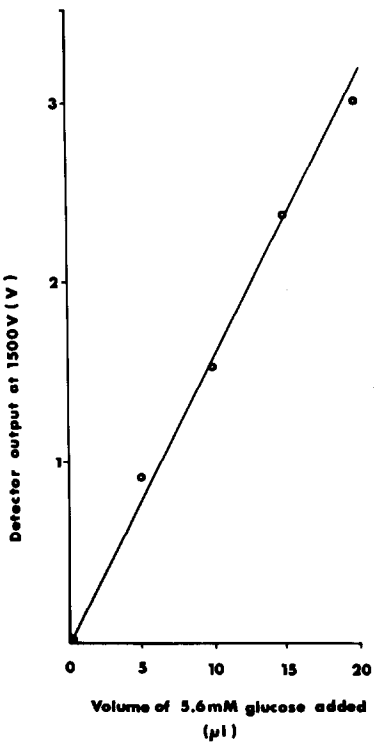

Fig. 3. Calibration curve for solid-phase luminol chemiluminescent assay of glucose (each point is the mean of duplicate determinations).

RESULTS AND DISCUSSION

The response of the two types of photographic film to a series of luminescent peroxide/lucigenin reactions is shown in Fig. 2. A linear relationship between light output and peroxide concentration was obtained in an identical series of reactions in which the light was measured with a photomultiplier tube. Type 47 film had insufficient sensitivity unless exposure times of several minutes were used. Type 410 film developed adequate density after an exposure time of 1 min, and despite its restricted exposure latitude, was chosen as the detection system for the glucose assay with solid-phase reagents.

The calibration curve obtained for the luminescent assay of glucose with solid-phase reagents was linear when a photomultiplier tube was used to monitor the light output. An identical series of reactions, with photographic film used as the detection system, showed (Fig. 2D) the viability of the solid-phase luminescent assay for glucose. However, because of the insufficient exposure latitude of the Type 410 film, discrimination between different amounts of glucose was limited since below 28 nmole the photographic emulsion was unexposed, whilst above this value the emulsion was fully exposed. In its present embodiment the solid-phase assay provides a very sensitive "threshold" type test for the presence or absence of an analyte, in this case glucose. A rapid and quantitative version of the assay would require a fast film (high ASA number) with as wide an exposure latitude as possible. An instant film having this combination of characteristics is not available. The exposure of the film was in some instances, non-uniform, indicating that flow through the filter discs was unsatisfactory when combined with photographic detection techniques. In contrast, the results obtained with an identical analytical system, but measuring the light output by means of a photomultiplier tube, showed much better proportionality to concentration (Fig. 3). This indicates that the fault lies primarily with the flow characteristics of the filter discs rather than with the concept as a whole. The problem of uniform and reproducible sample delivery through thin layers of reagents has been solved by other workers,[2] but the method is proprietary and was thus not available to us.

The prototype solid-phase chemiluminescent analytical system described in this paper has considerable potential for rapid quantitative or semi-quantitative analyses, and would offer a novel departure from current "dipstick" and other "disposable"-type methods. Its future development and exploitation will, however, depend upon the availability of suitable photographic films and a reliable method of delivering sample to the solid-phase reagents.

DETERMINATION OF TOTAL ARSENIC BY USE OF A ZINC-COLUMN ARSINE GENERATOR

W. A. MAHER

Department of Oceanography, The University, Southampton, England

(*Received* 7 *April* 1981. *Revised* 9 *September* 1981. *Accepted* 1 *November* 1981)

Summary—A method for the measurement of total arsenic in extracts of environmental materials is described. Arsenic is reduced to arsine with a zinc reductor column, the evolved arsine is decomposed in a heated carbon-tube furnace, and arsenic determined by measurement of its atomic-absorption at 193.7 nm. The detection limit is 0.002 μg/ml and the coefficient of variation is 1.4% at 0.01 μg/ml.

During a study of the chemical speciation of arsenic in the marine environment a method was required for determining the arsenic present in extracts derived from geological and biological material.

Arsenic forms a volatile hydride and this property is widely used to separate arsenic from matrices which might interfere in its determination by atomic-absorption spectroscopy. Various reductant systems such as $Zn/KI/SnCl_2/HCl$,[1] $NaBH_4/HCl$,[2] and $Mg/TiCl_3/HCl$,[3] have been used to reduce inorganic arsenic to its hydride, these being added as solid pellets or solutions. Most hydride separation methods are, however, limited in their application, owing to severe interference from other elements.[2,4,5]

Lichte and Skogerboe[6] have reported the use of a column of zinc for the generation of arsenic hydride, and Knudson and Christian,[7] and Shaikh and Tallman,[8] have used carbon furnaces for the determination of arsenic in its hydride form. This paper describes the coupling of a zinc-column reductor to a carbon furnace for the rapid and fairly interference-free determination of nanogram quantities of arsenic.

EXPERIMENTAL

Apparatus

A Varian–Techtron AA5 atomic-absorption spectrophotometer fitted with a Perkin–Elmer HGA 72 carbon furnace was used for all measurements. The standard carbon tube was replaced with a 10-mm bore carbon tube with a single central gas inlet hole (Fig. 1). The light-source was a Rank Hilger slotted arsenic hollow-cathode lamp, operated at 7 mA; the slit-width was 300 μm; the 193.7-nm resonance line was measured. The zinc-column arsine generator (Fig. 2) was connected into the inert-gas feed line between the HGA 72 control module and the inlet to the furnace.
