HIGH-PRESSURE LIQUID CHROMATOGRAPHIC DETERMINATION OF SOME 1,4-BENZODIAZEPINES AND THEIR METABOLITES IN BIOLOGICAL FLUIDS: A REVIEW

Anil C. Mehta

Department of Pharmacy, The General Infirmary, Leeds, Yorkshire, England

Summary—In recent years the need for rapid, sensitive and specific assays for benzodiazepines has resulted in the publication of a number of high-pressure liquid chromatographic (HPLC) methods for their determination. This paper reviews the methods available to date for the determination of chlordiazepoxide, clonazepam, diazepam, flurazepam, lorazepam, nitrazepam, oxazepam and their metabolites in biological fluids.

The benzodiazepines are an important class of psychotherapeutic agents. They act on the central nervous system and have hypnotic, tranquilizing and anticonvulsant properties. Since there are wide differences in selectivity among these drugs, their usefulness varies considerably. They are among the most frequently prescribed drugs for the treatment of anxiety, sleep disturbance and status epilepticus. They are also used in the treatment of alcohol withdrawal, and both to relieve tension in the pre-operative period and to induce amnesia in surgical procedures.

For the clinical, toxicological and biopharmaceutical study of the benzodiazepines, rapid methods for their determination in various biological fluids are required. The benzodiazepines are clinically effective at low doses ranging from 1 to 30 mg, resulting in blood concentrations in the 10–500 ng/ml range. They also undergo extensive metabolism[1-4] and many of the metabolites are pharmacologically active.[1] Thus it is essential that the assay methods be sensitive and specific, *i.e.*, capable of separating and determining the parent drug as well as its major metabolites.

Benzodiazepines in biological fluids are determined by various techniques,[5] of which gas–liquid chromatography (GLC)[4,6-9] and polarography[7,10-13] are dominant. The GLC methods, though extremely sensitive, require lengthy clean-up procedures and in some cases formation of more volatile derivatives. Furthermore, if high temperatures are used in the GLC they may cause the decomposition of certain benzodiazepines such as chlordiazepoxide, oxazepam, lorazepam and their metabolites. Polarography, despite the advantage of convenience and speed, lacks the sensitivity and specificity of GLC and requires large amounts of sample. For these reasons attention has shifted to development of HPLC methods for the determination of these drugs in body fluids. HPLC offers several advantages. The extrac-

tion procedures are relatively simple, formation of derivatives is not necessary (though there are exceptions), and operation at ambient temperature allows the determination of thermally labile benzodiazepines. The strong absorption in the 230–260 nm region gives sensitivity in the nanogram range and linearity over a wide concentration range. Moreover, since the technique is non-destructive, the eluted drugs can be recovered for further examination.

PHYSICOCHEMICAL PROPERTIES

The 1,4-benzodiazepines can be structurally generalized by the formula shown in Fig. 1. All the important benzodiazepines contain a 5-phenyl ring, a halogen or nitro group in the 7-position, and in many cases an additional halogen in the R_4-position. The substituents at key positions are shown in Table 1. Chlordiazepoxide (Fig. 2) differs from other benzodiazepines in that it is an *N*-oxide with a methylamino group at position 2 and no alkyl group at position 1.

Benzodiazepines are basic drugs and as free bases are lipid-soluble and water-insoluble. In contrast, the salts (*e.g.*, chlordiazepoxide and flurazepam hydrochlorides, dipotassium clorazepate) are water-soluble. Stock solutions of benzodiazepines are more stable (several weeks) in alcohol than in water.[5] Howard[14] and Kelly *et al.*[15] have studied the stability of diazepam and nitrazepam plasma samples respectively, under various conditions. Diazepam was found to be stable for 3 weeks at room temperature, 8 weeks at 4°, and 1 year at −20°. Nitrazepam in plasma was stable for at least 3 weeks at 4° in the dark, and more than 3 weeks in a deep-frozen sample; in contrast, there was a significant decrease in nitrazepam content in samples stored at room temperature in the dark. Analysts would welcome similar stability information on other benzodiazepines. Protein binding varies from a few per cent

Fig. 2. Chlordiazepoxide structure.

with flurazepam to over 90% with diazepam.[16–18] Plasma protein binding of benzodiazepines has been found to be concentration-independent[18] and pH-dependent.[19–21] The pK_a values of benzodiazepines are listed by Clifford and Smyth[5] and in Martindale.[22] Hulshoff and Perrin[23] have determined the partition coefficients of benzodiazepines in the aqueous oleyl alcohol system.

SAMPLE PREPARATION

Benzodiazepines and their metabolites are usually extracted as the neutral molecules from biofluids with a range of organic solvents under weakly alkaline conditions,[5] with recoveries in excess of 80%. Some workers[9] find it unnecessary to alkalize samples since the pK_1 values of benzodiazepines are considerably below the physiological pH. There seems to be no preference for a particular solvent and the normal extraction solvents are employed either alone or in combination. Some workers choose diethyl ether, ethyl acetate and chloroform, in that order,[5] while others[9] prefer a relatively non-polar solvent such as heptane, benzene or toluene, to which is added a small amount of a more polar solvent such as isoamyl alcohol or methylene chloride. One advantage of low boiling solvents is they can be readily evaporated for recovery of the drug(s). A single extraction step is sufficient for all benzodiazepines except oxazepam and lorazepam. Owing to their lower lipid solubility, they need a double extraction, and the combined extracts are evaporated to dryness before chromatography.[9] Smyth and Groves[24] have devised a scheme for the extraction of flurazepam and its metabolites, based on the distribution ratios for different pH values and various solvents.

Some investigators prefer enzymatic digestion (hydrolysis) of plasma,[25] urine[25–28] or tissue[29] samples of benzodiazepines before extraction to liberate the conjugated fraction of the drug. Hammond et al.[30] have described two procedures (enzymatic and non-enzymatic) for the extraction of benzodiazepines from cloth or paper. The enzymatic extraction is
preferred, especially for old stains strongly bound to the material.

Recently, commercially available C_{18} bonded-phase extraction columns (e.g., Bond-Elut) have been used for the rapid sample preparation of diazepam,[31,32] chlordiazepoxide[31] and their metabolites. These columns selectively adsorb benzodiazepines and their metabolites from biofluids at a pH of 9.0. The compounds are then eluted with methanol, making sample preparation quicker than the traditional solvent extraction procedure. This procedure can also be applied to the extraction of other benzodiazepines. Missen[33] compared three adsorption methods, which included the use of activated charcoal, Amberlite XAD-2 ion-exchange resin and Celite to extract nitrazepam, diazepam and desmethyldiazepam. The Celite extraction was rapid but a large amount of cholesterol was also extracted from blood samples, whereas the other two procedures extracted much less. The Celite extraction method was used for rapidly screening blood samples. For trace analytical work the XAD-2 resin method was preferred. Balkon et al.[34] have used the Du Pont Prep 1 system equipped with an Amberlite XAD-2 resin column for the isolation of diazepam from biological samples.

For rapid toxicological analysis Kabra et al.[35] have used serum protein precipitation by acetonitrile followed by centrifugation, as the only means of sample preparation. A suitable aliquot of the supernatant liquid is injected onto the HPLC column for drug screening.

Lensmeyer et al.[36] have tested commercially available blood collection tubes for substances that could leach into the blood samples and adversely affect the benzodiazepine assay. None of the tubes tested affected the extraction or the chromatography of chlordiazepoxide, diazepam, flurazepam and their metabolites.

HPLC METHODS

Columns

In the early days of HPLC (early and middle seventies), the benzodiazepine drug mixtures were

Table 1. Positions of various substituents in benzodiazepine structures

separated at μg levels on columns containing sil-ica,[37,38] anion-exchanger,[39] cation-exchanger,[40] Durapak OPN[41,42] and Carbowax 400 coated support[43] and detected by single-wavelength (254 nm) ultra-violet detectors. These methods are not sensitive and selective enough to analyse ng quantities of benzo-diazepines and their metabolites in biological sam-ples. More recently reversed-phase columns have become the columns of choice because a wide variety of drugs of varied polarity can be separated. They require relatively little maintenance and perform equally well with eluent gradients. Their use also facilitates injection of aqueous samples. In most of the current HPLC methods for benzodiazepines, reversed-phase columns are employed along with ultraviolet detectors and mobile phases consisting of organic solvents mixed with water or weakly acidic buffers.

The most popular reversed-phase column packing material for benzodiazepine analysis is chemically bonded silica containing octadecyl (C_{18}) groups, fol-lowed by silica containing octyl (C_8) groups. Hexyl-(C_6) and cyano-bonded reversed-phase columns as well as ordinary (silical gel) columns have also been used, but less frequently. The chromatography is generally performed at room temperature under iso-cratic conditions, but there are exceptions where it is performed at elevated temperature,[44-47] or under gra-dient elution conditions,[48] or both.[35,36]

Kinberger and Wahrgren[49] have used a reversed-phase (C_{18}) radial compression column (Waters Asso-ciates Ltd.) for the determination of diazepam and its metabolites. The column, which is made of a flexible polyethylene tube, is compressed in a specially de-signed holder (radial compression module) during use. The compression presumably reduces wall effects, thereby eliminating channels in the column packing. Radial compression columns afford shorter analysis time and can be operated at lower pressures, but they do not permit use of temperature pro-gramming.

Mobile phases

The most common solvent system for the reversed-phase HPLC of benzodiazepines is a mixture of acetonitrile or methanol and an aqueous acetate or phosphate buffer or water. Combinations of two organic solvents and an aqueous buffer have also been employed as mobile phases to achieve optimum conditions for the separation of closely related solutes such as diazepam,[25,49,50] chlordiazepoxide[50,51] and their metabolites. Lensmeyer *et al.*[36] have used a ternary solvent gradient system for the reversed-phase sepa-ration of diazepam, chlordiazepoxide, flurazepam and their metabolites. Three separate solutions (am-monium acetate, acetic acid and acetonitrile) were mixed so as to give pH and solvent-composition gradients. The chromatography was performed at 50° and complete resolution of benzodiazepines resulted in 15 min.

Detectors

Ultraviolet detection is still the most popular mode for HPLC benzodiazepine assays. The sensitivity is not as good as that of electron-capture GLC but can be improved by using a variable-wavelength detector. For example, monitoring at the absorbance max-imum of the drug (approximately 240 nm for most benzodiazepines) frequently improves the detection limit by a factor of two compared to detection at 254 nm.[52] Furthermore, use of the variable-wavelength detector may permit the reduction of sample volume. The sensitivity and specificity of detection can further be improved by the use of a fluorescence detector. Although benzodiazepines do not yield intense room-temperature fluorescence, they can be converted into highly fluorescent derivatives[5] or made to luminesce at low temperature.[53,54] These properties can be uti-lized in their fluorimetric HPLC determination pro-vided that practical difficulties are overcome. It should be remembered that on-line derivative for-mation or low-temperature luminescence is not as easy as an ultraviolet or fluorescence detector to incorporate in an HPLC apparatus.

The presence of easily reducible nitro and/or azo-methine ($>C = N-$) groups in benzodiazepines al-lows polarographic determination;[12] hence the devel-opment of a sensitive electrochemical detector oper-ating in the reduction mode would extend the poten-tial of HPLC.[7] This is a relatively new area and very few reports are so far available. Advances in electrode design should encourage wider applications in the future. Lund *et al.*[55] have studied a simple flow-through cell with interchangeable working elec-trodes constructed from vitreous carbon, carbon paste and mercury. Nitrazepam, diazepam and chlor-diazepoxide were studied as model compounds, and a detection limit of 3 ng was achieved for nitrazepam and 300 ng for diazepam and chlordiazepoxide. Hanekemp *et al.*[56,57] have used a pulse-polarographic detector incorporating a dropping mercury electrode (DME) for the determination of nitrazepam in serum[56] and for the detection of bromazepam, ni-trazepam, diazepam and clonazepam in a mixture.[57] Hackman and Brooks[58] have described a dual de-tector system for the reversed-phase HPLC deter-mination of chlodiazepoxide and desmethyl-chlordiazepoxide in plasma. The eluate was first passed through an ultraviolet detector (254 nm), then through a pulse-damper to a reductive amperometric detector equipped with a DME. The electrode was operated in the differential-pulse mode. The am-perometric and ultraviolet detectors were found to be of equal sensitivity and precision. The limit of de-tection was 50 ng/ml for chlordiazepoxide and its metabolite. Recently a similar approach (a dual detector system) has been used to determine hydroxyethylflurazepam glucuronide, a major metab-olite of flurazepam in urine.[28] The DME has the distinct advantage of presenting a continuously re-newable fresh surface during the chromatography

Table 2. HPLC methods for the determination of 1,4-benzodiazepines in biological fluids

and so is not subject to poisoning, as solid electrodes are.[58]

Screening procedures

Benzodiazepines have considerable potential for abuse and overdosage is very common. For their rapid identification and determination, screening procedures are required in clinical, toxicological and forensic laboratories. To this end many HPLC procedures have been published which use reversed-phase separation and ultraviolet detection.[26,29,35,36,59-63] The drugs are detected either intact[26,29,35,36,59-61] or as their benzophenone hydrolysis products.[59,62,63] Tjaden et al.[26] have reported capacity factors and separation coefficients for 16 benzodiazepines and have established optimum conditions for separating 9 of them in 12 min. A reversed-phase system with a methanol-based mobile phase and an ultraviolet detector (254 nm) was used for this purpose. Osselton et al.[29] have reported a reversed-phase HPLC method for the determination of benzodiazepines and their metabolites in human and animal tissues. An aqueous methanolic mobile phase and detection at 254 nm was used in the separation of drugs on a C_{18} column. Retention volumes and detection limits for various benzodiazepines were reported and the method was successfully applied in finding the concentrations of these drugs in cases of human self-poisoning. Kabra et al.[35] have published a rapid reversed-phase HPLC method for screening toxic drugs in serum, including chlordiazepoxide, diazepam, desmethyldiazepam, flurazepam and nitrazepam. In this method an acetonitrile–phosphate buffer (pH 3.2) is used as mobile phase and the ultraviolet detector is set at 210 nm. The separation is based on gradient elution at 50°. A complete analysis is achieved in 45 min. A normal-phase HPLC method described by Vree et al.[64] for the determination of flunitrazepam in body fluids also permits the separation of diazepam, desmethyldiazepam, nitrazepam and clonazepam. The drugs are eluted from a silica column with a mobile phase consisting of a mixture of hexane and ethanol and detected by their absorption at 230 nm.

Individual drugs

The HPLC methods currently available for benzodiazepines and their metabolites are summarized in Table 2. It is evident from the table that chlordiazepoxide and diazepam are the most frequently studied members of the series. Those methods in which other benzodiazepines are used as internal standards may have wider applications since one drug may be used as an internal standard for another. There are some methods in which no internal standards are used. There is a growing trend towards doing away with internal standards, particularly if a fixed-volume sample loop is used in a sample-injection system. Although the precision of such a device is very good, it will not account for the procedural drug losses in a multi-step assay.

McAllister[65] has recommended prazepam as a possible internal standard for the estimation of diazepam in plasma. Though the end analysis was done by GLC, the information (extraction, recovery, etc.) contained in the paper is equally useful for HPLC work. The limits of detection are governed by instrumental and procedural factors, and the values given in Table 2 should therefore be taken only as relative guidelines. It would also be sensible to reinvestigate a method before putting it to a new use, particularly with regard to specificity, since a method which works in one situation may give rise to problems (or even fail) in another. A drug assay should always be dynamic in nature and subject to continuous modification and improvement during its application.[66]

CONCLUSION

This review has shown that there is a wide choice of HPLC methods available for the determination of benzodiazepines and their metabolites in biological samples. Most methods have an acceptable sensitivity for routine and research applications and should provide a useful alternative to GLC. It has been demonstrated in the case of diazepam and desmethyldiazepam that the HPLC results show an excellent correlation with those generated by GLC.[27,45,67,68] The HPLC results have also been compared with those of homogeneous enzyme immunoassay (EMIT)[45] which was used to measure total diazepam and desmethyldiazepam. For serum levels there was very good agreement between the two methods, but EMIT urine assays gave higher results, presumably because of the sensitivity of the EMIT reagents to another urinary metabolite of diazepam, viz. oxazepam glucuronide, which is not measured by HPLC.

It must be emphasized that for certain benzodiazepines, HPLC still lacks the sensitivity of GLC, particularly if the sensitivity range of the ultraviolet detector is restricted to 0.01 absorbance units full scale (AUFS). Availability of more sensitive detectors (maximum sensitivity 0.001 AUFS)[69] should solve the sensitivity problems for those drugs which are more potent and given in low doses (clonazepam, flunitrazepam, lorazepam). There is also a dearth of HPLC methods for flurazepam, clorazepate dipotassium, medazepam and their active metabolites. Some promising results have been obtained by using electrochemical detectors,[28,55-58] but further work is required to see how these detectors compare with the well-established ultraviolet detectors, in terms of overall performance. The reader's attention is drawn to recent reviews on the metabolism[1,2] and pharmacokinetics[1,2,16,70] of benzodiazepines, which provide up-to-date information in these fields.

With the introduction of more sensitive detectors, novel column systems and automation of the equipment, the use of HPLC in benzodiazepine analysis is likely to increase. In particular, coupling of HPLC

with mass spectrometry may allow identification of new metabolites of these drugs.

A CONTINUOUS-DILUTION CALIBRATION TECHNIQUE FOR FLAME ATOMIC-ABSORPTION SPECTROPHOTOMETRY

J. F. TYSON and J. M. H. APPLETON

Department of Chemistry, University of Technology, Loughborough, Leicestershire, England

Summary—Calibration in atomic-absorption spectrometry is achieved by means of a concentration-gradient chamber using a single concentrated standard solution. Calibration is rapid and extends over the entire working concentration range of the analyte, irrespective of the shape of the conventionally obtained calibration curve. No curve-fitting approximations are involved. With well-designed apparatus, deviations are less than 1%.

In most instrumental analytical techniques no absolute mathematical relationship exists between the magnitude of the quantity observed and the quantity of determinand. The relationship is generally a complex function of instrumental parameters which rarely have long-term stability, and the chemical environment of the analyte. The latter often has a profound effect on instrument response, so it is then not possible to ignore the chemical matrix when relating signal to analyte. Accordingly, most instruments require calibration immediately before analytical determinations are made. This is certainly true of atomic-absorption spectrometry. Variation in cleanliness, optical alignment, and performance of the line-source, causes day-to-day changes in instrument response. During operation, baseline drift may arise from the gradual stabilization of electrical circuits and variations in source intensity, whilst overall sensitivity may be influenced by changes in nebulizer efficiency, sample flow-rate, and flame chemistry (resulting from changes in fuel-to-oxidant ratio and sample matrix). Certainly, whenever such operational parameters are changed, recalibration is necessary.

Calibration in atomic-absorption spectrometry is usually done by stepwise dilution of a concentrated stock solution to produce a range of standard solutions for analysis. The resulting set of points on the plot of absorbance *vs.* concentration is used as the basis of the calibration curve. In many modern instruments, a microcomputer fits an equation to the calibration data. Thus the development of microprocessor technology has allowed the calibration data-processing step to be incorporated within the instrument itself. The preparation of standards, however, remains a tedious and time-consuming task which greatly reduces sample throughput. Automated calibration is therefore an attractive prospect for atomic absorption.

In considering prospects for automated calibration procedures, the so-called "flow-injection" techniques[1] developed over the last eight years or so, look

promising. The basis of flow injection is the controlled, reproducible, flow-induced dispersion obtainable when a plug of sample is injected into a reagent carrier stream as it flows through narrow-bore tubing. The changing concentration profile of the sample solution may be monitored by downstream detectors, though usually it is the concentration of reaction product that is monitored as the basis of the analysis. The modification, by stages, of the sample concentration profile, from rectangular, through skew peak, to Gaussian peak, has been described by several authors.[1-3] Růžička and Hansen[4] defined the dispersion, D, by the equation:

$$D = C_m/C_p \qquad (1)$$

where C_m is the concentration of the injected sample and C_p is the concentration at the peak maximum.

These authors have described the dependence of dispersion on flow-rate and tube dimensions. The degree of dispersion may thus be preselected to match the requirements of a particular analytical procedure. The versatility and reproducibility of the dispersion process were such that Růžička and Hansen[4] were able to state, "We can replace beakers, pipettes and volumetric flasks with small open-ended tubes through which we pump the solutions." This is just the basis required for the automation of calibration procedures and it should be possible to produce a range of standards from a single stock solution by varying the dispersion to which it is subjected. Systems based on this concept are presently being studied.[5]

Methods of producing concentration gradients by using mixing-chambers and differential flow-rates have been described by Block and Ling.[6] Early work with continuous-flow titration techniques employed magnetically-stirred mixing-chambers.[7] Whilst the predictable, reproducible performance of mixing-chambers is well-known and understood, certain associated properties, notably sample hold-up and excessive sample dispersion, render them unsuitable
Fig. 1. Schematic diagram of basic apparatus for generating an exponential concentration gradient. A and B are constant-head reservoirs (Marriott bottles) containing water and concentrated stock solution, respectively. C is a rotary valve allowing rapid switching between one solution and the other. D is the mixing-chamber. E represents the detector and recording system.

for general use in flow-injection systems.[2] Their elimination was brought about by a recent return to a true flow-injection technique[8] wherein the mixing-chamber function was achieved by means of a carefully designed flow manifold equivalent to one theoretical mixing stage. The removal of the mixing-chamber enabled the realization of high-speed continuous-flow titrations.

Electrochemists studying continuous-flow titrations have employed concentration-gradient programming, achieved by the merging of a constant-flow carrier stream with either a constant-flow reagent stream of increasing concentration[9] or a reagent stream of constant concentration and increasing flow-rate. The practice of making measurements on alternately increasing and decreasing concentration profiles has been called the "Triangle-Programmed Titration" technique.[10]

Mixing-chambers have also long found favour amongst electrochemists,[11] who continue to defend the merits of the device.[12] Similar arguments may be advanced for the application of the mixing-chamber gradient technique to atomic-absorption calibration, namely, precise, reproducible performance described by exact mathematical equations readily related to the system parameters, and a smooth concentration profile compatible with the relatively slow response characteristics of the detection system, together with the fact that all this is achieved with simple, readily available apparatus.

The basic system, shown in Fig. 1, consists of a water-filled ideally-stirred tank into which a stream of stock solution is switched to produce an effluent concentration which is an exponential function of the time elapsed after switching. The use of this system for continuous-flow atomic-absorption calibration has previously been suggested.[13,14] In this paper, the

results of a preliminary study of the system represented in Fig. 1 are reported. The objectives were to assess the viability of such a calibration technique and to identify the experimental conditions necessary for its successful application.

PRINCIPLE OF THE METHOD

An arrangement of the type illustrated in Fig. 1 is used to generate an exponential concentration-time profile of the type described by the equation

$$C = C_m [1 - \exp(-ut/V)] \qquad (2)$$

where C is the effluent concentration at time t after the start of the concentration gradient, C_m is the concentration of stock calibrant solution, u is the flow-rate, and V is the volume of the mixing-chamber.

This equation may be derived from a consideration of the mass balance in the mixing-chamber (see e.g., Danckwerts[15] or Levenspiel[16]). The effluent from the mixing-chamber is led directly to the nebulizer of an atomic-absorption spectrometer, and the resultant absorbance–time profile is recorded with a rapid-response chart-recorder. Since in atomic-absorption work absorbance is generally not a linear function of concentration, this curve soon deviates from its initial simple exponential form, as shown in Fig. 2.

Used in conjunction with equation (2), Fig. 2 is a continuous calibration plot relating absorbance to concentration. In practice, instead of relabelling of the time axis, the absorbance–time profile is generated and then the sample is admitted directly to the nebulizer at the same flow-rate as the calibrant and its absorbance is noted. By interpolation (see Fig. 3), a corresponding value of t is obtained which is substituted into equation (2), giving the concentration of the sample. For fixed instrument settings, in the absence of interferents, absorbance is a function of only the concentration and flow-rate. Thus, if the absorbances of sample and calibrant (measured at

Fig. 2. Absorbance–time profile. Curve (a) corresponds to a hypothetical profile $A = A_m[1 - \exp(-ut/V)]$ where A is the absorbance at time t, and A_m the absorbance corresponding to C_m if the sensitivity were independent of concentration. Curve (b) is the profile generally observed, i.e., curve (a) modified by instrument response.
Fig. 3. Interpolation of sample absorbance on absorbance–time profile to find the characteristic time value for the sample, t^x.

the same flow-rate) are equal, their concentrations are equal and

$$C_x = C_m[1 - \exp(-ut^x/V)] \qquad (3)$$

where C_x is the concentration of the sample and t^x is the time found by interpolation from the absorbance–time profile.

However, in common with other flow techniques, the creation of practical conditions under which equation (3) is valid requires careful attention to methodology. The minimum requirements are that the assumptions made in the derivation of equation (3) are valid, namely,

(a) that mixing-chamber performance is ideal, i.e., it conforms with equation (2);

(b) that the flow-rate may be accurately determined and remains constant during the recording of both calibration and sample absorbances;

(c) that no instrumental drift occurs between the recording of the calibration and sample absorbances;

(d) the starting time of the absorbance–time calibration profile may be accurately located.

In addition, minimizing the length of connecting tubing, ensuring that fittings are well-matched and polished, minimizing pump noise by operating at maximum speed and minimum roller pressure, and avoiding air-bubbles, are reported[17] to have a beneficial effect on precision.

EXPERIMENTAL

Apparatus

Mixing-chamber. This was constructed from borosilicate glass, as a sealed unit in the form of a vertical cylinder (diameter 2 cm, maximum height 3 cm) with a slight dome to allow the escape of air bubbles. The volume (determined by filling with water and weighing) was 8.40 ml. The inlet and outlet guides were slightly tapered to allow a push-fit of the 0.58 mm bore PTFE tubing inside a sleeve of 1.14 mm bore PTFE tubing (Corning Ltd., Laboratory Division, Stone, Staffs.). A soft-iron magnet-follower was constructed from a pin (13 × 0.5 mm) sealed inside a short piece of the 0.58 mm bore PTFE tubing.

Investigation of mixing-chamber performance. The apparatus is represented in Fig. 1, with the carrier and stock calibrant solutions gravity-fed from two constant-head vessels. The valve was a Rheodyne type 5011 six-position rotary valve and the instrument used was a Varian 634 S spectrophotometer fitted with a home-made flow-cell measuring 50 × 2 × 1 mm, mounted vertically with the largest

faces normal to the light-beam. An identical cell, filled with distilled water, was mounted in the blank cell compartment of the instrument. The instrument response was monitored by a J. J. 100 chart-recorder (J. J. Lloyd Instruments Ltd.).

Solutions

Copper(II) sulphate pentahydrate (16 g/l.) in distilled water. Magnesium, nickel and chromium, 1000-ppm stock solutions (B.D.H. Chemicals Ltd.).

Procedures

Mixing-chamber performance. With conventional cuvettes it was established that solutions of copper sulphate pentahydrate exhibited an absorption maximum at 808 nm and obeyed Beer's law up to concentrations of at least 16 g/l. A range of flow-rates was obtained by varying the head of liquid between sample reservoir and waste outlet. Flow-rate was measured by averaging the volumes of effluent collected during six 1-min intervals. Seven absorption–time growth profiles were recorded at different flow-rates over the range 3.6–8.2 ml/min.

Atomic-absorption calibration. The apparatus is shown schematically in Fig. 4. Solutions of magnesium, nickel and chromium were used. Their concentrations and the respective instrument settings employed are shown in Table 1. Magnesium was chosen for its high sensitivity and for the limited curvature of its conventional calibration plot, nickel as an element exhibiting pronounced curvature of the calibration plot, and chromium because of its reported calibration irregularities.[18]

The absorbance–time growth profiles were generated by using the mixing-chamber, and the time taken for 10 ml of calibrant to be consumed from the reservoir was recorded simultaneously. The mixing-chamber was then "short-circuited" by making the direct connection Z (Fig. 4), and the samples were introduced through S without changing the flow-rate. Data from the chart were analysed with the aid of a microcomputer.

RESULTS AND DISCUSSION

Mixing-chamber performance

Assuming ideal mixing-chamber performance, the growth of concentration within the chamber is ex-

Fig. 4. Apparatus for instrument calibration. A is a Shandon Southern A3300 atomic-absorption spectrometer, C the mixing-chamber, M a Gallenkamp model SS615 combined magnetic stirrer and hot-plate, P a Gilson Minipuls 2 peristaltic pump, R a Tekmann TE200 chart-recorder, S a 10-ml Teflon non-wetting syringe barrel as sample reservoir, V an Altex model 201-25 eight-port injection valve, W a constant-head reservoir of distilled water; V and C were connected by 7.5 cm of 1.14 mm bore tubing, and C and A by 5.5 cm of 0.58 mm bore tubing.

Table 1. Solutions and instrument settings employed for atomic-absorption calibration

Setting	Magnesium	Nickel	Chromium
Monochromator, nm	285.2	232.0	357.9
Band-pass, nm	0.18	0.1	0.1
Lamp current, mA	3.5	5.0	3.0
Air flow, arbitrary units	8.0	8.2	8.65
Acetylene flow, l./min	2.8	2.8	5.0
Sample concentration, ppm	0.25–2.0	10–75	2–20
Calibrant concentrations, ppm	2, 5, 10	100, 200	25, 50, 75
Flow-rate, ml/min	8.4	8.5	8.4

Table 2. Investigation of mixing-chamber performance by solution spectrometry; data from plots of $\ln[A_m/(A_m - A)]$ against t

Flow-rate, ml/min	Gradient, min^{-1}	Correlation coefficient	V (calculated), ml
3.56	0.403	0.99994	8.8
4.48	0.505	0.99998	8.9
5.07	0.599	0.99999	8.5
5.68	0.630	0.99996	9.0
6.18	0.709	0.99998	8.7
6.72	0.764	0.99997	8.8
7.50	0.886	0.99999	8.5

pressed by equation (1). Applying Beer's law, we have $C/C_m = A/A_m$, and hence

$$A = A_m [1 - \exp(-ut/V)] \qquad (4)$$

and

$$\ln\left(\frac{A_m}{A_m - A}\right) = ut/V \qquad (5)$$

Thus a plot of $\ln[A_m/(A_m - A)]$ against t should be a straight line with slope u/V, from which V can be calculated for a known flow-rate. The results are summarized in Table 2, and show good agreement with the predicted exponential response. The values of the flow-rates were determined with a mean relative standard deviation of 1.4% and the mean and 95% confidence interval for V were 8.74 ± 0.41 ml.

Observation of a theoretical chamber-volume which probably exceeds the true volume confirms Pungor's findings, which suggested that the effect

Fig. 5. "Correction" of absorbance for instrument response. (a) is a hypothetical linear calibration plot, assuming constant sensitivity, (b) is the real atomic-absorption calibration curve.

might be due to a mixing contribution within the tubes connected to the chamber. Owing to non-linear instrument response, the corresponding atomic-absorption absorbance–time profiles are not simple exponential-growth functions. Therefore they cannot normally be used directly to evaluate mixing-chamber performance. Two methods of circumventing the difficulty have been employed for test purposes. First, truly exponential absorbance–time curves can be obtained for an element of high sensitivity by use of a solution sufficiently dilute for the conventional calibration curve to be linear over the concentration range from zero to C_m (for example 0.5-ppm magnesium solution). Secondly the generally non-exponential absorbance–time curve may be "corrected" to remove the modification due to instrument response. This is accomplished by reference to the conventional calibration curve, obtained under the same experimental conditions (see Fig. 5). The exponential profile is again observed. In correcting the atomic-absorption absorbance–time profile, any absorbance A observed at time t, and corresponding to a concentration C, is replaced by the corresponding absorbance A'.

The results for a 2-ppm magnesium solution are given in Table 3. The times are measured with respect to an arbitrary zero.

A plot of $\ln[A_m/(A_m - A)]$ against t [equation (5)] is a straight line (correlation coefficient 0.9997). It should be noted that the use of the conventional calibration curve was confined to this preliminary investigation of mixing-chamber characteristics, which is not part of the main calibration procedure.

Ideal mixing requires that a small element of calibrant entering the chamber is instantly and uniformly dispersed throughout the chamber, and is thus recognised at the exit at the same instant. Errors are introduced if this process takes an appreciable time. Inadequate stirring causes the apparent theoretical volume of the chamber to fall,[14] whilst dispersion in other parts of the apparatus causes it to rise. With such a large mixing-chamber, stirring must be vigor-

Table 3. The "correction" of absorbance for instrument response by using the conventional calibration curve

| t, sec	0	5	10	20	30	50	70	∞
A	1.5	11.1	19.8	34.6	45.9	61.2	70.5	83.0
A'	1.5	11.1	20.3	36.3	49.2	68.2	83.6	115.0

Fig. 6. Time-axis zero of the absorbance–time profile: Z = arbitrary time-zero; O = true zero; ZT = measured time, t_m; ZO = time error, t_e; OT = true time, t.

ous if ideal mixing is to be approached, but it must also be smooth. At very high stirring rates the magnetic-follower motion became erratic, resulting in excessive noise in the recorded calibration signal.

Atomic-absorption calibration

Flow-rate. The technique requires the flow-rates of calibrant and sample to be equal. Moreover, the flow-rate must be accurately measured, since it is required in the calibration equation. Ten replicate measurements of the time for the passage of 10 ml through the system gave a mean flow-rate of 8.37 ml/min with a standard deviation of 0.03 ml/min.

Instrumental drift. Any drift in instrument sensitivity between calibration and sample analysis causes an error. Such errors will be minimized in a fully-automated sequence in which calibration and measurement cycles can be run in close succession. The problem also arises, of course, in conventional calibration procedures.

Time-axis zero. In practice, the time-axis zero is not sharply defined on the chart. The interconnection of the various components by tubing, no matter how short, causes some dispersion of the water–calibrant boundary. This smooths the sharp intersection of the curve with the time-axis, see Fig. 6.

The problem of locating the time-zero on the horizontal scale has been overcome by computer-assisted analysis of a small interval (X) of the curve after the point of inflection but within the linear range of the instrument response, so that the portion X has truly exponential form. An arbitrary time-zero Z is chosen, from which all times, t_m, are measured. These measured times contain a constant time error t_e, given by

$$t_e = t_m - t$$

where t_m is the time measured from the arbitrary zero and t is the time measured from the true zero.

Over the interval X, the curve is given by equation (4). Substituting for t gives

$$A = A_m\{1 - \exp[-u(t_m - t_e)/V]\}$$
$$= A_m[1 - \exp(-ut_m/V)\exp(ut_e/V)]$$
$$= A_m[1 - k\exp(-ut_m/V)]$$

where $k = \exp(ut_e/V)$

With time measured from the arbitrary zero, equation (2) becomes, similarly,

$$C = C_m[1 - k\exp(-ut_m/V)] \qquad (6)$$

The value of k is computed by least-squares analysis of a plot of A vs. corresponding values of $\exp(-ut_m/V)$, using data from the arc X of the calibration curve; k is then the negative ratio of the slope to the absorbance intercept of this plot. An Apple II BASIC program has been written for doing the calculation. It also calculates concentrations from the time-values for the samples. Copies may be obtained from the authors by request. The results for a number of determinations are given in Table 4.

Table 4. Results obtained by continuous-dilution calibration method

The concentrations found rarely deviated by more than 4% from the sample concentrations, and in most of the analyses trends in the errors in the results were evident, suggesting that the deviations contained a contribution from systematic errors (*e.g.*, an incorrect flow-rate or deviation from ideal performance of the mixing chamber), rather than being entirely due to random errors. It is thought that systematic errors could be reduced and the results improved by use of a carefully-designed permanent assembly of the apparatus, incorporating precise measurement techniques. A particular improvement would be to extend the role of the microcomputer to include storage and processing of the absorption–time profile and thus dispense with the chart-recorder. Ultimately, a microcomputer-controlled system is envisaged wherein a sample-input device would be switched into a "calibration" mode to record this profile, before returning to the "analysis" mode to determine sample concentrations.

CONCLUSIONS

The viability of a continuous-dilution calibration technique for atomic-absorption work has been demonstrated. The technique uses readily available or easily constructed apparatus. The results obtained suggest that less than 1% uncertainty should be attainable with a carefully-designed assembly. This is confirmed by recent results obtained by using a microcomputer interfaced with the atomic-absorption spectrometer.[19]

Of fundamental importance in this system is an efficiently stirred mixing-chamber having the shortest possible connecting tubes and zero dead-volume. The technique depends upon the predetermined and reproducible performance of this chamber.

In addition to eliminating the need for preparation of standards, continuous dilution calibration has other advantages over conventional calibration. The technique is simple, easily automated, and operable with existing spectrometers. Instead of use of a limited number of data for calibration purposes, the entire calibration curve is recorded. This provides a vast amount of data suitable for computer smoothing and processing. No curve-fitting procedure is involved, and thus the technique may be applied regardless of any curvature or irregularities in the calibration plot.

INDIRECT DETERMINATION OF ORGANIC COMPOUNDS BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

E. R. Clark and El-Sayed A. K. Yacoub*
Department of Chemistry, University of Aston in Birmingham, Gosta Green, Birmingham B4 7ET, England

Summary—A review of the published methods for analysis of organic compounds by atomic-absorption spectrophotometry is given. Most of the applications are based on precipitation of metal compounds or solvent extraction of metal chelates or ion-association complexes. Although many of the methods offer great sensitivity, simplicity, and speed of analysis, few have been widely accepted by analysts, but some have proved to be satisfactory in field trials.

In a paper published in 1968, Christian and Feldman[1] pointed out that some inorganic anions and organic compounds could be determined indirectly by atomic-absorption spectrophotometry (AAS). In a review article in 1973, Kirkbright and Johnson[2] summarized the position at that time, and pointed out that much attention had been devoted to the development of indirect AAS methods in order (*a*) to extend the range of applications of AAS and (*b*) to take advantage of the inherent sensitivity of AAS. The review by Kirkbright and Johnson dealt mainly with the determination of non-metals, metals and anions, but a section was devoted to the determination of organic compounds. Since then, many more papers concerned with the indirect determination of organic compounds by AAS have been published. Pharmaceutical applications have received special attention and some comment in short reviews by Kidani,[3] Miller,[4] Rousselet and Thuller,[5] and Ebdon.[6] Here we give a critical discussion of developments in the organic field in the past ten years.

Procedures involving formation of copper or cobalt complexes have been particularly popular but are often non-specific. Many methods have been concerned with simulated ideal samples rather than real samples, and their authors have sometimes admitted that the results did not agree with those obtained by other techniques or recommended methods. Indirect AAS methods are limited in that the nature or composition of the sample must be known so that likely interferences can be dealt with. They should have found applications as routine methods, but few have been adopted, in spite of the many claims that they are rapid, sensitive and accurate.

Some of the methods do not distinguish between individual members of a class of compounds in a mixture, but merely determine the total concentration of that class of compounds in terms of the reactive group. Some of these methods could be useful for comparative routine assessment of a series of samples of similar origin. This would be particularly useful if a more complete analysis would be very time-consuming or complicated. Examples will be cited later.

Many of the procedures are modifications of established spectrophotometric methods involving metal chelate formation and solvent extraction, the metal being determined by AAS. Errors can arise from contamination at the extraction stage if the metal used in the reaction is one that commonly occurs as an impurity in the solvents employed. The limitations of the original spectrophotometric methods (interferences and non-specificity) will be inherent in the procedures.

However, the indirect AAS methods may offer some advantages. They may save having to buy a particular piece of equipment required for an alternative method, or may be more rapid (and cheaper) than other procedures. The introduction of the graphite furnace has led to lower detection limits for metals, and hence for species indirectly determined.

AAS has been combined with various chromatographic techniques, including ion-exchange, and this has introduced some selectivity. The use of AAS as a detector in gas chromatography is outside the scope of this review, however.

METHODS FOR THE INDIRECT DETERMINATION OF ORGANIC COMPOUNDS BY AAS

Six approaches can be used for the AAS determination of organic species, but only two have been employed extensively—precipitation of a salt, and formation of an extractable chelate or ion-association complex. A few methods are based on the other four

---

approaches: chemical interference in the flame, chemical multiplication methods, redox methods, and direct measurement (limited to metal-containing species).

Chemical interferences in the flame

The causes of interference in flames have been widely discussed.[7–9] An absorbance signal may be depressed owing to the formation of a species which is difficult to dissociate in the flame. For example, proteins such as glucose oxidase and ribonuclease, at concentrations below $2.5 \times 10^{-4}\%$ w/w cause a decrease in the absorption signal for calcium concentrations of 4–$6 \times 10^{-4}M$.[1] The decrease is proportional to the protein concentration but differs from one protein to another. Glucose at concentrations of less than $10^{-6}M$ also causes a noticeable decrease in the absorption signal for $6 \times 10^{-4}M$ calcium.[1] These interferences have been attributed to alteration in the droplet-size distribution in the spray from the nebulizer.[9]

On the other hand, absorption signals may be enhanced. For example, nitrogen-containing compounds have been found to enhance the absorption signal of zirconium in a nitrous oxide–acetylene flame, the magnitude of the enhancement being proportional to the concentration of nitrogen compound.[10] Aliphatic and aromatic amines and aminoacids may be determined; the enhancement has been attributed to the formation of relatively volatile and easily atomized compounds containing zirconium–nitrogen bonds.

Chemical multiplication procedures

These methods are really a subclass of the precipitation and complexation methods. They are based on formation of compounds having a high molar ratio of the element measured in the final step, to the species to be determined. For example, heteropoly acids are used as precipitants for organic bases, which can thus be determined by AAS measurement of the molybdenum content of the precipitate. Strychnine and brucine have been determined in this way, by reaction with molybdophosphoric acid (MPA) to give a precipitate;[11] the excess of MPA is masked with citric acid and the MPA–organic base species is extracted into methyl isobutyl ketone (MIBK), followed by stripping of the molybdenum into a basic buffer and AAS measurement at 313 nm. Alternatively, the organic phase may be aspirated directly into the flame for the molybdenum determination. Quinoline can be determined similarly. This method, which is not selective, can determine strychnine, brucine and quinoline in the ranges 0–40, 0–45 and 2–16 μg/ml respectively.

Redox methods

In these procedures a metal is used to reduce an organic species and AAS is used to measure the amount of metal ion produced, or alternatively a

metal ion is reduced to the elemental form by the organic species and AAS is used to measure either the amount of metal produced or the decrease in the metal ion concentration. A typical method is the determination of chloramphenicol and its esters in pure form, suppositories, eye drops, capsules and oral suspensions, without prior extraction.[12] The chloramphenicol is reduced with cadmium metal, and the cadmium ions produced are determined by potentiometric titration, spectrophotometry or AAS. All three methods give consistent results, the AAS method having a 98% recovery (standard deviation 2%). An alternative is slightly more complicated; the nitro group is reduced with zinc to yield a substituted hydroxylamine, which in turn is reacted with Tollen's reagent to yield silver, which is then dissolved in nitric acid and determined by AAS.[13] This method suffers interference from any reducing compounds present. Hassan and Eldesouki[12] claim that the cadmium reduction method is superior in some respects to other methods. For example, the argentimetric and spectrophotometric methods are not applicable to many pharmaceuticals, because of interference by excipients, whereas the cadmium method gives results in agreement with those obtained by the official method.[14] The use of Tollen's reagent for determination of aldehydes by means of its reduction to silver will be discussed below, under applications.

Direct measurements

Some organic species contain metals and thus can be determined by AAS directly. The determination of cyanocobalamine (vitamin B_{12}), which contains one atom of cobalt per molecule of the vitamin, has been reported.[15–19] Large positive errors are likely by the AAS method if the vitamin is contaminated with ionic cobalt, but some authors suggest prior extraction of the ionic cobalt with a chloroform solution of 8-hydroxyquinoline.[16] Injections and liquid preparations containing cyanocobalamine may be aspirated directly into the flame, but tablets and powders must be wet-ashed first with concentrated sulphuric and nitric acids. When internal standards are used, good agreement with USP standard methods is obtained. Peck[19] has developed an electrothermal atomization (ETA) method for the determination of vitamin B_{12} in which liquid formulations or tablets are dissolved in water, acidified with hydrochloric acid and injected into a graphite furnace. A calibration graph for 0–30 ng/ml cobalt is made.

The soap content (calculated as sodium oleate) of commercial samples of refined olive oil may be determined by analysis for sodium.[20] The oil is treated with absolute ethanol, the mixture dissolved in ethyl methyl ketone and the solution aspirated directly into the flame. A linear calibration graph is obtained if virgin olive oil and known amounts of sodium oleate in the range 3–1000 ppm are used. Errors will occur if any other source of sodium is present.

Dimethylarsinic acid (DMAA) has been determined[21] in sea-water after preconcentration on an ion-exchange column and chromatographic separation from other arsenicals and from Group I and II metals (which interfere in the final determination). A 20-ml sample containing a 10^5-fold ratio of inorganic arsenic to DMAA may be analysed with a detection limit of 0.02 ng/ml and recoveries of 100–102% (standard deviation 6.3%).

The trimethylselenonium ion has been determined in urine[22] after separation on a Dowex 50 W-X8 column with 4M hydrochloric acid. After digestion in a Teflon high-pressure vessel at 200°, and treatment with hydroxylammonium chloride, the selenium is extracted with dithizone in carbon tetrachloride and determined by AAS.

The speciation of some eleven mercury compounds has been studied by differential AAS.[23] The method was applicable to mercury-containing compounds in aqueous solution and in biological fluids.

Organotin compounds have been analysed for tin by direct AAS measurement,[23a] and the same method should be suitable for the assay of the tin compounds if they occur individually and their identity is known. Organoantimony compounds have similarly been analysed.[23b]

Precipitation procedures

The element or species of interest is precipitated in some form that contains another element determinable by AAS. This other element is then determined either in the precipitate (dissolved in a suitable solvent) or in the filtrate. Filtration is not always necessary if the precipitate is too refractory to be atomized in the flame. Thus, in the indirect AAS method for determination of sulphate by addition of barium, the barium sulphate does not yield any barium atoms in the flame. This simplified procedure does not seem to have been reported for measurement of organic species.

The metal ions used most frequently for precipitation methods are silver, and copper and nickel. Oxidation or reduction may also be involved when silver ions are used and the methods are then not specific for a particular reducing or oxidizing species. The methods using copper and nickel ions involve the formation of insoluble or extractable species with the analyte either directly or after its conversion into some suitable ligand. Many ligands form copper or nickel complexes, so the methods are non-specific and interferences are likely with real samples.

Ion-association or chelate complex formation followed by solvent extraction

The organic species (with an auxiliary species if necessary) is reacted with an excess of a metal ion to form an uncharged complex or ion-association compound which is then extracted into an organic solvent. The absorbance of the metal in the extracted species is measured in the flame, or alternatively the

unreacted metal remaining in the aqueous phase is measured and hence the organic species is determined. In another approach the species of interest acts as an interfering masking agent in the solvent extraction of a metal complex. The decrease in the concentration of metal extracted is measured by AAS and is proportional to the amount of organic analyte present in the aqueous phase.

Most chelating agents form co-ordinatively saturated neutral complexes of metals, and these are readily extracted. Ligands such as 1,10-phenanthroline form charged complexes which can be extracted into an organic solvent on neutralization of the charge with a bulky inorganic or organic anion. Hence such organic anions can be indirectly determined.

Organic solvents such as ketones, esters, alcohols, ethers, aliphatic and aromatic hydrocarbons, and nitro compounds may be used for extraction of the complexes. Electrothermal atomization possesses an advantage over flame atomization in that the range of solvents which may be used is less restricted, and the problems of toxic combustion products and other undesirable combustion characteristics are totally eliminated because very small amounts of sample solution are used. In general, the use of organic solvents in flame AAS improves the sensitivity of the metal determination and hence of the organic compound determination.

A wide range of applications has been reported, many of which are related to pharmaceutical analysis. The metal ions most frequently used are copper and cobalt. Iron, bismuth, zinc, and chromium have also been used. Most of the chromium methods involve use of Reinecke's salt [ammonium tetrathiocyanatodiamminochromate(III)].

Some indirect AAS methods involve several stages, one of which may involve conversion of the analyte into another species capable of complexation. Many of the methods are rapid and sensitive but they are often non-specific. In some cases prior separation of the components by chromatography or ion-exchange is advisable.

The compounds or classes of compounds will be dealt with in alphabetical order. Compounds such as acids, amino-acids and amines are listed under their class names but more complex molecules or compounds of special interest such as histamine will be found under their individual names. Alkaloids are listed as bases, and thiols and thiocarbamates as sulphur-containing compounds. Chelating agents and detergents have received attention as groups of compounds, and are listed under these headings.

Acids

Aromatic carboxylic acids such as phthalic acid, anthranilic acid and β-hydroxynaphthoic acid may be determined by AAS by formation of their ion-

association compounds with a metal–phenanthroline complex. Phthalic acid[24,25] may be determined by extraction as the ion-pair formed by biphthalate with copper(I)–neocuproine (2,9-dimethyl-1,10-phenanthroline; NC complex; [Cu(NC)$_2$][C$_6$H$_4$(CO$_2$)(CO$_2$H)]) into methyl isobutyl ketone (MIBK). The copper content of the organic phase is proportional to the initial concentration of the acid in the aqueous phase over the range 0–4 × 10^{-5}M, with a relative standard deviation of 1.0%. If isomers of phthalic acid are present, errors of up to 10% result. Anthranilic acid may be determined similarly by formation of its cobalt(II) bathophenanthroline (4,7-diphenyl-1,10-phenanthroline) ion-association complex[26] (linear calibration for 3–22 μg/ml; 99.5% recovery) or by formation of its iron(III) complex in acetate buffer (pH 5.9), and extraction into MIBK.[27] β-Hydroxynaphthoic acid at concentrations of 8 × 10^{-5}–4 × 10^{-4}M has been determined indirectly by the solvent extraction of tris(1,10-phenanthroline)nickel(II) β-hydroxynaphthoate into nitrobenzene, followed by measurement of the nickel in the organic phase.[28]

The determination of dissolved free fatty acids has been of great interest and importance for oceanographers for many years. Treguer et al.[29] have proposed a method for the determination of total free fatty acids in sea-water, from which the acids are extracted with a chloroform–heptane mixture. A copper complex is formed when a mixture of triethanolamine, acetic acid and copper sulphate is then added. The mixture is centrifuged and an aliquot of the organic phase evaporated to dryness, then ammonium pyrrolidine dithiocarbamate in MIBK is added. The complexed copper is determined by AAS. The speed of the method (which has a precision of ± 10%) and the fact that only one litre of water is required are the main advantages. The method is also applicable to the determination of long-chain free fatty acids (longer than C$_{10}$) at concentrations of 10–40 μg/l. Another method for total fatty acid determinations[30] also involves the formation of copper complexes and extraction into a chloroform–heptane–ethanol mixture (which does not give a smoky flame). In this method the non-esterified acids in serum can be determined simply and easily, with a relative standard deviation of 4.2%.

Alcohols

Thirteen alcohols have been determined by use of a simple technique based on the chromium complexes formed when a benzene solution of the alcohols is added to a reagent solution of chromium(III) iodide and pyridine in acetic acid.[31] The benzene phase is separated, dried with anhydrous sodium sulphate, filtered and mixed with methanol. Chromium is determined in the extract. The method is not specific and cannot be used to determine isopropyl alcohol.

Aldehydes and ketones

The determination of micromolar quantities of

aldehydes has been reported.[32,33] Tollen's reagent is used to oxidize the aldehydes to the corresponding carboxylic acids.[32] The reduced silver is filtered off, dissolved in nitric acid and the silver determined. Alternatively the silver in the filtrate is determined. This method was found to be advantageous for determining the "total aldehyde" content in many systems containing a number of aldehydes, e.g., distilled liquors, flavourings, or perfumes. The working range of aldehyde concentration (0.1–1.0 × 10^{-4}M) corresponds to a 2–20 μg/ml range for silver and the relative standard deviation[13] is 1.2–5.8% in the 1–4 μmole/ml range. A very similar method was used by Mitsui and Kojima[34] for determination of aldehydes at concentrations of 0.002–0.231 g/l. Many alcohols and phenols do not interfere, but o- and p-aminophenol, resorcinol, benzoin and benzil do.

Low molecular-weight ketones and aldehydes (acetone, cyclopentanone, ethyl methyl ketone, propionaldehyde, butyraldehyde and formaldehyde) may be determined by AAS.[35] Copper complexes are formed by addition of thiosemicarbazide and copper acetate. The mixture is heated to 70°, then cooled, and the copper complexes are extracted into benzene. The copper content of the organic layer is determined but there are some interferences from species such as cobalt(II), nickel(II), silver(I), zinc(II), isopropylamine and chlorobenzene. No interferences from magnesium(II), ninhydrin, isatin, phenanthrequinone, phenylacetaldehyde, p-dimethylbenzaldehyde, cinnamaldehyde or salicylaldehyde were reported. Recoveries of 96.7–102.2% were obtained for 0.01–2.01 mg of the organic species, but the method is not specific.

Amines

This class of compound may be determined indirectly by AAS in several ways. Mitsui and Fujimura[36] have described a method for the determination of primary amines in amounts greater than 1 mg, based on complexation with a reagent containing triethanolamine, 5-nitrosalicylaldehyde, acetaldehyde, and copper sulphate. Copper is determined either in a solution of the precipitate in nitric acid, or in the filtrate. The method suffers from some interferences, e.g., from zinc, magnesium and calcium, but secondary and tertiary amines do not interfere if they are present in not more than 20–30-fold w/w ratio to the determinand.

The reaction of secondary amines with carbon disulphide to give dialkyldithiocarbamic acids (DDTCH) has been utilized in an indirect AAS method for their determination in micromolar quantities.[37] The nickel complex, Ni(DDTC)$_2$, resulting from the reaction between carbon disulphide and the secondary amine in the presence of an ammoniacal nickel solution, is separated from the reaction medium, and dissolved in benzene–acetone (1:1 v/v); the solvent is evaporated, then the residue is digested

with HCl–HNO$_3$, and diluted with water, and the nickel is determined. The calibration graph for nickel is linear over a range corresponding to 2–15 μmoles of nine secondary amines. The practical detection limit is about 0.30 μmole/ml of secondary amine with a relative standard deviation of 7.3–12%. The reaction time is 1.5–2 hr, which is a disadvantage. Primary amines interfere and must be removed.

Hexylamine, diethylamine, triethylamine, dibutylamine, cyclohexylamine, diethanolamine and piperidine in quantities up to 0.5 mg have been determined in a procedure[38] based on the reaction between the protonated amine and tetrathiocyanatocobaltate(II). The complexes are formed when the reactants (in acetone) are warmed on a water-bath. After evaporation of the solvent, a few ml of benzene are added, a portion of this solution is diluted with methanol, and the cobalt content is measured by AAS. Many organic compounds do not interfere in this method and recoveries are reported to be between 96 and 103.7%.

Long-chain primary amines are sometimes added to boiler water as anti-corrosion agents. A sensitive AAS method for monitoring octadecylamine in cooling circuits of power stations is capable of determining 0.1–1.0 μg/ml concentrations of the amine.[39] A mixture of 10% sulphuric acid, 5% aqueous potassium chromate, sodium sulphate and 1,4-dioxan is added to the sample containing the amine, and the whole shaken for 1 min. The ion-association complex of chromate and protonated amine is extracted into nitrobenzene and the chromium content determined by using an air–acetylene flame. The detection limit for octadecylamine is stated to be 0.02 μg/ml. Interfering materials are normally present only in negligible concentrations in boiler waters.

Amino-acids

This class of compound has been determined by use of copper(II) solutions. A method claimed to be sensitive, reproducible, and specific has been proposed for the determination of total urinary amino-acids,[40] based on the formation of copper complexes in a borate–phosphate buffer solution. Copper is determined (air–acetylene flame) in the supernatant liquid, after centrifuging. Gawargious et al.[41] have described a similar method for determining α-amino-acids. Glycine, valine, phenylalanine, tyrosine, tryptophan,[42] and L-methionine and L-histidine[43] may be determined by reaction of the acids with salicylaldehyde in alkaline solution to give Schiff's bases which can be complexed with copper(II) and subsequently extracted into MIBK in the presence of bathophenanthroline. The copper is determined by AAS, and linear calibration graphs are obtained for 1.5–15.0 μg/ml of glycine, and 3.0–30 μg/ml for L-histidine and L-methionine. The last two amino-acids may both be determined in a mixture by extraction at different pH values. The relative standard deviation was about 2% and the

recovery > 97%, but the methods are not specific and not of wide applicability. The same applies to a similar procedure reported for the determination of p-aminobenzoic acid in pharmaceutical products, in which the acid is reacted with copper(II) to form a 2:1 complex and extracted with bathophenanthroline in MIBK.[44] The copper in the ternary complex extracted is determined. Calibration graphs are linear for 13.7–37.0 μg/ml with a recovery of 100.6%.

Aminodeoxyhexose

This compound has been determined[45] by utilizing a reaction with pyridoxal and cobalt(II) chloride, leading to the formation of a Schiff's base complex. The unprecipitated cobalt in the filtrate is measured by AAS, enabling 0.03–0.15 mmole of the hexose to be determined, with 97.2–102.7% recovery.

Aminoquinolines

Certain aminoquinoline antimalarial compounds may be determined by formation of their ternary complexes with cobalt(II) and thiocyanate.[46] Amodiaquine (Q) and chloroquine (Q) give complexes of the type $CoQ_2(SCN)_n$ whereas primaquine (P) forms a $CoP_4(SCN)_m$ ternary complex. The cobalt in the nitrobenzene extract of the complexes may be determined by spectrophotometry or AAS but the latter has higher sensitivity and may be utilized to determine the compounds in biological fluids. There is good agreement with standard methods when pharmaceutical preparations are analysed.

Barbituric acid derivatives

Barbituric acid derivatives (0.51–16.21 mg) have been determined in pharmaceutical products by precipitation as copper pyridine barbiturate complexes.[47] The copper, either in the precipitate (after dissolution in concentrated nitric acid) or in the filtrate, is determined. Although simple and rapid, the method suffers from interferences from some metals, but this may be overcome by prior precipitation of the metals with sodium carbonate solution. Sulphonal, bromovaleryl urea and bromodiethylacetyl urea do not interfere.

Another procedure for the determination of barbiturate derivatives[48] also relies on precipitation of copper complexes. Barbital, amobarbital, phenobarbital, allobarbital, pentobarbital, and ethylhexobarbital may be determined at concentrations of 10–240 μg/ml. The unprecipitated copper in the filtrate is determined by AAS. Sedatives such as sulphonal, bromovaleryl urea, bromodiethylacetyl urea, ethinamide and glutethimide, when present in considerable excess (19–51-fold ratio to analyte), do not interfere. Interferences from metal ions (Na$^+$, K$^+$, Ni^{2+}, Co^{2+}, Zn^{2+}, and Fe^{2+}) may be eliminated by extraction of the barbiturates with chloroform at pH 6.

Bases

Organic bases such as quaternary ammonium compounds,[49] azepine,[50] phenothiazines,[51] and noscapine[52] have been determined by various techniques, all of which are non-specific. Alary et al.[49] determined 4 μmoles of quaternary ammonium compounds by addition of sodium dioctylsulphosuccinate (DOSS) in the presence of sodium chloride, shaking the mixture, and addition of copper–1,10-phenanthroline to form a complex with the excess of DOSS. This complex is extracted with MIBK and the copper determined by flame AAS. The method is convenient for the assay of pharmaceuticals that are heavy heterocyclic compounds or contain long hydrocarbon chains. It is not recommended for pharmaceutical products containing esters, amides or hydroxy groups, even though it offers good sensitivity.[49]

A number of diazepine bases may be determined by using similar procedures, all of which are unselective. At low pH (about 3), the protonated base forms a 1:1 complex with bis(2-ethylhexyl) sulphosuccinate (EHOSS). The excess of EHOSS is reacted with copper–1,10-phenanthroline, and this complex is extracted into MIBK and finally the copper is determined by AAS. One of the azepine series, opipramol, forms a 1:2 complex with EHOSS.[50] A small amount of phenothiazine (1–4 μmole) may be determined by its reaction with DOSS at pH 3. The excess of DOSS is complexed with copper–1,10-phenanthroline and extracted with MIBK, and the copper determined. If the complex formed between DOSS and phenothiazine is not sufficiently stable, an extraction stage with chloroform is included.[51]

A complex can also be formed between noscapine and Reinecke's salt at pH 1.7 in the presence of tartaric acid, and extracted into chloroform, then the chromium is determined in the organic phase.[52] Good results are claimed for synthetic and commercial samples. The method is again non-specific, since Reinecke's salt may also be utilized to determine alkaloids such as strychnine, quinine, emetine, procaine, tetracaine and ephedrine.[53] The complex is extracted into nitrobenzene and the chromium in it is determined by AAS. A large number of inorganic cations and anions, glutamates, starch, and sucrose do not interfere.

Benzylpenicillin

Low concentrations of benzylpenicillin (18.6–111.6 μg/ml) have been determined by forming an ion-pair between the compound and the tris(1,10-phenanthroline)cadmium chelate, extracting into nitrobenzene and determining the cadmium.[54] The relative standard deviation is about 2%. The procedure is simple and no interference was found from compounds such as starch, lactose, dextrin and saccharin sodium.

Biuret

This compound may be determined in mixed fertilizers and urea by AAS.[55-57] Singhal et al.[55] state that the only disadvantage is that the copper hydroxide used for complexing must be kept for 5 hr before use. The method of Woodis et al.[56] is based on treatment of an ethanolic solution of biuret with copper(II) in order to form the copper complex, which is filtered off and analysed for copper. The method was said to give more reliable results than the AOAC official method, in which no corrections are made for mixed fertilizers.[58] Corominas[57] studied the method of Woodis et al. in collaboration with ten laboratories and also concluded that the method was better than the official method for mixed fertilizers. The two methods did not differ for urea samples, and the indirect AAS method was adopted, with the AOAC method retained as an alternative for biuret in urea.

Butylscopolamine salts

Butylscopolamine bromide and butylscopolamine tannate, which are parasympathetic nerve-blocking agents have been determined in blood, urine, and faeces by formation of the ion-pair complexes with $Co(SCN)_4^{2-}$ in acidic medium in the presence of tartaric acid.[59] The complexes extracted into chloroform are analysed by AAS after dilution with MIBK or ethyl acetate. The calibration graph is linear for 3–15 μg of butylscopoline bromide and 5–30 μg of the tannate.

Chelating agents

Chelating agents such as ammonium pyrrolidine dithiocarbamate and 8-hydroxyquinoline may be determined by formation and extraction of their copper or cobalt chelates into MIBK at an appropriate pH.[1]

Ethylenediaminetetra-acetic acid (EDTA) may be determined in two ways. The first uses the masking effect of EDTA on the extraction of the copper–oxinate complex into MIBK at pH 6.5. The decrease in the AAS signal for copper is linearly proportional to EDTA concentration over the range $0–4 \times 10^{-5}M$ in the aqueous phase.[1] The second method[60] is based on addition of excess of nickel, removal of the surplus by precipitation with dimethylglyoxime and filtration, followed by release of nickel from the EDTA complex by pH adjustment, and determination by AAS. The method has been applied to determination of EDTA added to streptomycin (during manufacture) to remove alkaline-earth metal impurities. The reproducibility is ± 1.3 μg/g with a detection limit of 4 μg/g. There is no interference from phosphate, a species frequently present in pharmaceutical products.

Nitrilotriacetic acid (NTA) has also been determined by AAS,[61] in an evaluation of the toxicity of aquatic systems. The method involves AAS measurement of the amount of solid lead carbonate initially dissolved by the NTA. It is claimed that the

method is easy and rapid, and no special reagents are required. However, the procedure was designed for use in controlled laboratory studies and is not recommended for field determinations. In natural and industrial waters, other complexing agents and calcium ions would interfere. The same limitations apply to a similar method which uses the complexation of copper in alkaline media for measurement of the total chelating agents.[62] The surplus copper is precipitated, and the copper left in solution is determined by AAS. Although the method is simple and sensitive, determination of individual chelating agents requires their prior separation.

Chinoform

The drug chinoform (5-chloro-7-iodo-8-quinolinol) can be determined by extraction of its zinc chelate into MIBK[63] and AAS measurement of the zinc at 213.8 nm; a linear calibration graph is obtained for 6–30 μg/ml of chinoform.

Chlorpheniramine maleate

This compound forms a 1:1:1 ternary complex with the copper–zincon chelate in water at pH 4.3. The ternary complex is extracted into chloroform and the copper determined by AAS.[64] A linear relationship is found for 1.9–27.4 μg/ml of chlorpheniramine maleate in the aqueous phase, with a relative standard deviation of 2.2%. Although the method offers simplicity and good sensitivity, some species, such as methylephedrine and diphenylhydramine interfere.

Chlorprothixene

A method for the determination of chlorprothixene in drugs involves precipitation with a freshly prepared solution of ammonium reineckate.[65] The precipitate is filtered off and chromium in the filtrate determined by AAS. The calibration graph is linear for 8–10 μg/ml of chromium and 98.6–100.9% recovery is achieved. Other basic drugs that form insoluble reineckates interfere, but tablet additives do not.

Colchicine

Colchicine in biological samples may be determined by extraction from alkaline solution with chloroform.[66] The extract is centrifuged and evaporated, and the residue dissolved in water. This solution is reacted with isonicotinohydrazide in the presence of sodium carbonate; the hydrazone produced reacts with copper acetate to form a copper complex. There are some interferences from carbonyl-containing drugs or their metabolites. The calibration curves are linear for 3–30 mg of colchicine with recoveries of 95–98%.

Detergents

Le Bihan and Courtot-Coupez[67–71] have described several methods for the determination of anionic and cationic detergents in water. In one of these,[68] it was possible to determine anionic detergents in water at very low concentrations (from 3 ng/ml to 2.5 μg/ml, calculated as the sodium salt). The ion-association species formed with the 1,10-phenanthroline–copper complex was extracted into MIBK, and the copper determined by AAS. Traces of cationic surfactants at the 5–200 ng/ml level have been determined[69] by formation and extraction (into benzene) of the tetrathiocyanatocobaltate ion-association complex with the surfactant, followed by determination of the cobalt in the organic phase by ETA. The same authors[70] have described a modified technique for the ETA determination of anionic and non-ionic detergents in which smaller water samples and simpler extraction processes were used, permitting determination at the 10-μg/l. level.

The benzene extraction of the tetrathiocyanatocobaltate ion-association complexes and AAS determination of the cobalt has also been used for the determination of non-ionic surfactants at concentrations down to 50 μg/l. (of Triton X-100) in the presence of up to 1 g/l. of polyoxyethylene glycol.[71] The method was based on that of Greff et al.[72] The relative standard deviation was found to be up to 15% and the method suffered interference from dithiocarbamates and humic acids. A method for the determination of anionic detergents at levels below 50 μg/l., reported by Crisp et al.,[73] involves solvent extraction (into chloroform) of the ion-association complex formed with bis(ethylenediamine) copper(II), followed by ETA determination of the copper in the extract. The limit of detection is 2 μg/l. for linear alkylsulphonic acids. Recoveries are 95–100% for 100 μg of the linear alkylsulphonic acids but lower for sea-water samples. Only sulphide and iron(III) interfere; the former may be destroyed by hydrogen peroxide and the addition of EDTA suppresses interference from 100 mg/l. of iron(III). The authors point out that the Methylene Blue active-substance test[74] is not adequate for concentrations below 50 μg/l. and has a detection limit of 25 μg/l. for fresh waters and poorer sensitivities with marine and estuarine waters. The selectivity of the AAS method should be an attraction, but it is not clear whether the method has been widely adopted.

Better limits of detection (0.3 μg/l.) have been achieved in a method[75] for the determination of anionic detergents in natural (fresh and saline) waters at the μg/l. level, based on the method of Crisp et al.[73] but with a lower chloroform/sample volume ratio and measurement by graphite furnace AAS. Calibration graphs were linear for 0–50 μg/l. Crisp et al.[76] also developed a method for determination of non-ionic surfactants at concentrations of 0.05–2 mg/l. by formation of the neutral adducts with potassium tetrathiocyanatozincate (at pH 6–8), extraction of these into 1,2-dichlorobenzene, stripping of zinc into dilute hydrochloric acid and its determination by flame AAS. Solutions of Triton X-100 were used as standards. Anionic surfactants do not produce large

errors (e.g., only the equivalent of 0.07 mg/l. when present at 5 mg/l.), but sulphides, iron(III), aluminium(III) and chromium(III) interfere at the 0.1-mg/l. level and copper(II) interferes at 10 mg/l. Soaps at 1.0 mg/l. do not interfere but cationic surfactants form extractable ion-association species with $Zn(SCN)_4^{2-}$ and interfere.

A precipitation technique has been used for the determination of 0.1–1.2 mg of non-ionic detergents in water and sewage samples.[77] A 5-litre sample is extracted with ethyl acetate by a foaming technique, the organic extract is evaporated, and the dry residue is mixed with molybdophosphoric acid solution and barium chloride. The unconsumed molybdenum present as molybdophosphoric acid after centrifugation or filtration is determined by AAS. The recoveries range from 97.3 to 102.1% and the method may be applied to samples containing proteins or calcium, magnesium or manganese salts.

Diketones

Minami et al.[78] have developed an indirect AAS method for the determination of 0.05–2.0 mg of biacetyl. The sample is heated with hydroxylammonium chloride and sodium acetate, then a known amount of nickel is added to precipitate the dimethylglyoxime formed and the nickel in the precipitate or the surplus nickel in the solution is determined. It is difficult to imagine applications to analysis of real samples, but the method is said to be free from interference from cations and many organic compounds such as acetone, ethyl acetate, ethanol, acetic acid and phenol. However, the method could probably be adapted for determination of hydroxylamine in water by the Pittwell method.[79]

Diols

Oles and Siggia[80] have described a rapid, sensitive AAS method for the determination of micromolar quantities of 1,2-diols in the presence of 1,3-diols. The 1,2-diols are oxidized with periodic acid and the iodate formed is separated by precipitation as silver iodate which is then dissolved in ammonia solution and analysed for silver. The precision of the method is 0.9–5.0% for 0.3–4.0 μmole of the 1,2-diol per ml. The practical limit of detection is 0.2 μmole/ml. This procedure was found to be particularly useful for the determination of 1,2-diol impurities in compounds containing non-adjacent hydroxyl groups. The sensitivity is equal to or greater than that of other procedures.

Esters

Aliphatic esters at concentrations of 0.04–3.5 mg/ml have been determined[81] by a procedure involving production of a ferric hydroxamate, followed by removal of surplus iron(III) as basic benzoate. The iron in the hydroxamate is determined by AAS. Potassium, magnesium, calcium, diethyl ether, acetone, acetic acid, aniline, nitrobenzene, pro-

pionaldehyde and phenol may be present, but there are interferences from copper and aluminium. Recoveries are between 92.4 and 105%.

Ethambutol

Up to 400 μg/ml of ethambutol has been determined by formation of its copper complex in alkaline medium (pH 8–11.5), extraction into methyl ethyl ketone and determination of copper in the extract.[82] The method is of limited application because so many other compounds form copper complexes.

Ethinyloestradiol

A suitable method for the determination of ethinyloestradiol in tablets[83] involves treatment by nitrous acid to form the O-nitrosoderivative, which is then converted into the cobalt chelate by treatment with sodium cobaltinitrite in acetic acid. The procedure gives a linear calibration graph for 0.5–1.0 mg of ethinyloestradiol.

Flufenamic acid

Minamikawa et al.[84] observed that flufenamic acid forms a chelate with copper in the presence of 2-(2-hydroxyethyl)pyridine and developed an indirect method for the determination of the compound in biological samples by extraction of the chelate into propyl acetate and AAS determination of the copper. The method is more sensitive than the thin-layer chromatographic method, and can be applied to samples without separation or preconcentration procedures.

Folic acid

Folic acid may be oxidized by potassium permanganate to 2-amino-4-hydroxypteridine-6-carboxylic acid, which reacts with nickel(II) to form a metal complex.[85] This complex, on extraction with MIBK in the presence of bathophenanthroline is converted into an ion-association complex which is then analysed for nickel. The method has been applied to pharmaceutical preparations and has a relative standard deviation of 1.8% at the 1.2–20 μg/ml level. The method shows no interference from nicotinamide, pyridoxal phosphate, thiamine, cyanocobalamine, calcium pantothenate, retinol acetate and riboflavine.

Histamine

Histamine in animal tissues and urine may be determined[86] by formation of the histamine–copper(I) cationic chelate which can be extracted as its ion-association complex with picrate into nitrobenzene. Copper is then determined in the organic phase. Many inorganic compounds may be present in 100-fold ratio to histamine without interfering but serotonin and histidine interfere strongly, an effect which may be depressed by addition of iron(II). Catecholamines (adrenaline, noradrenaline and dopamine) do not interfere if present in less than

fivefold molar ratio to histamine (up to $2 \times 10^5 M$). In the concentration range from $5 \times 10^{-6} M$ (0.92 μg/ml) to $3 \times 10^{-5} M$ (5.52 μg/ml) the relative standard deviation is 2%.

Hyoscine-N-butylbromide

Hyoscine-N-butylbromide in pharmaceutical preparations[87] can be determined by extraction of its ion-association complex with tetrathiocyanato-cobaltate(II), and AAS analysis for cobalt. The complex is readily soluble in most organic solvents, but 1,2-dichloroethane, in spite of its toxic combustion products, is the most suitable. A linear relationship was found for the 5×10^{-5}–$7 \times 10^{-4} M$ concentration range.

Isonicotinylhydrazine

This compound may be determined by formation of the isonicotinylhydrazine–copper chelate and extraction into MIBK.[88] The method is suitable for determination of the compound in pharmaceutical products. Determination of copper gives a linear calibration graph for concentrations of iso-nicotinylhydrazine in the range 0.2–1.7 $\times 10^{-4} M$ with a relative standard deviation of 0.4%.

Malathion

The compound is hydrolysed to give dimethyl-dithiophosphate (DMDTP) which is then reacted with bismuth(III) to give a complex extractable into MIBK.[89] The bismuth–DMDTP complex is used for calibration.

Methylamphetamine hydrochloride

Methylamphetamine hydrochloride (down to 16 μg/ml)[90] has been determined in drugs by precipitation as a bismuth complex, on addition of 7% hydrochloric acid and 7% potassium iodide solution saturated with bismuth(III) chloride. The unconsumed bismuth in the filtrate is determined by AAS. The determination may be done in the presence of ephedrine hydrochloride; metal ions and certain organic species do not interfere up to certain concentrations. Interferences can be eliminated by prior extraction of the methylamphetamine hydrochloride into chloroform. A more sensitive method[91] has been described for the determination of methyl-amphetamine, and also diethylamine hydrochloride and ephedrine hydrochloride, by reacting the amines with carbon disulphide in the presence of copper(II) and ammonia solution. The copper complex is extracted into MIBK for determination of copper. Linear calibration graphs for 1.9–8.0 μg/ml of methyl-amphetamine hydrochloride, 1.1–6.6 μg/ml of diethylamine hydrochloride and 1.2–8.0 μg/ml of ephedrine hydrochloride are reported. The recoveries range from 93.3 to 103.2% and it is claimed that the method is quicker than the precipitation method with bismuth.

Nitro groups

The method involves oxidation of the nitro group to nitrate with cerium(IV) sulphate or potassium permanganate.[92] The nitrate formed is then treated with copper–neocuproine complex to form an ion-pair which is extracted into MIBK, and the copper is determined. Tollen's reagent may also be used for the determination of some nitro-compounds.[13] The nitro group is reduced to the substituted hydroxylamine with zinc powder, then treated with Tollen's reagent to yield metallic silver. The precipitate is dissolved in nitric acid and the silver determined by AAS. Good precision is claimed but there are interferences from resorcinol, benzoin, p-aminophenol and ninhydrin. Benzoic acid, aniline, benzaldehyde and p-nitroso-N,N-dimethylaniline up to 2.5 times the concentration of the nitro-compound do not interfere. Interferences from metal ions are eliminated by prior extraction of the nitro-compounds into benzene.

Oxalic acid

In recent years there has been increasing demand for a method for determination of oxalic acid in urine samples, because calcium oxalate stones can form in the urinary system and routine clinical tests are required for urine samples. Two routine AAS micro-methods are based on the precipitation of oxalate with an excess of calcium ions at pH 5.[93,94] The calcium in the precipitate from the aliquot used is determined from the difference between the amount of calcium left in the supernatant liquid, and the total calcium in a second aliquot treated with the same amount of added calcium but at pH 2. Both methods give 95% recovery and are free from interferences from phosphate, ammonium, magnesium(II), and uric acid even at high concentration. Although the method of Koehl and Abecassis[94] gave a better precision (standard deviation 3.0 mg/l. for thirty 17-mg/l. samples) than that of Menache[93] (standard deviation 7.5 mg for a range of 0–40 mg), it is more time-consuming, the precipitation taking 48 hr.

Phenols

A number of phenols can be determined by forming their cobalt complexes by heating with sodium cobaltinitrite in acetic acid to 100°,[95] extracting into MIBK and analysing the organic phase for cobalt by AAS. Recoveries are 94.6–104.5%. Copper(II) and iron(III) interfere and the presence of aniline is a disadvantage. In another method,[96] catechol may be determined by extraction of its copper chelate into chloroform in the presence of trioctylmethyl-ammonium chloride. The extract is diluted with methanol and the copper determined by AAS; a linear relationship is found for the range 11–176 μg/ml. Many cations and anions do not interfere. Pentachlorophenol (PCP) may be determined by extraction as $[FePhen_3][C_6Cl_5O]_2$ into nitrobenzene from an aqueous phase containing an excess of

tris(1,10-phenanthroline)iron(II).[97] Concentrations in the range $0–3 \times 10^{-4}M$ may be determined.

Phenylacetylene

Phenylacetylene has been determined by Smith and Bailey[98] by reaction with ammoniacal silver nitrate at room temperature to form silver acetylide. The precipitate is washed, separated and dissolved in piperidine, and the silver is determined, either in the precipitate or in the supernatant solution. In the first technique, the calibration curve was linear for 1.0–4.0 μg/ml of silver with a mean recovery of 100.4% and a relative standard deviation of 6.5%. In the second technique the calibration curve was linear for 2.5–7.5 μg/ml of silver with a mean recovery of 100.3% and a relative standard deviation of 2.9%.

Porphyrins

Porphyrins have been determined by separation as their copper chelates.[99] The method is claimed to simpler and more suitable for routine use than the spectrophotometric method.

Sugars and polyhydroxy compounds

A method for the determination of sugars in plant material reported by Potter et al.[100] has the advantage of simplicity as well as good agreement with the official method. The AAS method utilizes the reduction of copper(II) in alkaline solution to insoluble copper(I) oxide, which is separated by centrifugation; the unreduced copper(II) in solution is then determined by AAS. Other reducing agents present will interfere so the method is not specific. Compounds such as glycerol, lactose, saccharose, glucose, and tartaric acid[33] have been determined in ethanol samples by utilizing their reaction with periodic acid to yield iodate, which is then precipitated by addition of silver nitrate solution. The silver iodate is washed with dilute nitric acid and water, then dissolved in ammonia solution, and the silver is determined by flame AAS. Limits of detection are 0.2–1.9 mg.

Sulphur-containing compounds

Several organic sulphur-containing compounds may be determined by precipitation of their silver compounds, followed by determination of the excess of silver in solution or in the precipitate after its dissolution in nitric acid.[101,102] The first procedure[101] was used to determine mercaptobenzothiazole and xanthates; good recoveries were obtained but this can be attributed to decomposition of the precipitate in the case of xanthate. The second procedure[102] gives an analysis time of 15 min per sample for the determination of total thiol content at the level of 0.8–20 μmole/ml, with a relative standard deviation of 0.8–3.2%. Individual thiols cannot be determined and hydrogen sulphide interferes. Compounds not containing sulphur but giving insoluble silver salts also interfere. Hence the method has also been used

to determine iodoform, theobromine and sodium salicylate.[10]

Electrothermal AAS has been used for the determination of the metabolites of tetramethylthiuramdisulphide[103] and tetraethylthiuramdisulphide,[104] (sodium dimethyldithiocarbamate and sodium diethyldithiocarbamate respectively). The method is based on formation of the copper dithiocarbamate complex, its extraction into carbon tetrachloride, and injection of the extract into the graphite furnace. The method offers a limit of detection of 0.5 mg/l., with linear calibration graphs for 1–10 mg/l.

Tannins

Tannins in aqueous tea extracts have been determined[105] by precipitation with copper acetate followed by AAS determination of copper, either in the precipitate (dissolved by digestion with a mixture of nitric and sulphuric acids) or in the filtrate. The authors report that the results agreed with those obtained gravimetrically but it would appear that the AAS method offers very little advantage.

Vitamin B_1

Hassan et al.[106] have developed a simple, rapid and accurate method for the determination of vitamin B_1 in pharmaceutical preparations, based on desulphurization with potassium plumbite and precipitation of lead sulphide. The unreacted lead(II) is measured by AAS. The method takes only 15 min. It is accurate and sensitive with a linear calibration graph for 1–10 μg/ml of lead. Recovery for pure vitamin B_1 was found to be 99.1% with a standard deviation of 0.8%. The effects of several common excipients and diluents used in the preparation of capsules, tablets and suspensions were examined. Magnesium stearate, talc, sodium citrate, carboxymethyl cellulose, Tween 80, poly(vinyl pyrrolidone), glucose and lactose in large amounts showed no interference. There was also no effect from vitamins B_2, B_6, B_{12} and nicotinamide.

CONCLUSIONS

Many of the authors of papers dealing with indirect AAS methods for the determination of organic species have claimed that their methods are rapid, simple, accurate, and sensitive. If the nature of the matrix and the likely interferences are known, some of the methods may offer some advantages, but few have found applications for real samples. Some procedures are specific and give results which agree with those of official methods, e.g., the cadmium reduction method for the determination of chloramphenicol[12] and the copper precipitation method for biuret,[56] and the latter has undergone laboratory trials that prove it to be better than the official method for mixed fertilizers.

Table 1. Principal metals used in organic analysis by AAS

Metal	Reaction or product	Applications
Chromium	Formation of reineckate	Alkaloids,[53] noscapine,[52] chloroprothixene[65]
	Complex formation	Alcohols,[31] octadecylamine[39]
Cobalt	Tetrathiocyanatocobaltate complex	Amines,[38] aminoquinoline antimalarials,[46] butylscopolamine,[59] detergents,[69] hyoscine-N-butylbromide[87]
	Schiff's base complex	Aminodeoxyhexose[45]
	Cobalt complex	Ammonium pyrrolidine dithiocarbamate,[1] ethinyloestradiol,[83] phenols[95]
	Bathophenanthroline ternary complex	Anthranilic acid[26]
Copper	Ternary or ion-association complex	Amino-acids,[42-44] azepine,[50] bases,[49] chlorpheniramine maleate,[64] detergents,[68,70,73] diazepines[50] flufenamic acid,[84] histamine,[86] nitro compounds,[92] noscapine,[52] phenothiazines,[51] phthalic acid,[24,25] quaternary ammonium salts[49]
	Complex formation	Aldehydes and ketones,[35] catechol,[96] colchicine,[66] diethylamine,[91] dithiocarbamates,[1,103,104] ephedrine hydrochloride,[91] ethambutol,[82] fatty acids,[29,30] 8-hydroxyquinoline,[1] isonicotinyl hydrazine,[88] methylamphetamine hydrochloride,[91] porphyrins[99]
	Masking of oxine complex	EDTA[1]
	Precipitation	Amino-acids,[40,41] barbiturates,[47,48] biuret,[55-57] primary amines,[36] sugars,[100] tannins[105]
Nickel	Precipitation	Aliphatic secondary amines,[37] biacetyl,[78] EDTA[60]
Silver	Reduction to metal	Aldehydes,[32-34] nitro compounds[13]
	Precipitation of silver iodate	Diols,[80] sugars,[33] tartaric acid[33]
	Precipitation of silver iodide	Iodoform[101]
	Precipitation of silver acetylide	Phenylacetylene[98]
	Precipitation of silver salt	Salicylate,[101] sulphur compounds,[101,102] theobromine[101]

However, many of the indirect AAS methods can be said to be notable for their ingenuity and little else. It has been pointed out that trace organic analysis presents more difficulties than does inorganic trace analysis.[107] Separation procedures are used extensively (except for a few cases of highly specific enzymatic methods) and the various chromatographic techniques are still the most favoured, followed by a final determination step which is specific.

For convenience in cross-reference, the main applications are listed according to the metal used in the final determination, in Table 1.

FLUORESCENCE PROPERTIES OF SOME SCHIFF'S BASES DERIVED FROM 3-HYDROXYPYRIDINE-2-ALDEHYDE AND OF THEIR METAL CHELATES

FLUORIMETRIC DETERMINATION OF MANGANESE BASED ON ITS CATALYTIC EFFECT ON THE OXIDATION OF THESE COMPOUNDS WITH HYDROGEN PEROXIDE

J. Vazquez Ruiz, A. Garcia de Torres and J. M. Cano-Pavon*

Department of Analytical Chemistry, Faculty of Sciences, The University, Malaga-4, Spain

Summary—The fluorimetric properties of the oxime, thiosemicarbazone, azine and 2-pyridylhydrazone of 3-hydroxypyridine-2-aldehyde have been studied; quantum yields have been measured in ethanol–water and ethanol–dimethylformamide media. Two kinetic methods are described for the determination of trace amounts of manganese(II), based on its catalytic effect on the oxidation of the thiosemicarbazone and of the azine by hydrogen peroxide. The reactions are followed by measuring the rate of change of the fluorescence. The calibration graph is linear over the manganese range 5–50 ng/ml with a precision of ±3.0% for the thiosemicarbazone, and 0.4–0.9 µg/ml with a precision of ±2.0% for the azine. Interferences by foreign ions have been investigated.

The fluorescence of Schiff's bases derived from salicyladehyde has been widely studied, as well as that of their metal chelates. The complexes of zinc with salicylaldehyde thiosemicarbazone, semicarbazone and acetylhydrazone have been investigated by Holzbecher,[1] although no analytical applications have been proposed. Other aromatic Schiff's bases, such as 2-hydroxyaniline-*N*-salicylidene (salicylidene-*o*-aminophenol) react with aluminium, gallium, beryllium and other metal ions to form complexes which give a fluorescent emission that can be utilized for the determination of these ions.[2] Recently, seventeen aromatic Schiff's base derivatives with alkyl groups *m*- or *p*- to the –CH=N– group of salicylidene-*o*-aminophenol have been described,[3] and the effects of the substituent groups on the fluorescence properties of their metal complexes reported.

Oxidations of Schiff's bases have been used as indicator reactions in oxido-reduction catalysis, especially when the reaction rate is determined by means of fluorimetric measurements. Kinetic fluorimetric methods for determination of traces of copper(II), mercury(II) and platinum(IV), based on their catalytic effects on aerial oxidation of 2,2′-dipyridyl ketone hydrazone have been described.[4,5] Titanium has been determined by a similar procedure involving oxidation of picolinaldehyde nicotinoylhydrazone.[6] A kinetic determination of traces of copper(II) by its catalytic effect on the oxidation of 4,4′-dihydroxybenzophenone thiosemicarbazone by hydrogen peroxide has been established.[7] Recently, a kinetic fluorimetric determination of nanogram amounts of manganese, based on its catalysis of the oxidation of 2-hydroxybenzaldehyde thiosemicarbazone with hydrogen peroxide has been described.[8]

In this paper, the fluorescence properties of the following compounds derived from 3-hydroxypyridine-2-aldehyde, as well as their metal chelates, have been studied: 3-hydroxypyridine-2-aldoxime (I), 3-hydroxypyridinaldehyde thiosemicarbazone, 3-OH-PAT (II), and 3-hydroxypyridinaldehyde azine, 3-OH-PAA (III). Results are compared with those for pyridine-2-aldehyde 2-pyridylhydrazone (IV). These compounds have been used previously in the photometric determination of diverse metal ions, and their physicochemical properties described.[9–11] Compound IV has been used by us in the fluorimetric determination of aluminium.[12]

EXPERIMENTAL

Apparatus

Fluorescence measurements were made with a Perkin-Elmer 204 spectrofluorimeter, equipped with a xenon-lamp source and an Ultrathermostat Colora K-5, and 1.0-cm quartz cells. Fluorescence curves were corrected with a standard solution of quinine sulphate.

Synthesis of reagents

These were synthesized as previously described[9-12] and identified by elemental analysis, melting point, and infrared and NMR spectroscopy.

Reagents and solutions

All reagents were used as $10^{-3}M$ solutions in ethanol. More dilute solutions were prepared as required from these solutions, which were stable for at least 1 week. All solvents and reagents were of analytical grade. Buffer solutions (pH 9.3 and 9.7) were prepared from $2M$ ammonium chloride and $2M$ ammonia solutions (pH 9.7: 214 ml of NH_4Cl solution and 586 ml of NH_3 solution, diluted to 1 litre; pH 9.3: 382 ml of NH_4Cl solutions and 418 ml of NH_3 solution, diluted to 1 litre).

Measurement of fluorescence quantum yields

The procedure described by Parker *et al.*[13] was used. It is based on the integrated area (F) under the fluorescence emission spectrum being proportional to the total intensity of the fluorescence emitted by the solution, this in turn being proportional to the product $I_0\phi\varepsilon cd$, where I_0 is the excitation intensity, ϕ the quantum yield, ε the molar absorptivity, c the concentration and d the path-length. If the fluorescence emission spectra of two solutions are measured with the same apparatus and the same excitation intensity, the ratio of the two fluorescence intensities is given by

$$\frac{F_2}{F_1} = \frac{\phi_2\varepsilon_2c_2d}{\phi_1\varepsilon_1c_1d} = \frac{\phi_2A_2}{\phi_1A_1}$$

where a_1 and A_2 are the absorbances of the two solutions. If one of the substances chosen has a known ϕ, the other ϕ value can be calculated very easily. In practice, quinine sulphate ($\phi = 0.55$) is used, and the areas under the curves of the corrected spectra, as well as the absorbances, are measured.

Kinetic determination of manganese with 3-OH-PAT

In a 25-ml standard flask, 2.5 ml of $10^{-3}M$ 3-OH-PAT solution in ethanol, and 3.5 ml of 0.1% hydrogen peroxide were mixed, and made up to volume with ammonia buffer (pH 9.7). Then 3.0 ml of this solution were placed in the quartz spectrofluorimeter cell and when the required temperature (25°) was reached, 50 μl of Mn(II) solution were injected from a microsyringe. The fluorescence intensity (λ_{exc} 370 nm, λ_{fl} 430 nm) was measured and its variation plotted *vs.* time.

Kinetic determination of manganese with 3-OH-PAA

In a 25-ml standard flask, 3.5 ml of dimethylformamide, 2 ml of 0.5% hydrogen peroxide solution and 3.5 ml of $10^{-3}M$ 3-OH-PAA solution were mixed in that order and made up to volume with ammonia buffer (pH 9.3). Then 3.0 ml of this solution were placed in the quartz spectrofluorimeter cell, and when the required temperature was reached, 50 μl of Mn(II) solution were injected from a microsyringe. The fluorescence intensity (λ_{exc} 325 nm, λ_{fl} 390 nm) was measured, starting 2.0 min after addition of the manganese, and plotted *vs.* time.

RESULTS AND DISCUSSION

Fluorescence of Schiff's bases and of their metal complexes

The fluorescence of the four Schiff's bases studied is quite different. Compound I is the most fluorescent, and the fluorescence of III is very small. Comparative values of the quantum yields of these compounds, in two different media (ethanol–water 1:4 and ethanol–dimethylformamide 1:4) are shown in Table 1, as well as the wavelengths of maximum excitation and fluorescence.

The influence of pH on the fluorescence intensity of these compounds in ethanol–water media was studied: II shows appreciable fluorescence in basic medium, and I only in weakly acidic medium; IV fluoresces in acidic and basic media, but the spectra are different.[12] Variation of fluorescence intensity with time was investigated for media of different ethanol concentrations. The most suitable concentrations were 30–40% for II and 35–50% for III.

The fluorescence properties of the metal complexes formed by I, II and III were investigated. Complexes formed by I and III with metal ions have similar fluorescence properties to the ligands themselves, so they are not analytically useful. II forms a fluorescent complex only with zinc (λ_{exc} 460 nm, λ_{fl} 520 nm); a detailed pH study showed that this complex has its highest fluorescence intensity at pH 9.5–11.5. The stoichiometry of the zinc–II complex was determined by Job's method (with fluorimetric measurement), and found to be 1:3 Zn–ligand. Unfortunately, the poor sensitivity of this reaction and the effect of foreign ions preclude its use in fluorimetric analysis.

Oxidation of 3-OH-PAT with hydrogen peroxide

Only compounds II (3-OH-PAT) and III (3-OH-PAA) can be oxidized easily by hydrogen peroxide to give fluorescent compounds. 3-OH-PAT exhibits a green fluorescence in basic medium but, in the presence of hydrogen peroxide, the fluorescence changes slowly, probably owing to formation of a new compound; this compound shows an excitation band at 370 nm, and a fluorescence band at 430 nm.

Catalytic effects of metal ions on this reaction were investigated. The reaction rate increases appreciably in the presence of traces of manganese(II), but only in ammoniacal media, so a systematic study was

Table 1. Values of quantum yields of fluorescence

| Compound	Ethanol–water (1:4)		Ethanol–dimethylformamide (1:4)	
	$\lambda_{exc}/\lambda_{fl}$, nm	ϕ	$\lambda_{exc}/\lambda_{fl}$, nm	ϕ
I	380/435	0.93	—	—
II	410/460	0.01	410/475	0.55
III	—	—	465/540	10^{-4}
IV	435/470	0.02	370/440	0.02

Fig. 1. Influence of experimental variables on the oxidation of 3-OH-PAT catalysed by Mn(II). (a) Variation of the initial reaction-rate with temperature. (b) Influence of the concentration of 3-OH-PAT, (c) Influence of the concentration of H_2O_2. (d) Influence of pH. (Concentration of manganese: 50 ng/ml in all cases).

made, to determine the experimental variables involved in the oxidation of 3-OH-PAT.

Temperatures. The influence of temperature on the initial rate was determined and the results are plotted in Fig. 1(a). The range 20–25°, in which, apparently, the reaction rate obtained by fluorescence measurements remains unaltered, is the most convenient.

Reagent concentration. Results are shown in Fig. 1(b). As may be observed, the reaction order is zero with regard to the reagent for the interval $0.8–1.2 \times 10^{-4}M$. A $10^{-4}M$ concentration of 3-OH-PAT was chosen to establish the determination conditions.

Hydrogen peroxide concentration. Samples were prepared in 25-ml standard flasks with different volumes of 0.1% hydrogen peroxide solution [Fig. 1(c)]. The reaction rate remains unaltered if the volume added is $\geqslant 3$ ml, so the optimum concentration of H_2O_2 is $\geqslant 3.5 \times 10^{-3}M$.

pH. Results of the optimization of pH are given in Fig. 1(d). The optimum pH (minimum reaction order) was found to be 9.6–10.0 (ammonia buffer). For this reason, this pH interval was chosen for the present study. Other buffers are not adequate for the purpose.

Oxidation of 3-OH-PAA

3-OH-PAA exhibits a very weak fluorescence in solution (see Table 1). However, in the presence of hydrogen peroxide, a new product (much more fluorescent; λ_{exc} 325, λ_{fl} 390 nm) is formed very slowly. When traces of manganese(II) are present, in ammoniacal media, the reaction rate increases, owing to the catalytic action of this metal ion. A study of the variables involved in this oxidation was made in the same way as for 3-OH-PAT.

The results obtained on the influence of temperature, reagent concentration, oxidant concentration and pH are plotted in Fig. 2. The optimal values found are $1.2–1.6 \times 10^{-6}M$ 3-OH-PAA; 0.5–3.5 ml of 0.5% H_2O_2 solution; temperature 30–40°; pH 9.4 (ammonia buffer).
Fig. 2. Influence of experimental variables on the oxidation of 3-OH-PAA catalysed by Mn(II). (a) Variation of the initial reaction-rate with temperature. (b) Variation of the initial rate with concentration of 3-OH-PAA. (c) Influence of the concentration of H_2O_2. (d) Influence of pH. (Concentration of manganese: 0.9 μg/ml in all cases).

Table 2. Interference levels of foreign ions in the determination of manganese
with 3-OH-PAT

Tolerance ratio ion/Mn(II), w/w	Foreign ions
100	Alkali and alkaline-earth metals
60	SCN^-
40	Al(III), Pb(II), Sn(II), F^-
20	Ga(III), Pd(II), CN^-
10	Ag(I), Bi(III), V(V), Os(IV), $C_2O_4^{2-}$
5	Mo(VI)
2.5	Ni(II), Co(II), Cu(II), Cr(III), Sb(III), Zn(II), Cd(II)
0.5	Fe(III)

Table 3. Interference levels of foreign ions on the determination of manganese
with 3-OH-PAA

Tolerance ratio ion/Mn(II), w/w	Foreign ions
100	Alkali metals
50	SCN^-
30	Ca(II), Mg(II), Ba(II), F^-
25	Pb(II), CN^-
15	Al(III), W(VI), $C_2O_4^{2-}$
3	Mo(VI), Os(IV)
2	Bi(III), Sn(II), Sb(III), Ga(III), In(III), Tl(I), Zr(IV), La(III)
1	V(V), Ag(I), Cr(III)

Nature of oxidation products

Oxidation of 3-OH-PAT must be similar to the oxidation of salicylaldehyde thiosemicarbazone[8] by hydrogen peroxide, and the corresponding semicarbazone is probably formed. 3-Hydroxypicolinaldehyde semicarbazone has been synthesized by us, and exhibits a fluorescence spectrum similar to the oxidation product of 3-OH-PAT (λ_{exc} 370, λ_{fl} 430 nm).

On the other hand, the oxidation product of 3-OH-PAA is probably 3-hydroxypyridine-2-carboxylic acid. Attempts were made to obtain this compound, but its high solubility made its isolation impossible. However, we have oxidized with hydrogen peroxide a similar compound, pyridine-2-aldehyde azine, and have isolated easily the copper salt of the pyridine-2-carboxylic acid formed. Elemental analysis confirmed its nature (found: C 46.4%, H 2.8%, N 9.5%; calculated for $C_{12}H_8O_4N_2Cu$: C 46.82%, H 2.68%, N 9.11%).

Kinetic determination of manganese with 3-OH-PAT

The initial-rate method was used in all determinations. The calibration curve was linear for the manganese concentration range between 5 and 50 ng/ml. The error was $\pm 3.0\%$ ($P = 0.05$; $n = 11$). The interferences are given in Table 2. The interference of iron(III) was severe, but addition of small amounts of fluoride (0.5–1.0 ppm) made possible the determination of manganese in presence of a 5-fold amount of iron. Nitrate, chloride, sulphate and perchlorate, up to at least 100 ppm, do not interfere.

Kinetic determination of manganese with 3-OH-PAA

The fixed-time method is the most convenient in this case, and was used in all determinations. In this method, a set time of 2 min is recommended; the calibration curve is linear for Mn(II) concentrations from 0.4 to 0.9 ppm. The error is $\pm 2.0\%$ ($P = 0.05$; $n = 11$).

Interferences in this method are given in Table 3 and show that the tolerance levels for anions are similar in both methods.

SPECTROPHOTOMETRIC DETERMINATION OF CARBON MONOXIDE WITH RUTHENIUM(II) OCTAETHYLPORPHYRIN

A. Corsini, A. Chan and H. Mehdi*

Department of Chemistry, McMaster University, Hamilton, Ontario, Canada

Summary—A novel spectrophotometric method for the estimation of carbon monoxide at levels from 2 to 250 ppm is presented. The method is empirical and based on formation of a carbonyl complex of ruthenium(II) octaethylporphyrin and measurement of the difference in absorbance at 393.5 nm between this complex and the porphyrin reagent. Oxygen and nitrogen do not interfere and up to 300 ppm of sulphur dioxide and about 1500 ppm of carbon dioxide can be tolerated in determination of carbon monoxide at the 4 and 10 ppm levels. Hydrogen sulphide interferes and must be removed before the determination. The method has been tested over the range 2–45 ppm of carbon monoxide with 16 synthetic and 2 commercial standard air samples. The average error was ±3%. Application to urban-air samples and car-exhaust gases yielded acceptable results. The main disadvantages are the tedious preparation of the initial ruthenium(III)–porphyrin compound and the decomposition of the reagent in the presence of hydrazine.

Synthetic porphyrins are being increasingly used as spectrophotometric reagents for the determination of metal ions at trace levels.[1-4] Less familiar is the use of metalloporphyrins as selective reagents for gases, especially carbon monoxide. This idea is due to Adler *et al.*[5] and the first study, which involved the evaluation of the dipiperidine complex of iron(II) *meso*-tetraphenylporphyrin, Fe(II)TPP(pip)₂, for the determination of CO, was reported shortly thereafter.[6] It was demonstrated that at room temperature, neither oxygen nor nitrogen reacted with Fe(II)TPP(pip)₂ in 1*M* piperidine and that irreversible air oxidation of Fe(II)TPP(pip)₂ to the *μ*-oxo-dimer was tolerably slow. The serious drawback was the poor limit of detection, about 300 ppm. Subsequent attempts to improve this limit by replacing piperidine as axial ligand by either sterically-hindered bases or pyridine were not successful.[6]

There have recently been several reports on the formation of stable carbonyl complexes of ruthenium(II) porphyrins.[7-14] The CO ligand is not only more inert to displacement but also more strongly bound than in the corresponding iron(II) porphyrins.[13,14] Indeed, Ru(II)TPP(aniline)₂ has been shown to remove carbon monoxide from acetic anhydride to form Ru(II)TPP(CO).[11] Also, the affinity of Ru(II)OEP (OEP = octaethylporphyrin) for CO has been demonstrated by its ability to strip CO from the surface of fused quartz.[15] This CO could not be fully removed by baking under reduced pressure or by other chemical agents.
The high affinity of ruthenium(II) porphyrins for CO suggested to us that they might be more sensitive reagents than iron(II) porphyrins for CO. Thus, a study of Ru(II)OEP as a spectrophotometric reagent for CO was undertaken. The structure is shown above. Although the reaction between the Ru(II) porphyrin and CO is incomplete, the results of this study show that this empirical method is still suitable for the determination of CO in two separate ranges, 2–25 and 25–250 ppm v/v. CO_2, SO_2, O_2, N_2 and a few organic species tested do not interfere, even when present in large amounts. H_2S is an interferent and its prior removal from air samples is required. Decomposition of the Ru(II)OEP reagent occurs but the effects of this can be minimized by making the absorbance measurements at specified times.

EXPERIMENTAL

Reagents

*Present address: Ontario Hydro, Toronto, Ontario, Canada.

All other reagents used were of sufficient purity for the purpose intended.

The principal reagent for the determination is $K[Ru(III)OEP(CN)_2]$. The synthesis of this and of the intermediate compounds $Ru(II)OEP(CO)(CH_3OH)$ and $Ru(II)OEP(py)_2$ (py = pyridine) has been described previously.[15]

Apparatus

The gas-line assembly for preparing air samples with various CO contents was essentially that used earlier.[6] Test mixtures of known amounts of CO in air were prepared (on a volume/volume basis) in a 2-litre gas-mixing flask as before, except that the "Ascarite" tube was not necessary. The mixture in the 2-litre flask was diluted by filling a second 2-litre flask with air to 1 atm pressure, withdrawing a calculated volume of the air through the side septum port with a gas-tight syringe, and replacing it with an equal volume of the initial stock mixture. At least 15 min were allowed for equilibration of the gas mixture in the second flask before samples were withdrawn from it.

All spectrophotometric measurements were made with a GCA McPherson double-beam spectrophotometer, Model EU-700, against methanol or distilled and demineralized water as reference. Stoppered 5-cm matched quartz cells (Helma) were used. About 4.5 ml of solution is sufficient to fill a cell. "Pressure-lok" 10-ml gas-tight syringes (Pierce Chemical Co.) were used to withdraw CO gas-samples from the 2-litre mixing flask and also as the reaction vessel for the subsequent interaction with the Ru(II) porphyrin. The contents of the syringes were agitated with a wrist-action shaker (Burrell).

A portable CO analyser (ECOLYZER, Energetics Science, Inc., Elmsford, New York) was used for measurement of the CO content in urban-air samples and in car-exhaust gases. These measurements were made to provide a convenient, albeit only semi-quantitative, comparison with results obtained by the Ru(II)OEP procedure.

Procedure

The following procedure was used to obtain the calibration graph for 25 ppm CO (maximum) and to test samples for CO content. Exactly 0.500 ml of a $5.0 \times 10^{-5}M$ stock solution of $K[Ru(III)OEP(CN)_2]$ in methanol was delivered into a 10-ml standard flask with a Gilmont micropipette, followed by addition of about 5 ml of methanol. Because the procedure requires critical time control for accurate results, a timetable was scheduled. At time zero, 20 μl of hydrazine (>95%) were transferred to a 10-ml standard flask with an Eppendorf pipette and diluted to the mark with methanol. Two min later, 1 ml of this hydrazine solution was pipetted into the 10-ml flask containing the $K[Ru(III)OEP(CN)_2]$ followed by dilution with methanol to the mark. This was the reagent solution (final concentration of Ru porphyrin, $2.5 \times 10^{-6}M$; of hydrazine, $6.3 \times 10^{-3}M$). Five ml of this were withdrawn into a 10-ml "Pressure-lok" syringe (sample syringe) and the remaining 5 ml were placed in a second "Pressure-lok" syringe for later measurement to provide a correction for reagent absorbance. At 7 min elapsed time, the CO sample (5 ml) was introduced into the syringe through the needle in such a manner that it bubbled through the reagent solution. (The CO sample was drawn into the syringe through the septum of the 2-litre flask, the needle being allowed to remain in the bulb atmosphere for 2 min before the syringe valve was closed). Both syringes were then mounted on the shaker and agitated at speed 7 for 45 min. The solutions were then placed in 5-cm quartz cells and 6 min after completion of the shaking the absorbance of the sample at 393.5 nm was recorded (58 min total elapsed time). The absorbance of the reagent was measured 2 min later.

For calibration graphs and samples in the 25–250 ppm range, the procedure was the same except that 1.00 ml of

$K[Ru(III)OEP(CN)_2]$ was taken, 20 μl of >95% hydrazine were added, the CO was introduced at an elapsed time of 2 or 5 min and shaking was conducted for 5, 15 or 45 min. The absorbances were taken at 11, 28 or 58 min after time zero.

Cleaning of apparatus

The quartz cells, syringes and 2-litre flasks can be cleaned adequately by thorough rinsing with methanol. Tests for possible contamination with CO through surface adsorption were performed with the Ru(II)OEP reagent as described earlier[15] and no memory effects were found. The occurrence of contamination in the previous study[15] was the result of exposure of the surfaces to undiluted CO gas in the absence of Ru(II)OEP reagent. In the present work, dilute mixtures of CO with air were used and the Ru(II)OEP reagent was present. CO has a higher affinity for the reagent than for glass or quartz surfaces.

RESULTS AND DISCUSSION

Solution species and spectra

The spectrum of $K[Ru(III)OEP(CN)_2]$ has been reported previously.[15] The Soret band at 390 nm and the broad less intense absorption band at about 480–560 nm are characteristic of Ru(III) porphyrins.[11,12] The addition of hydrazine to $K[Ru(III)OEP(CN)_2]$ effects reduction to Ru(II). The Soret band is shifted to 394 nm, with a shoulder at 403 nm [curve (a), Fig. 1]. The 394 nm band (and bands at 498 and 526 nm, not shown in Fig. 1) are typical of Ru(II) porphyrins. Other reductants such as sodium dithionite, sodium borohydride and piperidine were not as effective as hydrazine.

Curve (b) shows the Soret band (393.5 nm) after the solution yielding curve (a) has been agitated for 45 min with an air sample containing 20 ppm CO. If

Fig. 1. Spectrum of $Ru(II)OEP(L)_2$ taken 2 min after addition of hydrazine ($6.3 \times 10^{-3}M$) to $K[Ru(III)OEP-(CN)_2]$ ($2.5 \times 10^{-6}M$), curve (a); after 45-min contact with air-sample containing 20 ppm CO, curve (b); reagent solution from (a) after 58 min, curve (c).

the reagent solution that yields curve (a) is not contacted with CO but is merely allowed to stand, the absorbance at 394 nm decreases with time. Curve (c) shows the spectrum of the reagent solution after an elapsed time of 58 min. The decrease relative to curve (a), is the result of decomposition of the $Ru(II)OEP(L)_2$ complex (L = axial ligand) in the presence of a large excess of hydrazine. Evidence that the ligand L is hydrazine has been presented in an earlier study[15] but is not conclusive. Other ligands are possible. For example, the action of hydrazine on aqueous $RuCl_3$ solutions is known to produce $[Ru(NH_3)_5(N_2)]Cl_2$. The nitrogen molecule can be replaced by a water molecule and either can be readily displaced by CO.[16] Thus, the action of excess of hydrazine on $K[Ru(III)OEP(CN)_2]$ could produce $Ru(II)OEP(L)_2$ or $Ru(II)OEP(L)(L')$ in which L and L' can be NH_3, N_2H_4, CN^-, CH_3OH or H_2O. A nitrogen molecule is a less likely ligand.[13] Attempts to isolate and to characterize this complex were unsuccessful and were hindered by its decomposition. The decomposition itself appears to involve fragmentation of the porphyrin ring system; after 2 hr, the characteristic porphyrin bands in the Soret and visible regions are greatly reduced in intensity. In contrast to $Ru(II)OEP(L)_2$, the complex $Ru(II)OEP(CO)(L)$ is stable indefinitely [curve (b)].

Calibration graphs and decomposition of the reagent

This procedure for the determination of CO involves measurement of the difference in absorbance at 393.5 nm between curve (b) and curve (c) in Fig. 1 ($\Delta A_{393.5}$). When the reagent solution is contacted with CO, two processes occur simultaneously: (i) the CO complex is formed, and (ii) the excess of reagent not bound to CO undergoes decomposition. The absorbance of the solution containing CO is at all times greater than that of the reagent solution (Fig. 2). Curve (a) depicts the decomposition of
Fig. 2. Decay of absorbance of $Ru(II)OEP(L)_2$ ($2.5 \times 10^{-6}M$) in the presence of hydrazine ($6.3 \times 10^{-3}M$), curve (a); absorbance of identical solution (5 ml) in presence of an air-sample (5 ml) containing 16.5 ppm CO, curve (b).

$Ru(II)OEP(L)_2$; the decomposition is complex and the products of the reaction are not known. In the presence of CO [curve (b)], a maximum in absorbance is reached after about 15 min, indicating that the formation of the carbonyl complex is sufficiently fast to cause an overall increase in absorbance at 393.5 nm. Beyond the maximum, the formation of the carbonyl complex is slower and the absorbance decreases, being dominated by reagent decomposition. After about 55–60 min, $\Delta A_{393.5}$ becomes essentially constant. It is reasonable to assume that after this period, the reaction with CO is relatively slow and that the shape of both curves is determined mainly by the slow decomposition of the reagent. In the analytical application to 2–25 ppm CO, absorbance measurements were made after 58 min total elapsed time. It was necessary to use fresh hydrazine each time to obtain satisfactory reproducibility. The reagent concentration ($2.5 \times 10^{-6}M$) represents about a 1.5-fold excess relative to 25 ppm CO. However, because only 70% of the Ru(III) compound is reduced under these conditions, and because of reagent decomposition, the effective concentration is obviously lower. The calibration graph obtained (9 points, each in triplicate) was linear up to 25 ppm CO (slope = 0.0122 absorbance per ppm CO; intercept = -0.0043 absorbance). Curvature began at 30 ppm. Each point of the calibration curve was corrected for the fact that the absorbance of the reagent solution was measured 2 min after the absorbance of the CO complex. In a separate experiment, the additional decay in reagent absorbance in this 2-min period was found to be 0.004 ± 0.002. This amount was added to the reagent absorbance at 60 min and the sum subtracted from the sample absorbance to give $\Delta A_{393.5}$.

For the range 25–250 ppm CO, the reagent concentration was increased to $5.0 \times 10^{-6}M$ and the hydrazine concentration to $6.3 \times 10^{-2}M$. The Ru(III) complex is quantitatively reduced by this concentration of hydrazine. As in Fig. 2, the reagent solution plus CO always has a greater absorbance at 393.5 nm than the reagent solution alone. However, $\Delta A_{393.5}$ is not constant after about 60 min; for example, at 100 ppm CO, $\Delta A_{393.5} = 0.16$, 0.24, 0.29 and 0.34 after 30, 45, 60 and 80 min, respectively. Only after 100–120 min does $\Delta A_{393.5}$ become reasonably constant. Because such a long period reduces the attractiveness of an analytical method, it was decided to investigate the suitability of calibration with shorter reaction times, for the 25–250 ppm range. Agitation intervals of 5, 15 and 45 min were used, with absorbance measurement at 11, 28 and 58 min, respectively. Measurement of the reagent solutions 2 min later led to corrections of 0.009, 0.013 and 0.022, respectively. The corresponding calibration graphs are given in Fig. 3. The calibration graph for the 5-min period [curve (a)] is unsuitable because it lacks sensitivity and is very error-prone. As expected, the curve (c) for the 45-min period is the most sensitive, but the linear range is
Fig. 3. $\Delta A_{393.5}$ *vs.* CO concentration (25–250 ppm v/v) for Ru(II)OEP(L)$_2$ = $5.0 \times 10^{-6}M$, and hydrazine = $6.3 \times 10^{-2}M$, as a function of agitation ("reaction") time: 5 min, curve (a); 15 min, curve (b); 45 min, curve (c). All data points were obtained in triplicate.

Table 1. Determination of carbon monoxide in synthetic air-samples and in primary-standard samples

45*	45 ± 2

*Commercial primary-standard samples. The results quoted are the average and standard deviation of 10 and 9 determinations for the 9.9 and 45 ppm samples, respectively.

more limited (25–150 ppm). The 15-min period [curve (b)] is favourable since it yields reasonably large $\Delta A_{393.5}$ values and gives a wide linear working range (25–250 ppm). Accordingly, for the 25–250 ppm range, a 15-min agitation period was used and absorbance measurements of the samples were made after 28 min elapsed time.

The curvature in curves (b) and (c) (Fig. 3) results from a combination of at least two factors: (*i*) subtraction of the reagent absorbance to obtain $\Delta A_{393.5}$ provides an excessive correction, particularly at the higher CO concentrations in both ranges, where consumption of the reagent by CO is greatest, and (*ii*) the effect of reagent decay is most sensitive at the higher CO concentrations. Although a correction for the first factor can readily be made by iterative calculation, it leads to little change in the result obtained for CO and so is not worthwhile.

For calibration curve (b), the amount of reagent present is at most only about that stoichiometrically required for 125 ppm of CO, yet the calibration curve is linear up to about 250 ppm. This is because only a fraction of the 250 ppm of CO has reacted by the end of the reaction period. The amount of CO that has reacted depends on several factors: the solubility of CO in methanol, the rate of CO transfer from the gas to the solution phase, the rate of reaction with the reagent, the concentration of reagent and of hydrazine, and the equilibrium constant for the carbonylation reaction. Furthermore, the system cannot have reached overall equilibrium as absorbance changes still occur even after 1 hr. In spite of this, if

the conditions are rigorously controlled the system yields reliable data for the determination of CO, as shown below. In effect, the method is a fixed-time kinetic method of analysis.

Analytical application and interferences

The calibration curves proved reliable in testing 16 synthetic air-samples and two commercial primary-standard samples for CO (Table 1). The average error was 3%; the largest error was 6%. Duplicate results for the determination of CO in urban air-samples and car-exhaust gases are presented in Table 2. The readings obtained from the portable CO analyser can be regarded only as semi-quantitative; nevertheless, they lend support to the validity of the spectrophotometric method.

Calculation of the detection limit as defined by Kaiser[17] is questionable for this method, as the determination of a conventional blank correction is not straightforward. Because the noise level of the instrument for low signals corresponds to an absorbance no greater than 0.003 and measurement of small $\Delta A_{393.5}$ values with good precision has been

Table 2. Determination of carbon monoxide in urban air-samples and in car-exhaust gases

*By iterative procedure.

demonstrated (e.g., 0.004 ± 0.002), a conservative estimate for the lower limit for $\Delta A_{393.5}$ would be 0.01. This value gives a detection limit of 1 ppm CO for the low-concentration calibration. Experimentally, for 2 ppm, $\Delta A_{393.5}$ is 0.021. By contrast, for the 25–250 ppm range, 25 ppm gives $\Delta A_{393.5} = 0.032$, yielding a lower limit of application of about 8 ppm.

Ru(II)OEP is known to bind O_2 and NO.[12,13] There is some doubt as to the existence of nitrogen complexes of Ru(II) porphyrins.[13] Under the conditions of the present study, O_2 and N_2 do not bind to Ru(II)OEP but NO does and could cause interference. Because the background level of NO in air is only 0.0002–0.002 ppm,[18] this interference is not a serious problem. SO_2 and CO_2 in large excess do not interfere, but H_2S causes serious error (Table 3). Smaller amounts of H_2S result in less serious error. If the presence of H_2S is suspected, it should be removed prior to reaction of the sample with the reagent.[6] The interference by H_2S is not surprising, as alkanethiolate anions (RS^-) are reported to react with Ru(II)OEP(CO) at the metal centre.[19] Only a few simple hydrocarbons and halocarbons were tested and found not to have an effect at high concentration (Table 3). Formaldehyde at concentrations greater than 400 ppm caused oxidation to Ru(III). Cyclohexane (8000 ppm) and benzaldehyde (1000 ppm) added as liquids to the reagent solution did not interfere.

Limitations and advantages

The Ru(II)OEP method has two serious drawbacks. First, the preparation of $K[Ru(III)OEP(CN)_2]$ is very tedious.[15] Secondly, the Ru(II)OEP(L)$_2$ complexes are unstable in the presence of hydrazine. The possibility of synthesizing a stable, solid Ru(II)OEP complex (with appropriate axial ligands) that can be stored in a bottle and is sensitive to carbonylation is being pursued. In this regard, it is interesting that a methanolic solution of $K[Ru(III)OEP(CN)_2]$ reacts directly with CO to yield $Ru(II)OEP(CO)CH_3OH$. Chow and Cohen[11] have reported a similar observation with $K[Ru(III)TPP(CN)_2]$, but the reaction proceeds only at high CO concentrations and consequently the sensitivity for CO would be low. Otherwise, such a system would be superior to the system described here, on account of the stability of Ru(III) compounds.

A less serious disadvantage is the fact that only a fraction of the CO in the sample has reacted by the time the measurement is made. As mentioned earlier, several factors affect the rate and extent of reaction, the solubility of CO in the solvent being one. The solubility of CO is 6 and 10 times greater in perfluorobenzene and perfluoro-n-heptane, respectively, than in methanol[20] but unfortunately, $K[Ru(III)OEP(CN)_2]$ is insoluble in both solvents. A solid Ru(II)OEP(L)$_2$ complex might be sufficiently soluble, however.

Colorimetric methods for the determination of CO date back more than 50 years[21] but are still gaining importance.[22-27] The major drawbacks of most such methods include insufficient sensitivity, long reaction time and large sample size. The limit of detection is usually 10 ppm or higher, although in one paper[22] the detection limit is reported to be 2 ppm. However, this could be achieved only at the expense of using a large sample size (125 ml) and a long reaction time (2 hr). In general, sample sizes range from 50 to 250 ml, and the average reaction time is 2 hr. Compared to the p-sulphaminobenzoic acid method, which has been adopted as a tentative[22] and a standard method,[27] the Ru(II)OEP method requires a shorter time (28 or 58 min, against 2 hr) and a smaller sample (5 ml against 125 ml) and yields at least as favourable a detection limit. It also appears to be less prone to interferences.[24]

CONCLUSION

The Ru(II)OEP(L)$_2$ system represents a significant improvement over the Fe(II)TPP(pip)$_2$ system[6] for the determination of CO and has advantages over other spectrophotometric and colorimetric procedures. The time-consuming preparation of $K[Ru(III)OEP(CN)_2]$ and the instability of the Ru(II)OEP(L)$_2$ reagent solution are limitations, however, and for good reproducibility the conditions require to be rigorously observed.

MOLECULAR ABSORPTION SPECTROMETRY (MAS) BY ELECTROTHERMAL EVAPORATION IN A GRAPHITE FURNACE—IX

DETERMINATION OF TRACES OF BROMIDE BY MAS OF AlBr AFTER LIQUID–LIQUID EXTRACTION OF BROMIDE WITH TRIPHENYLTIN HYDROXIDE

Summary—The determination of traces of bromide by molecular absorption spectrometry (MAS) of AlBr (with electrothermal volatilization) is described. It is possible to determine 25 ng of bromide. Many problems are caused by various matrices, so an extraction method for separation (and also preconcentration) was developed. The combination of bromide extraction with triphenyltin hydroxide, stripping with $0.025M$ barium hydroxide and determination of the extracted bromide by MAS of AlBr (after addition of aluminium ions) gives a very sensitive and selective method for determination of traces of bromide in micro or macro samples, in the presence of large amounts of other species, including chloride and iodide.

Determination of traces of bromide, especially in samples of complex composition, is a difficult practical problem.[1] Sensitive determination of bromide is possible by applying molecular absorption spectrometry (MAS) to thermally stable diatomic bromide-containing molecules,[2–4] such as GaBr, InBr,[3,5] TlBr,[3] AlBr[4] generated by volatilization in a graphite furnace. The technique is similar to atomic-absorption spectrometry by electrothermal atomization. A disadvantage of MAS as an analytical method is the significant interference effect of the matrix on the molecular absorption signals and the background. It is expedient, therefore, to combine MAS of Br-containing molecules with a suitable method of separation of bromide ions from other components.

Because solutions are used as samples in MAS it is convenient to combine MAS with liquid–liquid extraction separation,[6] which also offers possibilities for enhancement of the sensitivity by preconcentration.

The extractants commonly used for anions, such as organic oxygen compounds and high molecular-weight amines, are not effective enough for bromide extraction.[7,8] Bankovsky et al. have shown that heptane solutions of amylmercury(II) salts quantitatively extract bromide over a wide acidity range, from pH 9 to $15M$ sulphuric acid,[9] but this high extraction power makes stripping difficult, and the reagent also extracts chloride and iodide. Bock et al.,[10,11] and

Schweitzer and McCarthy[12] have studied the extraction of halide ions with triphenyltin hydroxide (TPTH) and triphenyl-lead hydroxide into benzene, chloroform and methyl isobutyl ketone (MIBK). It has been shown that these reagents extract bromide quantitatively over the pH range 1–4; extraction from more acidic solutions has not been examined, nor has the possibility of preconcentration of bromide ion and its separation from large amounts of metal cations and other anions.

In this work we have studied the determination of bromide by MAS of AlBr, without and with solvent extraction of bromide by TPTH and stripping with aqueous barium hydroxide solution.

EXPERIMENTAL

Instruments

The molecular absorption was measured with a Jarrell Ash type 811 two-channel double-beam AA-spectrometer and a Beckman graphite furnace, type 1268. The light-source was a hydrogen hollow-cathode lamp run at 35 mA. The measurement was made at 278.9 nm. For background-correction the two-line method was used, with a non-specific wavelength of 281 nm.

The distribution of bromide between the organic and aqueous phase was estimated radiometrically with ^{82}Br. The radiochemical purity of the ^{82}Br was tested by means of a Nokia Ge(Li)-detector and an 800-channel analyser (LP 4840) as well as from the half-life measurements. The radioactivity of the organic and aqueous phase was measured on a Tesla Liberec NRG 603 automatic gamma spectrometer.

Table 1. Results of extraction of bromide ions by TPTH solution

C_{Br}, M	5.6×10^{-8}	1×10^{-4}	1.1×10^{-3}	1×10^{-2}	2×10^{-1}
Recovery, %	99.7	99.8	99.3	55.6	5.4

Reagents

TPTH solutions were prepared by equilibration of $0.03M$ triphenyltin chloride solution in a suitable diluent (*e.g.*, *o*-xylene) with several portions of aqueous $0.1M$ sodium hydroxide (in 1:1 organic to aqueous phase ratio) until chloride was no longer detectable in the stripping solution. The organic phase was washed free from hydroxide with water and then filtered. Unless otherwise noted, the concentration of TPTH in the diluent was $0.03M$, and the concentration of bromide in the aqueous solutions used in the extraction study was $5-10 \times 10^{-7}M$.

Other stock reagent solutions used were of aluminium nitrate (Al^{3+} 10 mg/ml), sodium hydroxide ($0.1M$); barium hydroxide ($0.05M$), sodium bromide (Br^- 1 mg/ml), sodium chloride, iodide, sulphate and monohydrogen phosphate (anion 10 mg/ml), metal nitrates [metal (K^+, Mg^{2+}, Ga^{3+}, In^{3+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}) 10 mg/ml].

Procedures

Measurement of absorption spectra. The molecular absorption was measured between 290 and 275 nm, point by point at 0.1-nm intervals in the 277-280 nm region (means of five values) and at 1-nm intervals elsewhere.

Analytical investigations without extraction. Aliquots (10 μl) of solutions containing bromide, aluminium and barium were injected into the graphite furnace. After drying and ashing, the solid was evaporated to give the so-called evaporation phase (the equivalent atomization phase in atomic-absorption spectrometry) and the molecular absorption of AlBr was measured.

Analytical determinations with extraction. Stoppered glass test-tubes or separatory funnels were used in studying the distribution of the elements between the phases. The extraction was done with various phase-volume ratios. For $V_o = V_{aq}$, the volume of each phase was 3 ml. The extraction studies were done at room temperature, and the phases were shaken together for 3 min (it was found in preliminary work that the equilibrium was attained in less than 3 min for all the systems studied). An aliquot of each phase was used for the radioactivity measurements, from which the recovery factors ($R\%$) were estimated. For the stripping $0.05M$ barium hydroxide was used. After separation of the stripping solution an appropriate volume of aluminium solution was added and the solution was injected into the graphite furnace.

RESULTS AND DISCUSSION

Investigation of the extraction

The extraction of bromide by $0.03M$ TPTH in *o*-xylene and MIBK from nitric acid and sulphuric acid medium with a 1:1 phase-volume ratio was examined. The recovery factors with use of *o*-xylene were greater than 99.5% over the nitric acid concentration range $0.01-5M$. With MIBK the R values were lower, and *o*-xylene was used as the diluent in all subsequent experiments. Bromide was also quantitatively extracted from $0.01-2M$ sulphuric acid ($R = 99.3\%$), but at sulphuric acid concentrations higher than $0.1M$ precipitates formed in the organic phase. No precipitate formed in the extraction from nitrate media. The recovery factors were not lower

than 99.7% for bromide extraction from $0.3M$ sodium, potassium, lithium, lead, cobalt and nickel nitrate solutions in $0.3M$ nitric acid at $V_o:V_{aq} = 1$, with practically no extraction of the cations.

The results (see Table 1) for the extraction of bromide from $0.01M$ nitric acid as a function of bromide concentration in the initial aqueous solution (C_{Br}) show that extraction by $0.03M$ TPTH in *o*-xylene was quantitative for $C_{Br} < 1 \times 10^{-3}M$. The possibility of preconcentration of bromide by extraction with different $V_o:V_{aq}$ ratios is shown in Table 2. It is also seen that TPTH allowed simultaneous separation of bromide from large amounts of metal cations and concentration before subsequent determination.

Table 2. Recovery values in the extraction of bromide ions by $0.03M$ TPTH in *o*-xylene

In contrast to metal cations, anions which are extracted by organotin extraction agents[10,12,12] can interfere with the extraction of bromide, as shown in Table 3.

The decrease in extraction of bromide with increasing concentration is due to competition for the reagent. A precipitate of TPT fluoride forms in the organic phase at fluoride concentrations higher than $10^{-4}M$ in the aqueous phase, which is why the extraction at higher fluoride concentrations was not examined. It should be noted that in contrast to the sulphuric acid system, no precipitate formed at high sodium sulphate concentrations in the aqueous phase. It is also noteworthy that phosphate depressed the extraction of bromide from $0.1M$ nitric acid, but not from more acidic solutions. Therefore, the extraction of phosphate and iodide (which strongly affects the extraction of bromide) from 0.01 and $1M$ nitric acid was studied at anion concentrations (C_{An}) of $1 \times 10^{-3}M$, with ^{32}P and ^{131}I as radioactive tracers.

It was found that more than 99% of the iodide was extracted in both cases, but the recovery factor for the phosphate decreased from 93.4% ($0.01M$ HNO$_3$) to 1.5% ($1M$ HNO$_3$). This explains the quantitative extraction of bromide at high phosphate concentrations from $1M$ nitric acid. Protonation of the phosphate results in formation of phosphoric acid, which is not extracted by TPTH and does not suppress the extraction of bromide.

The stripping of bromide into aqueous sodium or barium hydroxide solution was studied (Table 4). Both hydroxides proved effective stripping agents, so the extracts could be directly analysed by MAS. Additional preconcentration could be achieved in the stripping step.

Investigation of molecular absorption of AlBr (without extraction)

The absorption spectrum was investigated by use of solutions with the composition Al^{3+} 1 μg, Ba^{2+} 30 μg, Br$^-$ 0.5 μg in 10 μl sample volume. The spectrum was measured between 290 and 275 nm, and is shown in Fig. 1. The maximum of the AlBr absorption band was between 278.9 and 279.1 nm, in agreement with the literature,[14] which gives λ_{max} as 278.9 nm for the C-band system ($X^1\Sigma^+$—AΠ; v'/v'': 0/0 278.9 nm; 1/1 279.1 nm).

Because the band was narrow, it was possible to correct the background by difference measurement with the two-line method (279.1/281 nm).

Optimization of thermal conditions

In a general account of optimization of metal bromide molecule formation[2,15] it was stated that the choice of temperature for the drying, ashing and evaporation is very important, to avoid losses of bromide ions in the first two steps and to obtain simultaneous evaporation of the metal and bromine species in the third step.

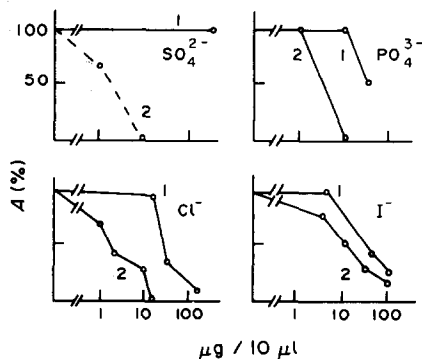
We therefore investigated the influence of the temperature of the ashing and evaporation steps and found that the ashing temperature should not be higher than 900°. The best evaporation temperature was the maximum temperature of the graphite furnace (about 3300°) (see Fig. 2), in spite of the fact that the dissociation energy of the AlBr molecule is not very high (4.5 eV),[14] and this molecule may dissociate at high temperature. The reason for use of this high temperature is the poor and late evaporation of the aluminium species.
Fig. 1. Molecular absorption spectra of the AlBr molecule (measurement point by point). (——): Al^{3+} 1 μg, Ba^{2+} 27 μg, Br$^-$ 0.5 μg in 10 μl; (———): Al^{3+} 1 μg, Ba^{2+} 27 μg in 10 μl.
Fig. 2. Dependence of AlBr MA on the temperature of ashing (a) and evaporation (b): (a) evaporation temperature 3300°; (b) ashing temperature 800°.


Fig. 3. Dependence of AlBr MA on the presence of other cations (as nitrates): 1, with preliminary extraction of Br⁻ from 0.1M HNO$_3$ by 0.03M TPTH in o-xylene; 2, without extraction.

Optimization of the chemical conditions

The addition of barium hydroxide solution up to a concentration of 0.025M to give a pH of 10–12 influenced the height of the AlBr signal by decreasing the loss of bromide by volatilization as hydrogen bromide (see also Dittrich and Meister[15]). After drying, the solid residue contained barium, bromide, hydroxide and nitrate, all of which are thermally stable. Losses of bromide as HBr by thermal hydrolysis in the ashing phase were avoided.

At the high temperature of the ashing step the substances formed reacted with the graphite of the tube. Hence the rate of volatilization of the bromide-containing particles was reduced. Because aluminium is difficult to vaporize, it evaporates late in the evaporation step, so the decreased rate of vaporization of bromine species was very useful for ensuring simultaneous evaporation of both species. Thus one prerequisite for the formation of a high AlBr concentration in the gas phase was fulfilled.

Next we investigated the influence of the aluminium and barium hydroxide concentrations on the molecular absorption of AlBr. The molecular absorption signal for AlBr increased with increased concentrations of both substances. At high aluminium concentrations the equilibrium

$$Al + Br \rightleftharpoons AlBr$$
is shifted to the right, and high barium hydroxide concentrations minimize loss of bromide ions. Very high concentrations of these substances are not so efficient, however, because both substances form stable carbides with the carbon of the graphite tube. Evaporation of the very involatile carbides and of the stable double oxides formed enhances the background signal during the evaporation step. The optimal concentrations are 1 μg of aluminium and 30 μg of barium in 10 μl of sample.

Influence of other cations

In Fig. 3 the very strong influence of certain cations is shown. They decrease the AlBr molecular absorption signals for various reasons. The effect of potas-

sium is due to formation of thermally stable KBr in the gas phase and formation of the easily volatilized KBr as a solid residue in the graphite cuvette, which prevents simultaneous evaporation of bromine and aluminium species. In the case of Mg^{2+}, Ga^{3+}, In^{3+}, Co^{2+}, Ni^{2+} and Zn^{2+} ions, which form only unstable diatomic molecules with bromine, decrease in the AlBr molecular absorption signals is caused by losses of bromide as HBr by thermal hydrolysis in the drying and ashing steps.

Influence of other anions

In Fig. 4 the influence of certain anions is shown. Chloride and iodide also form diatomic molecules with aluminium in the gas phase. Because the dissociation energy of AlCl (5.1 eV) is higher than that of AlBr (4.5 eV) and AlI (3.8 eV) the presence of chloride shifts the equilibrium

$$AlBr + Cl^- \rightleftharpoons AlCl + Br^-$$
to the right and the concentration of AlBr molecules in the gas phase is decreased.

Measurements in the presence of an excess of sulphate are impossible because the insoluble barium sulphate formed affects volatilization of the bromine species. Phosphate at higher concentrations also

Fig. 4. Dependence of AlBr MA on the presence of other anions (as sodium salts): 1, with preliminary extraction of Br⁻ from 0.1M HNO$_3$ by 0.03M TPTH in o-xylene; 2, without extraction.

Table 5. Results of bromide determination of AlBr MA with and without preliminary extraction of bromide (linear range 25–500 ng)

Sample volume, μl	Absolute reciprocal sensitivity ng for 0.01 A	Relative reciprocal sensitivity	
		ppm	M
Without extraction			
10	25	2.5	3.1×10^{-5}
40	25	0.31	7.5×10^{-6}
With extraction			
10*	25	0.5	6.2×10^{-6}
40*	25	0.125	1.6×10^{-6}
10†	25	0.25	3.1×10^{-6}
40†	25	0.031	7.5×10^{-7}

*Initial sample 10 ml, preconcentration factor 5:1.
†Initial sample 20 ml, preconcentration factor 10:1.

forms insoluble salts [e.g., $Ba_3(PO_4)_2$] and affects the formation of barium bromide residues. At low phosphate concentration the signals are lowered because of volatilization of hydrogen bromide by the much less volatile phosphoric acid.

Because of these effects of cations and anions, MAS is not convenient for direct analysis of complex samples. We therefore decided to combine it with a prior separation of the bromide.

Analytical results

Pure solutions. First we established the dependence of the AlBr signal on the bromide concentration under the optimal analytical conditions (see above). A linear calibration graph was obtained. The analytical data are given in Table 5. The blank value of 0.025 absorbance units cannot be compensated for. The reciprocal sensitivity is 25 ng of bromide for an absorbance of 0.01, which means that it is possible to determine 2.5 ppm of bromide in 10 μl of aqueous solution ($3.1 \times 10^{-5}M$). To a first approximation this reciprocal sensitivity is comparable to the detection limit. It is possible to improve the concentration detection limit by using a greater sample volume. The absolute amounts of aluminium and barium used should be the same as for the 10-μl sample. We found the same absolute detection limit (25 ng) for a sample volume of 40 μl, which gives a concentration detection limit of 0.3 ppm (or $0.75 \times 10^{-6}M$). The statistical detection limit gives an absorbance of about 0.01. Extraction was used in conjunction with the AlBr determination by shaking a 10 or 20 ml

Table 6. Results of bromide determination by AlBr MA with extraction in presence of other salts

Salt	Detection limit, ppm	Salt	Detection limit, ppm
KNO_3	2	$Ni(NO_3)_2$	1.3
$Mg(NO_3)_2$	1.5	$Co(NO_3)_2$	1.3
$Ga(NO_3)_3$	2.5	$Cu(NO_3)_2$	1.5
$In(NO_3)_3$	2.1	$Zn(NO_3)_2$	1.7

sample (in 0.1M nitric acid) with 4 ml of 0.03M TPTH solution in o-xylene. After separation, a known volume of the organic phase (e.g., 3.0 or 3.5 ml) was pipetted and stripped with half its volume of 0.025M barium hydroxide. After separation, 1 ml of the aqueous solution was pipetted, 0.01 ml of 10-mg/ml aluminium solution was added, and the AlBr molecular absorption was measured. The results are shown in Table 5. Comparison of the results with and without extraction show that it is possible to improve the relative reciprocal sensitivity of the bromide determination by about one order of magnitude by extraction. This sensitivity is adequate for trace determinations and compares well with that of other methods (e.g., the ISE method).

Solutions containing other anions. The effect of other anions is shown in Fig. 4. Chloride and iodide strongly depress the AlBr signals, whether extraction is used or not. Without extraction it is possible to determine traces of bromide in the presence of a 100-fold amount of iodide and 10-fold amount of chloride. Extraction gives an improvement, especially for chloride, which is extracted less efficiently than bromide. With extraction 25 ng of bromide can be determined in presence of a 500-fold amount of chloride and 200-fold amount of iodide. These results are very good in comparison with those for other methods.

The direct determination of bromide in presence of sulphate is impossible, because the sulphate forms insoluble barium sulphate with the barium added. If 0.01M nitric acid medium is used, sulphate is not extracted by the organic TPTH solution, so the sulphate interference is avoided. Bromide determination in presence of more than 1000-fold amount of sulphate is possible.

Bromide can be directly determined in presence of phosphate in up to 40-fold ratio. Extraction from 1.0M nitric acid, from which phosphoric acid is not extracted, gives a larger tolerance for phosphate.

Solution containing other cations. Figure 3 shows the strong influence of many cations on the AlBr signal. Separation of the bromide from these cations

can improve the detection limit by a factor of up to 1000.

By using the best conditions and a sample concentration of about 0.1–0.3M, it is possible to determine bromide traces in some metal nitrates in the ppm range. The results are shown in Table 6.

In conclusion, we can say that the combination of extraction with the selective determination by means of AlBr molecular absorption is a useful new technique for the determination of traces of bromide.

DETERMINATION OF LOW LEVELS OF BROMIDE IN FRESH WATER AFTER CHROMATOGRAPHIC ENRICHMENT

Ulla Lundström, Åke Olin and Folke Nydahl

Department of Analytical Chemistry, University of Uppsala, P.O.B. 531, S-751 21 Uppsala, Sweden

Summary—A method has been developed for the determination of bromide in fresh water. The analyte is enriched on the anion-exchanger Dowex 1 × 8, which exhibits a considerably greater affinity for bromide than for the major anions in fresh water. Sodium perchlorate is used as eluent and an enrichment factor of ~100 can be achieved. The eluted bromide is oxidized with peroxodisulphate to bromate, which is determined iodometrically by a previously published spectrophotometric method. The enrichment in the presence of the major components of fresh water has been studied. Only bicarbonate has been found to interfere, but this interference can be avoided by acidifying the sample with hydrochloric acid. The recovery from synthetic fresh water with ionic concentrations corresponding to 0.005 equivalent/l. and spiked with bromide was 100% at bromide concentrations larger than 50 nM (4 μg/l.) and about 90% at 10 nM. The detection limit is 1.5 nM and the limit of determination 5 nM for 1-litre samples.

The mean content of bromide in fresh water has been estimated to be about 10 μg/l.[1] With the exception of neutron-activation analysis, there seems to be no method available for the accurate determination of bromide at this concentration level. Recently two investigations have been reported on the determination of bromide in fresh water by ion chromatography.[2,3] With a sample volume of about 5 ml and a bromide-selective electrode as detector, bromide concentrations around 30–50 μg/l. were determined. The precision was reported to be 2–4% at the 50-μg/l. level. The accuracy is difficult to assess but is probably not better than 10% error. A number of colorimetric methods[4] are available for the determination of bromide. They are based on oxidation of bromide to bromine, which is then reacted with an added dye; the ensuing change in absorbance is used for determining the bromide. These methods require a bromide concentration exceeding about 100 μg/l. and the accuracy may be affected by organic material as well as inorganic constituents in the sample. The Phenol Red method has recently been automated by segmented-flow analysis.[5] Chloride interferes in this method and must be corrected for. The detection limit is 10 μg/l.

Thus it seems necessary to employ some method of enrichment before the final determination. In the method reported here, bromide is chromatographically enriched on the chloride form of Dowex 1 × 8, which has considerably higher affinity for bromide than for the major anions of fresh water. After elution with the strongly displacing perchlorate ion, the bromide is spectrophotometrically determined (by production of an equivalent amount of iodine), according to a previously published method,[6] which has a sensitivity of 2.25 absorbance units per

μmole of bromide (this means that the bromide content of about 350 ml of fresh water of "average" composition should be accumulated in order to obtain an absorbance of 0.1).

EXPERIMENTAL

Apparatus

The ion-exchanger tube was made with a cylindrical funnel at the top, ~70 mm long and wide enough to accommodate the mouth of an inverted 1-litre standard flask. The tube itself was 200 mm long and 8 mm in bore, and was drawn out to a tip with a 1-mm bore tip. Though the resin bed, enclosed between Pyrex wool plugs, was only 40 mm long (bed volume 2 ml) the column length stated was necessary for obtaining a convenient flow-rate under gravity.

Water samples were filtered through a 0.45-μm filter (HAWP 04700) in a Millipore filtration system. The filtration step did not influence the blank. The peroxodisulphate oxidation and the spectrophotometric finish were performed with the previously described equipment.[6]

Chemicals

All solutions were prepared from Merck analytical reagents unless otherwise stated.

Sodium chloride was purified as described earlier.[6] Hydrochloric acid was freed from iodine and bromine as follows. Add 0.1 g of sodium nitrite to 600 ml of hydrochloric acid (1 + 1), heat to boiling and boil for 10 min. Add 0.5 ml of 30% hydrogen peroxide and boil for another 10 min. Distil the acid and recover the middle 400-ml portion. The purified hydrochloric acid stock solution is ~6.4M and is used in all preparations containing this acid.

Ion-exchange resin. Dowex 1 × 8, (100–200 mesh), pract, Serva Feinbiochemica. Fines are removed by decantation. In order to obtain reproducible flow-rates the decantation procedure must be standardized. With the exchange column and bed height used in this work the following procedure is used. Slurry about 30 g of resin in a tall-form 250-ml beaker filled with water and allow to settle for 5 min. Decant the suspended particles and repeat the procedure until the supernatant liquid is virtually free from particles. The resin

can be further purified after the columns have been made as described in the general procedure below.

Determination of the ion-exchange constant, K_{Cl}^{Br}

The resin in chloride form was conditioned over calcium chloride hexahydrate and its saturated solution before use. The water content of the conditioned resin was about 13%. For each experiment 1 g of resin was shaken in an Erlenmeyer flask for 18 hr with 200 ml of a solution containing chloride and bromide. The resin and the equilibrated solution were then transferred to a column and allowed to drain thoroughly before being eluted with sodium perchlorate. Bromide was determined after oxidation, by titration with thiosulphate.[6] The capacity of the resin was determined by Mohr titration after elution of chloride with 1M sodium nitrate.

General procedure

The following procedure can be used for fresh water not containing abnormal amounts of dissolved salts and organic matter.

Column preparation. Prepare a 2-ml bed of the resin (chloride form) between two plugs of glass-wool. Treat fresh resin with 40 ml of 1M sodium hydroxide and rinse with water until neutral. Run one regeneration step as described below, before use with a sample.

Sample preparation

Add 2 drops of 0.05% Methyl Orange solution per litre of sample and acidify just to the red colour with 1M hydrochloric acid. Filter the sample if necessary, discarding the first 50 ml of filtrate. Take a sample of known volume, not exceeding 1 litre, in a standard flask.

Enrichment

Place the flask, mouth down, in the funnel of the column. The flow-rate will be about 100 ml/hr, and the equipment can be left unattended, for instance overnight, since the last portion of the sample is retained by capillary forces and hence the bed will not run dry. Elute with three 3-ml portions of 2M sodium perchlorate into a 50-ml Jena Duran bottle and proceed with the analysis as described earlier.[6]

Regeneration

Rinse the column with water and pass through it, in order, 200 ml of 2M sulphuric acid, 15 ml of 1M sodium bicarbonate and 10 ml of 0.6M hydrochloric acid, rinsing with water between each. Eliminate voids formed by the evolution of carbon dioxide, by momentarily applying gentle suction to the tip of the column. Finally, rinse with water until the effluent is neutral.

RESULTS AND DISCUSSION

The enrichment step

The success of the enrichment will depend on the net retention volume V_R', of the column for bromide. V_R' is given by the retention equation

$$V_R' = V_R - V_M = DV_t$$

where V_R is the total retention volume, V_m is the volume of the mobile phase in the resin bed and V_t is the total volume of the bed. In order to limit the volume eluted the bed volume is restricted to about 2 ml. The distribution ratio, D, of bromide between the bed and the mobile phase depends on the equilibrium constant of the ion-exchange process and the composition of the sample. The main cationic components of fresh water will not affect this distribution and, with the possible exception of Hg(II), trace metals should not cause interference, because of their low concentrations and the high ratio of chloride to bromide. Hence only the influence of the three main anions in fresh water (chloride, sulphate and bicarbonate) was studied.

Influence of chloride. The equilibrium constant for the exchange reaction $R^+Cl^- + Br^- \rightleftharpoons R^+Br^- + Cl^-$,

$$K_{Cl}^{Br} = \frac{[Br^-]_R[Cl^-]}{[Cl^-]_R[Br^-]}$$

has been determined from batch experiments at several bromide loadings on resins of various degree of cross-linking. The results are presented in Table 1. Since the value of K_{Cl}^{Br} is most favourable for Dowex 1 × 8, this resin was selected. The value of the constant (3.5) found in this investigation is somewhat higher than that previously reported (2.8).[7] The volume capacity of the resin is 1.6 meq per ml of bed volume, which gives $V_R' = 5.6\ V_t/[Cl^-]$ at low bromide loadings. For a 1000-ml sample and a bed volume of 2 ml the permissible chloride concentration would then be about 0.01M. This figure was corroborated by experiments in which 1000-ml samples that were 0.25μM in bromide and had various chloride concentrations were analysed according to the general procedure. The recovery was $(100 \pm 1)\%$ for $[Cl^-] \leq 0.01M$, as can be seen in Table 2. No difference in recovery was observed between fresh

Table 2. Test of the general procedure in the presence of chloride: 1000 ml of solution 0.25 μM in Br⁻ and of the stated concentration of NaCl was enriched on fresh and on regenerated resin beds

| [NaCl], M | Recovery of bromide, % | |

and regenerated resin beds. In this and the other measurements bromide standards were used for the calibration curve in the spectrophotometric finish.

Influence of sulphate. The influence of sulphate ions on the recovery of bromide was studied by analysis of solutions containing bromide and sulphate at various concentration levels. From the results presented in Table 3 we may conclude that quantitative recovery of bromide is obtained for a 1000-ml sample containing up to 2 mmole of sulphate; the average sulphate concentration in fresh water is about 0.25mM.[1]

Influence of bicarbonate. Bicarbonate is the main anionic component in fresh water. On passage of a large volume of sample through the column, the ion-exchanger will be largely converted into its bicarbonate form. The eluate from the column will therefore contain about 3 mmoles of HCO$_3^-$. After its titration to about pH 4 before the addition of the peroxodisulphate solution, the eluate will contain a substantial amount of dissolved carbon dioxide, which will be expelled during the oxidation step. It was found that the expulsion of the gas caused low recoveries of bromide. Most likely some bromine, formed as an intermediate in the oxidation, is carried away with the carbon dioxide. This interference can be avoided by acidifying the sample before the enrichment step, as outlined in the general procedure. Alternatively the titrated eluate can be heated to expel the carbon dioxide before the oxidation step.

The enrichment step was further tested on synthetic fresh water of the relative ionic composition suggested by Rodhe[8] as "standard composition", see Table 4. Chemicals used were specially prepared free from bromide. The blank obtained was the same as for distilled water. The results were very satisfactory,

Table 4. Test of the general procedure with solutions of "standard composition": 1000 ml of 0.005N "standard composition" containing the stated amounts of bromide was enriched; 0.005N "standard composition" contains (meq/l.): Ca^{2+} 3.175, Mg^{2+} 0.870, Na$^+$ 0.785, K$^+$ 0.170, Cl$^-$ 0.5, SO$_4^{2-}$ 0.785, HCO$_3^-$ 3.715

Bromide added, μmole	Recovery, % $\pm$ RDS ($n = 3$)
0.01	89 $\pm$ 10
0.05	101 $\pm$ 1
0.25	99.7 $\pm$ 0.2

especially considering the fact that 0.01 μmole of bromide corresponds to an absorbance of only 0.023.

The elution step

Quantitative elution within a volume suitable for the succeeding steps in the analytical procedure could only be obtained with perchlorate ions. Three 3-ml portions of 2M sodium perchlorate proved adequate for a 2-ml resin bed.

The enrichment factor (the ratio of the concentrations in the eluate and sample) is ~ 100 for a 1-litre sample. The eluate is diluted in the course of analysis however, so the final enrichment factor is ~ 30.

The regeneration step

The regeneration sequence utilizes the high affinity of the exchanger for bisulphate ($K_{Cl}^{HSO_4} = 4.1$) but low affinity for sulphate ($K_{Cl}^{SO_4} = 0.1$).[7] The perchlorate ions are first eluted with 2M sulphuric acid and the resin is then converted from the sulphate-form into the bicarbonate-form with sodium bicarbonate solution. Finally treatment with a small excess of hydrochloric acid restores the column to the chloride-form. Use of hydroxide instead of bicarbonate (in order to avoid evolution of carbon dioxide) cannot be recommended, since its repeated use tends to cause clogging of the plugs of glass wool used to keep the resin in place. Only a small decrease in capacity has been found after repeated regeneration of the ion-exchanger.

The blank

Significant amounts of bromide always seem to accompany chloride even in analytical-reagent grade chemicals and, therefore, the commercial ion-exchange resin in chloride form will give a rather high blank if not purified. Washing the resin with the specially prepared bromine-free hydrochloric acid reduced the blank considerably but entirely satisfactory results were only obtained if the resin had first been treated with 1M sodium hydroxide. The use of quite large amounts of bromine-free hydrochloric acid is, however, avoided by replacing it by use of the regeneration sequence with sodium hydroxide, sulphuric acid and sodium bicarbonate. The ordinary reagent grade of these chemicals is sufficiently free from bromide, and only 6 mmoles of hydrogen chloride are used for converting the resin into chloride form.

Although the blank may vary somewhat with the batch of ion-exchanger, the following results are typical. Ten determinations in each of which 1000 ml of distilled water were taken through the analytical procedure yielded a blank of 5.6 $\pm$ 0.5 nmoles. The corresponding figures from the peroxodisulphate oxidation of 10 ml of distilled water and the spectrophotometric finish were 2.8 $\pm$ 0.5 nmoles. From the standard deviation of the bromide blank a limit of detection (3σ) of 1.5nM and a limit of determination (10σ) of 5.0nM can be calculated, corresponding to 0.12 and 0.40 μg/l., respectively.

Table 5. Determination of the bromide concentration in some lake waters and in waste water (corrected for iodide)

Origin of sample	Sample volume, ml	Bromide, μM
Edasjön, Uppland	1000	0.252
depth 0.3 m	500	0.262
Valloxen, Uppland	896	0.482
depth 0.3 m	500	0.475
Åresjön, Jämtland	1000	0.050
depth 0.3 m		
Incoming waste water	100	3.27
(to the waste water	100	3.25
plant in Uppsala)		
Outgoing waste water	100	3.25
(from the waste water	100	3.25
plant in Uppsala)		

Iodide is taken up quantitatively during the enrichment step but is only partially eluted. A correction for the presence of iodine is made in the spectrophotometric finish.[6] Work is now in progress to adapt the procedure for a simultaneous determination of iodide.

Applications

The method has been applied to waters from three Swedish lakes and two waste water samples (Table 5). Edasjön and Valloxen are situated in the south of Sweden. Edasjön is a small lake, the first in a lake system, with a drainage area dominated by forests. Valloxen is a large lake, receiving its water from cultivated soils and wooded grounds. Åresjön is one of the first lakes in a large system in a mountain area; the water is poor in nutrients. The waste water samples were taken from the waste water plant at Uppsala. The incoming water was rich in suspended material.

Albeit limited in number, the results indicate that the bromide concentration in fresh waters varies considerably. This subject will be further investigated. It is also interesting to note the substantial increase of the concentration of bromide in waste water, above the natural level. As expected, no

reduction in the bromide content of the water occurs during passage through the waste water plant.

Humic acids present in the sample are, at least partly, taken up by the resin, as evidenced by the dark resin layer formed at the top of the resin bed. Some of the organic substance may be eluted but should be destroyed during the peroxodisulphate oxidation. The regeneration does not remove the humic acids completely but so far no negative effects have been observed from the sorbed material.

Without any special arrangements a single analyst can analyse 10 samples per day. Hence the present method cannot compete with the ion-chromatographic technique with respect to speed of analysis. For waters with bromide concentrations greater than 10–20 $\mu g/l.$, the ion-chromatographic technique is likely to become the method of choice, particularly in monitoring programmes. For the determination of bromide concentrations lower than 10 $\mu g/l$. the present method should be a valuable asset. Its high accuracy should also make it suitable as a reference method for more instrument-oriented procedures.

SIMPLIFIED DETERMINATION OF POLYCYCLIC AROMATIC HYDROCARBONS

Michael J. Avery, John J. Richard and Gregor A. Junk

Ames Laboratory-USDOE, Iowa State University, Ames, IA 50011, U.S.A.

Summary—Accurate quantitative analysis for selected polycyclic aromatic hydrocarbons present on urban dust can be obtained by using a simple procedure consisting of sonic-probe extraction with cyclohexane; clean-up with Florisil®–XAD-4®, and measurement by high-resolution gas chromatography with flame-ionization detection (HRGC/FID). The analysis can be further simplified by eliminating the clean-up step if HRGC/electron-impact mass-spectrometry (MS) is available. Both the FID and MS methods give results consistent with those obtained by standard procedures. The direct HRGC/MS procedure, combined with chemical ionization, can also be applied to the determination of polycyclic organic materials present in solvent-refined coal, shale oil and crude oil.

Polycyclic aromatic hydrocarbons (PAHs) are generated from a variety of sources[1,2] and are often associated with urban dust particles. This dust is a composite of particulate matter from sources such as automobile exhaust, wind erosion, road dust and stationary fires. Consequently, extracts of urban dust are usually complex mixtures containing organic compounds such as PAHs, heterocyclics, aliphatic hydrocarbons, aldehydes, ketones, acids and bases. Accurate measurement of individual compounds in these complex mixtures usually requires time-consuming procedures. For example, the determination of PAHs associated with urban dust involves extraction, isolation into a separate fraction, separation into individual compounds, and measurement.[3–5] Procedures for removing the PAHs from urban dusts are soxhlet extraction,[6–8] sonic-bath treatment,[9,10] and sonic-probe treatment[11–13] with various solvents and solvent mixtures. Removal by sublimation has also been reported.[14,15] Isolation of a PAH-rich fraction from the solvent extracts has included solvent partitioning[16–18] followed by column chromatography on various absorbents[19–21] or preparative high-pressure liquid chromatography (HPLC).[22,23] After pretreatment of the extract, the PAHs are separated and measured by high-resolution gas chromatography with flame-ionization detection (HRGC/FID)[24] and by analytical HPLC.[25] These multiple steps are time-consuming and tedious. Thus a rapid and simple method of screening urban dust samples for the presence of selected PAHs is desirable.

We describe in this report a straightforward procedure based, in part, on the extraction of dust samples and other particles by use of a sonic probe and cyclohexane. The extract is either cleaned by column chromatography and analysed by HRGC/FID or analysed directly by HRGC/mass-spectrometry (MS). The direct HRGC/MS analyses of polycyclic organic compounds in other complex mixtures such as alternative energy fuels is also described.

EXPERIMENTAL

Samples

Urban dust samples and standard reference material SRM 1649 were obtained from the National Bureau of Standards (NBS). Fly-ash from a coal-burning power plant was collected from the hopper of the electrostatic precipitator. Flue tar was obtained by scraping the inside of the chimney of an airtight wood-burning stove. Alternative energy fuels were obtained from the NBS during participation in an analytical characterization programme sponsored by the Department of Energy.

Extraction

An Artek-Sonic Dismembrator (Artek System Corporation, Farmingdale, NY) equipped with a 3/4-in. probe and operated at 240 W was used to extract 0.25-g samples with 30 ml of solvent. The sonic treatment time was 10 min. The solution was then filtered and extraction was repeated twice with fresh solvent. The three extracts were combined and reduced to 1 ml.

Clean-up

The extract was transferred to a 0.5-cm bore glass column containing 1 g of Florisil®, and then eluted with 15 ml of benzene. The eluate was concentrated to 0.5 ml and transferred to a 1.4-cm bore glass column containing 9 g of 80–100 mesh XAD-4® wetted with ethanol. The XAD-4 column was washed successively with 25 ml of ethanol and 25 ml of pentane, the effluents being discarded. The PAHs were then eluted with 25 ml of benzene, and this eluate was subsequently reduced to 1 ml. This XAD-4 clean-up is a modification of the procedure reported by Spitzer.[26]

Equipment

The HRGC analyses were performed on a Carlo Erba Fractovap equipped with an FID. The HRGC/MS analyses were performed on a Finnigan 4000 GC/MS operated in the multiple-ion-monitoring mode, with either electron-impact or chemical ionization. All solvent reductions were performed with a rotary evaporator.

HRGC analyses

The components in the extracts were separated on 30-m DB-5 fused silica capillary columns, with hydrogen or helium as carrier gas, on-column or splitless injection, and a temperature programme of 6°/min from 60° to 320° after an initial hold of 2 min. With this programme the analysis time is less than 50 min. External standards were used.

RESULTS AND DISCUSSION

Validation of methodology

The NBS has issued certified values for the concentrations of five PAHs in SRM 1649, a time-integrated, homogenized sample of Washington DC urban dust. The results of our analyses of this SRM are compared to these NBS certified values in Table 1. The average difference between values is 8%. Comparable reproducibilities were obtained by the two methods. These results are used as validation of the simple and rapid methodology for the determination of selected PAHs in samples as complex as urban dust.

Extraction tests

Tests were conducted to determine the best solvent, the most convenient method of removing residual particles from the extracts, and the optimum number of extractions.

Cyclohexane and dichloromethane (DCM) were both effective in removing the PAHs from the urban dust particles. The DCM extract, however, could not be successfully cleaned-up with the Florisil and XAD-4 columns. This observation reflects the superior efficiency of DCM over cyclohexane in removing organic substances from urban dust.[14] For PAH determination, however, cyclohexane is superior because it discriminates against many of the interfering polar substances while retaining efficiency for removing the neutral PAHs.

After each sonic extraction, the particles must be separated from the extract. Conventional centrifugation was judged to be unsatisfactory because the fine particles generated during the sonic treatment could not be removed from the solution. Ultra-centrifugation did remove these particles but this approach is too complicated for a routine procedure. Filtration of the extract through medium-porosity

Table 1. Comparison of the analysis of Washington urban dust SRM 1649.

Compound	Concentration, $\mu g/g$	
	NBS certified value	This study
Fluoranthene	7.1 ± 0.5	7.6 ± 0.5
Benz(a)anthracene	2.6 ± 0.3	2.9 ± 0.4
Benz(a)pyrene	2.9 ± 0.5	2.7 ± 0.6
Indeno(1,2,3-cd)pyrene	3.3 ± 0.5	3.1 ± 0.6
Benz(ghi)perylene	4.5 ± 1.1	5.0 ± 1.1

Table 2. Relative efficiencies for recovery of PAHs in successive sonic extractions of urban dust

Compound	Fraction in extract, %		
	1	2	3
Phenanthrene	73	27	0
Fluoranthene	80	20	0
Pyrene	79	21	0
Benz(a)anthracene	83	17	0
Chrysene	75	25	0
Benz(a)pyrene	63	37	0
Benz(e)pyrene	68	32	0
Indeno(1,2,3-cd)pyrene	71	29	0
Benz(ghi)perylene	58	34	8

sintered glass was successful and, at the concentrations of interest, no PAHs were lost.

The number of sonic extractions necessary to remove the PAHs was determined by extracting an urban dust sample three times and analysing each extract separately. The results, shown in table 2, indicate that all the PAHs except benz(ghi)perylene are removed in two extractions. This sonic extraction procedure is effective for PAHs present on urban dust at the $\mu g/g$ level. It is unlikely, however, that this technique can be extended to the ng/g level. Work done at this laboratory[27] and others[13] indicates that less than 30% of several representative PAHs present at the ng/g level are extracted by sonic treatment.

Clean-up

The simple two-step clean-up of the cyclohexane extract with Florisil and XAD-4 yields a fraction rich in PAHs that can be analysed by HRGC/FID. The Florisil removes polar materials and the XAD-4 completes the clean-up by removing any aliphatic hydrocarbons and semipolar materials from the extract. This clean-up is simple and fast, the only disadvantage being the loss of perylene on the Florisil.

The effectiveness of this clean-up procedure is illustrated in Fig. 1 where the HRGC/FID chromatograms of the original and the cleaned-up extracts are shown. Chromatogram A of the original extract is much more complex than chromatogram B from the cleaned-up extract. The original has a large number of interfering peaks at or near the retention times of the five PAHs indicated by the dotted lines between the chromatograms. Many of these interfering components are aliphatic hydrocarbons, which show up as intense discrete peaks. Other interferences appear as a wide unresolved hump. The discrete hydrocarbon interference peaks are not present in chromatogram B of the cleaned-up extract, which is rich in PAHs. Obviously, the PAHs can be determined by HRGC/FID from chromatograms such as B but cannot be measured from chromatograms such as A. A final note about the comparison of these two chromatograms is that the baseline drift, due to column bleed, becomes maximal between components 4 and 5 in chromatogram B, whereas in chromatogram A this drift overlaps the hump from
Fig. 1. HRGC/FID chromatograms of (A) original and (B) cleaned-up cyclohexane extracts from sonic-probe extraction of Washington urban dust. Peaks: 1 = fluoranthene; 2 = benz(a)anthracene; 3 = benz(a)pyrene; 4 = indeno-(1,2,3-cd)pyrene; 5 = benz(ghi)perylene.

Dibenz(ah)anthracene	84
Benz(ghi)perylene	86

*Relative reproducibility is ±10% (triplicate determinations).

amounts of components in a complex mixture are cleaned-up by some form of column chromatography. The probable loss of selected PAHs was investigated for the Florisil–XAD-4 clean-up employed in this investigation. Standard solutions were prepared and the recovery of individual PAHs was determined. The results are listed in Table 3 where the recoveries, except for perylene, ranged from 48% for phenanthrene to 91% for benz(e)pyrene. In all analyses corrections were made for these losses in the clean-up step.

Applications

The simplified procedure was applied to other PAHs in SRM 1649 and to PAHs on particles from other sources. The results of these analyses are listed in Table 4. Quantitative values for five additional PAHs in SRM 1649 are given in columns 2 and 3. The PAH content of St Louis urban dust was also measured and the values are given in column 4. For comparison, the NBS uncertified values for this same dust are listed in column 5. The PAHs measured in a sample of fly-ash from a coal-fired power plant and flue tar from a wood-burning stove are shown in columns 6 and 7. The low values for fly-ash and the high values for flue tar illustrate the effect of firing conditions on the PAH content of the emissions.

the unresolved components between components 3 and 4.

Losses occur whenever solutions containing small

Table 5. Direct HRGC/MS determination of selected PAHs in sonic-probe extracts of SRM 1649, with electron-impact (EI) and chemical ionization (CI)

Compound	Concentration, $\mu g/g$		
	Cyclohexane EI	Dichloromethane	
		EI	CI
Benz(*a*)anthracene	2.5	5.2	2.7
Benz(*a*)pyrene	2.9	7.0	2.3
Benz(*e*)pyrene	3.6	8.1	3.3
Indeno(*1,2,3-cd*)pyrene	3.9	12.7	3.4

Under the efficient burning conditions of the power plant, very low amounts of PAHs are formed, while the inefficient combustion in an airtight wood-burning stove leads to the formation of high amounts of PAHs.

Direct analysis

If GC/MS instrumentation is available, the analytical procedure for PAHs can be made even simpler. The increased selectivity of the mass spectrometer operated in the multiple-ion-monitoring mode enables the analyst to omit the Florisil–XAD-4 clean-up. Direct HRGC/MS analysis, using electron-impact ionization (EI), of a cyclohexane sonic-probe extract of SRM 1649 was performed and the results for four PAHs are listed in column 2 of Table 5. The values are within 15% of the results reported in Table 4, obtained by use of a clean-up procedure and HRGC/FID. If a more polar solvent, such as DCM, is used for the extraction, HRGC/MS with electron-impact ionization is not satisfactory. Use of this procedure gave the high values shown in column 3. This occurs because EI is not capable of discriminating against the large number of interfering components extracted by DCM. These interferences must be removed by an extensive clean-up procedure or by resorting to a higher level of instrumental sophistication such as chemical ionization (CI). For example, isobutane CI yields a simpler mass spectrum, thus reducing the possibility of interferences. When HRGC/CIMS was applied to the DCM extract the data listed in column 4, which agree with those in column 2, were obtained.

The direct HRGC/CIMS procedure, with isobutane as the reagent gas, has also been applied to

analysis for polycyclic organic materials (POMs) in other complex mixtures. Samples of solvent-refined coal, shale oil and crude oil were diluted 100-fold with hexane and analysed directly for selected POMs. The results of these analyses are listed in Table 6. The concentrations of the first six listed POMs agree with the results obtained by other laboratories[28] as part of an NBS programme sponsored by the Department of Energy. The results for 1- and 2-methylnaphthalene agree with those obtained by rotationally cooled fluorescence spectroscopy.[29] The direct HRGC/CIMS analyses are simpler and less time-consuming than the multi-step procedures normally employed for the determination of selected components in these kinds of complex samples.

CONCLUSION

The simplified procedures used to determine twelve PAHs and three POMs on urban dusts and in process streams can certainly be extended to determine other organic compounds. In each case, the additional compounds need only be tested and the procedure finely tuned to obtain quantitative results.

The simple Florisil–XAD-4 chromatography is not applicable to class separation of all the components present in complex mixtures. The reasons for this conclusion are the known irreversible adsorption of some components on the Florisil and the insufficient documentation of the class-separating capability of the XAD-4.

DETECTION LIMITS AND SURFACE INTERACTIONS IN QUANTITATIVE NEGATIVE CHEMICAL-IONIZATION MASS SPECTROMETRY

ULTRATRACE DETERMINATION OF METALS AND ORGANIC COMPOUNDS BY MEANS OF THEIR COMPLEXES

I. K. Gregor and M. Guilhaus

School of Chemistry, The University of New South Wales, Kensington, N.S.W., Australia

Summary—Details are given of a selective negative-ion mass-spectrometric method appropriate for the ultratrace determination of metals and organic compounds by means of their complexes. Direct introduction of the sample into the ion-source, attachment of low-energy electrons, and selected-ion monitoring are described, and comparative data are given relating to surface effects at the tips of insertion-probes on detection limits. Detection limits for chromium and cobalt, determined as their tris(2,2,6,6-tetramethylheptane-3,5-dione) chelates, were respectively 1.0 and 0.16 pg, and that for nickel [as its bis(*N*,*N*-diethyldithiocarbamate) complex] was 1.0 pg. Detection limits of 2.0 and 1.0 ng are attainable for malathion and ethion by measurement of the nickel(II) complexes of their *O*,*O*'-dialkyldithiophosphate hydrolysis products.

We have already drawn attention to some of the advantages and the potential afforded by the method of negative-ion mass spectrometry for the determination of organometallic compounds.[1] Since then there have been significant developments in the use of electron-attachment as a "soft" ionization technique under so-called negative chemical-ionization (NCI) conditions.[2-7] For molecules possessing positive electron-affinity, attachment of low-energy electrons can result in the formation of long-lived negative molecular ions capable of being detected and selectively monitored for quantitative purposes.[7-10] Electronic and structural criteria for gas-phase electron capture by organometallic substrates, as well as the function of various gases as electron-energy moderators in such reactions, have recently been more precisely defined.[11-18] Moreover, there have been considerable advances made in methods for quantitative introduction of solid samples of low volatility or thermal lability into mass-spectrometer ionization sources.[19-22] Previous mass-spectrometric determinations of metals (as various metal chelates) have been based largely on either electron-impact (EI) or positive-ion chemical ionization.[23-27] Under these conditions very low instrumental background contributions are essential if the analytes are to be detected at ultratrace levels. However, because the normal mass-spectrometer background species are relatively immune to electron attachment, such ion-current contributions are usually minimal under NCI conditions.[6,28,29] Introduction of gas-chromatography fractions and attachment of electrons under NCI ion-source conditions has been reported for certain classes of metal chelates.[30,31] In general, this method

has several drawbacks, including the non-quantitative introduction of sample into the ion-source, the thermal lability of various metal chelates, and interaction of the chelates with active sites and surfaces prior to entry into the ionization chamber.[32]

In this paper we present details and results of a selective method for ultratrace determination of metal chelates introduced directly into the ion-source under standardized electron-capture NCI conditions. The utility of the technique is demonstrated for the biologically significant metals chromium, cobalt and nickel, and by its extension to analysis for malathion and ethion by formation and determination of the nickel derivatives of their $(RO)_2PS_2^-$ hydrolysis products. The analytes tested are listed in Table 1.

EXPERIMENTAL

Instrumentation

Negative-ion mass spectra were obtained and quantitative measurements made on a VG MM-16F single-focusing mass spectrometer fitted with a combined EI/CI source, under conditions described previously[11-14,18] or specified below (Tables 2–4). Methane (Matheson UHP, 99.97% pure) was used as the electron-energy moderator under measured and controlled ion-source pressure (MKS Baratron system, type 170/315BHS-10) and temperature conditions to achieve optimum sensitivity for molecular-ion signals at the collector.[18] Detection-limit measurements were made by performing repetitive 0.1-sec integrating scans of a selected ion (usually the molecular ion). Thus the signal derived from the collector by the d.c. amplifier and a sample-and-hold circuit could be recorded during the complete evaporation of a quantity of sample within the ion-source, usually within about 30 sec. The signal recorded was Gaussian in shape and corresponded to an evaporation profile.[33] Samples were introduced quantitatively into the ion-source either in fused silica cups (in some cases silaned and sometimes also coated

with SE-30) or on dished Vespel® rods positioned in tapered Vespel® probe tips which ensured a tight seal in, and electrical insulation from, the ion-source block.[21,22] The desorption chemical ionization (DCI) method of sample introduction was also used;[19] this involved rapid evaporation of sample within the methane plasma from a platinum wire, heated by the passage of a ramp-programmed current supplied by a VG type MR609 source-heater/emitter-current control unit. Details of our DCI filament, Vespel® probe tip and the application of this technique to metal chelates have already been reported.[14]

Procedures

Analyte solutions of known concentration were delivered by microsyringe in precise volumes of 1–3 μl to the solid insertion-probe cups, Vespel® rod or DCI filament wire, and the solvent was evaporated in the vacuum lock for the solid insertion-probe. In this way, small accurately known amounts of samples deposited on fused silica, silaned or SE-30 coated silica,[22] Vespel® or platinum, were introduced quantitatively into the ionization-source methane plasma by the "in-beam" method.[19] Details of typical plasma temperatures and sample heating-rate data have already been given.[14] The evaporation profile data acquired during the evaporation and ionization of the sample were used to determine the total monitored-ion charge produced by a given mass of sample introduced into the ion source $(C/\mu g)$.[33]

Materials and reagents

The derivatives analysed were prepared and purified by established methods, and their purity was checked by positive-ion and negative-ion mass spectrometry.[34-37] Solutions of the analytes were prepared by dilution of stock solutions of accurately known concentration, made with n-hexane, chloroform or methanol, as appropriate.

Glassware was cleaned by procedures similar to those already described.[38]

RESULTS AND DISCUSSION

Ultratrace metal determination by chelation and NCI mass spectrometry

As speciation of metals in the environment is highly important, analytical methods are needed that not only have high sensitivity, but can also indicate the metal oxidation state and co-ordination number.[39-41] An analytical procedure based on a "soft" ionization method is well suited for this purpose. Both proton-transfer CI and NCI give less fragmentation of quasimolecular, $[M + 1]^+$, and molecular ions, $[M]^-$, than electron-impact ionization does. However, many metal chelates can be regarded as Lewis acids with the metal functioning as the active

Lewis acid site[42] and inhibiting proton attachment. Negative ionization, involving attachment of low-energy electrons in metal orbitals of suitable energy, can be seen as a more favourable ionization process, particularly as many metal chelates have been observed to undergo electron-attachment reactions leading to the formation of stable long-lived negative molecular ions.[11-15,30-31] Though it is known that fluorinated metal chelates may yield between 10 and 5000 times more negative-ion current when present as $[M]^-$ than positive-ion current when present as $[M + 1]^+$, no systematic comparison has been made of the sensitivity given by the three most common methods of ionization modes (EI, CI and NCI).[30,31] Table 1 lists the metal derivatives which we have determined quantitatively by direct sample introduction, electron-capture NCI, and mass spectrometry. The biologically significant metals, chromium and cobalt, in their tervalent states, were determined in the form of their tris(2,2,6,6-tetramethylheptane-3,5-dione) chelates, M(dpm)$_3$, which give long-lived molecular anions on electron attachment.[43] Nickel is best determined as its bis-(N,N-diethyldithiocarbamate) complex, Ni(Et$_2$dtc)$_2$.[14]

Ultratrace analysis by metal complexation and NCI mass spectrometry

Formation of complexes of metals and various organic analytes, coupled with solvent extraction and spectrophotometric analysis, is a commonplace procedure. The potential specificity and sensitivity afforded by negative chemical-ionization mass spectrometry has not so far been utilized in this way, and one of our aims was to evaluate the combination of metal derivative formation and NCI mass spectrometry. Ethion is commonly determined spectrophotometrically by hydrolysis and subsequent formation of the bis(O,O'-diethyldithiophosphate)copper(II) complex, with a practical limit of detection of *ca.* 25 μg of analyte.[37,44] A similar method is used for malathion, the corresponding O,O'-dimethyldithiophosphate complex being formed. These spectrophotometric methods are not specific for the individual O,O'-dialkyldithiophosphate ligands and thus cannot be specific for the parent pesticides.[37] Negative-ion mass spectra have

†Desorption chemical ionization.

been obtained for many organophosphorus pesticides[28,45] as well as for metal chelates formed from analogous O-O'-dialkyldithiophosphate ligands,[15] those for the former being characterized by a degree of fragmentation which is excessive for precise selective-ion monitoring, whereas those for the latter display little fragmentation under the optimum ion-source conditions. With such metal derivatives the specificity afforded by negative-ionization mass spectrometry can be used to identify (and determine) unequivocally the metal chelate, the chelating ligand and hence the original pesticide. In this work, the metal complexes $Ni(Me_2dtp)_2$ and $Ni(Et_2dtp)_2$ were selected as models for determination of malathion and ethion because for these compounds, under controlled conditons, ca. 90% of the total ion-current is carried by $[M]^-$ (the ion selected for monitoring).[46] These two metal complexes are known to be Lewis acids,[47,48] and this property serves to make their cross-sections for electron capture larger than those of the corresponding parent organic analytes.

Surface effects and their influence on the sensitivity

When the amount of sample introduced on the solid insertion-probe approaches that required to form a monolayer on the surface used (typically 0.1 nmole), the sensitivity can be severely affected by interaction between the surface and the sample.[22,49] Significant improvements in sensitivity as well as less decomposition of thermally labile compounds have been reported to result from the use of inert surfaces for direct sample introduction.[21,22] Such methods involve silaning glass surfaces (and sometimes then coating the surface with the non-polar gas-chromatography stationary phase SE-30). Vespel® has been used to an increasing degree as a chemically inert surface for direct introduction of thermally labile compounds.[21] The DCI method, whereby samples are desorbed within the ion-source from heated wires, has also been used for compounds that are thermally labile or difficult to volatilize.[19,49] However, no systematic evaluation of these surfaces has been made for metal chelate analysis.

To assess the suitability of the surfaces chosen in this work for ultratrace analysis, the average charge carried by negative molecular ions resulting from replicate introduction of 1 ng of nickel [as $Ni(Et_2dtc)_2$] on the various surfaces was measured.

This derivative was chosen because it has vacant co-ordination sites which could interact with active sites on the various surfaces. The results are summarized in Table 2, and show that the most suitable surface for this chelate is provided by Vespel®. The SE-30 coated surface is also effective, but is known to have an upper temperature limitation.[22] A considerable loss of sensitivity and precision, as well as tailing of the evaporation profiles, was apparent in the results for uncoated silica surfaces. The low sensitivity and poor reproducibility given by the platinum DCI filament wires is consistent with previously reported results obtained with organic analytes at the ng level.[19,50]

Detection limits

Detection limits were determined for the analytes listed in Table 1, by introducing into the ion-source successively smaller amounts of their derivatives, on a dished Vespel® rod. The detection limit was taken to be the smallest amount of analyte giving an evaporation profile distinguishable from that obtained when only pure solvent was delivered to the rod. The results are given in Table 3 and the calibration graphs are given in Fig. 1.

A major limitation to the realization of lower detection limits is the intensity of the background spectrum. Although the negative-ion background is of lower intensity than that for positive ions, it is significant when the gain of the detection circuitry is very high. The abundance of background ions in the VG mass spectrometer used in this work decreases at $m/z > 300$ and therefore the degree of background

Table 3. Detection limits determined by $[M]^-$ monitoring under NCl conditions

B: Ni(II) (□) as Ni[S$_2$CN·Et$_2$]$_2$, C:Malathion (△) and ethion (▲) as the Ni[(RO)$_2$PS$_2$]$_2$ derivatives; each point represents the mean charge detected for triplicate sample introductions, for which the worst r.s.d. was 20%.

interference in the detection of very low levels of analytes is decreased when the derivatives have high masses. It is therefore advantageous to use metal chelates with molecular weights >400. Background interference becomes apparent when the probe is inserted. When the probe makes contact with and seals the ionization chamber, the pressure in the chamber rises from about 0.01 to 0.10 mmHg (with methane as the electron-energy moderating gas) and this is accompanied by a rise in sensitivity, resulting from the corresponding increase in the thermal-electron concentration in the ionization chamber. If the gain of the detection system is high, then the rise in sensitivity is apparent as a rise in the background ion-current to a plateau representing equilibration of conditions within the ionization chamber. This is illustrated in Fig. 2 which reproduces the evaporation profile obtained on delivery of 1 μl of pure solvent (blank) to the Vespel® rod, with the mass spectrometer tuned to $m/z = 601$. Also shown are profiles for duplicate introduction of 3.3 and 1.0 pg of chromium [as the Cr(dpm)$_3$ chelate] in the same volume of solvent. In these evaporation profiles the current due to the analyte is superimposed on the rising background signal. The drop in ion-current at the end of the evaporation profile corresponds to the withdrawal of the probe. The detection limit of 1.0 pg obtained here for chromium is two orders of mag-

nitude better than that reported for a similar technique.[30] The use (in that work) of untreated glass capillaries for sample insertion could have contributed significantly to lowering the sensitivity. Further development of our technique, to minimize rising background signals and thereby produce an improvement in detection limits, could involve either temperature-programming of the probe tip[21] or the use of polyimide-coated DCI filament wires to eliminate direct interaction between the sample and the wire.[51]

At higher resolution some reduction of background interference can be accomplished at the expense of sensitivity.[33] A single-focusing magnetic-sector mass spectrometer with a maximum resolution of 2000 can accomplish this to a limited extent, and only in the low m/z range. In these experiments, a resolution of 1800 (10% valley definition) was used for all measurements except those for the Ni(Me$_2$dtp)$_2$, Ni(Et$_2$dtp)$_2$ and Co(dpm)$_3$ derivatives, for which a resolution of 400 was used. Use of the higher resolution reduced the overall sensitivity by 90% and necessitated more frequent tuning of the mass spectrometer to the top of the narrower peaks.

In some cases the detection limit was governed by carry-over of small traces of the sample derivative in the mass-spectrometer probe inlet-lock, with atten-

‖Total electron emission current 0.500 mA, all other instrumental conditions as given in Table 3.

dant superimposition on the background signal for the blank. This is illustrated in Fig. 3 for cobalt at the sub-picogram level, and is a potentially limiting factor for significantly volatile analytes at these ultra-trace levels. Nevertheless the extremely low detection limits obtained here for cobalt illustrate the high sensitivity of the NCI/direct sample-introduction technique.

The detection limits for the nickel(II) derivatives of the ethion and malathion hydrolysis products were higher than those for the other analytes in this work, yet they still represent a significant improvement (by a factor of about 1000) on those attainable by the standard spectrophotometric method.[37,44] Our method offers a sensitive procedure for a series of similar organophosphorus[45] pesticides capable of similarly forming metal derivatives. Further refinement of this approach, coupled with use of ion-counting methods for negative-ion detection, should result in still lower detection limits.

Comparative sensitivity of the EI, CI and NCI modes

Comparative measurements were made by separate introduction of 100 ng of each derivative under optimum conditions for each ionization mode. The total charge detected from molecular or quasimolecular ions was measured and the relative sensitivities determined (Table 4). The NCI mode was found to offer the greatest sensitivity for all the analytes tested, except $Ni(Et_2dtp)_2$. The sensitivity is better than that obtained by the CI mode, by factors in the range 100–1000, and this is consistent with predictions from a kinetic model for positive and negative chemical-ionization.[52] The high enhancement for the nickel chelate may be a reflection of a very low tendency for the complex to undergo a proton-attachment reaction, which is consistent with the known chemistry for such a square planar complex with a transition metal as the Lewis acid centre.[42]

It is noteworthy that the relative sensitivities determined for the EI mode are all higher than the corresponding positive-ion CI sensitivities. This is probably due, at least in part, to the larger ion-source exit-slit area used.

DETERMINATION OF TRACES OF OSMIUM BY THE CATALYSED HYDROGEN PEROXIDE–CYANOCUPRATE(I) REACTION

I. N. C. LING and G. SVEHLA

Department of Analytical Chemistry, The Queen's University of Belfast, Belfast, N. Ireland

Summary—The reaction between hydrogen peroxide and a mixture of cyanocuprate(I) species at pH 11.2 is selectively catalysed by traces of osmium. With potentiometric or amperometric monitoring, osmium concentrations up to 1 ng/ml can be determined, with a lowest determinable concentration of 0.03 ng/ml. In the presence of luminol a Landolt-type reaction proceeds and visual or instrumental monitoring of the chemiluminescence can be used. A large number of other cations can be tolerated. The kinetics, mechanism, rate constants and Arrhenius parameters have been investigated.

Many methods for the determination of osmium are based on its catalysis of various oxidation reactions.[1–31] In the literature searches connected with our studies of catalytic methods we came across the report[32] that the reaction between hydrogen peroxide and cyanide, in the presence of copper and luminol, can be used as a chemiluminescent clock reaction. Detailed study of the reaction reveals that it is sensitively and selectively catalysed by traces of osmium. In the absence of the luminol (which serves only as an "indicator" in the clock reaction), the reaction can be monitored by potentiometry and amperometry, but with luminol present chemiluminescent monitoring is also possible.

EXPERIMENTAL

Reagents

Analytical grade reagents were used whenever possible. A 1000-μg/ml standard osmium solution was made from commercially available osmium tetroxide, kept in the dark, standardized gravimetrically,[33] and further diluted as required. To avoid adsorption losses, standards of concentration below 100 ng/ml were made immediately before use.

Solution A. Dissolve 0.0395 g of potassium cyanide, 0.0543 g of cupric sulphate pentahydrate, 71.6 g of potassium dihydrogen phosphate and 32.0 g of sodium hydroxide in water, and dilute to 1 litre.

Solution B. Standardize a 3% hydrogen peroxide solution by iodimetric titration[34] and dilute the required volume to 1 litre to obtain a $1.176 \times 10^{-2} M$ solution.

Apparatus

All kinetic measurements were made at $20 \pm 0.2°$, unless otherwise stated, in Metrohm-type jacketed vessels fitted with Metrohm electrode heads; magnetic stirring was used. Potentiometric monitoring was done with platinum and saturated calomel electrodes, connected to a Radiometer model 26 pH-meter, the mV signal from which was recorded.

Amperometric monitoring was done with a rotating platinum electrode (400–800 rpm) and saturated calomel electrode, at zero applied potential difference with no *IR* compensation. A longer electrode than normal was con-

structed for use with the Metrohm electrode head. The current was recorded at a chart speed of 2 cm/min.

Chemiluminescence was observed visually in a darkroom, the reaction time being measured with a stopwatch.

Procedure

Prepare reagent solutions A and B freshly (they do not keep for more than 24 hr). Bring these and the neutralized sample solution to $20 \pm 0.2°$ in a water-bath.

Potentiometric monitoring. Set up the apparatus and to the reaction vessel add 10 ml of the neutral sample solution (containing up to 10 ng of osmium) and 10 ml of solution A. Start stirring and recording. Once the signal becomes steady, add 10 ml of solution B. Continue recording until a sharp maximum is observed (Fig. 1). Repeat, using standards and (for the blank) pure water instead of sample. From the recorded curve determine the reaction time t_L (t_L^0 for the blank). The corresponding distances on the chart can be used. Calculate the t_L^0/t_L values. Plot the values for the standards against osmium concentration; the calibration graph is linear.

Amperometric monitoring. Set up the apparatus with sample and solution A in the reaction vessel as above. Set the applied potential at zero and record the diffusion current as a function of time, at a sensitivity of 25–50 μA full-scale deflection. When the current is steady add solution B as above and continue recording until the "end-point" is reached (Fig. 2). Evaluate as above.

Monitoring by chemiluminescence. Dissolve 1.24 g of luminol and 0.4 g of sodium hydroxide in about 100 ml of water, dilute to 1 litre, and add 20 ml of this solution (which is stable for several months) to solution A before this is diluted to 1 litre. Mix the sample and solutions A and B in the dark,
Fig. 1. Potentiometric traces.

61
Fig. 2. Amperometric traces.

starting a stopwatch when solution B is added; stop the watch when a faint chemiluminescence appears. Alternatively a photoelectric instrument can be used as detector.

RESULTS AND DISCUSSION

Optimization

If we make the concentrations of hydrogen peroxide and potassium cyanide 100 times those for solutions A and B (and adjust the concentration of copper accordingly to obtain a suitable reaction time), the catalytic action of osmium practically disappears, and only in the presence of 100 ppm osmium does the catalytic action become noticeable. It is worth noting that under such conditions cobalt is the most sensitive catalyst, and can be determined in the range 10–100 ppm. A lengthy optimization procedure resulted in the choice of concentrations used for reagents A and B. It may well be true that even lower reagent concentrations would allow the sensitivity to be extended further, but the end-points on recorded potentiometric and amperometric traces become less sharp under such circumstances.

The sensitivity is maximal at pH 10.8–12.3, and for chemiluminescence monitoring the pH should be at least 11. If the pH is too high, however, some of the phosphate (used both as buffer and masking agent) may precipitate. We recommend using pH 11.2.

The role of the masking agent is to eliminate interferences from other (mainly metallic) ions, which would otherwise catalyse the reaction either on their own, or in combination with osmium. Of the obvious agents we tried tartrate, citrate, fluoride, phosphate and EDTA both on their own and in combination. Phosphate was found not only to act as a masking agent, but also to give remarkable enhancement of the catalytic effect of osmium (it also somewhat enhanced the effect of certain other elements, including Cu, Ag, Ru, Mo, W, U, Zn, Al, Ni, Cd and Co). Replacing phosphate by fluoride made the reaction rather insensitive to osmium, and cobalt was the most efficient catalyst. Tartrate, citrate or EDTA will prevent production of the chemiluminescence, but will not affect the potentiometric or amperometric monitoring.

The temperature affects the reaction times but not the sensitivity. The electrometric end-points are sharper at lower temperatures; 20° is recommended as optimal.

Results obtained with (simultaneous) amperometric and potentiometric monitoring are shown in Table 1. Results obtained by visual monitoring of chemiluminescence are less sensitive ($c_{min} = 0.05$ ng/ml) and precise.

Interferences

The interference of 37 ions was studied by measuring the reaction time for 0.05-ng/ml osmium in the presence of increasing amounts of interferent, and calculating the inverse of its ratio to the reaction time with no interferent present. A ratio between 0.95 and 1.05 was taken as indicating no interference. The results are listed in Table 2. Ratios less than 0.95 can be taken as resulting from reaction of the interferent with hydrogen peroxide, making the reaction time longer. Full details are given in a thesis.[37]

It can be seen that the tolerance limits are 0.005 μg/ml for Ni and Mn, 0.05 μg/ml for Cu, 0.5 ppm for Mo, W, Al, Cr, Ru, Au, Ag and Rh, 5 μg/ml for Co, V, Pd, Hg, Ce and Fe(III), 50 μg/ml for Ti, Zn, Fe(II), U, Pt, Re, Pb, Ba, Cd, La, Ir, Sb and Sn, and 500 ppm for Sr, Ca, Mg, Y, Zr and Se. Na and K did not interfere at even higher concentrations. Some tolerance levels may be slightly higher than those listed above, and may be obtained by interpolation in Table 2.

Kinetic study

Whenever a new catalytic method is introduced, it

*Immediate reaction.
†Very slow reaction.

is important to examine the kinetics and mechanism to find those parameters which influence the rates of the individual reactions and the sensitivity of the determination. A working hypothesis for the mechanism reduces the number of experiments needed.

The purpose of the kinetic study was to find a mechanism for both the uncatalysed and catalysed reactions, consistent with the kinetics, explain the shape of the calibration curve, and determine the Arrhenius parameters.

When formulating our working hypothesis for the mechanism and kinetics of the uncatalysed reaction, we made use of numerous reports in the literature,[38–44] even though some of these regarded the oxidation of luminol as an essential step in the process. The information available on the hydrogen peroxide–cyanide reaction (in the absence of copper)[45–49] also contained useful guidelines. As for the mechanism of the reaction in the presence of osmium, the earlier papers[27,50–53] all suggested that the catalytic action of osmium is based on an Os(VI)/Os(VIII) cycle.

It must be emphasized that the mechanisms described below are simplified in many ways. Even in the absence of osmium the reaction system will contain hydroperoxide (HOO^-), hydroxide, hydro-

gen, cyanate, copper(I) and at least two different cyanocuprate(I) ions. Several of these may be involved in the rate-determining step. The simplified mechanism proposed below is based on the following experimental facts.[37]

1. Though hydrogen peroxide reacts with cyanide in the absence of copper, this reaction is so much slower than the one proceeding in the presence of copper, that its rate can be excluded from the rate equations. For the bimolecular reaction between hydrogen peroxide and cyanide, Masson[49] found the value $1 \times 10^{-3} \, l.mole^{-1}.sec^{-1}$ for the second-order rate constant. It is possible to postulate a mechanism for this reaction that involves two simultaneous processes[37] and to calculate the appropriate rate constant. The figure for the uncatalysed rate constant obtained in this way is equal (within 2%) to the figure quoted below.

2. It has been possible to establish[37] that the uncatalysed reaction is first order with respect to hydrogen peroxide and second order with respect to copper. Also, the catalysed reaction was found to be first order with respect to osmium.

3. The rate depends on pH and shows a definite maximum at pH 11.3 (Fig. 3). As this pH is close to pK_{a1} for hydrogen peroxide[54] we may speculate as to

which species (H_2O_2, HOO^- or even the adduct [$H_2O_2 \cdot HOO^-$]) is involved in the reaction. However, the hydrogen-ion concentration could not be varied in a wide enough range for sound experimental results to be obtained. Thus, we omitted hydrogen and hydroperoxide ions from all the mechanisms, and simply based them on molecular hydrogen peroxide. In any case, in the analytical procedure we recommend the use of a pH 11.3 buffer and the nature of the peroxide species is unimportant from the practical point of view.

The uncatalysed reaction. In the absence of osmium, the predominant cyanocuprate(I) species in the solution is $Cu(CN)_2^-$, produced by the overall reaction

$$2Cu^{2+} + 5CN^- + 2OH^- \rightarrow$$
$$2Cu(CN)_2^- + CNO^- + H_2O \quad (1)$$
This dicyanocuprate(I) ion then forms an adduct with hydrogen peroxide:

$$Cu(CN)_2 + H_2O_2 \overset{K_2}{\rightleftharpoons} Cu(CN)_2 \cdot H_2O_2^- \quad (2)$$
which then reacts with another dicyanocuprate(I) ion:

$$Cu(CN)_2 \cdot H_2O_2^- + Cu(CN)_2 \overset{K_3}{\longrightarrow}$$
$$2Cu^{2+} + 2OH^- + 4CN^- \quad (3)$$
Reaction (3) is rate-determining. Note that by adding reactions (1)–(3) we can express the overall process simply as

$$H_2O_2 + CN^- \longrightarrow CNO^- + H_2O \quad (4)$$

That is, in the process, hydrogen peroxide and cyanide ions are consumed. The rate of disappearance of hydrogen peroxide (the "uncatalysed" rate) can be expressed as

$$-\left(\frac{d\{H_2O_2\}}{dt}\right)_{un}$$
$$= k_3 \{[Cu(CN)_2 \cdot H_2O_2]^-\}\{Cu(CN)_2^-\} \quad (5)$$

where the braces { } stand for instantaneous (actual) concentrations. Applying the law of mass action to
Fig. 3. Variation of the reciprocal reaction time with pH in the absence (A) and presence (B) of osmium.

reaction (2) we have

$$K_2 = \frac{\{[Cu(CN)_2 \cdot H_2O_2]^-\}}{\{Cu(CN)_2^-\}\{H_2O_2\}} \quad (6)$$

The following mass-balance equation can be written for copper:

$$c_{Cu} = \{Cu^{2+}\} + \{Cu^+\} + \{Cu(CN)_2^-\}$$
$$+ \{[Cu(CN)_2 \cdot H_2O_2]^-\} \approx \{Cu(CN)_2^-\} \quad (7)$$

Here c_{Cu} is the "analytical" or "total" concentration of copper, which remains constant during each experiment. As long as free cyanide is present, the approximation expressed by equation (7) is valid. By combining equations (5)–(7), we can express the reaction rate as

$$-\left(\frac{d\{H_2O_2\}}{dt}\right)_{un} = k_{un} c_{Cu}^2 \{H_2O_2\} \quad (8)$$

where $k_{un}(= k_3 K_2)$ is the uncatalysed rate constant. Expression (8) now represents a pseudo first-order rate equation, which can be integrated with the boundary conditions that at the beginning of the reaction (time zero) the concentration of hydrogen peroxide is its initial value $\{H_2O_2\}_0$, while at the end-point (time $= t_L^0$), when practically all the free cyanide is used up, its concentration decreases to

Table 3. Kinetic study of the uncatalysed reaction

15	5.90	2.02	7.25	187.5	3.59

$\{H_2O_2\}_0 - [\{CN^-\} - \frac{5}{2}c_{Cu}]$. Integration yields the following expression for the uncatalysed rate constant:

$$k_{un} = \frac{1}{c_{Cu}^2 t_L^0} \ln\left(\frac{\{H_2O_2\}_0}{\{H_2O_2\}_0 - \{CN^-\}_0 + \frac{5}{2}c_{Cu}}\right) \quad (9)$$

By varying the initial concentrations of hydrogen peroxide, cyanide and copper (within limits imposed by practicality) and measuring the t_L^0 reaction times, values for k_{un} were calculated and are shown in Table 3. The value of k_{un} remains constant for a wide range of reaction times, thus verifying the mechanism. An average value of $k_{un} = (3.70 \pm 0.33) \times 10^3$ $l^2.mole^{-2}.sec^{-1}$ is obtained for this third-order rate constant. The 95% confidence limits are given $(\pm 0.33 \times 10^3)$.

The catalysed reaction. In the following reaction scheme the actual ionic forms of osmium(VI) and (VIII) are not identified, but simply denoted as Os^{6+} and Os^{8+}.

When osmium tetroxide is added to the mixture, it will oxidize cyanide in a fast reaction. The overall process follows the stoichiometry

$$Os^{8+} + CN^- + 2OH^- \longrightarrow Os^{6+} + CNO^- + H_2O \quad (10)$$
When hydrogen peroxide is added, re-oxidation of the osmium takes place:

$$H_2O_2 + Os^{6+} \xrightarrow{k_{11}} Os^{8+} + 2OH^- \quad (11)$$
Step (11) is rate-determining. Though slow, it is faster than step (3), hence the catalytic effect of osmium. Note that the sum of steps (10) and (11) again equals the net reaction (4). Thus, both copper and osmium are acting as catalysts.

The rate of the catalysed reaction can be expressed from (11) as

$$-\left(\frac{d\{H_2O_2\}}{dt}\right)_{cat} = k_{11}\{H_2O_2\}\{Os^{6+}\} \quad (12)$$

The concentration of the osmium(VI) is unknown, but because reaction (10) is much faster than (11), it can be regarded as equal or at least proportional to the analytical concentration of osmium

$$\{Os^{6+}\} = \alpha c_{Os} \quad (13)$$

where α is an unknown constant. Combining equations (12) and (13) gives

$$-\left(\frac{d\{H_2O_2\}}{dt}\right)_{cat} = k_{cat} c_{Os} \{H_2O_2\} \quad (14)$$

where k_{cat} ($= k_{11}\alpha$) is a second-order rate constant. Since c_{Os} is constant for a given experiment, again a pseudo first-order rate expression results, which is easier to handle mathematically.

The overall rate. Unlike the uncatalysed reaction, the catalysed process cannot be examined experimentally on its own, as under the conditions of the analytical procedure both reactions always proceed

simultaneously. Hence the overall rate has to be expressed, by adding equations (8) and (14), as

$$-\frac{d\{H_2O_2\}}{dt} = [k_{un}c_{Cu}^2 + k_{cat}c_{Os}]\{H_2O_2\} \quad (15)$$

This differential rate equation can be integrated with the boundary conditions described earlier. Denoting the Landolt-reaction time by t_L, we can express the rate constant k_{cat} as

$$k_{cat} = \frac{1}{c_{Os}}\left[\frac{1}{t_L}\ln\left(\frac{\{H_2O_2\}_0}{\{H_2O_2\}_0 - \{CN^-\}_0 + \frac{5}{2}c_{Cu}}\right) - k_{un}c_{Cu}^2\right] \quad (16)$$

We tested this equation experimentally by varying the initial concentration of hydrogen peroxide, and the analytical concentration of osmium (within as wide ranges as possible), measuring the reaction times and calculating the k_{cat} value with equation (16). It was not possible to vary either the cyanide or the copper concentrations enough to support our mechanism, as their variation (just as in the case of the uncatalysed reaction, cf. Table 4) caused rather drastic changes in the reaction times. Their levels were kept at those recommended for the analytical procedure. As Table 4 indicates, however, the value of k_{cat} remains fairly constant (even though the errors in the k_{un} rate coefficient are included and magnified in the expression). Thus, for the concentration range covered, we can accept the proposed mechanism and kinetics. The mean of the k_{cat} values is $(11.27 \pm 1.22) \times 10^6$ $l.mole^{-1}.sec^{-1}$ (95% confidence limits).

The calibration curve

By combining equations (9) and (16) we can express the ratio t_L^0/t_L, used when constructing the calibration curve, as

$$\frac{t_L^0}{t_L} = 1 + \frac{k_{cat}c_{Os}}{k_{un}c_{Cu}^2} \quad (17)$$

Thus when t_L^0/t_L is plotted against c_{Os}, a straight line is expected, with an intercept of 1.00. The experimental calibration lines (cf. Table 2) agree with these predictions, showing again that the proposed mechanism and kinetics are basically correct.

Table 4. Kinetic study of the catalysed reaction*

No.	$\{H_2O_2\}_0$, $10^{-3}M$	c_{Os}, $10^{-13}M$	t_L, sec	k_{cat}, $10^6 l.mole^{-1}.sec^{-1}$

26.7	120.3	107.0	−173.21	−110.28	5.57
29.7	100.0	90.6	−171.75	−110.58	6.73

*$\{H_2O_2\}_0 = 5.9 \times 10^{-3}$ M, $\{CN^-\}_0 = 2.022 \times 10^{-4}$ M, $c_{Cu} = 7.25 \times 10^{-5}$ M, $c_{Os} = 3.50 \times 10^{-13}$ M.

Temperature effects. Reaction rates vary strongly with temperature. The temperature dependence of a rate constant k_T can be expressed by the modified Wynne-Jones–Eyring[55] equation:

$$k_T = \frac{kT}{h} \exp\left(\frac{\Delta S^{\ddagger}}{R}\right) \exp\left(-\frac{\Delta H^{\ddagger}}{RT}\right) \quad (18)$$

where k_T is the rate constant at absolute temperature T, k is the Boltzmann constant, h is Planck's constant, R the gas constant, $\Delta S^{\ddagger}$ the entropy of activation and $\Delta H^{\ddagger}$ the enthalpy of activation (the so-called Arrhenius parameters). To investigate the reactions of interest, equations (18) and (9) can be combined to define a temperature function $(F(T))_{un}$ for the uncatalysed reaction:

$$F(T)_{un} = \Delta S_{un}^{\ddagger} - \frac{\Delta H_{un}^{\ddagger}}{T}$$

$$= R \ln\left(\frac{h}{kTc_{Cu}^2 \, t_{L,T}^0}\right)$$

$$\times \ln\left(\frac{\{H_2O_2\}_0}{\{H_2O_2\}_0 - \{CN^-\}_0 + \frac{5}{2}c_{Cu}}\right) \quad (19)$$

while for the catalysed reaction, combination of (18) with (16) gives

$$F(T)_{cat} = \Delta S_{cat}^{\ddagger} - \frac{\Delta H_{cat}^{\ddagger}}{T}$$

$$= R \ln\frac{h}{kT \, c_{Os}}$$

$$\times \left[\frac{1}{t_{L,T}}\ln\left(\frac{\{H_2O_2\}_0}{\{H_2O_2\}_0 - \{CN^-\}_0 + \frac{5}{2}c_{Cu}}\right)\right.$$

$$\left. - k'_{T,un} \, c_{Cu}^2\right] \quad (20)$$

In these equations $t_{L,T}^0$ and $t_{L,T}$ represent the Landolt-reaction times at absolute temperature T for the uncatalysed and catalysed processes, respectively, while $k'_{T,un}$ is the uncatalysed rate constant at temperature T, as calculated from equation (18). Plotting the $F(T)$ values against the reciprocals of the absolute temperatures gives straight lines ("modified" Arrhenius plots) with intercepts equal to the entropies of activation, and slopes giving the enthalpies of activation.

To determine these parameters experiments were done at different temperatures, in the absence and presence of osmium. Initial concentrations of all the
Fig. 4. Modified Arrhenius plots for the (A) uncatalysed and (B) catalysed reactions.

reactants were kept constant. The results are shown in Table 5 and Fig. 4.

Linear regression analysis provided the following values for the Arrhenius parameters (95% confidence limits):

$$\Delta S_{un}^{\ddagger} = -23.1 \pm 3.8 \, \text{J.mole}^{-1}.\text{K}^{-1}$$

$$\Delta S_{cat}^{\ddagger} = -102 \pm 16 \, \text{J.mole}^{-1}.\text{K}^{-1}$$

$$\Delta H_{un}^{\ddagger} = 45.0 \pm 1.1 \, \text{kJ/mole}$$

$$\Delta H_{cat}^{\ddagger} = 2.5 \pm 4.8 \, \text{kJ/mole}$$

It is noteworthy that the enthalpy of activation of the catalysed reaction is exceptionally low (the Arrhenius plot is almost horizontal), which is in fact a manifestation of the high catalytic activity of osmium and accounts for the high sensitivity of the method. The error (4.8 kJ/mole) of $\Delta H_{cat}^{\ddagger}$ is no greater than would normally be expected from such measurements, in which the errors of the uncatalysed parameters are also accumulated [cf. equation (20)].

ELEKTROCHEMISCHE UNTERSUCHUNG VON BIS(DIPHENYLDITHIOPHOSPHIN) DISULFID

Angel Schischkov, Shivko Dentschev und Christina Malakova
Lehrstuhl für analytische Chemie an der Paissij Chilendarski-Universität-Plovdiv,
VRB-4000 Plovdiv, Bulgarien

Zusammenfassung—Die elektrochemischen Untersuchungen von bis(Diphenyldithiophosphin) Disulfid (RSSR), und Diphenylquecksilberdithiophosphinat [(RS)$_2$Hg], erfolgten in Äthanol–Lithiumperchlorat und Äthanol–Schwefelsäure Medium durch die Methoden der klassischen Polarographie, und Elektrolyse bei kontrollierbarem Potential und eine rotierende Scheibenelektrode. Die Ergebnisse weisen darauf hin, daß RSSR nicht direkt auf einer Quecksilbertropfelektrode reduziert, sondern erst adsorbiert wird. Anschließend unterliegt es einer schnellen chemischen Reaktion unter Bildung von elektroaktivem (RS)$_2$Hg. Die Elektrolyse bei kontrollierbarem Potential bestätigt, daß (RS)$_2$Hg eine Zwei-elektronenreduktion eingeht, bei der als Hauptprodukt Diphenyldithiophosphinsäure (RSH) gebildet wird, während die Oxydation von RSH zur Erhaltung von (RS)$_2$Hg führt. Obwohl das chemische und das Adsorptionsgleichgewicht bei der Reduktion von RSSR und (RS)$_2$Hg sehr kompliziert ist, ist die coulometrische Generierung von RSH nicht schwer und erlaubt den Einsatz von RSSR als coulometrisches Reagens.

Die Wechselwirkung der Dithiophosphinsäuren mit den Ionen einer großen Anzahl von Metallen ist eingehend untersucht.[1] Als analytische Reagenzien haben sie zur Extraktionstrennung der Elemente vorwiegend mit spektrophotometrischer Registrierung Anwendung gefunden.[2,3] Ein Teil der Dithiophosphinatkomplexe absorbieren kein Licht im sichtbaren Spektralbereich, was ihren extraktions-photometrischen Nachweis beträchtlich erschwert. In dieser Hinsicht erweisen sich die unterschiedlichen elektrochemischen Methoden, insbesondere Polarographie und Coulometrie, die ziemlich häufig bei der Untersuchung der verschiedenen Klassen organischer schwefelhaltiger Reagenzien zum Einsatz kommen,[4,5] als sehr wertvoll.

Mit Hilfe der klassischen Polarographie, der Elektrolyse bei kontrollierbarem Potential und einer rotierenden Scheibenplatinelektrode wurde das Verhalten von RSSR hinsichtlich dessen Anwendung als coulometrisches Reagens untersucht.

EXPERIMENTELLER TEIL

Geräte

Polarographen OH-103 und OH-105 (Radelkis, Ungarn), Potentiostat P-5848 (UdSSR), rotierende Scheiben-platinelektrode,[6] und Spektrophotometer Specord UV-VIS (DDR). Die Charakteristik der Kapillare in Äthanol-0,2M Lithiumperchlorat war $m = 3,51$ mg/sec; $t = 1,95$ sec.

Alle elektrochemischen Untersuchungen erfolgten bei $20 \pm 1°$. Sauerstoff wurde mittels Durchleitung reines Argons aus der Lösung entfernt. Als Vergleichselektrode diente eine gesättigte Kalomelelektrode.

Reagenzien

Äthanol, *p.a.*, Schwefelsäure, *p.a.*, Lithiumperchlorat, *p.a.*, (Merck), und destilliertes Wasser. Es wurden Lösungen von genau bestimmten Mengen an $1 \times 10^{-3}M$ RSSR[7] und $0,4 \times 10^{-3}M$ (RS)$_2$Hg verwendet.

ERGEBNISSE UND DISKUSSION

Elektrochemische Untersuchungen in Äthanol-0,2M LiClO$_4$ Medium

Polarographie von RSSR und (RS)$_2$Hg auf Queck-silbertropfelektrode. Auf dem Polarogramm sind zwei Reduktionswellen zu sehen (Abb. 1): $E_{1/2}$ der ersten Welle liegt bei $-0,45$ V, $E_{1/2}$ der zweiten dagegen bei $-0,8$ V. Die Diffusionsströme beider Wellen verändern sich linear mit Zunahme der RSSR-Konzentration. Die Reduktion des Disulfids erfolgt nach der Gleichung

$$RSSR + 2e^- + 2H^+ \rightarrow 2RSH \qquad (1)$$
Die Gleichung der polarographischen Welle

$$E_{de} = E' + 0,029 \log\left(\frac{i_d - i}{i^2}\right) \qquad (2)$$

zeigt daß E eine lineare Funktion von $\log (i_d - i)/i^2$ mit einer Steigung von 0,029 V ist. Dies bestätigten auch die experimentellen Ergebnisse für Konzentrationen von 1×10^{-5} bis $1 \times 10^{-4}M$ RSSR, nach denen die oben erwähnte Abhängigkeit als eine Gerade mit einer Neigung von 0,030–0,033 V erscheint. Trägt man i_d gegen $H^{\frac{1}{2}}$ auf, erhält man eine durch den Ursprung laufende Gerade (H = Höhe des Quecksilberniveaus). Diese Angaben weisen darauf hin, daß der elektrochemische Prozeß durch die Diffusion begrenzt wird.

Erhöht sich die Konzentration um das Zehnfache, so verschiebt sich $E_{1/2}$ der ersten Welle nach den
Abb. 1. Klassisches Polarogramm von $1 \times 10^{-4}M$ RSSR in Äthanol–$0,2M$ LiClO$_4$.

negativeren Potentialen unter Nichtbeachtung der linearen Abhängigkeit $E_{1/2} = E - 0,029 \log i_d/2$. Die in Äthanol in Abwesenheit und dann in Gegenwart von RSSR aufgenommenen elektrokapillaren Kurven zeigen eine Depression, die auf einen Adsorptionsprozeß zurückzuführen ist (Abb. 2).

Diese Angaben sprechen für einen komplizierten Prozeß bei der Reduktion von RSSR und Gleichung (1) gibt lediglich unvollständig die Natur der elektrochemischen Wechselwirkungen wieder.

Die für $1 \times 10^{-4}M$ RSSR und $1 \times 10^{-4}M$ (RS)$_2$Hg erhaltenen Polarogramme weisen identische Wellen auf, wobei $E_{1/2}$ von (RS)$_2$Hg um etwa 0,05 V nach den positiveren Potentialen als $E_{1/2}$ von RSSR verschoben wird. (RS)$_2$Hg geht folgende elektrochemische Reaktion ein:

$$(RS)_2Hg + 2e^- + 2H^+ \rightarrow 2RSH + Hg$$
Die Gleichung der polarographischen Welle ist mit Gleichung (2) identisch. Ein Gemisch von RSSR und (RS)$_2$Hg ergab eine verzerrte Zwischenwelle, wobei die lineare Abhängigkeit des Potentials E_{de} von $\log(i_d - i)/i^2$ im Unterschied zu RSSR nicht befolgt wird, was auf einen Komplizierten Prozeß hindeutet.

Polarographie von RSSR und (RS)$_2$Hg auf rotierender Scheibenplatinelektrode. Wird RSSR auf einer Quecksilbertropfelektrode direkt reduziert, ohne einer chemischen Reaktion zu unterliegen, so sollte es ebenfalls auf einer rotierenden Scheibenplatinelektrode mit annähernd gleichen Potentialen reduziert werden. Die Polarogramme beider Verbindungen wurden auf einer zweimal mit heißer,
Abb. 2. Elektrokapillarkurve von $1 \times 10^{-3}M$ RSSR in Äthanol–$0,2M$ LiClO$_4$; 1. in Abwesenheit von RSSR; 2. in Gegenwart von RSSR.

konzentrierter Salpetersäure behandelten und nacheinander mit destilliertem Wasser und Äthanol gewaschenen Platinelektrode erhalten. Die untere Grenze bei einer Kathodenpolarisation in Äthanol–$0,2M$ Lithiumperchlorat liegt bei $-1,05$ V gegen die gesättigte Kalomelelektrode. Für RSSR-Lösungen wurde in den Grenzen 0,05–1,05 V kein Kathodenpolarogramm erhalten. Für (RS)$_2$Hg-Lösungen erschien eine Einzelwelle mit $E_{1/2}$ bei $-0,45$ V. Bei einer zweiten Elektrolysierung der schon einmal benutzten RSSR-Lösung ohne Entfernung des Quecksilberfilms auf der Platinelektrode wurde eine Kathodenwelle mit $E_{1/2}$ ähnlich wie für (RS)$_2$Hg erhalten. Wird die Elektrode nach dem Hg-Dithiophosphinatpolarogramm mit heißer, konzentrierter Salpetersäure, dest. Wasser und Äthanol gereinigt, so ergibt RSSR keine Kathodenwelle.

Die Ergebnisse zeigen, daß RSSR vor der Elektroreduktion eine chemische Reaktion mit Quecksilber eingehen muß. Auf reiner rotierender Scheibenplatinelektrode wird praktisch keine Kathodenwelle von RSSR beobachtet.

Die lineare Abhängigkeit des Stroms i_d von $H^{\frac{1}{2}}$ und der RSSR-Konzentration beweist, daß diese Reaktion mit großer Geschwindigkeit verläuft.

Elektrolyse von RSSR bei kontrollierbarem Potential. Zur Untersuchung der Elektrolyse bei kontrollierbarem Potential wurden Lösungen von $1 \times 10^{-3}M$ RSSR in Äthanol–$0,2M$ Lithiumperchlorat eingesetzt. Das Volumen der elektrolysierten Lösung betrug 50 ml und das des Quecksilbers 20 ml. Das Potential wurde bei $-1,00$ V, der Hauptwelle von RSSR auf der Tropfelektrode, konstant eingehalten. Um den Strom bei der Elektrolyse zu kontrollieren, wurde eine keinen elektroaktiven Stoff enthaltende Lösung untersucht. Dabei war kein Stromfluß zu beobachten.

Nach Zugabe der RSSR-Lösung bei offener Kette ließ sich auf der Quecksilberkathode ein weißlicher Niederschlag erkennen. Sein UV-Spektrum zeigt ein Absorptionsmaximum $\lambda_{max} = 260$ nm und unterscheidet sich dadurch von RSSR mit $\lambda_{max} = 220$ nm. Die Analyse der erhaltenen IR-Spektren weist auf die Anwesenheit von (RS)$_2$Hg mit Schmp. $= 274 \pm 1°$ hin. Die mit dem präparativ gewonnenen (RS)$_2$Hg verglichenen Angaben stimmen völlig überein.

Um die Elektrolyseprodukte qualitativ zu bestimmen, wurden nach einer 0,2%igen Abnahme der Stromstärke 20 ml der elektrolysierten Lösung entnommen und portionsweise zu je 10 ml zu Ni^{2+} und Co^{2+} Ionen enthaltenden Lösungen getropft. Die erhaltenen Sedimente wurden mit Dichloräthan innerhalb von drei Minuten extrahiert. Gleich darauf wurden ihre Absorptionsspektren aufgenommen (Abb. 3). Sie zeigen eine völlige Übereinstimmung mit den von Larionov u.a. erzielten Ergebnissen.[8]

Die Zahl der am Reduktionsprozeß beteiligten Elektronen wurde für zwei Bestimmungen ermittelt $n = 2,02 \pm 0,06$.[9]

Das Erhalten von $(RS)_2Hg$ ist ein Beweis dafür, daß RSSR nicht direkt auf der Quecksilbertropfelektrode reduziert wird, sondern erst in eine zur Bildung von $(RS)_2Hg$ führende chemische Reaktion tritt, das als die elektroaktive Komponente erscheint.

Zusammenfassend läßt sich folgern, daß RSH das Endprodukt der Elektrolyse ist. Die wahrscheinlichen Beziehungen von RSSR auf der Quecksilbertropfelektrode sind nach dem folgenden Schema wiederzugeben:

$$RSSR + Hg \rightarrow Hg[RSSR]_{ads}$$

$$Hg[RSSR]_{ads} - 2e^- \rightarrow [(RS)_2Hg]_{ads}$$

$$[(RS)_2Hg]_{ads} + 2e^- + 2H^+ \rightleftharpoons 2RSH + Hg$$
Die wahrscheinlichen Beziehungen von $(RS)_2Hg$ auf der Quecksilbertropfelektrode sind schematisch folgenderweise zu veranschaulichen:

$$(RS)_2Hg_{Lös} + 2e^- + 2H^+ \rightarrow 2RSH_{Lös} + Hg$$

$$2RSH_{Lös} + Hg \rightleftharpoons [(RS)_2Hg]_{ads} + 2e^- + 2H^+$$

$$[(RS)_2Hg]_{ads} + 2e^- + 2H^+ \rightarrow 2RSH + Hg$$
Elektrochemische Untersuchungen in Äthanol–1M Schwefelsäure

Die polarographischen Kurven für unterschiedliche Konzentrationen sind auf Abb. 4 zu sehen.

Wenn man die polarographischen Wellen bedingt in einzelne Potentialzonen einteilt, so erkennt man bei niedrigeren Konzentrationen nur einen störenden Prozeß, bei höheren Konzentrationen dagegen drei solcher Prozesse. Zur Ermittling ihrer Natur wurden Elektrokapillarkurven in Äthanol–1M Schwefelsäure Medium aufgenommen (Abb. 5). Die hier ebenfalls zu beobachtende Depression deutet auf das Vorhandensein eines sich auf dem Quecksilbertropfen adsorbierenden Stoffes hin. Bei höheren RSSR-Konzentrationen nimmt die Adsorption zu und die verzögerte Stromzunahme läßt auf die Bildung eines, die elektrochemische Reaktion hemmenden, unlösbaren Films von Molekülen des Depolarisators auf der Quecksilberoberfläche schließen.

Abb. 4. Klassische Polarogramme von RSSR in Äthanol–1M H_2SO_4 Medium. 1. $0,5 \times 10^{-4}M$; 2. $1 \times 10^{-4}M$; 3. $1,5 \times 10^{-4}M$; 4. $0,3 \times 10^{-3}M$.
Abb. 5. Elektrokapillarkurven von $1 \times 10^{-3}M$ RSSR in Äthanol–1M H_2SO_4 Medium; 1. in Abwesenheit von RSSR; 2. in Gegenwart von RSSR.

Die schnelle Stromzunahme bei den nagativeren Potentialen läßt sich wahrscheinlich auf die Reduktion dieses Films zurückführen, indem RSSR schnell mit Hg reagiert unter Bildung eines unlösbaren Films aus $(RS)_2Hg$, der jedoch bei Kathodenpotentialen, negativer als 0,12 V, reduziert wird.

Es ergibt sich für die erste Welle eine nichtlineare Abhängigkeit der Stufenhöhe von der Konzentration, die auf einen Adsorptionsprozeß hinweist. Der Strom dieser Welle ist ziemlich unabhängig von $H^{\frac{1}{2}}$, was einen kinetischen Prozeß voraussetzt. Die auf dem Plateau der polarographischen Kurven gemessenen Ströme sind $H^{\frac{1}{2}}$ proportional und befinden sich in linearer Abhängigkeit von der RSSR-Konzentration, welches für eine Einschränkung des elektrochemischen Prozesses durch die Diffusion spricht. Die qualitative Analyse der Produkte der Elektrolyse bei kontrollierbarem Potential zeigt ebenfalls, daß RSH ein Endprodukt ist.

Wenn man von dem Verlauf komplizierter chemischer und elektrochemischer Prozesse absieht, so lassen die experimentellen Ergebnisse erkennen, daß auch die coulometrische Generierung von RSH in Äthanol–1M Schwefelsäure Medium leicht erfolgt.

Summary—The electrochemical behaviour of bis(diphenyldithiophosphine)disulphide (RSSR) and mercuric diphenyldithiophosphinate [$(RS)_2Hg$] in ethanol–lithium perchlorate and ethanol–sulphuric acid media was studied by the methods of classical polarography, and electrolysis at controlled-potential and at a rotating disc platinum electrode. The data obtained show that RSSR is not reduced directly on the dropping mercury electrode but is adsorbed. It then undergoes a rapid chemical reaction causing the formation of $(RS)_2Hg$, which is electroactive. The electrolysis at controlled potential proves that $(RS)_2Hg$ undergoes a two-electron reduction, giving diphenyldithiophosphinic acid (RSH) as a main product, whereas the oxidation of RSH leads to the production of $(RS)_2Hg$. Regardless of the fact that the chemical and adsorption equilibria during reduction of RSSR and $(RS)_2Hg$ are complex, the coulometric generation of RSH is not difficult to achieve, and permits the use of RSSR as a coulometric reagent.

SHORT COMMUNICATIONS

DETERMINATION OF TOTAL TIN IN GEOLOGICAL MATERIALS BY ELECTROTHERMAL ATOMIC-ABSORPTION SPECTROPHOTOMETRY USING A TUNGSTEN-IMPREGNATED GRAPHITE FURNACE

LIYI ZHOU,* T. T. CHAO† and A. L. MEIER
U.S. Geological Survey, Box 25046, Federal Center, Denver, CO 80225, U.S.A.

Summary—An electrothermal atomic-absorption spectrophotometric method is described for the determination of total tin in geological materials, with use of a tungsten-impregnated graphite furnace. The sample is decomposed by fusion with lithium metaborate and the melt is dissolved in 10% hydrochloric acid. Tin is then extracted into trioctylphosphine oxide–methyl isobutyl ketone prior to atomization. Impregnation of the furnace with a sodium tungstate solution increases the sensitivity of the determination and improves the precision of the results. The limits of determination are 0.5–20 ppm of tin in the sample. Higher tin values can be determined by dilution of the extract. Replicate analyses of eighteen geological reference samples with diverse matrices gave relative standard deviations ranging from 2.0 to 10.8% with an average of 4.6%. Average tin values for reference samples were in general agreement with, but more precise than, those reported by others. Apparent recoveries of tin added to various samples ranged from 95 to 111% with an average of 102%.

Tin occurs in geological materials either as a constituent of the silicate lattice,[1–3] or in the form of cassiterite.[1,2] Knowledge of the relative distribution of tin in the two forms is important in studies related to the geochemistry of tin and in geochemical prospecting for tin.[1,3]

Whereas cassiterite in geological samples can be converted into tin(IV) iodide and volatilized by heating with ammonium iodide,[2,4–7] total tin can only be released by fusion with an alkaline flux such as lithium metaborate.[8–10] The tin released may be determined by atomic-absorption spectrophotometry, as the hydride[7–10] or through aspiration of an organic tin extract into a nitrous oxide–acetylene flame,[4,5] or by ICP atomic emission spectroscopy following hydride generation.[6] The difference between the total tin determined by fusion with lithium metaborate and the cassiterite tin would give an approximate value for the tin held in the lattice of silicates.

The proposed method involves fusion of the sample with lithium metaborate to release the total tin, which is extracted with trioctylphosphine

oxide–methyl isobutyl ketone (TOPO–MIBK), by the procedure of Burke.[11] The tin in the organic extract is atomized in a tungsten-impregnated graphite furnace. The sensitivity, precision, and accuracy of the method are desirable features for the determination of tin in geological samples of diverse chemical composition.

EXPERIMENTAL

Apparatus

An Instrumentation Laboratory (IL) Model 951 atomic-absorption spectrophotometer was used for this study.‡ The spectrophotometer was equipped with the following accessories: controlled-temperature furnace atomizer (IL 555 CTF), auto-sampling device (IL 254 FASTAC), background corrector, and tin hollow-cathode lamp.

Settings for the spectrophotometer were: lamp current 10 mA; wavelength 286.3 nm; band-width, 0.5 nm; integration time, 8 sec; read-out mode, peak height; photomultiplier voltage (HV), adjusted by the HV control until the log intensity meter reads between 0.2 and 0.8 V.

Settings for the controlled-temperature furnace atomizer were: purge gas, nitrogen at 6.9 l./min; auto operation mode; temperature-feedback on; auto-clean off; atomization programme as follows:

	Drying		Charring		Atomizing	
Step	1	2	3	4	5	6
Temp., °C	0	150	750	1000	2500	2500
Time, × 5 sec	0	1	4	4	0	2

Settings for the auto-sampling device were: "door calibration", 150°; sample deposit time, 2 sec; delay time, 5 sec. The FASTAC sample-delivery system aspirates the sample through a pneumatic nebulizer and converts it into an aerosol in the graphite furnace.

Impregnated graphite tubes. The impregnation of pyrolytic graphite tubes was done following the general guidelines of Fritzsche *et al.*[12] The tubes were soaked overnight in a 7.8% solution of sodium tungstate dihydrate and dried at 120° in an electric oven for 4 hr. Before use, each impregnated tube was conditioned by application of the atomization programme five times.

Reagents

Ascorbic acid. Medium fine crystals (30–80 mesh).

TOPO (trioctylphosphine oxide)–MIBK (methyl isobutyl ketone). Dissolve 4.0 g of TOPO in 100 ml of MIBK.

Lithium metaborate. Anhydrous powder (G. Frederick Smith Chemical Company).

Stock and standard solutions. Prepare the 1000-μg/ml stock tin solution by dissolving 0.5000 g of reagent-grade tin metal in 250 ml of 50% v/v hydrochloric acid and diluting to 500 ml with water. Prepare the 1-μg/ml standard tin solution in 10% v/v hydrochloric acid by serial dilution of the stock tin solution. The dilute standard tin solution is stable for at least 6 months in a Pyrex glass bottle.

Organic tin standard solutions in TOPO–MIBK (Sn 0, 0.025, 0.050, 0.075, 0.100, 0.200, 0.300, 0.400 and 0.500 μg/ml). Using Eppendorf micropipettes, transfer 0, 0.25, 0.50, 0.75, 1.00, 2.00, 3.00, 4.00 and 5.00 of the 1 μg/ml standard tin solution to individual 25 × 200 mm screw-cap tubes and make up to a total volume of 40 ml with 10% v/v hydrochloric acid. Scoop 0.75 g of ascorbic acid into each tube and use a vortex mixer to dissolve the solid. Add exactly 10 ml of the TOPO–MIBK solution to each tube, shake for 1 min, and centrifuge the capped tubes to separate the organic phase. Transfer the organic tin extracts to 16 × 150 mm test-tubes and cap them to prevent evaporation. The tin in the extract is stable for at least 1 week if kept in a refrigerator.

Procedure

Weigh 0.750 g of lithium metaborate and 0.250 g of <100-mesh soil, rock or stream-sediment sample into a 10-ml platinum crucible. Mix the flux and sample by means of a thin glass rod, and fuse the mixture in a muffle furnace at 1000° for 1 hr. After cooling, place the crucible in a 50-ml beaker and put a small magnetic stirring bar in the crucible. Add 30 ml of 10% v/v hydrochloric acid to immerse the crucible. Heat the beaker at 50–60° on a hot-plate (fitted with a magnetic stirrer motor) for about 30 min to dissolve the contents of the crucible completely. Transfer the solution to a 25 × 200 mm screw-cap tube and wash the beaker and crucible with 10 ml of 10% v/v hydrochloric acid. Add 0.75 g of ascorbic acid and extract the tin with 10 ml of TOPO–MIBK as in the preparation of the organic tin standard solutions.

Determine the absorbance values for the tin in the organic extracts of the standards and samples, using the graphite

furnace/atomic-absorption spectrophotometer system. Correct the results for the blank and for the tin present as a contaminant in the lithium metaborate (as described under "sample decomposition" below).

RESULTS AND DISCUSSION

Sample decomposition

Fusion with lithium metaborate as a flux has been shown to decompose geological materials, bringing both lattice-bound tin and cassiterite tin into solution for the determination of total tin in the sample.[8–10] The lithium metaborate used in this study was analysed by the proposed procedure for possible contamination by tin, and found to contain 0.74 ± 0.017 ppm Sn (ten replicates). It follows that a correction must be applied for tin in the flux used. There are two ways of doing this: (*a*) running a complete blank (including the fusion) for each batch of samples, taking care to use virtually identical weights of flux for all tests, or (*b*) determining a reagent blank (excluding the flux), analysing the lithium borate for tin (and correcting for the reagent blank), and correcting the results for the samples by subtraction of both the reagent blank *and* the tin contained in the flux (which must be weighed accurately for each sample). The result is then calculated by means of the formula

$$\text{ppm Sn} = \frac{[(\text{tin in extract }(\mu\text{g/ml}) - \text{tin in fluxless blank }(\mu\text{g/ml})) \times \text{MIBK volume (ml)}] - \text{tin in flux }(\mu\text{g})}{\text{sample weight (g)}}$$

Sensitivity

The characteristic mass (weight of analyte giving 1% absorption) of the method described above has been found to be 7.0 pg. With a 0.250-g sample, the range of tin concentrations that can be determined is 1.00–20.0 ppm in the sample. If the volume of TOPO–MIBK used for extraction is reduced to 5 ml, the lowest tin concentration that can be accurately determined is 0.50 ppm, which is considered to be below the crustal abundance.[13]

The calibration graph for tin is linear up to 0.200 μg/ml, corresponding to an absorbance of 0.689 (Table 1), above which curvature occurs. When the concentration of tin in the sample exceeds 20.0 ppm,

the sample extract should be diluted with MIBK so that the absorbance is within the linear range of the calibration graph, preferably around 0.500, to reduce experimental error.

Effect of tungsten-impregnation on the performance of the graphite tube

Impregnation of the graphite tube with sodium tungstate solution nearly doubles the absorbance readings for tin standards (Table 1) thereby enhancing the sensitivity, and also improves the precision of the absorbance readings (Table 1). The tungsten-impregnated graphite tube can be used for at least 500 firings.

Interferences

The chelation and extraction of tin from the sample solution with TOPO–MIBK is adapted from

the procedure of Burke[11] for the determination of tin in aluminium, iron and nickel-base alloys. The same extraction has been used for determining tin in geological materials[5] and in mineralized rocks and ores.[4] Welsch and Chao[5] found no interferences from 1000 µg of Cu, Pb, Zn, Mn, Hg, Mo, V, and the equivalent of 20% Fe in a 1-g sample in the flame atomic-absorption determination of tin. It is inferred that interferences in the graphite-tube atomic-absorption determination of tin would be minimal. This is supported by the data of Tables 2 and 3 showing the general agreement of the tin values found for the reference samples with those reported by others, and the very good recoveries of tin added to various samples of diverse chemical composition.

Results for geological reference samples

The proposed method was applied to three sets of U.S. Geological Survey reference samples: (1) eight rock standards,[14] (2) six geochemical exploration reference samples,[15] and (3) four glass reference standards.[16] The average tin values obtained for the eight USGS reference rocks are in most cases in general agreement with, but more precise than, the values reported by Terashima,[17] as shown in Table 2.

Replicate analyses of eighteen reference samples with various matrices gave relative standard deviations ranging from 2.0 to 10.8%, with an average of 4.6% (Table 2). Recoveries of tin added to various samples ranged from 95 to 111% with an average of 102% (Table 3).

Thus, the proposed method can be applied to the determination of total tin in a wide range of geological materials of diverse chemical composition.

SPECTROPHOTOMETRIC DETERMINATION OF TRANEXAMIC ACID WITH CHLORANIL

Abdel-Aziz M. Wahbi, Essam A. Lotfi and Hassan Y. Aboul-Enein

College of Pharmacy, King Saud University, Pharmaceutical Chemistry Department, Riyadh,
Saudi Arabia

Summary—Tranexamic acid is reacted with aqueous alcoholic chloranil, buffered at pH 9, to give a complex with maximum absorption at 346 nm and with an apparent molar absorptivity of 15.7×10^3 $1.\text{mole}^{-1}.\text{cm}^{-1}$. A_{max} is linearly related to concentration over the range 2–10 μg/ml. When applied to tablets labelled as containing 500 mg each, the mean found was 496 ± 4 mg. The results were comparable with those of the traditional formol titration method for amino-acids.

Tranexamic acid (*trans*-4-aminomethylcyclohexanecarboxylic acid) is a synthetic ω-amino-acid with useful antifibrinolytic properties.[1] An electron-capture gas chromatographic method has been reported for its determination in biological fluids.[2] In view of the fact that tranexamic acid does not possess characteristic absorption in the ultraviolet region, it was felt useful to develop a spectrophotometric method for its determination. Chloranil (tetrachloroquinone) has been reported to form condensation products with primary and secondary arylamines, amino-acids, phenols and naphthalene.[3,4] The reaction of some amino-acids with chloranil in aqueous ethanol buffered at certain pH values has been described as $n \rightarrow \pi$ charge-transfer complex formation.[5] Lin and Cheng[6] studied the ultraviolet and infrared absorption characteristics, compositions, formation constants and pH dependence of the amino-acid–chloranil complexes. Several amino-acids[7] and a wide range of pharmaceutical amines[8,9] have been determined with chloranil buffered at pH 9. On the same basis, chloranil is now used for determination of tranexamic acid.

EXPERIMENTAL

Instrument

A Varian DMS 90 double-beam spectrophotometer with 1-cm quartz cuvettes was used.

Reagents

Chloranil solution. A saturated solution in ethanol.

Buffer solution, pH 9. A 0.05M solution of sodium tetraborate.

Tranexamic acid solution. A 0.010% solution in distilled water.

General procedure

Pipette 1–5 ml portions of standard tranexamic acid solution into 50-ml standard flasks. Add exactly 10 ml of chloranil solution and 2 ml of 0.05M buffer solution to each. Mix and dilute to volume with water. Prepare a reagent blank. Let all the solutions stand for 40 min at room temperature (20°), then measure the absorbance in 1-cm cells at 346 nm during the next 10 min. Treat samples in the same way. Because of the short time interval available for the measurement, it is best to prepare the test solutions in small batches and at suitable time intervals.

Procedure for tablets

Weigh and powder five tablets. Weigh accurately a quantity of the powder equivalent to about 100 mg of tranexamic acid into a 100-ml standard flask, add 80 ml of water and shake the flask for 30 min. Make up to volume with distilled water and mix. Pipette 10 ml into a 100-ml standard flask and dilute to volume with distilled water, then apply the general procedure to 4 ml of this solution. Calculate the amount of tranexamic acid from the calibration curve or from an equivalent linear equation.

RESULTS AND DISCUSSION

Chloranil in aqueous alcoholic solution buffered at pH 9 reacts with tranexamic acid to form a complex with maximum absorption at 346 nm. Under the experimental conditions described, the absorbance (A) in 1-cm cells is a linear function of the concentration $(c, \mu$g/ml), over the range 2–10 μg/ml, the equation being $A = 0.007 + 0.101c$. The apparent molar absorptivity was found to be 15.7×10^3 $1.\text{mole}^{-1}.\text{cm}^{-1}$. The standard deviation is 0.07 μg/ml at the 6-μg/ml level, so the error of prediction from the regression line (95% confidence limits) is 0.22 μg/ml.

The reaction time, the volume of chloranil solution, the volume of pH-9 buffer and the final dilution were selected as a compromise between optimum sensitivity, stability and minimum blank reading. Thus, the yellow colour of chloranil in ethanol slowly changes to violet when the solution is added to the pH-9 buffer. The absorbance of the blank solution, measured at 346 nm against water, is about 0.46, so a double-beam spectrophotometer is preferable, for precise results to be obtained. The absorbance of the reaction product at 346 nm increases slowly over a period of 40 min and then remains stable for 10 min, during which the absorbance must be measured (Fig. 1).
Fig. 1. Rate of colour development and stability of colour.

Table 1. Determination of tranexamic acid in tablets* by the chloranil and formol titration methods

Found, %	
Spectrophotometry	Titration
99.9	98.9
98.7	98.5
98.6	98.5
99.4	99.2
99.6	99.2
98.2	101.2
Mean ± s.d. 99.1 ± 0.7	99.2 ± 1.0

*Nominal content 500 mg.

The mechanism of the reaction between chloranil and amino-acids is still not known with certainty; it is generally supposed to be charge-transfer complex formation, but the lengthy reaction time does not support this. The amino-acid–chloranil reacting ratio has been found to be 1:1 or 1:2 according to the number of amino groups in the amino-acid.[6]

The method has been applied to the determination of tranexamic acid in commercial tablets, the results being compared with those obtained by the traditional formol titration method for amino-acids, which involves the addition of neutral formaldehyde solution to aqueous tranexamic acid solution, followed by titration with $0.1M$ sodium hydroxide. Table 1 shows that the mean values found were $99.1 \pm 0.7\%$ of the nominal content by the spectrophotometric method and $99.2 \pm 1.0\%$ by the titrimetric method. The results are in good agreement with each other.

The proposed method is suitable for the determination of tranexamic acid in μg quantities, but there is positive interference from other amino-acids and water-soluble compounds containing a primary or secondary amino group.

ESTIMATION OF CHLORIDE IN OXIDIZING MEDIA BY MEANS OF ION-SELECTIVE ELECTRODES

G. Subramanian, Navin Chandra and G. Prabhakara Rao

Central Electrochemical Research Institute, Karaikudi-623006, India

Summary—Chloride concentrations down to the ppm level in a large excess of chlorate or perchlorate can be quantitatively estimated by use of chloride ion-selective electrodes (ISEs). Similarly traces of chloride in chromic acid solutions can be estimated with a heterogeneous silicone-rubber based chloride ISE. However, homogeneous chloride ISEs pose a problem for practical applications, because their response in chromic acid solutions changes with time owing to chemical attack on the membrane surface. In permanganate solutions, both homogeneous and heterogeneous type electrodes can be used for monitoring chloride ions. The Orion electrode, however, was found to show a slightly super-Nernstian response in such solutions. The presence of $10^{-3}M$ iron(III) had no adverse effect on the performance of these electrodes in permanganate solutions.

It is generally accepted that the response of ion-sensitive electrodes (ISEs) is not influenced by oxidizing agents in solution. In the case of chloride ISEs both the homogeneous and heterogeneous type are claimed to be free from interference by Cu^{2+}, Fe^{3+} and MnO_4^- ions.[1,2] However, according to a recent report by Bixler *et al.*,[3] Fe^{3+} interferes seriously with the performance of homogeneous chloride ISEs in highly acidic solutions. They also observed that the response of these ISEs is unaffected under similar conditions if the iron is present as Fe^{2+}. Since a number of practical applications of Cl^- ISEs may involve monitoring chloride in the presence of a large excess of oxidizing agent (*e.g.*, in chromic acid anodizing baths and electrolytic cell liquors containing chlorate and/or perchlorate) it seemed worth studying the performance of the chloride ISEs in such oxidizing media.

EXPERIMENTAL

Three different ISEs were examined, *viz.* the Radelkis silicone-rubber based heterogeneous-membrane type electrode (Model OP-Cl-7111), the homogeneous-membrane electrode developed at CECRI, and the Orion electrode (Model 94-17 A). The CECRI electrode was based on a homogeneous membrane made of our $Ag_2S/AgCl$ composite.[4] The active surface of the electrodes was polished with Orion 94-82 polishing paper. For conditioning, the electrodes were dipped in $10^{-2}M$ potassium chloride for 1 hr. After thorough washing the electrodes were immersed in conductivity water for 12 hr. When not in use, the electrode surface was kept immersed in conductivity water.

An Orion Research Microprocessor 901 Ion Analyzer readable to ± 0.1 mV was used. The reproducibility of potentials recorded was ± 0.5 mV, corresponding to $\pm 2\%$ error in the estimation of chloride. A double-junction $1M$ potassium chloride calomel electrode was used as reference electrode, with the appropriate background solutions in the outer compartment. All the experiments were done at $25 \pm 0.5°$.

All the chemicals used were of analytical or general reagent grade. Stock solutions were prepared in conductivity water and diluted to the desired concentration.

Chromic acid solutions were prepared from Baker chromium trioxide (analysed low-sodium MOS electronic grade).

To estimate the accuracy of the determination in chlorate and perchlorate backgrounds, two methods, *viz.* the calibration-graph and standard-addition methods, were used. The calibration graphs were obtained for 10–1000 ppm chloride in the required background by the "litre beaker" method.[5] The potentials of the electrode in test solutions containing 50, 100 and 500 ppm chloride in appropriate chlorate or perchlorate media were then measured and the corresponding chloride concentrations read from the standard graph. In the standard-addition method, the change in potential (ΔE) of 100 ml of test solution on addition of a known amount of chloride (as a standard solution) was measured and the chloride concentration in the test solution was calculated by use of the equation[6]

$$C_x = C_s V_s / [(V_x + V_s) \, 10^{\Delta E/S} - V_x]$$

where C_x and C_s are the concentrations and V_x and V_s the volumes of the test solution and the standard solution, and S is the slope of the standardization graph.

Studies on the effect of chlorate and perchlorate backgrounds were done in neutral medium, which is of interest in real sample analysis, and extended to acid medium in view of the enhanced oxidizing power of these oxidants in such media. Perchloric acid and nitric acid were used to adjust the pH of the sodium perchlorate and potassium chlorate solutions, respectively.

RESULTS AND DISCUSSION

Chlorate and perchlorate baths

In the production of chlorate by electrolytic oxidation of chloride solutions, monitoring of the chloride concentration at various stages of the electrolysis is essential. During the electrolysis the chloride content of the cell liquors may vary from about 3×10^5 to 10^3 ppm (300–1 g/l.) and the maximum sodium chlorate concentration (at the end of electrolysis) may be about 400–500 g/l.[7,8] Since chloride in the range 1.8–3.55×10^4 ppm can be monitored by chloride ISEs, so a tenfold dilution of the sample will always bring its chloride concentration into the detection range of the ISEs. The response of the ISEs was

measured for the range $10–10^4$ ppm chloride in 42.5-g/l. potassium chlorate background (which also served as ionic strength adjuster). All three electrodes gave Nernstian response, showing that chlorate has no adverse effect.

Similarly in the production of sodium perchlorate the sodium chloride concentration in the cell liquor may also vary from about 3×10^5 to 10^3 ppm, depending on the stage of electrolysis, and the maximum sodium perchlorate content may be 500–600 g/l.[9] A tenfold dilution to keep the chloride concentration in the detection range of the ISEs will bring the concentration of sodium perchlorate to about 50–60 g/l., so this chloride range was tested in 50-g/l. sodium perchlorate background (which again gives almost constant ionic strength). All the three electrodes again gave Nernstian response, showing that perchlorate does not interfere.

These experiments were repeated with lower concentrations of the background salt (15 and 30 g/l.) and also studied at pH 1. The electrode performances remained the same in all cases.

The error of the determination was then evaluated for these systems by the methods used for the response to pure chloride solutions and the results are given in Table 1. The error is again about 2%. For comparison, chloride in neutral solutions containing chlorate and perchlorate was determined by conventional titration with silver nitrate, with potassium chromate as indicator. The results were invariably higher than the ISE results by about 5%.

Chromic acid medium

Analysis of chromic acid solutions is another example of chloride monitoring in an oxidizing media. Levels of chloride above a certain critical value are reported to have adverse effects on the performance of these solutions as anodizing baths. In the present study, the response of the chloride ISEs was measured for typical chromic acid anodizing baths[10] containing 50 and 100 g of chromic acid per litre. To investigate the effect of sulphuric acid another composition (250 g/l. CrO_3 and 2.5 g/l. H_2SO_4) was also studied. In the 50-g/l. chromic acid bath the Radelkis heterogeneous electrode exhibited Nernstian response over the 10–1000 ppm chloride range, and sub-Nernstian response at lower levels, in conformity with its performance in the absence of oxidizing agent (Fig. 1). For the Orion and CECRI ISEs, however, the potential of the electrodes was found to vary with time. Visual observation of the electrode surface after exposure to the chromic acid solutions showed slight etching of the surface of the Orion electrode, whereas the CECRI electrode was covered with a thin film which could be easily wiped off with paper, and no etching of the surface was observed. Since these surface effects were thought to be the cause of drift in the electrode potential, it was felt that the electrodes would give Nernstian response if the measurement were made quickly enough for no

Fig. 1. Response of chloride ISEs in chromic acid solutions. 1—Radelkis ISE, 2—CECRI ISE, 3—Orion ISE, in 50-g/l. chromic acid background; 4 and 5—Radelkis ISE in 100-g/l. chromic acid and 250-g/l. chromic acid/2.5 g/l. sulphuric acid respectively. The total experimental time for obtaining calibration plots 2 and 3 was 5 min (cf. text).

Fig. 2. Response of chloride ISEs in 0.02M potassium permanganate background. 1—CECRI ISE, 2—Orion ISE, 3—Radelkis ISE.

significant etching or film formation to take place. To confirm this, experiments were done in which the whole range of chloride concentration was covered within 5 min. The response of the Orion and CECRI electrodes in these experiments is also included in Fig. 1. Both electrodes showed Nernstian behaviour. Hence the homogeneous membrane electrodes which show a time-dependent response in the presence of chromic acid can be used only if the time of immersion of the electrodes can be kept short. Since the homogeneous-membrane ISEs were adversely affected by chromic acid, only the Radelkis heterogeneous membrane ISE was studied at the higher chromic acid concentrations. The electrode showed Nernstian behaviour (Fig. 1), confirming that it is not affected by chromic acid.

Permanganate medium

The effect of permanganate was also included in the study. The chloride range 5×10^{-5}–$10^{-2}M$ in 0.02M permanganate background electrolyte was examined. The electrode responses are shown in Fig. 2. The Orion electrode gave a response that was slightly super-Nernstian (68 mV/pCl), whereas the other two gave Nernstian response. The presence of iron is known to catalyse the oxidation of chloride by permanganate in acid medium. Hence the response of the electrodes to chloride in 0.02M permanganate

was also studied in the presence of $10^{-3}M$ Fe^{3+}. No adverse effect was observed over a period of 15 min.

DETERMINATION OF WATER IN ETHANOL AND ACETONE BY DIRECT INJECTION ENTHALPIMETRY BASED ON THE HEAT OF DILUTION

Walace A. de Oliveira and Celio Pasquini

Instituto de Química, Universidade Estadual de Campinas, C.P. 6154, Campinas, São Paulo, Brazil

Summary—Two analytical procedures based on the magnitude of the heat of dilution and direct injection enthalpimetry have been developed for determination of water in ethanol and acetone. The results obtained by means of the heat of dilution were compared with the values given by pycnometry, and gave a relative difference in the range 0.2–3%. The precision depends on the slope of the calibration curve, which varies with the procedure and the concentration of the sample.

Use of the heat of dilution for analytical purposes is not new and was first proposed over 60 years ago.[1] However, only a few applications[1-4] have been found in the literature. The enthalpy change due to dilution is very large for many compounds. The magnitude of the heat evolved or absorbed depends on the interactions between solute and solvent and is a function of the initial solute concentration. Thus, the temperature changes on dilution can be related to the solute/solvent ratio in a given sample. With the modern capability for measuring very small changes in temperature, the enthalpimetric signal due to dilution can give a precise analysis.

Ethanol and acetone are widely used in the laboratory and industry. Ethanol is employed as a fuel (as hydrated ethanol) and in fuel mixtures (as anhydrous ethanol). The water content is an important factor in the quality control of both ethanol and acetone. The Karl Fischer titration, normally used for water determination, has some disadvantages: active carbonyl groups, such as those present in ketones, cause formation of water by reaction with the alcohol present in the reagent, free SO_2 forms a yellow SO_2I^- species which makes visual recognition of the end-point rather difficult, and the reagent contains toxic substances that are unpleasant to work with.

The objective of the present work was to develop and evaluate analytical methods based on measurement of the heat of dilution. Procedures for the determination of water in ethanol and acetone have been developed.

EXPERIMENTAL

The determinations were performed by direct injection enthalpimetry (DIE) with an apparatus similar to that previously described.[5] It consists of a 100-ml Dewar flask which contains the thermistor probe (2200Ω, Thermometrics Inc.), a glass pipette tied to a plastic syringe, and a magnetic stirring bar. The thermistor is connected to a

Wheatstone bridge (Leeds & Northrup, catalogue number 4760), the output voltage from which is fed to a strip-chart recorder. The bridge sensitivity was 6.7 mV/deg. The pipette used delivered 1.30 ml, but any volume between 1 and 2 ml can be used, provided it is kept the same for all samples and standards.

Two procedures were used. In procedure I the Dewar flask was charged with 50.0 ml of distilled water, and the pipette was loaded with sample and immersed in the water in the Dewar flask; after temperature equilibrium had been attained (which was almost instantaneously), the sample was injected into the water and the temperature change due to the heat of dilution was recorded. In procedure II the Dewar flask was charged with 50.0 ml of sample and distilled water (1.30 ml) was added from the pipette after temperature equilibration.

All determinations based on the heat of dilution were accomplished by using calibration graphs obtained with solutions standardized by pycnometry. Comparative determinations were performed with a 30-ml pycnometer according to well-accepted procedures.[6] Reagent-grade chemicals were used throughout.

RESULTS AND DISCUSSION

The results for five replicates of ethanol and acetone, with various water contents, measured by both procedures, showed that the temperature change on dilution could be measured with a mean standard deviation of 0.002° for ethanol and 0.004° for acetone.

Typical calibration curves for procedure I are shown in Fig. 1. The heat of dilution is exothermic for the two compounds. The curves show similar behaviour, with the slopes increasing in dilute solutions and tending to decrease with high content of solute. In the range of concentration 50–70% and 20–60% of water for ethanol and acetone, respectively, there is a linear relationship, with a correlation coefficient of 0.9999. Figure 2 shows the behaviour of the heat of dilution as a function of the percentage of water in the sample, for procedure II.
Fig. 1. Calibration curve for determination of water in ethanol (●) and acetone (△) with procedure I. One arbitrary unit is equal to 0.003°C for ethanol and 0.006°C for acetone.

For ethanol, exothermic signals are obtained, which decrease as the amount of water is increased, probably indicating that the total number of hydrogen bonds in the mixture is diminishing. For acetone, the enthalpimetric signal is endothermic for samples with low concentrations of water, but becomes exothermic when the samples contain more than about 5.5% of
water. The endothermic portion of the curve probably indicates that the energy absorbed in the disruption of the water structure is not compensated for by hydrogen-bond formation in the mixture.

As seen from Figs. 1 and 2, the useful composition range for acetone application is 10–90% water for procedure I and 0–10% for procedure II, whereas for ethanol it is 5–80% water by procedure I and 0–5% by procedure II, so the two procedures are complementary.

The precision depends on the sample concentration and the procedure employed. Procedure I, in the linear range, gives a sensitivity of 0.019° and 0.009° per 1% of water for acetone and ethanol respectively. Within the precision of the thermometric measurement, the water content can be obtained with a mean standard deviation of 0.2%. Procedure II is the more attractive way for determination of small amounts of water, owing to the large sensitivity at levels lower than 1%. At this concentration, a sensitivity of about 0.240° and 0.440° per 1% of water was found for ethanol and acetone, respectively. This allows the determination of water with a mean standard deviation of 0.008 and 0.009%.

Because of the non-specific character of the heat of dilution, the enthalpimetric signal may be affected by the presence of other solutes in the sample. In order to assess such contributions to the enthalpimetric signal, the heat of dilution of ethanol was measured before and after the addition of various compounds usually present in fuel or commercial ethanol. The results are given in Table 1. It was observed that the magnitude of interference varies with the compound added to the sample and probably reflects the interactions with the binary system water–ethanol. Table 1 shows that the interference may be relevant if the compound is present in significant percentage. However, in actual samples the percentage of impurities is usually very low[7] and the influence of interferents on the enthalpimetric signal can be considered to be within the experimental error.

The effect of the ambient temperature on the enthalpimetric signal was studied by repeating the analysis of four samples of ethanol, by procedures I and II, at several temperatures in the range 20–30°. It was found that the magnitude of the signal decreases as the ambient and solution temperatures are

A_8	II	1.00	1.03	+3.0

increased. Nevertheless, the effect is smaller than the uncertainty of measurement, for variations of these temperatures within $\pm 2°$.

The accuracy of procedures I and II was checked against pycnometry with synthetic samples. The mean results of three determinations are given in Tables 2 and 3. As can be observed, good correlation was found.

CONCLUSION

The heat of dilution method described in this report is very simple and requires no reagents but the species to be determined (water, in this case). The time needed for one determination is about 3 min and the precision, accuracy and sensitivity are sufficient for water determination in fuel ethanol and commercial acetone and ethanol products. Water solutions of these two substances can be considered as two-component systems, due to the low level of im-

purities, and interference effects are therefore negligible. The Karl Fischer method is more sensitive, but has the disadvantages listed in the introduction. The characteristics of the method indicate potential applications to other substances besides those mentioned in this report.

DETERMINATION OF CYANIDE BY A HIGHLY SENSITIVE INDIRECT SPECTROPHOTOMETRIC METHOD

M. BLANCO* and S. MASPOCH

Departamento de Química Analítica, Facultad de Ciencias, Universidad Autónoma de Barcelona,
Bellaterra (Barcelona), Spain

Summary—Complexation of Pd^{2+} with cyanide inhibits the extraction of the palladium complex of 5-phenylazo-8-aminoquinoline. This effect is used for the indirect spectrophotometric determination of cyanide at the μg level. Cyanide in industrial waste water and in sea-water is determined after distillation as HCN from the sample and collection in sodium hydroxide solution.

The best known methods for the spectrophotometric determination of cyanide are based on the formation of cyanogen bromide or chloride, which can react with pyridine to yield glutaconaldehyde, which is then condensed with benzidine,[1] pyrazolone[2] or barbituric acid,[3,4] producing coloured polymethine dyes. These methods have good sensitivity, their main limitations being the instability of the colour and the need for strict experimental conditions if good reproducibility is to be obtained. Various indirect methods have been developed more recently, based on discharge of the colour of metal complexes by removal of the metal as cyanide complexes. Among these, the most sensitive are those based on the Ag–phen–BPR[5] and Ni–5BrPADAP[6] complexes. Palladium(II) reacts with 5-phenylazo-8-aminoquinoline (PAQ), producing a green precipitate which is extractable into methyl isobutyl ketone,[7] the sensitivity being about midway between those of the Ag–phen–BPR and Ni–5BrPADAP systems. This paper reports that the suppression of the reaction of PAQ with Pd(II) can be used to determine the concentration of cyanide.

EXPERIMENTAL

Reagents

Standard potassium cyanide solution (~ *0.5 mg/ml*). Prepared weekly from 1.30 g of potassium cyanide and 2 g of sodium hydroxide, dissolved and diluted to 1 litre, and standardized potentiometrically by titration with $0.03M$ silver nitrate; working solutions (~ 5 μg/ml) prepared daily by appropriate dilution.

Standard palladium(II) chloride solution. Prepared from $PdCl_2$ and $2M$ hydrochloric acid, to be approximately 0.1% Pd in $0.2M$ hydrochloric acid, and standardized with dimethylglyoxime.[8] Diluted to give a 10-μg/ml Pd working solution in $0.1M$ hydrochloric acid.

PAQ solution, 0.12% in ethanol.

Procedure

Transfer 25 ml of sample, containing less than 4 μg of cyanide, to a 75-ml glass-stoppered centrifuge tube. Acidify

slightly with $2M$ hydrochloric acid, add 1 ml of 10-μg/ml palladium solution and adjust (if necessary) to pH 2.0–2.5. After 1 hr add 1 ml of $2M$ formic acid and then $2M$ sodium hydroxide dropwise until the pH is 3.0, then immediately add 1 ml of PAQ solution, mix, and after 3–5 min add $2M$ sodium hydroxide until the pH is 11.5–12.0. Dilute to approximately 50 ml, add 10 ml of methyl isobutyl ketone (MIBK), shake the stoppered tube vigorously for 1–2 min, centrifuge, and measure the absorbance of the organic phase at 620 nm against an MIBK blank.

Separation of cyanide by distillation

Use the distillation procedure recommended by APHA.[4] Dilute 250 ml of the sample, free from oxidizing agents and sulphide, to approximately 500 ml, add 50 ml of sulphuric acid (1 + 1) and 20 ml of 50% magnesium chloride hexahydrate solution, and boil for 2 hr, collecting the vapour in 50 ml of $0.1M$ sodium hydroxide by suction. Dilute the alkaline solution to 100 ml and analyse a suitable fraction by the procedure above.

RESULTS AND DISCUSSION

The absorption spectra of the PAQ, Pd–PAQ and Pd–PAQ–cyanide systems are shown in Fig. 1. In the presence of cyanide the shape of the Pd–PAQ spectrum remains, but the absorbance is reduced, showing that formation of the Pd–PAQ complex is suppressed. A plot of the absorbance against the cyanide:palladium molar ratio (Fig. 2) indicates that the suppression is due to formation of the $Pd(CN)_2$ complex (and higher complexes when $[CN^-]/[Pd^{2+}] > 2$).

Effect of pH

The reaction between palladium and PAQ takes place in a narrow pH range (2.7–3.3).[7] The choice of pH range for the palladium–cyanide reaction is restricted by two facts. It was observed that if the palladium(II) solution is kept at pH $\geqslant$ 3.0 for relatively long periods of time (1 hr or more) before addition of PAQ, the absorbance is lower than it should be, and is less reproducible, possibly because of formation of palladium hydroxo-complexes. On the other hand, if the pH is around 1.5 the anion

---
Fig. 1. Absorption spectra of MIBK phase. 1, PAQ; 2, PAQ + 10.1 μg of Pd^{2+}; 3, PAQ + 10.1 μg of Pd^{2+} + 1.01 μg of CN^-; 4, PAQ + 10.1 μg of Pd^{2+} + 2.35 μg of CN^-. All spectra recorded against an MIBK blank.

concentration from the acid used (Cl^-, NO_3^- or SO_4^{2-}) is at the tolerance limit. For these reasons a pH range of 2.0–2.5 is recommended. Once this reaction is completed the solution is adjusted to pH 3.0, the PAQ solution is immediately added and the concentration of the Pd–PAQ complex determined.

Kinetics of the palladium–cyanide reaction

In Fig. 3, absorbance is plotted against the time elapsed from the addition of palladium to the cyanide
Fig. 2. Effect of cyanide on the extraction of Pd^{2+}–PAQ complex; 10.1 μg Pd^{2+}.
Fig. 3. Pd^{2+}–CN^- reaction kinetics. pH = 2–2.5, 10.1 μg of Pd^{2+} + 3.83 μg of CN^-.

sample at pH 2.0–2.5, to addition of the PAQ. It is observed that the inhibition reaction is complete in about 50 min. Thus, for analytical purposes, the PAQ reaction must not be applied earlier than 60–90 min after addition of the palladium to the cyanide solution.

Effect of foreign ions

The distillation procedure eliminates most of the interferences,[4] except that of sulphide, which has to be removed beforehand by precipitation with cadmium. A detailed study of the effect of foreign ions on the Pd–PAQ system has already been reported.[7] The effect of the presence of some of the more frequently encountered metal ions that can form cyanide complexes was therefore studied, by addition of 10 μg of the metal ion and 5 ml of $0.01M$ EDTA to 25 ml of a solution containing 2.4 μg of cyanide. Table 1 shows that only Co(II) and Hg(II) interfere at this level. The effect of anions on the direct determination was also studied, and it was found that 0.3 mg of SCN^- and I^-, 9 mg of PO_4^{3-} and SO_4^{2-},

Table 1. Effect of foreign ions*

Cation	CN^- found,† μg	Recovery, %
Mg(II)	2.41	100.4

Table 2. Determination of cyanide

	CN⁻ added, $\mu g/ml$	CN⁻ found, $\mu g/ml$	No. of determinations	Recovery, %
Distilled water	0.097	0.097 ± 0.008	4	95–102
Sea-water		0.025 ± 0.007	5	
	0.095	0.126 ± 0.009	5	101–111
Waste water		2.35 ± 0.22	7	
	2.37	4.82 ± 0.47	5	94–116

50 mg of Cl^- and 100 mg of NO_3^- can be tolerated (these are approximately the maximum permissible amounts for these anions). Sulphide interferes at any level.

The calibration must be done with a recently prepared cyanide solution since the degradation products of cyanide stored in alkaline medium interfere.

Determination of cyanide in waste water and sea-water

The method was tested by analysing an artificial sample containing approximately 0.1 ppm of cyanide and was applied to the analysis of waste water from a water-purification tank in a plastic-products factory and from sea-water near the underwater sewage exit of the same factory. In both cases the presence of oxidizing agents and sulphide ion was tested for first. Only sulphide was found, in the waste water. It was eliminated by adding 10 ml of 0.1% cadmium solution to 2 litres of sample, leaving for 24 hr, then filtering. The cyanide was determined after distillative separation.

The results are shown in Table 2, where the recovery percentage shows the extreme values found. The uncertainty of the results is expressed at the 95% confidence level.

Sensitivity

The absorbance is linearly related to amount of cyanide up to 4 μg, and its relative standard deviation, for seven analyses of a sample containing 2.42 μg of cyanide, was found to be 3.4%. The detection limit of 0.005 μg/ml compares favourably with that of previous methods (*e.g.*, 0.01 μg/ml for barbituric acid, 0.02 μg/ml for pyrazolone, 0.02 μg/ml for Ni5–BrPADAP and 0.04 μg/ml for Ag–phen–BPR).

ANNOTATION

COMPARISON OF SILVER RESULTS FOR CANADIAN REFERENCE ORES AND CONCENTRATES AND ZINC-PROCESSING PRODUCTS BY ACID DECOMPOSITION, TRIBENZYLAMINE/CHLOROFORM EXTRACTION AND FIRE-ASSAY COMBINED WITH ATOMIC-ABSORPTION SPECTROPHOTOMETRY

Elsie M. Donaldson, E. Mark and Maureen E. Leaver
Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

Summary—The results obtained for silver in Canadian reference ores and concentrates and in zinc-processing products by three atomic-absorption spectrophotometric methods are compared. "Wet chemical" methods based on the decomposition of the sample with mixed acids yield more accurate results than those based on fire-assay collection techniques. A direct acid-decomposition method involving the determination of silver in a 20% v/v hydrochloric acid–1% v/v diethylenetriamine medium is recommended for the determination of ~ 10 μg/g or higher levels of silver. A method based on chloroform extraction of the tribenzylamine–silver bromide ion-association complex from 0.08M potassium bromide–2M sulphuric acid is recommended for samples containing < 10 μg of silver per g.

Recently, as part of a current CANMET project involving a study of the behaviour of silver in conventional hydrometallurgical processes designed to recover metallic zinc from zinc ores and concentrates, one of the authors developed a simple, sensitive and reliable atomic-absorption spectrophotometric method for the determination of ~ 0.1 μg/g or more of silver in ores and concentrates and ~ 0.001 μg/ml or more in zinc-process solutions.[1] In this method, the sample is decomposed with acids and silver is separated from the matrix elements by chloroform extraction of the tribenzylamine (TBA)–silver bromide ion-association complex from 0.08M potassium bromide–2M sulphuric acid. Silver is stripped from the chloroform phase with 9M hydrobromic acid and ultimately determined by atomic-absorption spectrophotometry (AAS) in a 10% v/v hydrochloric acid–1% v/v diethylenetriamine medium. Because subsequent work showed that relatively large amounts of iron, zinc, lead, nickel and copper do not cause significant error in the determination of silver under these conditions, it was considered probable that, after decomposition with suitable acids, most ores, concentrates and zinc-processing products containing moderate amounts of silver could be analysed directly and relatively rapidly in a dilute hydrochloric acid–diethylenetriamine medium without prior separation of silver. Such a method would also be a useful

alternative to the fire-assay/AAS lead collection method currently used in the CANMET chemical laboratory,[2,3] and could be used as a comparison (or umpire) method. However, during attempts to evaluate this method by applying it to iron-leach residues and roaster and other zinc-processing products, the results obtained were not always in good agreement with previous results obtained by the fire-assay/AAS method. Ultimately, it was found that these materials were of questionable homogeneity. Consequently, various diverse Canadian Certified Reference Materials Project (CCRMP) reference ores and concentrates, which have been certified for silver and which are of proven homogeneity, were used to evaluate the method. The results obtained for these materials by the recommended acid-decomposition/AAS method are compared with those obtained previously at CANMET during the respective inter-laboratory certification programmes by the fire-assay/AAS method mentioned above and by a similar method based on the collection of silver with molten tin.[4] The results are also compared with those obtained by the TBA-extraction method[1] and the fire-assay methods (including classical and AAS methods) and acid-decomposition/AAS results obtained during the certification programmes.

EXPERIMENTAL

Apparatus

A Varian-Techtron model AA6 spectrophotometer, equipped with a 10-cm laminar-flow air–acetylene burner

and a silver hollow-cathode lamp, was used under the following conditions.

Wavelength: 328.1 nm
Lamp current: 3 mA
Spectral band-pass: 0.20 nm
Height of light-path above burner: 4 mm
Acetylene flowmeter reading: 2.0 ($\sim$1.5 l./min)
Air flowmeter reading: 6.5 ($\sim$11.5 l./min)
Flame: strongly oxidizing
Aspiration rate: 8 ml/min

Reagents

Standard silver solution, 100 μg/ml. Dissolve 0.1000 g of pure silver foil in $\sim$25 ml of 25% v/v nitric acid, add $\sim$10 ml of 50% v/v sulphuric acid and evaporate the solution to fumes of sulphur trioxide. Dissolve the salts in $\sim$100 ml of 50% v/v hydrochloric acid and transfer the solution to a 1-litre standard flask containing $\sim$350 ml each of concentrated hydrochloric acid and water. Allow the solution to cool to room temperature, then dilute to volume with water. This solution is stable for at least 2 months. Prepare a 10-μg/ml solution by diluting 10 ml of this stock solution and 36 ml of concentrated hydrochloric acid to 100 ml with water. Prepare this diluted solution fresh as required.

Diethylenetriamine. A 10% v/v solution in water.

Bromine. A 20% v/v solution in carbon tetrachloride.

Hydrochloric acid, 25% v/v. Store in a plastic squeeze-type wash-bottle.

Hydrochloric acid, 50% v/v.

Nitric acid, 50% v/v.

Sulphuric acid, 50% v/v.

Recommended acid-decomposition method

Calibration solutions. Add 10 ml of 10% diethylenetriamine solution to each of eleven 100-ml standard flasks (Note 1); then, from a burette, add to the first five flasks 2, 4, 6, 8 and 10 ml of 10-μg/ml standard silver solution. To the next five flasks, add 1.5, 2, 2.5, 3 and 4 ml of 100-μg/ml standard silver solution. The last flask contains the zero calibration solution. Add sufficient concentrated hydrochloric acid to each flask for the final solution to be 20% v/v hydrochloric acid, then dilute each solution to volume with water (Note 2).

Procedure. Transfer up to 0.25 g (Notes 1 and 3) of powdered sample, containing up to $\sim$700 μg of silver (Note 4), to a 150-ml beaker. Cover, and add 5 ml of 20% bromine solution in carbon tetrachloride (Note 5) and 10 ml of 50% nitric acid. Mix and allow the solution to stand for $\sim$15 min, then heat gently to remove the bromine and carbon tetrachloride. Add 5 ml each of concentrated hydrochloric and perchloric acids and 5 ml of 50% sulphuric acid and heat until fumes of perchloric acid are evolved. Continue to heat the solution for $\sim$10 min (Note 6), then allow to cool to room temperature. Remove the cover, wash down the sides of the beaker with water (Note 7) and carefully evaporate the solution to dryness. Depending on the expected silver content, add sufficient 50% hydrochloric acid for 20 ml to be present for each 50 ml of final solution (Note 8) and heat gently to dissolve the salts. Cool, then filter the solution (Whatman No. 1 or No. 40 paper) into a standard flask of appropriate size (50–200 ml) containing sufficient 10% diethylenetriamine solution for 5 ml to be present for each 50 ml of final solution (Note 8). Wash the beaker twice with 3–5-ml portions of 25% hydrochloric acid, followed by water, then wash the paper in a similar manner. Discard the paper and dilute the solution to volume with water.

Measure the absorbance at 328.1 nm when the sample solution is aspirated into a strongly oxidizing air–acetylene flame (Notes 9 and 10). Calculate the silver content (in μg) from the absorbances for the sample and for calibration solutions that bracket the sample concentration.

Notes

1. All glassware should be washed with $\sim$25% ammonia solution followed by water.

2. The solutions in the first series (*i.e.*, up to 1 μg of silver per ml) are stable for at least 2 weeks. Those in the second series should be prepared fresh every day because the absorbance obtained slowly decreases with age of the solution.

3. To avoid possible viscosity or interference effects from matrix elements, the use of more than 0.25 g of sample for a final volume of 50 ml is not recommended. Up to 0.5 g of sample can be taken if the final volume is to be 100 or 200 ml. However, this is not recommended if the sample contains appreciable silica, unless the silica is removed by volatilization with hydrofluoric acid. In that case, use a Teflon beaker for the decomposition step and add $\sim$5 ml of concentrated hydrofluoric acid before the solution is evaporated to fumes of perchloric acid. After cooling the solution, add $\sim$15 ml of water and wash down the sides of the beaker with 50% hydrochloric acid from a plastic squeeze-type wash-bottle. Transfer the solution to a 250-ml Pyrex beaker, evaporate to dryness and proceed as described.

4. If lead is present, the amount of sample taken should be such that the lead concentration of the final solution will not exceed $\sim$2500 μg/ml, because otherwise lead chloride may precipitate in the solution either before or after the filtration step. This can cause low results for silver because of adsorption on the precipitate.

5. Bromine is added to oxidize sulphur and sulphides to sulphate.

6. Continued heating of the solution results in the dehydration of any silica present.

7. If appreciable antimony is present, add 5 or 10 ml of concentrated hydrobromic acid at this stage.

8. For final sample solution volumes of 50, 100 and 200 ml, add 20, 40 and 80 ml of 50% hydrochloric acid, respectively. The solution should not be diluted with water at this point because silver chloride may precipitate. The volumes of 10% diethylenetriamine solution to be added are 5, 10 and 20 ml, respectively.

9. About 3–10-fold scale expansion is recommended for the determination of $\leq$1 μg of silver per ml. Sample solutions containing more than 1 μg/ml should be analysed on the day that they are prepared (Note 2).

10. If dilution of the sample solution is necessary, sufficient 50% hydrochloric acid and 10% diethylenetriamine solution must be added to the aliquot taken for the concentrations of acid and amine in the diluted solution to be the same as in the calibration solutions. For a two-fold dilution, transfer a 25-ml aliquot of the solution to a 50-ml standard flask, add 2.5 ml of the amine solution and 10 ml of 50% hydrochloric acid and dilute the resulting solution to volume with water. For a four-fold dilution, transfer a 25-ml aliquot to a 100-ml standard flask and add 7.5 ml of amine solution and 30 ml of the acid solution.

RESULTS AND DISCUSSION

Preliminary investigation of the direct acid-decomposition/AAS method

Most investigators have found that the determination of silver by AAS is relatively free from interelement effects.[5-8] Probably the greatest source of error in all AAS methods for silver is that caused by contamination of the final sample solution with chloride. In nitric or sulphuric acid media, this results in the precipitation of silver chloride, which is adsorbed on the walls of glass containers.[6] Ammonia,[8]

potassium cyanide,[9] mercury(II) nitrate[6,10] and $\geq 25\%$ hydrochloric acid[7] have been used to dissolve silver chloride and to keep silver in solution for its determination by AAS. However, diethylenetriamine (DTA),[11] which is used in conjunction with hydrochloric and nitric acids in the tribenzylamine (TBA) extraction/AAS and fire-assay/AAS methods[2,3] developed at CANMET, is also effective, convenient to use and considerably less hazardous than potassium cyanide. An acidic DTA medium is also more advantageous than an ammonia medium because iron, aluminium and various other elements form precipitates in ammoniacal media. In the presence of DTA, less hydrochloric acid can be employed, which helps to reduce burner corrosion. Although a 10% hydrochloric acid–1% DTA medium is used in the TBA-extraction method,[1] preliminary work showed that about a 20% hydrochloric acid–1% DTA medium is required for the direct determination of silver in ores and concentrates to keep moderate amounts of lead in solution. Under these conditions, up to at least 7 mg of iron(III), 4 mg of zinc, 2.5 mg each of lead and nickel and 1.5 mg of copper(II) per ml will not cause significant error in the determination of silver in a strongly oxidizing air–acetylene flame. Higher concentrations of lead can cause low results because of the precipitation of lead chloride, which occludes or adsorbs silver.

Tests showed that, after decomposition of the sample as described in the recommended method and the ultimate dissolution of the salts by heating with 50% hydrochloric acid, the solution should be allowed to cool to room temperature before the addition of DTA solution. Low results will be obtained if the DTA solution is added before the heating step. It was also found that some jarosites and iron-leach residues contained black material which was insoluble in a mixture of hydrochloric, nitric and sulphuric acids and which contained microgram quantities of silver. These samples could be effectively decomposed by treatment with this acid mixture, followed by refluxing of the solution with perchloric acid. This also dehydrates any silica present.

Application of the acid-decomposition method to CCRMP reference ores and concentrates and to jarosite residues

Table 1 shows that the results obtained for seven CCRMP reference ores and concentrates[12–19] of complex composition by the recommended acid-decomposition method are in reasonably good agreement with the mean values obtained by the TBA-extraction method[1] and, except for PTM-1,[15] with the certified values. Except for PTM-1, previously analysed by an earlier CANMET fire-assay/AAS tin-collection method,[4] and for MP-1 and MP-1a, the results agree well with those obtained at CANMET by the current fire-assay/AAS lead-collection method[2,3] during the respective interlaboratory certification programmes. The results obtained for several jarosite residues are

also in reasonably good agreement with those obtained at CANMET by the current fire-assay method. For the tests with the jarosite residues all the subsamples were taken within 2 days to eliminate possible error resulting from the absorption of moisture. All the results shown for the recommended acid-decomposition method are for individual subsamples. Each result is the mean of 6 AAS measurements, and the relative standard deviations found under these conditions at about the 0.2, 2 and 3 μg/ml silver levels were ~ 1.1, 0.7 and 0.6%, respectively. This is in good agreement with the precision of AAS measurements for silver reported by other investigators.[8,9]

The results obtained for PTM-1 by both the TBA-extraction and acid-decomposition methods are in excellent agreement with those obtained at the National Institute of Metallurgy (NIM) in South Africa[20] by "wet-chemical" AAS methods involving leaching of the sample with nitric acid. In that work, silver was determined either directly with compensation in the calibration solutions for viscosity and matrix effects, or after extraction into toluene containing iso-octyl thioglycollate. The mean values obtained at NIM were 73.8 μg/g for 11 results ranging from 69 to 77 μg/g and 74.4 μg/g for 10 results ranging from 73.2 to 75.6 μg/g, respectively. The low results obtained for PTM-1 by the tin-collection method[4] could be due to incomplete co-precipitation of silver with tin powder after the dissolution of the tin button with concentrated hydrochloric acid.[20] From the results of early work carried out at CANMET to evaluate the classical fire-assay/lead-collection method for silver,[21] it is considered probable that slag losses are largely responsible for the low results obtained for MP-1 and MP-1a by the CANMET fire-assay/AAS lead-collection method. Faye and Inman[21] showed that for materials rich in copper and/or nickel sulphides, or those that produce viscous slags, $\sim 2\%$ or more of the silver present can be lost to the slag. Up to $\sim 0.5\%$ can also be retained by the crucible during fusion. These investigators and others[22–25] also showed that, depending on the temperature used, a considerable amount of silver (up to 2% or more[21]) can be lost during the cupellation step in classical fire-assay procedures. However, the CANMET fire-assay/AAS lead-collection method is not subject to this error because it does not involve a cupellation step. Table 2, which shows the mean results (including outliers) obtained for silver in the CCRMP reference materials during the respective interlaboratory certification programmes by both classical fire-assay and fire-assay/AAS methods and by direct acid-decomposition/AAS methods, shows that PTM-1 was certified on the basis of fire-assay results alone. Consequently, from the results obtained by the TBA-extraction and recommended acid-decomposition methods and those obtained at NIM, it is considered highly probable that the certified value for PTM-1 is too low and that it should be ~ 75 μg/g of silver.

Table 1. Determination of silver in CCRMP reference ores and concentrates and jarosite residues by the recommended acid-decomposition method

Sample	Nominal composition, %	Certified value and 95% confidence limits, Ag, μg/g	Ag found, μg/g		
			Fire-assay/AAS method*	TBA-extraction/AAS method†	Recommended acid-decomposition method

#Result corrected for cupellation and slag losses.
¶Corrected values (#) omitted in calculation of the overall mean value.

Table 3. Comparison of the mean results obtained for CCRMP materials by the recommended acid-decomposition/AAS method with the mean fire-assay (FA) and acid-decomposition (AD) results obtained during the certification programmes

| | Ag found, $\mu g/g$ | | |
Sample	Mean CCRMP FA value	Mean CCRMP AD/AAS value	Mean value by the recommended AD/AAS method*
CCU-1	139.3	138.2	141.0
CPB-1	622.6	627.6	628.6
CZN-1	92.3	93.0	94.9
KC-1	1133	1139	1123
MP-1	56.1	61.3	60.5
MP-1a	66.9	69.8	70.2

*Calculated from values given in Tables 1 and 4.

Comparison of results obtained by the recommended acid-decomposition method with those obtained by fire-assay and acid-decomposition/AAS methods during the CCRMP certification programmes

Table 3 shows that the mean values obtained for the CCRMP materials listed in Table 1 (excluding PTM-1) by the recommended acid-decomposition method are all in excellent agreement with the overall mean acid-decomposition/AAS values (Table 2) calculated from the results obtained during the certification programmes. Except for MP-1[18] and MP-1a,[19] the results are also in reasonably good agreement with the overall mean CCRMP fire-assay results obtained by both classical and AAS methods. The overall mean CCRMP fire-assay and acid-decomposition results (Table 3) are also in good agreement, except for MP-1 and MP-1a. Most of the acid-decomposition methods used in these certification programmes involved the AAS determination of silver in $\geq 25\%$ hydrochloric acid media to avoid error resulting from the precipitation of silver chloride.

In Table 2 the low mean fire-assay value for MP-1a is probably due to the fact that only 4 sets of results were reported compared with 12 sets by acid-decomposition/AAS methods. The low mean fire-assay value for MP-1, as suggested in the certification document,[18] is probably caused by cupellation and slag losses.[21] As mentioned previously, both types of loss can occur in classical fire-assay methods, but in fire-assay/AAS methods the major loss of silver is to the slag. When the original certified value for MP-1 was calculated, the fire-assay results shown in Table 2 were all corrected by 3% to compensate for these losses, even though some of the methods used involved AAS finishes. Since their certification both MP-1 and KC-1 have undergone oxidation of their sulphide minerals, with subsequent changes in composition. Consequently, in 1978, the certified values were recalculated with correction factors based on the changes in the zinc contents of these ores.[17] That is the reason for the difference between the certified values shown for these ores in Tables 1 and 2. To obtain true overall mean values, all the outliers omitted in the calculation of the CCRMP certified values have been included in Table 2 and used in the calculations of the overall mean fire-assay and acid-decomposition values. However, in the case of KC-1, classical fire-assay results that were corrected for silver losses by the participating laboratory were not included in the calculations because most of these results were high. For these reasons and because results by methods other than fire-assay and acid-decomposition/AAS methods were not included, some of the overall mean values shown in Table 2 (viz. for PTM-1 and PTC-1[26]) are not the same as the certified values.

Precision for silver in ores by the recommended acid-decomposition method

Table 4 shows that the precision of the results for silver by the recommended acid-decomposition/AAS method at about the $70-100\,\mu g/g$ level is reasonably good, considering the small amount of sample taken (0.2–0.25 g) in these tests. The relative standard deviation obtained for MP-1a is comparable with the mean value obtained for the two series of results by the CANMET fire-assay/AAS method, but better than that obtained by the TBA-extraction method. The mean relative standard deviation for KC-1 is slightly higher than, but still compares favourably with, the values obtained by the fire-assay and extraction methods. As shown in Table 4 and mentioned previously,[1] the precision of the fire-assay/AAS method would be expected to be slightly better than that of the recommended acid-decomposition and TBA-extraction methods because of the much larger samples usually taken, i.e., $\sim 15–30$ g.

CONCLUSIONS

From Table 2 it is apparent that direct AAS methods involving an acid attack of the sample are being used increasingly for the determination of silver in ores and related materials.[27] However, it is also apparent from the variations in the results obtained for SU-1a by direct acid-decomposition/AAS methods that such methods are not the best for the analysis of samples containing very small amounts of silver, because of the low concentration in the final solution. This was why neither SU-1a[28] nor PTC-1[26]

Table 4. Precision of results for determination of silver in ores

Sample and method	Ag found, $\mu g/g$	Mean, $\mu g/g$	Standard deviation, $\mu g/g$	Relative standard deviation, %
Acid-decomposition/AAS				
MP-1a	70.9, 69.6, 70.8, 70.1, 69.4	70.2	0.68	1.0
KC-1a	1116, 1129, 1128, 1131, 1139	1129	8.26	0.7

*Silica removed by volatilization with HF (Note 3).
†Results obtained at CANMET during the interlaboratory certification programmes.

was analysed by the recommended acid-decomposition method. The results obtained for SU-1a (Table 2) by fire-assay methods involving AAS finishes show better precision than those obtained by direct acid-decomposition/AAS methods. Furthermore, even though losses can occur, the fire-assay methods are probably more accurate for samples of low silver content than direct acid-decomposition methods because of the much larger subsamples usually taken. However, as reported recently, indirect acid-decomposition/AAS methods, such as extraction methods that involve preconcentration of silver, also yield precise and probably the most accurate results for small amounts of silver.[29,30] In recent years, many such methods have been reported.[31] Donaldson[1] obtained a mean value of 5.9 $\mu g/g$ (3 determinations) with a standard deviation (SD) of 0.4 $\mu g/g$ for PTC-1 by the TBA-extraction method. This is in excellent agreement with the mean fire-assay/AAS value (Table 2) of 6.0 $\mu g/g$ (SD = 0.2 $\mu g/g$ for 10 determinations) obtained at CANMET by the tin-collection method[4] during the certification programme. It also agrees with the overall mean fire-assay value and with the certified value calculated from 5 sets of fire-assay results mostly obtained by using AAS finishes. The precision of the results obtained for silver in SU-1a by the TBA-extraction method is also comparable with that obtained at CANMET by the fire-assay/AAS lead-collection method. Mean values of 4.6 (6 determinations) and 4.3 $\mu g/g$ (10 determinations) with standard deviations of 0.3 and 0.2 $\mu g/g$, respectively, were obtained. It is noteworthy that the mean value obtained for SU-1a by the extraction method is in excellent agreement with both the overall mean fire-assay and acid-decomposition/AAS results shown in Table 2, but is slightly higher than the certified value. The mean value also agrees with the overall mean value of 4.7 $\mu g/g$ obtained for the 17 sets of silver results reported during the certification programme.[28] However, because of the low silver content of SU-1a and the relatively wide variation in the results obtained during the programme, particularly by direct acid-decomposition methods, it was concluded that that value was not the most suitable estimate of the silver

content. Consequently, the certified value was based on the 10 sets of results in which the individual mean values lay within two standard deviations of the overall mean of the five best fire-assay results. In the calculation of the certified value, five of the results obtained by acid-decomposition methods and the first of the fire-assay results shown in Table 2 were treated as outliers. The true silver content of SU-1a is probably closer to 4.6 $\mu g/g$ than to the certified value of 4.3. However, the difference is probably not too significant at this level.

This investigation has shown that for most ores and related materials of acceptable homogeneity, the recommended acid-decomposition/AAS method yields results that are more accurate than those obtained by classical fire-assay methods and probably often more accurate than those obtained by fire-assay/AAS methods. This is because of the losses of silver that can occur in these methods, particularly to the slag during the fusion process and during some of the subsequent procedural steps.[21-25] Because of these losses, and depending on the amount of silver present, materials that produce viscous slags or have high copper and/or nickel sulphide contents are probably best analysed by direct acid-decomposition/AAS or extraction/AAS methods. Other investigators have also found that these methods yield more accurate results than those based on fire-assay techniques.[7,8,32] The acid-decomposition method used in this work is recommended for the analysis of samples containing ~ 10 $\mu g/g$ or more of silver. Both the TBA-extraction/AAS and the CANMET fire-assay/AAS methods are recommended for samples containing < 10 $\mu g/g$ of silver. However, at this level, if only a small amount of sample is available, the extraction method is preferable because the final solution can be concentrated to 5 or 10 ml. In the fire-assay method, silver is usually determined in a volume of 100 ml or more after dissolution of the lead button with dilute nitric acid. The detection limits of both the extraction and fire-assay methods can be improved by using an electrothermal atomization technique.[31] Although the recommended acid-decomposition method is extremely simple and relatively rapid, the fire-assay method is probably quicker

when large batches of sample are to be analysed. A minor disadvantage of the method is that calibration solutions containing more than ~ 1 μg of silver per ml must be prepared fresh every day. To obtain accurate results, it is emphasized that all glassware should be washed with $\sim 25\%$ ammonia solution, followed by distilled water, just before use.

EIN NEUES GRAPHISCHES AUSWERTEVERFAHREN ZUR ERMITTLUNG STÖCHIOMETRISCHER FAKTOREN GELÖSTER KOMPLEXE

Th. Prange, U. Lechner-Knoblauch und F. Umland

Anorganisch-chemisches Institut der Universität Münster, Corrensstraße 36,
D-4400 Münster/Westf., BRD

Zusammenfassung—Es wird eine computerunterstützte Auswertemethode zur Ermittlung von Komplexzusammensetzungen vorgestellt. Die Methode ist frei von jeglichen Voraussetzungen oder Vereinfachungen und eignet sich daher sowohl für starke als auch für schwache Komplexe. Unterschiedliche Komplexzusammensetzungen in Abhängigkeit vom Konzentrationsverhältnis Metall zu Ligand können in einem einzigen Diagramm identifiziert werden. Nicht stöchiometrische Verbindungen werden von stöchiometrisch zusammengesetzten unterschieden.

Nahezu gleichzeitig mit der Einführung der Photometrie als Analysenmethode begannen Versuche, aus den erhaltenen Daten Rückschlüsse auf Komplexzusammensetzungen zu ziehen. Zu den bekanntesten und geläufigsten Methoden zählen diejenigen von Job,[1] Yoe und Jones,[2] die Geradenmethode nach Asmus[3] und die logarithmische Methode nach Bent und French.[4]

Gemeinsam ist allen vier Methoden eine Einschränkung hinsichtlich der Art der Komplexdissoziation: so sind die beiden erstgenannten nur auf starke, die letzten nur auf schwache Komplexe anwendbar. Der Benutzer dieser Methoden muß daher vor der Ermittlung der Komplexzusammensetzung zumindest annähernd das Dissoziationsverhalten des interessierenden Komplexes kennen.

In der Regel läßt sich nach diesen Methoden *nur eine* Komplexzusammensetzung ermitteln, obschon die stufenweise Dissoziation von Komplexen bekannt ist. Von den innerhalb eines Systems Metall:Ligand möglichen Komplexzusammensetzungen wird die scheinbar stabilste erfaßt.

Dieser Nachteil äußert sich besonders drastisch bei den stark dissoziierenden Komplexen, deren Zusammensetzung nur bei Ligandenüberschuß bestimmbar ist. Über den manchmal recht interessanten Bereich des äquimolaren Verhältnisses von Metall zu Ligand oder den Metallüberschußbereich lassen sich keine Aussagen machen.

Obwohl es eine Verbesserung der Bent/French-Methode gibt, die keine Vereinfachungen mehr vornimmt,[5,6] so fehlt doch ein umfassender theoretischer Ansatz, der die beschriebenen Probleme zu lösen vermag. Eine solche Möglichkeit soll im folgenden geschildert werden.

THEORIE

Für eine Komplexbildung nach

$$M + nL \rightleftharpoons ML_n$$
mit $[M] = (m - k)$, $[L] = (l - nk)$ wobei $m =$ Ausgangskonzentration Metall, $l =$ Ausgangskonzentration Ligand, $k =$ Komplexkonzentration, lautet das Massenwirkungsgesetz:

$$\frac{(m - k)(l - nk)^n}{k} = C. \tag{1}$$

Im Falle sehr schwach dissoziierender Komplexe kann man in erster Näherung annehmen, daß bis zur vollständigen Komplexbildung die Gleichgewichtskonzentration der in steigendem Maße zugegebenen Komponente annähernd gleich Null ist. Die daraus resultierende Proportionalität zwischen Komplexkonzentration und zugegebener Komponente bildet die Grundlagen des Yoe/Jones- und des Job-Verfahrens.

Mit zunehmender Komplexdissoziation gelten diese einfachen Zusammenhänge jedoch nicht mehr. Ziel einer jeden graphischen Auswertemethode für schwache Komplexe ist es nun, durch geeignete Umformung und zulässige Vereinfachung von Gleichung (1) aus den bekannten Größen m bzw. l und der Meßgröße $E \sim k$ die Stöchiometrie n zu ermitteln. Schwierigkeiten bereitet dabei offensichtlich die Umformung des komplexen Gliedes $(l - nk)^n$. Häufig wird daher die Vereinfachung gemacht, den Subtrahenden nk zu vernachlässigen, was bei hohem Ligandenüberschuß auch durchaus zulässig erscheint. Formt man dann die derart vereinfachte Gleichung (1) um, so erhält man die bekannte Proportionalität $1/l^n \sim 1/k$, die der Näherungsmethode nach Asmus zugrundeliegt. Eine bessere Annäherung an das exakte Ergebnis von n ist nur möglich unter Berücksichtigung des vollständigen Gliedes $(l - nk)^n$, das zur Rechenerleichterung in eine Reihe entwickelt werden sollte.

Es ergibt sich für $1 \leq n \leq 3$:

$$(l - nk)^n = l^n - n^2 l^{(n-1)} k$$
$$+ \binom{n}{2} n^2 l^{(n-2)} k^2 - \binom{n}{3} n^3 k^3 \tag{2}$$

mit $\binom{a}{b} = a!/b!(a - b)!$ Für $n = 1$ sind die beiden letzten, für $n = 2$ das letzte Glied gleich Null.

Setzt man zur Auswertung seiner Meßdaten Gleichung (2) in Gleichung (1) ein, multipliziert zunächst die Klammern aus und dann jedes Glied mit dem Faktor $l^{(n-1)}/k$, und ordnet anschließend alle k enthaltenden Glieder auf die linke Seite, so erhält man Gleichung (3):

$$ml/k + n^2k + \binom{n}{2}n^2k(m - k)/l + \binom{n}{3}n^3k^2l^{(1-n)}(k - m)$$
$$= n^2m + (C + l^n)l^{(1-n)}. \quad (3)$$

Es resultiert eine Geradengleichung der Form $y = ax + b$ mit $a = n^2$, $x = m$, $b = (C + l^n)l^{(1-n)}$, der Ausdruck für y umfaßt allerdings die gesamte linke Gleichungsseite und wird sinnvollerweise mit Hilfe einer Rechenanlage bestimmt. Trägt man für $n = 1$, 2, 3 den jeweils linken Gleichungsteil gegen die variable Metallkonzentration auf, so erhält man drei Kurvenzüge. Man vergleicht die Steigungen der Kurvenzüge mit den theoretisch zu erwartenden Steigungen n^2. Stimmt—gegebenenfalls nur in einem bestimmten Konzentrationsbereich—die Steigung einer Kurve mit der theoretischen überein, so besitzt der Komplex in diesem Bereich die Stöchiometrie ML_n.

Setzt man in Gleichung (3) die Werte von $n = 1$, 2 und 3 ein, erhält man drei Einzelgleichungen, die sich durch Umformen noch etwas vereinfachen lassen:

$$n = 1 \Rightarrow ml/k + k = m + l + C \quad (4a)$$

$$n = 2 \Rightarrow ml^2/k + 4mk + 4lk - 4k^2$$
$$= 4lm + l^2 + C \quad (4b)$$

$$n = 3 \Rightarrow ml^3/k + 27\,mlk - 27\,mk^2$$
$$+ 9\,l^2k - 27\,lk^2 + 27\,k^3$$
$$= 9\,l^2m + l^3 + C. \quad (4c)$$

Der Vorteil von Gleichungen (4a–4c) gegenüber Gleichung (3) liegt in der besseren Übersichtlichkeit der gegeneinander aufgetragenen Werte; man muß allerdings dabei in Kauf nehmen, daß die erhaltenen Steigungen noch eine Potenz von l als Faktor enthalten. Welche der Gleichungen, (3) oder (4a–4c), man zur Auswertung benutzt, ist auf Grund der mathematischen Äquivalenz gleichgültig.

Bei Benutzung einer Rechenanlage ist es in jedem Fall zu empfehlen, die Werte der linken Gleichungsseite (n) nicht nur berechnen, sondern mit Hilfe eines Plot-Programmes die drei Kurvenzüge und die theoretisch zu erwartende Steigung ausdrucken zu lassen. Der Arbeitsaufwand dieser Methode reduziert sich dadurch auf das Eingeben von Meßwerten und Konzentrationen in den Rechner und Vergleich von experimenteller und theoretischer Steigung des ausgedruckten Diagrammes.

Ein willkürlich gewähltes Beispiel mit typischen Kurvenzügen zur Veranschaulichung der Auswertemethode zeigt Abb.1. In diesem Beispiel liegt im

Bereich $m:l = 0$–0.13 ein $1:3$-, im Bereich 0.29–0.42 ein $1:2$- und im Bereich > 0.51 ein $1:1$-Komplex vor. Dazwischen liegen jeweils die Bereiche der Komplexumformierung (zwei Komplexe nebeneinander), in denen die theoretisch geforderten Steigungen nicht mit den experimentell gefundenen übereinstimmen können.

Nichtstöchiometrische Verbindungen können dagegen leicht identifiziert werden. Im Übergangsbereich stöchiometrischer Verbindungen ändert sich die experimentelle Steigung derart, daß sie von einem n-Wert weg auf einen anderen hin zustrebt; bei nichtstöchiometrischen Verbindungen dagegen entfernen sich mit zu- oder abnehmendem Metallgehalt alle experimentellen Steigungen zunehmend von allen theoretischen, und eine Übereinstimmung aller drei experimentellen mit den theoretischen Steigungen kann im gleichen Konzentrationsbereich auftreten.

Abbildung 2 zeigt als Beispiel dafür die unstöchiometrische Adsorptionsverbindung zwischen Mg und Titangelb, ausgewertet nach obigem Verfahren.

Die Vorteile der beschriebenen Auswertemethode sollen abschließend durch Vergleich mit den üblichen Verfahren aufgezeigt werden. Komplexiert man beispielsweise Co^{2+} mit 4-[Pyridyl-(2)-azo]-resorcin (PAR) bei pH 7.0 (Phosphatpuffer) und überträgt die gemessenen Extinktionen nach der Methode von Yoe und Jones in ein Diagramm, so ergibt sich der Kurvenzug von Abb. 3.

Der Informationsgehalt dieses Diagrammes ist gering. Da der gebildete Komplex anscheinend deutlich dissoziiert, liegen nur die ersten 5 Meßpunkte auf der Extrapolationsgeraden. Die daraus ermittelte Komplexstöchiometrie von $1:3$ ist auf Grund mangelhafter Übereinstimmung sehr unsicher.

Wegen der scheinbar nicht zu vernachlässigenden Komplexdissoziation und zur Kontrolle der Ergebnisse empfiehlt sich eine weitere Auswertung nach einer Methode, die für stark dissoziierende
Abb. 1. Ermittlung der verschiedenen Komplexzusammensetzungen in Lösung: $f(n) =$ linke Seite der Gleichungen (4a–4c).
Abb. 2. Graphische Auswertung der unstöchiometrischen Adsorptionsverbindung Mg/Titangelb nach Gleichungen (4a–4c).

Komplexe geeignet ist. Abbildung 4 zeigt die Auswertung der Meßergebnisse nach der Asmus-Methode. Da bei unseren Messungen nicht die Reagenz-, sondern die Metallionenkonzentration variiert wurde, gibt der reziproke Wert von n Aufschluß über die Komplexstöchiometrie.

Aus den gegenläufig gekrümmten Kurvenzügen für $n = 1$ und $n = \frac{1}{3}$ geht hervor, daß die tatsächliche Komplexzusammensetzung dazwischenliegen sollte. Die demnach zu erwartende Stöchiometrie von $M:L = 1:2$ wird aber nur in einem kleinen Konzentrationsbereich durch die Geradenform für $n = \frac{1}{2}$ bestätigt, oberhalb und unterhalb dieses Bereiches ist die $n = \frac{1}{2}$-Kurve ebenfalls gekrümmt. Die Form der Krümmung deutet dabei auf einen Komplex hin, dessen Zusammensetzung zwischen ML und ML_2 liegt. Andererseits läßt sich der obere Teil des Kurvenzuges (niedrige Metallkonzentrationen) für $n = \frac{1}{3}$ ebensogut durch eine Gerade wiedergeben wie für $n = \frac{1}{2}$; die Abweichungen bei steigender Metallkonzentration werden allerdings bei $n = \frac{1}{3}$ größer als bei $n = \frac{1}{2}$.

Sollte man aus diesem Diagramm eine Komplexstöchiometrie ermitteln, müßte man trotz der nur mäßigen Übereinstimmung und hauptsächlich gestützt auf die gegenläufig gekrümmten Kurvenzüge für $n = 1$ und $n = \frac{1}{3}$ auf einen 1:2-Komplex schließen.

Die Unstimmigkeiten und Ungenauigkeiten lassen das Ergebnis jedoch keinesfalls als gesichert erscheinen.

Somit unterscheiden sich die Ergebnisse aus der Yoe und Jones- bzw. der Asmus-Auswertung; eine Entscheidung über die Komplexstöchiometrie ist nicht möglich.

Weitergehende Aufschlüsse vermittelt dagegen Abb. 5, die die Auswertung nach der hier beschriebenen Methode zeigt. Innerhalb des Konzentrationsbereiches ≤ 0.12-fach molare Kobaltmenge (die erstens 5 Meßpunkte) liegt ein 1:3-Komplex vor, der sich in genau diesem Bereich auch nach der Methode von Yoe und Jones nachweisen läßt (vgl. Abb. 3). Mit steigender Kobaltmenge ergeben sich Abweichungen vom theoretischen Verhalten eines 1:3-Komplexes. Die theoretische Steigung eines 1:2-Komplexes berührt die experimentelle Kurve nur als Tangente, und lediglich die letzten beiden Meßpunkte (> 0.4-fach molare Kobaltmenge) stehen in Übereinstimmung mit dem theoretisch zu erwartenden 1:1-Komplex.

Als Resultat dieser Auswertung ergibt sich, daß bei hohem Ligandenüberschuß ein 1:3-Komplex gebildet
Abb. 4. Kobalt/PAR-Komplex, Auswertung nach Asmus.

Abb. 3. Kobalt/PAR-Komplex, Auswertung nach Yoe-Jones.
Abb. 5. Kobalt/PAT-Komplex, Auswertung nach Gleichungen (4a–4c).

wird, der bei weiterer Metallzugabe zerfällt. Ein eventuell existierender 1:2-Komplex kann nicht sehr stabil sein, da er in keinem größeren Konzentrationsbereich rein vorliegt. Amwahrscheinlichsten ist der über einen weiten Konzentrationsbereich ausgedehnte Zerfall in einen 1:1-Komplex, der mit abnehmender Ligandkonzentration zunehmend Oberhand gewinnt. Man kann aber einen mehrkernigen M_pL_q-Komplex nicht auschließen. (Zur Ermittlung der Stöchiometrie solcher Komplexe mit den beiden Unbekannten p und q ist die Meßung einer weiteren Größe, zum Biespiel [L], erforderlich; ein Verfahren dazu wurde ausgearbeitet[7] und wird in Kürze publiziert.[8]

Das Ergebnis dieser Auswertung läßt sich mit den Resultaten der Yoe/Jones- und der Asmus-Methode vergleichen. Der stabilste Komplex innerhalb des Systems Co/PAR ist der 1:3-Komplex. Dieser wird zwar von der für stabile Komplexe geeigneten Yoe/Jones-Methode erkannt, sollte der Auswertung nach jedoch instabil sein. Komplexumformierungen lassen sich nach Yoe und Jones nicht erkennen.

Die Asmus-Methode legt die Existenz eines 1:2-Komplexes nahe, doch ist die Aussage nicht gesichert. Erklären läßt sich das falsche Ergebnis durch den großen Konzentrationsbereich, in dem weder 1:3- noch 1:1-Komplexe rein vorliegen. Deren Mischung läßt sich in der Asmus-Darstellung am besten durch einen 1:2-Komplex wiedergeben.

Die Vorteile der beschriebenen Methode liegen in folgenden Punkten.

Es sind—im Gegensatz zu den bisherigen Verfahren keine Vorabinformationen über die Stabilität der untersuchten Komplexe erforderlich.

Die Komplexbildung läßt sich mit *einer* Versuchsreihe und *einer* Auswertemethode über einen sehr großen Bereich Metall:Ligand untersuchen.

Die Methode erlaubt Aussagen über sukzessive Komplexbildungsgleichgewichte.

Aus dem Ordinatenabschnitt der bestangepaßten Geraden läßt sich die Gleichgewichtskonstante C für die jeweilige Komplexbildungsreaktion abschätzen.

Summary—A computerized plotting method for the determination of the stoichiometry of complexes is introduced. The method has no assumptions or simplifications, and is applicable to both strong and weak complexes. Different stoichiometries, as a function of the metal to ligand concentration-ratio, can be identified in a single diagram. Furthermore, non-stoichiometric complexes can be recognized.

DIFFERENZSPEKTROSKOPISCHE UND PULSPOLAROGRAPHISCHE UNTERSUCHUNGEN ZUR ZUSAMMENSETZUNG DER KUPFER–ALIZARIN S-KOMPLEXE

Th. Prange, H. D. Sommer und F. Umland
Anorganisch-chemisches Institut der Universität Münster, Corrensstraße 36,
D-4400 Münster/Westf., BRD

Zusammenfassung—Aus differenzspektroskopischen, konduktometrischen und pulspolarographischen Daten ließ sich nachweisen, daß drei Cu–Alizarin S-Komplexe mit den Zusammensetzungen 1:2, 1:1 und 2:1 existieren. Die kupferreiche 2:1-Verbindung läßt sich aus wäßriger Lösung fällen. In dem daraus entstehenden 1:1-Komplex in Dimethylformamid Wasser-Mischungen ist das Kupferion in peri-Stellung gebunden.

Trotz der schon seit über 100 Jahren bekannten und auch analytisch genutzten Alizarin–Metall-Farbstoffe herrscht noch weitgehende Unklarheit über ihre Stöchiometrie und Ort der Bindung des Metalls in *ortho*- oder *peri*-Stellung. Wir konnten kürzlich zeigen, daß aus pulspolarographischen Daten[1] Rückschlüsse gezogen werden können: zum Beispiel ist in den voltammetrisch nachweisbaren 1:1-Komplexen Aluminium in *ortho*- und Beryllium in *peri*-Stellung an Alizarin S gebunden. In anderen Fällen gibt es noch Unsicherheiten, auch bezüglich der Zusammensetzung.[2–4]

Babko und Nazarchuk[4] fanden nach der Methode von Job bei pH 4.7 in allen Konzentrationsbereichen Cu:Alizarin S nur 1:1-Komplexe, während Yasukouchi und Yashinobu[5] auf Grund amperometrischer Titrationen Komplexzusammensetzungen Cu:Alizarin S = 1:1 und 1:2 angaben. In der vorliegenden Arbeit wurden zur Untersuchung der Kupfer–Alizarin S-Komplexe verschiedene Methoden kombiniert.

EXPERIMENTELLER TEIL

Geräte

Differenzspektren wurden mit dem registrierenden Spektralphotometer Zeiss DMR 21 bei einer Registriergeschwindigkeit von 30 min/Trommeldrehung und einem Wellenlängenvorschub von 1 nm/mm aufgenommen. Als Küvetten dienten spezialgefertigte Tandemküvetten[6] aus Quarzglas der Firma Hellma mit Schichtdicken von jeweils 0.438 cm pro Kammer.

Die pulspolarographischen Untersuchungen wurden mit dem PRG 5 der Firma Tacussel durchgeführt. Als Bezugselektrode wurde eine Silber/Silberchlorid-Elektrode benutzt.

Die konduktometrischen Daten wurden mit dem Konduktoskop E 365 B der Firma Metrohm unter Verwendung der Leitfähigkeitsmeßzelle EA 608 erhalten.

Reagenzien

Alizarin S Lösung, $10^{-4}M$.

Puffer. Essigsäure/Acetat-puffer $0.1M$, pH 4.7.

Als Lösungsmittel bei den differenzspektroskopischen Untersuchungen diente Wasser. Die Polarogramme wurden in Dimethylformamid/Wasser-Mischungen aufgenommen, und bei den konduktometrischen Daten wurde ein 1:1 Ethanol/Wasser-Gemisch benutzt.

ERGEBNISSE UND DISKUSSION

Spektroskopische Messungen

Da sich die Spektren von freiem Ligand und Komplex stark überlappen (Abb. 1), bot sich als empfindliche photometrische Methode die Differenzspektroskopie an.[6] Bei dieser Meßmethode werden in Meß- und Vergleichsstrahl eines registrierenden Photometers zwei Küvetten mit halbhoher Scheidewand, sogenannte "Tandemküvetten", benutzt, deren eine Hälfte jeweils mit der Lösung des Metallsalzes, und deren andere mit der Lösung des Liganden gefüllt wird. Mißt man beide Küvetten gegeneinander, so muß eine gerade Basislinie resultieren. Nach Durchmischen des Küvetteninhalts im Meßstrahl setzt die Komplexbildung ein, und das Differenzspektrum wird registrierbar (Abb. 2). Dieses ist nicht streng identisch mit der Differenz der Einzelspektren gegen Wasser gemessen (Abb. 1). Es läßt sich aber zeigen,[6] daß sowohl die positiven als auch die negativen Extinktionswerte der Komplexkonzentration proportional sind und daß differenzspektroskopische Daten sich deshalb vorbehaltlos zur Ermittlung von Komplex stöchiometrien verwenden lassen.

Es wurden Differenzspektren mit konstanter $(10^{-4}M)$ Alizarin S und variabler Cu^{2+}-Konzentration $(0.1-8 \times 10^{-4}M)$ aufgenommen und aus der absoluten Summe der Differenzextinktionen bei 519 nm und 417 nm mit Hilfe des vor kurzem beschriebenen Auswerteverfahrens[7] die Komplexstöchiometrien dieses Systems ermittelt. Abbildung 3 zeigt das erhaltene Computerdiagramm. Die theoretischen Steigungen sind gestrichelt eingezeichnet.
Abb. 1. Spektren von $10^{-4}M$ Cu–Aliz S-Komplex (1:1) bei Kupferüberschuß ($5 \times 10^{-4}M$) und $10^{-4}M$ Aliz S in Wasser gegen Wasser gemessen.

Der Deckungsbereich mit den experimentellen Kurven gibt ungefähr den Existenzbereich der Komplexe an: der 1:1 Cu–Alizarin S-Komplex liegt in Wasser erst bei mehr als zweifachem Metallüberschuß vollständig vor. Bei kleineren Molverhältnissen steht er im Gleichgewicht mit 1:2-Komplexen, die unterhalb Cu:Alizarin S = 0.9:1 dominieren. 1:3-Komplexe konnten nicht nachgewiesen werden.

Konduktometrische Messungen

Weitere Aussagen über Komplexbildung und -umlagerung sind möglich, wenn man die Protonenfreisetzung bei steigender Metallkonzentration und konstanter Ligandenkonzentration in ungepufferter Lösung konduktometrisch verfolgt (Abb. 4).

Die Leitfähigkeitskurve zeigt einen steilen Anstieg bis zum *ca.* zweifachen Kupferüberschuß, dann ein flaches Übergangsgebiet bis zum *ca.* fünffachen Kupferüberschuß, gefolgt von einem erneuten, weniger steilen Anstieg. Ab dem *ca.* achtfachen Kupferüberschuß begann der Komplex auszufallen.

Im flachen Übergangsgebiet werden keine Protonen freigesetzt, da die Steigungen der Leitfähigkeitskurve (Abb. 4*a*) in diesem Bereich und in einer reinen Kupferlösung (Abb. 4*b*) gleich sind. Der Anstieg der Leitfähigkeitskurve *vor* dem Übergangsgebiet läßt sich mit den spektroskopischen Aussagen korrellieren und gestattet die Aufstellung der Reaktionsschemata [Gleichungen (1) und (2)].

Die eingesetzten Ladungen sagen über die tatsächliche Ladung des Komplexes nichts aus. Es

Abb. 3. Ermittlung der Komplexzusammensetzungen im System Kupfer/Aliz S; $f(n) =$ linke Seite der Gleichungen (4a–4c) der vorangehenden Veröffentlichung.[7]

wurde aber durch Fällung mit Kationentensiden nachgewiesen, daß die 1:2- und 1:1-Cu-Alizarin S-Komplexe negativ geladen sind. Sie können aber— wie auch Yasukouchi[5] für Alizarinkomplexe beschrieb—noch weitere gebundene Anionen enthalten, die hier unberücksichtigt bleiben. Der nach Gleichung (3) ausfallende Komplex ist im ganzen ungeladen.

Zu Beginn der Komplexbildung entsteht bei Ligandüberschuß der 1:2-Komplex (vgl. Abb. 3). Dadurch müssen je Komplexmolekül zwei Protonen frei werden ($H_2L =$ Alizarin S):

$$Cu^{2+} + 2H_2L \rightleftharpoons Cu(HL)_2^{2-} + 2H^+. \qquad (1)$$

Bei mehr als 0.9-fach molarer Kupfermenge entsteht aus dem 1:2-Komplex zunehmend der 1:1-Komplex, der ab der zweifach molaren Kupfermenge rein vorliegt (vgl. Abb. 3).

In diesem Schritt müssen nach Abb. 4 zwei weitere Protonen frei werden. Wir formulieren deshalb den (1:1)-Komplex als Kupferhydroxo–Alizarin-Komplex:
Abb. 4. Leitfähigkeitskurven in Wasser/Ethanol (1:1): (*a*) einer Aliz S-Lösung in Abhängigkeit von der zugesetzten Cu^{2+}-Menge; (*b*) einer Aliz S-freien Cu^{2+}-Lösung, bei der die zugesetzte Cu^{2+}-Menge in gleichen Schritten wie bei (*a*) erhöht wurde.

Abb. 2. Differenzspektrum des Cu/Aliz S-Systems in Wasser (Ausgangskonzentrationen $10^{-4}M$ Aliz S und $6 \times 10^{-4}M$ Cu^{2+}).

$$Cu(HL)_2^{2-} + Cu^{2+} + 2H_2O$$

$$\rightleftharpoons 2Cu(OH)(HL)^- + 2H^+ \quad (2)$$
Der bei *ca.* achtfachem Kupferüberschuß ausfallende Komplex wurde isoliert und analysiert. Er hat die Zusammensetzung Cu:Alizarin S = 2:1. Man kann ihn präparativ am besten aus acetatgepufferter Lösung (pH 4–5) durch Fällung mit der *ca.* zehnfach molaren Kupfermenge herstellen. Unter Berücksichtigung des konduktometrischen Befundes (Abb. 4) müssen bei der Bildung dieses Komplexes noch weitere Protonen frei werden. Es kann sich also nicht um eine einfache Salzbildung mit der Sulfonatgruppe handeln. Wir nehmen deshalb an, daß ein weiteres Cu^{2+} chelatartig gebunden wird. Man kann also schreiben:

$$Cu(OH)(HL)^- + Cu^{2+} \rightleftharpoons Cu_2(OH)(L) + H^+ \quad (3)$$
wobei bis Beginn der Fällung bei achtfachem Kupferüberschuß nur *ca.* 50% umgesetzt werden. Bei vollständigem Umsatz muß die doppelte Menge Protonen freigesetzt werden als nach Abb. 4 angezeigt wird.

Wenn es sich bei der mit Kupferüberschuß ausgefällten Verbindung um ein definiertes zweikerniges Chelat handeln sollte, müßten die beiden Cu-Ionen verschieden—eines in *ortho*-, das andere in *peri*-Stellung—an Alizarin S gebunden sein. Es taucht die Frage auf, welche Stellung in den 1:2- und 1:1-Komplexen zuerst besetzt wird.

Polarographische Messungen

Für rein wäßrige Lösungen ließ sich diese Frage pulspolarographisch lösen (s.u.), allerdings nur bei sehr kleinen Kupferkonzentrationen im Bereich des $Cu(HL)_2$-Komplexes. Bei Erhöhung der Kupferkonzentration treten zusätzliche positive Peaks durch Adsorption von Kolloidteilchen auf, die eine Auswertung unmöglich machen. Wir gingen deshalb von dem durch Fällung isolierten 2:1-Komplex aus.

Versuche ergaben, daß sich die ausgefällten Partikel in Dimethylformamid (DMF) recht gut lösen. Diese Lösungen wurden pulspolarographisch untersucht. Die Polarogramme der Komplexlösungen in reinem DMF waren jedoch schlecht interpretierbar, deshalb wurde vorzugsweise in DMF/Wasser-Mischungen gearbeitet.

Man erhält ein Spektrum von drei Peaks (Abb. 5a), die wie folgt zuzuordnen sind: der positivere Peak (I) entspricht dem Cu^{2+}-aqua-Ion, der mittlere Peak (II) dem an Alizarin S gebundenen Kupfer, der negativere Peak (III) ist der Reduktionspeak des komplexgebundenen Alizarin S.

Aus der annähernd gleichen Höhe der Peaks folgt, daß der Komplex in 1:1 DMF/Wasser-Mischungen vollständig in die 1:1-Verbindung und freies Kupfer dissoziiert.

Aus Mischungsreihen darf—wegen der schlechten Auswertbarkeit der Polarogramme in reinem DMF mit Vorbehalten—geschlossen werden, daß in DMF-
Abb. 5. Pulspolarogramme: (*a*) Lösung des Cu_2Aliz S-Komplexes in DMF/Wasser (1:1); (*b*) wie (*a*), nach Zusatz von Al^{3+}; (*c*) wie (*a*), nach Zusatz von Be^{2+}.

reichen Lösungen die Dissoziation unvollständig ist und Wasser die Dissoziation sehr stark begünstigt.

Eine weitere Möglichkeit, quantitativ zwischen freiem und gebundenem Kupfer zu unterscheiden, ergibt sich, indem man der Lösung Al^{3+} zusetzt (Abb. 5b). Dieses wird im Komplex gegen Cu^{2+} ausgetauscht, da der Al–Alizarin S-Komplex wesentlich stabiler ist als der Cu–Alizarin S-Komplex. Der Cu–Alizarin S-Peak (II) verschwindet, der Cu-Peak (I) steigt auf das Doppelte. Damit konnte gezeigt werden, daß in Lösung ein 1:1-Komplex vorliegt.

Gegen Be^{2+} läßt sich das gebundene Cu^{2+} nicht austauschen (Abb. 5c). Die Stabilität des 1:1 Cu–Alizarin S-Komplexes liegt also zwischen der des Be–Alizarin S- und des Al–Alizarin S-Komplexes.

Aus der Lage des Peak (III) kann man nun auf die Stellung des noch gebundenen Kupfers rückschließen. Wie bereits früher ausgeführt,[1] verschiebt sich der Reduktionspeak des Alizarin S kaum bei einer komplexen Bindung eines Metallions, wie Al^{3+}, an die beiden phenolischen OH-Gruppen in *ortho*-Stellung. Eine deutliche positive Verschiebung beobachtet man dagegen bei Bindung der Ionen, wie Be^{2+}, in *peri*-Stellung, wobei das polarographisch aktive, chinoide System stärker beansprucht wird. Der Reduktionspeak (III) des Cu–Alizarin S-Komplexes liegt nun beim gleichen Potential wie der entsprechende Be–Alizarin S-Peak und ist gegenüber dem Al–Alizarin S-Peak deutlich positiv verschoben. Das bedeutet, daß sich das in DMF-Lösung gebundene Kupfer in *peri*-Stellung des Alizarin S befindet.

Einen entsprechenden Befund erhält man für sehr verdünnte rein wäßrige Lösungen im Bereich des 1:2-Komplexes.

Zusammenfassend ergibt sich also: bei Zugabe von Cu^{2+} zu einer $10^{-4}M$ Alizarin S-Lösung bildet sich zunächst ein 1:2 Komplex mit *peri*-ständig gebundenem Kupfer, der ab etwa dem Verhältnis Cu:Alizarin S = 0.9:1 zunehmend in einen 1:1-Komplex übergeht. Die Bildung des 1:1 Komplexes ist etwa bei der Kupferkonzentration $2 \times 10^{-4}M$ abgeschlossen. Bei weiter steigender Kupferkonzentration bildet sich

etwa von $5 \times 10^{-4} M$ Cu^{2+} an unter Protonen-
freisetzung ein weiterer Komplex, der zunächst in
einer Wasser/Äthanol-Mischung in Lösung bleibt.
Bei etwa achtfachem Kupferüberschuß ($8 \times 10^{-4} M$)
beginnt ein 2:1-Komplex auszufallen. Dieser dis-
soziiert in 1:1 Wasser/DMF-Mischung vollständig in
Cu^{2+} und einen 1:1-Komplex, in dem das Cu^{2+}
ebenfalls peri-ständig gebunden ist. Es ist an-
zunehmen, daß das bei hoher Kupferkonzentration
zusätzlich eintretende Kupfer ortho-ständig gebun-
den wird.

Summary—From differential spectrophotometric, conductometric and pulse polarographic data, three copper–Alizarin S complexes (with compositions 1:2, 1:1 and 2:1) can be identified. The copper-rich 2:1-compound can be precipitated from aqueous solution. In dimethylformamide/water solutions the copper in the 1:1-complex is bound in the peri-position.

MODIFIED NORMAL PULSE POLAROGRAPHY OF ALKALI-METAL IONS IN ACID SOLUTION

MINORU HARA and NOBORU NOMURA
Faculty of Education, Toyama University, 3190 Gofuku, Toyama-shi, Toyama 930, Japan

Summary—Well-defined polarograms of five alkali-metal ions in $0.01M$ hydrochloric acid were obtained by means of modified normal pulse polarography. The method uses the procedure of anodic stripping chronoamperometry during the life-time of a drop from a dropping mercury electrode, namely preparation of electrode, accumulating step and anodic stripping step of a metal. The instantaneous polarographic currents were sampled only once per mercury drop after the fall of each pulse. The wave heights for alkali-metal ions by the present method are free from the interference caused by $0.01M$ hydrochloric acid. The present method is applicable to monitoring of alkali-metal ions in fluid acid streams.

Normal pulse polarography (NPP) and differential pulse polarography (DPP) have been used for the determination of many metal ions, but have scarcely been applied to the determination of alkali-metal ions. D.C. polarography and A.C. polarography of alkali-metal ions have been performed, with tetra-alkylammonium hydroxides as supporting electrolyte,[1,2] but it is difficult to determine alkali-metal ions in acid solutions by means of D.C. polarography, because the large hydrogen wave interferes in the measurement of the wave heights. Moreover, at low pH the dislodgement of the mercury drops from the dropping mercury electrode (DME) is disturbed by the adhesion of hydrogen bubbles on the electrode surface.

Ishibashi *et al.* investigated the A.C. polarographic behaviour of alkali and alkaline-earth metal ions and reported that the peak heights for a fixed concentration of sodium were constant at pH ⩾ 4 but decreased with the pH at lower pH-values.

In a previous paper,[4] we reported on modified normal pulse polarography (MNPP) in which the current is sampled after the fall of each pulse. A well-defined polarogram for barium in $0.01M$ hydrochloric acid and $0.1M$ tetramethylammonium bromide was obtained by means of MNPP, and no hydrogen-ion waves were observed. The timing sequence in modified normal pulse polarography is shown in Fig. 1. The drop-interval of the DME is controlled by a mechanical knocker and the measurement of current is synchronized with dislodgement of the mercury drop. Pulses of short duration, T_2, and increasingly negative potential are added to the fixed initial potential, E_1, to give a regularly increasing potential E_2. The pulses are applied to the DME when the pulse delay time, T_1, has elapsed after growth of a new drop. The polarographic current is sampled and held after a delay time of T_3 from the fall of the pulse, when charging current has decayed to an insignificant

value. The amalgamated metals deposited during the pulse duration T_2 are oxidized and the dissolution current is measured. The mercury drop then falls off and a new cycle begins.

In this study, the behaviour of the five principal alkali-metal ions in MNPP was investigated with a view to their determination at lower pH. The effects of initial potential, pulse duration and pH of the sample solution, on the polarograms, are discussed.

EXPERIMENTAL

Apparatus

The modified normal pulse polarograph used was the one reported previously.[4] The homemade polarograph consisted of a pulse generator, potentiostat, sample-hold circuit and timing circuit, which were constructed from LF356 JFET-input operational amplifiers (National Semiconductor), μPC252 MOSFET-input operational amplifiers (Nihon Electric), 3SK38A MOSFET switches (Toshiba Electric) and NE555 timer ICs (Signetics). The current–time curves were measured with a Kawasaki Electronica TM-1410 transient memory in combination with a Hitachi 056 pen recorder. A saturated calomel electrode with Vycor glass-plug double junctions was used as a reference electrode in order to avoid contamination of the sample solutions with potassium. The mercury column of the DME was divided
Fig. 1. The timing chart of the modified normal pulse polarograph. The arrow A indicates the sampled value in NPP, and the arrow B shows that in the present method.

into two parts by an air layer just above the capillary, so as to suppress the noise resulting from the A.C. source.[4] The lead-wire from the DME to the polarograph was attached to the lower part of the column. The flow-rate of the DME was fixed at 0.630 mg/sec.

Reagents

A standard lithium solution was made from lithium chloride prepared from lithium carbonate and hydrochloric acid. Standard solutions of the other alkali-metal ions were prepared by dissolving their chlorides. Reagent-grade tetramethylammonium bromide was employed as supporting electrolyte without further purification. All chemicals used in this experiment were reagent grade. The sample solutions were deaerated by passage of nitrogen through them for 15 min, and nitrogen was flushed over the solutions during measurements.

RESULTS AND DISCUSSION

Polarograms

Three kinds of pulse polarograms for lithium in $1 \times 10^{-3}M$ hydrochloric acid are shown in Fig. 2. The normal pulse polarogram (1) has a large reduction wave for hydrogen ion at -1.71 V and a small reduction wave for lithium ion at -2.35 V. The reduction wave of hydrogen ion in the reverse pulse polarogram (2) is smaller than that of the normal pulse polarogram. The small wave which appears at -2.1 V seems to be due to alkali-metal ions in the tetramethylammonium bromide. In reverse pulse polarography of this solution, E_1 should be set at -2.50 V or a more negative potential, where the reduction of lithium ion is diffusion-controlled,[5] but was set at -2.40 V in order to avoid the irregular dislodgement of mercury drops. Curve 3 shows a modified normal pulse (MNP) polarogram, which has no hydrogen waves in it. Curve 3 is identical with the polarogram of lithium ion in a neutral solution. Therefore, the present method is suitable for the polarography of species which are reduced together with hydrogen ion in acid solutions.

Effect of initial potential

As shown in Fig. 2, there are no hydrogen waves in the MNP polarogram if E_1 is appropriately chosen.

Fig. 3. Effect of E_1 on the oxidation current of sodium: $0.1M$ Me$_4$NBr (HCl), $4.02 \times 10^{-4}M$ NaCl. $T_1 = 1.111$ sec, $T_2 = 117.6$ msec, $T_3 = 2.3$ msec. $E_2 = -2.40$ V. pH: (1) 5.6, (2) 2.9, (3) 1.8.

The effect of E_1 on MNP polarograms of sodium chloride at different pH values was therefore studied. The result is shown in Fig. 3. The pulse potential E_2 was fixed at -2.40 V and E_1 was varied. The current was measured 2.3 msec after the fall of the pulse. Curves analogous to reverse pulse polarograms were obtained. At pH 2.9, the currents for the E_1 potential range from -1.5 to -2.0 V are the sums of the oxidation current of sodium and the reduction current of the hydrogen ion. When E_1 is set at a more positive potential than -1.4 V, the currents do not contain the hydrogen-ion component, irrespective of pH. An E_1 of -1.00 V was therefore chosen.

Effect of pulse duration

When the pulse potential is set in the range for the diffusion-current plateau of the alkali-metal ions, the alkali metals are accumulated in each mercury drop during pulse duration T_2. Figure 4 shows the effect of pulse duration on the oxidation current of the amalgamated sodium (neutral solution). The currents increase with pulse duration T_2, but the relation is not simple.[5,6] The currents may be affected by growth of the mercury drop and the complicated concentration gradient of sodium in the mercury drop. Similar behaviour (at a glassy carbon electrode) was reported for the reverse differential normal pulse voltammetry of iron(II).[7] In neutral solution, the anodic half-wave

*$0.2M$ Me$_4$NBr.

potentials of sodium were constant, regardless of the pulse duration.

The effect of pulse duration on oxidation current in acid solution is shown in Fig. 5. The wave height decreases and the half-wave potential shifts to more negative potential with decrease in the pulse duration. When the pulse durations are 12, 23, 57, 118, 240 and 524 msec, the half-wave potentials are -2.34, -2.26, -2.20, -2.17, -2.16 and -2.15 V vs. SCE, respectively. The dashed line shows the polarogram of sodium chloride in a neutral solution, in which the pulse duration is 524 msec and the half-wave potential is -2.11 V vs. SCE. In neutral solution the half-wave potential for sodium is independent of the pulse duration. To investigate the cause of the shift of half-wave potentials (Fig. 5), the reduction current vs. time curves of hydrogen ion during the pulse period were measured and the results are shown in Fig. 6. The same results as those shown in Fig. 6 were obtained for a solution which did not contain sodium ions. The plateaus on the initial parts of these curves indicate that the reduction of hydrogen ion at the DME is not diffusion-controlled in the plateau range. When the current is very large, the iR-drop between the DME and the tip of the reference electrode cannot be neglected and the real potential drop across the DME–solution interface is smaller than the applied potential. This effect is more significant at the

Fig. 6. Current–time curves for reduction of hydrogen ion during pulse periods: $0.1M$ Me$_4$NBr, $0.01M$ HCl, $4.02 \times 10^{-4}M$ NaCl. $T_1 = 1.111$ sec, $T_2 = 117.6$ msec. $E_1 = -1.00$ V, E_2: (1) -1.80 V, (2) -2.00 V, (3) -2.20 V, (4) -2.40 V.

beginning of the pulse. Therefore, the shorter the pulse duration, T_2, the more negative the potential at which the reduction of the sodium ion occurs. Hence the shift of the half-wave potential with decrease of pulse duration may result from insufficient conductivity of the solution, and the large reduction current of the hydrogen ions. Positive feed-back compensation is necessary to eliminate the iR-drop between the DME and the reference electrode.[8]

Effect of pH

As can be seen in Fig. 5, the half-wave potential of sodium (for a fixed pulse duration) becomes more negative as the acidity is increased, but the wave shape does not change remarkably. Table 1 shows the wave heights and the half-wave potentials of alkali-metal ions at various pH values. The current values shown in Table 1 are corrected for the blank value. The wave heights of sodium at these pH values are almost constant, but the half-wave potential becomes more negative with decrease of pH. No sodium waves are observed at pH 0.8. The disappearance of the wave may result from insufficient output from the potentiostat and/or the uncompensated resistance in the cell. The half-wave potential of sodium changes by 0.07 V in $0.1M$ supporting electrolyte between pH 5.6 and pH 1.8, and by 0.04 V in $0.2M$ tetramethylammonium bromide for the same pH range. The current vs. time curves for $0.01M$ hydrochloric acid in $0.2M$ tetramethylammonium bromide and reduction during the pulse period had higher and narrower plateaus than the corresponding curves in Fig. 6. This indicates that the shifts of the half-wave potentials are due to insufficient conductivity of the sample solutions. The half-wave potentials and the wave heights for the other alkali metals are also listed in Table 1. The half-wave potentials obtained by the present method for the alkali metals in neutral solu-
Fig. 7. Three kinds of pulse polarogram for sodium chloride in hydrochloric acid: $0.1M$ Me$_4$NBr, $0.01M$ HCl, $4.02 \times 10^{-4}M$ NaCl. $T_1 = 1.111$ sec, $T_2 = 117.6$ msec, $T_3 = 2.3$ msec. E_1: (1) -1.00 V, (2) -2.40 V, (3) -1.00 V. (1) NPP, (2) RPP, (3) present method.

tions were in fair agreement with those for D.C. polarography.

Figure 7 shows three kinds of pulse polarograms of a $4.02 \times 10^{-4}M$ sodium chloride/$0.01M$ hydrochloric acid/$0.1M$ tetramethylammonium bromide solution. Only a hydrogen wave was observed in the normal pulse polarogram (1). In the reverse pulse polarogram (2), the current in the potential region more positive than -1.5 V was proportional to the concentration of sodium chloride, but the limiting current was not reproducible. The fluctuation of the limiting current resulted because adhesion of hydrogen bubbles on the DME caused irregular dislodgement of the mercury drops. A well-defined polarogram (3) was obtained by the present method, and the limiting current was reproducible. In the present method, the short period of reduction of hydrogen ions served to dislodge the mercury drops regularly. Therefore, the polarograms for the five alkali-metal ions in $0.01M$ hydrochloric acid medium were well defined.

Calibration curve

The height of the anodic wave resulting from the dissolution of sodium was proportional to the concentration of sodium chloride, even in $0.01M$ hydrochloric acid medium. The calibration curve for sodium ion, obtained under the same conditions as those for curve 3 in Fig. 7 has good linearity at the $10^{-4}M$ level but does not pass through the origin, because of impurities in the tetramethylammonium bromide. The concentration of these impurities in $0.1M$ tetramethylammonium bromide was $6.3 \times 10^{-5}M$ calculated on the assumption that sodium was the only alkali-metal impurity. The relative standard deviation of the wave height for $4.02 \times 10^{-4}M$ sodium chloride in $0.01M$ hydrochloric acid was 1.0% (six replicates).
Fig. 8. Modified normal pulse polarograms of sodium nitrate: $0.1M$ Me$_4$NBr, $4.07 \times 10^{-4}M$ NaNO$_3$. $E_1 = -1.00$ V. $T_1 = 1.111$ sec, $T_2 = 524$ msec, $T_3 = 2.3$ msec. HCl: (1) absent, (2) $0.01M$.

Effect of anions

Figure 8 shows the polarograms of $4.07 \times 10^{-4}M$ sodium nitrate in $0.1M$ tetramethylammonium bromide. The polarogram of sodium nitrate in neutral solution was the same as that of sodium chloride. In acid solution, however, the polarographic wave of sodium nitrate not only shifted toward more negative potential but also had a sloping limiting current plateau. Though the reason for this is not clear, the presence of nitrate will cause a positive error in the determination of alkali metal ions in acid solutions.

The polarogram of sodium chloride in $5 \times 10^{-3}M$ sulphuric acid was identical with that in $0.01M$ hydrochloric acid. With appropriate selection of E_1 in the present method, in a similar manner as in reverse pulse amperometry,[9] there is no faradaic contribution to the analytical signal from either the dissolution of mercury or the reduction of dissolved oxygen in $0.05M$ tetramethylammonium sulphate. Therefore the present method should be useful for the monitoring of alkali-metal ions in acid streams containing dissolved oxygen.

SPECTROPHOTOMETRIC DETERMINATION OF Mn(II) WITH 1-(2-QUINOLYLAZO)-2,4,5-TRIHYDROXYBENZENE AND MICRODETERMINATION OF Mn IN FOODSTUFFS

Ishwar Singh and Mrs. Poonam

Department of Chemistry, Maharshi Dayanand University, Rohtak 124001, India

Summary—A method is described for the spectrophotometric determination of manganese in foodstuffs by means of its complex with 1-(2-quinolylazo)-2,4,5-trihydroxybenzene, formed in alkaline medium. The molar absorptivity of the complex is 4.6×10^4 l.mole^{-1}.cm^{-1}.

Most widely used methods for the determination of manganese are based on the oxidation of manganese(II) to manganese(VII),[1-3] but because of the low sensitivity these methods are not considered useful for trace analysis. Among other reagents for manganese, the heterocyclic azo-dyes PAN[4-6] and PAR[6-10] give high sensitivity but nickel interferes when PAN is used, and iron, cobalt and nickel interfere in determinations with PAR. Moreover, in both cases the manganese is determined by difference, by destruction of the manganese complex. In the work presented here, we have tried to overcome these difficulties by using a newly synthesized heterocyclic azo-dye, 1-(2-quinolylazo)-2,4,5-trihydroxybenzene (QATB).

EXPERIMENTAL

Reagents

Synthesis of QATB. Stoichiometric amounts of 2-hydrazinoquinoline[11] (1.59 g, 0.01 mole, dissolved in the minimum amount of dilute hydrochloric acid) and 2,5-dihydroxy-1,4-benzoquinone[12] (1.4 g, 0.01 mole, in ethanol) were refluxed together for 30 min. The solution was cooled and made ammoniacal. Excess of ammonia was boiled off and the solution was allowed to stand overnight. The dark red precipitate obtained was recrystallized from ethanol and dried over phosphorus pentoxide. The purity of the compound was checked by thin-layer chromatography and elemental analysis (found: C 64.2%, H 3.8%, N 15.1%; $C_{15}H_{11}N_3O_3$ requires C 64.05%; H 3.91%; N 14.95%). A 0.002M reagent solution was prepared by dissolving 0.562 g in 1 litre of ethanol. Reagent solutions were discarded when a week old.

Manganese(II) solution. Stock 0.01M manganese(II) solution prepared by dissolving an appropriate amount of
1-(2-Quinolylazo)-2,4,5-trihydroxybenzene (QATB)

analytical grade manganese(II) chloride tetrahydrate in water, standardized complexometrically with EDTA,[13] and further diluted as required for working standards.

Ascorbic acid solution. A fresh 1% solution prepared and kept in an amber-coloured bottle.

Potassium cyanide solution, 1%.

Determination of manganese(II)

To a suitable portion of sample (between 1 and 3 ml) containing 1–14 μg of manganese(II) add 0.5 ml of 1% ascorbic acid solution and 1 ml of 0.002M QATB. Add 2.0 ml of 1M sodium hydroxide solution and dilute to volume in a 10-ml standard flask with ethanol, to give a final 50% v/v ethanol concentration. Measure the absorbance at 560 nm against a reagent blank prepared under identical conditions.

RESULTS AND DISCUSSION

Effect of reductant

Addition of an ethanolic solution of QATB to a very dilute solution of manganese(II), in a medium containing not less than 40% v/v ethanol (otherwise a precipitate was obtained), resulted in a dark red solution in alkaline medium, but erratic results were obtained and the colour intensity of the complex decreased on standing. This effect could have been caused by partial aerial oxidation of the manganese(II) to manganese(III) in alkaline medium.[14,15] Oelschläger[16] and Starý[17] proposed that this effect could be prevented by addition of a reducing agent, *viz.* hydroxylamine hydrochloride. We tried various reducing agents (hydroxylamine hydrochloride, ascorbic acid, hydrazine hydrate *etc.*) and observed that addition of 0.2–1.0 ml of 1% ascorbic acid solution yielded consistent and reproducible results.

Spectral characteristics, and effect of pH, etc.

A series of 50% v/v ethanol solutions containing manganese(II) ($2 \times 10^{-5}M$), ascorbic acid (0.1%) and QATB ($2 \times 10^{-4}M$) at different pH values was pre-
Fig. 1
Fig. 2

pared. The spectra were recorded, with a reagent blank as reference. At pH above 9.0 the complex had maximum absorbance at 560 nm (Fig. 1). The complex had maximum absorbance at high alkalinity, and investigation of the effect of sodium hydroxide concentration showed that constant and maximum absorbance was exhibited in 0.1–0.3M sodium hydroxide medium (Fig. 2).

Absorbance data for a series of solutions [2 × 10^{-5}M manganese(II), 0.1% ascorbic acid, 0.2M sodium hydroxide, 50% v/v ethanol, and varying amounts of reagent] showed that at least an 8:1 molar ratio of QATB to Mn(II) is required to ensure full complexation.

Beer's law is obeyed up to 1.7 μg/ml manganese in the solution measured, and the optimum concentration range for accurate determination (as determined by a Ringbom plot) is 0.1–1.4 μg/ml. The composition of the complex is shown by Job's method to be 1:3 (metal:ligand).

The molar absorptivity is 4.6 × 10^4 l.mole^{-1}.cm^{-1}. Table 1 gives a comparison of the sensitivities of various reagents for the determination of manganese(II). The mean absorbance found for 10^{-5}M manganese(II) was 0.460 (1-cm cell, 8 replicates) with a standard deviation of 0.005.

Effect of diverse ions

In the determination of manganese(II) at the

1.1-μg/ml level in the final solution, sulphate, sulphite, citrate, tartrate, borate, phosphate, alkaline-earth metal ions, lanthanides, aluminium(III), indium(III), antimony(III), bismuth(III), chromium(III), platinum metal species [except palladium(II)], and thorium(IV) did not interfere at all. Certain metal ions were precipitated at the pH used, and the precipitates were removed by centrifugation; these ions did not cause interference, and examination of the precipitates for manganese revealed no loss by co-precipitation. For other ions, the tolerance limits defined as the concentration (μg/ml in the final solution) causing a deviation of less than ±2% in the absorbance, were: bromide, thiocyanate, cyanide, EDTA, 400; sulphide 200; fluoride, iodide 100; oxalate 60; thiosulphate 50; molybdenum(VI), tungsten(VI) 40; uranium(VI), vanadium(V), cadmium(II), mercury(II) 20. Zinc(II) 2, iron(III) 20, and iron(II), cobalt(II), nickel(II), copper(II), palladium(II) 10, were masked by 1% potassium cyanide solution, and zinc(II) 10, was masked by 200 ppm EDTA solution. Potassium cyanide also inhibits the colour formed by lead(II) with QATB.

APPLICATIONS

In recent years considerable attention has been paid to the role of trace elements in human health and

disease. Public health problems have been correlated with trace element imbalances[18] in the human system and thus analysis of foodstuffs is of great importance. We have analysed some foodstuffs for trace amounts of manganese by use of QATB, and the results are given in Table 2.

Analysis of tea leaves and coffee powder

Dry-ash 2 g of material at 450° and digest the ash with 2 ml of a 3:1 v/v mixture of nitric and perchloric acids. Heat gently almost to dryness, repeat again with 2 ml of acid mixture and dilute to volume in a 25-ml standard flask with water. Set aside overnight and then filter, add to a suitable aliquot (up to 1.0 ml of solution) 0.5 ml of 1% ascorbic acid solution and 0.5 ml of 1% potassium cyanide solution. Add 1.0 ml of 0.002M QATB and 2–3 ml of 1M sodium hydroxide, and finally dilute to 10 ml (standard flask) with water and ethanol to give a final 50% v/v ethanol concentration. Measure the absorbance at 560 nm against a reagent blank.

Analysis of foodstuffs

Add to the sample a 5% ethanolic solution of magnesium acetate tetrahydrate, evaporate to dryness and then heat at ~900° until the ash is white. Cool and add ~5 ml of a 1:1 mixture of nitric and perchloric acids. Heat gently almost to dryness, add 3–4 ml of water, filter, and wash the residue 3 or 4 times with hot water. Combine the filtrate and washings and make up to volume in a 25-ml standard flask. Determine the manganese content as already described.

Results obtained for the determination of man-

ganese in various foodstuffs are summarized in Table 2.

The recovery was tested by adding a known amount of manganese to the sample solutions and applying the recommended procedure, and found to be between 94 and 105% in all cases.

SPECTROPHOTOMETRIC ANALYSIS OF SIMULTANEOUS PROTOLYSIS EQUILIBRIA*

Jürgen Polster

Lehrstuhl für Allgemeine Chemie und Biochemie der Technischen Universität München, D-8050 Freising-Weihenstephan, BRD

Summary—Simultaneous protolysis equilibria $(BH + H_2O \underset{}{\overset{K_1}{\rightleftharpoons}} B^- + H_3O^+; CH + H_2O \underset{}{\overset{K_2}{\rightleftharpoons}} C^- + H_3O^+$ can be spectrophotometrically analysed easily by means of absorbance diagrams. The dissociation constants K_1 and K_2 can be determined directly from distinct points on the absorbance diagram by correlation with a photometric titration plot of absorbance *vs.* pH. Furthermore, from the absorbance diagram the ratio K_2/K_1 can be evaluated from the ratio of corresponding sides, and pH-measurement is not necessary. The titration systems of a mixture of 2-nitroso-1-naphthol-4-sulphonic acid with *p*-nitrophenol, and a mixture of *p*-nitrophenol with *o*-nitrophenol have been analysed by these methods, and are described as examples.

Two basic questions of this and earlier works[1-5] are (1) what information can be obtained in titration systems from spectrophotometric data alone, and (2) how can this information be correlated with the pH data, to determine equilibrium constants?

As shown below, the quotient of the dissociation constants for two protolysis systems in the same solution can be evaluated from spectrophotometric data alone, by means of absorbance diagrams. Thus an unknown dissociation constant can be obtained from that of a standard substance without any pH measurements. This is useful for systems in which pH measurement presents problems, for example in organic or strongly acidic solutions.[6]

Furthermore, the dissociation constants themselves can be easily evaluated by means of tangents and lines in the absorbance diagram, in combination with a plot of absorbance *vs.* pH. Two systems, consisting of 2-nitroso-1-naphthol-4-sulphonic acid/*p*-nitrophenol and *p*-nitrophenol/*o*-nitrophenol, are used here to illustrate the use of the methods.

The equations required for the analysis can be derived simply by use of a concentration diagram, which can be transformed into the absorbance diagram by linear transformation.

For the pair of protolysis equilibria

$$BH + H_2O \overset{K_1}{\rightleftharpoons} B^- + H_3O^+$$
$$CH + H_2O \overset{K_2}{\rightleftharpoons} C^- + H_3O^+ \quad (1)$$
taking place in the same solution, the mixed dissociation constants are defined as[1,2]

$$K_1 = \frac{h[b]}{[bh]} \quad \text{and} \quad K_2 = \frac{h[c]}{[ch]} \quad (2)$$

where h is the hydrogen-ion activity ($h = a_{H_3O^+} = 10^{-pH}$), and [b], [bh], [c] and [ch] are the molar concentrations of B, BH, C and CH respectively. From this and the additional stoichiometric conditions

$$b_0 = [b] + [bh]; \quad c_0 = [c] + [ch] \quad (3)$$

(where b_0 and c_0 are the total molar concentrations of the protolytes) and the definition

$$\kappa = \frac{K_2}{K_1} \quad (4)$$

we obtain the equations

$$[b] = \frac{b_0 K_1}{h + K_1}; \quad [c] = \frac{c_0 K_2}{h + K_2} \quad (5)$$

and

$$[b] = \frac{b_0[c]}{c_0 \kappa + [c](1 - \kappa)} \quad (6)$$

A plot of [b] *vs.* [c] (as functions of pH) is a conic section (hyperbola) which is dependent on κ (provided $\kappa \neq 1$). Figure 1 presents the curves for $\kappa = 0.316$ and $\kappa = 3.16$. The curves pass through the points $B_1(0,0)$ and $B_3(b_0, c_0)$. The side $B_1 B_3$ is an axis of symmetry for the curves κ and $1/\kappa$.

The distinction $\kappa > 1$ and $\kappa < 1$ is arbitrary. It depends on which protolysis system $[BH \rightleftharpoons B^- (H^+)$ or $CH \rightleftharpoons C^- (H^+)]$ is the stronger [see equation (1)]. For reasons of graphical representation both cases are shown in Fig. 1.

The tangent vectors to the curves at these two points are $B_1 B_2$ and $B_3 B_2$ or alternatively $B_1 B_2'$ and $B_3 B_2'$. At the origin $B_1(0,0)$, all of B is in the form BH and all of C in the form CH. The two points (0,0) and
Fig. 1. Concentration diagram of b *vs.* c for the system BH
$\stackrel{K_1}{\rightleftharpoons}$ B⁻ (H⁻); CH $\stackrel{K_2}{\rightleftharpoons}$ C⁻ (H⁺). The triangles (0,0), (b_0,0),
(b_0,c_0) and (0,0), (0,c_0), (b_0,c_0) and their interior represent
physically admissible points of the system. Outside these
areas at least one of the concentrations is negative. P_1, P_2,
T_1 and T_2 are distinct points of the conic section. The
distinction $\kappa > 1$ and $\kappa < 1$ is arbitrary; for reasons of
graphical representation the triangles $B_1 B_2 B_3$ and $B_1 B_2' B_3$
are both constructed.

(b_0, c_0) simply represent limiting conditions of the
pH:

very low pH: [b] = [c] = 0; [bh] = b_0 and [ch] = c_0
very high pH: [b] = b_0, [c] = c_0; [bh] = [ch] = 0

The points shown in Fig. 1 have the following
properties (P_1, P_2, T_1 and T_2 are points of the conic
section):

(*a*) H_1 and H_2 are the mid-points of sides $B_1 B_2'$ and
$B_2' B_3$ (or alternatively $B_1 B_2$ and $B_2 B_3$);
(*b*) the vectors $B_3 P_1$ and $B_1 P_2$ have the same direction
as $B_3 H_1$ and $B_1 H_2$;
(*c*) the vectors $B_2 T_1$ and $B_2 T_2$ lie parallel to the axes;
(*d*) S_1 and S_2 are the points of intersection of sides
$B_2 B_3$ and $B_1 T_1$ or alternatively $B_1 B_2$ and $B_3 T_2$ [anal-
ogously S_1' for $B_2 B_3$ and $B_1 T_2$ (not shown) and S_2' for
$B_1 B_2$ and $B_3 T_1$ (not shown)].

The values pK_1, pK_2 and κ can be calculated easily
from particular points of the curve. The pH values
corresponding to T_1 and T_2 give directly the two pK
values:

$$pH(T_1) = pK_1; \quad pH(T_2) = pK_2 \qquad (7)$$

For the pH values corresponding to P_1 and P_2 the
following equations apply:

$$pH(P_1) = pK_I; \quad pH(P_2) = pK_{II} \qquad (8)$$

where

$$K_I = K_1 + K_2; \quad K_{II} = \frac{K_1 K_2}{K_1 + K_2} \qquad (9)$$

Thus pK_1 and pK_2 can be determined directly from
the pH values corresponding to T_1 and T_2, or P_1 and
P_2, but only in the case of equations (7) is it possible
to assign the dissociation constants to the individual
equilibria. Thus in Fig. 1 T_2 lies nearer to B_1 than T_1
does. Therefore the pK value of CH $\rightleftharpoons$ C⁻ (H⁺) is
smaller than that of BH $\rightleftharpoons$ B⁻ (H⁺).

The ratio of corresponding sides can be referred to
κ. For example (see Fig. 1):

$$\frac{B_2 S_2'}{B_1 S_2'} = \frac{B_2 S_1'}{B_3 S_1'} = \frac{1}{1 + \kappa} \qquad (10)$$

and

$$\frac{B_2 S_2}{B_1 S_2} = \frac{B_2 S_1}{B_3 S_1} = \frac{\kappa}{1 + \kappa} \qquad (11)$$

The measurements required are the absorbance
values (A_λ) obtained at various pH values. If $\epsilon_{\lambda_1 BH}$
designates the molar absorptivity of BH at wave-
length λ_1, *etc.*, the absorbance is given by the
Lambert–Beer law:

$$A_{\lambda_1} = \epsilon_{\lambda_1 BH}[bh] + \epsilon_{\lambda_1 B}[b] + \epsilon_{\lambda_1 CH}[ch] + \epsilon_{\lambda_1 C}[c] \quad (12)$$

(for unit path-length).

This equation is assumed to be valid for all wave-
lengths. Thus the two independent variables, [b] and
[c], can be transformed into the absorbances (A_{λ_1},
A_{λ_2}) by a linear transformation including translation.
A plot of A_{λ_1} *vs.* A_{λ_2} is called the absorbance (A)
diagram[1]. The equations (7)–(11) are also represented
in the A diagram. The triangle $B_1 B_2 B_3$ (or alterna-
tively $B_1 B_2' B_3$) in Fig. 1 leads to the linearly distorted
triangle $B_1 B_2 B_3$ in the A diagram.

EXPERIMENTAL

Reagents

p-Nitrophenol (Merck and Fluka), *o*-nitrophenol
(Merck, recrystallized from water[1]), 2-nitroso-1-naphthol-
4-sulphonic acid (Fluka), potassium chloride (Merck),
sodium hydroxide and hydrochloric acid standard solutions
("Titrisol", "Fixanal" ampoules), standard buffer solutions
(Riedel-de Haen and Merck).

Procedure

The system oNP/pNP was investigated as described
earlier,[1] with the same apparatus. The system
2-nitroso-1-naphthol-4-sulphonic acid/pNP was studied
spectrophotometrically with a Perkin-Elmer model 555
spectrophotometer. The pH measurements were made (un-
der nitrogen) with a Beckman model 3560 digital pH-meter.
The titrations were performed with a Radiometer ABU 12
auto burette (maximal titration volume 2.5 ml).

RESULTS AND DISCUSSION

Determination of pK_1 and pK_2

In Fig. 2 the spectra of 2-nitroso-1-
naphthol-4-sulphonic acid and *p*-nitrophenol at vari-
ous acidities are shown. For construction of the A
diagram the absorbances measured at two wave-
lengths (for the same set of pH values) are plotted
against each other. The most suitable wavelengths are
those where large absorbance differences occur. The
Fig. 2. Titration spectra of 2-nitroso-1-naphthol-4-sulphonic acid and p-nitrophenol (with $0.05M$ KCl as background electrolyte, at $25.0°$). The numbers given designate the pH values.

measured points lie on a curve (see Fig. 3). A pH value can be assigned to each point, from a plot of A_λ vs. pH.

In Fig. 3 the points B_1 and B_3 are obtained at low (<3) and high (>10) pH values. The tangents constructed at these points intersect at B_2. For the determination of pK values the bisecting lines B_3H_1 and B_1H_2 are constructed. They intersect the curve at P_1 and P_2, for which the pH values are pK_I and pK_{II}. Finally, by use of equations (9) the pK values are obtained: $pK_1 = 6.23$ and $pK_2 = 7.15$.

Without additional information, however, it is not possible to assign the pK values to the individual substances.

The pK values can also be evaluated by using equation (7). In Fig. 3 the sides BHB^- and CHC^- indicate the lines for the separately measured protolysis equilibria of 2-nitroso-1-naphthol-4-sulphonic acid (pK_1) and p-nitrophenol (pK_2). Their parallels through B_2 intersect the conic section at T_2 and T_1. The pH values corresponding to T_2 and T_1 lead to the pK values: $pK_1 = 6.30$ and $pK_2 = 7.20$.

Spectrophotometric analysis[3] of the two equilibria separately gives the values $pK_1 = 6.34$ and $pK_2 = 7.18$ ($0.05M$ potassium chloride medium; temperature $25°$).

Determination of κ

The ratio of the dissociation constants can easily be determined by means of A diagrams. All the components may absorb, and no pH measurement is necessary. However, the determination of κ is critical for $\kappa \sim 1$, and the method fails at $\kappa = 1$. As a critical test, the p-nitrophenol/o-nitrophenol system is examined here, because the two pK values are similar.[1]

Figure 4 shows the diagram for A_{368} vs. A_{225}, in which the curve is only slight. The titration points for the separately measured p-nitrophenol system lie on the straight line BHB^-. The parallel through B_2 intersects the conic section at T_2. By analogy T_1 can

be constructed from the data for the separately measured o-nitrophenol system (only B_2T_1 is shown in Fig. 4). Because T_2 lies nearer to B_1 than does T_1 the pK value of p-nitrophenol is smaller than that of o-nitrophenol.

By use of T_2 the lines B_1T_2 and B_3T_2 can be constructed. Their intersections with the tangents B_2B_3 and B_1B_2 then give S_1' and S_2. Evaluation by means of equations (10) and (11) leads to the value 1.26 for κ. Because p-nitrophenol (pNP) is more acidic than o-nitrophenol (oNP), the final result is
Fig. 3. Absorbance diagram A_{430} vs. A_{380} obtained from Fig. 2. For the construction of B_2 the tangents at B_1 and B_3 were determined by means of the polynomial $A_1 = a_1 + a_2A_2 + a_3A_2^2$. The coefficients a_1, a_2 and a_3 were obtained by regression analysis from seven measured points. The points of the separately measured protolysis equilibria of 2-nitroso-1-naphthol-4-sulphonic acid and p-nitrophenol lie on the sides BHB^- and CHC^-. The parallels to these lines through B_2 lead to T_2 and T_1. Because T_2 lies nearer to B_1 than does T_1, 2-nitroso-1-naphthol-4-sulphonic acid is the stronger acid.

ight116

JÜRGEN POLSTER
Fig. 4. (a) Absorbance diagram A_{368} vs. A_{225} for pNP and oNP (at 25.0°). For the construction of B_2 the tangents at B_1 and B_3 were determined by means of the polynominal $A_1 = a_1 + a_2A_2 + a_3A_2^2$. The coefficients a_1, a_2 and a_3 were obtained by regression analysis from nine measured points. The titration points of the separately measured pNP system lie on the straight line BHB⁻. Its parallel through B_2 leads to T_2. By analogy the separately measured system oNP leads to T_1. pNP is more acidic than oNP because T_2 lies nearer to B_1 than does T_1 (*i.e.*, $K_{pNP}/K_{oNP} > 1$). (b) An enlargement (×2) of the central part of (a).

$\kappa = K_{pNP}/K_{oNP} \approx 1.26$. The mean value found earlier[1] for κ was 1.25.

Conclusions

These model systems demonstrate that the values pK_1, pK_2 and κ for two protolysis equilibria in the same solution can be determined simply and exactly by the method described. More complicated systems may also be studied. Thus similar problems in biological systems, for example distinct dissociable groups (tyrosine) in a macromolecule (protein), can be studied spectrophotometrically. Nor is the method limited to spectrophotometric data. Any physical measurements, *e.g.*, NMR, circular dichroism, may be evaluated if the measured signal is linearly dependent on the concentrations of the components.

A PROGRAMMABLE POSITIONING STEPPER-MOTOR CONTROLLER WITH A MULTIBUS/IEEE 796 COMPATIBLE INTERFACE

P. PAPOFF and D. RICCI

Istituto di Chimica Analitica Strumentale del C.N.R., c/o Istituto di Chimica Analitica dell'Università di Pisa,
Via Risorgimento, 35, 56100 Pisa, Italy

Summary—A programmable positioning stepper-motor controller, based on the Multibus/IEEE 796 standard interface, has been assembled by use of some intelligent and programmable integrated circuits. This controller, organized as a bus-slave unit, has been planned for local management of up to four stepper motors working simultaneously. The number of steps, the direction of rotation and the step-rate for the positioning of each motor are issued by the bus master microcomputer to the controller which handles all the required operations. Once each positioning has been performed, the controller informs the master by generating a proper bus-vectored interrupt. Displacements in up to 64,000 steps may be programmed with step-rates ranging from 0.1 to 6550 steps/sec. This device, for which only low-cost, high-performance components are required, can be successfully used in a wide range of applications and can be easily extended to control more than four stepper motors.

The increasing use of microprocessors in instrumentation control has given rise to a more efficient exploitation of stepper motors whenever precise and accurate mechanical positioning of instrumental parts is required.

Drive circuits for stepper motors can be easily implemented, in particular with specific integrated circuits.[1,2] Their control by microcomputer is usually accomplished by direct management of two signals, one to select the direction of rotation and the other to make the motor advance one step for each pulse generated.[3]

This kind of approach has two main limitations: (1) degradation of the potentiality of the microcomputer, which has to spend time in performing trivial operations such as counting the steps and handling the time interval between them; (2) difficulties may arise in real-time control of the motors when several are required to work simultaneously.

These limitations can be overcome by using an intelligent device able to perform locally all the operations for stepper-motor positioning according to microcomputer instructions. Some devices of this kind are available on the market,[4] but they may result in redundance and be relatively expensive in some applications. This paper describes a programmable device, implemented with low-cost components, which handles the displacements and velocities of four stepper motors. Moreover the device is implemented as a general-purpose Multibus-compatible unit, that can be connected to any microcomputer system based on the Multibus, which is a widely used IEEE standard interface.

The Multibus is a communications device for microcomputer systems. It connects the printed circuit boards of the system over several parallel lines by using a defined mechanical structure as support. It was originally developed by Intel and then became an IEEE standard (IEEE-796). It supports two independent address spaces: one for the memory, using 20-bit addressing; the other for input/output devices, using 16-bit addressing; the data transfer is bidirectional and asynchronous, with 8- or 16-bit data-word size. In addition eight multilevel interrupt lines are available. The units working with the Multibus are either masters or slaves; the master unit can control the bus, whereas the slave unit cannot control the bus but, upon decoding its own address, acts on the command signals from the bus master.[5,6]

EXPERIMENTAL

Stepping-motor controller architecture

Figure 1 shows the block diagram of the stepping-motor controller, which is a slave Multibus unit based on some very sophisticated and intelligent programmable support integrated circuits. These consist of three programmable interval-timers 8253 (PIT), one programmable peripheral interface 8255 (PPI) and one programmable interrupt-controller 8259 (PIC). These integrated circuits are connected to the Multibus with their address decoder and proper bidirectional bus drivers.[7–10]

The 8253 PIT consists of three independent 16-bit presettable down-counters working in six different modes; the mode and the counting number for each counter are software-programmable. Two counters are used for each stepping motor, one (P_i) for the step-rate control, the other (Q_i) for the step-number control.

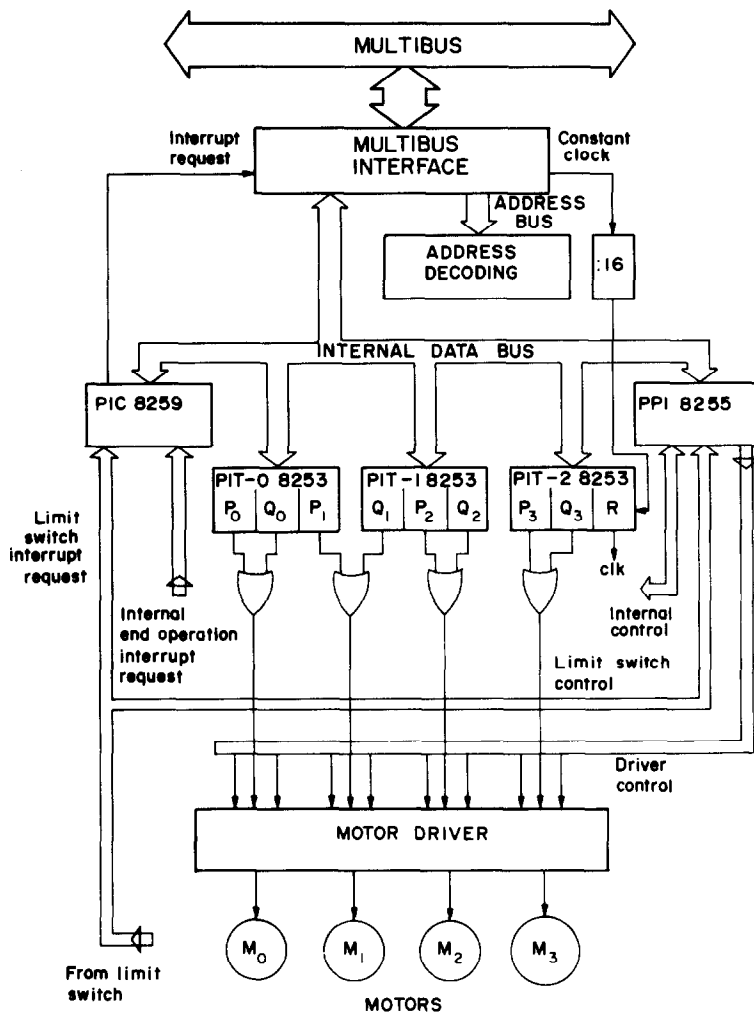
The 8255 PPI manages three 8-line groups (A, B and C) each of which may be software-programmed as an input or output port. This integrated circuit is used for the management of the control lines in the system, such as the direction selection for each stepping motor.


Fig. 1. Controller block diagram.

The 8259 PIC is a device for management of the interrupt logic in microcomputer systems. It handles eight levels of interrupt with priority resolution and addresses the specific service routines according to its programmed working mode. The 8259 PIC is used to inform the master when one (or more) stepping-motors have ended an operation, so as to allow synchronization between software and mechanical operations.

Functional description

Figure 2 shows a schematic diagram for control of one stepping motor (i). One counter (P_i) of a PIT is programmed as a square-wave generator; it receives a clock signal at the input, with period $t_0 = 152\,\mu$sec (internal clock) and gives a square wave at the output, with period $T = Nt_0$, where N is a 16-bit binary integer number software-loaded on the counter. [The internal clock is obtained by dividing by 1408 the output from the 9.22-MHz constant-clock of the Multibus; for this purpose a PIT counter (R) is used]. Another counter (Q_i) is programmed as a one-shot generator, receiving the square wave ($T = Nt_0$) at the input. A one-shot pulse, with duration $D = MT$, is generated at the output of Q_i every time a rising edge is sent to the counter trigger; M is a 16-bit binary integer number software-loaded on the counter.

The outputs of each counter are connected to the inputs of an OR gate, the output of which is a burst of M pulses with a period Nt_0, as shown in the timing diagram of Fig. 2. This burst of pulses is sent to the step-line of the drive

circuit of the motor, so that it performs M steps at a rate of $1/Nt_0$ steps/sec. M can range from 1 to 65,535, and $1/Nt_0$ from 0.1 to 6550 steps/sec, since M and N are both 16-bit integer binary numbers, and $T_0 = 152\,\mu$sec.

The 8255 PPI is programmed to work with its ports A and C as latched output and port B as input. Its output lines manage (for each motor):

(a) the "cw/ccw" control of the motor drive, to select the rotation direction: cw/ccw = 0 for clockwise rotation; cw/ccw = 1 for counterclockwise rotation;

(b) the "trigger" of the counter Q_i to enable the stepping motor to start the programmed operation at the rising edge;

(c) the "off" control of the motor drive; when this line is in the high logic level the motor current is set at zero, and the motor is left without holding-torque.

The 8255 input lines are used to test, for each motor, the status of:

(a) the "busy" line, *i.e.*, the output of counter Q_i; when the line is in the low logic level the motor is busy performing some operation;

(b) the "zero" line which is connected to the motor limit switch to define the "zero" position for absolute positioning.

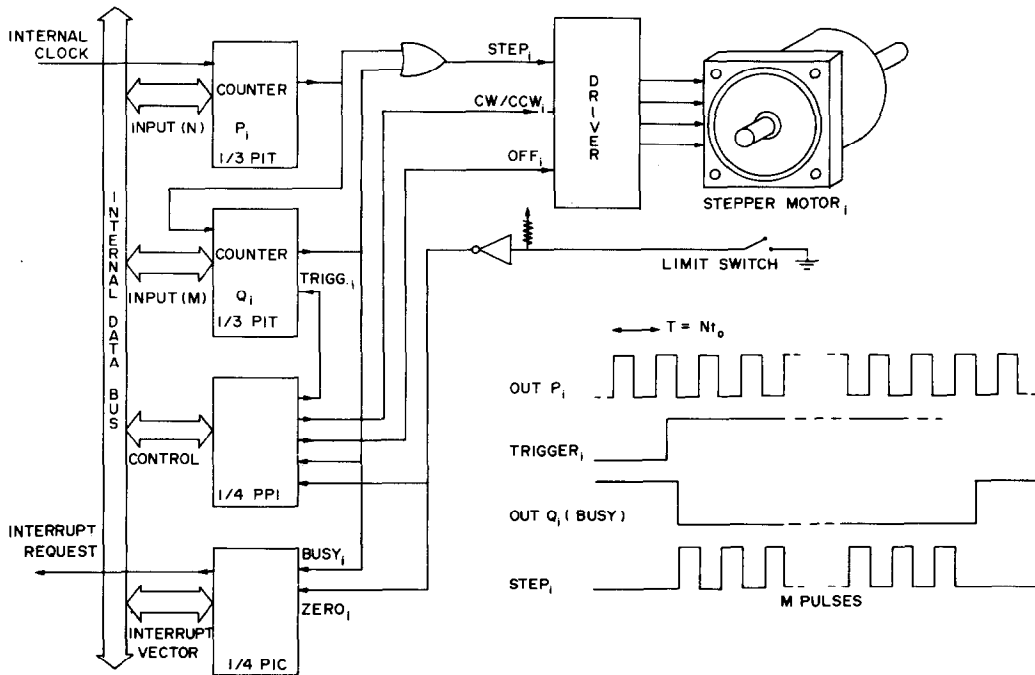
The "busy" and "zero" lines of each motor are also connected to the inputs of the 8259 PIC. When the PIC is warned by these lines that one or more motors have performed a positioning or have reached their "zero" position, the PIC causes a vectored interrupt to be sent to


Fig. 2. Motor (i) control schematic diagram.

the master and gives it the restart address of the proper service routine locally resolving the interrupt priority.

Programming of the controller

Controller programming is accomplished by the master microcomputer through the input/output operations issued to the specific addresses assigned to the programmable chips: 8253 PIT, 8255 PPI and 8259 PIC. These addresses are reported in Table 1.

Figures 3a and 3b show the flow-chart of output operations for initialization of the programmable chips. These are programmed to work according to the function required in stepper-motor control. Initialization is necessary only after the powering up or reset of the system. The 8255 PPI is programmed first, then the three 8253 PITs and finally the 8259 PIC of the controller. Since the 8259 PIC of the controller works interactively with the 8259 PIC of the master microcomputer the latter is concordantly programmed.

Figure 4 shows the flow-chart of the input/output operations on the programmable chips to make motor (i) perform M steps at the rate of $1/Nt_0$ steps/sec. The 16-bit digital numbers N and M are sent to counters P_i and Q_i respectively, after the "busy$_i$" line has been tested with an input from port B. The direction of motor operation is selected by setting the proper control line "cw/ccw$_i$" and the start enabled by "trigger$_i$", by means of two outputs to port C. Once the motor has been started the master is free to move on to another operation. The end of the motor operation is signalled by the local 8259 PIC.

REMARKS

The programmable controller described can be successfully used in automatic control of chemical instrumentation, whenever stepper motors are required. The device was used at our laboratory in a computer-controlled spectrometer, combined with an inductively-coupled plasma source, designed for au-

tomatic sequential determinations.[11,12] In the spectrometer the controller handles:

(a) two stepper motors for the wavelength indexing in an echelle monochromator (where one motor controls the grating, the other the prism);

(b) a stepper-motor controlled rotatable mirror for the selection of the proper observation zone within the plasma-plume;

(*c*) a stepper-motor peristaltic pump for control of sample flow-rates in the plasma nebulizer.

A Single Board Computer "Intel 86-12A", based on Multibus (its primary features are reported in Table 2), was used as bus master for the controller and the data-acquisition system. The aim was to implement the instrument control along with data acquisition, storage and reduction.

The primary features of the drive circuit for the motors are reported in Table 3.

In the controller, the software routines for the system management were implemented by use of Assembly 86 language, there being one for the con-

troller initialization, one for automatic search of the motor limit switch, and another for the relative positioning. These programs require only a minimum amount of instructions, and can be written by any user, even with little programming experience, owing to the "friendly" programmability of the intelligent circuits used. Details, circuit diagrams and programs are available on request.

COULOMETRIC TITRATION BY MEANS OF A CONTROLLED-POTENTIAL–PULSED-CURRENT POTENTIOMETRIC TECHNIQUE—I

METAL IONS BY ELECTRO-DEPOSITION

Theologos Andronidis and Anna Maria Ghe

Istituto Chimico G. Ciamician dell'Università, Scuola di Specializzazione in Chimica Analitica,
via Selmi 2, 40126 Bologna, Italy

Cesare Pagura and Sergio Valcher*

Istituto di Polarografia ed Elettrochimica Preparativa del C.N.R., Corso Stati Uniti 4, 35100 Padova, Italy

Summary—A new method for electrochemical titrations is proposed, based on the redox transformation of the test species by means of a controlled-potential pulsed current, followed by measurement of the potential in the intervals between the current pulses: the end-point is found by means of Sörensen's linearization technique. Investigations on various metal ions (Ag^+, Cu^{2+}, Cd^{2+}, Pb^{2+}) have shown that the accuracy and sensitivity, which depend on the nature of the species titrated, are comparable with those of other titration techniques. The method permits analytical separations and determinations of metal ions in mixtures. No particularly elaborate instrumentation is required and the apparatus described is simple to use, reliable and inexpensive.

Controlled-potential coulometry is usually used for analytical separations of metal ions and other electroactive species when the more popular constant-current and pulsed-current coulometry[1,2] cannot be applied because of their lack of selectivity.

For the controlled-potential technique, the electrolysis current is the parameter generally used to determine the end-point, but this approach may sometimes not be accurate enough, particularly at low concentrations, where the background current becomes significant. A means of direct monitoring of the transformed species may then improve the performance.

Potentiometry is one such means and gives sensitive end-point detection provided equilibrium is obtained rapidly at the indicator electrode. Since this is usually not the case under constant-current electrolysis conditions, potentiometric end-point detection is more effective if the current is switched off while the potential is being measured.

A controlled-potential pulsed-current technique has therefore been devised, which is based on repetitive cycles of the following stages.

(1) Passage of a current pulse at a working-electrode potential controlled at a value suitable for redox transformation of the single species to be determined. The electrolysis current is integrated until a preset charge has been passed and is then instantaneously reduced to zero.

(2) Measurement of the indicator-electrode potential (at zero current) once its value is steady.

The set of potentials is then processed in order to get a linear function with respect to the charge passed, and from this the titration end-point can be extrapolated.

Besides accuracy, the main advantage of the method is the possibility of evaluating the equivalence point without completing the electrolysis.

EXPERIMENTAL

Apparatus

The apparatus outlined in Fig. 1 has been used for the separation and determination of metal ions according to the principle described above.

The printer and potentiometer are commercial units (Laben 6061 and Orion 701 A, respectively), and the potentiostatic-coulometry unit is specially designed and constructed for use in the method.

The potentiostat (a) provides current at controlled potential. The charge passed in a single pulse is controlled by means of the current-to-voltage converter (b) and the integrator (c), the pulse being terminated by a suitable logical network as soon as the charge passed reaches the value preset on the comparator (d).

The potentiostat–galvanostat (a) and current-to-voltage converter (b) are operationally closely linked.

In the potentiostatic configuration [(i) in Fig. 2] the use of the high-current operational amplifier (No. 1) is quite conventional[3,4] whereas in the current-to-voltage converter the high-current operational amplifier (No. 2) is used as a

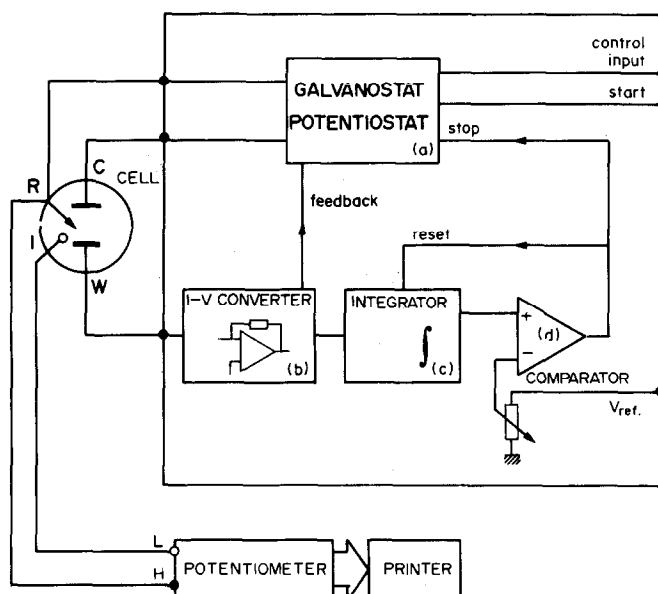
---


Fig. 1

voltage follower, in conjunction with a second operational amplifier. Diagram (ii) in Fig. 2 clarifies the reasons for this doubling, by showing the logic diagram for current interruption under potentiostatic conditions: instead of the current being switched off, it is instantaneously reduced to zero by activation of a negative feedback loop from the current-to-voltage converter to the potentiostat. This is done to avoid the disadvantages associated with the switching of relatively high currents.

To prevent an unsuitable choice of current range from invalidating the coulometric data, a current limiter has been incorporated which operates by taking control of the working-electrode potential when the output of the current-to-voltage converter reaches the highest allowed value (about 11 V). The high-current operational amplifiers HCA.1 and HCA.2 are made by coupling current boosters (limited at 100 mA) to LH0042 and LM308 operational amplifiers respectively.

The integrator (c), comparator (d) and stop–reset/start logic network, which is suitable for manual operation, is shown in Fig. 3. A flip-flop (1/2 SN7401) is used to switch the system between the potentiostatic and zero-current configurations and to reset the integrator.

Titrations

As can be seen in Fig. 1, the electrolysis and the potential measurements can, if desired, be performed at different electrodes. Nevertheless this configuration has been employed only for special cases, it being generally sufficient to use a single electrode as both working and indicator electrode. The electrode potential is transmitted from the digital output of the potentiometer to a printer (at 10-sec intervals) and is taken as constant if it does not vary by more than 0.1 mV during a time-period chosen in accordance with the behaviour of the electrochemical system.[5] The charge to be passed in the pulse is preset by means of the current-range and time-constant selectors (according to the concentrations used and the area of the working electrode) so that about 20–30 data points are obtained for titration of a single species.

Cell and electrodes

The cell is equipped with a magnetic stirrer, and a nitrogen inlet for deaeration of the test solution. The counter-electrode (generally made of platinum) is separated from the titration cell by a porous glass disk and is housed in a compartment containing the same background electrolyte as the test solution. The saturated calomel reference electrode is similarly connected.

The working electrode has a surface area of about 1 cm^2 and is made of various materials, as indicated below.

Solutions

Titrations were done (at 25°) on 20-ml samples, containing the species to be tested, and a background electrolyte chosen to give the best current yield and speed of response of the indicator electrode.

The solutions employed are listed in Table 1; they were generally acidic to prevent hydrolysis but care was taken to avoid concentrations at which hydrogen discharge would occur.

Table 1. Composition of the supporting electrolytes for the determination of single ions or ion mixtures

Type	Reagents and concentrations	pH
A	$CH_3COONa\ 10^{-1}M + CH_3COOH \sim 5 \times 10^{-3}M$	5.8
B	$H_2SO_4\ 2.5 \times 10^{-3}M$	2.4

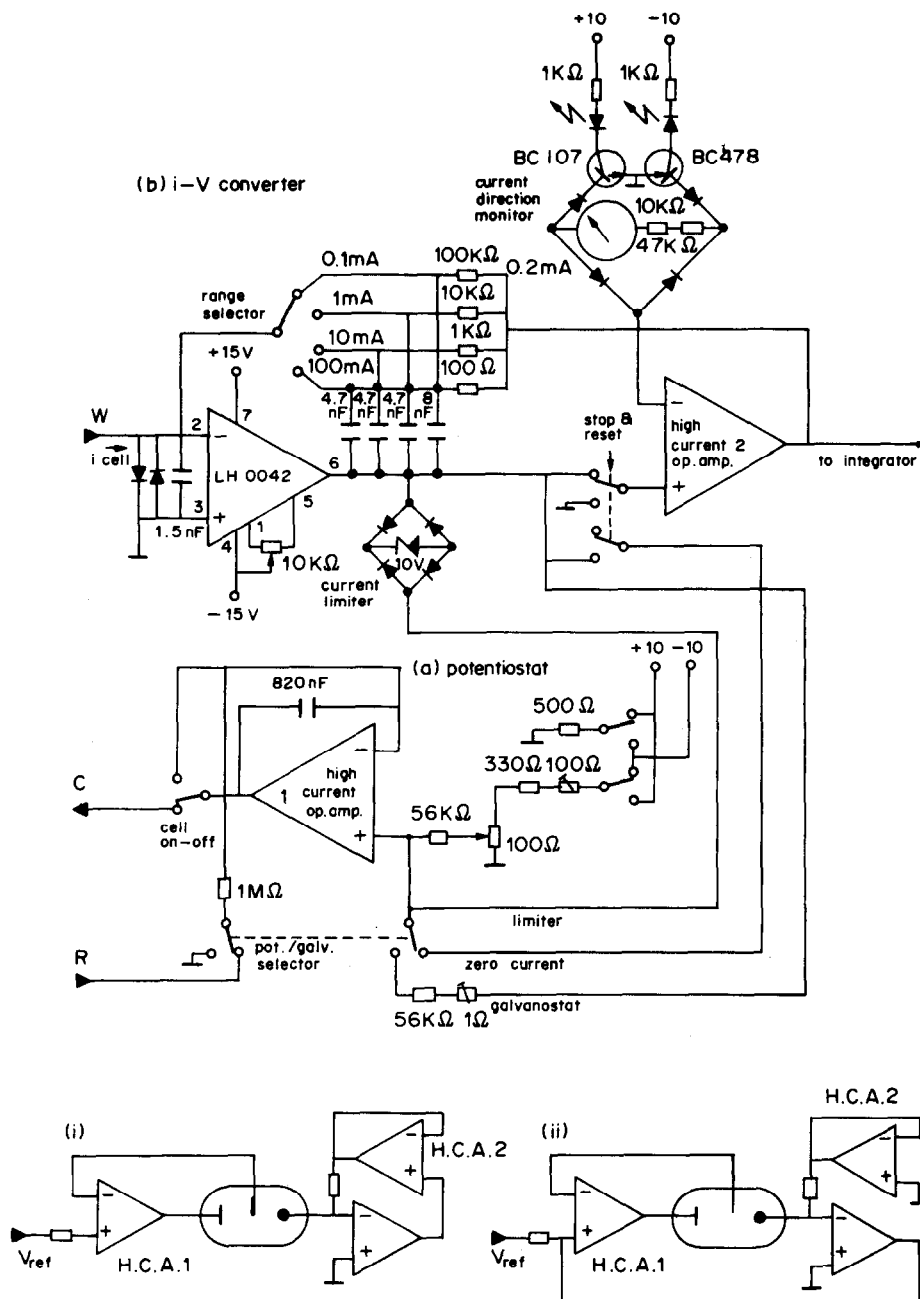

Fig. 2

End-point determination

A linearization technique is used so that the end-point can be deduced from the potentiometric data without completion of the electrolysis reaction.

Sörensen's[6] method was used instead of Gran's,[7] as the latter makes corrections for dilution, which does not occur in our method.

Since deviations from linearity may be encountered both for the initial points (because of the state of the indicator electrode surface) and for those near to the end-point (at low concentrations), the straight lines for extrapolation to the equivalence-point are obtained by using only the most linear subset of the experimental data.

This subset is extracted by numerical analysis as described elsewhere[8] and is referred to here as the highest linearity segment. For a complete set of c data points, it contains $(c + 8)/4$ consecutive points. This segment, comprising the points $P(n)...P(n + m)$, is selected on the basis of the variance minimum given by the three intercepts (on the charge axis) of the segments: (a) $P(n - 1)...P(n - 1 + m)$; (b) $P(n)...P(n + m)$ and (c) $P(N + 1)...P(n + 1 + m)$.

The selected subset is then used for linear regression analysis, which leads to the best straight line, the correlation coefficient, and the 90% confidence limits.

RESULTS AND DISCUSSION

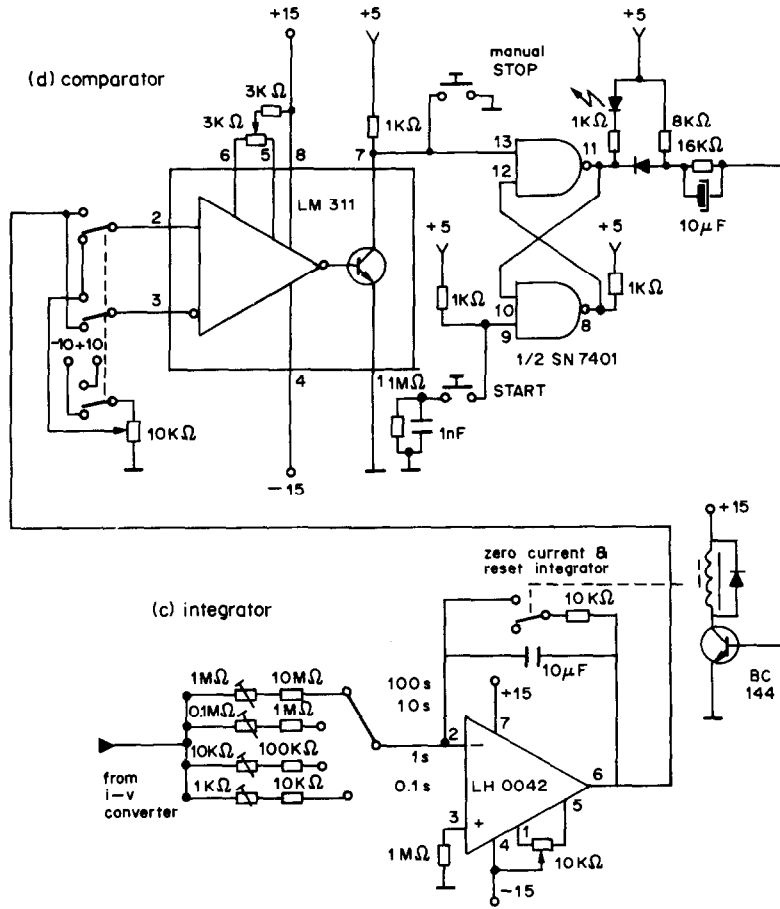
The proposed technique was developed for the determination of ions by electro-deposition, both in systems containing a single species, and in mixture of several metal ion; in other words, for an electrolytic precipitation titration.


Fig. 3
Fig. 4

An example of the diagrams used for the determination of the equivalence point is shown in Fig. 4, where a titration of $5 \times 10^{-4}M$ silver is shown.

In the plot, the Sörensen function S (defined as $S = 10^{nE/0.059}$, n being the number of electrons involved in the reaction, and E the measured electrode potential) is plotted as a function of charge consumed (expressed as $C = Q/nFm$, where m is the number of moles of silver deposited. The points denoted by $\square$ pertain to the highest linearity segment, selected as indicated. In the same figure the linear-regression straight line is shown together with the corresponding 90% confidence hyperbolas, the intercepts of which with the charge axis are the confidence limits for location of the end-point.

Typical results of determinations of single ionic species at various concentrations are shown in Table 2. It is apparent that with all the species tested a comparison between the present technique and conventional controlled-potential coulometry is in favour of the former since lower concentrations of the ions can be determined.[2] This is especially true for silver and cadmium, which can be determined with acceptable error levels down to concentrations of $5 \times 10^{-5}M$ and $2.5 \times 10^{-5}M$ respectively. Of course the accuracy decreases with decreasing concentration, so the uncertainty range, as given by the confidence limits, broadens.

To improve this situation, titrations were done with a four-electrode configuration (see for instance experiment 5) and gave much better results for silver, both in terms of relative error and of confidence limits. Another possible source of deviation is manifested in titration 8 (of lead) which gave the highest relative errors for high concentrations. This can be related to the fact that lead, at high current densities, produces dendritic deposits, which make it difficult for the potential of the working-indicator electrode to equilibrate rapidly. The formation of dendritic lead is enhanced if silver electrodes are used, because their smoothness is initially poorer than that of platinum. However, the accuracy obtained is similar to that of other potentiometric titrations based on the Gran linearization method.[9]

The technique proposed is particularly interesting for separate determination of ions in mixtures. Various concentration ratios have been explored in this connection.

Table 3 shows typical results obtained for a number of determinations of silver and copper present in the same solution.

The relative error in the determination of silver, the first ion titrated, is very similar, in most instances, to that obtained when silver is the only ion present. The second species to be determined deserves more attention. The overall error for a pair of ions is less than or equal to the sum of the relative errors for the various ions. When the amount of copper is calculated from the difference between the total charge passed and the theoretically "known" amount of

silver, the error is less than when it is calculated on the basis of the charge passed between the two end-points.

This points to the absence of a specific interference between the two ions and indicates that the only additional source of error is the uncertainty affecting the determination of the first ion to be titrated.

Fig. 5

Similar considerations can be applied to determinations of ions in other binary mixtures, such as silver and lead (Table 4), for which the figures obtained are quite satisfactory.

The relative proportions of the two components do not greatly affect the results (Tables 3 and 4).

Figure 5 shows that successive determination of more than two metals is a possibility; in particular the system Ag$^+$–Cu^{2+}–Pb^{2+} has been tested (experimental conditions: three-electrode system; Ag working electrode; solution E; electrolysis potentials respectively +150, −200, −800 mV vs. SCE). The relative errors in the various determinations were of the same order of magnitude as those found when the same ions were determined separately.

CONCLUSIONS

During the present investigation a controlled-potential pulsed-current coulometric method has been developed. The technique, based on the potentiometric determination of the equivalence point by

means of Sörensen's linearization procedure permits reasonably short run times as it does not require the titration to be taken to completion.

The use of a linearization function permits easy statistical analysis and therefore provides a test of the accuracy of the determination. The procedure offers the advantage over constant-current coulometric titrations that it can be used for analytical separations of mixtures of metal ions which can be electrodeposited. The sensitivity and the accuracy compare favourably with those of other titration techniques.

It should be noted that the end-point can also be predetermined in conventional controlled-potential electrolysis (by using plots of log i $vs.$ time), but there are instrumental complications regarding the stirring conditions, which must be rigorously controlled; furthermore this variation of the method does not have general applicability. In contrast, the proposed technique calls for less sophisticated instrumentation and, because of the short integration times for each current pulse, makes less severe demands on the integrator performance.

FLOW ENTHALPIMETRIC DETERMINATION OF GLUCOSE, BASED ON OXIDATION BY 1,4-BENZOQUINONE AND USE OF AN IMMOBILIZED GLUCOSE OXIDASE COLUMN

Nobutoshi Kiba, Tosimitsu Tomiyasu* and Motohisa Furusawa
Department of Chemistry, Faculty of Engineering, Yamanashi University, Takeda-4, Kofu-shi 400, Japan

Summary—A flow enthalpimetric method for the determination of glucose is presented. The method is based on the reaction of glucose with 1,4-benzoquinone in the presence of immobilized glucose oxidase. D-Glucose concentrations ranging from 0.02 to 75mM can be determined. The method is applicable to the determination of glucose in soft drinks, wines, beers, jams and serum.

Enthalpimetric flow systems using immobilized enzyme reactors have been developed for the determination of glucose. Glucose oxidase (EC 1.1.3.4)[1-6] and hexokinase[6,7] were the enzymes immobilized in the reactors. Co-immobilization of glucose oxidase and catalase[8,9] resulted in an increase in sensitivity and an extension of the linear range of the calibration curve. Glucose oxidase is highly specific for glucose. However, the enzyme can react very rapidly with a variety of acceptors. Oxygen, which is the natural enzyme acceptor, can be replaced by benzoquinone.[10] Williams *et al.*[11] and Gorton *et al.*[12] proposed the use of benzoquinone as the enzyme acceptor in an electrochemical assay of glucose. This paper describes the adaption of the reaction to a flow enthalpimetric system for determination of glucose. The method has a wide linear concentration range (0.02–75mM) which would not be possible with oxygen as acceptor in the co-immobilized enzyme system.

EXPERIMENTAL

Reagents

Glucose oxidase (from amagasakienese, 110 units/mg, Nagase Seikagaku Co., Tokyo, Japan) (70 mg) was immobilized on 1 g of the aminoaryl derivative of controlled-pore glass beads (120–200 mesh, pore diameter 55 nm, Electro-Nucleonics, Fairfield, U.S.A.) by diazotization.[13] A 0.1M buffer solution (KH₂PO₄/Na₂HPO₄, pH 6.0) was used. 1,4-Benzoquinone (Tokyo Kasei, Tokyo, Japan) was recrystallized twice from cyclohexane and dried in a vacuum for 3 hr. The quinone was further purified with a high-speed zone refiner.[14] The activity of the immobilized enzyme was reduced by adhesion of some black compounds present in the crude benzoquinone. Up to 6 g could be purified in a

day. The quinone solution was prepared in the buffer. The stock solution of D-glucose (Merck) (1.0M) was also prepared in the buffer. The solution was allowed to come to anomeric equilibrium (β-D-glucose 63.5%)[15] at room temperature. Calibration standards were made by dilution of the stock glucose solution with the buffered quinone solution.

Apparatus

The enthalpimeter (Japan Electron Optics Laboratory, Tokyo, Japan), piston pump and loop injector used were those employed previously.[16,17] The detection column (bed 0.8 cm diameter, 3.5 cm length) was packed with the immobilized enzyme (1 g).

Procedure

The quinone solution (45mM) was pumped at a flow-rate of 4.0 ml/min. The sample (1.0 ml) was diluted to 10 ml with 50mM quinone solution in the pH 6.0 buffer, and 2.0 ml of this solution were introduced into the flow-stream by means of the loop injector. The height of the temperature peak was measured as the maximum deflection from the base-line.
Fig. 1. Dependence of peak-height on flow-rate. A, $6.02 \times 10^{-2}M$ D-glucose; B, $2.00 \times 10^{-4}M$ D-glucose. Sample volume 2.0 ml, 45mM benzoquinone solution (pH 6.0), column temperature 30°.

*Coefficient of variation.

Four calibration curves were prepared, covering the D-glucose concentration ranges of 0–0.1, 0.1–1.0, 1.0–10 and 10–75mM.

RESULTS AND DISCUSSION

Peak-height as a function of flow-rate was studied over the range 1.0–8.0 ml/min. As shown in Fig. 1, the reaction was complete at all flow-rates tested, since the peak-height increased linearly with flow-rates above a certain value (3 ml/min). At these higher flow-rates, the rapid passage through the reaction column narrows the peak-width. The apparent fall-off in response at flow-rates below 3 ml/min is due to heat loss from the column.[18] The influence of pH of the buffer on the peak-height and the stability of the quinone solution was studied. Two kinds of buffer solution, acetate buffer (0.1M, pH 4.0–6.0) and phosphate buffer (0.1M, pH 5.5–8.0), were used. The peak-height was independent of pH in the range 4.0–7.0. The type of buffer did not influence the peak-height (at pH 5.5 and 6.0). At pH 8, the quinone solution turned rapidly from yellow to black and a black precipitate separated out within 6 hr. The peak-height was almost independent of sample volume, provided this was larger than 2.0 ml. The linearity of the calibration curve was not influenced by the presence of dissolved oxygen in the quinone solution. Because of vaporization of quinone from the solution, the quinone solution was only stable at concentrations below 50mM. A flow-rate of 4.0 ml/min, a sample volume of 2.0 ml, a phosphate buffer of pH 6.0 and a quinone concentration of 45mM were therefore chosen.

Under these conditions a linear relationship was obtained between peak-height and D-glucose concentration in the range 0.02–75mM. The rate of analysis was 40 samples per hr. The immobilized glucose oxidase served for at least 3000 samples. Table 1 summarizes the results obtained with solutions of known concentration.

The method was applied to the determination of glucose in soft drinks, wines, beers, jams and serum. A 1-ml sample of beverage was boiled for 3 min in a 10-ml evaporation tube, then transferred to a 10-ml standard flask and made up to volume with 50mM

Table 2. Determination of glucose in some samples

Sample	D-glucose, g/100 ml	C.V., % ($n = 6$)	Certificate value, g/100 ml
Soft-drink 1	4.37	0.44	4.3
Soft-drink 2	4.34	0.68	4.3
White wine 1	0.222	1.0	0.2
White wine 2	1.29	0.41	1.2
Red wine 1	0.0536	1.7	0.05
Red wine 2	0.0869	1.5	0.07

Beer 2	0.0358	1.6	0.03
Strawberry jam	10.8*	0.1	10*
Apricot jam	9.81*	0.1	10*
Serum	0.0984	1.2	0.094–111

*g/100 g.

quinone solution in pH-6.0 buffer. Red wine was filtered through 5 g of Bio-gel P-300 (50–100 mesh) to remove colouring matter before analysis. Jam (1.0 g) was dissolved in hot water, followed by dilution to 50 ml with the buffer. Any insoluble material was filtered off and a 1.0-ml portion of the filtrate was diluted to 10 ml with the quinone solution. For the determination of glucose in serum (Boehringer Mannheim, Precinorm S), a precolumn (0.8 cm bore, 3.5 cm length, CPG beads, 200–400 mesh) was placed in the line between the injector and the enthalpimeter to remove adducts of benzo-quinone and proteins in the serum. The results (Table 2) were in agreement with the certified values.

DETERMINATION OF INDIUM AND THALLIUM BY HYDRIDE GENERATION AND ATOMIC-ABSORPTION SPECTROMETRY

Du Yan,* Zhang Yan, Guang-shen Cheng and An-mo Li

Department of Chemistry, Peking University, Peking, People's Republic of China

Summary—Hydride generation coupled with atomic-absorption spectrometry was applied to the determination of indium and thallium. The hydrides were generated in $1M$ HCl (In) and 1–$1.5M$ HCl or HNO_3 (Tl) with 1% $NaBH_4$ solution, and were flushed with argon into an electrically heated silica tube. The characteristic mass for indium and thallium were 0.13 and 0.12 μg, respectively.

Since 1972, when Braman *et al.*[1] first used sodium borohydride to generate arsine and stibine, hydride generation coupled with atomic-absorption spectrometry (HGAAS) has been widely used for the determination of trace elements in Groups IV, V and VI of the Periodic Table, such as Ge, Sn, Pb, As, Sb, Bi, Se and Te.[2-6] In 1982 Busheina and Headridge[7] extended the method to other elements and found that indium could be determined by atomic-absorption spectrometry with hydride generation from aqueous solution. These authors found that not all of the indium(III) is converted into its hydride, a black precipitate (presumed to be metallic indium) being produced on addition of sodium borohydride. The method of determination had poor sensitivity and its characteristic mass was 0.3 μg. We have repeated these experiments and found that the black precipitate produced is probably not metallic indium but a complex of indium hydride, because on addition of water it decomposes with the evolution of a gas which gives absorption signals for indium. Thallium hydride can also be generated by addition of sodium borohydride solution, but the sensitivity of the hydride-generation AAS method is very low (characteristic mass 2.9 μg). However, when other hydride-forming elements such as As, Pb, Te and In are also present, they facilitate thallium hydride formation and the characteristic mass is lowered to 0.12 μg.

EXPERIMENTAL

Apparatus

The hydride generator and quartz tube atomizer have been described previously;[8] instrumental parameters are summarized below.

Reagents

Standard indium solution. Dissolve 0.1000 g of indium metal (99.99% pure) in the minimum volume of $6M$ hydrochloric acid, add 2 drops of 30% hydrogen peroxide with gentle heating, and dilute to 100 ml with $1M$ hydrochloric acid.

Standard thallium solution. Dissolve sufficient pure thallium acetate in 100 ml of demineralized water to give a solution containing 1 mg of Tl per ml.

Sodium borohydride solution. Use 1% solution for indium and a 1% solution containing 0.15% of sodium hydroxide for thallium.

Procedure

Indium. Pipette the sample solution (100 μl) into the reaction vessel and place this in a hot water-bath (60 ± 5°). Attach the reaction vessel to the apparatus and purge with argon for 1 min at a flow-rate of 0.87 l./min. Inject 1 ml of 1% sodium borohydride solution (a black turbidity is produced). Record the absorbance at an atomization temperature of 1080 ± 20°. As soon as the recorder pen returns to the base-line inject 1–1.5 ml of water. Repeat until no further signals are observed. Calculate the total absorbance from a summation of the peak heights (Fig. 1).

Thallium. Pipette 200 μl of standard thallium solution into the hydride generator and place this in an ice-bath. Attach the generator to the apparatus and purge with argon for 1 min at a flow-rate of 0.44 l./min. Inject 2 ml of sodium borohydride solution. Record the absorption signal at an atomization temperature of 980 ± 20°.

RESULTS AND DISCUSSION

Indium

The rate of formation of indium hydride is rather

low and temperature has a great influence on it. At 60 ± 5° the absorbance is about twice that at room temperature. The acid concentration influences not only the production of indium hydride but also its complex formation. When the acid concentration is high (5M) no black precipitate is formed after injection of sodium borohydride solution, and no further signal is produced after injection of water (Table 1). The total absorbance is constant when the acid concentration is in the range 0.5–2.0M, but the first absorption signal increases with decrease in acidity. A concentration of 1M hydrochloric acid was selected. If the sample volume is increased, the absorbance is decreased (100 μl, $A = 0.470$; 200 μl, $A = 0.350$; 300 μl, $A = 0.040$); the optimum volume is 100 μl, as found by Busheina and Headridge.[7] Attempts were made to use a freezing-out technique (liquid-nitrogen cold trap and helium as purge gas) to collect all the indium hydride and obtain a single absorption signal. The experiment failed because the indium hydride was very unstable. The weight of indium giving 1% absorption is 0.13 μg. The reproducibility (RSD) of the method, based on 10 determinations, is 8.5% (6 μg of indium).

Thallium

There are no previous reports dealing with the

hydride-generation AAS determination of thallium. The present work shows that thallium hydride can be generated in hydrochloric acid or nitric acid (1–1.5M). The optimum volume range is 100–400 μl. Thallium hydride is very unstable and the absorbance obtained on generation at 0° was twice that obtained at room temperature.

Addition of elements which readily form hydrides, such as arsenic and tellurium, produced enhancement effects (Table 2).

It can be seen that tellurium has the greatest effect. Addition of 2 μg of tellurium increased the absorbance due to 5 μg of thallium by a factor of more than 10 (Table 3). The quantity of tellurium to be added depends on the amount of thallium to be determined. If an excessive amount of tellurium(IV) is added, a large quantity of elemental tellurium is produced during the reduction reaction, and the absorbance due to thallium drops.

From these results it is suggested that the addition of hydride-forming elements accelerating the formation of thallium hydride causes the production of complex hydrides. The problems involved in the determination of indium and thallium by hydride-generation AAS in the presence of foreign ions due to the formation of such complex hydrides require further investigation.

ELECTRO-DEPOSITION OF Cu AND Ag FROM SOLUTIONS OF *PPM* CONCENTRATION, FOLLOWED BY INDUCTIVELY-COUPLED PLASMA SPECTROMETRY

Roman E. Sioda*

Department of Chemistry, The University of Georgia, Athens, GA 30602, U.S.A.

Summary—An examination has been made of the kinetics of electro-deposition of copper and silver from acid solution, with special reference to the rate of chemical dissolution of the deposited metal.

Inductively-coupled plasma atomic-emission spectrometry (ICP–AES) is the most sensitive analytical technique for simultaneous determination of several metals in solution at μg/ml and ng/ml concentrations.[1,2] It also has the advantage that it is very specific, and to a high degree free from interferences. It therefore seems ideal for studies of the mechanism and rates of electro-deposition of metals from such solutions. No such study has been made so far.

Electro-deposition of metals has been studied extensively in the past.[3] Two main ranges of metal ion concentration have been used in these studies: (1) millimolar or higher, and (2) below micromolar. In the first case, the amount of deposit and hence the rate of electro-deposition could be determined gravimetrically. In the second case, radiotracers were generally used.[4] The intermediate concentration range, between micromolar and millimolar, has been studied least. The modern instrumental methods of analysis such as atomic-absorption spectrometry, fluorescence spectrometry, neutron-activation, and especially ICP–AES now make it feasible to study this range, but such investigations are still rare, and the understanding of the kinetic laws of electro-deposition is still based on the early studies using gravimetric or radiotracer analytical techniques.

The aim of the work described in this paper was to use ICP–AES to study the kinetics of the simultaneous electro-deposition of copper and silver from millimolar solutions of their salts.

EXPERIMENTAL

The electro-deposition was conducted on a platinum foil cathode with a surface area of 22 cm². The anode was a straight platinum wire. The electrolysis was done in a covered beaker containing 150 ml of test solution, stirred by a magnetic stirrer. Galvanostatic electrolysis was used, with a current of 0.4 A from a rectifier. The applied voltage was

*Present address: Institute of Industrial Chemistry, ul. Rydygiera 8, Warsaw, 01-793 Poland.

10–15 V. The compositions of the test solutions are presented in Table 1. Four of the solutions contained sodium sulphate (0.1M) as supporting electrolyte. All reagents used were of analytical purity (Baker Analyzed). At the start of the electrolysis the solution was at room temperature (25°), and during the electrolysis the temperature of the solution increased to 36–38°.

The solutions were analysed with an Applied Research Laboratories ICP-QA 137 ICP spectrometer, as previously described.[5–7]

RESULTS

As shown in Table 1 the first two experiments were conducted with solutions containing several heavy-metal salts; in the next three experiments only copper and silver salts were present besides the supporting electrolyte. Figures 1 and 2 present the kinetics of the copper and silver electro-deposition. Analysis of the plots shows the kinetics to be first-order or more complex, depending on the composition of the solutions. The highest rate of deposition of copper observed was from a solution containing sulphuric acid (Tables 1 and 2, experiment 4). The presence of nitric acid visibly slows down the rate of electro-deposition (experiment 5) of both copper and silver, but in this experiment copper was deposited slower at the beginning and towards the end of the electrolysis (Fig. 1). The mid increase in the rate of electro-deposition is most probably due to the increase of pH during the electrolysis, from reduction of the nitric acid to ammonia. After 4.5 hr of electrolysis the pH in experiment 5 had increased to 9.6 from the initial value of 2.2, and the solution contained ammonia.

Experiment 6 was different from the others in that the solution did not initially contain heavy metal cations, and a copper foil with surface area 12.5 cm² was used as the cathode. After 5 hr of electrolysis at a current of 0.4 A (solution composition as for experiment 5, but without added AgNO₃ and CuSO₄)

Table 1. The solutions electrolysed

Experiment	Initial solution compositon
1	0.36M NaNO$_3$; 6.3mM Cd(NO$_3$)$_2$; 9.3mM Co(NO$_3$)$_2$; 7.2mM Cr(NO$_3$)$_3$; 6.4mM Cu(NO$_3$)$_2$; 5.2mM Fe(NO$_3$)$_3$; 11.7mM Pb(NO$_3$)$_2$; 17.9mM Zn(NO$_3$)$_2$; solution acidified to pH = 2.2 with nitric acid.
2	2.0mM AgNO$_3$; 1.8mM Hg(NO$_3$)$_2$; 5.0mM Mn(NO$_3$)$_2$; 1.8mM Ni(NO$_3$)$_2$; solution acidified to pH = 1.4 with nitric acid.
3	0.10M Na$_2$SO$_4$; 0.25mM AgNO$_3$; 0.93mM CuSO$_4$.
4	0.10M Na$_2$SO$_4$; 0.27mM AgNO$_3$; 1.00mM CuSO$_4$; solution acidified to pH = 2.0 with sulphuric acid.
5	0.10M Na$_2$SO$_4$; 0.27mM AgNO$_3$; 1.00mM CuSO$_4$; solution acidified to pH = 2.2 with nitric acid.
6	0.10M Na$_2$SO$_4$; solution acidified to pH = 3.2 with nitric acid; electrode pure copper foil.

copper was detected in the solution at a concentration of 1.75 μM (110 ng/ml), well above the limit of detection (40 ng/ml) for copper, with the Babington-type nebulizer used.

The rate of chemical dissolution of copper foil was also directly measured, under the conditions of experiment 6 but without an applied external potential, by determining the decrease in weight of the copper foil with time. The values of the rate obtained from two such determinations (for times of 60 and 90 min) were 0.8×10^{-9} and 1.4×10^{-9} mole.cm^{-2}.sec^{-1}.

DISCUSSION

Anderson and Sioda recently discussed the mechanism of electro-deposition from solutions of low
Fig. 1. Semilogarithmic plot of concentration *vs.* time for copper electro-deposition. The initial compositions of the solutions are shown in Table 1, and the symbols for experiments are: ○—1; △—3; □—4; ▲—5; ●—6.
Fig. 2. Semilogarithmic plot of concentration *vs.* time for silver electro-deposition. The initial compositions of the solutions are shown in Table 1, and the symbols for experiments are: ○—2; △—3; □—4; ▲—5. The lowest concentration point corresponds to the limit of detection (LOD).

concentrations of heavy metal cations.[8] By use of the hypothesis of Joliot,[9] the rate equation of the electro-deposition was shown to result from two simultaneous processes of deposition and dissolution. When these two rates become equal an equilibrium concentration of the metal cation in solution is reached. Some of the present results seem to indicate approach to such equilibrium concentrations, namely those from experiment 5 for copper, and experiment 4 for silver. The result of experiment 6 for copper confirms this mechanism, since despite the cathodic current protection of the copper cathode, some of the copper foil dissolved during the electrolysis. The measured concentration of copper in solution after 5 hr of electrolysis may be close to an equilibrium concentration.

Table 2. The measured rate constants of electro-deposition of copper and silver*

Experiment	Rate constants†, 10^{-3} cm/sec	
	Copper	Silver
1	2.62 ± 0.14	—
2	—	8.3
3	1.50 ± 0.09	7.71 ± 0.70
4	3.68 ± 0.16	6.88 ± 0.14
5	1.70 ± 0.05	3.34 ± 0.09

*The first-order rate constants are calculated from the slopes of the straight-line segments of the curves in Figs. 1 and 2, obtained by the least-squares method. The slopes corresponding to the semilogarithmic plots have been divided by 3600 sec/hr and the electrode surface area (cm^2) and multiplied by the solution volume (ml) and ln 10 (= 2.303).
†Mean and standard deviation.

An equation was recently derived for the equilibrium concentration of metal ion in solution after prolonged electrolysis, when an excess of deposit is present on the electrode surface.[10] Such a case is exemplified by an electrode composed of the metal which is being deposited. The equilibrium concentration, c_∞, according to the hypothetical model, is

$$c_\infty = k_2/k_1 \qquad (1)$$

where k_1 is the rate constant of deposition (in cm/sec), and k_2 is the rate of dissolution (in $mole.cm^{-2}.sec^{-1}$). Substituting into equation (1) the measured values of the equilibrium copper concentration ($1.75 \, \mu M$ from experiment 6) and the rate constant of deposition, (1.7×10^{-3} cm/sec from experiment 5) gives the rate of copper dissolution as 3.0×10^{-9} $mole.cm^{-2}.sec^{-1}$ for the conditions used, including the presence of nitric acid.

The similarity of the values found for k_2 from equation (1), 3.0×10^{-9} $mole.cm^{-2}.sec^{-1}$, and by direct measurement of the dissolution rate, 1.1×10^{-9} $mole.cm^{-2}.sec^{-1}$, may be considered to support the mathematical model leading to equation (1).

The numerical discrepancy between the two values may result, to some extent, from the exclusion of the roughness factor of the deposit in the calculation of k_1 from the measurements in the deposition experiments. The deposits formed were microcrystalline and fluffy, and their true areas probably much higher than the geometrical area of the electrode. As k_1 calculated from the measurements is inversely proportional to the electrode surface area, any increase in the true electrode surface area caused by the roughness of the deposit should decrease k_1 and, according to equation (1), also decrease the calculated k_2. Thus, the two separately measured values of the dissolution rate may actually be closer.

It is believed that similar studies to these will be helpful in elucidation of the mechanism and kinetics of electro-deposition of metals from solutions of low concentrations. Such investigations are of special value for the application of electro-deposition as a preconcentration and separation technique for trace and ultratrace analysis.

DETERMINATION OF HEROIN BY MEANS OF THE PITCH OF INDUCED CHOLESTERIC MESOPHASES

Giovanna Bertocchi

Istituto di Chimica Farmaceutica e Tossicologica, Facoltà di Farmacia, Università di Bologna, Italy

Giovanni Gottarelli

Istituto di Scienze Chimiche, Facoltà di Farmacia, Università di Bologna, Italy

Romano Prati

Istituto di Chimica Organica, Facoltà di Chimica Industriale, Università di Bologna, Italy

Summary—A method is described for the determination of chromatographic fractions of heroin and strychnine in the μg and sub-μg range by measurement of the pitch and handedness of their induced cholesteric mesophases in MBBA and Phase IV, respectively.

When a chiral "guest" substance is dissolved in a nematic liquid crystal, its molecular chirality is transferred to the bulk of the solvent, which becomes organized into a macrostructural cholesteric helix.[1-3] A cholesteric structure is characterized by its handedness and pitch.

Equal amounts of enantiomeric "guests" of equal optical purity induce helical structures with identical pitch and opposite handedness.[2] Different substances show different abilities to twist a nematic phase. The twisting power of a chiral dopant (β_M) can be defined as[4,5]

$$\beta_M = 1/pcr$$

where p is the pitch (μm), c is the mole fraction and r the enantiomeric purity of the dopant. For very dilute solutions the concentration can be expressed as the mass ratio of solute to solvent. The parameter β (μm^{-1}), together with the sign $+$ or $-$ for the P-helix or M-helix, characterizes the chiral solute in a similar way to the specific optical rotation. However, the physical origin of the two quantities is entirely different; optical rotation depends on the interaction of light with molecules, while the twisting power originates from interactions between molecules of solute and solvent.[6] In principle, the quantity β can give information in the same area as that given by the optical rotation, but of different quality owing to the difference in its origin. In particular, the passage from molecular to macrostructural chirality amplifies the molecular dissymmetry. This can be used to characterize molecules with very low optical rotation, such as compounds made chiral by isotopic substitution,[7] and to detect small amounts of chiral organic substances.[8]

In the present communication, we report determination of heroin and strychnine from the pitch of induced cholesteric mesophases.

EXPERIMENTAL

The pitch was determined by means of the Grandjean–Cano method, based on the observation of the discontinuity lines appearing when a cholesteric liquid crystal is inserted into a cell of variable thickness.[9-11] A drop of the cholesteric solution (*ca.* 2.5 mg) was placed between a planoconvex lens and a glass plate, both rubbed previously with tissue paper, the rubbing direction of the lens and plate being kept parallel.[11] The preparation was observed with a polarizing microscope and showed both the Grandjean–Cano disclinations (concentric circles, Fig. 1) and the coloured rings which are connected with the variation of the rotatory power with sample thickness.[12,13] The separation of disclination lines gives the pitch value[11] p as

$$\frac{r^2}{R} = (n - \tfrac{1}{2})\,|p| \qquad (n = 1,2,3)$$

where R is the radius of curvature of the lens and r is the radius of the Grandjean–Cano circles.

Rotation of the analyser displaces the coloured rings, owing to the rotatory power. In particular, if a clockwise rotation of the analyser displaces the circles towards increasing thickness of the sample, the rotatory power is right-handed, and so is the cholesteric helix (if the wavelength of the light used is shorter than the wavelength of the selective reflection band).[13]

The measurements were done with a Zeiss polarizing microscope and "Galileo" planoconvex lenses of radii from 20 to 40 mm.

In order to obtain the disclinations more easily, both the lens and the glass plate were treated with *N*-methylaminopropyl-triethoxysilane (MAP, Dow-Corning).[14] Pitch measurements were made at 18–20°. Temperature effects on the pitch values were negligible.

The liquid crystals used as solvent were MBBA (*p*-methoxybenzylidene-*p′*-n-butylaniline) from Riedel de Haen, and PCH [mixture of *trans*-4-alkyl (4-cyanophenyl) cyclohexanes] (nematic phase 1083) and Phase IV (mixture

Fig. 1. Grandjean–Cano disclinations in a sample of heroin dissolved in MBBA.

of azoxy compounds) from Merck. The solutions used for calibration were obtained from a standard solution of GLC-purity heroin in chloroform. Before addition of the liquid crystal, the sample was completely freed from chloroform. Once the liquid crystal was added, the solution was mechanically shaken and heated several times, to above the clearing point. A similar procedure was used for strychnine.

GLC measurements were made on a Varian Aerograph 1400, with SP 2100 glass columns and a flame-ionization detector.

TLC separation of illicit heroin was done on a silica gel plate (5 × 20 cm) with chloroform–methanol (9:1 v/v) as eluent. The spot corresponding to heroin was extracted with anhydrous chloroform and the solution evaporated to dryness; MBBA was then added and the resulting cholesteric mesophase measured directly.

RESULTS AND DISCUSSION

The twisting power of heroin is positive in both the liquid crystals studied, MBBA and PCH, and the average value of β in MBBA is $+22.0 \pm 0.5 \ \mu m^{-1}$.

Plots of $1/p$ as a function of the concentration of the dopant are given in Fig. 2. The concentration was expressed in mg of heroin/5 mg of solvent, as 5 mg of cholesteric mesophase are more than sufficient for two determinations. In MBBA the plot is linear over the concentration range from 1.4×10^{-2} down to 7.75×10^{-4} mg/5 mg, the latter value representing the lowest concentration at which reproducible values

of the pitch were obtained. At concentrations higher than 1.4×10^{-2} mg/5 mg the value of β decreases, probably because of the limited solubility of heroin. In PCH the plot is linear between 4.0×10^{-2} and 9.4×10^{-3} mg/5 mg the significance of these values being the same as for MBBA.

The calibration curve obtained for strychnine in Phase IV is also linear from 2.5×10^{-2} down to
Fig. 2. Plots of inverse of the pitch (1/p) vs. concentration of heroin in MBBA (——) and PCH (–·–·–).

3×10^{-3} mg/5 mg; the twisting power is $+8.0 \pm 0.3$ μm^{-1}.

In MBBA the minimum amount of heroin detectable is 0.38 μg, *i.e.*, at the level of gas chromatographic determination, and the $+$ sign of the cholesteric mesophase represents a further identification factor.

The technique was checked on a sample of illicit heroin after a TLC analytical separation, the quantity of heroin being determined by the liquid crystal technique. The purity obtained was in good agreement with that determined by GLC.

The general method reported earlier[3] is based on the determination of the pitch of induced cholesteric mesophases by an infrared optical rotatory dispersion technique. The present method offers the advantage of variable path-length, so that a wide range of pitch is accommodated, and requires only an inexpensive commercial microscope available in all laboratories. Coupled with standard analytical TLC it could be of practical use when more sophisticated and expensive procedures are not available.

INDIRECT DETERMINATION OF CYANIDE IN WATER BY ATOMIC-ABSORPTION SPECTROPHOTOMETRY

Xu Bo-Xing, Xu Tong-Ming and Fang Yu-Zhi

Department of Chemistry, East China Normal University, 3663 Chung Shan Road (N.), Shanghai, People's Republic of China

Summary—An indirect method for determination of trace cyanide in water by atomic-absorption spectrophotometry is described. Cyanide forms a stable complex anion with Pd in alkaline solution. This complex anion can form an ion-association complex with tetra-alkylammonium ions which can be extracted into n-butyl alcohol with an efficiency higher than 90%. The extract can be analysed directly for palladium (and hence indirectly for cyanide) by flame atomic-absorption spectrophotometry. The detection limit for cyanide by this method is 0.1 μg/ml in the n-butyl alcohol extract. Beer's law is obeyed for 0.13–9 μg of CN^- per ml of n-butyl alcohol. Several foreign ions do not interfere.

The determination of cyanide in water is important in monitoring water quality. The methods usually used for determination of trace cyanide in water include colorimetry,[1–6] potentiometry with ion-selective electrodes,[7,8] etc. The standard method is colorimetry, but it involves preseparation and use of a carcinogenic reagent (benzidine).

Considerable effort has been devoted to development of rapid and simple methods for determination of cyanide in water. Indirect determination of cyanide in water by atomic-absorption spectrophotometry (AAS) was developed several years ago.[9,10] Danchik proposed two methods, one involving formation and extraction of the cyanide ion-association complex with tris(1,10-phenanthroline) iron(II) and the other the formation and removal of a precipitate of silver cyanide. In the first method iron is determined in the extract, and in the second the excess of silver is measured.

In this paper a rapid and simple AAS method for determination of cyanide in water is proposed, based on the following principle. In alkaline solution, cyanide and palladium form a stable tetracyano-palladate(II) complex with *m*-phenoxyphenyl-methyltriethylammonium ions, extractable into n-butyl alcohol. n-Butyl alcohol has a low background absorbance in an air–acetylene flame, so palladium in the extract can be determined directly and accurately by flame AAS. The amount of Pd is related to the concentration of cyanide in the water sample. Various foreign ions do not interfere.

The method is highly sensitive and convenient, and can be used for routine determination of cyanide in water.

EXPERIMENTAL

Reagents

Palladium chloride stock solution (Pd 1 mg/ml). Prepared by dissolving palladium chloride in concentrated hydrochloric acid, almost neutralizing with sodium hydroxide and diluting to the requisite volume. Dilute 100-fold with demineralized water to give a 10 μg/ml working palladium solution.

Stock cyanide solution (100 μg/ml). Dissolve 0.125 g of potassium cyanide in water and dilute to volume in a 500-ml standard flask. Dilute 1 ml of this stock solution and 2 drops of 1*M* sodium hydroxide to volume in a 100-ml standard flask with demineralized water to obtain the working standard (1 μg/ml).

Buffer solution. Adjust 500 ml of 1*M* ammonium chloride with concentrated ammonia solution to pH 9.5 (pH-meter control).

General procedure

To a 60-ml separatory funnel add the following solutions in the order given: 1 ml of 10-μg/ml Pd^{2+} solution, 3 ml of water sample containing <9 μg of cyanide (for the blank solution used 3 ml of demineralized water), 1 ml of pH-9.5 ammonia–ammonium chloride buffer, 0.1 ml of 40% aqueous solution of *m*-phenoxyphenylmethyltriethylammonium chloride and 1 ml of n-butyl alcohol. The total volume of the aqueous solution is about 5 ml. Shake the funnel for 1 min, then let it stand for several minutes. Separate the water phase and aspirate the organic phase into the air–acetylene flame, under the following conditions:

Wavelength:	2476 Å
Pd lamp current:	15 mA
Band-pass:	3.3 Å
Air:	6.5 l./min
Acetylene:	1.2 l./min

RESULTS AND DISCUSSION

Composition of the complex anion

It is known that in alkaline solution the complex anions $Pd(CN)_4^{2-}$ and $Pd_2(CN)_6^{2-}$ may be formed.[11] To find the molar ratio of CN^- to Pd^{2+} in the complex formed under the experimental conditions, the general procedure was applied to a series of solutions with fixed cyanide concentration and in-
Fig. 1. Mole ratio between CN^- and Pd^{2+} in the CN–Pd complex (5.0 μg of CN^- taken).
Fig. 2. Effect of pH.

creasing palladium concentration. Figure 1 shows that the mole ratio was nearly 3.8, in reasonable agreement with the expected value of 4. Therefore the species extracted is presumably:

$$[Pd(CN)_4^{2-}]\,[C_6H_5OC_6H_4CH_2N(C_2H_5)_3^+]_2.$$

Effect of pH

The pH of the solution strongly affects the formation and extraction of the ion-association complex. Figure 2 shows that the degree of extraction is constant and maximal over the pH range 9.0–10.5.

Effect of amount of counter-ion

Increasing the concentration of m-phenoxyphenylmethyltriethylammonium chloride in the aqueous phase increases the absorbance of both the sample and the blank solution, but the net absorbance of the sample remains constant when the volume of 40% counter-ion reagent solution added is 0.06–0.20 ml, so a volume of 0.1 ml is recommended (Fig. 3).

Calibration graph, detection limit and precision

The calibration graph was linear from 0.13 to 9 μg of cyanide per ml of organic phase, and the detection

limit 0.10 μg of cyanide in the organic phase. The relative standard deviation for 10 determinations of 2.5 μg of cyanide was 2%.

Recovery and efficiency of extraction

Apparent recoveries of 90–110% were obtained for the determination of cyanide in five water samples spiked with 3 and 5 μg of cyanide (Table 1). Four analyses of a solution of known cyanide concentration indicated that the extraction efficiency was >90%.

DOSAGE DE DERIVES DE L'ACIDE PHENYLPROPIONIQUE

A ACTIVITE PHARMACOLOGIQUE PAR TITRAGE COULOMETRIQUE

G. KANOUTE, E. NIVAUD,* B. PAULET et P. BOUCLY

Laboratoire de Chimie Analytique et d'Electrochimie Organiques, Centre d'études pharmaceutiques,
Université de Paris-Sud, rue J. B. Clément, 92290 Chatenay-Malabry, France

Résumé—L'électrolyse à intensité constante dans un milieu eau–éthanol permet de générer à la cathode les bases fortes éthylate et hydroxyle. Les dérivés de l'acide phényl-2 propionique se réduisant uniquement par attaque du proton carboxylique peuvent être dosés par coulométrie avec indication potentiométrique ou conductimétrique de la fin d'électrolyse.

En milieu neutre dans l'éthanol, les dérivés de l'acide phényl-2 propionique: Ibuprofène, Naproxène, Pirprofène et Acide protizinique (Tableau 1) sont réductibles à une électrode de mercure ou à une électrode de platine, en une seule étape, monoélectronique.

En milieu basique, l'intensité limite des courants de diffusion diminue proportionnellement à la quantité de base forte ajoutée; elle disparaît lorsqu'un équivalent de base est introduit. La réduction de la fonction carboxylique conduit à la formation de l'anion correspondant avec départ d'un hydrogène radicalaire.[1]

Nous proposons dans ce mémoire un dosage par coulométrie à intensité imposée avec détection conductimétrique ou potentiométrique du point équivalent après génération de bases fortes *in situ*, dans un mélange éthanol–eau (4:1 v/v).

PARTIE EXPERIMENTALE

Réactifs

Solvants. L'eau bidistillée, utilisée dans la proportion de 20% v/v, permet d'obtenir la réduction du solvant à des potentiels moins négatifs, éliminant l'éventualité d'une réduction de l'électrolyte support. L'éthanol est distillé sur magnésium selon la méthode de Lund et Bjerrum.[2] Sa neutralité à la phénolphtaléine est vérifiée.

Electrolyte indifférent. Le perchlorate de lithium pour analyses est purifié par recristallisation dans l'éthanol.

Produits étudiés. Ibuprofène, Naproxène, Pirprofène et Acide protizinique sont desséchés sous vide partiel à 25–30° en présence d'anhydride phosphorique.

Appareillage et conditions opératoires (*Fig. 1*)

L'électrolyse à intensité imposé de 50 mA, est effectuée à l'aide d'un chronoampérostat Tacussel type CEAMD 6, dans 2 compartiments séparés par un pont d'agar–agar afin d'éviter la réaction des protons dûe à l'oxydation de l'eau à l'anode. Dans le compartiment cathodique contenant la solution à doser plongent une électrode de platine indi-

catrice et, soit une électrode de verre reliée à un millivoltmètre, soit une cellule conductimétrique reliée à un résistivimètre. Dans le compartiment anodique plonge une électrode de platine auxiliaire.

Un millivoltmètre Metrohm E 516 et une électrode de verre combinée à une électrode au calomel sont utilisés pour la détection potentiométrique.

Un conductimètre Tacussel type CD 7 N et une cellule conductimétrique sont utilisés pour la détection conductimétrique.

Les variations de potentiel ou de conductance sont enregistrées sur un graphispot Sefram type GRVA 5.

Les mesures sont réalisées sur des quantités voisines de 50 mg dissoutes dans 50 ml de solvant contenant du perchlorate de lithium à la concentration 0,1*M*. Les solutions sont privées d'oxygène par barbotage d'un courant d'azote pendant 10 min. La quantité d'électricité nécessaire à la transformation totale d'une prise d'essai *p* (mg) de substance, de poids moleculaire *M*, étant égale au produit du temps *t* (sec) par l'intensité *A* (mA), la quantité obtenue (%) est donnée par 100 $AtM/96487p$.

Tableau 1

Fig. 1. Schéma de montage.

PRINCIPE

La méthode coulométrique mise en oeuvre consiste à imposer dans un circuit d'électrolyse dont les compartiments anodique et cathodique sont séparés, une intensité maintenue constante à l'aide d'un montage intensitostatique. Lorsque le bilan de toutes les réactions chimiques ou électrochimiques possibles aboutit à la transformation d'un seul composé, il existe selon la loi de Faraday, la relation:

$$Q = mnF/M$$

où m = masse d'un produit de poids moléculaire M, n = nombre d'électrons échangés par molécule, F = faraday.

Pour pouvoir utiliser cette relation à des fins analytiques quantitatives il est obligatoire de mesurer avec précision, en fonction du courant imposé, le temps nécessaire pour atteindre le terme de la réaction.

Les différentes réactions électrochimiques susceptibles d'intervenir à une électrode de platine correspondent à la réduction des molécules d'eau, des molécules d'éthanol et des molécules d'acides phénylpropioniques:

$$H_2O + e^- \rightarrow OH^- + H\cdot$$
$$C_2H_5OH + e^- \rightarrow C_2H_5O^- + H\cdot$$

$$\underset{\text{Ar—CH—COOH}}{\overset{CH_3}{|}} + e^- \rightarrow \underset{\text{Ar—CH—COO}^-}{\overset{CH_3}{|}} + H\cdot$$
La réduction électrochimique des molécules d'eau et d'éthanol aboutit dans ce mélange de solvant à la formation de bases fortes, ions hydroxyle et éthylate, que réagissent chimiquement avec les acides en solution selon les réactions:

$$\underset{\text{Ar—CH—COOH}}{\overset{CH_3}{|}} + OH^-$$
$$\rightarrow \underset{\text{Ar—CH —COO}^-}{\overset{CH_3}{|}} + H_2O$$

$$\underset{\text{Ar—CH —COOH}}{\overset{CH_3}{|}} + C_2H_5O^-$$
$$\rightarrow \underset{\text{Ar—CH —COO}^-}{\overset{CH_3}{|}} + C_2H_5OH$$
Le bilan global réactions chimiques et électrochimiques fait ressortir la consommation d'un faraday par molécule transformée, la totalité du courant étant utilisée à cette fin.

Détection du point équivalent

Deux méthodes sont proposées afin de détecter le temps nécessaire pour atteindre le point équivalent: une méthode conductimétrique et une méthode potentiométrique.

Détection conductimétrique. La technique consiste à mesurer l'impédance de la solution entre deux plaques de platine platiné entre lesquelles est imposé un courant alternatif de fréquence convenablement choisie. Par étalonnage, l'impédance est reliée à la conductance de la solution; la conductance (Λ) est elle-même reliée à la concentration selon la relation:

$$\Lambda = K \Sigma\, l_i z_i c_i$$

où K = constante de cellule, l_i = conductivité équivalente de l'ion i en solution, z_i = charge de l'ion i, et c_i = concentration de l'ion i.

Au cours du titrage, avant le point d'équivalence, il y a formation d'ions phénylpropionate, et après le point équivalent formation d'ions hydroxyle et éthylate. La conductivité équivalente limite des ions hydroxyle étant nettement supérieure à celle des autres ions, la pente de la droite $\Lambda = f(t)$ est considérablement modifiée. La courbe représentée (Fig. 2) présente une nette cassure au point équivalent.

Détection potentiométrique. Le point équivalent peut être également détecté en suivant l'evolution du pH de la solution au cours du titrage. Dans le compartiment cathodique de la cellule d'électrolyse la différence de potentiel entre une électrode de verre et une électrode de référence au calomel est mesurée. Avant le point équivalent, le système tampon acide phénylpropionique–phénylpropionate impose le pH, après ce point les bases fortes électrogénérées, éthylate et hydroxyle sont à l'origine d'une brusque variation de pH.

RESULTATS ET DISCUSSION

Pour les quatre dérivés, les résultats présentés (Tableau 2) correspondent à une détection potentiométrique. Afin de déterminer la précision de la
Fig. 2. Courbe conductimétrique de l'Ibuprofène.

méthode nous avons réalisé cinq mesures par échantillon. Les moyennes, les écart-types et la dispersion des résultats expérimentaux sont rassemblés (Tableau 3).

La détection conductimétrique est appliquée à l'Ibuprofène (Tableau 4); la comparaison des moyennes montre que les résultats ne sont pas significativement différents.

La méthode développée ici peut être appliquée à tous les dérivés possédant un hydrogène acide dont la réduction électrochimique conduit uniquement à la forme anionique; elle ne s'applique pas aux dérivés de l'acide phénylpropionique qui, possédant une fonction cétone (Kétoprofène) conduisent à la forme alcool par fixation de deux électrons.[3] Ce dernier composé peut être dosé en voltampérométrie classique.[4]

	51	479,0	100,4
	51	476,6	99,9
	51	478,0	100,2
	51	475,3	99,6

Conclusion

L'électrolyse à intensité constante permet de générer in situ le réactif titrant; il en résulte un gain de temps et une reproductibilité qui confèrent à cette méthode des possibilités d'automatisation.

Ces avantages la désignent par conséquent comme une méthode de choix dans le contrôle analytique de certaines matières premières pharmaceutiques. Appliquée aux dérivés de l'acide phénylpropionique ne possédant pas de fonction carbonylée elle donne, quelle que soit la détection, une dispersion des résultats inférieure à 0,5%.

Summary—Generation of ethoxide and hydroxide ions in aqueous ethanolic medium by controlled-current electrolysis is suggested for coulometric titration of 2-phenylpropionic acid derivatives. The electroreduction of the carboxylic hydrogen atom leads to the anion by elimination of a hydrogen radical. Potentiometric or conductimetric methods can be used for detection of the end-point.

DETERMINATION BY HPLC OF TRIFLUOROACETATE LEVELS IN PLASMA AND URINE OF PATIENTS ANAESTHETIZED WITH HALOTHANE

Summary—A new method is described for determination of trifluoroacetic acid (TFA) in biological fluids. Optimum extraction is achieved by addition of 18-crown-6 ether and acidification of the sample. The 4-bromomethyl-7-methoxycoumarin derivatives of the carboxylic acid are prepared and a sample is subjected to HPLC. A linear analytical curve of peak area against TFA concentrations ranging between 0.2 and 20 μg/ml is obtained, and the minimum detectable concentration is estimated to be 0.1 μg/ml.

Halothane (2-bromo-2-chloro-1,1,1-trifluoroethane) is an important volatile anaesthetic currently used at concentrations ranging from 0.5 to 3% v/v. The previous publications on the determination of one of its metabolites, trifluoroacetic acid (TFA), deal with gas chromatographic methods.[1-4] We attempted direct measurement of TFA levels in biological samples by the head-space method, because of the high volatility of TFA, but without success. The usual methods of derivative formation to lower the volatility, and hence reduce losses, were then applied. The main problem is the high solubility of TFA in aqueous media, which makes its extraction from biological fluids difficult. Most of the derivatives used cannot be made in aqueous media and therefore attempts were made to dehydrate biological samples by lyophilization or drying with sodium sulphate, followed by derivative formation by esterification or reaction with alkylating agents. Methylation with methanol–boron trifluoride mixture and methyl sulphate, followed by esterification with trichloroethanol (TCE) was tried, by analogy with the determination of trichloroacetic acid.[5] However, even with use of the head-space method, no peak was observed which could be assigned to the ester. Attempts were made to prepare this ester from pure TFA, its anhydride and TCE, but it could not be detected with sufficient sensitivity by gas chromatography. Alkylation with pentafluorobenzyl bromide and tetrabutylammonium hydrogen sulphate in methylene chloride[6] was also unsuccessful. Gas chromatographic methods were therefore abandoned and it was decided to apply HPLC to the determination of TFA in biological samples.

The purpose of this study was to determine TFA in the plasma and urine of patients anaesthetized with halothane, by HPLC of the 4-bromomethyl-7-methoxycoumarin derivative.

EXPERIMENTAL

Apparatus

The chromatography system consisted of a Varian model 5000 equipped with a Vari-chrom ultraviolet detector set at 320 nm, and a Varian Fluorichrom fluorescence detector. A 330 I excitation filter and a 3-74 emission filter with a wavelength cut-off at 385 nm were selected because of the fluorescence characteristics of the 4-bromomethyl-7-methoxycoumarin ester of TFA. The column (300 mm × 6 mm bore) was packed with RP 18 phase (10 μm).

Reagents

The HPLC solvents were Merck methanol and ultrapure water. Fluka 4-bromomethyl-7-methoxycoumarin, "Pestipur" acetone and Merck 18-crown-6 ether were used.

Chromatographic conditions

The mobile phase was a 60:40 v/v mixture of methanol and water, used at a flow-rate of 1 ml/min under isocratic conditions. The solvents were filtered and degassed before use. The temperature was 20° and the pressure 80 bar. The volume injected was 50 μl and the detector sensitivities were set at 0.05 absorbance units for ultraviolet detection and 10 units for fluorescence detection, for full-scale deflection.

RESULTS AND DISCUSSION

The 4-bromomethyl-7-methoxycoumarin ester of TFA was prepared according to the general procedure of Dünges[7] and its retention time (4.1 min) determined.

In order to extract the maximum amount of trifluoroacetate from the plasma and urine of patients anaesthetized with halothane, 250 μl of a 0.007M solution of 18-crown-6 ether in acetonitrile are added to the sample (0.5 ml). The proteins are precipitated but the trifluoroacetate is expected to remain in solution, as an ion-pair with the crown-ether com-

plexes of the sodium and potassium ions present. Acidification with 100 μl of 5M hydrochloric acid then leads to formation of undissociated trifluoroacetic acid. Addition of 10 ml of dry acetone results in a single liquid phase which can be recovered by centrifugation (10 min at 2000 rpm) and contains only the molecular form CF_3CO_2H (because of solvation phenomena and the low dielectric constant). The general procedure for making the 4-bromomethyl-7-methoxycoumarin derivative of a carboxylic acid is then applied (treatment with 500 μl of a 0.004M acetone solution of the reagent and 2 mg of potassium carbonate for 30 min in a tube protected from light by being wrapped in aluminium foil). The resulting solution is evaporated, the residue dissolved in the solvent system and a sample chromatographed. A representative chromatogram is shown in Fig. 1a. In order to check that no interference is caused by other components of the plasma and urine, a blank test is performed with samples obtained just before the anaesthesia. A typical chromatogram is shown in Fig. 1b.

The optimal conditions for ultraviolet and fluorescence detection are achieved with the solvent system methanol–water (60:40 v/v). There is no interference and the elution times are 4.1 min for the coumarin ester and about 10 min for the
Fig. 2. Ultraviolet absorption spectra in methanol, of a, 4-bromomethyl-7-methoxycoumarin; b, its trifluoroacetate ester.

reaction by-products. The ultraviolet absorption spectra of methanolic solutions of 4-bromomethyl-7-methoxycoumarin and its trifluoroacetate ester are shown in Fig. 2. The wavelength used for ultraviolet detection (320 nm) is that at which the absorbance due to the coumarin ester is maximal in the solvent system used.

The area under the chromatographic peak is a linear function of the TFA concentration over the range 0.2–20 μg/ml. The precision is good, as shown by the regression coefficient of 0.997. Moreover the slope (4.17 mm^2.ml.μg^{-1}) shows the sensitivity is good, the minimum detectable concentration being 0.1 μg/ml. The reproducibility is also good. This method is therefore appropriate for the determination of the pharmacokinetic parameters of halothane.

APPLICATION OF MATRIX-MODIFICATION IN DETERMINATION OF THALLIUM IN WASTE WATER BY GRAPHITE-FURNACE ATOMIC-ABSORPTION SPECTROMETRY

SHAN XIAO-QUAN*, NI ZHE-MING and ZHANG LI

Institute of Environmental Chemistry, Academia Sinica, P.O. Box 934, Beijing, People's Republic of China

Summary—A method has been developed for the determination of thallium in waste water at the ng/ml level by graphite-furnace atomic-absorption spectrometry. If microgram amounts of palladium or platinum are used as a matrix modifier, the ashing temperature for thallium can be raised to 1000°, and the interference of halides and mineral acids is greatly reduced. The relative standard deviation found was 2% (9 replicate determinations) at the 8-ng/ml thallium level, and the detection limit 1 ng/ml.

Severe interference effects are encountered in the determination of thallium by graphite-furnace atomic-absorption spectrometry in the presence of halide, because the atomization temperature for thallium is lower than that required to remove halide in the ashing step, so large concentrations of halide are present in the vapour phase during the atomization step, and produce interference. Fuller[1] found that the absorbance for a 0.5-μg/ml thallium solution in a Perkin-Elmer HGA-70 was seriously suppressed by 0.01% v/v levels of hydrochloric acid and perchloric acid but there was negligible interference by a mixture of nitric acid and sulphuric acid. He also reported that as little as 0.2 μg of sodium chloride completely suppressed the thallium absorbance and that the presence of sulphuric acid could reduce this interference.

Many efforts have been made to reduce or eliminate the interference effects in thallium determination. Manning et al. used a tungsten wire[2] and the L'vov platform[3] at constant temperature for the determination of thallium in the presence of halide. With the platform, no interference was found with concentrations of less than 0.01% MgCl₂ and 0.05% NaCl, whereas much smaller amounts of halide interfered with atomization at the graphite tube wall. Kujirai et al.[4] described a method for the determination of thallium in nickel and cobalt alloys. It was found that tartaric acid and sulphuric acid permitted a higher ashing temperature of 600°. They therefore dissolved the alloys with hydrofluoric acid, sulphuric acid and hydrogen peroxide and used matrix-matched standards. However, the determination of thallium in complex matrices is still a difficult task, and it seems that a separation or preconcentration procedure is indispensable. The solvent extraction of thallium with diethyldithiocarbamate,[5] Brilliant Green,[6] and hydrogen bromide[7] has been reported and applied for the separation of thallium in geological samples. There

are also a few reports on the separation and preconcentration of thallium by a volatilization technique[8] or by adsorption on an activated carbon filter after complexation of the thallium with *O,O*-diethyl dithiophosphate.[9]

The present study describes the application of palladium or platinum in microgram amounts as a matrix-modifier for the direct determination of thallium at ng/ml levels in waste water. In the presence of palladium or platinum the ashing temperature for thallium can be raised to 1000° to decompose halides and thus minimize the interference effects and allow the direct determination of thallium, down to 1-ng/ml.

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 4000 atomic-absorption spectrometer fitted with a model HGA-400 graphite furnace and a Hitachi model 056 chart-recorder was used for the measurement of thallium absorbance at the 276.8-nm resonance line under "argon stop" conditions. A thallium hollow-cathode lamp was used, operated at 10 mA. The band-width was set at 0.7 nm. A deuterium background corrector was employed throughout. A 20-μl Eppendorf pipette with disposable polypropylene tips was used to introduce sample solution into the graphite tube.

Reagents

Standard thallium solution, 1000 μg/ml, was prepared by dissolving 0.1147 g of thallium carbonate (analytical-reagent grade) in 10 ml of nitric acid (1 + 1) and diluting to volume in a 100-ml standard flask with demineralized water. Working thallium standards were prepared from this stock solution by serial dilution with demineralized water. The palladium and platinum solutions were prepared from palladium chloride and platinum chloride (analytical-reagent grade).

Procedure

All waste water samples were stored in polyethylene bottles and refrigerated at 4°. Equal volumes (20 μl) of waste water and 150-μg/ml aqueous palladium solution were introduced into the graphite furnace. The temperature program was drying at 110° for 30 sec, ashing at 1000° for

30 sec, atomizing at 1800° for 5 sec and cleaning at 2600° for 5 sec. The internal argon flow was interrupted during atomization. The concentration of thallium was determined in the waste water by the standard addition method. Waste water samples containing higher amounts of thallium were diluted further with demineralized water. A wet digestion procedure was used for some samples containing higher levels of organic compounds which interfere with the determination of thallium, even with matrix modification. In this, 20 ml of waste water, in a 50-ml beaker, were evaporated to small volume by heating on a hot-plate, then treated with 0.5 ml of concentrated nitric acid and reheated until the yellow colour disappeared, then cooled to room temperature and diluted with 0.01M nitric acid before thallium was determined by the recommended procedure.

RESULTS AND DISCUSSION

Stabilizing effects of palladium and platinum

Thallium is one of the relatively volatile elements, so a certain loss may occur during the preatomization steps, and the loss during ashing will increase with temperature and time. A search for suitable matrix modifiers was made and it was found that in the presence of palladium or platinum, the critical ashing temperature for thallium can be raised to 1000°. The results are schematically shown in Fig. 1. Palladium not only raises the critical ashing temperature more than platinum does, but also increases the sensitivity for thallium, and was therefore used in the remainder of this study.

The stabilizing effect of palladium depends on its concentration (Fig. 2). Because palladium can also stabilize mercury,[10] tellurium,[11] lead[12] and arsenic,[13] some competing reactions may occur if these elements are also present in the heated graphite tube, and a certain amount of palladium will be consumed in stabilizing these elements, so a volume of 20 μl of 150-μg/ml aqueous palladium solution was used for sample analysis (but any concentration in the range 100–200 μg/ml will do).

Effect of halides and recovery of thallium

The interference of halides in the thallium determination was studied with and without palladium present. The absorbance data were referred to the values obtained for a pure solution, and are summarized in Table 1. No interference was observed for the determination of thallium (at the 50-ng/ml level) from concentrations of 4 mg/ml for NaCl, 1 mg/ml for $MgCl_2$ or KI, 2 mg/ml for $CaCl_2$, 0.4 mg/ml for

Na_2SO_4, and 0.05% v/v HCl, 0.01% v/v $HClO_4$ and 8% v/v HNO_3 when palladium was used as matrix modifier, but the tolerance level was much lower in the absence of palladium. In contrast to the suppression effect of sodium chloride reported in the literature, a certain enhancement was observed if palladium was used as matrix modifier.

If waste water was introduced into the heated graphite furnace without matrix modification no thallium could be detected, even with a standard thallium solution also directly injected. However, direct determination of thallium in waste water is practicable and recovery quantitative if palladium is added. As can be seen from Table 2, the recovery was found to be 92–105%.

Determination of thallium in waste water

Although no serious interferences were observed and quantitative recovery was obtained when matrix modification was used, the standard-addition method is recommended for the analysis of waste water samples to prevent unpredictable interferences arising from the extreme complexity of industrial effluents.

The relative standard deviation was found to be 2% for 9 replicate determinations for a waste water with a thallium concentration of 8 ng/ml. The detection limit was found to be 1 ng/ml (three times the standard deviation for the blank) if a volume of 20 μl was injected.

ANALYTICAL DATA

PALLADIUM COMPLEXES WITH TRIETHYLENETETRAMINEHEXA-ACETIC ACID

ALDO NAPOLI

Dipartimento di Chimica, Università "La Sapienza", 00100 Roma, Italy

Summary—The formation of complexes between palladium(II) and triethylenetetraminehexa-acetic acid (TTHA, H_6L) was studied by measuring the hydrogen-ion concentration with a glass electrode; 1:1 and 2:1 metal to ligand complexes with different degrees of protonation were observed and the corresponding equilibrium constants evaluated.

Triethylenetetraminehexa-acetic acid (TTHA, abbreviated as H_6L) is an aminopolycarboxylic acid extensively employed for analytical purposes. It has been used for complexometric titrations utilizing metallochromic indicators[1] or ion-selective electrodes,[2,3] in the spectrophotometric[4-6] and spectrofluorimetric[7] determination of some metal ions, and in amperometric titrations.[8-11]

This complexing agent has ten donor atoms, and therefore easily forms polynuclear species with several metal ions. Also, the metal complexes can be protonated at low pH to form polyprotonated species.

Metal complexes with TTHA have been studied extensively, but no information has been reported on the palladium complex. Therefore, a potentiometric investigation was made at 25° (0.50M sodium perchlorate medium), to identify the various complex species formed in aqueous solution and evaluate the stability constants.

EXPERIMENTAL

The TTHA was obtained from Sigma Chemicals and used as received. The purity was checked by potentiometric titration with sodium hydroxide. The equivalent weight was determined by titration of the ligand in the presence of excess of copper(II) as described by Bohigian and Martell.[12]

Palladium perchlorate was prepared from palladium chloride (Carlo Erba), by addition of the stoichiometric amount of silver perchlorate.

The ionic strength was adjusted to 0.50M with sodium perchlorate.

Potentiometric measurements were made at $25.0 \pm 0.1°$ with glass and reference electrodes immersed in the test solution. The reference electrode was similar to that described by Forsling *et al.*[13]

Ag, AgCl | NaCl, 0.01M; NaClO₄, 0.49M | NaClO₄, 0.50M

The Ag/AgCl electrode was prepared according to Brown[14] and the glass electrode was a Radiometer type G202B, calibrated in concentration units.

In a medium of constant ionic strength, activities can be replaced by concentrations,[15] so the potential of the cell can be expressed, in mV, as:

$$E = E° + 59.16 \log[H^+] + E_j$$

where E_j is the junction potential ($-100[H^+]$ mV under our experimental conditions) and $E°$ is a constant determined (in the absence of the ligand) before and after each set of measurements. During the potentiometric titrations a stream of purified nitrogen was used to mix the solutions and to remove carbon dioxide.

RESULTS

Potentiometric titrations, with sodium hydroxide, of the ligand alone and when mixed with palladium in molar ratios 1:1 and 1:2 are shown in Fig. 1.

For an equimolar mixture of Pd(II) and TTHA, two inflection points are evident, corresponding to 5 and 6 equivalents of sodium hydroxide respectively. These correspond to the reactions:

$$Pd^{2+} + H_6L + 5OH^- \rightleftharpoons PdHL^{3-} + 5H_2O$$

$$PdHL^{3-} + OH^- \rightleftharpoons PdL^{4-} + H_2O.$$
In addition, beyond the formation of the monoprotonated species, in the first buffer region (up to 5 equivalents of base per mole of ligand), polyprotonated complexes, PdH_qL, may also be formed.

For the 2:1 Pd:L mixture a marked lowering of the $-\log[H^+]$ values is observed and only one inflection point is seen; this corresponds to the equation:

$$2Pd^{2+} + H_6L + 6OH^- \rightleftharpoons Pd_2L^{2-} + 6H_2O.$$
Again, protonated complexes can be formed in acidic medium.

The stability constant for the 1:1 complex and that for the 1:2 complex were initially calculated from the titration data for the mixture of corresponding molar composition. As pointed out by Harju,[16] however, binuclear complexes may be present even in equi-
Fig. 1. Potentiometric titration curves of TTHA alone (curve A) and in the presence of palladium perchlorate in molar ratio of 1:1 (curve B) and 1:2 (curve C). $C_L = 2 \times 10^{-3}M$; a = moles of sodium hydroxide added per mole of ligand.

Table 1. Equilibrium constants for the palladium(II)–TTHA complexes

Equilibrium	$\log K$
$Pd^{2+} + L^{6-} \rightleftharpoons PdL^{4-}$	18.73
$PdL^{4-} + H^+ \rightleftharpoons PdHL^{3-}$	6.92
$PdHL^{3-} + H^+ \rightleftharpoons PdH_2L^{2-}$	2.90
$PdH_2L^{2-} + H^+ \rightleftharpoons PdH_3L^-$	2.50
$PdH_3L^- + H^+ \rightleftharpoons PdH_4L$	2.45
$2Pd^{2+} + L^{6-} \rightleftharpoons Pd_2L^{2-}$	27.50
$Pd_2L^{2-} + H^+ \rightleftharpoons Pd_2HL^-$	3.20
$Pd_2HL^- + H^+ \rightleftharpoons Pd_2H_2L$	2.0*

Probable errors in $\log K$ units: ± 0.05 (* ± 0.1).

relationship:

$$a_{exp} = (6C_L - [H^+] + [OH^-] - \Sigma i[H_iL^{(6-i)-}]$$
$$- \Sigma i\,[PdH_iL^{(4-i)-}] - \Sigma i\,[Pd_2H_iL^{(2-i)-}])/C_L$$

where C_L represents the analytical concentration of the ligand and $[OH^-] = K_w/[H^+]$ ($pK_w = 13.73$ under our experimental conditions[19]).

Also a value of σ was calculated:

$$\sigma = \sqrt{(\Delta a)^2/(n_e - n_k)}$$

where n_e is the number of experimental points and n_k the number of constants. From the σ value ($= 0.11$ in our case) the deviation between experimental and calculated points can be evaluated.

The equilibrium constants found are collected in Table 1.

molar solutions, so the values thus calculated are likely to be incorrect.

Therefore, from the analysis of the single curves, approximate values for the formation constants were derived, and successively refined by considering the simultaneous presence of all the species found. The approximate values were obtained by the procedure of Bohigian and Martell[12] by using the protonation constants of the ligand determined in the same experimental conditions:[17]

$$\log K_1 = 9.73 \quad \log K_2 = 8.76 \quad \log K_3 = 5.92$$

$$\log K_4 = 3.94 \quad \log K_5 = 2.75 \quad \log K_6 = 2.30.$$

The first values for the formation constants of the complexes were used to calculate titration curves, which were compared with the experimental curves. The value

$$(\Delta a)^2 = (a_{calc} - a_{exp})^2$$

was computed for each experimental point (a represents the degree of neutralization) and the values of the constants were varied until the sum of $(\Delta a)^2$ was minimized.

The concentrations of the various species in solution were calculated by the computer program DISDI,[18] and the value of a_{exp} was obtained from the

ANNOTATIONS

POLAROGRAPHIC STUDY OF SIMPLE AND MIXED-LIGAND COMPLEX FORMATION

P. H. Tedesco and J. Martinez

Facultad de Ciencias Exactas de la Universidad Nacional de La Plata, 1900—La Plata, Argentina

Summary—Theoretical, experimental and statistical aspects of the polarographic method applied to simple and mixed-ligand complex formation have been studied. Some misunderstandings and erroneous interpretations have been clarified according to experimental results obtained with several systems. A criterion for establishing the number of complex species present in a simple system is proposed. For the first time the polarographic method has been applied to a mixed-ligand complex system where fourteen species co-exist.

There are numerous applications of the polarographic method for the study of complex formation. Simple complex formation is studied principally by the DeFord and Hume method[1] and the Ringbom and Erickson method[2] (which extends the treatment to the study of complexes irreversibly reduced at the dropping mercury electrode). Mixed-ligand complex formation was first studied by Schaap and McMasters[3] and pursued by others.[4–7] Nevertheless, several points remain obscure and others require definitive correction, because misunderstandings and erroneous interpretations have been made.

In this paper we deal with the experimental, theoretical and statistical aspects of the polarographic method, based on results obtained with the simple systems copper–acetate, copper–propionate, cadmium–acetate, cadmium–propionate,[8,9] cadmium–formate, cadmium–iodide and cadmium–bromide, and with the mixed-ligand system cadmium–bromide–iodide.

EXPERIMENTAL

Polarograms were obtained with a manual Sargent polarograph model III and a precision Leeds & Northrup potentiometer at a temperature of $25 \pm 0.1°$, controlled by a Lauda thermostat. Solutions at pH 5.0 with metal-ion concentration of $10^{-3}M$ and increasing ligand concentrations up to $1.5M$ were used in an H-type cell. The system cadmium–bromide–iodide was studied in a cell consisting of a tube, containing the dropping mercury electrode (DME) and the sample solution, connected to the reference SCE through a porous ceramic plug covered by two drops of agar gel, as indicated in Fig. 1. In the SCE sodium chloride was used instead of potassium chloride to prevent precipitation in the perchlorate medium. This cell worked quite well for many days, which was confirmed by the fact that the reference electrode maintained its potential within 0.2 mV (before any change was noticed the agar gel was renewed

and the SCE potential checked). All measurements were made at ionic strength 2.0 (sodium perchlorate). The half-wave potentials were reproducible within 0.8 mV.

RESULTS AND DISCUSSION

Formation of simple complexes

The DeFord and Hume treatment of formation of simple complexes[1] allows calculation of overall stability constants through the relationships:

$$F_0 = \text{antilog}\left(\frac{0.435\,nF}{RT}\Delta E_{1/2} + \log\frac{I_s}{I_c}\right)$$

$$= 1 + \beta_1[X] + \beta_2[X]^2 + \ldots$$

$$F_1 = \frac{F_0 - 1}{[X]} = \beta_1 + \beta_2[X] + \beta_3[X]^2 + \ldots$$

$$F_N = \frac{F_{N-1} - \beta_{N-1}}{[X]} = \beta_N + \beta_{N+1}[X]$$

*Constants calculated from experimental results published by Piljac et al.[11]

where [X] is the free ligand concentration, n, F, R and T have the same meaning as in the Nernst equation, $\Delta E_{1/2}$ is the difference in the half-wave potential when [X] = 0 and when [X] ≠ 0, I_s and I_c are the corresponding diffusion current constants and the β values are the stoichiometric overall stability constants at constant ionic strength. The stability constants can be calculated graphically by plotting the F_N functions vs. ligand concentration or numerically by a least-squares treatment. We have used the weighted $1/F_0^2$ method proposed by Momoki.[10]

The question of the number of species present in the solution cannot be answered independently by the graphical or the numerical methods. Piljac et al.[11] have proposed calculating the constants numerically, with a previous graphical derivation of the number of complexes in solution. Nevertheless it has to be pointed out that this derivation is not always unequivocal, especially when three or more species are present. As we have stated before,[9] F_2 (in the case of three or more complexes) frequently shows uncertain values at low ligand concentrations, because it results from the quotient $[(F_0 - 1/[X]) - \beta_1]/[X]$ and the plotting of the curve is not always precise. This can be seen in Fig. 2 for the cadmium–formate system: if the points at low ligand concentrations are dismissed, F_2 can be considered a straight line; otherwise a curve can be plotted, with no constant slope, and in that case the function F_3 is nearly a straight line and a set of four constants is calculated. For the cadmium–acetate and cadmium–propionate systems the same situation occurs and three or four constants can be derived graphically.[9]
Piljac has proposed that the calculated stability constants have to meet the following conditions: (a) all must be positive, (b) the standard error of any constant must be lower than the constant itself, (c) β_1 obtained by the graphical method must agree with the numerically obtained constant, within the standard error of this method. We think that these conditions are necessary but not sufficient and that the definitive criterion is that the correct set of stability constants is that for which reasonable agreement for all the constants is obtained by both methods. Table 1 gives results obtained under the same conditions (ionic strength 2.0, perchlorate medium) for several systems. Calculations are made by the graphical and the numerical Momoki method. It can be seen that the Piljac conditions are generally but not always applicable.

It is possible to predict, according to Filipović et al.[12] three complexes for systems 3, 4 and 5 and two complexes for system 9, but for systems 1, 2, 6 and 10, two sets, with different numbers of constants, can equally well be predicted. In these cases, the agreement between the values of the constants obtained by the two methods suggests three complexes for systems 1, 2 and 6 and two complexes for system 10. This criterion is supported by the fact that when the graphical method offers no doubt about the number of complexes, the numerical method gives values of the constants in very good agreement with the graphical method.

Figures 3–6 illustrate the graphical treatment of the simple systems cadmium–bromide and cadmium–iodide. It can be seen that four complexes are formed in each case, that F_2 cannot be taken as a straight line, and that the plot of F_3 vs. [X] is an unequivocal straight line. Table 1 shows the excellent agreement between the stability constants obtained by the methods of calculation.

Three conclusions seem in order regarding the calculation of stability constants of simple systems from polarographic data. First, all the systems we

Fig. 2. F_2 as a function of ligand concentration for the cadmium formate system.
Fig. 3. Plots of ΔE (O) and I_d (×) vs. ligand concentration for cadmium–bromide system.
Fig. 4. Plots of F_1 (O), F_2 (●) and F_3 (×) vs. ligand concentration for cadmium–bromide system.

have studied show that the experimental half-wave potential shifts $\Delta E_{1/2}$ and the function F_0 have to be plotted vs. the ligand concentration, and values taken from the resulting smooth curve; the numerical or graphical processing of the crude polarographic data can give quite uncertain results. Secondly, the possible uncertainty of the F_N values is a consequence of the nature of the system, of the polarographic method and of the mathematical treatment, and this frequently makes useless any effort to improve the reproducibility of ΔE values to better than 0.8 mV. Thirdly, a complete graphical treatment followed by the numerical calculation seems advisable in any case, to be sure about the number of complex species and to obtain the statistical errors.

For the cadmium–bromide and cadmium–iodide systems it has been claimed[13-15] that adsorption of anions by the DME would produce "additional complexation" and the apparent stability constants obtained would be considerably higher than those from other methods. Our results for these systems agree satisfactorily with others indicated in the literature[16] and obtained by other methods (or even are lower), so we think that under our experimental
Fig. 6. Plots of F_1 (O), F_2 (●) and F_3 (×) vs. ligand concentration for cadmium–iodide system.

conditions anion adsorption—if it exists—does not produce any noticeable additional complexation and hence any noticeable change in the stability constants.

Formation of mixed-ligand complexes

Schaap and McMasters pointed out[3] that in a system in which two or more ligands are present, mixed-ligand complexes should be formed in preference to simple complexes whenever $\beta_{MXi}[X]^i \sim \beta_{MYj}[Y]^j$. We can say that even purely statistical considerations confirm this assertion.

What is more important in consideration of formation of mixed-ligand complexes is to emphasize that generally there is no polarographic signal to show it. The common interpretation[4-6] that a further shift of the half-wave potential on the addition of a second ligand to a simple system is a proof of mixed-ligand complex formation is not necessarily correct. It merely indicates additional complexing, which may be with either the original ligand or the

Fig. 5. Plots of ΔE (O) and I_d (×) vs. ligand concentration for cadmium–iodide system.
Fig. 7. Plots of ΔE vs. iodide concentration at three bromide concentrations for the mixed-ligand system.

additional ligand. The only case in which the shift in half-wave potential is a proof of formation of mixed-ligand complexes is that in which, at a given concentration of both ligands, the negative shift of the half-wave potential is larger than the shift obtained for either of the simple systems at the same metal and total ligand concentrations, but this is not the common case.

The formation of mixed-ligand complexes is unequivocally indicated by agreement of the experimental results with the equations:

$$F_{00}(X, Y) = \text{antilog}\left(\frac{0.434\,nF}{RT}\,\Delta E_{1/2} + \log\frac{I_s}{I_c}\right)$$
$$= A + B[X] + C[X]^2 + D[X]^3 + E[X]^4$$

where

$$A = \beta_{00} + \beta_{01}[Y] + \beta_{02}[Y]^2$$
$$+ \beta_{03}[Y]^3 + \beta_{04}[Y]^4$$
$$B = \beta_{10} + \beta_{11}[Y] + \beta_{12}[Y]^2 + \beta_{13}[Y]^3$$
$$C = \beta_{20} + \beta_{21}[Y] + \beta_{22}[Y]^2$$
$$D = \beta_{30} + \beta_{31}[Y]$$
$$E = \beta_{40}$$

the β_{ij} values being the overall stability constants of the system (for simple complexes i or $j = 0$).

This treatment represents an extension of the Schaap and McMasters method[3] for mixed-ligand complexes to the case in which in the single systems a maximum of four ligands attached to the central ion, as we have seen for cadmium–bromide and cadmium–iodide. This is the first time the Schaap and McMasters treatment has been applied to a system where fourteen complexes co-exist.

The values of all the stability constants in the equations above can be obtained if the half-wave potentials and diffusion currents of at least three

series of solutions are measured, each series at a constant concentration of Y (bromide in our case) and increasing concentrations of X (iodide), as indicated in Fig. 7 for $\Delta E_{1/2}$. The stability constants of the simple systems have already been determined. The constants B, C and D can be obtained from a least-squares treatment of the functions:

$$F_{10} = \frac{F_{00} - A}{[X]} = B + C[X] + D[X]^2 + E[X]^3$$
$$F_{20} = \frac{F_{10} - B}{[X]} = C + D[X] + E[X]^2$$
$$F_{30} = \frac{F_{20} - C}{[X]} = D + E[X]$$

or an extrapolation to zero ligand concentration of the graphical plot of the corresponding functions, as in Figs. 8–10. A can be obtained in the same way from F_{00} or from the stability constants of the cadmium–bromide system; F is the highest constant of the cadmium–iodide system. As can be seen in Figs. 8–10 and Table 2, A and E obtained graphically or numerically agree satisfactorily with the values obtained from the simple systems.

Graphical and numerical values of B, C and D in each series show excellent agreement, which is a proof of the applicability of the method.

In Table 3 experimental values of the stability constants obtained by graphical and numerical calculation are shown together with maximum deviations calculated from the standard deviations of the constants A, B, C, D and E obtained by least-squares calculation; statistical constants are also shown.

Statistical calculations. The logarithm of the Nth root of β_N for a simple complex—log $\beta_N^{1/N}$—may be taken as a measure of the free enthalpy change per ligand, due to replacement of the bound water in the aquo complex. Bjerrum[17] used this value as a measure of the tendency of a ligand to form a complex.
Fig. 8. Plots of F_{00} ($\bigcirc$), F_{10} ($\times$), F_{20} ($\bullet$) and F_{30} ($\square$) vs. iodide concentration at [bromide] $= 0.05M$ for the mixed-ligand system.
Fig. 9. F_{00} (O), F_{10} (×), F_{20} (●) and F_{30} (□) vs. iodide concentration at [bromide] = $0.2M$ for the mixed-ligand system.

Assuming that in a system there are two ligands A and B (at the same concentration), each of which is capable of forming four complexes with the central ion, the probability that four successive ligands of the same kind (e.g., A) will be attached to the central ion M is $(1/2)^4 = 1/16$. The same probability holds for MB_4. The other fourteen combinations are divided among MB_3A, MB_2A_2 and MBA_3. According to this, the stability constants for these complexes would be predicted to be

$$\beta_{31} = 4.66\beta_{40}^{3/4}\beta_{04}^{1/4}$$

$$\beta_{22} = 4.66\beta_{40}^{2/4}\beta_{04}^{2/4}$$

$$\beta_{13} = 4.66\beta_{40}^{1/4}\beta_{04}^{3/4}.$$

In the case of the complexes MAB, MA_2B and MAB_2 the statistical factors favouring mixed-ligand complex formation are two for the first and three for the second and third. The term $\beta_N^{1/N}$ contains a gross statistical factor of 4/2 for MAB and 4/3 for MA_2B and MAB_2, because there are two and three ligands, respectively, available to occupy four sites around the central ion. Then the ligand factors will be $(2/4)^{1/N}$ and $(3/4)^{1/N}$. In summary, the statistical stability constants for these complexes would be:

$$\beta_{11} = 2(\tfrac{2}{4}\beta_{20}\cdot\tfrac{2}{4}\beta_{02})^{1/2}$$

$$\beta_{21} = 3(\tfrac{3}{4}\beta_{30})^{2/3}(\tfrac{3}{4}\beta_{03})^{1/3}$$

$$\beta_{12} = 3(\tfrac{3}{4}\beta_{30})^{1/3}(\tfrac{3}{4}\beta_{03})^{2/3}.$$

The statistical values according to these calculations are given in Table 3. Attention is drawn to the good agreement between the statistical and experi-
Fig. 10. F_{00} (O), F_{10} (×), F_{20} (●) and F_{30} (□) vs. iodide concentration at [bromide] = $0.3M$ for the mixed-ligand system.

β_{31}	590×10^3	$(607 \pm 9) \times 10^3$	619.8×10^3

mental values, with only the (unexplained) exception of β_{21}.

It has been claimed that the experimental stability constants of mixed-ligand complexes are higher than the statistically calculated constants,[3,6,7] for electrostatic or steric reasons. According to the results of this work we think that no such effect should be expected when the ligand characteristics are similar. As Table 3 indicates, the experimental values are not generally higher than the statistical values for the systems examined.

SOME REMARKS ON THE INFORMATION POWER AND SELECTIVITY OF ANALYTICAL PROCESSES

J. Inczédy

Institute of Analytical Chemistry, University of Veszprém, Veszprém, Hungary

Summary—The consistency of the equation given by Shannon for the transfer of maximum amount of information in one channel, and the equation deduced by Kaiser for the expression of the information power of analytical methods is shown. The fundamental difference between the maximum amount of information obtainable by an instrument and that by an analytical procedure is reported. In the second case the selectivity of the analytical procedure also has to be taken into consideration.

In the early fundamental work of Shannon,[1] an equation was deduced for the transfer of the maximum average amount of information through a channel, the input being a continuous signal–time function $x(t)$, of duration T and sampled at constant intervals with a sampling frequency of $f_s = 2f_{max}$, where f_{max} is the maximum-frequency component of the signal function (carrying useful information). This equation is

$$H_{x(t)} = n_t \log_2 \left[\frac{P_S + P_N}{P_N} \right]^{1/2}$$
$$= f_{max} T \log_2 \left[\frac{P_S + P_N}{P_N} \right] \text{ bits} \qquad (1)$$

where n_t is the number of sample points (and so is equal to $2f_{max}T$), P_S is the signal power, P_N is the noise power.

This equation is one of the most important in the theory of telecommunication, because it gives quantitative relations between frequency band-width, time, signal-to-noise ratio and amount of information, the last being expressed in bits. Using a longer time interval and narrower band-width allows the same amount of information to be transferred as with a larger band-width but shorter time interval. To increase the amount of information transferred in unit time, either the frequency band-width or the signal-to-noise ratio has to be increased.

The channel capacity c (expressed in bits) is defined as the maximum average amount of information transferred in unit time.

$$c = \frac{H_{x(t)}}{T} = f_{max} \log_2 \left[\frac{P_S}{P_N + 1} \right] \text{ bits.} \qquad (2)$$

If we wish to transpose equation (1) from the time domain into the frequency domain, *i.e.*, we wish to find the analogous expression in the frequency domain into the frequency domain, *i.e.* we wish to find the analogous expression in the frequency domain, the following points need consideration.

The $x(t)$ signal–time function corresponds to its Fourier transform in the frequency domain. Because

the duration of the signal transfer is finite and the sampling gives discrete data, the transformation can be carried out by the s.c. discrete Fourier transform (which is an estimation of the Fourier transform), which will contain $n_t/2$ terms and $n_t/2$ amplitudes. Using a formulation very similar to equation (1), but defined in the frequency domain, we obtain

$$H_{X(f)} = \frac{n_t}{2} \log_2 \left[\frac{X_i}{\delta X_i} \right] \text{ bits} \qquad (3)$$

where X_i stands for the ith amplitude of the spectrum

$$X_i = \sqrt{A_i^2 + B_i^2} \qquad (4)$$

A_i denoting the real and B_i the imaginary part of the transform; δX_i denotes the smallest distinguishable difference between two values of the amplitudes. This difference depends on the quality of the channel, *i.e.*, on the noise level. If we use this formula for description of the amount of information obtainable from an instrument then δX depends on the noise of the instrument. Equations (1) and (3) are similar. The square root of the power ratio in equation (1) corresponds to the ratio $X_i/\delta X_i$ in equation (3), with the difference that in the latter case—by convention—the signal and noise are not summed in the numerator, and δX is not the root mean square of the noise, but a value proportional to the noise (*viz.* $2ks$ where k is the value of student's t for the significance level chosen, s is the standard deviation of the noise, and the factor 2 allows for deviation in either direction).

Taking the resolution $R_{(f)}$ as

$$R_{(f)} = \frac{f}{\delta f}, \qquad (5)$$

considering that $\delta f = 1/T$, and setting the limits of the frequency band between $f = 0$ and f_{max} as f_1 and f_2, then the number of distinguishable amplitudes in the frequency domain will be

$$n_f = \int_{f_1}^{f_2} \frac{R_{(f)}}{f} \, df \qquad (6)$$

and n_f will be less than $n_t/2$ (except when the bandwidth is from $f = 0$ to f_{max}).

Since the ratio $X/\delta X$ usually depends on the frequency, the mean value of the ratio can be obtained by integration over the frequency range f_1-f_2. Thus, the mean value of the $X/\delta X$ ratio, expressed as the average number of distinguishable steps, $\bar{N}$, is:

$$\bar{N} = \frac{1}{n_f} \int_{f_1}^{f_2} \frac{X}{\delta X} \, df. \qquad (7)$$

By substitution from equations (5)–(7), equation (3) becomes:

$$H_{X(f_1-f_2)} = \int_{f_1}^{f_2} R_{(f)} \frac{df}{f} \log_2 \bar{N}. \qquad (8)$$

This equation was first introduced by Kaiser[2] for expressing the information power of spectroscopy. By generalization—using the z co-ordinate instead of frequency—the equation can be used for any two-dimensional instrumental analytical method. In this general formula the intensity of the amplitude, i.e., the signal we use, is simply x. Thus,

$$H_{x(z_1-z_2)} = \int_{z_1}^{z_2} R_{(z)} \frac{dz}{z} \log_2 \bar{N} \qquad (9)$$

Kaiser's ingenious concept corresponds to the general aspects of the telecommunication theory. However, in connection with the use of equation (9) two very important points must be considered.

The first is that it has to be distinguished very clearly whether we speak of the *amount* of information (not the information *power*, because time is not included) obtainable by an instrument, or by an analytical procedure. Equation (9) is valid for both. If we use it for instruments, then the resolution of the instrument $R = z/\delta z$ and $N = x/\delta x$ have to be taken into consideration, and if we use it for an analytical procedure, then the resolution of the procedure, which is the resolution of the components to be determined, (i.e., the selectivity), $R = z/\Delta z$ and $N = c/\Delta c$ has to be used. Thus the R and N values differ considerably, depending on whether the instrument or the analytical procedure is concerned. For expressing N for the instrument we use the signal intensity x, but to express it for the procedure we use the concentration c.

For example, let us consider a spectrophotometer. It has quite a large resolution in the wavelength range 200–800 nm, because $\delta z = 1$ nm can be distinguished. The resolution depends on the dispersion unit and the slit setting used, i.e., on the technical parts of the instrument. The value of δx again depends on the noise of the instrument. It can be approximated by taking four times the root mean square of the noise power. If, however, we wish to express the amount of information obtainable by an analytical procedure, then for R we have to take the resolution of the components, or the resolution of the corresponding wave bands Δz, and the least discernible concentration difference distinguished by the analytical pro-

cedure, Δc, which is connected with the standard deviations of the determinations. The Δz value is usually 50–100 nm. The standard deviations of the determinations include not only the precision of the instrument, but also all the other statistical errors which arise from sampling, preliminary treatment of the sample, the evaluation of the result, calibration errors, etc. Thus, $\Delta z \gg \delta z$ and $\Delta c \gg \delta x$.

It is interesting to note that the resolution of a procedure usually does not depend on the resolution of the instrument used for detection, because in most cases $\Delta z \gg \delta z$. This is also the case in chromatography, where the resolution of the detector is fairly high, but the resolution of the procedure depends on the column parameters (selectivity factor, plate number of the column). The detection system becomes the limiting factor of the selectivity of procedure only when Δz is less than δz, or they are comparable in magnitude.

The smaller the value of Δz for a procedure, the greater is the selectivity, and the greater the number of components with similar behaviour which can be determined by the same procedure in the presence of each other, assuming that their distribution in the direction of co-ordinate z is optimal or favourable. With increasing selectivity, i.e., decreasing Δz value, the maximum amount of information obtained by the procedure will increase. This fully corresponds to the points made in our previous paper[3] on the quantitative expression of the selectivity of analytical procedures.

The second important point is that when we use equation (9) for calculation of the amount of information, then in some cases Δz or δz can be considered constant over the range z_1-z_2 investigated. This is the case, for example, with spectrophotometers or spectrophotometric determinations. In some other cases, however, the ratio $z/\Delta z$ can be taken as constant, e.g., when we want to calculate the amount of information obtainable by a column chromatographic method. When an isocratic elution procedure is used in liquid chromatography the plate number of the column (N) can be assumed constant in the range investigated, since

$$\sqrt{N} = \frac{t_r}{w} = \frac{z}{\Delta z} \qquad (10)$$

where t_r and w are the retention time and peak width, respectively.

For a one-dimensional analytical procedure, e.g., determination of iron by titration, or by spectrophotometry in the absence of other components which can be determined similarly, equation (9) reduces to

$$H = \log_2 N = \log_2 \frac{c}{\Delta c} \qquad (11)$$

EXAMPLES

(1) The working range of a spectrophotometer is

200–800 nm and its resolution is 1 nm. Hence $z_1 = 200$; $z_2 = 800$; $\delta z = 1$. The precision of determination of the transmittance is *ca.* $\pm 0.5\%$ (*i.e.*, $\delta x = 1.0$). The absorption band-width of a molecule is, in general, 60 nm. The confidence interval for the spectrophotometric determination is *ca.* $\pm 5\%$. What is the maximum amount of information obtainable with the spectrophotometer (maximum number of distinguishable signal values), and what is the maximum amount of information when the spectrophotometer is used as an analytical tool for the determination of the concentration of different molecules?

In both cases equation (9) is used. For the instrument:

$$\int_{200}^{800} \frac{z}{1} \frac{1}{z} \, dz = \left[z \right]_{200}^{800} = 600$$

$$H_{\text{instr}}^{\text{max}} = 600 \log_2 \frac{100}{1.0} = 3986 \text{ bits.}$$

For the analytical procedure

$$\int_{200}^{800} \frac{z}{60} \frac{1}{z} \, dz = \frac{1}{60} \left[z \right]_{200}^{800} = 10$$

$$H_{\text{proc}}^{\text{max}} = 10 \log_2 \frac{100}{10} = 33.2 \text{ bits.}$$

This is the maximum amount of information which can be obtained by the analytical procedure if optimal conditions are ensured, *i.e.*, the components are present in equal amounts, the spectra show a uniform distribution, the resolution is optimum, *etc.* Six components can be determined in the presence of each other.

If the spectrophotometer is used for the determination of a single component, then the information obtained is:

$$H_{\text{proc}}^{1} = \log_2 10 = 3.32 \text{ bits.}$$

The relative redundancy is

$$100 \left(\frac{33.2 - 3.32}{33.2} \right) = 90\%.$$

(2) An ion-exchange column is used for the separation of cations, with hydrochloric acid as eluent.

The mean plate number of the column for the elution of simple univalent ions under the given conditions (temperature, flow-rate, column length, *etc.*) is 16. The dead-time of the column is 2 min. The detection is based on conductivity measurements. The amounts of the ions present are determined from the recorded peak areas, with an error of $\pm 1\%$. What is the maximum information obtainable by the chromatographic system, if the chromatographic procedure takes (*a*) 10 and (*b*) 20 min?

The calculation is done by using equations (10) and (9). First, the value of the resolution is calculated:

$$\sqrt{16} = \frac{t_r}{w} = \frac{z}{\Delta z} = 4.$$

When the elution takes 10 min, since the dead-time is 2 min, the detection is confined to an effluent volume corresponding to the last 8 min of flow, so:

$$4 \int_{2}^{10} \frac{1}{z} \, dz = 4 \ln \frac{10}{2} = 6.4$$

$$H_{10}^{\text{max}} = 6.4 \log_2 \frac{100}{2} = 36 \text{ bits.}$$

For the 20-min procedure:

$$4 \int_{2}^{20} \frac{1}{z} \, dz = 4 \ln \frac{20}{2} = 9.2$$

$$H_{20}^{\text{max}} = 9.2 \log_2 \frac{100}{2} = 52 \text{ bits.}$$

Thus, the maximum amount of information obtainable by the chromatographic system is 36.1 bits for a 10-min run. In the luckiest case six different ions can be determined. If the 20-min run is chosen, then the total amount of information is remarkably less than twice that obtainable in the 10-min run, since the peak-widths are increasing linearly with time, and only two (or possibly three) further components can be determined by use of the additional 10 min of running time.

ION-PAIR EXTRACTIONS WITH 12-CROWN-4 AND ITS ANALOGUES

G. E. PACEY and Y. P. WU

Miami University, Department of Chemistry, Oxford, OH 45056, U.S.A.

Summary—The complexing abilities of 12-crown-4 and its analogues have been investigated by using ion-pair extractions. A relationship exists between the type of substitution on the 12-crown-4 and the complexing ability and selectivity. Additionally, the selectivities vary according to the reagent concentrations. The compound 12-crown-4 can be used to complex sodium selectively in the presence of other alkali-metal ions. A method for determining serum sodium-ion concentrations has been developed.

Potassium and sodium have been determined by flame emission spectrophotometry, potentiometry with ion-selective electrodes, and atomic absorption. Recently, the crown ether and cryptand types of reagent have been used to complex alkali-metal ions selectively. Crown ethers and cryptands can be used in intermolecular ion-pair extractions[1,2] or synthetically modified to make chromogenic crown ethers[3–7] which can be used in intramolecular ion-pair extractions for the determination of alkali metals. Unfortunately, the determination of sodium by ion-pair extraction has only been accomplished by using the expensive compound called cryptand 211, with picrate as the counter-ion and toluene as the solvent.[2]

Recent studies on the ion-pair extraction behaviour of 12-crown-4 and benzo-12-crown-4 with picrate as the counter-ion and dichloromethane as the solvent have disclosed another choice of crown ether for the determination of sodium by ion-pair extraction. In addition, several analogues of 12-crown-4 have been studied. This paper reports the ion-pair data for 12-crown-4 and its analogues for various solvents, anions and reagent concentrations. A method for the determination of serum sodium with 12-crown-4 is presented.

investigation were added, and the mixture was mechanically shaken at a constant rate for 10 min at room temperature (*ca.* 24°). After phase separation the concentration of the picrate–crown ether ion-pair complex in the organic phase was determined spectrophotometrically at the appropriate wavelength (Table 1) and compared with the original aqueous concentration of picrate.

Extraction constants were determined by mixing equal volumes of 0.1–$10^{-4}M$ alkali-metal chloride and $10^{-4}M$ picric acid in a 100-ml round-bottomed flask, and diluting to 10 ml with water, extracting with 10 ml of $10^{-4}M$ crown ether solution in the solvent under investigation, and analysing the extracts as already described.

Partition coefficients were determined by the Frensdorff method[1] by equilibration of equal volumes of water and the solution of crown ether in organic solvent, followed by spectrophotometric determination of the amount of crown ether extracted into the aqueous phase. The determination was done by addition of picric acid and potassium hydroxide to the aqueous phase and extraction of the crown ether/potassium/picrate complex into dichloromethane. The concentration found in this way for the aqueous phase was subtracted from the initial total concentration of crown ether to deduce the concentration left in the organic phase. The partition coefficients were determined at several crown ether concentrations between 0.01 and $0.1M$ in the organic phase.

The recommended procedure for serum sodium-ion determination is to take 1 ml of serum sample in a 10-ml centrifuge tube and add 4 ml of 1.5% aqueous tri-

EXPERIMENTAL

Reagents

The reagents were 12-crown-4 (Aldrich) and 12-crown-4 analogues[8] (shown in Fig. 1), spectrophotometric grade solvents (Aldrich) and at least 99.5% pure alkali-metal chlorides (Alfa). The picric acid was titrated potentiometrically to determine its purity. All water was prepared with a Barnstead "Nanopure" system.

Extraction procedures

For all procedures using alkali-metal chlorides the pH of the solution was 3.2, but 11.7 when the hydroxides were used.

The degree of extraction was determined by transferring standard alkali-metal chloride and picric acid solutions into a 100-ml round-bottomed flask and diluting to 10 ml with water to give final concentrations of alkali-metal ion and picric acid of $0.1M$ and $10^{-4}M$ respectively. Then 10 ml of a crown ether solution (10^{-4}–$10^{-2}M$) in the solvent under
Fig. 1. Crown ethers used: DDC = dodecyl group.

Table 1. Spectral data for picrate–crown ether ion-pair complex in various solvents

Solvent	λ_{max}, nm		Complex ε_{max},
	Picric acid	Complex	$l.mole^{-1}.cm^{-1}$
CH_2Cl_2	350	375	1.8×10^4
CH_3Cl	—	360	7.3×10^3
CCl_3CH_3	—	380	7.7×10^3

The value of λ_{max} for the complex is practically independent of which crown ether is used.

chloroacetic acid solution. After thorough mixing (for approximately 5 min), centrifugation of the protein precipitate, and decantation, 1 ml of the solution is transferred into a 250-ml standard flask and diluted to volume with water. In the rest of the procedure the reagent volumes must be dispensed as reproducibly as possible, as slight variations in the reagent concentrations can adversely affect the results. Five ml of the diluted sample are placed in a 100-ml round-bottomed flask with 10 ml of $7 \times 10^{-4}M$ crown ether solution in dichloromethane and 5 ml of $7 \times 10^{-4}M$ picric acid, and the flask is mechanically shaken for 10 min at constant temperature. The absorbance of the organic phase is measured and evaluated with a calibration graph.

RESULTS

The extraction equilibrium for alkali-metal ion (M^+), picrate ion (Pic^-) and crown ether (Cr) is represented by the equation

$$M_{aq}^+ + Pic_{aq}^- + Cr_{org} \xrightleftharpoons{K_{ex}} MCrPic_{org} \quad (1)$$
where MCrPic denotes the ion-pair in the organic phase. Therefore, the extraction constant is given by[1]

$$K_{ex} = \frac{[MCrPic]_{org}}{[M^+]_{aq}[Pic^-]_{aq}[Cr]_{org}} \quad (2)$$

Four other equilibria must be kept in mind in order to account for the distribution of all components; the dissociation of MCrPic(org) [equation (3)], the distribution of the crown ether [equation (4)], the complexation of the metal with the crown ether in the aqueous phase [equation (5)] and the distribution of undissociated picric acid [equation (6)]. If the organic phase is polar, at low concentrations the ion-pair will partially dissociate according to equation (3). Evaluation of the K_d value proved this dissociation to be negligible.

$$MCrPic_{org} \xrightleftharpoons{K_d} MCr_{org}^+ + Pic_{org}^- \quad (3)$$

$$Cr_{org} \xrightleftharpoons{D_c} Cr_{aq} \quad (4)$$

$$M_{aq}^+ + Cr_{aq} \xrightleftharpoons{K_s} MCr_{aq}^+ \quad (5)$$

$$HPic_{aq} \xrightleftharpoons{K_d} HPic_{org} \quad (6)$$
The partition coefficients shown in Table 2 indicate that the best solvent to use is dichloromethane; 12-crown-4 is not appreciably soluble in any other solvent tested. Additionally, the partition coefficients suggest that practically no crown ether will be lost to

the aqueous phase by partition during the extraction. Resazurin (previously used for ion-pair studies with cryptands) exhibited little extraction as a crown ether ion-pair complex, and could not be used.

No detectable extraction was found in the absence of either picrate or crown ether when alkali-metal hydroxides were used, so the concentrations of hydroxide ion and uncomplexed alkali-metal picrate in the organic phase can be taken as negligible under these conditions. However, a certain amount of the picric acid was extracted when alkali-metal chlorides were used and the extraction was done at pH 3.2. This is in agreement with the findings of Gustavii and Schill,[11] who reported a value of $10^{2.04}$ for the distribution coefficient of picric acid between water and dichloromethane $[K = [HPic]_{org}/([HPic]_{aq} + [Pic^-]_{aq})]$. The same authors reported that the apparent dissociation constant of picric acid at $0.1M$ ionic strength is $10^{-0.33}$, which implies that at pH 3.2 about 13% of the free picrate would be extracted as picric acid. The molar absorptivities $(l.mole^{-1}.cm^{-1}$ at 375 nm) in dichloromethane are about 2×10^3 for picric acid and 1.8×10^4 for picrate in an ion-association complex, so the picric acid extracted would give a signal equivalent to that for a crown ether/alkali metal/picrate concentration equal to about 1.5% of the free picrate concentration in the aqueous phase (if equal volumes are used). As the free picrate concentration will depend on the alkali-metal ion concentration, this source of error will also be dependent on the alkali-metal concentration, but will be automatically compensated for in the calibration, provided that the pH and the volume of picrate added are kept practically constant for samples and standards. Under those conditions a blank should not be necessary for a particular batch of reagents and the accompanying calibration graph.

Table 3 indicates several interesting points. First, 12-crown-4, when used with dichloromethane and picrate, is a selective reagent for sodium. With equal concentrations of crown ether and picrate, lithium is extracted more efficiently than potassium, but the reverse is the case at higher crown ether concentrations. This is not surprising since potassium preferentially forms a 2:1 crown ether:metal complex.[12]

Table 2. Partition coefficients (D_c) of 12-crown-4 and benzo-12-crown-4 between various solvents and water $(D_c = [Cr]_{aq}/[Cr]_{org})$

Solvents	Crown ether	D_c
Dichloromethane	12-C-4	3.1×10^{-3}
	B-12-C-4	7.4×10^{-4}
Chloroform	12-C-4	NE
	B-12-C-4	6.9×10^{-3}
1,1,1-Trichloroethane	12-C-4	NE
	B-12-C-4	1.6×10^{-3}
Toluene	12-C-4	NE
	B-12-C-4	NE

NE = no extraction.

The degree of extraction is increased when the alkali-metal hydroxides are used instead of the chloride.

We believe this is due to the shift in picric acid dissociation, caused by the change in pH, since the effective picrate concentration will be increased (see preceding paragraph).

Benzo-12-crown-4 does not extract lithium at all in the presence of picrate. For other alkali-metal ions, benzo-12-crown-4, picrate and various solvents, the degree of extraction depends on the solvent used, increasing in the order toluene ≪ 1,1,1-trichloro-ethane < chloroform < dichloromethane. This order is not a function of dielectric constants, since these are in the order chloroform (4.8) < 1,1,1-trichloro-ethane (7.1) < dichloromethane (9.1).

Compounds 3 and 4 are interesting in comparison to 12-crown-4 and benzo-12-crown-4 in terms of extraction ability. Compound 4 is much more selective than compound 3 for sodium. Molecular models suggest that this may be due to the rigid benzene ring acting as a cap to the cavity. This should increase the stability of the potassium, rubidium and caesium complexes. The dodecyl group would not form a good cap, so only ions that fit well into the cavity would be extracted efficiently. This explanation seems acceptable since the degree of extraction for sodium is essentially the same for both compounds, whereas that for the larger cations varies markedly. Compound 4 behaves similarly to 12-crown-4 but compound 3 has extraction behaviour in between that of benzo-12-crown-4 and of 12-crown-4.

Compound 5 behaves more like benzo-12-crown-4. Deprotonation of the phenolic group enhances the extraction, probably because the charged group will

act as an additional stabilizing factor when positioned over the cyclic crown ring. Interestingly, the difference between compounds 3 and 5 was the extra methylene group in compound 3 and the phenol group in compound 5. If we assume that the protonated phenolic group has little effect on the extraction process, then the addition of the methylene group has a significant impact on the extraction system, possibly because of the extra flexibility of the side-chain.

It appears from all the data that a change in extraction selectivity can be accomplished by varying the ratio of crown ether to counter-ion. With potassium, rubidium and caesium capable of forming 2:1 and 3:2 crown ether to metal complexes, any increase in the crown ether concentration improves the degree of extraction of these ions. If the crown ether concentration is more then ten times that of picrate, the selectivity of the crown ethers will change in favour of the larger alkali-metal ions. The selectivity for the smaller ions is increased by lower (preferably equal) concentrations of crown ether and picrate, but there is some loss of overall extraction efficiency.

Table 4 gives the extraction constants for the crown ether/alkali metal/picrate complexes. The data in Tables 3 and 4 indicate that the ion-pair system with dichloromethane as the solvent and picrate as the counter-ion transforms 12-crown-4 into a selective complexing agent for sodium, in the presence of other alkali metals. The data also indicate that only high concentrations of lithium would interfere seriously. On the other hand, benzo-12-crown-4 exhibits no selectivity other than its exclusion of lithium in the extraction process. The data in Table 4 confirm the

selectivities (especially that of 12-crown-4 for sodium). The data for ion-pair extraction with picrate and benzene show that our system is considerably better and more selective.

In an attempt to find a "real" application for this extraction system, 12-crown-4, picrate and dichloromethane were used to determine sodium in blood serum. A calibration curve was prepared with standard sodium chloride solutions. It was linear over the sodium range 5–150 ppm Na$^+$ (2.1–65 × 10^{-4}M). The least-squares equation for the calibration curve had a small intercept on the ordinate and the correlation coefficient was 0.9983. The dilution needed to bring the sample solution sodium concentration into the linear range was considerably less than that for

the previous cryptand ion-pair method. The results in Table 5 show the concentrations obtained by this method and the value given to us by the hospital where the samples were taken. The agreement is excellent, with no indication of interference from potassium.

SPECTROPHOTOMETRIC STUDIES OF THE REACTIONS OF PENTACYANOFERRATE(II) COMPLEXES WITH THREE *N*-HETEROCYCLIC ALDOXIMES

Nicoletta Burger and Vinka Karas-Gašparec
Department of Chemistry and Biochemistry, Faculty of Medicine,University of Zagreb, 41000 Zagreb, Šalata 3, Yugoslavia

Summary—The colour reactions of three oximes with ammine- and nitrosyl-pentacyanoferrate(II) ions have been studied. The optimum reaction conditions, spectral characteristics and molar compositions have been found and some instability constants determined. The reactions can be used for the detection and determination of small amounts of the oximes examined.

The aquopentacyanoferrate(II) ion (AqP) reacts with different aliphatic and aromatic oximes to form intensely coloured water-soluble complexes,[1] and so do amminepentacyanoferrate(II)[2] and nitrosylpentacyanoferrate(II)[3] ions (abbreviated here as AmP and NP). These reactions have been applied for the detection and determination of small quantities of certain oximes,[4-8] and probably take place through a common intermediate, the aquopentacyanoferrate(II) ion, which forms in aqueous solutions of amminepentacyanoferrate(II)[9,10] and alkaline solutions of nitrosylpentacyanoferrate(II).[11]

The nature of the reaction product depends very much on the chemical nature of the reacting oxime. In this paper the reactions of AmP and NP with pyridine-2-aldoxime (PA-2), 1-methylpyridinium-2-aldoxime methyl sulphate (PAM-2 CH_3SO_4) and 1-dodecylpyridinium-2-aldoxime chloride (PAD-2 Cl) are described. Because the last two of these oximes, PAM-2 and PAD-2, are antidotes to poisoning with organophosphorus compounds,[12] these investigations also had a practical importance.

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade. Redistilled water was used throughout. Britton and Robinson buffers[13] were prepared by mixing 100 ml of phosphoric, boric and acetic acid mixture (all 0.04M) with different volumes of 0.20M sodium hydroxide.

Aqueous solutions of $Na_3[Fe(CN)_5NH_3]\cdot3H_2O$ (Touzart-Matignon) were prepared 10–15 min before use. The aqueous $Na_2[Fe(CN)_5NO]\cdot2H_2O$ (Kemika) solutions remained stable for several days if kept in the dark.

The oximes were from different sources, PA-2 and PAM-2 CH_3SO_4 from Fluka and Specia and PAM-2 Cl from Bosnalijek. PAD-2 Cl and PAD-2 I were synthesized.[12] Their solutions were prepared in water (pure ethanol in the case of PAD-2).

Constant ionic strengths of 0.05 and 0.1 were obtained by addition of sodium chloride solutions of appropriate concentrations.

Preparation of samples for measurements

A. To 2 ml of Britton and Robinson buffer of appropriate pH add the oxime, sodium chloride, AmP and enough water to give a volume of 5 ml.

B. To an alkaline NP solution which has stood for 10 min in the dark, add the oxime, sodium chloride and water to give a total volume of 5 ml.

For PAD-2 Cl use 50% ethanol–water medium, leave all solutions in the dark at room temperature to reach equilibrium. Measure the absorbance at the appropriate wavelength of maximum absorption (λ_{max}) against a reagent blank or water.

Determination of oximes

To 2 ml of Britton and Robinson buffer of pH 6.06 (or pH 7.90 for PAM-2 CH_3SO_4) add 2.5 ml of the oxime solution (containing 50–500 μg of PAM-2 CH_3SO_4, 100–800 μg of PAD-2 Cl or 50–100 μg of PA-2) and 0.5 ml of 0.01M AmP (0.04M AmP in the case of PAM-2 CH_3SO_4). Mix well and measure the absorbance at λ_{max} against a reagent blank after equilibrium is reached. Find the amount of oxime by reference to a calibration graph or equation.

Isolation and characterization of the AmP–PAD-2 and AmP–PAM-2 products

Because of the low solubility of PAD-2 Cl and its AmP complex in water the reaction can be used to isolate the latter by precipitation. The oxime (0.0654 g) was dissolved in 2 ml of ethanol and 0.0132 g of AmP was dissolved in 1 ml of water. The solutions were mixed and after 1–2 hr the precipitate was filtered off, washed first with 78% ethanol, then with water, and dried first in the dark in air, then in a desiccator over sodium hydroxide and finally in a vacuum desiccator over phosphorus pentoxide. Qualitative analysis showed that the compound did not contain sodium. Iron was determined complexometrically as Fe^{3+} after decomposition of the compound with *aqua regia*, and C, H and N were determined by elemental analysis. Analysis: C 63.3%, H 8.8%, N 14.6% and Fe 6.9%; $C_{40}H_{62}N_8O_2Fe\cdot H_2O$ requires C 63.14%, H 8.48%, N 14.73% and Fe 7.34%. The product is a dark powder, sparingly soluble in ethanol and insoluble in benzene, acetone, carbon tetrachloride and ether. The same preparation method may be used with 1-dodecylpyridinium-2-aldoxime iodide. The infrared spectra were recorded (KBr pellets). The bands observed were v_{CN} at 2106 and 2048 cm^{-1} and v_{NO} at 1018 cm^{-1}.

The product of the reaction between AmP and PAM-2 Cl was isolated by evaporation of a mixture in which the oxime

was in ninefold molar excess over the AmP (PAM-2 Cl was used instead of PAM-2 CH_3SO_4 because we had more of it). One ml of water containing 0.0621 g of the oxime and 5 ml of water containing 0.0130 g of AmP were mixed and left for 4–5 hr in the dark, then evaporated to dryness *in vacuo*. The residual solid was transferred onto a Schleicher & Schüll white band filter paper and washed with about 50 ml of ethanol until the washings no longer contained oxime (as shown by evaporation). It was dried in the dark in air and later in desiccators over anhydrous calcium chloride and phosphorus pentoxide. Elemental analysis gave C 40.1%, H 4.6%, N 20.1%, Fe 10.7%; sodium hydrogen diox-imatotetracyanoferrate(II) pentahydrate requires C 39.57%, H 4.98%, N 20.51%, Fe 10.22%, Na 4.21%. The analysis is not satisfactory proof of composition, but the product was difficult to obtain and dry reproducibly. The compound was very soluble in water, and its spectrum had λ_{max} at 525 nm. The colour faded rapidly on addition of hydrogen peroxide but not on addition of ascorbic acid, suggesting that all the iron was present as iron(II). Its infrared spectrum had a broad absorption band at about 3400 cm^{-1}, confirming the presence of water, ν_{CN} at 2110, 2068, 2048 and 2024 cm^{-1} and ν_{NO} at 1012 cm^{-1}. It is not known whether the proton is involved in the complex anion or not.

RESULTS AND DISCUSSION

The products are formed very slowly and the kinetics depend on many factors, primarily on pH and ionic strength. NP forms coloured complexes even in very alkaline media, if its alkaline solution is kept in the dark for 10 min before addition of the oxime. The effects of pH on the AmP reactions are presented in Fig. 1 and some characteristics of the complexes are given in Table 1. It is found that increasing the ionic strength decreases the absorbance.

The composition of the complexes was determined by the method of continuous variations[14,15] and by the slope-ratio method;[16] the instability constants were calculated from the Job plots and by the methods of Budešinský[17] and of Frank and Oswalt.[18]
Fig. 1. Effect of pH on the complex formation. 1—[PA-2] = [AmP] = $4 \times 10^{-4}M$; 2 − [PAM-2 CH_3SO_4] = [AmP] = $5 \times 10^{-4}M$; 3—[PAD-2 Cl] = [AmP] = $5 \times 10^{-4}M$. Absorbances measured against water at λ_{max}.

As is evident from Table 1, PA-2 reacts with AmP very slowly indeed. The reactions take 4 days to reach completion, and the composition of the orange product obtained at pH ∼ 6 is 1:2 oxime:pentacyanide (Table 2). With NP it reacts even more slowly; at pH < 11 it forms a rose complex with $\lambda_{max} = 520$ nm, and at pH > 11 a compound with $\lambda_{max} = 480$ nm and lower absorptivity. The reaction takes about 15 days to reach completion, during which the initial broad spectrum is narrowed and shifted, the direction and magnitude of the shift being a function of the pH (Fig. 2). The pH decreases from the initial value.

With NP, PAM-2 CH_3SO_4 forms a 1:1 complex, which was investigated earlier.[3] In the reaction with AmP it seems to react in two different ways. In acid and neutral media it forms a 1:1 complex in about 24 hr whereas in strongly alkaline medium a 2:1 (oxime:pentacyanide) complex is formed within 4 hr.

Table 1. Spectral characteristics and stability of the complexes produced in the reaction of AmP ($I = 0.05$) and NP ($I = 0.1$) with the examined oximes.

Compound	Reagent	λ_{max}, nm	Optimum pH region	Stability of the complex solutions, hr	Reaction time, hr
PA-2	AmP	470	5–6		96
	NP	480	∼11	24	360
		520	∼10		360
PAM-2 CH_3SO_4	AmP	520–530	8		8–12
	NP	540	11.7	1	4–8
PAD-2 Cl	AmP	570–580	5.5–6.5	2	2
	NP		>11	0.01–0.02	0.25

Table 2. Spectral characteristics, compositions and instability constants of the complexes with AmP ($I = 0.05$) determined by different methods (22°C)

Complex	pH	Composition	Instability constants, pK			ϵ, $l.mole^{-1}.cm^{-1}$
			Job plot[14,15]	Budešinský[17]	Frank–Oswalt[18]	
PA-2–AmP	6	1:2	6.93			
	6	1:1		2.82	2.72 ± 0.10	3700
PAM-2 CH_3SO_4–AmP	8	∼1:1		3.29	3.12 ± 0.09	3800
	11.7	2:1				
Fig. 2. Dependence of the PA-2–NP reaction on the base concentration. [PA-2] = [NP] = 4 × $10^{-3}M$. The spectra are labelled with the number of days elapsed at the time of measurement. O——O [OH$^-$] = 0.02M. The pH on the 15th day was 9.95. ●——● [OH$^-$] = 0.04M. The pH at the end of the reaction was 11.61.

In a slightly alkaline medium a mixture of the two forms is probably present but the 1:1 complex predominates (Fig. 3). The spectra of the complexes differ (Fig. 4). The molar compositions, absorption coefficients and instability constants of the complexes are given in Table 2.

PAD-2 Cl forms a 2:1 complex with both reagents, in 50% v/v ethanol–water solution. The ethanol lowers the absorbance, and if present in higher concentration shifts the position of λ_{max}.

All our investigations of the reactions of aliphatic and N-heterocyclic aldoximes of the mono- and bis-pyridinium type with aquo-, ammine- and nitrosyl-pentacyanoferrate(II) ions[1–8] show that all three reagents give the same product with a particular oxime.

PA-2 probably forms the same complex with AmP and NP but the complex formed in the latter case at pH < 11 exhibits a colour change, probably as a result of dissociation of the oxime hydrogen atom. This conforms with another report[20] on the effect of pH on the complex of PA-2 and iron(II). PAD-2 Cl also forms the same complex with AmP and NP. The reaction of PAM-2 with AmP has not yet been completely elucidated.

Applications

The colour reactions described may be used for the detection and determination of small quantities of the oximes.

The recommended qualitative method consists of observing the colour obtained by mixing the oxime with the pentacyanide reagent and the appropriate
Fig. 3. Job curves at different pH. Total concentrations $10^{-3}M$ except for the solutions at pH 11.7, for which the concentration was 2 × $10^{-3}M$.

buffer or base. As already described,[19] 2–3 μg of PA-2 and PAM-2 CH$_3$SO$_4$ or 15 μg of PAD-2 Cl can be detected in this way. For quantitative analysis the reactants are mixed under the optimum conditions and the absorbance at λ_{max} is measured after equilibrium is reached. It is possible to determine 50–500 μg of PAM-2 CH$_3$SO$_4$, 100–800 μg of PAD-2 Cl or 50–100 μg of PA-2 in 5 ml of reaction mixture by means of a calibration graph. It is also possible to run a standard in parallel with the sample and calculate the amount of oxime in the sample by simple proportion from the absorbances and weight of standard. In this way it is possible to avoid the long delay needed to reach equilibrium (Table 3). The reactions may be used successfully for determination of small quantities of the oximes in tablets and injections. Nitro-
Fig. 4. Absorption spectra at different pH. [PAM-2 CH$_3$SO$_4$] = [AmP] = 5 × $10^{-4}M$ except for pH 11.5, for which the concentrations were 1 × $10^{-3}M$.

Table 3. Precision of the determinations

Oxime	Taken, μg	ΔA	Found,* μg	Standard deviation, μg	Rel. std. devn., %	No. of detns.

prusside can be used similarly, but the reactions are less sensitive.

Species forming precipitates or complexes with the pentacyanoferrate(II) under the conditions used will interfere, e.g., Cu^{2+}, Hg^{2+}, Au^{3+}, some pyridine derivatives,[4,21] alkyl and aryl hydrazines and hydroxylamines.[22]

RAPID ASSAYS BASED ON IMMOBILIZED BIOLUMINESCENT ENZYMES AND PHOTOGRAPHIC DETECTION OF LIGHT-EMISSION

K. Green and L. J. Kricka*

Department of Clinical Chemistry, University of Birmingham, Birmingham B15 2TH, England

G. H. G. Thorpe and T. P. Whitehead

Department of Clinical Chemistry, Wolfson Research Laboratories, Queen Elizabeth Medical Centre, Birmingham B15 2TH, England

Summary—Sensitive assays have been developed for adenosine 5'-triphosphate, the reduced form of nicotinamide adenine dinucleotide, cholyl glycine and alcohol, with immobilized and co-immobilized preparations of bacterial and firefly luciferase as reagents. With high-speed (ASA 20000) instant photographic film as detector, picomole amounts of the various analytes can be detected rapidly. The simplicity and convenience of the analytical combination of co-immobilized bioluminescent enzymes and photographic film for the detection of light make this an ideal technique for rapid screening tests.

Immobilized and co-immobilized bioluminescent enzymes, such as bacterial luciferase and firefly luciferase can be used as reagents for very rapid and sensitive assays.[1-6] For example, primary bile acids can be measured in femtomole amounts, according to the reaction sequence shown in equations (1)–(3), by means of bacterial luciferase, NADH:FMN oxidoreductase and 7α-hydroxysteroid dehydrogenase co-immobilized onto Sepharose particles.[3]

NAD + primary bile acid (cholyl glycine)

$$\xrightarrow{\text{7α-hydroxysteroid dehydrogenase}} \text{7α-oxo bile}$$

$$\text{acid} + \text{NADH} \quad (1)$$

NADH + FMN

$$\xrightarrow{\text{NADH:FMN oxidoreductase}} \text{NAD}$$

$$+ \text{FMNH}_2 \quad (2)$$

$$\text{FMNH}_2 + \text{decanal} + O_2$$

$$\xrightarrow{\text{bacterial luciferase}} \text{FMN} + \text{decanoic}$$
$$\text{acid} + CO_2 + \text{light} \quad (3)$$

Light-emission from such reactions is usually measured by means of a photomultiplier tube or a photodiode. It is also possible, however, to detect and measure light-emission from luminescent reactions by using photographic film, although in the past this has been mainly confined to chemiluminescent assays for metal ions.[7] We have recently described an assay for glucose based on filter pads impregnated with glucose oxidase and peroxidase, a chemiluminescent indicator reaction involving luminol, and instant photographic film.[8] The advantages of this approach to analysis are that it is rapid, a permanent record of the results is obtained, and the detection system is simple and requires no power source. The object of this study was to investigate the feasibility of producing analytical systems based on bioluminescent enzymes co-immobilized onto an insoluble microparticulate solid support (Sepharose), and use of instant photographic film.

EXPERIMENTAL

Reagents

Luciferin, dithiothreitol (DTT), decanal, *N*-tris(hydroxymethyl)methyl-2-aminoethanesulphonic acid (TES), cyanogen bromide, and glycylglycine were purchased from Sigma London Chemical Co. Sodium pyrophosphate was obtained from BDH Chemicals Ltd. The glycine conjugate of cholic acid was synthesized as described previously.[9]

Nucleotides

Adenosine 5'-triphosphate (ATP), flavin mononucleotide (FMN) and the reduced form of nicotinamide adenine dinucleotide (NADH) were supplied by Sigma. Nicotinamide adenine dinucleotide (NAD) was purchased from Boehringer Mannheim Corporation.

Enzymes

Firefly luciferase, 7α-hydroxysteroid dehydrogenase, and alcohol dehydrogenase immobilized onto agarose beads were obtained from Sigma. "NADH monitoring reagent" (a mixture of bacterial luciferase and NADH:FMN oxidoreductase) was purchased from LKB. Bacterial luciferase and NAD(P)H:FMN oxidoreductase were supplied by Boehringer Mannheim Corporation.

Solid supports

Sepharose 4B and cyanogen bromide-activated Sepharose 4B were obtained from Pharmacia Fine Chemicals.

Immobilized enzymes

Various enzymes or mixtures of enzymes were immobilized according to the procedure described by Ford and DeLuca[1] onto CNBr-activated Sepharose 4B (1 g) or onto Sepharose 4B (1 g) which had been freshly activated by treatment with cyanogen bromide according to the method of March *et al.*[10] They were firefly luciferase (10 mg); bacterial luciferase (5 mg) and NAD(P)H:FMN oxidoreductase (10 U); bacterial luciferase and NADH:FMN oxidoreductase (one vial of LKB Monitoring Reagent); bacterial luciferase, NADH:FMN oxidoreductase (one vial of LKB Monitoring Reagent) and 7α-hydroxysteroid dehydrogenase (3.5 mg). Immobilized enzymes were stored at 0–4° as a suspension (100 g/l.) in phosphate buffer (0.1M, pH 7.0) containing DTT (2mM) and sodium azide (3mM).

The efficiency of the immobilization procedure was assessed by determination of the protein concentration (from the absorbance at 280 nm) in the coupling mixture before and after addition of the activated Sepharose and from the minimum amount of analyte detectable by use of the immobilized enzyme(s).

Enzymes were immobilized on both freshly activated and preactivated cyanogen bromide–Sepharose in order to compare their relative performance. The advantage of using the preactivated Sepharose was that it avoided the local use of cyanogen bromide, which is toxic.

Measurement of light-emission

Photomultiplier tube. A luminometer designed and built in the laboratory, and based on a side-window photomultiplier tube (EMI type 9781A, 94 μA/lumen) and having facilities for automatic injection of reagents into reaction cuvettes, was used to measure the light-emission.[11]

Photographic film. Polaroid Land film type 612 (ASA 20000) was used in conjunction with a mask containing 6 plastic tubes (44 × 11 mm diameter) as described previously.[8] Exposure times of up to 2 min were used. Photographic results were assessed visually.

Assays

ATP. The principle of the assay is shown in equation (4):

$$ATP + luciferin + O_2 \xrightarrow{\text{firefly luciferase}} ADP + oxyluciferin$$

$$+ \text{ inorganic pyrophosphate} + CO_2 + \text{light} \quad (4)$$
A series of ATP standards was prepared by serially diluting an aqueous stock solution (2mM) in glycylglycine buffer (25mM, pH 7.8). Stock assay mixture comprised 8 ml of glycylglycine buffer (25mM, pH 7.8), 1.0 ml of magnesium chloride solution (0.1M, pH 7.8), and 0.8 ml of aqueous luciferin solution (1mM). A 10-μl sample of an ATP standard and 10 μl of a suspension of immobilized firefly luciferase were placed in a 10 × 10 × 45 mm cell and the reaction was initiated by injecting 1.0 ml of assay mixture. Peak light-emission was recorded.

NADH. The principle of the assay is shown in equations (2) and (3). A series of NADH standards was prepared by serially diluting an aqueous stock standard (2mM) with distilled water. A decanal–water emulsion was prepared by shaking 5 ml of decanal with 10 ml of distilled water. This was prepared daily and stored at 0–4°. Stock assay mixture comprised 100 μl of decanal emulsion, 200 μl of aqueous FMN solution (0.15mM) and 10 ml of phosphate buffer (0.1M, pH 7.0). A 10-μl sample of an NADH standard, and 10–50 μl of co-immobilized bacterial luciferase and NAD(P)H:FMN oxidoreductase were placed in a cell and the reaction was initiated by injection of 1.0 ml of assay mixture. Peak light-emission was recorded.

Cholyl glycine. The principle of the assay is shown in equations (1)–(3). A series of cholyl glycine standards was prepared by serial dilution of a stock standard (0.1mM)

with distilled water. A 10-μl sample of a standard and 10–50 μl of a suspension of co-immobilized bacterial luciferase, NAD(P)H:FMN oxidoreductase, and 7α-hydroxysteroid dehydrogenase were placed in a cell and the reaction was initiated by injecting 1.0 ml of an assay mixture prepared by mixing 1 ml of aqueous NAD solution (200mM), 200 μl of aqueous FMN solution (0.15mM), 100 μl of decanal emulsion and 10 ml of TES buffer (0.05M, pH 7.0). Peak light-emission was measured.

Ethanol. The principle of the assay is shown in equation (5).

$$ethanol + NAD$$

$$\xrightarrow{\text{alcohol dehydrogenase}} \text{acetaldehyde} + NADH \quad (5)$$

$$NADH \xrightarrow{\text{equations (2) and (3)}} \text{light}$$
A series of alcohol standards was prepared by serial dilution of an aqueous stock standard (0.1mM) in distilled water. A 10-μl sample of an alcohol standard, 25 μl of a suspension of alcohol dehydrogenase immobilized onto agarose [0.1 g/ml in TES buffer (0.05M, pH 7.0)], 10 μl of a suspension of co-immobilized bacterial luciferase and NADH:FMN oxidoreductase and 10 μl of aqueous NAD solution (20mM) were mixed together in a cuvette and incubated at room temperature for 2 min. This incubation time was increased to 5 min when plasma or whole blood was used. The bioluminescent reaction was initiated by injecting 1 ml of an assay mixture comprising 100 μl of decanal emulsion, 200 μl of aqueous FMN solution (0.15mM) and 10 ml of TES buffer (0.05M, pH 7.0). Peak light-emission was recorded.

In assays using photographic film to detect light-emission the volume of assay mixture added to initiate the bioluminescent reaction was reduced to 400 μl in order to keep the level of glowing reaction mixture below the top of the mask and thus eliminate exposure of other areas of the film.

Accelerated thermal stability study

A suspension of the immobilized enzymes (1 ml) was incubated at 50° in a water-bath. Samples were removed at various times and the remaining enzyme or coupled enzyme activity was measured by using a 10-μl sample of the appropriate standard with the highest concentration.

RESULTS AND DISCUSSION

The efficiencies of the coupling of the enzymes to the activated Sepharose, the lower limits of detection of the various substrates and the linear ranges of detection (Table 1) were similar to those previously reported.[1,3,4,12] Freshly prepared CNBr-activated Sepharose produced a more active immobilized enzyme preparation, as judged by the detection limit for the particular analyte, than the commercially available material. This was not due to a difference in the capacity of the activated Sepharoses, since the efficiency of coupling, determined by loss of protein from the enzyme coupling mixtures, was 5–10% lower for the freshly activated Sepharose. The difference may arise from the surface concentration of reactive groups being higher on freshly activated than on preactivated Sepharose, which would lead to multiple attachments between the Sepharose surface and enzyme molecules and hence less protein denaturation and loss of enzyme activity.

Table 1. Linear ranges and detection limits for bioluminescent analysis, obtained by use of a photomultiplier tube or photographic film to detect light emission

Immobilized enzymes	Coupling efficiency, %	Analyte	Photomultiplier tube detection limit,* pmole			Photographic film detection limit,† pmole
			A	B	Linear range	
Firefly luciferase	86–96	ATP	0.02	0.2	0.02–20000	2
Bacterial luciferase, NAD(P)H:FMN oxidoreductase	85–95	NADH	2	20	2–2000	200
Bacterial luciferase, NAD(P)H:FMN oxidoreductase, 7α-hydroxysteroid dehydrogenase	80–95	cholyl glycine	50	50	50–5000	50
Bacterial luciferase and NAD(P)H:FMN oxidoreductase –alcohol dehydrogenase	85–95	ethanol	1	—	1–1000	1

*Detection limit; amount of analyte giving twice background light-emission; A, freshly activated; B, preactivated cyanogen bromide Sepharose.

†The amount of analyte giving a photographic response (assessed visually) greater than that given by the blanks.

The thermal stability of the various immobilized enzyme preparations was greater on preactivated Sepharose (Fig. 1); it must be remembered that the initial enzyme activity of these preparations was much lower (by a factor of about 10) than that of those prepared from freshly activated Sepharose.

The lower limits of detection obtained for the various analytes by using instant photographic film are summarized in Table 1. A film with a speed of 20000 ASA was used, as this was the fastest and therefore the most sensitive instant film available. Generally, the detection limits were inferior (by a factor of 100) to those obtaining by using a photomultiplier tube as the detector, but nevertheless they were much lower than those for conventional assays. Detection limits obtained by using the two types of detector are not strictly comparable, as with the photomultiplier tube a peak light-emission was measured whereas with the photographic film the degree of exposure is a measure of the total light emitted. A feature of the light-emission from reactions involving immobilized bioluminescent enzymes is that they produce a steady glow rather than a flash of light (Fig. 2). This feature makes it possible to initiate the reaction before placing the cell in front or on top of the detection system. Exposure times of up to 2 min were used and an example of an ATP assay exposed for 30 sec is presented in Fig. 3. The imprecision of the assay and the insufficient exposure latitude limits the discrimination between different amounts of ATP and thus no attempt was made to determine the real threshold, which lies between 2 and 20 pmole. Thus in its present form this type of assay is best used as a "threshold" or "screening" test, e.g., the detection of the presence of >20 pmole of ATP in a specimen. Biological specimens were also analysed. Ethanol present in either whole blood or plasma could be detected photographically in a 10-μl sample, down to levels of 20 mg/100 ml (4.3mM). The presence of proteins and cells reduced the light-emission but the
Fig. 1. Thermal stability study (50°) of bacterial luciferase, NADH:FMN oxidoreductase and 7α-hydroxysteroid dehydrogenase co-immobilized onto (A) preactivated, and (B) freshly activated cyanogen bromide Sepharose 4B. Activity of the coupled enzymes was assessed by using cholyl glycine.
Fig. 2. Time course of light-emission from the reaction of 2000 pmole of NADH with co-immobilized bacterial luciferase and NADH:FMN oxidoreductase.

ATP (pmoles)

photographic system was still sufficiently sensitive to make it a usable method for screening for alcohol in blood.

CONCLUSIONS

Luminescent assays based on immobilized and co-immobilized bioluminescent enzymes and photographic detection of light-emission by means of "in-stant" film are both rapid and sensitive. This type of assay is widely applicable since it is possible to base the determination of a range of NAD- and ADP-dependent enzymes and their substrates on the bioluminescent firefly or bacterial luciferase reactions. A limitation of the photographic detection system is the restricted exposure latitude of currently available instant film, which limits this to a threshold-type test, but in the authors' opinion this is far outweighed by the simplicity of the detection system.

STUDY OF HIGH-VOLTAGE BREAKDOWN AND MATERIAL CONSUMPTION IN SPARK-SOURCE MASS SPECTROMETRY AND THEIR SIGNIFICANCE IN ANALYTICAL APPLICATIONS

J. Van Puymbroeck, J. Verlinden, K. Swenters and R. Gijbels

Department of Chemistry, University of Antwerp (U.I.A.), Universiteitsplein 1, B-2610 Wilrijk, Belgium

Summary—The breakdown voltage has been found to be dependent on the gap width between the electrodes and on the melting point of the sample elements in spark-source mass-spectrometry (SSMS). The number of discharges per pulse train and the time required to reach the first discharge depend only on the chosen breakdown voltage. The spark gap is proportional to the "radius" of the volume sampled (for a given element) and this radius is linearly related to the reciprocal of the melting point of the elements (23 different elements, metals or semiconductors), when fixed spark-parameters are used. The effect of electrode temperature on material consumption can be qualitatively explained by a fictive increase or decrease in melting point of the element. Knowledge of the relations between the different spark and instrumental parameters and the volume or weight of sample consumed can be applied to the study of the homogeneity of samples, to in-depth analysis by SSMS and to the analysis of microsamples.

It is necessary to know the amount of material consumed during spark-source mass-spectrometric analysis and to know the influence of different spark parameters on the weight loss of the electrodes, in order to arrive at an adequate understanding of the erosion by the spark and at a better evaluation of the effect of sample heterogeneity, and before attempting the analysis of thin solid films and microvolumes.

Derzhiev *et al.*[1] have recently discussed the use of spark-source mass-spectrometry (SSMS) for the analysis of thin solid films. SSMS may have some advantages over other surface-analysis techniques (AES, RBS, SIMS, ESCA) when the microvolume has to be checked for nearly all elements of the periodic table simultaneously, the roughness of the sample surface prevents the application of other techniques, and better than semi-quantitative results are required though no suitable standards are available. Since it is possible[1] to keep the spark penetration depth below 0.1 μm, SSMS can be used for surface analysis and depth profiling and is more promising than sputtering techniques when layers of > 5 μm thickness are to be analysed.

EXPERIMENTAL

Measurements were performed with a double-focusing spark-source mass-spectrometer (JMS-01 BM-2, JEOL, Tokyo), equipped with an automatic spark-control system (MS-AS-01, JEOL).

As a measure of the breakdown voltage (U_{br}), the selected "anode voltage" was multiplied by the chosen spark level of the automatic spark controller (100% electrodes not sparking; 0% short circuit). The effective gap voltage is approximately 15 times this "breakdown voltage".

The spark gap was determined by measuring the distance between the electrodes at which stable sparking at a given U_{br} changed to short-circuit. The time required to reach the

first breakdown of each pulse train and the number of breakdowns per pulse train were determined by analysing the oscillograms of the voltage between the electrodes, stored in a fast-memory oscilloscope.

The weight loss of the electrodes sparked in an "as constant as possible" configuration in the ion-source was determined by weighing them before and after collection of a 100-nC charge. The time needed to collect this charge was also measured for each sample.

The influence of the width of the main slit on the times required to collect a charge of 1 nC was also investigated, with the position of the electrodes kept rigidly constant.

Three kinds of electrode geometry were used: graphite powder pressed in the form of cylinders (diameter 2 mm); for diamond, Al, Si, Ti, V, Fe, Co, Ni, Cu, Zn, Ge, Zr, Mo, In, Sn, Sb, W, Au and Pb: rods (cross section 2 × 2 mm); for Rh, Ag, Ta and Re: thin plates (0.1 mm thickness × 2 mm width). Most of the elements were more than 99% pure. In addition, rods (2 × 2 mm) of the following alloys were studied: CuBe (*ca.* 10 atom% Be), AlZn (25, 50 and 75 atom% Zn). The spark parameters were (unless otherwise stated): U_{br} 3.2 kV (80% spark level), repetition frequency 3 kHz, pulse width 20 μsec. The slit settings were constant: main slit 20 ± 5 μm, α- and β-slits 0.7 mm.

RESULTS AND DISCUSSION

For Al, Zr, Mo and Au the gap width (*g*) was measured as a function of U_{br}, and gave the relationship

$$U_{br} = ag^{0.61} \qquad (1)$$

The relative standard deviation (rsd) of the exponent of *g* was 8% and the value of 0.61 is in excellent agreement with that obtained by Slivkov[2] and by Germain and Rohrbach,[3] namely 0.625. The dependence of the gap width on the breakdown voltage is illustrated in Fig. 1 for some elements (our relative gap-width unit corresponds to about 7 μm). The
Fig. 1. Dependence of spark-gap width (relative units) on breakdown voltage for Al, Zr, Mo and Re.

relationship is practically linear in the range 10–100 μm.

From Fig. 1 it is clear that the gap width, at a given breakdown voltage, depends on the metal sparked, as has been reported by Ito et al.[4] Therefore, the gap widths measured at constant values of U_{br} were correlated with different physical parameters of the metals. The best correlation was found between g and the melting points (T_m, K) of the elements and the following equation could be derived:

$$g = bU_{br}^{1.6}/T_m \qquad (2)$$

The rsd of b was 19% (8 data points, for the elements Al, Ti, Cu, Zr, Mo, Rh, Re and Au). In Fig. 2 the relation between the gap width and the reciprocal of the melting point is shown for these 8 elements at a breakdown voltage of 3.2 kV. Similar relationships were also observed between g and T_m for breakdown voltages of 2.4 and 4.0 kV.
Davies and Biondi[5] measured the influence of initial anode and cathode temperatures on the breakdown voltage. Breakdown was seen to be completely independent of the local cathode-emitter temperature, but in all cases took place when the local temperature in the heated spot of the plane copper anode reached a critical value of 1100 ± 150 K. This temperature is about 250 K lower than the melting point of copper. Observations from arc melting measurements showed that surface melting already occurs at 200–300 K below the melting point of the metal.[6] These observations suggest that a relation between g and $(T_m - 250)$ would be more appropriate.

The energy liberated per spark pulse (E) is assumed[1] to be proportional to U_{br}^2; in order to correlate this energy with the volume of electrode material sampled per pulse or with the number of atoms consumed per pulse, it is necessary to know the number n_p of pulses (discharges) per pulse train, as a function of U_{br}. Therefore, the oscillograms for Au, obtained at different U_{br}-values, were analysed, the repetition frequency and the pulse width being kept constant (3 kHz and 20 μsec respectively). In Fig. 3 the results of such measurements are shown. The following relationship is valid in the region from 1 to 5 kV:

$$n_p = c/U_{br} \qquad (3)$$

For the 5 measurements the rsd of c was 10%. The same constant c was also obtained for Mo, indicating that c is an instrumental parameter.

The time necessary to reach (from the onset of the RF-voltage) the first breakdown of a pulse train (t_{br}) was also measured. For gold electrodes, a linear relationship between t_{br} and U_{br} was obtained:

$$t_{br} = d + eU_{br} \qquad (4)$$

A correlation coefficient of 1.00 for 6 pairs of values of t_{br} and U_{br} was obtained. Again, Mo yielded results identical with those for Au. In Fig. 4 the relation between t_{br} and U_{br} is illustrated.

The weight loss of Al, Cu, CuBe and Au electrodes was measured as a function of U_{br}, with the repetition frequency and pulse width kept constant (3 kHz, 20

Fig. 2. Relationship between gap width (1 relative unit is about 7 μm) and melting point for 8 metals measured at constant spark parameters (U_{br}, 3.2 kV, repetition frequency 3 kHz, pulse width 20 μsec).
Fig. 3. Number of discharges per pulse train as a function of breakdown voltage, measured for Au electrodes.
Fig. 4. Time taken to reach the first discharge (after the onset of the radio frequency voltage) as a function of breakdown voltage, measured for Au electrodes.

μsec). The gap width and the number of pulses per pulse train for these experimental conditions were calculated by using equations (2) and (3). Hence, from the time needed to collect a charge of 100 nC, the volume of Al, Cu, CuBe or Au sampled per pulse can be calculated. These results are listed in Table 1a. As stated above, the energy of each pulse was assumed to be proportional to U_{br}^2 and was correlated with the volume loss per pulse. The data were fitted to the equation

$$E = f(\mu m^3/pulse)^h \qquad (5)$$

The values of f, h and the correlation coefficients for the different metals investigated are listed in Table 1b. A mean value of 0.40 (standard deviation 0.07) was obtained for h. It should be noted that this equation only describes the relation between the energy per pulse and the volume effectively lost per pulse. The fraction of material originally vaporized but condensing later on the electrode surfaces could not be taken into account in the experimental approach. In this context it should be noted that variation of the angle between two identically shaped copper electrodes from 0° to 120° did not result in a measurable difference in volume consumed per pulse, indicating that the effect of condensation is not important for weight-loss studies. Combination of equations (1) and (5) then leads to

$$g = k\,(\mu m^3/pulse)^{0.33} = kr \qquad (6)$$

i.e., there seems to exist a direct proportionality relationship between the gap width g (in μm) and the "radius" r (in μm) of the sampled volume per pulse. The standard deviation of the exponent 0.33 in equation (6) was 0.07.

The weight loss of different metals, for collection of a charge of 100 nC, was measured, at constant spark parameters (U_{br}, repetition frequency, pulse width) and slit settings. The results of these measurements are given in Table 2. A log–log plot of the volume or number of atoms consumed per pulse train (pulse) vs. various physical parameters resulted in straight line

relationships. The best correlation was found with the melting point. In Fig. 5 a log–log plot of the number of atoms consumed per pulse train vs. the melting point is given. None of the points deviates from the straight line by a factor greater than 2.

However, we know from equation (2) that there exists a relationship between g and $1/T_m$ and from equation (6) that g and r are correlated, hence we can try to relate r to $1/T_m$:

$$r = l/T_m \qquad (7)$$

For the 22 elements investigated (other than carbon), an rsd of 21% was obtained for l, and a correlation coefficient of 0.96 between r and $1/T_m$. This is very satisfactory and no better correlation coefficients were obtained between r and other physical parameters: 0.68 vs. reciprocal of the boiling point, 0.55 vs. heat of melting, 0.67 vs. heat of vaporization, 0.75 vs. heat of sublimation, 0.43 vs. vapour pressure at 1600 K. This relationship (r vs. reciprocal of the melting point) is illustrated in Fig. 6 and the results are summarized in Table 2.

It is very surprising that the material consumption is independent of the vapour pressure of the elements. For example, Sn and Zn differ by a factor of 10^{12} in vapour pressure at their melting point, but the material consumption seems to be solely dependent on their melting point, judging from the agreement with equation (7) (Table 2). This probably means that there is no direct or initial evaporation of material from the solid electrodes. The elements, sparked as filaments, systematically yielded too high values for l (Table 2), the average difference being +36% from the mean value of l calculated for the other 21 elements. This, we think, is due to poor heat dissi-

pation and thermal contact to the bulk. The very large positive deviation observed for graphite powder may point to a different mechanism of sampling of material by the spark. Probably, for metals, the surface needs to be melted in order to form a "drop" which leaves the surface and evaporates on its way to the cathode (Davies and Biondi model[5]); for graphite powder, the material may be torn off as a solid particle (Cranberg model[7]).

Three observations may be made.
Fig. 5. Number of atoms consumed per pulse train vs. melting point at fixed spark parameters (U_{br} 3.2 kV, repetition frequency 3 kHz, pulse width 20 μsec).
Fig. 6. Radius of sampled volume *vs.* $10^4/T_m$ (K) for different elements at fixed spark parameters (U_{br} 3.2 kV, repetition frequency 3 kHz, pulse width 20 μsec); 1, 2 and 3 refer to Al alloys containing 25, 50 and 75 atom% Zn, respectively; $\bigcirc$ = graphite.

1. It is possible to spark graphite electrodes at moderately low U_{br} values, compared with those used for elements having nearly the same melting point.

2. Photomicrographs of the sparked area (metallographic microscope, scanning electron microscope) show, for *all* metallic samples, very strong evidence for a molten surface, whereas this can *not* be concluded for sparked graphite electrode surfaces (Fig. 7).

3. For carbon in the form of diamond the sampled volume is in much better agreement with equation (7) (Fig. 6). It is to be expected from the phase diagram of carbon that the surface of a diamond electrode will become graphitized during sparking but probably the resulting graphite layers will be more coherent than in an electrode of compressed graphite powder. In any case, the experimental data for diamond are in much better agreement than the graphite data with those for other elements.

Besides studying the material consumption for pure metal matrices, we also investigated the weight loss during sparking of AlZn alloys, containing 25, 50 and 75 atom% Zn. The values of r obtained after sparking under the standard experimental conditions obeyed the relationship given in equation (7). This is also illustrated in Fig. 6.

The effect of electrode temperature on material consumption was also investigated. The weight loss of 7 metals, sparked under the experimental conditions described, was measured, the electrode holders being cooled with liquid nitrogen. Assuming that the melting point of the elements studied here is virtually increased by this cooling, then we can calculate [using equation (7)] the radius and consequently the volume sampled for the different metals with and without cooling. The best agreement between experimental and calculated volume ratios (Table 3) was obtained assuming a virtual increase of melting point (with cooling) of 125 K. This is in good agreement with an

experimentally measured temperature difference between cooled and uncooled aluminium electrodes of 113 K (measured 210 sec after sparking), reported by Van Hoye[8].

For practical purposes it is necessary to know the weight loss per unit charge (expressed in nC), collected at the coulometer, for the given experimental conditions. The most important experimental parameters determining the time per nanocoulomb collected at fixed spark parameters, are the position of the electrodes with respect to each other and to the accelerating and main slits, the main slit-width and the α- and β-slit-widths. By measuring the time needed to collect 1 nC, as a function of the main slit-width (keeping all other spark parameters constant), we can calculate (using the data of Table 1a) the number of ions collected per number of atoms atomized (n_i/n_a). This approach was repeated at various breakdown voltages and the results are summarized in Tables 4a and 4b. It can be seen that the efficiency (n_i/n_a) increases with decreasing U_{br} (but analysis time increases) and with increasing main slit-width (but mass-resolution decreases). The optimum choice of experimental conditions depends on the particular analytical problem.

APPLICATIONS

Sample inhomogeneity

The error in the determination of an element in a sample depends on the analytical error, the weight of the sample analysed and the nature and history of the sample. This has been dealt with by Ingamells and Switzer,[9] who derived the equation

$$R = 100\sqrt{K_s/w} \qquad (8)$$

where R = relative standard deviation (%) for the determination of one component ("error-free" ana-

lytical method), K_s = sampling constant and w = weight of analytical subsample.

It is obvious from Tables 4a and 4b that if there is sufficient sample material available, it is best to spark at high U_{br} values and narrow slit settings: this gives a compromise between speed of analysis, resolution requirements and material consumed, in order to reduce the effects of sample inhomogeneities [equation (8)].

For the analysis of complex matrices by SSMS, photoplate detection is imperative and consequently a number of exposures must be made for different total collected charges, and hence different weights of sample consumed. For determination of the elemental concentrations, the results from the different exposures are used, each having its own subsample weight and inherent R. This is not commonly taken into account in SSMS analyses. If, on the other hand, one element has the same sampling constant in two different matrices, the relative standard deviation of

its determination may depend critically on the weight of the subsample in both matrices.

Depth profile analysis

From our results, it is possible to estimate the depth eroded, in the case of two identical electrodes:

$$d = \frac{VFt}{2A} = \frac{10^{12} W}{\rho A} \quad (9)$$

where d = depth eroded (μm), V = volume consumed per pulse train under the given experimental conditions (μm^3/pulse train), F = repetition frequency (Hz), 2 = factor taking into account that only one electrode is considered, t = erosion time (sec), A = area over which the electrode is sparked (μm^2), W = weight loss of the material (one electrode) and ρ = density of metal studied (g/cm^3).

We have observed that the weight loss per pulse train is independent of the repetition frequency. The effect of the pulse width was not investigated (all our measurements were made with a pulse width of 20 μsec). It is also important to note that in our spark-source mass spectrometer both electrodes gave the same weight loss. By using equation (9) and the results reported in Table 1a, we can select erosion rates ranging from a few nm/sec, or less, up to some μm/sec, depending on the specific problem and sample to be studied. This is a very wide dynamic range, which very few analytical techniques offer. It should, however, be noted that the minimum effective erosion depth is limited by the depth obtained with a single discharge[1] and the problem of depth resolution is not taken into account.

As an application we have measured the depth distribution profile of magnesium in aluminium, obtained by annealing an Al–AlMg diffusion couple at 462° for 525 hr. The magnesium profile in this particular sample is well known from lateral SIMS measurements[10] and extends over more than 2 mm.

For SSMS depth profiling, pure aluminium was used as a counter-electrode. The diffusion couple and the pure aluminium electrode were machined, and bars of 10 mm length, 1.0 mm thickness and 2.3 mm width were obtained. The erosion rate of both electrodes was estimated from the results in Table 1a. The volume loss per pulse was the same for both the Al and AlMg (3 atom% Mg) electrodes, within experimental error. The depth analysis was performed by using electrical detection in the magnetic peak-switching mode. The experimental parameters se-

*Spark parameters: normal, U_{br} 2.8 kV, repetition frequency 3 kHz, pulse width 20 μsec; micro, U_{br} 1.6 kV, repetition frequency 1 kHz, pulse width 20 μsec.

†Internal standard element (determined by instrumental neutron-activation analysis).

lected were U_{br} 3.8 kV, repetition frequency 3 kHz, pulse width 20 μsec, accelerating voltage 29 kV, main slit-width 100 μm, α- and β-slit-widths 2 mm, collector slit-width 500 μm. The collector current of the $^{24}Mg^+$ isotope was integrated until a charge of 10^{-11} C was collected at the total ion-beam monitor. The time per measurement point was about 10 sec.

By weighing the sample electrode before and after analysis it was possible to convert time into depth. The result of our measurements is shown in Fig. 8 and is compared with the previously obtained profile from lateral SIMS analysis. Fair agreement is obtained, the diffusion coefficient from our SSMS analysis being 7.6×10^{-10} cm²/sec, whereas with SIMS a value of 8.6×10^{-10} cm²/sec was found.

One difficulty associated with our measurements was that the counter-electrode had to be polished after some time of sparking, in order to maintain flat surfaces. This may become unnecessary if more refractory counter-probes are used.

Analysis of "microsamples"

With the help of the results reported above, the minimum volume or weight of a sample needed for analysis can be calculated and the appropriate spark parameters selected (low U_{br} values, slit settings as wide as possible). We were able to analyse 5-mg samples of graphite electrodes doped down to the sub-ppm level.[11] The results and spark parameters of a comparative study ("normal" *vs.* "micro") are summarized in Table 5.

Summary—An ion-exchange separation followed by spectrophotometric determinations is applied to some metamict minerals. These minerals, containing very high amounts of elements which present some problems to the analyst, such as uranium, titanium, niobium and rare-earth elements, are fused with potassium bisulphate, and the cooled melts dissolved in sulphuric acid. The solutions are passed through a series of three ion-exchange columns to separate those mineral-forming elements for which the colorimetric procedures suffer interference from the elements listed above. The procedure has been tested with a synthetic solution and with solutions of the minerals.

The term "metamict" means "after-mixed", implying either the rearrangement of the original structure to a new amorphous structure, or denoting an unusual non-crystalline condition for certain minerals of complex composition containing uranium and/or thorium, which in the course of time have passed from a truly crystalline state to an amorphous state.[1,2] Generally metamict minerals are chemically complex.[3] They characteristically show large-scale heterovalent isomorphism in both the cationic and anionic parts of their structures. Metamict minerals occur as oxides, phosphates and silicates. Most are multiple oxides containing niobium, tantalum and/or titanium. Owing to their particular properties, the identification of metamict minerals is difficult, and various physical and chemical methods have been tried, but many of them have limited efficiency.[4] On account of the complexity of the chemical composition of these minerals, complete chemical analyses are difficult and may be lengthy. Ti, Nb, U, Ta, Th, Zr and rare-earth elements (REE) are the major elements present.[5,6] Unfortunately these elements are the least sensitive for determination by atomic-absorption spectrophotometry, which is one of the most powerful and selective techniques in inorganic analytical chemistry. The best analytical methods for these elements in terms of sensitivity and accuracy are spectrophotometric: titanium with tiron,[7,8] niobium and tantalum with PAR,[9] zirconium, thorium, uranium and lanthanides plus yttrium with Arsenazo III.[10–13] Unfortunately there is mutual interference between these elements when these procedures are used. Moreover, because of the scarcity of these minerals, the analysis is ideally done on a single portion of sample. Hence two problems must be solved in reaching a complete chemical identification of these minerals: first, the complete dissolution of the sample, and second, the elimination of the interferences.

Sample dissolution

Acid decomposition is unable to dissolve the oxides of all the refractory elements present in metamict minerals such as betafites. When it is used, it is usually necessary to collect the insoluble residue, ignite it and fuse it with sodium carbonate or another suitable flux.[14] However, this may introduce into the solution a large amount of foreign ions which will interfere in the subsequent separation and determination procedures.

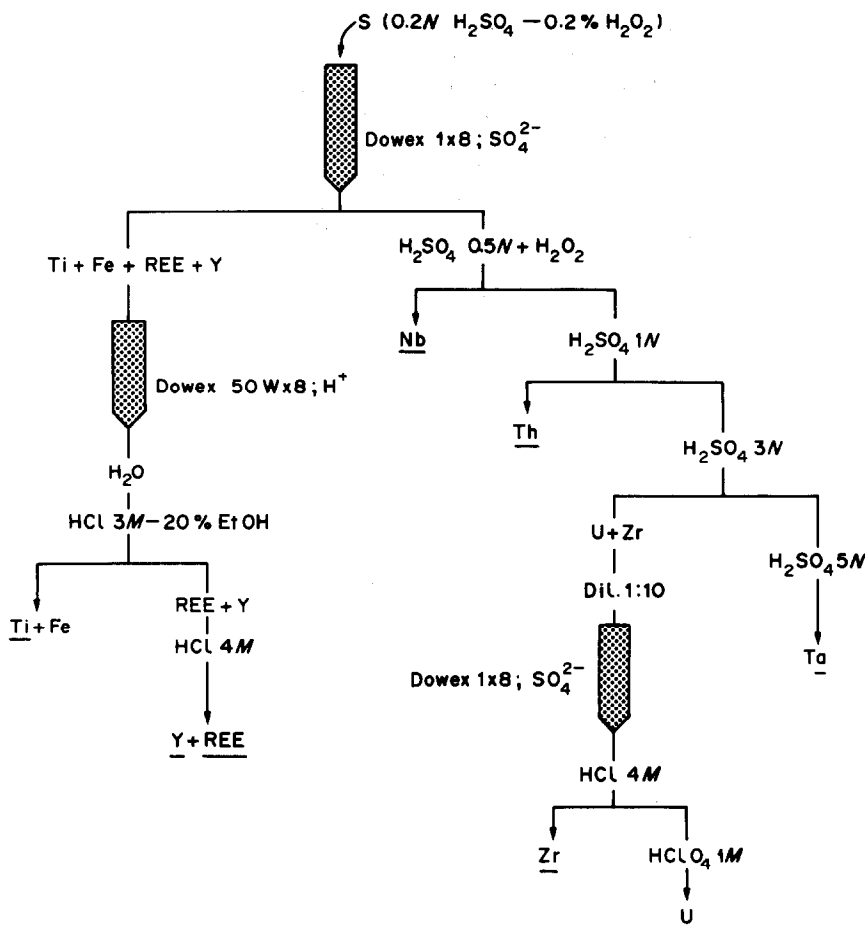
Hitchen and Zechanowitsch[15] have used several procedures for the decomposition of low-grade uranium ores, including potassium pyrosulphate fusion followed by leaching with dilute sulphuric acid, which Bock[16] considers the most powerful method for dissolving refractory and rare-earth oxides. We have


Fig. 1. Scheme of separation procedure.

chosen to use this last method partly because of its power, and partly because it gives a convenient solution matrix for the subsequent separation.

Ion-exchange separations

Several authors[14,15,17-24] have studied separation methods for complex mixtures of REE, zirconium, hafnium, thorium and scandium, based on solvent-extraction with tri-n-butyl phosphate or liquid anion-exchangers in malonate media. However, these procedures generally relate only to pure solutions of these metals or present some difficulties in extraction of one or more of these elements when they are all present in the sample.

Ion-exchange seem to be the most powerful technique for complete separation of these elements in a single sample.

Because of the decomposition procedure chosen we examined only the separation procedures using sulphuric acid media, and some other schemes[25-27] for the isolation of refractory or rare-earth elements in rocks and minerals were not considered. Kiriyama and Kuroda[28] have described an ion-exchange separation of zirconium, thorium and uranium in silicate rocks, followed by determination with Arsenazo III.

The sample, dissolved in sulphuric acid, was passed through an anion-exchange column, and Th, Zr and U were successively eluted with sulphuric, hydrochloric and perchloric acids. In this procedure Ti, REE and (presumably) Y, and the silicate matrix are not retained; no mention was made of the behaviour of niobium and tantalum (which are main constituents of betafite minerals).

Strelow and Bothma[29] described an anion-exchange separation on a strongly basic resin for elements in sulphuric acid medium and gave the anion-exchange equilibrium coefficients for 52 elements. The coefficients for elements with strong hydrolytic tendencies, such as tantalum and niobium, were determined for media containing hydrogen peroxide. Elution curves were given for the systems Y(III)-Th(IV)-U(VI)-Mo(VI) and Th(IV)-Hf(IV)-Zr(IV)-Mo(VI) to demonstrate the potential of the system.

The chromatographic behaviour of species such as Ti(IV), Fe(II), Fe(III), REE(III) and Y(III) may be inferred from the separations described in a previous paper.[30] The separation procedure reported earlier for use in the determination of barium in silicates allows complete separation of the major and minor elements

(such as titanium and iron), present in a common silicate rock, from a group of trace elements, including yttrium and rare-earth elements (plus strontium and barium). The entire separation is done on a cation-exchanger and allows accurate determination of titanium (in presence of large amounts of iron) and of the REE plus yttrium. The yttrium can be separated from the individual REE if desired,[31] but this can be omitted to simplify the procedure.

Separation procedure

The proposed separation scheme (shown in Fig. 1), is based on the three procedures[28–30] mentioned above.

The sample solution (in 0.2N sulphuric acid) is mixed with hydrogen peroxide to make the separation of elements such as niobium and tantalum easier.[9,29] The solution is passed through a column of Dowex anion-exchanger: titanium, REE, yttrium and the major elements of the silicate matrix are not retained, and are collected on a Dowex cation-exchange column to separate REE and yttrium from the other matrix elements.[30]

The elements retained on the anion-exchanger are successively eluted with various sulphuric acid media: niobium with 0.5N acid plus hydrogen peroxide, thorium with 1N acid, uranium and zirconium with 3N acid and tantalum with 5N acid. Uranium and zirconium are separated on another anion-exchange column by successive elution with hydrochloric acid and perchloric acid.[28] These elements are then all determined spectrophotometrically.

EXPERIMENTAL

Reagents

Triethanolamine buffer. Mix 15 g of triethanolamine and 3.3 ml of concentrated nitric acid and dilute to 200 ml with water.

"Niobium buffer". Dissolve 40 g of ammonium acetate and 2.5 ml of glacial acetic acid with water and dilute to 500 ml.

"Titanium buffer". Dissolve 136 g of sodium acetate trihydrate in 1000 ml of water and add 390 ml of glacial acetic acid.

Procedure

Weigh accurately 1 g of finely powdered sample into a platinum crucible. Add about 3 g of potassium bisulphate and mix it with the sample. Insert the crucible in a suitably sized hole in an asbestos board (to avoid overheating of the walls) and heat it with a Bunsen burner until a clear melt is obtained. Allow the crucible to cool, add 3 ml of concentrated sulphuric acid and warm until a clear solution is obtained. Cool, transfer this solution and 1 ml of 100-volume hydrogen peroxide into a 500-ml standard flask and dilute to volume with water.

Pass half this solution at a flow-rate of 3.5 ± 0.05 ml/min through a borosilicate glass tube (15 mm bore) filled with an 18-cm long column of Dowex 1 × 8 resin (200–400 mesh, sulphate form), and wash the column with 0.2N sulphuric acid/0.2% hydrogen peroxide solution, collecting the effluent in a Teflon beaker and then passing it through a column of Dowex 50W × 8, as described earlier.[30]

Elute titanium and other matrix elements (*i.e.*, iron, sodium, potassium, calcium and magnesium) from the Dowex 50W × 8 with 250 ml of 3M hydrochloric acid

containing 20% v/v ethanol, and determine the titanium by the spectrophotometric tiron procedure.[7,8] Elute yttrium plus REE with 4M hydrochloric acid and determine the whole group by the Arsenazo III procedure.[13,37]

Elute the elements from the anion-exchange column successively, niobium with 100 ml of 0.5N sulphuric acid/0.2% hydrogen peroxide solution, then thorium with 150 ml of 1.0N sulphuric acid, uranium plus zirconium with 200 ml of 3.0N sulphuric acid and finally tantalum with 100 ml of 5N sulphuric acid. Determine niobium with PAR,[9,32] thorium with Arsenazo III,[13,31] and tantalum with PAR.[9] Separate uranium and zirconium by passing their solution through another Dowex 1 × 8 column and eluting zirconium with 100 ml of 4M hydrochloric acid, and then uranium with 100 ml of 1M perchloric acid. Determine both with Arsenazo III.[10,12]

RESULTS AND DISCUSSION

The scheme was tested with synthetic sample solutions made from pure salts, with the elements in the concentration ratios expected for natural samples. The results obtained are summarized in Table 1.

Table 1. Results of analysis of a standard solution with composition similar to "betafite" samples, by the ion-exchange procedure (6 replicates)

Element	Taken, mg	Found, mg	Standard deviation, mg	Mean recovery, %
Si	2.00	1.90	0.03	95.0

L.O.I.†	10.20	12.00	11.30
Total	99.9	100.0	99.9

*Expressed as Ce$_2$O$_3$.
†Loss on ignition.

Three betafite samples were then analysed: B1 from the Ambatofotsy–Soavinandriana pegmatite of Madagascar, B2 from the Antsirabe–Vinaninkarena pegmatite and B3 from the pegmatite of Tongafeno Mountain (southern part of Betafo, Madagascar).

The results (Table 2) show good agreement with the literature data.

The minor elements, such as Si, Ca, Mg, Fe, Mn, Pb and Al, were determined by the classical procedure and AAS. They are not important for betafite characterization, and were determined only in order to complete the analysis of the samples studied.

The proposed method is useful for the chemical analysis of minerals (such as betafites) which are of great scientific and economic importance but present severe problems when analysed by purely instrumental techniques.

EXTRACTION OF RUTHENIUM THIOCYANATE AND ITS SEPARATION FROM RHODIUM BY POLYURETHANE FOAM

Sargon J. Al-Bazi and Arthur Chow

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba,
Canada R3T 2N2

Summary—Conditions for the formation and extraction of the thiocyanate complex of ruthenium are reported. Distribution coefficients of more than 10^4 and a capacity of about 0.24 mole per kg of foam were obtained. The effect of the chloride salts of various univalent cations on the extraction of $Ru(SCN)_6^{3-}$ indicated that the efficiency of ruthenium extraction depends on how well the cation fits into the polyether segment of the polyurethane foam, which agrees with the "cation-chelation" mechanism. The separation of ruthenium and rhodium indicated that more than 95% of the rhodium remained in the aqueous phase and about 95% of the ruthenium was retained by the polyurethane foam and could be easily recovered.

The oxidation of ruthenium to the volatile tetroxide, followed by distillation, has been widely used for its separation from other platinum metals (except osmium).[1] For preconcentration of the metal, the tetroxide can be extracted into carbon tetrachloride,[2–4] chloroform[2] or mepasine.[5] The chlorocomplex can be extracted by means of various organophosphorus compounds[6] and amines.[7–10] The thiocyanate complexes are also extractable.[11–15]

The separation of rhodium and ruthenium is of interest to radiochemists since rhodium is a daugher of ruthenium by beta decay. It is usually done by extraction of ruthenium tetroxide into carbon tetrachloride.[16–18]

The purpose of the present work was to study the extraction of the thiocyanate complex of ruthenium by means of polyether-based polyurethane foam, and the separation of ruthenium from rhodium.

EXPERIMENTAL

Apparatus and reagents

A Varian 634 spectrophotometer and a Fisher Accumet model 520 pH-meter were used.

Ruthenium trichloride [$RuCl_3 \cdot 3H_2O$] and sodium hexachlororhodate(III) [$Na_3RhCl_6 \cdot 12H_2O$] were supplied by Johnson-Matthey Chemicals Ltd. All other chemicals were of analytical grade. Polyether-type polyurethane foam (No. 1338 M) was obtained from G. N. Jackson Ltd, Winnipeg, Manitoba, and washed by the procedure previously reported.[19]

A $2.5 \times 10^{-3}M$ stock solution of ruthenium(III) was prepared by dissolving the chloride in $0.1M$ hydrochloric acid. A $3.0M$ stock solution of potassium thiocyanate was prepared in doubly distilled demineralized water.

Extraction procedure

A known volume of the stock ruthenium chloride solution and the desired amount of thiocyanate were mixed, diluted to about 60 ml, adjusted to pH 2.5 ± 0.1 and transferred quantitatively to a 100-ml standard flask. The solution was heated at 90° for a measured time, cooled to room temperature in ice-water and finally diluted to volume. Then

99 ± 1 mg of the foam was repeatedly squeezed in 95 ml of this solution for a minimum of 10 hr as described previously.[19]

The percentage extraction (%E) was calculated by measuring the metal concentration before and after extraction. The distribution coefficient (D, l./kg) was calculated from the concentration ratio of metal in the foam to metal left in solution.

RESULTS AND DISCUSSION

First we established the conditions for maximum formation of the ruthenium–thiocyanate complex in aqueous medium. A fixed amount of ruthenium (5.35 μmole) and appropriate amounts of the other reagents were diluted to about 30 ml, adjusted to pH 2.5 ± 0.1, heated at 90° for the desired time, then immediately cooled in ice-water to room temperature. The violet-blue solution was then diluted to 50 ml and its absorbance at 590 nm, which has been assigned to the $Ru(SCN)_6^{3-}$ complex,[20–22] was measured.

Varying the heating time for solutions containing 30 mmole of thiocyanate (Fig. 1) indicated that heat-
Fig. 1. Influence of time of heating on the formation of ruthenium–thiocyanate complex. Time after solution preparation: (○) immediately, (△) 1 day, (□) 2 days, (●) 9 days.

ing for 6 min is enough for maximum formation of
the complex. With shorter heating times, complex
formation was incomplete, and subsequent reaction
at room temperature very slow, up to 9 days being
required to reach an equilibrium value. This experi-
ment also showed that the $Ru(SCN)_6^{3-}$ complex
formed was stable for up to 9 days. In the presence
of 100 mmole of lithium chloride in the reaction
mixture, the absorbance at 590 nm was 0.353 with no
heating, rising with heating time to a maximum of
0.476 after 6 min of heating and then decreasing to
0.445 after 9 min of heating. Since heating the
solution for 6 min at 90° in presence or absence of
lithium chloride is enough for the maximum for-
mation of $Ru(SCN)_6^{3-}$, this was used as the optimum
time for further studies.

The effect of increasing the amount of lithium
chloride present, on the formation of the complex in
solutions containing 30 mmole of thiocyanate and
heated for 6 min, was to increase the absorbance from
0.451 with no lithium chloride added to 0.478 with
100 mmole or more added. The presence of sufficient
neutral salt is not only important in the formation of
the $Ru(SCN)_6^{3-}$ complex, but was also recommended
by Shlenskaya and Piskunov[23] for obtaining constant
and reproducible values of the absorbance in studies
on the reaction of Ru(IV) with thiocyanate.

Varying the hydrochloric acid concentration in
solutions containing 15 mmole of thiocyanate caused
a decrease in absorbance from 0.397 for 0.1M hydro-
chloric acid medium to 0.303 for 0.5M and 0.125 for
1M acid (measured after filtration of the brownish
cloudy solution). This decolorization of the solution
has been attributed to decomposition of the
ruthenium–thiocyanate complex[15] and to reduction[22]
of $Ru(SCN)_6^{3-}$ to $Ru(SCN)_6^{4-}$. The reduction process
was confirmed in our study by the fact that addition
of hydrazine hydrate to the violet-blue solution of the
ruthenium–thiocyanate complex turned it yellow (the
same change in colour in molten thiocyanate medium
was observed by De Haas[22]). Addition of hydrogen
peroxide to the yellow solution turned it back to
violet-blue.

Since ruthenium has a high tendency to hydro-
lyse,[24-27] the stability of the ruthenium–thiocyanate
complex was studied in solutions containing 30
mmole of thiocyanate and adjusted to different pH
values with lithium hydroxide after preparation of
the complex. The absorbance decreased from 0.453 at
pH 2.5 to 0.398 at pH 5.5 and to 0.320 at pH 8.3. The
solutions were therefore adjusted to pH 2.5 ± 0.1 in
the extraction studies.

Extraction of ruthenium(III)

Under the optimum conditions for formation of
the ruthenium–thiocyanate complex, a study was
made of the effect of various parameters on the
distribution of the complex between the polyurethane
foam and the aqueous phase. The addition of hydro-
chloric acid *after* the heating of solutions that were
Fig. 2. Effect of hydrochloric acid (added after heating the
solution) on ruthenium extraction. Thiocyanate concen-
tration: (○) 0.1M, (●) 0.4M.

initially 0.4M in thiocyanate and 2M in lithium
chloride (Fig. 2) caused a slow decrease from 83%
extraction (log D = 3.67) with no hydrochloric acid
added to 53% extraction (log D = 3.04) at 1M acid
concentration. The absorbance of these solutions at
590 nm indicated that $Ru(SCN)_6^{3-}$ was stable at
hydrochloric acid concentrations up to 0.7M but was
partly decomposed (by 8%) in 1.0M hydrochloric
acid. The absorption spectra did not show bands
at 284 and 342 nm, which indicates that
5-amino-1,2,4-dithiazole-3-thione was not formed in
the solution.[28] Therefore the observed decline in
degree of extraction with increase in acid concen-
tration up to 0.7M is probably due to the formation
and subsequent extraction of thiocyanic acid. When
the experiment was repeated with 0.1M thiocyanate
and no lithium chloride present, the extraction
(Fig. 2) increased sharply from 49% (log D = 2.96)
with no hydrochloric acid added, to 80% (log
D = 3.59) at 0.1M acid concentration and then more
slowly to 95% (log D = 4.28) at 1.0M acid concen-
tration. The absorbance of these solutions at 590 nm
increased only by 4% with increasing acid concen-
tration from zero to 1.0M. Therefore hydrochloric
acid mainly influences the distribution of the
$Ru(SCN)_6^{3-}$ complex between the foam and the liquid
phase.

A comparison of the two curves in Fig. 2 shows
that the effect of hydrochloric acid on the extraction
of ruthenium is highly dependent on the thiocyanate
concentration of the solution. Therefore at the opti-
mum thiocyanate concentration for formation of the
$Ru(SCN)_6^{3-}$ complex, it is more efficient to perform
the extraction at low acidity, and this can only be
successful if the complex is extractable through the
"cation–chelation" mechanism.[29,30] Addition of po-
tassium chloride after the heating of ruthenium solu-
tions (at pH 2.5 ± 0.1; 0.4M initial thiocyanate and
2M lithium chloride) increased the extraction from
82% (log D = 3.63) with no potassium chloride ad-
ded, to 96% (log D = 4.37) at 1.0M potassium chlo-
ride. The absorbance at 590 nm was independent of
potassium chloride concentration. Therefore, the
Fig. 3. Effect of initial thiocyanate concentration on the formation and the extraction of ruthenium–thiocyanate complex: (●) formation, (○) extraction.
Fig. 4. Effect of salt concentration on the distribution of ruthenium–thiocyanate complex: (○) NH_4Cl, (□) KCl, (●) LiCl.

effect of potassium chloride is mainly on the distribution of $Ru(SCN)_6^{3-}$.

The dependence of ruthenium extraction on the thiocyanate concentration in solutions at pH 2.5 ± 0.1 that were $2M$ in lithium chloride (added before heating) and $1M$ in potassium chloride (added after cooling to room temperature) is shown in Fig. 3. At zero thiocyanate concentration, less than 0.5% of the metal was extracted and the absorption spectrum showed absorbances at 386 and 460 nm, which have been related to a mixture of $[RuCl_m(H_2O)_{6-m}]^{3-m}$ ions $(m = 0–6)$ by Shukla.[31] The results also indicate that 97% (log $D = 4.56$) of the ruthenium was extracted from a solution initially $0.1M$ in thiocyanate, but only 89% (log $D = 3.92$) from $1.0M$ thiocyanate medium. The absorbance at 590 nm (Fig. 3) increased by 9% when the thiocyanate concentration was increased from 0.1 to $0.4M$, then remained constant up to $0.8M$ thiocyanate and decreased again by 9% at $1M$ thiocyanate. The decrease in absorbance at high thiocyanate concentrations is mainly due to reduction by thiocyanate.[22,23] Therefore, the decrease in the extraction of ruthenium may be due to interference by thiocyanate, as shown for palladium,[33] and/or to the formation of less extractable species.

The effect of changing the ruthenium concentration on its extraction from solutions that were $0.8M$ in initial thiocyanate, and $2M$ in lithium chloride (added before heating) and $1M$ in potassium chloride (added after cooling), indicated that the amount of metal on the foam was almost linearly proportional to the amount left in solution, up to $8 \times 10^{-5}M$ initial ruthenium, and then started to level off with increasing initial ruthenium concentration, reaching a maximum value at $3 \times 10^{-4}M$ ruthenium. At higher concentrations, the amount of ruthenium on the foam remained constant, indicating that 0.24 mole/kg [24.3 g/kg] is the capacity of the polyether-type polyurethane foam for the extraction of ruthenium under the given conditions.

A qualitative study on the recovery of ruthenium from the foam showed that acetone can be used for this with high efficiency.

To confirm that the ruthenium is extracted by the "cation–chelation" mechanism, the effect of various chlorides was investigated and the results (Fig. 4) showed that though even $1M$ lithium chloride had only little effect on the extraction of ruthenium, on the other hand the extraction from solutions containing potassium or ammonium chloride increased linearly with salt concentration up to $0.4M$ and then more gradually at higher concentrations. A significant increase in the extraction of $Ru(SCN)_6^{3-}$ was also observed from thiocyanate solutions that were $1M$ in sodium chloride. The absorbance values at 590 nm were almost equal, suggesting that the effect of the salt is mainly on the distribution of the $Ru(SCN)_6^{3-}$ complex between the foam and the aqueous phase.

When the distribution coefficient for the 0.1, 0.5 and $1.0M$ salt solutions (only $1.0M$ for sodium chloride) are plotted as a function of cation size (Fig. 5), the efficiency of extraction is seen to increase with increasing ionic radius. Since these results are similar to those obtained for the extraction of the $Pd(SCN)_4^{2-}$ complex[19,33] and the $Pt(SCN)_4^{2-}$ com-
Fig. 5. Effect of the size of various univalent cations on the distribution of ruthenium–thiocyanate complex. Salt concentration: (□) $0.1M$, (△) $0.5M$, (○) $1M$.

plex,[34] it can be concluded that the "cation–chelation" mechanism is also the major mode of $Ru(SCN)_6^{3-}$ extraction into polyurethane foam.

Separation of ruthenium and rhodium

Several differences in the formation as well as the distribution of the thiocyanate complexes of ruthenium and rhodium were observed. For example, 6 min of heating at 90° was found enough for maximum formation of the $Ru(SCN)_6^{3-}$ complex, whereas heating for 30 min was required[35] for $Rh(SCN)_6^{3-}$. A minimum of 2M hydrochloric acid was required for the extraction of rhodium,[36] but a pH of about 2.5 was sufficient for the extraction of ruthenium. Furthermore, the rhodium extraction increased with increasing hydration number of the cation present[35] whereas the ruthenium extraction decreased. On this basis, the optimum conditions for the separation of these two metals were determined.

The minimum heating time for maximum formation of $Ru(SCN)_6^{3-}$ in the presence of ammonium chloride was found by heating about 30 ml of solution (at pH 2.5 ± 0.1 and containing 5.35 μmole of ruthenium, 30 mmole of thiocyanate and 8.03 g of ammonium chloride) at 90° for 4, 5 or 6 min, immediately cooling in ice-water to room temperature, diluting to 50 ml, and measuring the absorbance at 590 nm. Absorbances of 0.452, 0.456 and 0.459 were obtained at 4, 5 and 6 min, respectively. Therefore, a 5-min heating of the solution before extraction was chosen in the separation of ruthenium and rhodium.

Since the efficiency of the separation depends on the differences in the amounts of $Ru(SCN)_6^{3-}$ and $Rh(SCN)_6^{3-}$ complexes formed, the time elapsed between preparation of the ruthenium complex and its extraction may be critical. To determine the optimum time, a solution (about 60 ml) at pH 2.5 ± 0.1, containing 10.7 μmole of ruthenium, 60 mmole of thiocyanate and 16.05 g of ammonium chloride was heated at 90° for 5 min, cooled in ice-water to room temperature, and diluted to 100 ml. A foam cube weighing 0.3 g was then equilibrated with 95 ml of this solution for a selected period of time and the degree of extraction determined. The degree of extraction was found to rise sharply with extraction time to 93% for 19 min then more slowly to 97% for 1 hr, remaining practically constant for longer times. Therefore, 1 hr was chosen as the optimum period of extraction.

The effect of different concentrations of rhodium on the extraction of ruthenium under the optimum conditions was investigated. The results in Table 1 indicate that rhodium in up to threefold molar ratio to ruthenium has almost no effect on the extraction. An atomic-absorption study showed that less than 5% of the rhodium was extracted under these conditions.

CONCLUSIONS

The relatively high distribution coefficients indicate that polyether-type polyurethane foam is highly efficient for the extraction of hexathiocyanatoruthenate(III), compared to many organic solvents.[3,6,8] Furthermore, the ability of the foam to extract ruthenium at low acidity (pH = 2.5 ± 0.1) minimizes the tendency of thiocyanate to decompose[37] and to trimerize.[28] The low acidity also reduces interference by thiocyanic acid and the trimerization product, 5-amino-1,2,4-dithiazole-3-thione, which are produced in solutions having high thiocyanate and acid concentrations.[19,33-36]

The separation of rhodium and ruthenium by polyurethane foam is a useful alternative to the commonly used methods[16-18] in which ruthenium is oxidized to the tetroxide. Small losses of the metal can be caused by volatilization of RuO_4 from the organic solvent[4] and by reduction of the tetroxide by the extractant.[4,17] The use of polyurethane foam in the separation of ruthenium and rhodium is also important because no reasonable ion-exchange methods have been reported, on account of the labile character of the chloro-complexes of these two metals toward aquation.

STUDIES ON THE LANTHANUM ARSENATE ION-EXCHANGER: PREPARATION, PHYSICOCHEMICAL PROPERTIES AND APPLICATIONS

Ashis K. Mukherjee* and Suchitra K. Mandal

Department of Chemistry, Presidency College, Calcutta 700073, India

Summary—The cation-exchange behaviour of lanthanum arsenate has been studied. This paper reports the preparation and physicochemical properties of the exchanger. Its analytical utility is compared with that of other arsenate exchangers. Some practical analytical applications are described.

The analytical applications of synthetic ion-exchangers[1,2] have received considerable attention owing to their high degree of selectivity for certain elements,[3] and resistance to nuclear radiation. Of the various inorganic ion-exchangers that have been studied, those based on lanthanum are probably the least investigated. The literature reports deal with the arsenates of Zr, Ti, Cr, Sn, Th, Ce, Fe, Nb and Ta; we now add lanthanum arsenate to the list.

EXPERIMENTAL

Reagents

All reagents and chemicals were of analytical grade. Doubly distilled water was used throughout.

Preparation and composition of the exchanger

The exchanger was synthesized in two ways. In the first, $0.1M$ lanthanum nitrate solution in $0.1M$ nitric acid was mixed dropwise in various proportions with $0.1M$ disodium hydrogen arsenate solution, and the precipitate was digested. In the other, $0.1M$ lanthanum nitrate solution in $0.1M$ nitric acid was added in different proportions to $0.1M$ sodium arsenate solution in presence of excess of hydrogen peroxide, and the precipitate was digested on a water-bath. The products were allowed to stand with the mother liquor for 24 hr, then filtered off, washed, and dried first in air, and finally over anhydrous calcium chloride in a vacuum desiccator. They were converted into the H^+-form with $1M$ nitric acid and dried as before.

*To whom correspondence should be addressed.

The powdered product (0.5 g) was dissolved in 25 ml of concentrated nitric acid, and the mixture was evaporated to small volume on a water-bath to expel oxides of nitrogen, and diluted to 100 ml with water. The lanthanum was precipitated as oxalate and ignited at 800° to the oxide,[4] which was weighed. For the arsenate estimation, 0.5 g of exchanger was dissolved in 25 ml of concentrated hydrochloric acid, and arsenate was determined iodometrically in $4M$ hydrochloric acid medium. A separate 0.5-g sample was heated at 800° for 1 hr, and the $La:H_2O$ ratio calculated from the weight loss, according to Alberti *et al.*[5] Details of the syntheses and composition are given in Table 1.

Characteristics

Chemical stability (Table 2). The solubility was determined by shaking 0.5 g of exchanger with 100 ml of solvent for 15 hr, then determining lanthanum in the solution spectrophotometrically[4] at 550 nm with sodium alizarin sulphonate in acetate buffer, and arsenate at 840 nm by the Molybdenum Blue method.

Potentiometric titration (Fig. 1). A 0.5 g sample was shaken with 100 ml of $2M$ sodium (or potassium) chloride for 16 hr and the mixture was titrated potentiometrically with standard alkali.

Ion-exchange capacity. One-g portions of specimen B-4 (H^+-form) were shaken with 100 ml of various metal ion solutions for 2 days with intermittent shaking, and the liberated hydrogen ions were titrated; the exchange capacities are given in Table 3.

The effect of the salt concentration and the time of equilibration on the apparent exchange capacity of lanthanum arsenate are shown in Figs. 2 and 3, respectively. The exchange capacity was also determined for samples of the exchanger that had been heated to different temperatures and compared with that for similarly treated ferric arsenate[6] and tantalum arsenate[7] (Fig. 4).

Table 1. Details of synthesis and composition of lanthanum arsenate

Batch	Reactants	Volume ratio La/As, v/v	Stirring time, hr	Temp., °C	pH of mother liquor	Composition, La:As:H₂O	Ion-exchange capacity for Na⁺, meq/g
B-1	0.1M lanthanum nitrate in 0.1M nitric acid + 0.1M disodium hydrogen arsenate	1:2	4	27 ± 2	1.8	1:1.18:1.17	0.67

All batches were practically completely insoluble in doubly distilled water, 2M NaOH, 5% NH$_4$NO$_3$ solution, 2N oxalic acid and acetylacetone.

Break-through capacity (Table 4). This was determined in the usual way with a column of 5 g of 100–200 mesh exchanger B-4 (H$^+$-form) and 0.01M solutions of the metal ions.

Distribution coefficients. The K_D values were determined with preparation B-4, 0.5 g of exchanger being equilibrated with 100 ml of $\sim 10^{-3}M$ test solution by intermittent shaking during two days. After equilibration, the aqueous phase was analysed, colorimetrically[8,9] for metal ions giving high K_D values and complexometrically[8,10] for the others. The results are given in Table 5.

Ion-exchange separations. Some binary mixtures of cat-ions were separated on a column of 5 g of 100–200 mesh exchanger (B-4) with eluents chosen on the basis of the distribution coefficient. Hg(II) was separated from Pb(II), Mn(II), Cd(II), Cu(II) and Ce(III); Zn(II) from Pb(II) and Mn(II); Ni(II) from Pb(II), Mn(II), Cd(II) and Ce(III); Co(II) from Pb(II) and Mn(II); Mg(II) from Cd((II), Mn(II) and Pb(II), all with < ± 1% error. Certain ions in solutions obtained from copper–nickel alloy, ferromanganese and stainless steel were also separated, but there was difficulty in separating Fe(III) from Cu(II) or Cr(III), since their K_D values are similar. It is necessary first to separate these pairs of ions from others with 0.5M ammonium nitrate as eluent and then to separate the components of the pair by ion-exchange in phosphoric acid medium; the iron(III) phosphate complex is sorbed and the chromium or copper comes out in the effluent. Iron can then be eluted with 0.05M hydrochloric acid.

The copper–nickel alloy (0.5 g) was dissolved in hot 6M hydrochloric acid, a few drops of concentrated nitric acid were added, then the mixture was boiled to remove oxides of nitrogen, cooled and diluted to 250 ml. Ferromanganese (0.5 g) was dissolved in a mixture of concentrated hydro-chloric acid (20 ml) and nitric acid (5 ml), then the solution was evaporated almost to dryness, cooled and diluted to 250 ml. Stainless steel (0.5 g) was dissolved in hot 6M hydro-

chloric acid, then iron(II) was oxidized with 20 drops of concentrated nitric acid. The solution was evaporated to small volume, cooled and diluted to 250 ml with water. Appropriate fractions were analysed and the results are given in Table 6.

RESULTS AND DISCUSSION

Having high exchange capacities and inertness towards dilute acids, specimens B-2 and B-4 were the most suitable as exchangers. The solubility in acids decreases considerably if the exchanger is heated to 200–300° before use. Table 1 shows that the ex-changer is non-stoichiometric, presumably because of partial polymerization or protonation of the arsenate.

Table 4. Breakthrough capacity of lanthanum arsenate (B-4)

Ion	System	Breakthrough capacity, $meq/5g$
Ni^{2+}	Water	1.14
Co^{2+}	Water	1.36
Zn^{2+}	Water	1.44
Cu^{2+}	Water	1.76
Cu^{2+}	pH 2 (nitric acid)	1.06

The potentiometric titration (Fig. 1) characterizes the exchanger as having two types of proton-binding sites, resembling crystalline zirconium arsenate in this respect.[1] The breaks in the potentiometric curves suggest that in the equilibration with sodium or potassium chloride solution only the "strong acid" protons are exchanged, and that these give the endpoint break at about pH 4.2; the "weak acid" protons are only exchanged on further titration, by a "push–pull" mechanism of ion-exchange and neutralization. Hence the ion-exchange capacity rises with increasing pH of the solution. The following affinity sequences have been found for univalent and bivalent cation series, with the lanthanum arsenate ion-exchanger.

$$Li^+ < Na^+ < NH_4^+ < K^+ < Cs^+$$

$$Mg^{2+} < Ni^{2+}(Co^{2+}) < Zn^{2+} < Cu^{2+}$$
$$< Cd^{2+} < Mn^{2+} < Pb^{2+}.$$
The sequence for univalent ions resembles that for ion-exchangers of cross-linked type. The exchange capacity (especially for univalent ions) under similar conditions is directly related (Table 3) to the radii of the non-hydrated ions in a homovalent series. This suggests that the hydrated ions of smaller radii are strongly sorbed, since the radii of the hydrated ions tend to decrease with atomic number and the coulombic interaction would increase. However, this is
Fig. 3. Time equilibrium curve.
Fig. 4. Effect of heat treatment of exchanger on the exchange capacity. ●, Tantalum arsenate; ○, ferric arsenate.

less evident for the bivalent cations, where not only the ionic size is important, but the electronic structure and polarizing power of the metal ions, together with the solubility products of the metal arsenates, also play a part. Similar irregularities (for which the solubility product factor seems to play a dominating role) have been observed for stannic arsenate.[1]

Stainless steel	Ni	D.D.W.	30	1.03	1.03	0.0
(Indian Standard	Cr	A	45[a]	2.07	2.09	+1.1
Institution No. 302)	Fe	A	80[b]	8.01	7.90	−1.4
	Mn	B	35	0.232	0.228	−1.7

*D.D.W. = Doubly distilled water. B = 1M NaNO$_3$ in 0.01M HNO$_3$. A = Cu(II) and Fe(III) or Cr(III) and Fe(III) eluted simultaneously with 0.5M NH$_4$NO$_3$, leaving Mn(II) on the column. Then 0.1–3 ml of 1N H$_3$PO$_4$, depending on the concentration of iron, was added to the mixture of Cu(II)–Fe(III) or Cr(III)–Fe(III) and this was passed through the second resin bed where Cu(II) or Cr(III) was not retained, and the iron sorbed was eluted with 0.05M HCl.
[a]Phosphoric acid solution was used as final eluent for Cu(II) and Cr(III); [b]0.05M HCl was used as final eluent for iron.

Thermal treatment has less effect on the exchange capacity of this material than on many similar materials such as ferric arsenate[6] or tantalum arsenate,[7] and lanthanum arsenate resembles stannic arsenate[11] in this respect.

The concentration of salt solution and the equilibration time affect the exchange capacity. Constant exchange capacity was obtained with 1.5M sodium chloride (Fig. 2) after equilibration for 14 hr (Fig. 3).

GEL SPECIATION STUDIES—I

THE INTRINSIC DISSOCIATION CONSTANT OF WEAKLY ACIDIC CATION-EXCHANGE GELS

Yves Merle* and Jacob A. Marinsky

Department of Chemistry, State University of New York at Buffalo, Buffalo, NY 14214, U.S.A.

Summary—The acid-dissociation properties of three weakly acidic cation-exchange gels, CM-Sephadex C-50–120, Biogel CM-2 and CM-Biogel A, have been studied. Each of the gels was equilibrated in sodium polystyrene sulphonate (NaPSS) solutions at three different concentration levels (0.1, 0.01 and 0.001M). The volume of the gels was measured as a function of α (their degree of neutralization), and C_p (the NaPSS concentration); pH and pNa were also measured at each α-value. Intrinsic pK values of 3.25 and 4.55 have been found for CM-Sephadex C-50–120 and Biogel CM-2 respectively.

In the investigation of gel-phase equilibria such as the dissociation of a weakly acidic group that is repeated in a regular way throughout the gel structure, and/or the complexation of metal ions by this acidic group, a Donnan potential term must be calculated to permit estimate of non-ideality at the site of reaction. For this purpose it is necessary to know the gel-phase concentration of the potential-determining counter-ion (Na^+) as well as the solution pH and pNa at every experimental point[1] since

$$pC_H^g = pH_{(s)} - pNa_{(s)} + pC_{Na}^g \qquad (1)$$

where

$$pC_H^g - \log \frac{\alpha}{1-\alpha} = pK_{(HA)}^{app} \qquad (2)$$

and

$$pK_{(HA)}^{app} - pK_{(HA)}^{int} = -0.434 \frac{e\psi_{(a)}}{kT} + \log y_{H^+}^g. \qquad (3)$$

In equation (1) the subscript (s) and the superscript g refer to the solution and gel phases respectively, with C_H^g and C_{Na}^g representing the molar concentration of H^+ and Na^+ in the gel. In equation (2), α refers to the fraction of gel acidic groups that is dissociated and $pK_{(HA)}^{app}$ corresponds to the apparent pK of the acid unit (HA) which is repeated in the polymer. Finally, in equation (3) the superscript int designates the intrinsic pK of the repeating HA unit, $\psi_{(a)}$ refers to the potential at the surface of the charged gel matrix and $y_{H^+}^g$ is the molar activity coefficient correction for long-range Debye-type ion-interaction forces acting on the H^+ ion in the gel phase.

To permit the accurate assessment of C_{Na}^g in these studies for computation of pC_H^g, it is desirable to

avoid imbibement by the gel of the sodium salt employed to adjust the ionic strength of the aqueous phase. With highly cross-linked resins, almost complete exclusion of salt is observed when the ionic strength of the aqueous medium is low.[2] However, with two of the three different gels used in this experimental programme this is not the case. The CM-Sephadex C-50–120 gel is very flexible, swelling remarkably and increasingly as the ionic strength is lowered and as the degree of neutralization is increased,[1,3] whereas the CM Biogel A is rigid with a very open structure. In either case imbibement at even low ionic strength is considerable. In order to avoid this complication, sodium polystyrene sulphonate (NaPSS) was employed as the ionic medium,[3] diffusion into the gel phase being resisted by a sieve effect, the size and charge of the macromolecule causing resistance to its entry.

With invasion of sodium ion avoided in this way, it was possible to evaluate C_{Na}^g directly,[1,4] as follows. Since electroneutrality must be preserved in the gel phase, the Na^+-ion content of the gel ($Na_{(g)}^+$) can be equated directly with the quantity (meq) of acid dissociated, $(A^-)_v$ or αv, on controlled addition of standard base:

$$(A^-)_v = \alpha v = bV_b + hV_s = Na_{(g)}^+ \qquad (4)$$

where v is the degree of polymerization, b and h correspond to the molarity of base and acid, respectively, and V_b and V_s represent the volume of base added and the volume of the aqueous phase after addition of the base. Measurement of the gel volume, V_g, then permits evaluation of C_{Na}^g:

$$C_{Na}^g = \frac{\alpha v}{V_g}. \qquad (5)$$

The neutralization by sodium hydroxide of the cation-exchange gel in equilibrium with a solution of

---

*Present address: Laboratoire de Chimie Macromoléculaire—ERA 471, Faculté des Sciences de Rouen, F-76130 Mont Saint Aignan, France.

the sodium salt of a strongly acidic polyelectrolyte can be expressed by the equation:[1,3]

$$pH_{(s)} - pNa_{(s)} + \log V'_g$$
$$= pK^{app}_{(HA)} + \log y^g_{Na} + \log \frac{\alpha^2}{1-\alpha} = S \quad (6)$$

where V'_g is the specific volume of the gel (in ml/meq).

A plot of S vs. $\log \alpha^2/(1-\alpha)$ generally yields a straight line for the range $0.2 < \alpha < 0.8$. By analogy with the Kern-modified Henderson-Hasselbalch expression, equation (6) can be rewritten as

$$S = pH_{(s)} - pNa_{(s)} + \log V'_g$$
$$= pK' + n \log \frac{\alpha^2}{1-\alpha} \quad (7)$$

where n is the slope of the straight line that results and pK' is equal to the value of S at $\alpha = 0.618$ [corresponding to $\log \alpha^2/(1-\alpha) = 0$].

For certain gels, such as CM-Sephadex C-50-120, the value of n is approximately 1,[3] and the sum, $pK^{app} + \log y^g_{Na}$, is constant over certain intervals of α in the presence of sodium salts of strongly acidic polyelectrolytes.

By including y^g_{Na} and other terms such as y_{A-}, the activity coefficient of the acidic unit of the gel, and y^h_{Na} and y^h_H, the solvation contributions for both the H$^+$ and Na$^+$ ions in the pK^{app} term, as done by Slota and Marinsky,[1] the pK^{app} value can be obtained by means of the relationship:

$$pK^{app}_{(HA),v} = pH_{(s)} - pNa_{(s)} + \log V'_g - \log \frac{\alpha^2}{1-\alpha}. \quad (8)$$

The research described in the next section was embarked upon to show that with the computation of the Donnan potential term in these two-phase systems, the thermodynamic properties of gels could be uniquely and meaningfully characterized. Until the research of Slota and Marinsky[1] such characterization of gels was based only on the solution-phase measurements: as a consequence the results obtained were a function of the ionic strength employed in a particular study and bore little relationship to the absolute parameters sought.

With the attainment of this goal, the second phase of this study, i.e., the meaningful analysis of multivalent-cation complexation-reactions with the acidic group of the gels selected for study, facilitated by proper assignment of Donnan potential terms, would be ready for entry.

EXPERIMENTAL

Distilled, demineralized water was used in all operations.

Preparation of NaPSS

Sodium polystyrene sulphonate with an average molecular weight of 5×10^5 (Lot ST475-4-87B) was kindly supplied by the Dow Chemical Company of Midland, Michigan. In its preparation for use it was first converted into the H$^+$ form by passage through a Dowex 50 W × 8 cation-exchange resin column in the H$^+$ form. Low molecular-

weight impurities were then removed over a one-week interval by dialysis through a cellulose acetate membrane into distilled, demineralized water, which was periodically replaced. The resultant dilute solution of HPSS was then reconcentrated at ambient temperature by continuous removal of water vapour by the action of a fan on the membrane surface. The solution of HPSS so obtained was neutralized to pH 7 with $1M$ sodium hydroxide. It was then used as the source material for the NaPSS medium employed in a particular series of experiments, its dilution depending on the concentration level chosen for these experiments.

Preparation of gels

The three gels, CM-Sephadex C-50-120 supplied by the Pharmacia Company, and Biogel CM-2 and CM Biogel A supplied by the Bio-Rad Company, were cycled in the Na$^+$ and H$^+$-ion forms by use of $0.5M$ sodium hydroxide and $0.5M$ hydrochloric acid. The H$^+$ forms of the gels were then washed with demineralized, distilled water to remove all traces of the free acid.

Gel volume and density determinations

Gel volumes were determined by the following procedure. First, the ion-exchange capacity per gram of swollen gel was measured by adding an excess of sodium hydroxide to the weighed sample and back-titrating with standard hydrochloric acid. The gel, washed free from simple electrolyte, was then transferred quantitatively to an NaPSS solution at the desired concentration, and allowed to equilibrate for 48 hr. The volume and density of the gel, removed quantitatively from the NaPSS solution by filtration, were measured with n-heptane in a pycnometer. The volume and density of the gel in the H$^+$-form were measured similarly. Volume estimates at degrees of dissociation ranging between these two extremes were obtained by measuring the settled gel volumes in a graduated cylinder and subtracting the interstitial volumes from these gross values. Plots of these volume data for the three gels are presented in Fig. 1. The density data are listed in Table 1.

Measurement of pH and pNa of solutions

The pH and pNa of the equilibrated solutions were measured concurrently with Corning Glass electrodes (No. 47621000 for Na) and a Radiometer model 4 pH-meter. The Na-specific electrode was calibrated with standard sodium chloride solutions, and the glass pH electrode with standard reference buffers. All pH and pNa measurements were made in media saturated with nitrogen.

When the pH of the solution was too low, pNa could not be measured directly because of the selective uptake of H$^+$-ions by the Na$^+$-ion electrode. It was necessary in these instances to employ an isotope dilution technique to measure the Na$^+$-ion concentration in solution. The radioactivity of ^{22}Na was measured for this purpose. The single-ion activity coefficient assigned to Na$^+$ in NaPSS by two different research groups[5,6] was then used to convert these Na$^+$ concentrations into Na$^+$ activities.

For a particular set of experiments a controlled quantity of the ^{22}Na radioisotope was added to NaPSS at the appropriate concentration level. A 15-ml aliquot of this solution was then combined with a known amount (0.1–1.0 meq) of the water-swollen gel in its H$^+$-form. After three days of equilibration in the vial container the pH, pNa and radioactivity of the solution were measured. The radioactivity was measured with a Tricarb Packard No. 3375 beta-counter.

In a particular experimental series a controlled quantity of standard sodium hydroxide solution was added by microburette to dissociate the gel further after completion of the measurements of solution radioactivity, pH and pNa at the preceding gel dissociation value. The effect of dilution of the NaPSS by addition of the sodium hydroxide was taken into account.
Fig. 1. Variation of the specific volume V'_g (in ml/meq) as a function of the degree of ionization, α, at different concentrations, C_p, of sodium polystyrene sulphonate (NaPSS); $C_p = 0.1M$ (●); $0.01M$ (×), $0.001M$ (▲). (A) CM-Sephadex C-50–120; (B) Biogel CM-2; (C) Biogel A.

RESULTS

Exchange capacity and swelling of gels

The three gels were studied in solutions of NaPSS at three different concentrations (0.10, 0.010 and $0.0010M$).

The CM-Sephadex C-50–120 gel has a high exchange-capacity (4.8 meq/g of dry gel). Its extent of swelling, which is considerable, depends on the initial NaPSS concentration (C_p) and the degree of ionization (Fig. 1A). The capacity of the swollen gel is as low as 0.031 meq/ml at $\alpha = 1$ in $0.001M$ NaPSS. The density of the gel is slightly higher than that of the solution (Table 1) except when $C_p = 0.10M$ and $\alpha = 1$. In this case the gel floats and its volume has to be measured with a pycnometer.

The Biogel CM-2 also exhibits a high exchange-capacity (5.3 meq/g of dry resin), but it swells much less than the CM-Sephadex C-50–120 gel, the extent of swelling depending only on the degree of ionization. The dependence of the swelling on the NaPSS concentration is insignificant (Fig. 1B). The capacity of the swollen gel remains high (1.39 meq/ml at $\alpha = 1$) because of its moderate flexibility, and its density is always higher than that of the solution (Table 1).

The CM-Biogel A has a low exchange-capacity (1 meq/g of dry resin) and because of the rigid, open

structure its volume is practically independent of the degree of ionization and of the NaPSS concentration (Fig. 1C). The exchange capacity is 0.04 meq/ml at $\alpha = 1$. The density is always slightly higher than that of the solution (Table 1).

Neutralization of gels

The neutralization properties of the CM-Sephadex C-50–120 gel are strongly affected by the NaPSS concentration of the solution. This result is illustrated in Fig. 2, which presents the neutralization curves obtained at three different NaPSS concentrations (0.1, 0.01 and $0.001M$). These data produce three straight-line plots of S vs. log $\alpha^2/(1 - \alpha)$ (Fig. 3). Their slopes are greater than 1 for $C_p = 0.001$ and $0.01M$ and not very different from 1 for $C_p = 0.1M$ (Table 2). The variation of the sum $pK^{app} + \log y^g_{Na}$ with α at $C_p = 0.01$ and $0.001M$ indicated by these results is to be expected. The sensitivity of the gel volume to changes in α and C_p leads to sizeable variability in polymer concentrations. Just as with linear polyelectrolytes, e.g., polymethacrylic acid, polymer dilution results in less effective screening of the polymer surface charge and greater increase in the value of pK^{app} with increasing degrees of dissociation.[7] At $C_p = 0.1M$, however, the volume of the gel is reduced and the effect of α on the gel volume

Table 1. Densities (g/ml) of the different gels at the beginning, $\bar{\alpha} = 0$, and the end, $\bar{\alpha} = 1$, of neutralization at different concentrations, C_p, of sodium polystyrene sulphonate (NaPSS), and the density of the NaPSS solutions (density of water at 25°C = 0.99707 g/ml)

Table 2. Values of n [equation (7)] for the three gels at different molar concentrations of NaPSS, C_p

Gel	C_p	n		
		0.1	0.01	0.001
CM-Sephadex C50–120		0.96	1.12	1.34
Biogel CM-2		1.25	1.25	1.25
CM-Biogel A		0.57	0.94	1.23

higher concentration of the repeating functional unit in Biogel CM-2.

All the experimental points obtained for Biogel CM-2 with the three different NaPSS solutions fall on a single straight line when S is plotted vs. $\log \alpha^2/(1 - \alpha)$ (Fig. 5). This is to be expected when the swelling properties of a gel are independent of C_p, as is the case here, and when there is no penetration of the gel phase by the ionic solution medium (NaPSS). The slope of the straight line, n, is 1.25 (Table 2), showing that the apparent pK of the repeating gel functional unit increases with the degree of ionization, as it does with the CM-Sephadex C-50–120 gel at the two lower NaPSS concentrations.

is not nearly as large as before. The net effect is a buffered effective surface-charge which results in constancy of the $pK^{app} + \log y_{Na}^g$ term.

In an earlier study of French supplied CM-Sephadex C-50–120 gel[3] less swelling was observed under comparable experimental conditions. The slope of the straight-line plot of S vs. $\log \alpha^2/(1 - \alpha)$ was unity, as it is for the most concentrated NaPSS system ($C_p = 0.1M$) in the present investigation. It is probable that the gel used in the earlier study was slightly more cross-linked than the gel employed in this one.

The neutralization curves obtained with Biogel CM-2 are presented in Fig. 4. The solution-phase pH under comparable experimental conditions is always more than one unit higher than that in the CM-Sephadex C-50–120 gel study, which indicates the

Fig. 4. Neutralization curves of Biogel CM-2 as a function of the degree of ionization α; symbols as in Fig. 1.

Fig. 3. Variation of S [$= (pH - pNa + \log V_g^0)$] as a function of $\log [\alpha^2/(1 - \alpha)]$ for CM-Sephadex C-50–120; symbols as in Fig. 1.
Fig. 5. Variation of S [$= (pH - pNa + \log V_g^0)$] as a function of $\log [\alpha^2/(1 - \alpha)]$ for Biogel CM-2; symbols as in Fig. 1.
Fig. 6. Neutralization curves for Biogel A as a function of the degree of ionization, α; symbols as in Fig. 1.

The neutralization curves obtained with the CM-Biogel A are presented in Fig. 6. In this case the solution-phase pH is much lower than that in the CM-Sephadex C-50–120 gel study under comparable experimental conditions. The influence of NaPSS concentration is lower, however. Plots of S vs. $\log \alpha^2/(1 - \alpha)$ for the data obtained produce three straight lines, one for each concentration level of the NaPSS employed (Fig. 7). Unlike the result obtained with the CM-Sephadex C-50–120 gel the largest value of S and the lowest slope are obtained with NaPSS at a concentration of $0.1M$ (Table 2). This discordant result is due to the fact that there is diffusion of the NaPSS into the gel. That the rigid, open structure of this gel permits entry of the NaPSS is not too surprising. The macroporous stucture is achieved by cross-linking the basic functional unit with a rigid spacer molecule.

Such entry of the NaPSS by diffusion can be sizeable because of the low concentration of functional units and the very weak Donnan exclusion factor which results from this. Equation (6) is no longer applicable since a correction must be made for the effect of NaPSS imbibement on the value of pC^g_{Na}.

Apparent pK values

Equation (8) was employed to evaluate $pK^{app}_{(HA)}$ as a

Fig. 8. Apparent pK of CM-Sephadex C-50–120: a plot of pK_{app} vs. degree of ionization, α; the pK_{app} is calculated by means of equation (8); symbols as in Fig. 1.

function of α for both the CM-Sephadex C-50–120 and the Biogel CM-2 gels at the three different NaPSS concentrations. The results are graphically presented in Figs. 8 and 9. It is evident from Fig. 8 that the apparent pK of the CM-Sephadex C-50–120 gel is strongly influenced by its swelling properties and by the degree of dissociation. Extrapolation of the curves in Fig. 8 to $\alpha = 0$ provides an estimate of the Sephadex $pK^{int}_{(HA)}$; as $\alpha \to 0$, $\psi_{(a)} \to 0$, and $pK^{app}_{(HA)} \to pK^{int}_{(HA)}$. The extrapolation may not be too accurate, but the convergence of the extrapolated lines drawn to merge at a value in the region of 3.3–3.5 at $\alpha = 0$ is consistent with the $pK^{int}_{(HA)}$ value of 3.25 obtained earlier for the CM- Sephadex C-50–120 gel and its polyelectrolyte analogue, carboxymethyl-dextran.[8]

Swelling of the Biogel CM-2 was found to be independent of the ionic strength of the aqueous medium so $pK^{app}_{(HA)}$ should vary only as a function of α. In Fig. 9 the increasingly large scatter in the $pK^{app}_{(HA)}$ values at α values above about 0.7 must therefore be due to other factors. In the α-range from 0.7 to 1.0 the measured pH was equal to or greater than 7 in the study of this system, and inadvertent introduction of CO_2 from the atmosphere is most probably responsible for the observed scatter. At $\alpha < 0.5$ the reproducibility of $pK^{app}_{(HA)}$ is much better and extrapolation to $\alpha = 0$ is straightforward, yielding a $pK^{int}_{(HA)}$ value of about 4.6.

Conclusion

The first objective of this research has been success-

Fig. 7. Variation of S $[= (pH - pNa + \log V_g)$ as a function of $\log [\alpha^2/(1 - \alpha)]$ for Biogel A; symbols as in Fig. 1.
Fig. 9. Apparent pK of Biogel CM-2: a plot of pK_{app} calculated by means of equation (8); symbols as in Fig. 1.

fully achieved through the correct assignment of Donnan potential terms. We have been able to determine for each experimental situation the concentration of hydrogen ion at the site of its reaction with the repeating conjugate-base unit (carboxylate ion) of the gel. Extrapolation to $\alpha = 0$ of a plot of the apparent pK obtained for each gel by this approach [equation (8)], vs. α, has led to resolution of the intrinsic pK characterizing the dissociation of the repeating acidic ligand unit in two of the three gels for which the Donnan term was calculable.

It has been of special interest to show how the behaviour of the highly flexible CM-Sephadex C-50–120 gel seems exactly like that of a linear polyelectrolyte if the apparent pK measurement is based on the gel-phase pH. As the gel phase becomes more dilute (i.e., as the NaPSS concentration is decreased) the apparent pK of the acidic group of the gel increases more rapidly with increasing α, from a common intercept on the ordinate at $\alpha = 0$ (intrinsic pK), just as it does for a linear polyelectrolyte, because screening of the charge at the macromolecule

surface by counter-ions is decreased in both cases by dilution of the polymer.

Finally, with this demonstration of the utility and validity of our approach to the thermodynamically sound analysis of equilibria in gels through appropriate assessment of the Donnan potential terms encountered, the second phase of the research, the evaluation of metal-ion complex-formation constants in these gels, is ready for entry.

SHORT COMMUNICATIONS

SPECTROPHOTOMETRIC DETERMINATION OF OSMIUM WITH 1-PHENYL-4,4,6-TRIMETHYL-(1H,4H)-2-PYRIMIDINETHIOL AND EXTRACTION INTO MOLTEN NAPHTHALENE

A. Wasey, R. K. Bansal and B. K. Puri

Department of Chemistry, Indian Institute of Technology, Hauz Khas, New Delhi 110016, India

A. L. J. Rao

Department of Chemistry, Punjabi University, Patiala, India

Summary—Conditions have been developed for the spectrophotometric determination of osmium with 1-phenyl-4,4,6-trimethyl-(1H,4H)-2-pyrimidinethiol after extraction of the complex into molten naphthalene. Beer's law holds for the concentration range of 4–77 μg of osmium in 10 ml of the final solution. The molar absorptivity is 1.33×10^4 1.mole^{-1}.cm^{-1}. The reagent is highly selective for osmium.

Several pyrimidinethiols have been synthesized and used successfully as analytical reagents.[1,2] Osmium forms an extractable complex with 1-phenyl-4,4,6-trimethyl-(1H,4H)-2-pyrimidinethiol (PTPT) but only on heating for some time, so the usual liquid–liquid extraction methods are tedious. The present communication describes the extraction of osmium with PTPT into molten naphthalene and its spectrophotometric determination after dissolution of the solidified extract in dimethylformamide (DMF). This technique is especially useful for the extraction of complexes which are formed only at higher temperatures[3,4] or have low solubility at room temperature.

EXPERIMENTAL

Reagents

Doubly distilled water and analytical-reagent grade acids and salts were used unless otherwise stated. A solution of osmium tetroxide was prepared in 0.2M sodium hydroxide and standardized.

1-Phenyl-4,4,6-trimethyl-(1H,4H)-2-pyrimidinethiol was prepared and purified according to the method given by Mathes *et al.*[5,6] and a 0.001M solution was prepared in DMF.

Procedure

Take in a beaker a volume of sample containing 3.8–76.8 μg of osmium and add 2 ml of PTPT solution. Add perchloric acid to give an acid concentration of 1.0–3.5M. Transfer the solution to a round-bottomed stoppered flask, warm it to about 60° on a water-bath and add 2 g of naphthalene. Raise the temperature to about 90° to melt the naphthalene and stir the mixture for about 15 min on a combined magnetic stirrer and hot-plate. Cool the solution, filter off the solidified naphthalene, dry it on a filter paper,

dissolve it in DMF and make it up to 10 ml in a standard flask with DMF. Dry this solution with 2 g of anhydrous sodium sulphate and measure the absorbance in a 1-cm cell at 520 nm against a reagent blank. Prepare calibration graph under similar conditions.

RESULTS AND DISCUSSION

Absorption spectrum

The absorption spectrum of the osmium–PTPT complex in naphthalene–DMF medium, measured against water or a reagent blank, has its absorption maximum at 520–530 nm, where the reagent does not absorb at all.

Experimental conditions

Effect of acidity. Osmium is quantitatively extracted over the perchloric acid range 1.0–3.5M. Extraction is incomplete at higher and lower acidity.

Reagent concentrations. The absorbance is constant and maximal with 0.8–4.5 ml of 0.001M PTPT solution, and 1.3–3.5 g of naphthalene. Extraction is incomplete with less than 1.3 g of naphthalene; with more than above 3.5 g it is difficult to dissolve the naphthalene in the 10 ml of solvent used.

Effect of aqueous phase volume. The absorbance is unaffected if the aqueous phase volume does not exceed 60 ml. With larger volumes the extraction is not quantitative.

Stirring time. At 85–90° complete extraction takes a minimum of 10 min (Fig. 1).

Calibration graph. Under the optimum conditions described, the calibration graph (measurement at 520 nm) is linear over the osmium concentration range of
Fig. 1. Effect of stirring time. Os 38.0 μg, PTPT
$(1 \times 10^{-3}M)$ 2.0 ml, hydrochloric acid 2.0M, naphthalene
2.0 g, wavelength 520 nm.

3.8–76.0 μg in 10 ml of DMF. The molar absorptivity
is 1.33×10^4 l. mole^{-1}. cm^{-1}. The mean absorbance
found in ten replicate determinations of 38 μg of
osmium was 0.505, with a standard deviation of
0.0025.

Interferences

It was found that 5.0 mg of Cl$^-$, SO$_4^{2-}$, I$^-$, F$^-$,
NO$_3^-$, PO$_4^{3-}$, and tartrate, 4.0 mg of citrate, 3.0 mg of
SCN$^-$, 500 μg of Mn(II), Ni(II), Fe(III), Pb(II),
Co(II), Th(IV), Mo(VI), W(VI), V(V), Sb(III),
As(III), Pt(IV), Ru(III) and Rh(III), and 100 μg of
EDTA^{2-}, when added to a test solution containing 38
μg of Os caused less than 2% error. Ir(III) and Pd(II)
interfere, and must be removed by prior extraction.
Copper (500 μg) does not interfere if the extraction
is done at pH 10.

Determination of osmium in various synthetic mixtures

Various synthetic mixtures containing osmium
were prepared in 100-ml standard flasks (Table 1),
and each was analysed in triplicate for osmium
according to the general procedure. The results are
summarized in Table 3.

PULSE POLAROGRAPHY OF NITROSATED GPC FRACTIONS OF HUMIC ACIDS

Maria Teresa Lippolis, Vittorio Concialini and Giuseppe Chiavari
Istituto Chimico G. Ciamician, Università di Bologna, Via Selmi 2, Bologna 40126, Italy

Summary—A pulse polarographic method for the analysis of humic acids fractionated by gel permeation chromatography is described. It is concluded that the pulse polarography of the nitroso-derivatives, already reported as an analytical method for the determination of humic acids, really gives responses due to the presence of iron in the samples. Atomic-absorption measurements confirm this conclusion quite unambiguously.

Humic acids are extremely complex polymeric substances, which have been the subject of extensive research because of their importance in environmental chemistry.[1-4] Their composition varies according to the origin and nature of the water or soil in which they are found and methods for characterizing them are highly desirable. A variety of techniques have been used for this purpose, such as X-ray scattering,[5] gel chromatography, viscosity measurement, dialysis and ultrafiltration,[6,7] chemical analysis[8] and polarographic determination of the nitroso derivatives.[9]

We have very recently investigated the gel filtration of humic acids, using an electrochemical detector and comparing its performance with that of the usual ultraviolet detector.[10] The present work is a continuation of the investigation, with the aim of comparing the pulse polarography of the nitroso-derivatives of the various fractions obtained in the gel filtration, with the responses given by the electrochemical detector. To clarify a discrepancy observed between the two methods, atomic-absorption measurements were also made.

EXPERIMENTAL

Reagents

Commercial samples of humic acid were purchased from Aldrich and Fluka. The other chemical products were of analytical grade (C. Erba RPE) and used without further purification. The gel filtration columns were made with Ultrogel (LKB) having exclusion limits of 1000–15000. A 0.05M solution of sodium pyrophosphate was used as eluent, at a flow-rate of *ca.* 0.5 ml/min.

Apparatus

The electrochemical detector was a Metrohm model 656 with a three-electrode detection cell (model EA 1096/2). The working electrode was a carbon-paste electrode, the counter-electrode a glassy-carbon electrode and the reference electrode an Ag/AgCl system.

Atomic-absorption measurements were done with a Perkin-Elmer model 372 instrument.

The gel filtration column was 25 × 1.6 cm, packed according to the maker's instructions and used with an LKB 2112

Redirac fraction collector. Molecular weight calibration of the column is reported elsewhere.[10]

The pulse polarograph was a Southern Analytical model A 3100.

Procedure

The nitrosation procedure was essentially the same as that reported by Ederle *et al.*[9] Each fraction (*ca.* 3.5 ml) was acidified to pH 4.5 with 1M acetate buffer, 1 ml of 10% sodium nitrite solution was added and the mixture was left at 50–60° for 20 min. After cooling, the solution was diluted to volume in a 25-ml standard flask with water and transferred to a conventional three-electrode polarographic cell, with a platinum counter-electrode and a saturated calomel electrode as reference. After deaeration with pure argon for 10 min, the solution was polarographed with a pulse amplitude of 50 mV and a sweep-rate of 133 mV/min. The peak height (at $E_{peak} = -0.63$ V *vs.* SCE) was measured and corrected with respect to that found for a blank solution treated similarly.

RESULTS AND DISCUSSION

Figures 1 and 2 summarize the elution curves obtained by the three techniques, for the gel filtration of the two commercial samples.
Fig. 1. Elution curves of Fluka humic acid. Sample volume: 0.5 ml of 0.5% solution in 0.05M $Na_4P_2O_7$: —— electrochemical detector response (sensitivity 0.5 μA full-scale deflection); ——— ppm of iron from pulse polarographic measurements of the nitrosated fractions; ·—·—· ppm of iron from atomic-absorption measurements.
Fig. 2. Elution curves of Aldrich humic acid. Conditions and symbols as for Fig. 1.

The curves obtained by use of the electrochemical detector and by pulse polarography of the nitrosated fractions differ noticeably in shape and in the position of the maximum.

In the earlier communication[10] it was pointed out that the response of the electrochemical detector is mainly due to the oxidation of phenolic and amino groups present in the humic acids. The comparison therefore suggests that the pulse polarographic response is not attributable to nitrosated phenolic compounds.

It is known that the humic acids contain variable amounts of several metals such as Al, Fe, Cu, etc., so we have made atomic-absorption (AA) measurements on the chromatographic fractions, to try to elucidate the discrepancy.

The elution curves obtained by AA by determination of iron, show excellent agreement with those obtained by pulse polarography, so it seems reasonable to attribute the polarographic response to the reduction of some nitroso-complex of iron.

This assumption has been confirmed by nitrosation of solutions containing known quantities of Fe(III),

followed by polarography: these solutions gave a reduction peak at -0.63 V vs. SCE, confirming the attribution to reduction of an iron complex. The peak can be used to evaluate the concentration of iron, as shown in Figs. 1 and 2.

Conclusions

From the results reported we can conclude that though phenolic and amino groups are certainly present in the humic acids, they are not all easily converted into nitroso derivatives, so the nitrosation technique[9] may give unreliable results.

However, since under our chromatographic conditions the iron is practically concentrated in one or two fractions, the nitrosation technique, coupled with pulse polarography, can be used for the determination of iron traces in natural humic acids.

THALLIMETRIC OXIDATIONS—IV

ESTIMATION OF MALONIC ACID

S. R. Sagi, K. Appa Rao and M. S. Prasada Rao

Inorganic Chemistry Laboratories, Andhra University, Waltair 530003, India

Summary—Malonic acid is quantitatively oxidized to carbon dioxide and water when refluxed for 120 min in sulphuric acid medium (concentration $\geqslant 1.5M$) with at least four times as much thallium(III) as that stoichiometrically required for complete oxidation. The thallium(I) formed is estimated bromatometrically in the presence of 1.5–2M hydrochloric acid, with Methyl Orange as indicator. The indicator correction is negligible. The relative mean deviation is 0.2%. Possible side-reactions and their suppression are discussed.

Most reactions used for the determination of malonic acid do not proceed quantitatively to give the ultimate oxidation products of carbon dioxide and water, and stop either at the formic acid stage[1-3] or some non-stoichiometric intermediate stage.[4,5] For example, in the methods described by Masayoshi *et al.*[4] and Willard and Young[5] the consumptions of oxidant are 4.34 and 6.66 equivalents respectively per equivalent of reductant. Jaiswal and Yadava[6] have described a method for determination of malonic acid by oxidation with excess of ditelluratocuprate(III) to carbon dioxide and titration of the unconsumed oxidant with arsenic(III), but the oxidant used is not quite stable. Sharma and Mehrotra[7] have described a two-stage procedure in which the malonic acid is first refluxed with excess of cerium(IV) in 1M sulphuric acid for 15 min and then in 12M sulphuric acid for 90 min. This stepwise procedure was said to oxidize the malonic acid first to formic acid and then to carbon dioxide and water. For the second stage concentrated sulphuric acid is added through the condenser by pipette so that no formic acid is lost during the addition. Later, the same authors[8] reported that pure cerium(IV) sulphate cannot oxidize formic acid to carbon dioxide and water in the second stage, and attributed the complete oxidation reported earlier to the presence of Cr(III) as impurity in the cerium(IV) sulphate used. The drawbacks of their method are (*i*) it requires 12M sulphuric acid for complete oxidation, which restricts the volume of malonic acid and cerium(IV) solutions that can be used, (*ii*) the high sulphuric acid concentration used in the oxidation poses difficulties in the estimation of unconsumed cerium(IV), (*iii*) the addition of concentrated sulphuric acid for the second stage is cumbersome. We have investigated the reaction between thallium(III) and malonic acid and established the conditions for a convenient direct determination of malonic acid by quantitative oxidation to carbon dioxide and water.

EXPERIMENTAL

Reagents

Thallium(III) hydroxide was prepared as reported earlier[9] and dissolved in a suitable amount of sulphuric acid. The thallium content was estimated iodometrically[10] and verified by other methods.[9,11]

An aqueous malonic acid solution was prepared and standardized by the procedure of Sharma and Mehrotra.[7]

All the other reagents used were of analytical-reagent grade.

Recommended procedure

To an aliquot containing 0.01–0.10 mmole of malonic acid add 45 ml of 2.5M sulphuric acid and 1.6 mmole of thallium(III) and dilute the mixture to 75 ml. Reflux for 120 min. Add 15 ml of concentrated hydrochloric acid, 0.1 ml of 0.1% Methyl Orange solution, maintain at 60° and titrate the thallium(I) with 0.00829M (1.392 g/l.) potassium bromate until the indicator is destroyed. From the amount of thallium(I) formed, calculate the amount of malonic acid. Malonic acid (mmole) = 0.75 × molarity of $KBrO_3$ × volume (ml) of $KBrO_3$.

RESULTS AND DISCUSSION

The reaction between thallium(III) and malonic acid when these are refluxed in sulphuric acid medium was monitored by potassium bromate titration of the thallium(I) formed. At sulphuric acid concentrations $\geqslant 2M$ the decolorization of Methyl Orange (as indicator) is slow, so Brilliant Ponceaux 5 R was used instead. At lower acidity either indicator can be used. Unreacted malonic acid does not interfere in the titration of thallium(I) at concentrations up to $1.6 \times 10^{-3}M$, but causes positive errors for higher concentrations.

The effect of the concentration of thallium(III) and acid on the oxidation of malonic acid was investigated, and typical results are given in Tables 1 and 2. From these the following conclusions can be drawn.

(*a*) Refluxing for about 120 min in 1.5M sulphuric acid medium with four times the amount of thal-

lium(III) required for complete oxidation of malonic acid, gives complete oxidation to carbon dioxide and water.

(b) At lower sulphuric acid concentration and/or with a smaller excess of thallium(III), negative errors are obtained even with longer reflux times.

It is clear that under the conditions stated in (b) above, side-reactions occur which result in incomplete oxidation. The probable routes of oxidation of malonic acid are:

plete oxidation of malonic acid showed that acetic acid resists oxidation, glyoxylic acid requires more than 120 min for complete oxidation and glycolic acid undergoes only partial oxidation. Hence the oxidation probably does not take place by routes (1), (2) or (3). On the other hand, tartronic, meso-oxalic and oxalic acid all require less time for complete

Studies on the oxidation of glyoxylic acid, glycolic acid and acetic acid under the conditions for com-

oxidation than that needed for complete oxidation of malonic acid. Furthermore, the presence of glyoxylic acid or formaldehyde could not be detected in the solution under the conditions [stated under (a) above] for quantitative oxidation of malonic acid. Under the conditions in (b), both glyoxylic acid and formaldehyde can be detected.* Hence the course of complete oxidation of malonic acid by thallium(III)

*The chromotropic acid and pyrogallol carboxylic acid tests[12] were used but thallium(III) was found to interfere. Hence, the thallium(III) was first reduced to thallium(I) by heating[9] in the presence of excess of oxalate. Thallium(I) and oxalate do not interfere in these spot-tests.

Table 3. Effect of thallium(III) concentration on the extent of oxidation of 0.05 mmole of malonic acid in 75 ml of 1.5M sulphuric acid [x mmole of thallium(III) added, reflux for 120 min, then $(0.8 - x)$ mmole of thallium(III) added and reflux continued for a further 120 min]

0.80	100.0	100.0	100.0	100.0

is probably by route (4) and may be written as

$$CH_2(COOH)_2 + Tl(III) + H_2O \rightarrow$$
$$HOHC(COOH)_2 + Tl(I) + 2H^+$$

$$OHCH(COOH)_2 + Tl(III) \rightarrow$$
$$OC(COOH)_2 + Tl(I) + 2H^+$$

$$OC(COOH)_2 + Tl(III) + H_2O \rightarrow$$
$$Tl(I) + CO_2 + 2H^+ + (COOH)_2$$

$$(COOH)_2 + Tl(III) \rightarrow Tl(I) + 2CO_2 + 2H^+.$$
Separate studies were made on the oxidation of malonic acid with less than the necessary amount of thallium(III) in 1.5M sulphuric acid medium, with refluxing for different initial periods, and followed by refluxing for a further 120 min after addition of enough thallium(III) to bring the reaction mixture to the conditions required for complete oxidation. The results are given in Tables 3 and 4 and show that:

(a) as the thallium(III) concentration initially ad-

Table 5. Estimation of malonic acid

Malonic acid, mmole	
Taken	Found
0.0100	0.0100
0.0188	0.0188
0.0200	0.0200
0.0495	0.0495
0.0500	0.0499
0.0600	0.0603
0.0800	0.0803
0.1000	0.0996

ded is decreased (Table 3), the percentage of malonic acid oxidation is also decreased;

(b) as the time of initial refluxing increases (Table 4), the percentage of malonic acid oxidation is decreased.

These observations show that in the presence of less than 1.5M sulphuric acid and/or less than four times the stoichiometric amount of Tl(III), malonic acid undergoes side-reactions (probably giving rise to acetic acid, glycolic acid or glyoxylic acid) and oxidation is incomplete.

Interferences

Acetic, propionic, succinic, glutaric, adipic and pimelic acids do not interfere. Oxalic, formic, lactic, malic, tartaric and citric acids interfere because they also react with thallium(III) under the conditions used.

Typical results for determination of malonic acid are given in Table 5.

DETERMINATION OF BISMUTH(III) BY DIRECT POTENTIOMETRY AND POTENTIOMETRIC TITRATION, WITH AN ELECTRODE SENSITIVE TO Bi³⁺

Walenty Szczepaniak and Maria Ren

Department of Instrumental Analysis, Faculty of Chemistry, A. Mickiewicz University, Poznań, Poland

Summary—A liquid-state ion-exchange electrode containing the chelate bismuth(III) complex with 5-mercapto-3-(naphthyl-2)-1,3,4-thiadiazole-2-thione in tetrachloroethane is applied to the determination of bismuth(III) by direct potentiometry and potentiometric titration. The influence of various interfering cations is discussed. In the presence of potassium cyanide as masking agent, Ni(II), Co(II), Cu(II), Ag(I) and Hg(II) do not interfere in the potentiometric EDTA titration. Satisfactory results have been obtained for the determination of bismuth(III) in Wood's metal and two pharmaceuticals.

In a previous paper[1] we described a liquid-state membrane electrode sensitive to bismuth(III) cations. The slope of the calibration graph was 18.7 mV/$pa_{Bi^{3+}}$ in the $pa_{Bi^{3+}}$ range 6.5–9.5. The potential of the electrode was established within about 10 sec for 10^{-4}–$10^{-2}M$ Bi(III) solutions and 3 min for 10^{-6}–$10^{-5}M$ Bi(III). The potentials obtained were constant over a 20-day working period. The electrode was characterized by good selectivity coefficients for bivalent cations, and also for Al^{3+}, Fe^{3+} and Th^{4+} ($K_{Bi^{3+}/M^{z+}} < 10^{-5}$). Cations found to interfere were Ag^+, Hg^{2+} and Cu^{2+}.

The potentiometric methods proposed below broaden the known possibilities for the determination of bismuth(III).

EXPERIMENTAL

Reagents and apparatus

All reagents used were of analytical-reagent grade. The water used was doubly distilled in a quartz still.

A 0.2M ammonium acetate and 0.7M acetic acid buffer was used throughout unless otherwise stated.

E.m.f. measurements were made with an Elpo pH-meter type N-512, connected to a Zeiss recorder (type $G_1 B_1$) and a Meratronik V 530 digital voltmeter. This system allowed the e.m.f. to be read to ±0.1 mV. The ion-selective electrode was of liquid-membrane type, based on a $5 \times 10^{-3}M$ solution of the bismuth complex of 5-mercapto-3-(naphthyl-2)-1,3,4-thiodiazole-2-thione(bismuthiol III) in 1,1′,2,2′-tetrachloroethane. The construction of the working electrode and measuring cell were as described previously.[1] Measurements were made on the final sample solutions prepared as described below.

Preparation of samples

Wood's metal. A 1-g sample was dissolved in concentrated nitric acid in a heated quartz flask. Metastannic acid was filtered off and washed and the filtrate diluted to volume with water in a 25-ml standard flask. A 1-ml aliquot was diluted to volume with ammonium acetate buffer in a 100-ml standard flask.

Pharmaceutical No. 1. A 2-g sample of the powder was dissolved in hot concentrated nitric acid and the solution diluted to volume with water in a 100-ml standard flask. A 10-ml aliquot was taken and diluted to volume in a 100-ml standard flask with ammonium acetate buffer.

Pharmaceutical No. 2. A weighed tablet was dissolved in hot concentrated nitric acid in a quartz flask. The solution was filtered and made up to volume in a 100-ml standard flask with water. A 10-ml aliquot was further diluted to 100 ml (standard flask) with ammonium acetate buffer.

RESULTS AND DISCUSSION

As shown in the previous paper[1] the electrode can be used for the determination of Bi(III) in the range $pC_{Bi(III)} = 2$–5. The linearity of the calibration graph is not affected by Ca(II), Mg(II), Zn(II), Ni(II), Co(II), Mn(II), Cd(II) and Fe(III) in concentrations up to 0.01M. The effect of Cu(II) and Pb(II) is illustrated in Fig. 1.
Fig. 1. Calibration curves of the electrode in Bi(III) solutions in the presence of interfering ions; all calibration curves start at $pC_{Bi} = 2.1$, Bi or Bi + Ni(II), Zn(II) or Fe(III) ($10^{-2}M$); 2, Bi + Cu(II) ($10^{-4}M$); 3, Bi + Cu(II) ($10^{-3}M$); 4, Bi + Cu(II) ($10^{-2}M$); 5, Bi + Pb(II) ($10^{-3}M$); 6, Bi + Pb(II) ($10^{-2}M$).

The application of the method is restricted to the bismuth concentration range 10^{-3}–$10^{-2}M$ in the presence of $10^{-2}M$ Pb(II) and $10^{-4}M$ Cu(II). The effect of lead is especially severe at bismuth concentrations below $10^{-3}M$, and it is therefore necessary to know the approximate molar Pb/Bi ratio in the sample; if this exceeds 10, the determination by potentiometry is impossible. The determination of Bi(III) by direct potentiometry is impossible when the concentration of Cu(II) is greater than $10^{-4}M$. In the presence of a large excess of Cu(II), Pb(II), Hg(II) and Ag(I), the bismuth(III) in its Bismuthiol III complex in the membrane is replaced by the interfering ion, making the electrode sensitive to that ion. A statistical analysis of the results of bismuth determination in the presence of some interfering ions, by the standardization-graph and standard-additions methods, is shown in Table 1. The presence of interfering ions reduces both the accuracy and precision of Bi(III) determination by direct potentiometry. An advantage of this method, however, is that Bi(III) can be determined in the presence of Pb(II) and Cd(II) whereas these ions make the potentiometric titration of bismuth impossible.

The electrode operates successfully as the indicator electrode in potentiometric titrations of Bi(III) with EDTA. Good titration curves are obtained for titration of 5×10^{-5}–$10^{-2}M$ bismuth, but the shape of the titration curves is affected by the presence of certain other cations. Ca(II), Mg(II), Mn(II), Al(III) and Fe(III) ions at concentrations up to $10^{-3}M$ do not interfere with the course of titration of $10^{-3}M$ bismuth (Fig. 2), but Co(II), Ni(II), Cu(II), Zn(II), Ag(I) and Hg(II) causes significant changes in the shape of the titration curves because of their effect on the electrode potential. Despite the good selectivity coefficients for Ni(II), Co(II) and Zn(II), the influence of these ions is apparent at the low concentrations of Bi(III) in the vicinity of the end-point (e.g., Figs 3).

In the presence of Cu(II) ions, it is the sum of Bi(III) and Cu(II) which is titrated, unless the copper is masked, e.g., with cyanide. When Ag(I) and Hg(II) are present, the changes in the shapes of the titration curves are so extensive that Bi(III) can only be determined if the silver and mercury are masked.
Fig. 2. Potentiometric titration curves for Bi(III) $10^{-3}M$ with EDTA in the presence of interfering ions. 1. Mn(II) or Mg(II), or Ca(II) ($10^{-3}M$). 2. Fe(III) ($10^{-3}M$), 3. Al(III) ($10^{-3}M$), pH = 6.
Fig. 3. Potentiometric titration curves for Bi(III) $10^{-3}M$ with EDTA in the presence of Ni(II) ($10^{-3}M$) pH = 6, 1. without masking, 2. in the presence of CN^-.

Table 1. A statistical evaluation of the results of Bi(III) determinations in the presence of interfering ions (concentration $10^{-3}M$) by the standardization graph method (1) and the method of standard additions (2); Bi(III) present = 8.36 mg, $n = 10$

Interfering ion	Average result of determination, mg		Standard deviation, mg		Relative standard deviation, %		Error, %	
	1	2	1	2	1	2	1	2
	8.36	8.33	0.09	0.16	1.1	2.0	0	−0.4
Pb(II)	8.32	8.32	0.27	0.29	3.3	3.5	−0.5	−0.5
Zn(II)	8.28	8.32	0.24	0.13	2.9	1.6	−1.0	−0.5
Cd(II)	8.46	8.28	0.30	0.27	3.6	3.3	+1.2	−1.0
Fe(III)	8.51	8.32	0.30	0.22	3.6	2.7	+1.8	−0.5

Table 2. A statistical evaluation of Bi(III) determination by potentiometric titration with EDTA in the presence of interfering ions and in pure solutions; Bi(III) content 10.45 mg, $n = 10$; for each titration a freshly-mounted electrode was used

Solution analysed	Average result, mg	Standard deviation, mg	Relative standard deviation, %	Error, %
Bi(III)*	10.39	0.04	0.4	−0.6
Bi(III)	10.56	0.09	0.9	+1.0
Bi(III) + $10^{-3}M$ Fe(III)	10.47	0.09	0.9	+0.2
Bi(III) + $10^{-3}M$ Hg(II) (masked with CN⁻)	10.43	0.05	0.5	−0.2

*The same electrode was used for all titrations.

Table 3. Determination of Bi(III) in various samples (5 replicates)

Sample	Method*	Mean ± confidence interval (95%), g	Relative standard deviation, %
Wood's metal	A	0.440 ± 0.011	0.5
	B	0.439 ± 0.017	0.7
Bismuth nitrate pharmaceutical	C	0.3804 ± 0.0013	0.2
	D	0.381 ± 0.013	2.5
	B	0.381 ± 0.007	0.9
Bismuth aluminate pharmaceutical	C	0.1317 ± 0.0011	0.6
	D	0.132 ± 0.005	2.3
	B	0.132 ± 0.003	1.3

A = standardization graph method. B = EDTA titration (Pyrocatechol Violet).
C = EDTA titration (potentiometric). D = standard additions method.

Cyanide can be used for this purpose, and also for masking copper, nickel and cobalt.

Zinc(II) can be satisfactorily masked with 1,4,8,11-tetra-azacyclotetradecane-N,N',N'',N'''-tetra-methylphosphonic acid (TATMF).[2]

The determination of Bi(III) by potentiometric titration both in pure solution and in the presence of $10^{-3}M$ Fe(III) and Hg(II) masked with cyanide has been statistically evaluated (Table 2). The accuracy and precision are not reduced by the presence of interfering ions, and the low values of the standard deviation show that this is a precise method of determining Bi(III).

To test the usefulness of the electrode in the analysis of natural samples, Bi(III) in Wood's metal and two pharmaceuticals was determined. Because of the presence of Cd(II) and Pb(II), the bismuth in

Wood's metal was determined by direct potentiometry (standardization-graph method). Bismuth(III) in the two pharmaceuticals (bismuth nitrate and bismuth aluminate) was determined by potentiometric titration and by the standard-additions method. For comparison, an independent determination was done by EDTA titration, with Pyrocatechol Violet as indicator. The results are presented in Table 3. The results of the determinations by the present method are consistent with those obtained by complexometric titration and show a greater precision.

LIQUID–LIQUID EXTRACTION OF ZINC(II) AS ITS ETHYL XANTHATE*

A. K. Chakravarti,† S. Mukherjee, H. K. Saha and T. Chakrabarty

Max-Planck-Institut für Biophysik, Kennedy-Allee 70, 6000 Frankfurt 70, West Germany

Summary—A method for quantitative extraction of zinc with potassium ethyl xanthate into carbon tetrachloride is described. The optimum conditions are: pH 5–6 and Zn(II) to reagent ∼1:8 mole ratio. The effects of other ions on the extraction of Zn^{2+} have been investigated, and its separation from As^{3+}, Pb^{2+}, Cu^{2+} and Fe^{3+} is described. The possibility of repeated use of the solvent (still loaded with xanthate after the zinc has been stripped) for further extractions (after addition of a little extra xanthate) has been explored. Various stripping agents have been examined, and the optimum conditions found.

Extraction of their alkyl xanthate complexes is useful for the separation of certain metal ions,[1-8] and the solvent extraction of ethyl xanthate complexes has been reviewed by Donaldson.[9] Zinc(II) forms an extractable ethyl xanthate complex, and this paper describes improved conditions for extraction of the complex, the effect of diverse ions on the extraction, stripping of the zinc from the extract, separation of zinc from interfering ions, and the possible use of the extraction system in counter-current processes.

EXPERIMENTAL

Reagents

Potassium ethyl xanthate was either prepared[10,11] or purchased (>99% pure, Fluka), and used as a 1% solution in water. All other chemicals used were of CP or analytical-reagent grade. The water used was always demineralized and doubly distilled.

General procedure

Zinc solution (0.08*M*, 1.0 ml), 9 ml of water and a drop of acetic acid (1:1) were placed in a 100-ml separatory funnel, 10 ml of 1% xanthate solution were added, and the mixture was shaken with 20 ml of carbon tetrachloride for 1–2 min (at about 2 strokes per sec). The organic layer was separated, and the aqueous layer extracted with a further 5 ml of carbon tetrachloride. The combined extracts were used for subsequent studies. The zinc in the organic phase was determined after evaporation of the carbon tetrachloride in the presence of 20 ml of water. In the stripping experiments the organic extract was shaken with an equal volume of stripping solution for 3–4 min (at about 2 strokes per sec), and the zinc concentration in the aqueous phase was determined complexometrically by EDTA titration at pH ∼6 (hexamine buffer) with a mixed indicator consisting of Xylenol Orange (0.5% solution, 3 drops) and Methylene Blue (0.1%, 1 drop).

RESULTS AND DISCUSSION

The results are discussed on the basis of single extractions unless otherwise mentioned.

Complete extraction of Zn–xanthate complex and iterative use of the extractant

The stable Zn–xanthate complex (1:2)[9] is completely extracted at pH 5–6 (Fig. 1). It has been found that if the aqueous zinc solution is adjusted to pH 3–4 (with acetic acid) before addition of the xanthate, the necessary pH value is reached after the xanthate addition. The complex is 97–98% extracted into carbon tetrachloride (1:1 phase-volume ratio) when a 300% excess of xanthate is present. Extraction into chloroform is less complete (∼90%)[12,13] under these conditions. Furthermore, if the carbon tetrachloride extract is stripped with 0.1*M* hydrochloric acid, the stripped solvent can be used for extraction of another zinc solution, and because the solvent contains the xanthate liberated in the stripping, less xanthate needs to be added to the zinc solution. Thus tests showed that after extraction of 5 mg of zinc (80 μmole) in the presence of 100 mg of potassium ethyl xanthate, and stripping, the carbon tetrachloride could be used for at least five more similar extractions if 25 mg of xanthate (2.5 ml of 1%
Fig. 1. Effect of pH on extraction of zinc.

solution) were added to each fresh zinc solution taken for extraction. This offers economy in the use of xanthate, and has potential applications in counter-current extraction or recycling systems.

Interferences

The effect of various ions on a single extraction of 4 mg of zinc under the conditions of the general procedure was examined. The results are shown in Table 1. It can be seen that Cu^{2+}, Co^{2+}, Fe^{3+}, Hg^{2+}, Cd^{2+}, F^-, VO_3^-, citrate^{3-} and $EDTA^{2-}$ always interfere. It is known[14,15] that trace amounts of Cu^{2+} and Fe^{3+} form stable xanthate complexes over a wide range of pH (3–11). The copper xanthate is practically insoluble in carbon tetrachloride, but appears to adsorb some zinc xanthate, since the recovery of zinc increases with repeated extraction. Again, a very stable Zn–EDTA complex (conditional stability constant at pH 5 is $\sim 10^{10}$) is formed at the pH at which the zinc xanthate complex is formed. Vanadate probably oxidizes some xanthate. Positive interferences are due to co-extraction (and subsequent co-titration) of the metal xanthates.

Separation of Zn^{2+} from the interfering ions

From Pb^{2+}, Co^{2+} and As(III). Zn^{2+} can be separated from mixtures with Pb^{2+}, Co^{2+} and As(III) by extracting Zn^{2+}, Pb^{2+} and Co^{2+} with xanthate and carbon tetrachloride at pH ~ 6, which separates them from As(III), then shaking the organic layer with twice its volume of $1.3M$ $NH_4Cl/7.5M$ NH_3 buffer (pH ~ 10) for 5 min, which strips only Zn^{2+}.

From Cd^{2+}. Zinc is quantitatively separated from cadmium by extraction of a mixture of the two with xanthate at pH ~ 6 into chloroform (two 20 ml portions) and then stripping of the zinc with two portions of $0.87M$ $NH_4Cl/0.05M$ NH_3 buffer (pH ~ 8), each equal in volume to the organic phase, by shaking the mixture for 3 min. Higher concentrations of the buffer components strip some cadmium as well.

From Cu^{2+}. The separation can be accomplished in two ways. (a) Thiourea is added before the xanthate, then the mixture is shaken with an equal volume of 6:1 v/v carbon tetrachloride–pyridine mixture (~ 5 ml of pyridine) for each 2 mg of Cu^{2+}. The brown organic layer (which turns light yellow on standing) is separated from the aqueous phase and shaken with an equal volume of $0.3–0.5M$ hydrochloric acid, which strips only the zinc. (b) The zinc is extracted by the general procedure, and the organic phase is separated from the insoluble yellow copper xanthate present in the aqueous layer.

As already mentioned, large quantities of copper hinder the zinc xanthate extraction. However, repeated extraction with either fresh carbon tetrachloride or organic extract that has been stripped of zinc with $0.1M$ hydrochloric acid, will separate the rest of the zinc almost completely. A typical set of results is given in Table 2.

Table 2. Separation of Zn^{2+} from Cu^{2+}–Zn^{2+} mixture and iterative use of the extractant

Cu^{2+} soln.* added, ml	Xanthate soln. added, ml	CCl_4 used, ml	Zn^{2+} extracted,† %	Total Zn^{2+} extracted, %
1.0	15.0	1st ~ 25.0	95.7	99.7
		2nd ~ 25.0	4.0	
2.5	20.0	1st ~ 30.0	83.0	99.5
		2nd ~ 30.0	14.0	
		3rd ~ 30.0	2.5	
5.0	30.0	1st ~ 40.0	71.0	98.6
		2nd ~ 40.0	22.0	
		3rd ~ 40.0	5.6	

*Cu^{2+} 2 mg/ml.
†Referred to the 5 mg of zinc taken; extract stripped before reuse.
Fig. 2. Stripping of zinc from organic phase to aqueous phase with electrolyte solutions and buffer solutions. Molar concentrations used: (▲) NH_4Cl, 0.02–4.0; (■) NH_4Ac, 0.02–5.0; (□) KCl, 0.05–4.0; (○) NaAc, 0.01–3.0; (△) $NaClO_4$, 0.01–5.0; (×) NH_4Cl/NH_3 buffer (pH ~ 7), 0.217/0.0013–4.35/0.025; (●) NaAc/HAc buffer (pH ~ 6), 0.1/0.1–1.0/1.0.

Carbon tetrachloride, when used in this way, became faint yellow in colour but did not lose much extracting capacity for zinc. In an experiment with extraction of 5 mg of zinc in presence of 5 mg of copper, with two 30-ml portions of carbon tetrachloride, the first extract removed 85% of the zinc, and the second 10%. Addition of further xanthate before the second extraction did not appreciably improve the yield.

From Fe^{3+}. Quantitative separation of 5 mg of Zn^{2+} from 50 mg of Fe^{3+} can be achieved by adding ascorbic acid and then raising the pH to ~4 with sodium acetate before adding the xanthate (at least twice the amount needed for the zinc alone), followed by extraction as usual.

Stripping of zinc

Various solutions were tested for stripping the zinc, ranging from $2M$ hydrochloric acid to pH 10 buffer ($1.3M$ $NH_4Cl/7.5M$ NH_3), and including solutions of potassium iodide, bromide, chloride and nitrate, sodium acetate and perchlorate, ammonium chloride, acetate, nitrate and sulphate, of various concentrations, and two other buffer solutions.

Stripping is almost complete with $0.01M$ or higher concentrations of hydrochloric acid; with equal vol-

umes of extract and pure water it is ~34.5% complete. NH_4Cl/NH_3 buffer (pH ≥ 7) also strips zinc almost completely. The effect of the other stripping agents is shown in Fig. 2. Only $5.0M$ ammonium acetate and the most concentrated pH ~ 7 buffer proved really effective.

Ion-exchange tests showed that zinc was present as a cationic species when stripped with sodium acetate or low concentrations of potassium or ammonium chloride, but as anionic complexes when stripped with higher concentrations of the chlorides. The greater efficiency of ammonium acetate as a stripping agent may be due to formation of zinc ammine complexes.

INVESTIGATION OF THE USE OF THERMOMETRIC TITRIMETRY FOR THE DETERMINATION OF ACIDIC SUBSTANCES IN WINE

O. E. S. GODINHO, J. A. COELHO, A. P. CHAGAS and L. M. ALEIXO

Instituto de Química, Universidade Estadual de Campinas, C.P. 6154, 13100 Campinas, SP, Brasil

Summary—The use of thermometric titrimetry in the determination of acidic substances in red wine is described. The titration curve obtained in the thermometric titration of red wine with strong base presents two inflections. The stoichiometry corresponding to the first inflection presents good agreement with the so-called "total acidity" of wine, and is proposed for its determination. The second inflection is related to the content of phenolic substances in red wine.

The use of thermometric titrimetry in the determination of inorganic acids, carboxylic acids and phenols has been extensively studied.[1,2] It is well known that this technique can be used for the alkalimetric titration of even very weak acids.[1] Moreover, being a linear method, thermometric titrimetry may be more suitable than potentiometric titrimetry for end-point detection of components of a mixture of weak acids.[3]

It is also well known that various acids and phenolic substances are important components of wine, and it appeared to us to be of interest to investigate the application of thermometric acid–base titrimetry to this material, especially in view of the simplicity and low cost of the apparatus, and the ease of automation of the technique.

We first compared the results of conventional thermometric titrimetry with the "total acidity" and the phenolic-substance content of red wine. The values of "total acidity" used for comparison were obtained by potentiometric titration to pH 8.2.[4] The content of phenolic substances was obtained by permanganate titration according to the procedure of Ribereau-Gayon and Maurie,[5] modified by Ribereau-Gayon and Peynaud.[6]

EXPERIMENTAL

Procedure for thermometric titration

A 50-ml sample of wine was placed in a 100-ml Dewar flask and titrated with 1.0*M* sodium hydroxide delivered at a constant rate of 0.4 ml/min from a syringe burette (Syringe pump 351, Sage Instruments). The detection and recording system has already been described.[7] The first end-point was easy to detect and was given by the intersection of the extrapolations of the linear portions of the first and second parts of the curve (Fig. 1). The second end-point was determined in the same manner, as the intersection of the corresponding extrapolations of the second and third parts of the curve. However, in some cases the third part tended to be continuously rounded, and it was necessary to draw a tangent to it, in a standardized manner. A preliminary estimate of the second end-point is made by visual selection

of point G as the point of deviation of the titration curve from line AB, and drawing a tangent at point F′, (located so that the projected distances D′ and E′ are equal). The intersection locates the "trial" end-point. The tangent can then be redrawn at F, which is located so that projected distances D and E are equal, and the new intersection gives the end-point, B. However, small variations in the length of E do not significantly affect the position of the second end-point.

Procedure for potentiometric titration

A 10-ml sample of wine was pipetted into a 250-ml Erlenmeyer flask, 100 ml of distilled water were added and the solution was titrated with 0.1*M* sodium hydroxide, the end-point being located at pH 8.2. A Metrohm EA109 glass electrode and EA104 saturated calomel electrode, and an Orion Model 701 pH-meter were used for the pH measurements. The electrodes were calibrated with NBS pH 6.86 buffer before starting the titration.

RESULTS AND DISCUSSION

A typical curve for the thermometric titration of red wine with sodium hydroxide solution is shown in Fig. 1. There is a very distinct break at point A and a second but less distinct one at point B. The stoichiometry corresponding to titration volume C was compared with the so-called "total acidity" obtained by potentiometric titration to pH 8.2,[4] and that for titration volume D was compared with the content of phenolic substances. If phenol was added to the wine, there was an increase in D, whereas C was unaffected, which supports the attribution of D to titration of phenolic components.

Data for total acidity of wine

The "total acidity" obtained potentiometrically is compared with the stoichiometry corresponding to C, in Table 1. A plot of the potentiometric results, *y*, *vs.* the thermometric results, *x*, gave a straight line described by the equation $y = 0.945x + 0.0045$ (correlation coefficient 0.9884). In view of this we think that the thermometric titration may be proposed for determination of the "total acidity" of wine.
Fig. 1. Curve corresponding to the titration of 50 ml of red wine with 1.0M sodium hydroxide by conventional thermometric titrimetry. A—First equivalence point. B—Second equivalence point. C—Titrant volume corresponding to "total acidity". D—Titrant volume corresponding to phenolic substances. (For D', E, E', F, F', G, see text).

Data for content of phenolic substances in red wine

In Fig. 2 the thermometric titration curves of tartaric acid, gallic acid and a mixture of these acids are shown. The curve for tartaric acid, in which only the carboxylic acid group is titratable, has only one break point. On the other hand, gallic acid, which contains one carboxylic acid and three phenolic groups per molecule, gives two breaks on the curve. The first must correspond to titration of the carboxylic acid group and the second to titration of the phenolic groups. However, the reaction stoichi-

ometry for the phenolic groups is lower than expected. This may be due to a very high pK_a for one of the phenolic groups or to hydrogen-bond formation. It is also seen that the addition of gallic acid to tartaric acid results in the appearance of a second break on the titration curve. Addition of phenol to the tartaric acid solution has the same effect.

The titration curve for red wine, shown in Fig. 1, resembles that of the mixture of tartaric and gallic acids or of tartaric acid and phenol. Further, the addition of phenol to the wine results in an increase in the consumption of base in the second part of the titration, and if the red wine is first treated with charcoal there is a large decrease in base-
Fig. 2. Curves corresponding to the titration of tartaric and gallic acids with 1.0M sodium hydroxide by conventional thermometric titrimetry. A—50 ml of 0.030M gallic acid; B—40 ml of 0.050M tartaric acid; C—mixture of 40.0 ml of 0.050M tartaric acid and 35.0 ml of 0.03M gallic acid.

16	0.0795	0.0901	+0.8

Samples number 1, 4, 5, 6, 7, 8, 9, 10 and 11, Brazilian dry red wine; 12, Chilean dry red wine; 2, 3 and 13, Brazilian sweet red wine; 14 and 15, Brazilian green wine; 16, Portuguese green wine.

Fig. 3. Relation between the results for content of phenolic substances in red wine by thermometric titrimetry (○) and by permanganate titration (□). Samples number 1, 4, 5, 6, 7, 8, 9, 10 and 11, Brazilian dry red wine; 2, 3 and 13, Brazilian sweet red wine; 12, Chilean dry red wine; 14 and 15, Brazilian green wine; Portuguese green wine.

consumption in the second part. These facts all lead us to conclude that the phenolic groups in the phenolic substances of wine are titrated after the carboxylic acid groups, to give the second part of the curve. However, in view of the results for gallic acid we suppose that the phenolic groups may not be totally titrated.

The second break in the curve is usually very rounded, which is why a standardized procedure is used for locating the second end-point.

The results based on the determination of the end-point as described above are presented in Fig. 3, along with the results obtained by permanganate titration. The results are presented in terms of the number of equivalents of permanganate or sodium hydroxide consumed in titration of 1 litre of the wine.

DETERMINATION OF CADMIUM(II) AT A GOLD ELECTRODE IN THE PRESENCE OF SELENIUM(IV) BY ANODIC-STRIPPING VOLTAMMETRY WITH ENHANCEMENT BY IODIDE ION

Cui Chunguo

Institute of Environmental Chemistry, Academia Sinica, P.O. Box 934, Beijing,
People's Republic of China

Summary—Anodic-stripping voltammetry (ASV) has been used in the derivative mode for the determination of cadmium, with a gold electrode in sulphuric acid medium containing selenium(IV). The peak height for cadmium is enhanced by the presence of iodide. The sensitivity for cadmium is very high, with a peak in the stripping voltamperogram at -0.27 V (*vs.* Ag/AgCl). The peak height for cadmium is not affected by over a 100-fold level of lead in the presence of selenium(IV). The dependence of peak height on the cadmium concentration is linear in the range 0.05–10 ng/ml.

Heavy-metal species such as copper(II), lead(II) and cadmium(II) are present at above normal levels in natural water in some areas. Cadmium is thought to be brought into the environment mainly by human agency. In the seas and rivers of some industrial areas cadmium concentrations may be a hundred or more times those in unpolluted regions. This creates a need for the determination of cadmium at various levels. This paper presents a method in which cadmium is determined by ASV.

Solid electrodes, the hanging mercury drop electrode and mercury-film electrodes on various solid supports such as carbon paste, graphite and glassy carbon have all been used in anodic-stripping voltammetry. We used a gold electrode in our study because (*a*) it is easily treated, (*b*) it is unnecessary to remove oxygen, (*c*) since the hydrogen overpotential on gold is higher than that on platinum, and gold does not form an oxide film at potentials less positive than $+1.0$ V in mineral acids, it is especially well suited to the determination of metals having a potential more positive than that of mercury.

Gold or gold-film electrodes have previously been used in the determination of copper(II),[1] arsenic(III),[2] bismuth(III),[3] selenium(IV),[4] mercury(II),[5] nickel-(II),[6] germanium(IV)[7] and lead(II).[8] The work reported here demonstrates the use of a gold electrode for the determination of cadmium in sulphuric acid–iodide medium by derivative anodic-stripping voltammetry.

EXPERIMENTAL

Instruments and apparatus

A model JP-1A oscillopolarograph (Chengdu Electronic Equipment Factory, China) was used in the first-derivative mode, and a 79-1 voltammetric analyser (Jinan Fourth Radio Factory, China) was used in the second-derivative mode. A three-electrode system was used, and current–potential curves were recorded with an X–Y recorder. Solutions were stirred during the deposition step, with a general-purpose magnetic stirrer.

A gold-disc electrode with a diameter of 2 mm was employed as the working electrode. The surface of the gold electrode was first rubbed with emery paper and then polished with alumina paste to a mirror-like finish. A platinum-coil auxiliary electrode and an Ag/AgCl reference electrode were used, the latter being connected to the sample solution by a saturated potassium chloride salt bridge. The body of the auxiliary electrode and the reference electrode were assembled individually in quartz tubes fitted with porous quartz plugs.

Reagents

The sulphuric acid employed was of super-pure grade. The tetraethylammonium iodide and potassium iodide were of analytical grade. The concentrated ammonia solution was of general-reagent grade. Distilled water from a quartz still was used throughout. Stock solutions (1 mg/ml) of cadmium were prepared by dissolving weighed quantities of the high-purity (99.99%) metal in nitric acid (1 + 1) and diluting to volume with distilled water. Working standards containing up to 1 μg/ml were prepared daily by diluting the stock solutions with distilled water.

Procedure

The sample solution was introduced into the electrolysis cell and stirred with an electromagnetic stirrer at a constant rate. Cadmium was then deposited at a selected potential for a definite time, after which stirring was stopped and the solution was allowed to rest for 15 sec, during which time the deposition potential was adjusted to the initial value for the scan. The potential was scanned at 100 or 250 mV/sec and the stripping curve recorded. The concentration of cadmium was evaluated by the standard-addition method. After each determination, the potential was swept from $+1.0$ to $+1.8$ V for 1–2 min, to eliminate any trace substances on the electrode.

RESULTS AND DISCUSSION

Choice of base solution

Acidic media have often been used in conjunction with gold electrodes in anodic-stripping analysis, but

when we tried sulphuric acid media no stripping peaks were observed for cadmium (Fig. 1). When tetraethylammonium iodide was added to the sulphuric acid media, however, a stripping peak for cadmium appeared in the voltamperogram (Fig. 1) with a peak potential of -0.27 V and very high sensitivity. This mixed electrolyte was therefore chosen for the determination of cadmium by ASV.

When potassium iodide was used instead of tetraethylammonium iodide the same anodic stripping peak for cadmium was obtained. Thus it may be concluded that the stripping peak of cadmium can be attributed to the effect of the iodide ion.

Choice of concentrations in the base electrolyte

The peak for cadmium was not affected by changes in sulphuric acid concentration over the range $0.0002–1.44N$ when 50 ppm of Et_4NI were present. It can be noted from Fig. 2 that the stripping peak height for cadmium was constant for Et_4NI concentrations ranging from 25 to 200 ppm at a sulphuric acid concentration of $0.36N$, but its repeatability was poorer for Et_4NI concentrations above 150 ppm, owing to oxidation of the iodide on the surface of the gold electrode. Therefore $0.0002–1.44N$ sulphuric acid with 50 ppm Et_4NI was chosen as the base electrolyte. When the cadmium content is very small, the sulphuric acid concentration must not be too high (pH should be 2–4) so as to avoid hydrogen evolution on the surface of the gold electrode.
Influence of deposition potential

The stripping current was measured after deposition for a definite time at various potentials. The results obtained are shown in Fig. 3. It can be seen that the peak height is independent of deposition potential in the range from -0.4 to -0.7 V, and diminished at more positive values. More negative potentials are unsuitable because hydrogen evolution on the surface of the electrode would influence the repeatability of the determinations. Therefore, deposition potentials ranging from -0.4 to -0.7 V were chosen as the optimum for the anodic-stripping determination of cadmium.

Influence of deposition time

A solution containing 5 ng of cadmium(II) per ml was used for testing the dependence of the peak height on deposition time. The results obtained are shown in Fig. 4. It can be seen that the peak height is linearly proportional to deposition time but the proportionality constant changes at a deposition time of about 3 min.

Interferences

It was observed that when the concentration of cadmium was as low as 2 ng/ml the following concentration levels of metal ions did not interfere: 100-fold calcium, copper, iron(III), cobalt, nickel, titanium(IV), arsenic(III), molybdenum(VI), chromium(III), manganese(II), zinc and selenium(IV); 30-fold bismuth; 20-fold silver, tin(IV) and mercury; 10-fold antimony(III), indium and lead. It should be

Fig. 3. Dependence of anodic-stripping peak height on the deposition potential in $0.36N$ H_2SO_4–50 ppm Et_4NI medium. Cd(II) $= 1$ ng/ml, ($t_{dep} = 1$ min).

Fig. 2. Dependence of anodic-stripping peak height on Et_4NI concentration. Cd(II) $= 5$ ng/ml, ($H_2SO_4 = 0.36N$ $E_{dep} = -0.4$ V, $t_{dep} = 1$ min).
Fig. 4. Dependence of anodic-stripping peak heights on deposition time in $0.36N$ H_2SO_4–50 ppm Et_4NI medium. Cd(II) $= 5$ ng/ml, ($E_{dep} = -0.6$ V).

noted that selenium has an interesting influence on the cadmium peak. A 100-ng/ml concentration of selenium(IV) diminishes the stripping peak for lead at the 2-ng/ml level and a peak potential of -0.14 V, but a 200-ng/ml level of selenium(IV) does not interfere with the stripping peak for cadmium; even a 300-ng/ml concentration of selenium only reduces the cadmium peak height by 25%. Therefore lead interference with the cadmium peak can be reduced by adding a suitable amount of selenium(IV) to the test solution. For example, the cadmium in tap water can only be determined correctly after addition of a suitable amount of selenium(IV) to the sample solution (Fig. 5). The appropriate amount of selenium(IV) to add can be found from Fig. 6. The peak height for cadmium is not affected by over 100 times as much lead in the presence of selenium(IV) when anodic-stripping voltammetry is used in the second-derivative mode. For such determinations it is therefore preferable to add 60 ng of selenium per ml to all sample and standard solutions.

Calibration

Calibration curves for cadmium under the conditions described are linear over the concentration range 0.05–10 ng/ml. It has been found that calibration curves based on the peak-heights measured in

Fig. 6. Influence of selenium(IV) on peak heights of cadmium and lead. (a) Cd(II) = 2 ng/ml, (b) Pb(II) = 2 ng/ml, ($E_{dep} = -0.6$ V, $t_{dep} = 1$ min).

Table 1. Recovery tests

Sample	Cd(II) added, ng/ml	Cd(II) found, ng/ml	Recovery, %
Tap water	0.50	0.52	104
River water	1.0	1.1	110
Waste water	2.5	2.3	92

Table 2. Results for cadmium determination in some water samples

Sample	Cd(II) content, ng/ml
Tap water	0.12 ± 0.01 (3)*
River water	0.48 ± 0.03 (3)
Waste water	1.1 ± 0.1 (3)

*Average ± standard derivation (number of determination).

the first, second and third sweeps after one deposition are linear, both in the absence and in the presence of selenium, though the peaks became progressively smaller in later scans. Interestingly, the peak for lead becomes rapidly smaller in repeated scans, the effect being much more pronounced than it is for cadmium. Thus it is possible to determine small amounts of cadmium in the presence of much larger amounts of lead by measuring the height of the stripping peak in the second or third scan.

Recovery and application

A 10-ml sample of water, which had been acidified before use, was introduced into the electrolysis cell, the pH adjusted to 2–4 with 5% ammonia solution or $0.9N$ sulphuric acid, then 0.05 ml of 10-mg/ml Et$_4$NI solution and 0.06 ml of 10-μg/ml selenium(IV) solution were added. Deposition was performed for a set time, with stirring, then after a 15-sec pause the voltamperogram was recorded. Calibration was done by the standard-addition method. The recoveries were 92–110% (Table 1). The analytical results obtained are listed in Table 2. With this method it is possible to determine cadmium in domestic tap water and in some natural waters.

ANALYSIS OF EQUILIBRIUM IN HEME MODEL SYSTEMS, BY A SUCCESSIVE LINEAR REGRESSION METHOD

Luiz A. Morino and Henrique E. Toma

Instituto de Química, Universidade de São Paulo, C.P. 20780, São Paulo, SP, Brasil

Summary—A method for determination of equilibrium constants in heme model systems is proposed, based on successive linear regression applied to spectrophotometric titrations. The method is illustrated for bis(dimethylglyoximate) iron(II) complexes with pyridine and 4-cyanopyridine ligands.

In this work we describe a convenient approach for dealing with successive equilibria, based on a simple computational method adapted for spectrophotometric titrations. As a matter of interest, we have chosen typical iron(II)-glyoximate complexes, because of their importance as models for the heme group.[1,2] These complexes are usually stabilized in the presence of axial bases, such as N_2H_4, py and imidazole, forming $Fe(Hdmg)_2(base)_2$ adducts. Mixed complexes of the type $Fe(Hdmg)_2XY$ are also known, especially with contrasting X and Y ligands, such as N_2H_4 and CO. When the bases are chemically similar, the mixed complexes are formed in equilibrium with the pure species. Their characterization requires a detailed analysis of the equilibrium reactions involved in the system.

EXPERIMENTAL

Reagents

Iron(II) acetate was prepared by reacting iron powder (Carlo Erba) with glacial acetic acid (Merck) under argon. Pyridine (Carlo Erba), 4-cyanopyridine (Aldrich), dimethylglyoxime (Carlo Erba) and chloroform (Merck) were used as supplied.

$Fe(Hdmg)_2(CNpy)_2$ and $Fe(Hdmg)_2(py)_2$ were synthesized from iron(II) acetate and the corresponding ligands, by the method of Pang and Stynes.[3] $C_{18}H_{24}N_6O_4Fe$ requires C 48.66%, N 18.92%, H 5.90%: analysis gave C 48.6%, N 19.1%, H 5.4%. $C_{20}H_{22}N_8O_4Fe$ requires C 48.60%, N 22.67%, H 4.49%: analysis gave C 48.4%, N 22.8%, H 4.5%.

Measurements

The electronic spectra of the complexes were recorded on a Cary 17 spectrophotometer fitted with constant-temperature cell compartments. The titration cell consisted of a conventional rectangular cuvette directly attached to a 10-ml cylindrical reservoir. The complexes and reagents were transferred under an argon atmosphere by syringe techniques. The measurements were made in duplicate, after 10–15 min, to ensure complete equilibration of the system.

Calculations

The procedure employed for the evaluation of equilibrium constants is described in the next section. The data used for computational analysis were selected from the experimental plots of measured molar absorptivities *vs.* ligand concentration. The calculations were done on a Burroughs B6900 computer.

RESULTS AND DISCUSSION

The measured absorptivity of a system involving a series of successive equilibria, equation (1), can be expressed by equation (2).

$$MA_x + B \rightleftharpoons MA_{x-1}B + A \qquad (1)$$

$$\epsilon_i = \frac{\epsilon_0 + \epsilon_1\beta_1 X + \epsilon_2\beta_2 X^2 + \dots \epsilon_n\beta_n X^n}{1 + \beta_1 X + \beta_2 X^2 + \dots \beta_n X^n} \qquad (2)$$

In equation (2) the subscript zero refers to the starting complex, and $X = [B]/[A]$. It is assumed that the ligands A and B do not absorb at the wavelengths employed for the measurements. When A is the solvent, the concentration of B should replace X in equation (2).

There are several methods[4,5] dealing with the evaluation of the equilibrium constants and molar absorptivities from equation (2). An extensive review has already been made by McBryde[6] and will be omitted from this paper. One of the problems associated with the methods available is the error introduced by using successive extrapolations. To overcome this problem, we have modified equation (2) in the following way:

$$H_i = \frac{(\epsilon_i - \epsilon_0) - \sum_{j=1}^{n-2} (\epsilon_j - \epsilon_i)\beta_j X^j}{(\epsilon_n - \epsilon_i)X^{n-1}}$$

$$= \frac{(\epsilon_{n-1} - \epsilon_i)}{(\epsilon_n - \epsilon_i)} \beta_{n-1} + \beta_n X \qquad (3)$$

In equation (3), $j = 1, 2, \dots n - 2$, and the other terms have the conventional meaning. Starting with previously known ϵ_0, ϵ_n, ϵ_j and β_j parameters, it is possible to evaluate ϵ_{n-1}, β_{n-1} and β_n by linear regression analysis. As a matter of fact the linear dependence between H_i and X in equation (3) provides a means of finding ϵ_{n-1}. By assuming an initial value of ϵ_{n-1} and varying it successively in a series of linear regression analyses, we can find the point of maximum correlation. This point leads to the opti-
Fig. 1. Spectrophotometric titration of $Fe(Hdmg)_2(CNpy)_2$ $(6.32 \times 10^{-5}M)$ (spectrum a) with pyridine $(0.150–143.0\ mM)$ (spectra b–j), in the presence of 4-cyanopyridine $(8.36\ mM)$, in chloroform solution, at $25°$, argon atmosphere.

Fig. 2. Variation of the standard deviation of (a) β_2, (b) β_1 and (c) the correlation coefficient as a function of ϵ_1 (535 nm), based on equation (3).

mum parameters, minimizing simultaneously the errors for β_{n-1} and β_n. The computational work is quite simple, and can be performed even with small pocket computers.

Using this method, we have investigated the equilibrium reactions of the *trans*-bis(4-cyanopyridine)bis(dimethylglyoximate)iron(II) complex, in the presence of pyridine, in chloroform solutions:

$$Fe(Hdmg)_2(CNpy)_2 + py$$

$$\xrightarrow{K_1} Fe(Hdmg)_2(CNpy)(py) + CNpy \quad (4)$$

$$Fe(Hdmg)_2(CNpy)(py) + py$$

$$\xrightarrow{K_2} Fe(Hdmg)_2(py)_2 + CNpy \quad (5)$$
Typical spectral changes observed for this system are shown in Fig. 1. A large excess of 4-cyanopyridine and pyridine relative to the iron(II) complex was used to make the free ligand concentrations practically identical to the total concentrations.

The variation of the correlation coefficient, and of the standard deviations of β_1 and β_2, as a function of ϵ_1, is shown in Fig. 2. The best correlation was found at $\epsilon_1 = 5.4 \times 10^3\ l.mole^{-1}.cm^{-1}$, coinciding

with the minimum on the standard deviation curves for β_1 and β_2. The optimum parameters are collected in Table 1.

When a computer is not available, ϵ_{n-1}, β_{n-1} and β_n can be calculated by a graphical procedure. By plotting the left-hand side of equation (3) against X, we obtain from the intercept:

$$\lim_{X \to 0} H_i = \frac{(\epsilon_{n-1} - \epsilon_0)\beta_{n-1}}{\epsilon_n - \epsilon_0} = I \quad (6)$$

Combining equations (6) and (3) gives

$$\frac{H_i}{X} - \frac{I(\epsilon_n - \epsilon_0)}{(\epsilon_n - \epsilon_i)X} = \beta_n + \beta_{n-1}\frac{(\epsilon_0 - \epsilon_i)}{(\epsilon_n - \epsilon_i)X} \quad (7)$$

The equilibrium constants β_n and β_{n-1} are obtained from the linear plots of the left-hand side of equation (7) against $(\epsilon_0 - \epsilon_i)/(\epsilon_n - \epsilon_i)X$. Substitution of β_{n-1} into equation (6) leads to ϵ_{n-1}. The results calculated in this way for the dimethylglyoximate complexes can also be seen in Table 1. There is a reasonable

agreement with the optimum values based on the computational analysis.

Equation (7) is also suitable for linear regression. Starting with an estimate of I, the point of maximum correlation can be easily determined, yielding the optimized equilibrium constants.

The distribution plots for the dimethylglyoximate complexes are shown in Fig. 3. The fact that K_1 is 20 times K_2 indicates a strong *trans* influence (in addition to the statistical effect), preferentially stabilizing the mixed (CNpy)Fe(Hdmg)$_2$(py) complex. It is consistent with the observed tendency for the heme group to bind contrasting axial ligands, such as imidazole and CO, or imidazole and thioether residues of amino-acids (*e.g.*,[5] in cytochrome-c).

As shown in Table 1, the method gives accurate results. It is ideal for a system with two successive equilibria, as for the complexes investigated here. In a system with three equilibria, K_1 and ϵ_1 should be previously determined, by working, for instance, with a large excess of the metal ion relative to the ligands. Like other methods based on equation (2), the actual free ligand concentrations are now known. Refinement cycles, starting with the total concentrations, might be necessary, until self-consistency is achieved.

ANALYTICAL DATA

EFFECT OF pH ON CHROMIUM(VI) SPECIES IN SOLUTION

R. K. TANDON,* P. T. CRISP and J. ELLIS
Department of Chemistry, University of Wollongong, Wollongong, N.S.W. 2500, Australia

R. S. BAKER
Cell Biology Laboratory, Commonwealth Institute of Health, University of Sydney,
N.S.W. 2006, Australia

Summary—Published values of equilibrium constants were used to calculate the percentage of each chromium(VI) species (CrO_4^{2-}, $Cr_2O_7^{2-}$, $HCrO_4^-$ and H_2CrO_4) present in aqueous solution at total chromium(VI) concentrations of 10^{-2}–$10^{-6}M$ in the pH range 1–8.

The analytical chemistry of chromium(VI) has been described extensively in the literature[1-3] but no tabulation of the abundance of chromium(VI) species at different pH values and metal concentrations has been published apart from a brief account of the $HCrO_4^-/CrO_4^{2-}$ equilibrium. Such data are essential for studies of environmental chromium speciation. Chromium(VI) may be present in aqueous solution as chromate (CrO_4^{2-}), dichromate ($Cr_2O_7^{2-}$), hydrogen chromate ($HCrO_4^-$), dihydrogen chromate (chromic acid, H_2CrO_4), hydrogen dichromate ($HCr_2O_7^-$), trichromate ($Cr_3O_{10}^{2-}$) and tetrachromate ($Cr_4O_{13}^{2-}$). The last three ions have been detected only in solutions of pH < 0 or at chromium(VI) concentrations greater than $1M$.[2-4] Polyanions containing > 4 chromium atoms are not known, and probably do not exist, on account of chromium–oxygen multiple bonding.[4] Three pH regions may be distinguished for chromium(VI) species: (*i*) pH ≤ 0, where H_2CrO_4 is a significant species, (*ii*) pH = 2–6, where $HCrO_4^-$ and $Cr_2O_7^{2-}$ occur together, and (*iii*) pH > 6, where CrO_4^{2-} predominates.

The published values of the chromium(VI) equilibrium constants used in the calculations in this paper are given in Table 1. Contributions from

$HCr_2O_7^-$, $Cr_3O_{10}^{2-}$ and $Cr_4O_{13}^{2-}$ are negligible at pH > 1 and at chromium(VI) concentrations $\leq 10^{-2}M$. The concentration of H_2CrO_4 (x) in a solution of pH p and total chromium(VI) concentration C was obtained by solving the quadratic equation

$$x + \frac{k_1 x}{p} + \frac{k_1 k_2 x}{p^2} + \frac{k_3 k_1^2 x^2}{p^2} - C = 0$$

The concentrations of the other chromium(VI) species were obtained from

$$[HCrO_4^-] = k_1 x/p$$
$$[CrO_4^{2-}] = k_1 k_2 x/p^2$$
$$[Cr_2O_7^{2-}] = k_3 k_1^2 x^2/p^2$$

The equations were solved on a Univac 1100 computer by using a Fortran program (available on request from the authors).

RESULTS AND DISCUSSION

Results obtained by using $k_3 = 98$ are given in Table 2. This value of k_3 was determined at an ionic strength (μ) of unity.[7] If a value of $k_3 = 35.5$ ($\mu = 0$) is used, the dichromate concentrations are approximately half those given in Table 2 and the concentrations of the other species are correspondingly greater. The results in Table 2 are consistent with

---

Service Commun de Spectrométrie de Masse de l'Université de Nancy I, 54001 Nancy, France

Résumé—On propose un schéma de dégradation de la tétryzoline [(tétrahydro-1,2,3,4 naphtyl-1)-2Δ₂-imidazoline] après avoir soumis cette molécule à des réactions d'hydrolyse en milieu alcalin et acide. Les composés intermédiaires ont été isolés, purifiés et identifiés par les techniques modernes d'analyse. L'utilisation de la spectrométrie de masse a permis d'établir leur structure. Après ouverture du cycle imidazoline en milieu alcalin, l'hydrolyse acide conduit à la perte de la chaine latérale précédemment obtenue et à l'obtention d'acide tétrahydro-1,2,3,4 naphtoïque-1 et d'éthylènediamine.

La tétryzoline, [(tétrahydro-1,2,3,4 naphtyl-1)-2Δ₂-imidazoline], est une molécule à propriétés vaso-constrictrices entrant dans la composition de plusieurs spécialités pharmaceutiques et dont le schéma de dégradation n'a pas été décrit à ce jour. Cependant, d'autres imidazolines ont fait l'objet d'études de stabilité: naphazoline,[1-3] indanazoline,[4] tolazoline.[5] Dans tous les cas, la première étape de dégradation conduit à une amide substituée, qui est ultérieurement hydrolysée en acide aromatique et en éthylènediamine. La tétryzoline n'étant pas fondamentalement différente de ces imidazolines par sa structure chimique (Fig. 1), son schéma de dégradation doit être voisin. Nous nous proposons de le vérifier en isolant les produits intermédiaires et en déterminant leur structure par les techniques spectroscopiques habituelles.

PARTIE EXPERIMENTALE

Méthodes

Chromatographie en couche mince. Elle est réalisée sur des plaques de silice type 60 F 254 (Merck). Le solvant est un mélange ammoniaque 25%–eau–éthanol (5:15:80 v/v). La révélation est effectuée soit par le rayonnement ultra-violet à 254 nm, soit par pulvérisation d'une solution de nin-hydrine à 1% dans de l'éthanol.

Chromatographie en phase gazeuse. L'appareil utilisé est de marque Girdel série 30. La colonne de verre est remplie de phase OV₁ 3% sur Chromosorb Q (100–120 mesh). Le détecteur est à ionisation de flamme. Les conditions de température sont fixées à 180° pour le four, 240° pour l'injecteur et le détecteur. Le débit d'azote est de 25 ml/min.

Spectroscopie infra-rouge. Les spectres sont réalisés avec un appareil Beckman type Acculab IV. Les composés sont analysés à la concentration de 1% sous forme de pastilles de bromure de potassium.

Spectrométrie de masse. Les spectres de masse sont obtenus par introduction directe sur un appareil LKB 2091 avec les conditions opératoires suivantes: energie d'ionisation par impact électronique 70 eV; potentiel d'accélération 3,5 kV; température de la source 280°; courant "trap" 50 μA.

Obtention du produit d'hydrolyse alcaline de la tétryzoline. Le chlorhydrate de tétryzoline (1,18 g, 5 mmole) est chauffé à reflux et à l'ébullition sous agitation magnétique pendant 1 hr en présence de 50 ml de soude 1N. Après refroidissement, le produit est extrait successivement par deux fois 20 ml de chloroforme. Les phases organiques sont séchées par du sulfate de sodium anhydre, filtrées et évaporées sous pression réduite. Le produit (P₁) est blanc, visqueux et cristallise progressivement (Tf = 81–82°).

Obtention du produit d'hydrolyse acide du composé P₁. Composé P₁ (0,5 g) est chauffé à reflux en présence de 25 ml d'acide chlorhydrique 2M pendant 20 hr. Après refroidissement et alcalinisation par de la lessive de soude, le milieu est extrait par deux fois 20 ml de chloroforme afin d'éliminer les composés neutres et basiques éventuellement présents. Après acidification de la phase aqueuse par l'acide
Fig. 2. Schéma de fragmentation du composé P_1.

chlorhydrique concentré, les composés sont extraits par deux fois 20 ml de chloroforme. Les phases organiques sont réunies, séchées par du sulfate de sodium anhydre, filtrées et évaporées sous pression réduite. Le résidu cristallise sous forme de cristaux blancs (P_2) de point de fusion voisin de 79–81°.

RESULTATS ET DISCUSSION

Analyses chromatographiques

Le composé P_1 présente les caractéristiques d'un produit pur aussi bien en chromatographie en couche mince ($R_f = 0,61$) qu'en chromatographie en phase gazeuse ($t_r = 3$ min). Dans chacune de ces analyses, on ne retrouve pas la tétryzoline ($R_f = 0,33$ et $t_r = 2$ min). De plus, le composé P_1 est révélable par la ninhydrine, ce qui indique la présence d'un groupement amine primaire.

Le composé P_2 est obtenu à partir de P_1 par hydrolyse acide. Le temps de réaction a été déterminé en suivant la disparition de P_1 par chromatographie en phase gazeuse. En chromatographie en couche mince, le composé P_2 présente un R_f de 0,71. Il est révélé uniquement par le rayonnement ultra-violet.
Fig. 3. Schéma de dégradation de la tétryzoline.

Analyses par spectrométrie infra-rouge

Le spectre infra-rouge du composé P_1 présente les bandes caractéristiques d'un groupement amide: bande CO à 1640 cm^{-1} et bandes NH à 3280 cm^{-1} et 1540 cm^{-1}. Par contre, le spectre du composé P_2 présente uniquement les bandes caractéristiques d'un groupement carboxyle à 1680 cm^{-1} et 2930–3100 cm^{-1}.

Analyses par spectrométrie de masse

L'emploi d'un spectromètre de masse à secteur magnétique met en évidence un certain nombre d'ions dits "métastables". Ce type d'ions permet de suivre directement l'ordre de certaines fragmentations grâce à la relation $m^* = m_2^2/m_1$ dans laquelle m^* est la position en u.m.a. de l'ion métastable, m_1 celle de l'ion père et m_2 celle de l'ion fils. L'étude analytique de Porter et Baldas sur les imidazolines nous donne également de précieuses indications.[6]

Spectre de masse de la tétryzoline. Il présente un pic moléculaire qui est aussi pic de base à $m/z = 200$. L'ion à $m/z = 185$ résulte très certainement de la perte d'un groupement $(CH_2 + H)^*$ d'un noyau imidazoline tandis que l'ion à $m/z = 171$ provient de l'ion moléculaire par perte du fragment $CH_2 = NH$ (ion métastable à $m/z = 147$). L'ion à $m/z = 131$ résulte de la perte du cycle imidazoline et le pic à $m/z = 91$ (ion tropylium) est le résultat de la rupture du cycle tetrahydronaphtalénique.

Spectre de masse du composé P_1. Il présente un pic moléculaire à $m/z = 218$. Le fragment à $m/z = 189$ provient de l'ion moléculaire par perte d'un fragment $CH_2 = NH$ (ion métastable à $m/z = 164$). De même le pic à $m/z = 176$ a pour précurseur le pic à $m/z = 218$ par perte d'un fragment de masse 42 (ion métastable à $m/z = 141$). Le pic à $m/z = 189$ est lui-même précurseur de l'ion à $m/z = 160$ (ion métastable à $m/z = 135,5$). Le pic de base à $m/z = 131$ correspond à la perte de la totalité de la chaine latérale. Ces observations permettent de considérer le composé P_1 comme résultant de l'addition d'une molécule d'eau après ouverture du cycle imidazoline pour donner l'amide correspondante. Le schéma de fragmentation proposé est représenté à Fig. 2.

Spectre de masse du composé P_2. Le pic moléculaire est situé à $m/z = 176$ et correspond à l'acide tétrahydro-1,2,3,4 naphtoïque-1. Le pic de base à $m/z = 131$ résulte de la perte du groupement carboxylique pour obtenir comme précédemment le noyau tétrahydronaphtalénique.

Proposition d'un schéma de dégradation

Considérant les résultats des analyses spectrales pratiquées, les composés P_1 et P_2 peuvent être dénommés respectivement la N (amino-2 éthyl) tétrahydro-1,2,3,4 naphtamide-1 et l'acide tétrahydro-1,2,3,4 naphtoïque-1. Le schéma de dégradation logique proposé est représenté à Fig. 3.

CONCLUSION

Plusieurs imidazolines ont fait l'objet d'études concernant leur mode de dégradation.[1-5] Cependant, la structure des composés n'avait pas été clairement établie et il s'agissait surtout de suivre la teneur en imidazoline soit par colorimétrie,[3] soit par chromatographie liquide haute pression.[4] Seul, Schwartz et al.[2] ont séparé les produits acides et basiques résultant de l'hydrolyse. Ils ont déterminé leur composition centésimale et ont étudié leur spectre d'absorption dans l'ultra-violet.

L'étude que nous avons menée sur la tétryzoline apporte les éléments d'analyse structurale nécessaires à caractériser sans ambiguité les produits formés. Elle montre également que l'originalité structurale de la tétryzoline—absence de pont entre les noyaux tétrahydronaphtalénique et imidazoline—ne conduit pas à un schéma particulier de dégradation.

Summary—The products of hydrolysis of tetrahydrozoline [2-(1,2,3,4-tetrahydro-1-naphthyl)-2-imidazoline] have been isolated by thin-layer chromatography and identified by ultraviolet and infrared spectroscopic analysis. Their structure has been well established by use of mass spectrometry and a degradation scheme advanced. Alkaline hydrolysis opens the imidazoline ring to give an amide compound which undergoes further hydrolysis, in acid solution, to 1,2,3,4-tetrahydronaphthoic acid and ethylenediamine.

LETTER TO THE EDITOR

THE SPECTROPHOTOMETRIC EVALUATION OF ACIDITY CONSTANTS: THE DOUBLE INCOMPLETE COLOUR CHANGE

SIR,

On the basis of the indirect colorimetric methods described by Sacconi,[1] Ingman[2] formulated various equations applicable in cases in which the molar absorptivity of one or both of the limiting forms of an acceptor-donor system, e.g., $\mathcal{E}_{HR}$ and $\mathcal{E}_R$ of an acid-base conjugate pair HR/R, is unknown. There is a point in this paper which deserves attention.

Linear equations in four terms and three unknowns[3] can be used to evaluate the pK_a of a monoprotic acid:

$$\frac{[H]_i \, A_i}{K_a} - \frac{[H]_i \, \mathcal{E}_{HR}}{K_a} - \mathcal{E}_R = A_i$$

in which A_i is the absorbance of a solution containing a mixture of HR and R, and charges are omitted for simplicity. The results for any three solutions give, after an appropriate arrangement:

$$K_a = \frac{[H]_3 \, (A_3 - A_2) \, ([H]_1 - [H]_2) + [H]_1 \, (A_1 - A_2) \, ([H]_2 - [H]_3)}{(A_3 - A_2) \, ([H]_2 - [H]_1) + (A_1 - A_2) \, ([H]_3 - [H]_2)}$$

By dividing numerator and denominator of this equation by $[H]_1 \, (A_1 - A_2)$ and writing, as in Ingman's paper, $(A_3 - A_2)/(A_1 - A_2) = r''$, $[H]_1/[H]_2 = q_I$ and $[H]_3/[H]_2 = q_{II}$, we get:

$$K_a = \frac{q_{II} r'' \, (q_I - 1) + q_I \, (1 - q_{II})}{r'' \, (1 - q_I) + (q_{II} - 1)} [H]_2 \tag{1}$$

which is equivalent to the expression established by Ingman for the case that Sacconi called the double incomplete colour change.[1] An expression equivalent to (1) was deduced by Romain and Colleter.[4] It means that the only restriction to be imposed on the absorbance and pH values selected for the evaluation of pK_a is that they differ enough to be accurately distinguishable. Likewise, for $\mathcal{E}_{HR}$ and $\mathcal{E}_R$ we obtain:

$$\mathcal{E}_{HR} = \frac{A_3 \, (q_{II} - 1) + A_1 \, r'' \, (1 - q_I)}{r'' \, (1 - q_I) + (q_{II} - 1)} \tag{2}$$

$$\mathcal{E}_R = \frac{q_{II} \, r'' \, (A_1 - A_2 q_I) + q_I \, (A_2 q_{II} - A_3)}{q_{II} \, r'' \, (1 - q_I) + q_I \, (q_{II} - 1)} \tag{3}$$

Equations $(2) - (3)$ have not been reported so far by other workers. A program (input data pH_1, $\underline{A}_1$, pH_2 $\underline{A}_2$, pH_3, $\underline{A}_3$; output data, $\underline{K}_a$, $p\underline{K}_a$, $\mathcal{E}_{HR}$, $\mathcal{E}_R$; 6 labels, 193 steps) for use with a Texas Tl 58/59 pocket calculator and based on equations $(1) - (3)$ has been devised and is available upon request to the authors.

SOLVENT EXTRACTION-SPECTROPHOTOMETRIC DETERMINATION OF PHOSPHATE WITH MOLYBDATE AND MALACHITE GREEN IN RIVER WATER AND SEA-WATER

SHOJI MOTOMIZU, TOSHIAKI WAKIMOTO and KYOJI TÔEI
Department of Chemistry, Faculty of Science, Okayama University, Tsushimanaka, Okayama-shi, Japan

Summary—Molybdophosphate, formed between orthophosphate and molybdate in sulphuric acid solution, is extracted into a mixture of toluene and 4-methylpentan-2-one (1:3 v/v) with Malachite Green as counter-ion. A single extraction with equal phase volumes gives an apparent molar absorptivity for phosphate of 2.3×10^5 $1.\text{mole}^{-1}.\text{cm}^{-1}$ at 630 nm; the absorbance of the reagent blank is 0.03. With an organic to aqueous phase-volume ratio of 1:10, the molar absorptivity is 2.5×10^5 $1.\text{mole}^{-1}.\text{cm}^{-1}$ and the absorbance of the reagent blank 0.08. By the proposed method, ng/ml levels of phosphorus can be determined, and the detection limit is about 0.1 ng/ml. The standard deviation and relative standard deviation for the determination of phosphorus in tap water (4.3 ng/ml) are 0.05 ng/ml and 1.1%, respectively. The method can also be applied to the determination of phosphorus in river water and sea-water.

Most spectrophotometric methods for phosphate are based on the formation of a heteropoly acid with molybdate. The heteropoly acid formed can be extracted into an organic phase, as an ion-pair with a bulky cation such as a quaternary ammonium ion or cationic dye. Several studies on the solvent extraction of molybdophosphate with cationic dyes have already been reported.[1-6] The main advantage of cationic dyes over that of quaternary ammonium salts is their greater light-absorbing ability. We have already used Ethyl Violet as counter-ion for molybdophosphate.[6] The spectrophotometric determination of phosphate by solvent extraction of molybdophosphate with Ethyl Violet is more sensitive than those previously reported[1-5] and less troublesome: a single extraction is adequate. However, in the determination of phosphorus at ng/ml levels in waters it has certain disadvantages. First, the absorbance of the reagent blank becomes too large for the concentration effect achieved by the solvent extraction to be of much use: for example, when 20 ml of sample solution and 5 ml of organic solvent were used, the absorbance of the reagent blank was 0.14. Secondly, the shaking time needed was long and the colour of the extract faded gradually if the shaking lasted more than 30 min. In the course of attempts to improve on this method, we noticed that Malachite Green gave a stable dark yellow species in 1.5*M* sulphuric acid (probably a protonated one), whereas Ethyl Violet became colourless within 30 min even in only 0.5*M* sulphuric acid.

Malachite Green has been used as the chromophore for the determination of phosphate in serum, plasma and urine[7-15] and in water.[16] Altman *et al.*[17]

reported the mechanism of the colorimetric reaction between molybdophosphate and Malachite Green. This dye has also been used in a flotation separation of molybdophosphate.[18] However, it has been seldom used as the counter-ion for the extractive spectrophotometry of phosphate, because an ion-pair formed between Malachite Green and molybdophosphate has been considered less extractable than that formed by Safranine T or Crystal Violet.

In this work, we attempt to improve the extractability of the ion-pair formed between Malachite Green and molybdophosphate. Though the molar absorptivity obtained is about 10% less than that for the Ethyl Violet system, the method has several advantages: (1) the absorbance of the reagent blank is very small, and 20-fold concentration of phosphate by solvent extraction is possible, (2) the reagent solution, which consists of Malachite Green, molybdate and 1.5*M* sulphuric acid is stable at least for a month, (3) the method is less troublesome and shaking for 5 min is enough to complete the extraction, and (4) colour fading in the organic phase does not occur during shaking and standing.

EXPERIMENTAL

Apparatus

The absorptiometric measurements were made on a Hitachi EPS recording spectrophotometer and a Hitachi-Perkin-Elmer Model 139 spectrophotometer in glass cells of 10-mm path length. An Iwaki Model V-S Type KM shaker was used to shake the separatory funnel and the stoppered test-tubes.

Reagents

Cationic dyes. Triphenylmethane dyes [pararosaniline, Crystal Violet, Ethyl Violet, Malachite Green (chloride and

oxalate), Brilliant Green, Hoffman's Violet, New Fuchsin and Methyl Violet] and Methylene Blue were examined. These dyes were commercially available and used (without further purification) as solutions in distilled water.

Standard phosphate solution. Potassium dihydrogen phosphate was dried at reduced pressure (about 5 mmHg) and 60° to constant weight; 0.2722 g of the dried compound was dissolved in distilled water and diluted to give 1 litre of $2 \times 10^{-3}M$ solution. For calibration purposes, this solution was accurately diluted with distilled water before use.

Extracting solvent. Ketones, alcohols, esters, benzene and toluene were examined.

Reagent solution. Dissolve 86 g of ammonium heptamolybdate tetrahydrate in about 900 ml of distilled water, add 86 ml of concentrated sulphuric acid, dissolve 0.23 g of Malachite Green (oxalate) and 20 g of tartaric acid in the mixture, and dilute to 1 litre with distilled water. About 1 hr after mixing, filter the solution through a 0.45-μm membrane filter.

All reagents used were of analytical-reagent grade.

Procedure

Transfer 10 ml of the sample solution, containing up to 0.7 μg of phosphorus as orthophosphate, into a 25-ml test-tube. Add 1 ml each of 4.5M sulphuric acid and the reagent solution and mix. Shake the solution with 5 ml of a 1:3 v/v mixture of toluene and 4-methylpentan-2-one (MIBK) for 5 min. After phase separation, measure the absorbance of the organic phase at 630 nm against a reagent blank, in 1-cm cells.

RESULTS AND DISCUSSION

Selection of the cationic dye and extracting solvent

The colour changes and ionization of triphenylmethane dyes are very complex. Adams and Rosenstein[19] studied the behaviour of Crystal Violet at various pH values. The mechanism of colour change was explained by considering three kinds of coloured quinonoid ions, four kinds of colourless benzenoid ions and colourless carbinol and its protonated ions. Goldacre and Phillips,[20] and Cigén,[21] have also studied the ionization behaviour of Crystal Violet. They found that in acidic medium it is easily transformed into a protonated but colourless carbinol. Ethyl Violet may behave similarly to Crystal Violet and transform into its carbinol.

We have examined the colour fading of cationic dyes in acidic medium. Of the nine dyes listed under *Reagents*, above, Malachite Green, pararosaniline, New Fuchsin, Hoffman's Violet and Methylene Blue were dark yellow, pale yellow, red, violet and blue in 0.5M sulphuric acid, respectively, and the others were colourless within about 60 min from preparation of the solution. When Hoffman's Violet, Methyl Violet and Methylene Blue were used as the counter-ion for molybdophosphate, a coloured precipitate occurred at the interface and the ion-pair was scarcely extracted at all into a 1:3 v/v mixture of toluene and 4-methylpentan-2-one. Pararosaniline and New Fuchsin also failed as reagents for extraction of the molybdophosphate. The oxalate of Malachite Green was preferable to the chloride, because it gave a more stable aqueous solution and was purer than the

chloride. Recrystallization did not significantly improve the purity ($\sim$90%).

Table 1 shows the results for the efficiency of the extracting solvent, with Malachite Green as the counter-ion. A 1:2 v/v mixture of benzene and 4-methylpentan-2-one is best in terms of molar absorptivity and reagent blank absorbance. However, we prefer a 1:3 v/v mixture of toluene and the ketone, because of the lower toxicity of toluene.

Effect of acidity and reagent concentration

To 10 ml of sample solution containing 0.364 μg of phosphorus, sulphuric acid, molybdate and Malachite Green solutions were added in that order. The solution was diluted to 12 ml, and shaken with 5 ml of an extracting solvent for 5 min.

Sulphuric acid concentration. When the acid concentration was varied from 0.3 to 1.0M, the absorbance for phosphorus samples measured against the reagent blank was maximal and constant for the acidity range 0.42–0.67M. The absorbance of the reagent blank decreased gradually with increase in sulphuric acid concentration, but was almost constant in the acid range of 0.5–0.83M. A sulphuric acid concentration of about 0.5M was therefore selected as optimal.

Malachite Green concentration. The dye concentration was varied from 2×10^{-5} to $2 \times 10^{-4}M$. The absorbance for phosphorus (measured against the reagent blank) was maximal and constant with a dyestuff concentration between 2.5×10^{-5} and $8.5 \times 10^{-5}M$. The absorbance of the reagent blank increased gradually as the dye concentration was increased. A dye concentration of $4 \times 10^{-5}M$ was therefore chosen.

Molybdate concentration. When the molybdate concentration was varied from 1×10^{-2} to $7.5 \times 10^{-2}M$, the absorbance for phosphorus, measured against the reagent blank was maximal and constant for [molybdate] = 1.5–$4.5 \times 10^{-2}M$. The absorbance of the reagent blank increased gradually as the molybdate concentration was increased. A molybdate concentration of $4 \times 10^{-2}M$ was chosen.

Contamination from reagents. When sulphuric acid, molybdate and Malachite Green solutions were added in that order to the sample solution, the reagent blank was larger than that obtained by adding the mixed reagent solution, and differed according to the source of the ammonium molybdate. Table 2 shows the absorbances obtained by varying the concentration of molybdate. The small absorbance of about 0.02 obtained without the addition of molybdate may be attributed to some degradation products of Malachite Green. The difference between the absorbances of solutions with and without molybdate is probably due to phosphate contained in the molybdate. From the slope of plots of absorbance *vs.* molybdate concentration, the phosphate content of the ammonium molybdate was calculated and found to range from 6×10^{-5} to 8×10^{-5}%. On the other hand, the absorbances obtained by using the mixed

reagent solution were almost all the same. This is because the ion-pair formed between molybdo-phosphate and Malachite Green is only slightly soluble in water and filtration of the reagent solution 1 hr after its preparation removes about two-thirds of the molybdophosphate.

On the basis of these results, the mixed reagent solution was used throughout further work.

Shaking and standing time. Figure 1 shows that 3 min of shaking is adequate. Compared with the Ethyl Violet method the proposed method has the advantages that (1) the shaking time is shorter, (2) there is

no colour fading during 60 min of shaking and (3) the absorbance of the reagent blank is constant during 30 min of shaking. Complete phase separation after the shaking takes about 1 min, and the absorbance of the organic phase remains constant for at least one day.

Absorption spectra and calibration graph

The absorption spectra of the ion-pair and the reagent blank are shown in Fig. 2. Linear calibration graphs are obtained even when the aqueous phase volume is increased to 100 ml (and 7 ml of extracting solvent are used). The results obtained by varying the volume of sample solution are shown in Table 3,

which shows that when 50 ml of sample solution are used, 0.1 ng/ml of phosphorus can be detected.

Effect of other ions

This was examined by using 10 ml of sample solution and the results are shown in Table 4. Most cations and anions commonly found in natural waters do not interfere, but arsenic(V) causes large positive errors: arsenic(V) at a concentration of 10 ng/ml produces an absorbance of 0.070 but can be masked with tartaric acid (added in the reagent

Table 6. Determination of phosphorus in river and sea-water, and recovery test

Ushimado		12.8	8	102	248	351	100
Nishiwaki		20.9	8	167	248	419	101

The samples were adjusted to about pH 3 with dilute sulphuric acid after sampling, and filtered through a membrane filter (0.45 μm). An appropriate amount of sample was transferred to a 25-ml test-tube, 1 ml of 4.5M sulphuric acid was added, and the mixture was heated at 95° for 30 min. The sea-water samples were diluted to 25 ml with distilled water. A 10-ml sample was used, except for Yoshii River sample D and the Kojima sea-water for which 5-ml samples were used. In the recovery tests, the river water was diluted to 10 ml with distilled water after the addition of 248 ng of phosphorus (as phosphate), and the sea-water was diluted to 25 ml with distilled water after the addition of phosphorus.
*The values are the means of 3 determinations.

solution). When arsenic(V) was present at concentrations of 50 ng/ml, it was masked with 0.1 ml of $10^{-4}M$ sodium thiosulphate added after the sulphuric acid (see *Procedure*).

For a 25-ml sample, almost all the foreign ions tested, when present at the concentrations listed in Table 4, produced an absorbance of less than 0.005.

With 50 ml of sample solution, the effect of several ions commonly found in fresh water was examined. The following ions produced an absorbance of less than 0.005: Mg^{2+} $(10^{-2}M)$, Ca^{2+} $(10^{-2}M)$, SO_4^{2-} $(10^{-2}M)$, Na^+ $(10^{-3}M)$, K^+ $(10^{-3}M)$, Fe^{3+} $(10^{-3}M)$, Al^{3+} $(10^{-3}M)$, NH_4^+ $(10^{-3}M)$, Cl^- $(10^{-3}M)$, HCO_3^- $(10^{-3}M)$, SiO_3^{2-} $(5 \times 10^{-4}M)$ and NO_3^- $(5 \times 10^{-4}M)$. These concentrations refer to the sample itself; the effect of the sulphate and ammonium ions present in the reagent solution is compensated for by the reagent blank.

Determination of phosphorus in waters

Phosphorus occurs in natural water as orthophosphate, condensed phosphate and organically-bound phosphorus, all of which may be present in soluble forms and in suspension. By the method proposed in this work, only orthophosphate can be directly determined. Condensed phosphate, however, can be completely hydrolysed to orthophosphate by acidifying the solution with sulphuric acid $(0.4M)$ and heating for 30 min at above $90°$.[6,16] In Table 5, the efficiency of conversion of phosphorus compounds into orthophosphate is shown. Under the conditions used for hydrolysis of condensed phosphate, these compounds were scarcely decomposed, but in the presence of ammonium peroxodisulphate were completely converted into orthophosphate by heating for more than 90 min. When 0.1 ml of 40% peroxodisulphate solution was used, the absorbance of the reagent blank became a little larger: 0.080. In further experiments on determination of phosphorus in natural waters, the decomposition treatment with peroxodisulphate was omitted, because it did not increase the amount of phosphate found. Table 6

shows the results for determination of phosphorus in waters. Less than 15 ml of sea-water was taken as sample, and was diluted to 25 ml with distilled water, because of its high chloride content $(\sim 0.5M)$.

Recovery tests were done by adding known amounts of phosphate. The results are also shown in Table 6. The recovery of phosphorus was good: 99–103%. The relative standard deviation for phosphorus was 0.6% for 21.0 ng/ml in sea-water (12 replicates) and 1.1% for 4.28 ng/ml in tap water (10 replicates).

INFLUENCE AND ROLE OF METAL IONS IN ENZYMATIC CATALYSIS WITH E.C. 1.2.3.2. XANTHINE OXIDASE*

APPLICATION TO TRACE ANALYSIS

Anna Maria Ghe,† Claudio Stefanelli and Daniela Carati

Istituto Chimico "G. Ciamician" dell'Università, Scuola di Specializzazione in Chimica Analitica,
Via Selmi 2, 40126 Bologna, Italia

Summary—The effect of metal ions on the reductive half-reaction of xanthine oxidase (XOD) in the catalytic conversion of xanthine into uric acid has been studied spectrophotometrically in Tris–HCl buffer at pH 7.4, $37 \pm 0.1°$ and ionic strength $0.04M$. Some metal ions display inhibitor properties, the sequence of inhibiting efficiency being Ag(I) > Hg(II) > Cu(II) > Cr(VI) > V(V) > Au(III) > Tl(I) and for these the I_{50} values were determined. Only Tl(I), V(V) and Cu(II) showed reversible inhibition and therefore for these the mechanisms were assessed [competitive for V(V) and Tl(I); uncompetitive for Cu(II)]. The conditional inhibition constants (K_i) were also determined. The effect of EDTA for protection of the enzyme against metal inhibition, and for its reactivation after inhibition, was also investigated. Utilization of the linear relationship between relative enzyme activity and inhibitor concentration allowed sensitive and selective (though not specific) determination of Ag(I) and Hg(II) (10^{-9}–$10^{-8}M$), and of Cu(II) and Cr(VI) (10^{-7}–$10^{-6}M$), the maximum relative error being $\pm 4\%$. For a few metal ions, *e.g.*, Ag(I) and Cr(VI), in the presence of EDTA, a certain specificity is observed.

The study of the effect of traces of metal ions on enzymatic activity has attracted considerable interest in recent years, particularly in the use of enzymes for the analysis of substrates and inhibitors,[1–6] and in the modification of biological systems.[7–9] The concentration limit for determination depends on the stability of the complex formed [(enzyme–inhibitor) or (enzyme–activator) or possibly (enzyme–substrate)–inhibitor].[10] The method is not always specific, but is both sensitive and selective. These characteristics can be improved, in the case of prosthetic metal determination of metal-enzymes, by means of apo-form reactivation, *e.g.*, by removal of the metal by complexation.[11]

The accuracy of the analytical determination of trace elements, and the study of the role of metallic ions in a given metabolic cycle, are not, however, the sole goals of these studies, since the acquisition of structural data on the active sites or the nature of the metal–enzyme bond, and on the formation and decomposition mechanism of metal complexes is also a worthwhile objective.[12]

In the present work we have studied the enzymatic catalysis of xanthine oxidase (XOD). This enzyme (average molecular weight[13] $\sim 2.8 \times 10^5$) is composed of two subunits, generally considered identical,[14] each containing three prosthetic groups: (*a*) one Mo atom at the active site for oxidation of xanthine, (*b*) an FAD (flavinadenine dinucleotide) molecule at the active site for reduction of oxygen and (*c*) two iron/sulphur systems (I and II), non-equivalent,[15] which probably act as electron-reservoirs during the catalytic cycle, so that electron transfer takes place according to the sequence:[13]

$$\text{xanthine} \rightarrow \text{Mo} \rightarrow \text{Fe/S} \rightarrow \text{FAD} \rightarrow \text{O}_2$$

The enzyme oxidizes xanthine to uric acid, molecular oxygen acting as the electron acceptor and being reduced to hydrogen peroxide and the superoxide radical (O_2^-), within an overall reaction which, on the basis of the behaviour of milk xanthine oxidase,[16–18] can be shown schematically as

$$3X + 3H_2O + 4O_2 \xrightarrow{\text{XOD}} 3U + 2H_2O_2 + 2O_2^- + 2H^+$$
where X stands for xanthine and U for uric acid.

This overall reaction can be subdivided into two half-reactions, the enzyme reductive step leading to the formation of uric acid[16] and the enzyme oxidative half-reaction[17,18] leading to the formation of H_2O_2 and O_2^-.

The first half-reaction can be envisaged as follows:
$$\begin{array}{c} \text{X} \qquad\qquad\qquad\qquad \text{U} \\ \downarrow + \qquad\qquad\qquad\qquad \uparrow \\ E_0 \rightleftharpoons [E_0X] \xrightarrow[K_2]{} [E_2X] \xrightarrow[K_3]{+H_2O} E_2 \end{array} \qquad (1)$$

$$\begin{array}{c} \text{X} \qquad\qquad\qquad\qquad \text{U} \\ \downarrow + \qquad\qquad\qquad\qquad \uparrow \\ E_2 \rightleftharpoons [E_2X] \xrightarrow[K_2]{} [E_4X] \xrightarrow[K_3]{+H_2O} E_4 \end{array} \qquad (1')$$

†Author to whom correspondence should be addressed.

$$\begin{array}{cc} X & U \\ \big\downarrow + & \uparrow \\ E_4 \underset{K_d}{\rightleftharpoons} [E_4X] \underset{K_2}{\dashrightarrow} [E_6X] \underset{K_3}{\overset{+H_2O}{\dashrightarrow}} E_6 \end{array} \qquad (1'')$$
where E = enzyme (XOD). The subscript accompanying E stands for the number of electrons responsible for reduction of the enzyme (E_0 = fully oxidized XOD; E_6 = fully reduced enzyme, the 6 electrons being supplied in pairs by X). K_d is the dissociation constant of the enzyme–substrate complex; K_2, K_3, etc. are the rate constants of the respective reactions.

In our work we have concentrated our attention on this half-reaction, with reference to the way it is affected by the presence of metallic ions. Other authors who have examined this problem, either directly or indirectly, include Bergel,[19] Guilbault,[20] Kela[21,22] and Ramadoss.[23]

EXPERIMENTAL

Apparatus

The enzyme reaction was monitored spectrophotometrically by means of a double-beam Perkin-Elmer grating spectrometer (Model 554), with a microcomputer-driven recorder and a water-circulation thermostat, Iulabo R5-6A. The pH readings were taken with an Orion Model 701 A pH-meter at $37 \pm 0.1°$. Conductivity measurements were obtained by means of an Analytical Control Model 101 Conductimeter.

Reagents

All reagents and solutions were prepared with doubly distilled demineralized water (conductance = 1×10^{-6} mho at 25°) and stored in the dark in polyethylene containers to avoid any cation-exchange in the solution.[24] Glassware was washed according to Thiers,[25] stored in 6% v/v nitric acid[26] and washed with doubly distilled demineralized water before use.

Buffer. Tris-buffer [tris(hydroxymethyl)aminomethane], $0.05M$, prepared[27] with "Trizma base" and "Trizma HCl" (Sigma Chemical Co.), pH 7.40 at 37°, was used throughout.

Enzyme. Grade I buttermilk xanthine oxidase suspension in $2.3M$ ammonium sulphate containing 0.02% sodium salicylate (Sigma Chemical Co.), nominal specific activity 0.76 U/mg of protein at 25°, essentially uricase-free, was used and kept refrigerated at 4°. The working solution was prepared daily (to avoid loss of enzyme activity) by dissolving 10 μl in 1 ml of Tris-buffer at pH 7.4 (concentration = 370 μg/ml, $\sim 1.3 \times 10^{-6}M$; specific activity = 1.4 U/mg of protein, at 37° and pH 7.4). The solution was kept refrigerated at 4° and proved stable over a 6-hr period.

Substrate. The $1 \times 10^{-3}M$ xanthine stock solution was prepared by dissolving the necessary quantity of purine base (U.S. Biochemical Corp., Cleveland. Ohio) in 0.5 ml of $2M$ potassium hydroxide and diluting to 200 ml with Tris-buffer. The solution was kept at 4° and protected from light.

Cation and anion solutions. The $3 \times 10^{-2}M$ stock solutions of the various metal ions were prepared by dissolving in water suitable quantities of the Merck analysis-grade reagents (chlorides and sulphates of most ions; nitrate for Ag^+; ammonium and sodium salts for the anions); the concentration of solutions was checked complexometrically[28] or by AAS. Before use, solutions of the desired concentration were obtained by dilution with Tris-buffer (pH 7.4).

Analytical procedure

The XOD-catalysed enzymatic oxidation of xanthine to uric acid was monitored spectrophotometrically in Tris-buffer (pH 7.4) at an ionic strength of $0.04M$ and at $37 \pm 0.1°$, by measuring the uric acid absorption at 291 nm. The experiments were done under pseudo zero-order conditions, *i.e.*, with a large excess of substrate. The kinetic behaviour was studied by means of the initial rate method,[29] during the first 10 min of the reaction.

The effect of inhibitors was measured under the following standard conditions; into a quartz cell, with an optical path of 10 mm, the following solutions were placed in the order given: 0.18 ml of $1 \times 10^{-3}M$ xanthine (this gave a final concentration of $6 \times 10^{-5}M$); 1.30 ml of Tris-buffer; 1.50 ml of cation or anion solution of suitable concentration in Tris-buffer. The mixture was brought to $37 \pm 0.1°$ and 20 μl of $1.3 \times 10^{-6}M$ enzyme solution (to give $\sim 8.9 \times 10^{-9}M$ final concentration, equivalent to 2.5 μg of protein per ml) were added. The total solution volume in the cell was 3 ml in all experiments. Absorbance readings were taken against a blank containing no enzyme. A similar procedure was followed for monitoring the reaction rate in the absence of inhibitors. Plots of absorbance *vs.* time were used to determine the initial reaction rate (v_0), expressed as ΔA_{291}/min.

In order to minimize errors due to loss of activity of the enzyme during successive determinations, the relative activity was used:

$$\alpha = \frac{v_{0_i}}{v_0} = \frac{\text{(initial reaction rate in presence of inhibitor)}}{\text{(initial reaction rate in absence of inhibitor)}}$$

RESULTS AND DISCUSSION

The optimum standard operating conditions described were chosen on the basis of a few preliminary investigations aimed at determining (a) the optimum substrate concentration with respect to assessment of metal effect on the reaction of interest; (b) the effect of pH on the initial rate of the XOD-catalysed reaction, it having been previously established that, under standard conditions, there was a linear relationship between v_0 and XOD concentration.

The dependence of v_0 on substrate concentration is shown in Fig. 1. It appears that over the concentration range 4×10^{-5}–$1 \times 10^{-4}M$, v_0 is independent of substrate concentration (pseudo zero-order conditions), and no inhibition by excess of substrate is
Fig. 1. Substrate-concentration dependence of initial reaction rate v_0 for XOD-catalysed xanthine to uric acid conversion.

observed.[30] On the basis of this behaviour the standard xanthine concentration was established, namely $6 \times 10^{-5}M$.

As illustrated in Fig. 2, v_0 is practically constant in the vicinity of pH 7.4 ± 0.1. This is therefore the optimum operating pH because it is also close to physiological values. (The study was done over the pH range 6.7–8.7, the usual pH range available at 37° with this buffer.)

At the chosen pH, the Michaelis constant K_m for xanthine was determined at different enzyme concentrations, according to the method of Lineweaver and Burk,[31] and found to be $5.77 \pm 0.17 \times 10^{-6}M$, in good agreement with literature values[32,33] obtained under similar conditions.

The effect of a number of ions at low concentration on the XOD-catalysed xanthine→uric acid conversion was examined without considering the form in which they were present in solution under typical experimental conditions.[34] A few showed no measurable effect when present in the concentration range 1×10^{-7}–$1 \times 10^{-4}M$, viz. Li(I), Ca(II), Ba(II), Mg(II), Cd(II), Zn(II), Fe(II), Fe(III), Cr(III), Al(III), Se(IV), Mo(VI) and W(VI).

Another series, composed of Co(II), Pb(II), V(III) and V(IV), was not stable in the buffer utilized. Finally, a third series, comprising Tl(I), Ag(I), Cu(II), Hg(II), Au(III), V(V) and Cr(VI), showed inhibiting effects to varying degrees.

The inhibition strength of these species, expressed as I_{50} [the overall metal concentration producing 50% inhibition ($\alpha = 0.5$)], is shown in Table 1, and Fig. 3 shows how α and $I\%$ $[= (1 - \alpha)\%]$, vary with metal ion concentration. It is apparent that strong inhibition is brought about by Ag(I) and Hg(II), which have a considerable effect even at concentrations similar to the enzyme concentration, and at 2×10^{-7} and $1.3 \times 10^{-6}M$ concentrations, respectively, produce almost complete and irreversible deactivation (Table 2). The order of decreasing inhibiting power of the other five ions in this group is Cu(II) > Cr(VI) > V(V) > Au(III) > Tl(I).

The behaviour of Ag(I) and Hg(II) can be explained in terms of their high affinity toward a thiol group in the enzyme,[35] although the role of the thiol itself is still not clear.[36] The much lower inhibiting power of Cu(II) can be reasonably ascribed to the formation of an $Me(Tris)^{2+}$ complex, which appears to be very stable.[34]

The reactivation of the enzyme (type R experiments) and the protection of the enzyme against inhibitor (type P experiments) were also examined for all inhibitors. Type R measurements were obtained by incubating the enzyme for 1 min in the presence of the inhibitor (with formation of the enzyme–inhibitor [EI] complex), then treating it with a strong metal-complexing agent (EDTA) to free the enzyme and restore its activity.

Type P data (protection data) were obtained by treating the inhibitor with the complexing agent to

Table 1. Effect of various metals on XOD-catalysed xanthine oxidation to uric acid

Ag(I)	7.7×10^{-8}

*Inhibitor concentration necessary to produce 50% inhibition ($\alpha = 0.5$).

form the complex [EDTA–I], which if stable enough will prevent formation of complex [EI] when the enzyme is added, leaving the enzyme free to exert catalytic activity.

For both R and P measurements and for the blank (without EDTA), the substrate was then added to the reaction mixture to initiate the catalysed reaction.

Inhibition by Cr(VI) could not be studied in this way since it does not form an EDTA complex under the experimental conditions.[37] Alizarin Red S [which should complex Cr(VI) at pH 3–8],[38] did not work either.

The results obtained for enzyme reactivation (R) and protection (P) are reported in terms of relative activity (α_R and α_P, respectively) in Table 2.

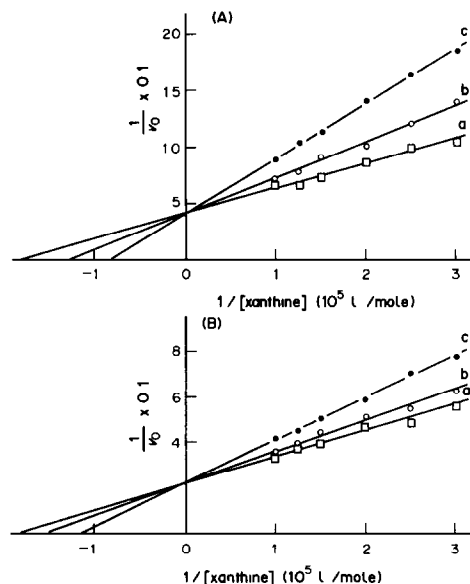
α_B = relative activity of the inhibiting reaction in the absence of EDTA (blank).
α_R = relative activity of the inhibition reversibility reaction due to EDTA.
α_P = relative activity of protection against inhibition reaction in the presence of EDTA.
†Experiments carried out in Tris–HNO$_3$; pH 7.4; AgNO$_3$ solution.


Fig. 4. A, Inhibition mechanism for Tl(I) (competitive); (a) [Tl] = 0; (b) [Tl] = $1 \times 10^{-4}M$; (c) [Tl] = $3 \times 10^{-4}M$. B, Inhibition mechanism for V(V) (competitive); (a) [V] = 0; (b) [V] = $3 \times 10^{-5}M$; (c) [V] = $1 \times 10^{-4}M$.

It can be seen that there is very efficient enzyme reactivation (hence reaction reversibility) for Tl(I), V(V) and Cu(II), but none for Au(III), Hg(II) and Ag(I). On the other hand, enzyme protection by EDTA is about 100% in all cases studied, except for Ag(I) which forms only a weak EDTA complex.

For the reversible inhibitors [Tl(I), V(V) and Cu(II)] it proved possible to determine the inhibition mechanism and the conditional inhibition constant K_i, given either by the dissociation constant of complex [EI] (in the case of a competitive linear mechanism) or by the dissociation constant of the enzyme–substrate–inhibitor complex [ESI] (the dissociation reaction being [ESI] = [ES] + I), in the case of uncompetitive inhibition.

Methods described in the literature[39] were applied, utilizing double reciprocal plots with lines fitted by the least-squares procedure. The results obtained are shown in Table 3, where pK_i values for the various inhibitors are collected, and in Figs. 4 and 5.

Tl(I) and V(V) show a similar inhibition mechanism (linear competitive)[40] characterized by the inhibitor (I) competing with the substrate (S) in binding to the enzyme (E):

$$E + S \underset{K_2}{\overset{K_1}{\rightleftharpoons}} [ES] \overset{K_3}{\longrightarrow} E + p \quad (p = product)$$

$$E + I \underset{K_i}{\rightleftharpoons} [EI]$$
The inhibitor complex [EI] does not undergo any further reaction such as formation of a ternary complex [EIS] between enzyme, inhibitor and substrate.

For this type of inhibition the rate equation, expressed in the reciprocal form suitable for the

Table 3. Inhibition mechanism and values of the conditional inhibition constant K_i for reversible inhibitors in XOD-catalysed xanthine to uric acid conversion

Inhibitor	Inhibiting mechanism*	K_i, M	pK_i

Cu(II)	Linear uncompetitive	$2.49 \pm 0.25 \times 10^{-5}$	4.60 ± 0.05

*pH 7.4; $\mu = 0.04M$ (Tris buffer); $T = 37 \pm 0.1°$; $K_m = 5.77 \pm 0.17 \times 10^{-6}M$; $pK_m = 5.24 \pm 0.01$.

double reciprocal plots, is

$$\frac{1}{v_0} = \frac{1}{v_{max}}\left[1 + \frac{K_m}{[S]}\left(1 + \frac{[I]}{K_i}\right)\right]$$

where v_0 = initial rate, v_{max} = maximum rate, [S] and [I] are the concentrations of substrate and inhibitor, respectively, K_m is the Michaelis constant and K_i the conditional inhibition constant.

Cu(II), on the other hand (Fig. 5A), gives inhibition of the linear non-competitive type,[40] according to the scheme

$$[ES] + I \underset{K_i}{\rightleftharpoons} [ESI]$$
which is described by the initial-rate law

$$\frac{1}{v_0} = \frac{1}{v_{max}}\left[\left(1 + \frac{[I]}{K_i}\right) + \frac{K_m}{[S]}\right]$$

This mechanism has been confirmed (Fig. 5B) by construction of a Hanes[41] plot, of [S]/v_0 vs. [S] at different inhibitor concentrations. Thus inhibition by Cu(II) involves the formation of the ternary complex [ESI], which prevents the formation of uric acid.[39]

The behaviour of V(V), in agreement with a recent suggestion of Ramadoss,[23] can be envisaged as a competitive interaction of the metal at the active site of oxidation of xanthine (in particular interaction with Mo), which prevents the substrate from interacting at this site. The behaviour of Tl(I) can be similarly explained, although the identification of Mo as the interaction site is less certain.

The linear relationship between α and the inhibitor concentration over ranges typical of each metal allows some analytical determinations down to the nanogram region. The determination is selective but not specific, since different metals can act simultaneously as inhibitors. Modifications such as change of buffer, or masking of interferents by complexation, may give more specificity, however.

Calibration curves for Ag(I), Hg(II), Cu(II), Cr(VI), V(V), Au(III) and Tl(I) are shown in Fig. 6; Table 4 shows the detection limits, analytical concentration ranges, and relative standard deviations. The method is most useful for silver and mercury, which have detection limits of about 1×10^{-9} and $1 \times 10^{-8}M$, respectively, which is much better than the value $2.5 \times 10^{-7}M$ obtained by other authors[20] for the same reaction but a different method. The XOD-method for silver has a lower detection limit than those using alcohol dehydrogenase,[42] urease,[43] invertase,[44] or glucose oxidase[45], whereas the limit of detection for mercury is much the same as that obtained by Townshend and Vaughan with alcohol dehydrogenase.[42] Thus of the enzymes studied for subnanogram levels of silver and mercury,[4,42–46] XOD and alcohol dehydrogenase are the most effective.

XOD is also promising for determination of Cu(II) and Cr(VI), the detection limit being about $10^{-7}M$, but other techniques are to be preferred for V(V), Au(III) and Tl(I), for which the XOD performance is not as good.
Fig. 5. Inhibition mechanism for Cu(II) (uncompetitive); A, double reciprocal plots, B, Hanes plot: (a) [Cu] = 0; (b) [Cu] = $5 \times 10^{-6}M$; (c) [Cu] = $1 \times 10^{-5}M$.

Table 4. Detection limits and concentration ranges for inhibitor determination in XOD-catalysed xanthine to uric acid conversion

Inhibitor	Detection limits,* ng/ml	Concentration range, M
Ag(I)	0.11	1×10^{-9}–1×10^{-7}
Hg(II)	2	1×10^{-8}–5×10^{-7}
Cu(II)	6.3	1×10^{-7}–5×10^{-6}
Cr(VI)	16	3×10^{-7}–1×10^{-5}
V(V)	2×10^2	4×10^{-6}–1×10^{-5}
Au(III)	2×10^3	1×10^{-5}–1×10^{-4}
Tl(I)	6×10^3	3×10^{-5}–1×10^{-4}

*Minimum inhibitor cell concentration to produce a detectable decrease in α ($\Delta\alpha$). Standard conditions.

For the four best applications the relative standard deviation ranges from 1 to 10%, the average being about 2.5%, and the relative error of the mean of 5 determinations does not exceed $\pm 4\%$ (see Table 5).

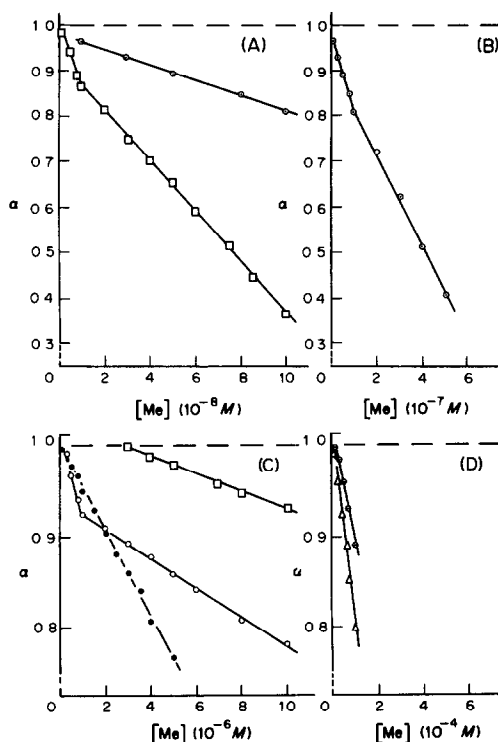
The lack of specificity can be partially circumvented as already explained. In particular a degree of specificity for Ag(I) and Cr(VI) can be achieved by use of EDTA. Cr(VI) cannot be complexed under the experimental conditions,[37] and Ag(I) has very strong affinity for the enzyme and very little for EDTA. This can be explained as follows. The conditional inhibition constant K_i is the inverse of the stability constant of the [EI] or [ESI] complexes, and pK_i can be directly compared with $\log K'_{MY}$ [the logarithm of the conditional stability constant of the EDTA (Y) complex of the inhibitor metal (M)]. At pH 7.4, the $\log K'_{MY}$ values are 4.2 for Ag(I), 3.5 for Tl(I), 15.6 for Cu(II), 10.4 for Hg(II), 15.1 for V(V); Cr(VI) cannot be complexed under the conditions used,[37] and Au(III) is reduced to the metal by EDTA.[47]


Fig. 6. Enzymatic determination of metal ions. Variation of α with inhibitor concentration. A, $\square$ Ag(I); $\odot$ Hg(II); B, $\odot$ Hg(II); C, $\bullet$ Cu(II); $\bigcirc$ Cr(VI); $\square$ V(V); D, $\triangle$ Au(III); $\ominus$ Tl(I).

Whereas pK_i is very high for Ag(I), it is only about 3.6 for Tl(I), which is comparable with the $\log K'_{TlY}$ value, and this means that the ratio of [TlE] to [TlY] would be about the same as the concentration ratio of XOD to EDTA, and that excess of EDTA could

*Average value from 5 determinations.

effectively mask the Tl(I), whereas Ag(I) will not be masked. The Cu(II) and V(V) complexes with EDTA are much stronger than the XOD complexes, so these species are masked by EDTA. Hg(II) presents an interesting case. As a result of formation of hydroxo-complexes of mercury(II), log K'_{HgI} is comparatively low (10.4 at pH 7.4), but Hg(II) has high affinity for the enzyme thiol groups. It is of interest that the mercury(II) can be masked by a large excess of EDTA added *before* the enzyme, but the enzyme activity cannot be restored if the EDTA is added after the (EI) complex has already been formed.

Obviously the strongest inhibitors, Ag(I) and Hg(II), can be separately determined at low concentrations (1×10^{-9}–$1 \times 10^{-7} M$) in the presence of the weaker inhibitors when these are present at concentrations below the detection limits ($\sim 1 \times 10^{-7} M$, Table 4).

In the case of XOD, where two active sites with different functions are present, a certain specificity in the determination of inhibitors might be achieved if they react differently with the two sites.

This possibility is currently being explored by studying the metal–enzyme interaction through the XOD-catalysed NADH–NAD$^+$ oxidation, since it is known that in this reaction the substrate NADH interacts with the active site of flavin.[13]

SPECTROPHOTOMETRIC DETERMINATION OF TRACE AMOUNTS OF BERYLLIUM IN SILICATE MATERIALS

ALFRED SAUERER and GEORG TROLL*
Institut für Mineralogie und Petrographie der Universität, Theresienstrasse 41, D-8000 München 2, BRD

Summary—Although photometric determination of beryllium is generally quite satisfactory in trace analysis, application to geochemical samples is restricted because of the numerous interfering ions. Introduction of an extraction procedure eliminates the interference of Al and Fe, which occur in high concentrations in most silicate rocks, and enables beryllium to be determined with Eriochrome Cyanine R. Use of the method for analysis of six international geochemical reference samples containing between 1 and 30 ppm beryllium has given satisfactory results (relative standard deviation from 1.6 to 7.8%).

Although a great number of photometric methods for determining beryllium have been proposed, very few are suitable for determining traces of beryllium in rocks and minerals. For this analysis the technique used must meet several criteria.

1. The limit of detection should be near 0.5 μg (preferably 0.1 μg) of beryllium.
2. Aluminium and iron contents up to 10^5 times that of beryllium must not interfere.
3. The results must be reproducible.
4. The standard deviation should be within the limits usual for trace analysis.

A survey of the literature shows that only a few of the published procedures for the photometric determination of beryllium in silicate materials fulfil these requirements.

To work out an analytical technique for determining beryllium in geochemical samples, we chose Eriochrome Cyanine R from the numerous substances which form chelates with beryllium (Beryllon, Fast Sulphon Black, Eriochrome Cyanine R, Quinalizarin, Aluminon, *etc.*). The complex has a molar absorptivity of 1.5×10^4 l.mole^{-1}.cm^{-1} at 512 nm, the wavelength of the absorption maximum, so the method should have relatively high sensitivity. Hill[1] obtained good results by using Eriochrome Cyanine R, and his work was made the basis of our initial investigations. Hill had found that Al, Fe, Ti and P interfered, and used EDTA for masking. The extent to which these ions interfere in Hill's procedure was therefore investigated. It was found that while the measurements were only slightly influenced by phosphate and permanganate, aluminium and iron(III) interfered considerably in the determination of beryllium despite the addition of EDTA as masking agent (see Table 1). The negative absorbances for solutions

containing aluminium are presumably due to precipitation of the dyestuff (the absorbance is measured against a reagent blank). Since aluminium and iron are abundant in rocks and soils their influence on the beryllium determination was examined carefully. Figures 1 and 2 show the individual effects and Fig. 3 shows their combined influence. The graphs show that the determination is highly sensitive to the iron and aluminium concentrations above a certain level, and that there is a variable degree of compensation when both elements are present, depending on their concentration ratio. Such effects tend to conceal the true magnitude of the individual interferences. The experiments performed indicate that when Hill's method is used, the simultaneous presence of 2 mg each of iron and aluminium will cause significant interference in determination of 2.5 μg of beryllium. Hence for an "average" granite (13% Al$_2$O$_3$, 1.5% Fe$_2$O$_3$, 3 ppm Be), Hill's method in its original form would not be suitable for determination of beryllium.
Fig. 1. Interference with the beryllium–Eriochrome Cyanine complex by Al^{3+}, as a function of AlCl$_3$ concentration, in presence of EDTA ($\lambda = 512$ nm).

*Author for correspondence.

Table 1. Effect of various ions on absorbance (at 512 nm) of Be solutions

Present	Absorbance
2.5 μg Be	0.096
5.0 μg Be	0.180
7.5 μg Be	0.248

We have therefore combined the photometric determination of beryllium by the Eriochrome Cyanine R method with prior extraction of the beryllium to separate it from the interfering substances. We have modified the extraction procedure given by Adam et al.,[2] who used acetylacetone and chloroform for the purpose and masked interfering ions such as aluminium and iron with EDTA.

EXPERIMENTAL

Apparatus

A Perkin-Elmer 552 double-beam grating spectrophotometer equipped with thermostatically controlled cells (Haake, FRG), and a Metrohm E532 pH-meter were used. The extractions were done in Pyrex funnels cleaned with $3M$ hydrochloric acid and thrice rinsed with distilled water. As far as possible polyethylene apparatus was used.

Reagents

A 5% solution of Merck analytical grade acetylacetone in distilled water was prepared. The Eriochrome Cyanine R

Fig. 2. Interference with the beryllium–Eriochrome Cyanine complex by Fe^{3+}, as a function of $FeCl_3$ concentration, in presence of EDTA ($\lambda = 512$ nm).

Fig. 3. Interference with the beryllium–Eriochrome Cyanine complex by the simultaneous presence of Al^{3+} and Fe^{3+} and EDTA ($\lambda = 512$ nm).

solution was prepared by dissolving 500 mg of the Merck reagent in 125 ml of distilled water along with 12 g of sodium chloride, 12 g of ammonium nitrate and 1 ml of concentrated nitric acid, adding 50 ml of ethanol, and diluting to volume with water in a 500-ml standard flask. Chloroform stabilized with ethanol (Merck) was used. Aqueous 5% disodium EDTA and sodium acetate solutions were prepared. All chemicals were of analytical grade. Standard 50-μg/ml beryllium solution was prepared by dissolving 983 mg of $BeSO_4 \cdot 4H_2O$ in 25 ml of $5M$ hydrochloric acid and diluting accurately to 1000 ml with water, and further diluted as required (several drops of $5M$ hydrochloric acid being added whenever dilutions were made).

Extraction procedure

A known volume (40 ml is suitable) of the acid sample solution (containing 1–10 μg of Be) is pipetted into a 100-ml separatory funnel, mixed with 5 ml of EDTA solution, and adjusted to pH 6.9–7.0 with dilute ammonia solution ($\sim 3M$). Then 5 ml of the acetylacetone solution are added, and the pH is readjusted to 7.0. The mixture is shaken with 10 ml of chloroform for 2 min. The organic phase is collected in a second separatory funnel. A further 0.1 ml of acetylacetone solution and 10 ml of chloroform are added to the aqueous phase and the mixture is shaken for 2 min, and the organic phase is added to the first. The combined organic phases are shaken for 2 min with 15 ml of $5M$ hydrochloric acid and the aqueous phase is collected. The stripping step is repeated. The two hydrochloric acid phases are combined and evaporated on a hot-plate to about 0.25 ml and then diluted to about 5 ml with water.

Photometric determination

The concentrated aqueous phase is adjusted to pH 2–3 with 2.5M sodium hydroxide, and 2 ml each of the EDTA, sodium acetate and Eriochrome Cyanine R solutions are added. Sodium hydroxide solution is then added until the colour of the solution changes from yellow to reddish violet (the pH then lies between 10.5 and 11.5). The solution is diluted to 20 ml, the pH is adjusted with hydrochloric acid to exactly 9.8, and the solution is transferred to a 25-ml

standard flask and diluted to the mark with water. After 45 min for colour development the absorbance is measured at 512 nm against a blank solution prepared by applying the photometric procedure to 1.0 ml of 3M hydrochloric acid.

Because of the formation and stability of the complex and hence the absorbance are strongly temperature-dependent (Fig. 4), all measurements must be done at the same temperature. Although measurement at lower temperatures would increase the sensitivity, for reasons of speed it is desirable to use temperatures close to room temperature.

Calibration graph

For construction of the calibration graph, different amounts of standard solution are pipetted and treated by the procedures of extraction and analysis described above. The calibration graph is linear in the range up to 0.25 μg/ml in the final solution. A decrease of pH from 9.8 to 9.7 diminishes the absorbance by about 9%.

RESULTS AND DISCUSSION

The beryllium concentrations of six international geochemical reference samples were determined; for every determination a separate digestion was performed (routine digestion with 15 ml of concentrated hydrofluoric acid and 2 ml of concentrated sulphuric

acid for 0.5–1.5 g of sample). The results of the determinations (Table 2) demonstrate an accuracy and precision satisfactory for most geochemical problems and for analysis of a wide variety of matrices containing beryllium at concentrations down to 1.5 ppm. For routine analysis of large numbers of samples, the various steps of the procedure should be systematized, e.g., by using two sets of separatory funnels set up in two ranks, one above the other, and by using an automatic shaker for the extractions. In this way the analysis time and possible external contamination can be reduced.

Note added in proof

During the period this article was in press, Watkins and Thompson published a paper on "Determination of beryllium and zirconium in 45 geochemical reference samples by inductively coupled plasma emission spectrometry" (*Geostand. Newslett.*, 1983, 7, 273) and reported beryllium data on the reference samples SY-2, NIM-G and NIM-L.

FLUORIMETRIC KINETIC STUDIES AND SUB-μM DETERMINATION OF ALUMINIUM WITH 2-HYDROXY-1-NAPHTHALDEHYDE p-METHOXYBENZOYLHYDRAZONE

P. C. Ioannou and P. A. Siskos*
Laboratory of Analytical Chemistry, University of Athens, 104 Solonos Street,
Athens 10680, Greece

Summary—A fluorimetric study has been made of the kinetics of the reaction of 2-hydroxy-1-naphthaldehyde p-methoxybenzoylhydrazone with aluminium, and a rate equation and a possible kinetic scheme are proposed. Experimental conditions are defined under which 0.020–$10.0\mu M$ aluminium can be determined with an average error of 3.7% and a coefficient of variation of about 4.6%.

Hydrazones (characterized by the grouping C=N—N, and related to Schiff's bases), have been used as photometric and fluorimetric analytical reagents for the determination of metals.[1] The formation of a highly fluorescent chelate through the combination of a metal ion and an organic ligand has often proved to be a sensitive and specific method for the determination of metals, particularly those which are difficult to measure by atomic-absorption spectroscopy.[2]

Fluorescent complexes of aluminium have received a great deal of attention. Some scores of papers give analytical methods for a wide variety of samples.[3] Fluorimetric applications of hydrazones for the determination of aluminium, on the other hand, are few in number, the main reasons being the slow reactions and the lack of kinetic and mechanistic studies.

2-Hydroxy-1-naphthaldehyde p-methoxybenzoylhydrazone (HNAMBH) has been used recently for fluorimetric determinations of aluminium, scandium and thorium,[4–8] though the procedure for the determination of aluminium has some limitations.[7] Kinetic methods of analysis offer greater speed and specificity.

In this study we have combined the merits of kinetic methods and spectrofluorimetry to study the kinetics of the reaction between HNAMBH and aluminium ions and, on the basis of optimized experimental conditions, have developed a kinetic fluorimetric method for the determination of aluminium in aqueous solution. A rate equation and a possible kinetic scheme are proposed for the reaction. The method developed is simple, rapid, very sensitive and more selective than non-kinetic methods. Microamounts of aluminium in the range 0.020–10.0 nmole in the spectrofluorimeter cell have been determined

with a relative standard deviation of 4.6% and measurement times of about 60 sec.

EXPERIMENTAL

Apparatus

A Perkin-Elmer model 512 double-beam fluorescence spectrophotometer with a 150-W xenon lamp was used. For all measurements standard rectangular cells of 1.000-cm path-length, made of fluorescence-free fused silica, were used. The cell compartment was modified and a magnetic stirrer was mounted under the sample cell holder. A constant temperature of $25.0 \pm 0.1°$ in the sample cell was maintained by using a thermostatic water-bath. The fluorescence intensity *vs.* time curves were recorded on a Sargent-Welch XKR potentiometric recorder.

The following instrumental settings were used for measurements: ratio mode; dynode voltage 750 V; excitation wavelength 420 nm with a band-width of 20 nm; emission wavelength 475 nm with a band-width of 20 nm.

Reagents

All solutions were prepared in demineralized distilled water from reagent-grade materials, unless otherwise stated.

2-Hydroxy-1-naphthaldehyde p-methoxybenzoylhydrazone (HNAMBH), *solution*, $10^{-3}M$, *in acetone*. The synthesis of the reagent has been previously described.[4] The stock solution is stable for several months.

Standard aluminium solution, 1000 ppm (37mM). This solution was prepared by dissolved an ampoule of Merck "Titrisol" aluminium standard solution (1.000 ± 0.002 g of Al) in 1 litre of $0.1M$ hydrochloric acid. Working solutions were prepared by appropriate dilution with water.

Stock 0.1M glycine/0.1M sodium chloride buffer, pH 3.50. Prepared by dissolving 7.51 g of glycine and 5.85 g of sodium chloride in 700 ml of water, adjusting to pH 3.50 with $0.1M$ hydrochloric acid and diluting with water to 1 litre.

Working buffer solution, pH 4.80. Prepared by mixing 300 ml of the stock glycine buffer with 600 ml of acetone, adjusting the pH to 4.80 with hydrochloric acid and diluting with water to 1 litre.

Procedure

Transfer 2.00 ml of buffer solution and 1.00 ml of sample or standard aluminium solution into the cuvette and start the stirrer. Cover the cell and record the fluorescence

---

intensity until it is steady. Inject, through a plastic septum in the cover, 100 μl of the reagent solution and record the changing fluorescence intensity for 2–3 min. Construct a kinetic calibration curve by plotting initial reaction rate (slope method) vs. aluminium concentration.

RESULTS AND DISCUSSION

Kinetic studies of the HNAMBH–Al system

Choice of buffer solution. It is known that aluminium ions form a 1:1 complex with HNAMBH in weakly acidic solution and that the maximum fluorescence intensity of the complex (λ_{ex} 420 nm and λ_{em} 475 nm) is obtained in the pH range 3.50–4.50 (40% acetone solution), depending on the aluminium concentration.[7] In that study it was noticed that acetate buffer solutions were not suitable, because acetate forms complexes with aluminium ions. Likewise, citrate buffers gave no measurable fluorescence. Glycine buffers, on the other hand, were found suitable, since the same maximum fluorescence intensity was observed as for solutions with the same pH but adjusted only with hydrochloric acid. Hence glycine buffer was chosen for the kinetic studies of this reaction.

Figure 1 shows the effect of pH on the initial reaction rate for different aluminium concentrations. The maximum reaction rate was observed at pH 4.7–5.1, a range which is not so broad as that when measurements are made under equilibrium conditions, and means that the optimal pH range does not depend largely on aluminium concentration.[7] This situation makes the kinetic conditions more favourable for analytical application. A pH of 4.8 was chosen for the kinetic studies and the analytical method.

Determination of the equilibrium constants. The formation of complexes between aluminium ions and HNAMBH(H_2R) in weakly acidic solution can be expressed by the equations:

$$Al^{3+} + H_2R \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} AlHR^{2+} + H^+ \qquad (1)$$

$$Al^{3+} + H_2O \overset{K_h}{\longrightarrow} AlOH^{2+} + H^+ \qquad (2)$$

$$AlOH^{2+} + H_2R \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} AlHR^{2+} + H_2O \qquad (3)$$
where reaction (2) is known to be fast.

H_2R has two dissociation constants and in the pH range 3.00–5.50 the predominant species is H_2R.[5] The equilibrium constant of reaction (1)

$$K_1 = \frac{k_1}{k_{-1}} = \frac{[AlHR^{2+}][H^+]}{[Al^{3+}][H_2R]} \qquad (4)$$

was calculated by using the first ionization constant of H_2R,[5]

$$K_{H_2R} = \frac{[H^+][HR^-]}{[H_2R]} = 1.1 \times 10^{-9} \qquad (5)$$

and the instability constant of the complex, K_{inst}:[7]
Fig. 1. Effect of pH on the initial slope. [HNAMBH] = $32\mu M$, [Al], μM: (1) 1.6; (2) 4.8; (3) 6.4; other conditions as in procedure.

$$K_{inst} = \frac{[Al^{3+}][HR^-]}{[AlHR^{2+}]} = 1.6 \times 10^{-6} \qquad (6)$$

Combining equations (4)–(6) we get

$$K_1 = \frac{K_{H_2R}}{K_{inst}} = 7.0 \times 10^{-4} \qquad (7)$$

so this reaction is not significant.

The equilibrium constant for reaction (3) at pH 4.8 is given by

$$K_2 = \frac{k_2}{k_{-2}} = \frac{[AlHR^{2+}]}{[AlOH^{2+}][H_2R]} \qquad (8)$$

and was calculated by combining the aluminium hydrolysis constant[9]

$$K_h = \frac{[AlOH^{2+}][H^+]}{[Al^{3+}]} = 6.2 \times 10^{-6} \qquad (9)$$

with K_{H_2R} and K_{inst} to yield

$$K_2 = \frac{K_{H_2R}}{K_{inst}K_h} = 1.14 \times 10^2 \qquad (10)$$

Thus reaction (3) will predominate at the optimum pH.

Determination of reaction order and rate constants. If the formation of the complex is monitored fluorimetrically, the following general reaction-rate equation can be written:

$$Rate = \frac{d[AlHR^{2+}]}{dt} = k[Al]^a [H_2R]^b [H^+]^c \qquad (11)$$

where [Al] stands for the total initial concentration of aluminium.

By keeping the concentrations of two of the three reagents constant and in large excess and varying the concentration of the third, pseudo first-order conditions were achieved with respect to each reagent in turn.

Figure 2 shows the first-order plots for the reaction of three different concentrations of aluminium with an excess of HNAMBH at optimum pH. The mean calculated pseudo first-order rate constant, k_{obs}, was $(1.83 \pm 0.11) \times 10^{-3}$ sec^{-1} (mean of 3 experimental results), which means that under these conditions the initial slope, $\Delta F / \Delta t$, where F is the fluorescence intensity, is directly proportional to the aluminium concentration. From recorded kinetic curves for runs with different concentrations of aluminium, a mean value for a of 1.13 ± 0.09 (3 determinations) was found.

By using the infinite time method for pseudo first-order conditions, k_{obs} can be determined from the recorded reaction traces by plotting $\ln[F - F_t]$ vs. time, where F and F_t are the fluorescence intensities at equilibrium and time t respectively. In this way, a series of k_{obs} values was obtained for different HNAMBH concentrations (Table 1). The reaction order (b) with respect to [HNAMBH] can be obtained by plotting $\ln k_{obs}$ vs. $\ln$[HNAMBH]. By regression analysis a value of 0.96 was obtained for b, indicating that the reaction is first-order with respect to the organic reagent.

Table 2 shows kinetic results for the determination of reaction order with respect to pH. The pH range studied covers values above and below the optimum pH range. By regression analysis a value of -1.15 (4 results) was obtained for c, indicating a first-order reaction with respect to pH in the range 3.8–4.8.

The experimental kinetic results can be explained by taking into consideration the hydrolysis of aluminium, and that the complex is formed according to reaction (3), for which the following rate equation can be written:

$$\frac{d[\text{AlHR}^{2+}]}{dt} =$$

$$k_2[\text{AlOH}^{2+}][\text{H}_2\text{R}] - k_{-2}[\text{AlHR}^{2+}] \quad (12)$$
Fig. 2. First-order plots. [HNAMBH] $= 20\mu M$, [Al], μM: (1) 0.50; (2) 1.00; (3) 1.50. Other conditions as in procedure.

Table 1. Kinetic results for the determination of reaction order with respect to [HNAMBH]

k_{obs}, sec$^{-1} \times 10^4$	$-\ln$[HNAMBH]	$-\ln k_{obs}$
6.80	11.869	7.368
12.0	11.226	6.725
18.0	10.820	6.320
22.0	10.557	6.113

Regression equation $y = 4.08 + 0.96x$; ($n = 4$, $r = 0.999$). [Al] $= 0.50\mu M$, optimum pH 4.80 in 40% acetone, $T = 25°$, ionic strength 0.02M NaCl.

or, taking into consideration equation (9):

$$\frac{d[\text{AlHR}^{2+}]}{dt} =$$

$$k_2 \frac{K_h}{[\text{H}^+]}[\text{Al}^{3+}][\text{H}_2\text{R}] - k_{-2}[\text{AlHR}^{2+}] \quad (13)$$

At low pH (pH $< pK_h$) the reaction rate depends inversely on [H$^+$], [see equation (13) and Fig. 1], because as [H$^+$] is decreased [AlOH^{2+}] is increased.

In the optimum pH range, where [H$^+$] $\sim K_h$, the reaction rate is independent of pH. If [H$_2$R] is in constant excess, so that

$$k_2' = k_2[\text{H}_2\text{R}] \quad (14)$$

equation (13) can be rewritten as

$$\frac{d[\text{AlHR}^{2+}]}{dt} = k_2'[\text{Al}^{3+}] - k_{-2}[\text{AlHR}^{2+}]. \quad (15)$$

By using the infinite time method, the pseudo first-order constant

$$k_{obs} = k_2' + k_{-2} \quad (16)$$

can be determined (see Fig. 2). From equations (8) and (16) k_2 and k_{-2} can be calculated:

$$k_2 = \frac{K_2 k_{obs}}{1 + K_2} \quad (17)$$

$$k_{-2} = \frac{k_{obs}}{1 + K_2} \quad (18)$$

giving $k_2 = 90.9 \pm 5.7$ l.mole^{-1}.sec^{-1} and $k_{-2} = 0.80 \pm 0.05$ sec^{-1} (3 observations).

For pH > 5.20, the observed decrease in reaction rate is due to further hydrolysis of aluminium ions

Table 2. Kinetic results for the determination of reaction order with respect to pH

   Range B $y = -0.225 + 1.74x$, $(n = 5, r = 0.996)$.
   Range C $y = -0.040 + 0.21x$, $(n = 5, r = 0.999)$.

and probably a new chromogenic complex is formed, of the type $Al(HNAMBH)_2$.[7]

Effect of ionic strength. The rate of the reaction is independent of ionic strength over the range $0.05-0.30M$ sodium perchlorate in the optimum pH range. This provides evidence that one of the reacting species should be uncharged, namely H_2R.

Effect of temperature. The reaction rate has a mean temperature coefficient of about $14 \pm 3\%$/deg over the range 27–41.5°. From an Arrhenius plot the activation energy was found to be 19 kcal/mole and the pre-exponential factor 5.4×10^{10}. The large activation energy and hence the large temperature variation, is both disadvantageous, because strict temperature control is needed, and advantageous in analytical applications, because the sensitivity of the reaction could be increased by increasing the temperature.

Analytical applications

The initial reaction rate under pseudo first-order experimental conditions is linear with respect

to aluminium concentration in the range $0.020-0.100\mu M$ (range A), $0.20-1.00\mu M$ (range B) and $2.0-10.0\mu M$ (range C). Figure 3 shows typical recorded kinetic curves. Results for the determination of aluminium in pure aqueous solution are given in Table 3. They indicate that aluminium in the range $0.020-10\mu M$ (0.54–270 ng/ml) can be determined with a mean relative error of about 3.7%. The

*The oxides were dissolved in concentrated hydrochloric acid.

linearity of the method covers the range $0.020-10.0\mu M$. The sensitivity of the method can be increased by increasing the temperature.

Five replicate determinations at each of the 0.020, 0.20 and $2.0\mu M$ aluminium levels had relative standard deviations of 5.4, 4.4 and 4.0% respectively.

Interferences

Table 4 summarizes the effects of interfering ions. Scandium and gallium cause positive errors, whereas the other ions investigated cause negative errors. It seems that all the ions examined form complexes with the reagent, but the tolerance levels for some ions are lower in the kinetic method than in the equilibrium method.[6] Scandium reacts 300 times faster with HNAMBH than aluminium does. The possibility of developing a differential simultaneous kinetic method for the determination of scandium and aluminium in aqueous mixtures and real samples is being examined.

ANALYTICAL CHARACTERIZATION
OF CuInS₂ SEMICONDUCTOR MATERIAL

C. F. Hung, P. Y. Chen, L. Y. Weng, H. L. Huang
and M. H. Yang*
National Tsing Hua University, Hsinchu, Taiwan 300, People's Republic of China

Summary—Systematic analytical procedures have been developed for determination of the stoichiometry of $CuInS_2$ and estimation of trace elements, including dopants and impurities, in the material. Samples of $CuInS_2$ are digested in an oxidizing acid to ensure completely transformation into Cu^{2+}, In^{3+} and SO_4^{2-} ions. The stoichiometry determination is made sequentially by controlled potential electro-deposition of copper, followed by its EDTA titration, titrimetric determination of indium and gravimetric determination of sulphate, in a single sample solution. The relative errors for the determination of Cu and In are found to be -0.08% and $+0.11\%$ respectively, fulfilling the requirement for accurate stoichiometry assessment; that for S is -0.66%, which though rather high is still acceptable. For the determination of trace elements in $CuInS_2$, multistage combined procedures are employed. Cu in the sample solution is removed by electro-deposition and In by extraction of $HInBr_4$ with isopropyl ether, then most of the trace elements are finally determined by atomic-absorption spectrometry, and the rest by neutron-activation analysis. All the steps involved in the procedures have been optimized by using radioisotopes as tracers. By the procedures developed, a wide range of trace elements in $CuInS_2$, down to submicrogram level, can be determined.

Copper indium sulphide ($CuInS_2$) is an important ternary semiconductor material.[1] As with other semi-conductors, determination of the stoichiometry of this compound is important to avoid crystal defects.[2] Equally important is the absence, or control at the nanogram level, of certain trace elements which can seriously affect the electrical, optical and other physical properties.[3]

The analytical approaches chosen by us were largely dictated by the limited amount of sample available, consisting of single crystals or thin films of $CuInS_2$. By necessity, the methods therefore had to be suitable for the determination of all three elements in the same sample portion. We chose the following approach. After dissolution of the sample in concentrated nitric acid under pressure, copper is removed by electro-deposition, then dissolved in nitric acid and titrated with EDTA at pH 2.3–2.5. The electrolyte from the copper determination is treated with hydrochloric acid to expel nitric acid, then indium is titrated with EDTA under the same conductors as for copper. After titration of the indium, sulphate is precipitated and finally weighed as barium sulphate.

The trace elements are mainly determined by flame atomic-absorption spectrometry (AAS), and some by neutron-activation analysis (NAA) after sequential removal of copper either electrolytically or by precipitation with thioacetamide, and indium by extraction with isopropyl ether from $5M$ hydrobromic acid or $6M$ hydrochloric acid medium. We used radiotracer techniques to check and optimize the recovery of the

trace elements concerned throughout the separation procedure.

EXPERIMENTAL

Reagents and radiotracers

Reagent grade chemicals were used throughout. Stock analyte solutions (0.1%) were prepared, and diluted to give the other standard solutions used. The water used throughout the stoichiometry analysis was prepared by single distillation followed by passage through a demineralizer. For the trace analysis, the water was further distilled in a two-stage quartz distillation apparatus (Berghof, West Germany) and the acids (nitric and hydrochloric) in a sub-boiling quartz distillation apparatus (Becher, West Germany).

The radiotracer solutions (^{65}Zn, ^{64}Cu, ^{56}Mn, *etc.*) were obtained by irradiating appropriate salts in the Swimming Pool Reactor of the National Tsing Hua University (1 MW power, flux 10^{12} n.cm^{-2}.sec^{-1}), followed by dissolution and adjustment to a suitable medium composition. The radiotracer ^{210}Pb was purchased from the Radiochemical Centre, Amersham, England.

Apparatus

A Berghof pressure digestion system, with a 10-ml PTFE liner, was used for decomposition of the $CuInS_2$ samples.

Two radioactivity counting systems were used: one was a multichannel γ-ray spectrophotometer comprising a 4096-channel pulse-height analyser coupled with a Hewlett-Packard 2116 C Basic Computer, and a 43-cm³ Ge(Li) detector (ORTEC). The other was a NaI(Tl) γ-scintillation counter (ORTEC). The choice of system depended on whether one nuclide was to be determined or several, and on the counting efficiency required.

Atomic-absorption spectrometry was done with an Instrumentation Laboratory 257 unit with a flame furnace.

A Hilger and Watts spectrometer, digital Model H 1620/H 1621, was also used.

*To whom correspondence should be addressed.

259

The controlled potential electro-deposition system consisted of a 30-ml lucite electrolysis cell (with two platinum electrodes, each of 6.3 cm^2 area, and one calomel reference electrode), a potentiostat and d.c. power supply, and a magnetic stirrer.

Procedures

CuInS$_2$ stoichiometry. A portion of powder or crystal samples weighing 50–100 mg is heated for 2 hr at 100° in a PTFE-lined pressure bomb with 5 ml of concentrated nitric acid. The solution is evaporated to expel the excess of acid and diluted to 20 ml. Copper is then electroplated on a platinum electrode for 100 min at −0.5 V *vs.* SCE. The copper deposited is dissolved with 2 ml of concentrated nitric acid, and after dilution with water to 20 ml, the solution is adjusted to pH 2.3–2.5 with ammonia solution and the copper is titrated with 0.01*M* EDTA with PAN as indicator.

The copper-free electrolyte is heated with three successive 5-ml portions of concentrated hydrochloric acid to expel the nitric acid, the pH is adjusted to 2.3–2.5 with ammonia solution and the indium is titrated with 0.01*M* EDTA, with Cu–PAN as indicator.

After titration of the indium, the sulphate is precipitated with barium chloride solution. The barium sulphate is filtered off, washed, ignited at 950° for 5 hr, cooled and weighed.[4]

Determination of trace elements in CuInS$_2$. Another sample portion (50–100 mg) is dissolved in nitric acid and copper removed electrolytically as above. The electrolyte is evaporated to dryness, and 3 ml of 5*M* hydrobromic acid are added, followed by extraction of the indium with two portions of di-isopropyl ether (total volume 5 ml). The organic phase is discarded. The aqueous phase is evaporated to dryness and taken up in 0.1*M* nitric acid. Cd, Co, Sb, Ca, Mg, Ni, Mn, Pb and Zn are determined in this solution by flame AAS, and P is determined by conversion into Molybdenum Blue, and spectrophotometry at 840 nm. The sensitivity of the Cd, Co, Mn, Ni, Pb and Zn determinations can be increased by extracting these elements at pH 4.5 with 5 ml of 0.1% ammonium pyrrolidine dithiocarbamate (APDC) solution into 5 ml of chloroform and determination by neutron-activation analysis (NAA). Elements such as Ag and Hg which are co-deposited with Cu are dissolved off the electrode with 2 ml of 6*M* nitric acid, and then subjected to neutron irradiation. The irradiated sample is set aside for 1 week to allow the decay of ^{64}Cu, and finally measured by gamma-spectrometry.

In an alternative procedure, some trace elements (Ga, Tl and Fe) are directly extracted from 6*M* hydrochloric acid medium with di-isopropyl ether after evaporation of the copper-free electrolyte to dryness. AAS is used to determine the elements thus isolated.

DISCUSSION

CuInS$_2$ has the chalcopyrite structure and a high melting point.[5] It is only sparingly soluble in hydrofluoric, hydrochloric or nitric acid but is readily decomposed by heating with nitric acid under pressure, about 5 ml being sufficient for 100 mg of CuInS$_2$. Hydrochloric acid cannot be used because part of the sulphur would be lost as hydrogen sulphide. Nitric acid has the advantage that it oxidizes the sulphur in the sample to sulphate, which can then be precipitated as barium sulphate. Nitric acid also provides the proper medium for electro-deposition of the copper and oxidation of trace elements such as Fe, Sb and Tl to their higher oxidation states.

Stoichiometry of CuInS$_2$

Determination of copper. Electro-deposition was finally chosen for the separation of copper because of its high selectivity. Preliminary tests were made, to verify that this procedure is applicable to the limited sample weights available for analysis. From the current *vs.* cathode-potential curve it was found that a cathode-potential maintained at about −0.5 V *vs.* SCE., was optimal for the deposition. The amount of copper remaining in the electrolyte was determined by extraction with diethyldithiocarbamate into chloroform and spectrophotometric measurement at 435 nm.[6] It was established that 100 min of electrolysis time is ample to reduce the copper content to below 30 μg.

Determination of indium. The solution left after the electrolysis is well suited for the determination of indium by titration with EDTA. We have found that a direct EDTA titration of indium in the presence of copper is not feasible. Such a method, applied in alkaline medium, with potassium cyanide as masking agent, has been described,[7] but we always obtained low results (from −3 to −5% error) when we applied this procedure to CuInS$_2$. In our opinion this is possibly due to partial interaction of In(III) with excess of cyanide, and this method is suitable only when copper is present as a minor constituent of the sample.

Determination of sulphur. The determination of sulphur in the solution remaining after the titration of indium, while not as precise as that of copper and indium, is adequate and is being used by us in routine analysis.

An alternative based on the evolution of hydrogen sulphide is under investigation, and the initial results look encouraging.

Results for determination of copper, indium and sulphur in simulated samples by the scheme outlined above are given in Table 1. They show good precision and accuracy for copper and indium. The

somewhat greater errors observed in the sulphur results can be largely attributed to the limited quantity of sample available for analysis and to an effect of the In–EDTA complex on quantitative precipitation of barium sulphate. When the proposed procedure was applied to actual samples of CuInS₂, the results reported in Table 2 were obtained.

The correlation of stoichiometry with physical properties will be discussed sometime in the future.

Determination of trace elements in CuInS₂

In the determination of trace elements in metal samples, the detectability and accuracy obtainable by direct instrumental techniques will in most cases be seriously affected by matrix effects. To determine the trace elements in CuInS₂ sensitively and accurately, special efforts must be made to develop and optimize the analytical procedures, involving first the elimination of copper and indium, and then determination of the isolated trace elements by instrumental methods. The efficiency of isolation of the trace elements was mainly estimated by using radioisotopes as tracers.

Removal of copper. Since the proposed procedure involves the electro-deposition of copper, it was necessary to determine the extent, if any, of co-

deposition of trace elements expected to occur in CuInS₂. This information is provided in Table 3. As would be expected, silver and mercury are quantitatively deposited with the copper. Gold was not considered in this study because it remains insoluble when a sample of CuInS₂ is dissolved in nitric acid. An alternative method for removal of copper, by precipitation with thioacetamide in hydrochloric acid medium,[8] was also investigated. Table 4 shows the retention of various elements in solution when CuS is precipitated with thioacetamide at 90°.

Comparison of the two copper-removal techniques indicates that the CuS precipitation is simpler and less time-consuming but gives poorer decontamination of copper and greater chance of introduction of impurities. We therefore prefer the electro-deposition method. It must be realized, however, that some elements such as Ag, Hg, and probably Pd are co-deposited with copper and hence cannot be determined by this procedure without modification (see Table 3).

Removal of indium. Indium must be removed before the final determination of trace elements. We prefer the ion-association extraction of indium with di-isopropyl ether from 5M hydrobromic acid to extraction of indium chelate complexes[9,10] (which are all pH-dependent).

In addition to In(III), Tl(III) is also quantitatively extracted with di-isopropyl ether, while As(III), Ga(III), Fe(III), Sn(IV) and Sb(V) are partially extracted.[11] Table 5 gives the results of tests to establish

Volume ratio: Aqueous phase 15 ml/organic phase 5 ml.

the degree of the retention of trace elements in the aqueous phase after extraction with di-isopropyl ether. About 99.8% of the indium is extracted. More than one extraction may be required to reduce the indium in the aqueous phase to a level suitable for AAS determination of the Ca, Cd, Co, Mg, Mn, Ni, Pb and Zn. P is determined spectrophotometrically after conversion into Molybdenum Blue. If the final measurement of the trace element is to be based on neutron activation, species such as Na^+, Br^- and SO_4^{2-} which form interfering nuclides (^{24}Na, ^{82}Br and ^{32}P) must also be removed. This can be achieved by APDC-chloroform extraction, thus allowing the determination of a group of trace elements such as Co, Cd, Mn, Ni and Zn. The data in Table 5 also indicate that important trace elements, such as Ga, Tl, Fe and Mo, are either partially or completely extracted into di-isopropyl ether. Also of interest is the extraction of some trace elements into di-isopropyl ether from $6M$ hydrochloric acid, with indium left in the aqueous phase.[12,13] Tests done with the help of tracers have indicated that Ga, Tl and Fe are extracted with yields ranging from 86 to 98%, but Mo is extracted poorly.

By use of both these extraction procedures, from hydrobromic and hydrochloric acid media, a wide range of elements can be determined. The two schemes do not cover Ag and Hg, which are co-deposited with Cu, but these elements can be deter-

mined by neutron activation. After irradiation, the sample is allowed to stand until the ^{64}Cu (half-life 12.7 hr) has completely decayed. The trace elements of interest can then be determined by measuring the characteristic gamma peaks of the nuclides with half-lives greater than that of ^{64}Cu. The suggested extraction procedure is not suited for the determination of As, Mo and possibly some other elements not covered by this investigation.

In the multistage procedures outlined above, the blank values for Ag, Sb, Co and Zn are in the range 1–10 ng/g while those for Hg, Cd, Mn, Pb and Ni are of the order of 10–100 ng/g. Sources of the blanks are presumably impurities in the reagents, the apparatus, and the laboratory surfaces and air, all of which should be meticulously controlled. The limit of detection of the elements listed is estimated to be in the range of 10–100 ng/g, based on the criterion $X_S = X_B + 3\sigma_B$ where X_S and X_B are the values of the sample signal and the mean blank signal respectively, and σ_B is the standard deviation of the mean blank value.[14]

Table 6 gives typical results obtained for trace elements in the form of impurities and dopants in actual samples of $CuInS_2$. The limit of detection and the relative standard deviation for triplicate analysis of each element are indicated. The reliability of the analytical data have been checked for some elements (Co, Cd, Zn and P) by the method of standard additions.

EXTRACTIVE-SPECTROPHOTOMETRIC DETERMINATION OF MOLYBDENUM WITH 4-UNSUBSTITUTED-5-PYRAZOLONES

A. Ahmad, F. Ik. Nwabue* and G. E. Ezeife
Department of Chemistry, University of Nigeria, Nsukka, Nigeria

Summary—A fairly sensitive and selective method for rapid determination of tracer amounts of molybdenum(V) as mixed-ligand complexes with thiocyanate and 4-unsubstituted-5-pyrazolones is described. The red complexes are extractable into chloroform from 1–5M hydrochloric or perchloric acid or 1–3M sulphuric acid media. The molar absorptivities are in the range 1.72–2.15×10^4 l.mole^{-1}.cm^{-1} at 455 nm (λ_{max}). The method has been applied to the estimation of molybdenum in various synthetic and alloy-steel samples. In presence of excess of the reagent, Cu(II), Co(II), Mn(II), Fe(II), Fe(III), Al(III), Cr(III), Cr(VI), Ti(III), Ti(IV), Zr(IV), Hf(IV), V(III), V(IV), V(V), Nb(V), Ta(V), W(VI) and U(VI) do not interfere.

Since Braun's work[1] in 1863 on the use of thiocyanate for the determination of molybdenum, a considerable literature has appeared on the subject. Much of it concerns improved methods of reducing Mo(VI) to Mo(V)[2–10] prior to determination, as well as formation of mixed-ligand complexes of molybdenum with thiocyanate and O-, N- or S-containing complexants[11–17] to enhance sensitivity and selectivity. Spectrophotometric methods based on the use of these systems suffer from various difficulties, including the poor availability and low purity of many of the complexants.

In our search for various analytical uses of 5-pyrazolones we have found 2,3-dimethyl-1-phenylpyrazol-5-one (HDMPP), **A**, commonly known as antipyrine, and 3-methyl-1-phenylpyrazol-5-one (HMPP), **B**, most promising as simple and selective reagents for the determination of trace amounts of molybdenum in presence of thiocyanate. The reagents are easy to prepare pure and are commercially available, and the method is fairly sensitive and rapid.
A, HDMPP   B, HMPP

EXPERIMENTAL

Reagents

All reagents and solvents used were of analytical grade. All aqueous solutions were prepared with distilled and demineralized water.

Standard molybdenum(VI) solution. Prepared by dissolving 0.1840 g of ammonium heptamolybdate tetrahydrate in water and standardized by the oxine method.[18] The working solution was prepared by appropriate dilution.

HDMPP and HMPP solutions. Prepared as 1% solutions in chloroform.

Ammonium thiocyanate and ascorbic acid solutions. Freshly prepared as 20% and 10% solutions respectively.

Procedure

To about 3 ml of solution containing 1–90 μg of Mo(VI) add 2 ml each of the ammonium thiocyanate and ascorbic acid solutions and of 10M hydrochloric or sulphuric acid. Dilute to 10 ml with distilled water and shake with 10 ml of either HDMPP or HMPP solution for 2 min. Separate the organic layer, dry it for 2 min over anhydrous sodium sulphate (1 g) and measure its absorbance at 455 nm against a reagent blank.

Procedure for steel analysis

Dissolve 0.1 g of steel sample in a few ml of *aqua regia* and evaporate the solution to dryness. Heat the residue with 3 ml of concentrated sulphuric acid until fuming; repeat this step twice and then heat to fumes with 3 ml of concentrated perchloric acid. Cool and take up the salts in 10 ml of 1M hydrochloric acid. Add 1 g of ammonium oxalate to mask any interference from V(V), U(VI) and W(VI) and make up accurately to 100 ml with distilled water. Determine molybdenum in a suitable aliquot, as already described.

RESULTS AND DISCUSSION

Spectral characteristics

The absorption spectra of the metal chelates, ligands and the Mo–SCN complex extracted into chloroform from 1M hydrochloric acid are shown in

---

*Author to whom correspondence should be addressed.
Fig. 1. Absorption spectra. [HCl] $2M$; [SCN] 4%; [ascorbic acid] 2%; (O—O—O) Mo–SCN–DMPP complex; (⊙--⊙--⊙) Mo–SCN—MPP complex; (●—●—●) Mo–SCN–complex; (■--■--■) 1% HMPP; (▽—▽—▽) 1% HDMPP.

Fig. 1. The spectra of the chelates are similar, with maxima at 455 nm and about 350 nm. The absorption at 455 nm is the higher and is therefore used for the determination. The reagents and the Mo–SCN complex have negligible absorption at this wavelength.

Choice of solvent and reducing agent

Chloroform, carbon tetrachloride, benzene, toluene and methyl isobutyl ketone (MIBK) were tried as solvents. The reagents are readily soluble in chloroform and MIBK but dissolve with difficulty in the rest. MIBK, however, developed an undesirable colour by reaction with thiocyanate, and this interfered with the determination. Chloroform showed high extractibility and its solution gave the highest absorbance for the metal chelates; hence it was chosen as solvent. Ascorbic acid has been shown[10,17] to have advantages as a reducing agent in molybdenum determinations involving thiocyanate. The effect of variation in the amount of ascorbic acid was examined by using the recommended procedure with the acid concentration varied in the range 1–10% with 4 μg of molybdenum. Maximum colour development and extraction were observed over the concentration range 1.5–2.7%. Outside this range the absorbance decreased considerably. A concentration of 2.0% was chosen as the final ascorbic acid concentration in the solution to be extracted.

Effect of other variables

The effect of variation in the HMPP and HDMPP concentration was examined in the range 0.1–10%.

Complete extraction was obtained with concentrations above 1%, without variation in absorbance. Hence 1% was selected as a convenient concentration. The effect of variation in thiocyanate concentration was examined similarly and it was found that the range 3.4–5.0% was necessary for complete recovery of molybdenum. A total thiocyanate concentration of 4.0% in the solution to be extracted was chosen.

The acidity of the aqueous phase was systematically varied with hydrochloric, sulphuric and perchloric acids. The optimum acidity ranges for HDMPP were 1–5M hydrochloric or perchloric acid, and 1–3M sulphuric acid, and for HMPP 1–3.5M hydrochloric or sulphuric acid, and 1–2M perchloric acid. Within these ranges the same values of λ_{max} and molar absorptivity were obtained. Acid concentrations above these ranges decreased the extraction efficiency because of increased miscibility of chloroform with the aqueous phase, and below these ranges colour development was either slow or incomplete. Hence 2M hydrochloric or sulphuric acid was preferred for ease of manipulation and increased selectivity. Nitric acid gave no colour development but fumes of nitric oxide were evolved, probably owing to its redox reaction with ascorbic acid.

Preliminary tests indicated that a shaking time of 2 min was sufficient for quantitative extraction of molybdenum. Variations in temperature from 18 to 40° and in volume of the aqueous phase from 5 to 40 ml had no effect on the absorbance and extraction efficiency. Stability of the colour was studied at room

†In presence of 1% ammonium oxalate.

temperature (about 25°). Maximum absorbance was obtained within 1 min after extraction and remained constant for at least 3 days. The order of addition of the reagents was not critical.

Calibration range, sensitivity and precision

The calibration graph is linear over the range 0.1–9 ppm of Mo with an optimal working range of 0.3–6 ppm (Ringbom plot). At 455 nm, the molar absorptivities of the metal–DMPP–SCN and metal–MPP–SCN chelates in chloroform are 2.15×10^4 and 1.72×10^4 $l.mole^{-1}.cm^{-1}$. The relative standard deviation (twelve determinations of 4 ppm Mo) is 0.9% with both reagents.

Effect of diverse ions

The effect of some ions, particularly those associated with molybdenum ores and alloy steels, in the determination of 4 ppm of molybdenum by the recommended procedure, was examined. Chloride, bromide, sulphate, phosphate, chlorate, oxalate and

alkali metals in up to 5000-fold amount, alkaline-earth metals and fluoride up to 3000-fold amount, and nitrate up to 1000-fold amount (relative to molybdenum) do not interfere. The tolerance limits for other ions are given in Table 1.

Composition of the complex

Job's method and the mole-ratio method indicated a mole ratio of 1:2:1 for Mo:thiocyanate:HDMPP or HMPP. The species extracted are probably $MoO(SCN)_2(DMPP)$ and $MoO(SCN)_2(MPP)$, in which the deprotonated ketonic form of the pyrazolone (as a carbanion) co-ordinates to the metal through the 5-keto oxygen atom and the carbon atom at the 4-position, which has previously lost an active hydrogen atom. Thus a carbon–metal bond is formed, conferring increased stability on the 4-membered chelate ring, as expected of such organometallic compounds. This is probably why the colour is stable for many days.

Applications

The recommended procedure was tested with synthetic solutions and two British Chemical Standard steels. Results for analysis of the alloy steels were 0.15–0.16% for BCS 325 (certified value 0.16%) and 0.22–0.24% for BCS 320 (certified value 0.22%). The relative standard deviations for six replicates were 0.8% and 1.1% respectively. Results of analysis of the synthetic solutions are given in Table 2.

Summary—A functional resin for the collection of selenium(IV) has been prepared simply by the conversion of a common ion-exchange resin with bismuthiol-II which has three functional properties, namely the capabilities of selective reaction with selenium(IV), ion-exchange reaction with ion-exchange resin and strong physical sorption to the ion-exchange resin matrix. The binding ratio of selenium(IV) to bismuthiol-II on the resin was confirmed to be 1:4. The reaction was represented as follows: $4RSH + H_2SeO_3 \rightarrow R\text{–}S\text{–}Se\text{–}S\text{–}R + R\text{–}S\text{–}S\text{–}R + 3H_2O$. Highly selective sorption of selenium(IV) was achieved, based on the formation of stable selenotrisulphide on the resin. Selenium(IV) sorbed on bismuthiol-II resin was eluted effectively with 8–13M nitric acid or some thiols, such as cysteine and penicillamine. In the cases of thiols, the elution of selenium was found to be also based on the formation of selenotrisulphide, and the bismuthiol-II resin was regenerated. Satisfactory results were obtained when this resin was applied to the determination of selenium(IV) in river, estuarine or sea water samples.

The development of a simple method for the selective collection of trace amounts of selenium in environmental and biological material has been attempted by the use of a common ion-exchange resin loaded with a reagent which has three important analytical properties: selective reaction with selenium(IV), an ion-exchange reaction with the resin, and strong physical adsorption on the resin. We have found that selenium(IV) can be collected on an anion-exchange resin loaded with azothiopyrine disulphonic acid,[1] but the method is not satisfactory for low selenium levels. The selenium is collected by means of its reaction with the thiol group of azothiopyrine disulphonic acid to form a selenotrisulphide. We have now found that bismuthiol-II (Fig. 1) also forms a stable selenotrisulphide and can be used for making a functional resin for selective collection of selenium(IV), even at trace levels. This bismuthiol-II resin is suitable for analysis of environmental samples.
Fig. 1. Bismuthiol-II.

EXPERIMENTAL

Apparatus

Absorption spectra in the ultraviolet and visible regions were measured with a Hitachi 330 spectrophotometer. A Shimadzu RF-500 spectrofluorophotometer was used for the fluorometric determination of selenium(IV) with 2,3-diaminonaphthalene (DAN). Metal ions were determined by atomic-absorption spectrometry with a Shimadzu AA-630-01 atomic-absorption spectrophotometer.

Reagents

Amberlite IRA-400 (8% divinylbenzene) in the chloride form, 100–200 mesh, was used as the anion-exchange resin. The exchange capacity of the resin was found to be 3.2 meq per g of air-dried resin. Bismuthiol-II and DL-penicillamine were obtained from Dojindo Laboratories and Siguma Chemicals Co., respectively. All other reagents used were of analytical grade quality.

Preparation of bismuthiol-II resin

The anion-exchange resin was added to an aqueous solution of bismuthiol-II and the mixture was shaken at 30° for 60 min. The resin loaded with bismuthiol-II was filtered off, washed with water and methanol, and dried, stored in a refrigerator, and vacuum-dried before use. The amount of bismuthiol-II in the supernatant solution was found by absorbance measurement at 335 nm, for determination of the exchange capacity.

Determination of amount of chloride ion released in ion-exchange reaction

One g of the anion-exchange resin was shaken for 12 hr with 50 ml of solution containing bismuthiol-II (0.1, 0.2, 0.4 and 1.0 mmole). Twenty-five ml of the solution were titrated with standard silver nitrate solution for determination of chloride.

Determination of bismuthiol-II released by sodium chloride

A 50-mg portion of resin, loaded with various amounts of bismuthiol-II (0.2, 0.4 and 1.0 mmole/g), was shaken for 24 hr with 5 ml of sodium chloride solution (0.1, 0.5 and 1.0M) in a test-tube. The amount of bismuthiol-II released was determined by measurement of the absorbance at 335 nm and pH 5.

Binding-capacity for selenium(IV)

Resin, 50 mg, loaded with various amounts of bismuthiol-II (0.2, 0.4, 0.6 and 1.0 mmole/g) was shaken with an excess of selenium(IV). The hydrochloric acid concentration of this sample solution was adjusted by addition of 5M hydrochloric acid, before it was shaken with the resin. The amount of selenium(IV) left in the solution was determined fluorometrically. The resin with 0.2-mmole/g bismuthiol-II loading was used to determine the binding ratio of selenium(IV) to bismuthiol-II by the molar ratio method.

Collection of selenium(IV) and the effect of metal ions at various pH values

Bismuthiol-II resin (0.2 mmole/g, 100 mg) was shaken for 5 hr with 50 ml of 2-mg/l. solutions of copper(II), manganese(II), chromium(VI), iron(III), zinc(II) and selenium(IV), adjusted to the desired pH with acetate buffer and hydrochloric acid. The ionic strength was maintained at 0.5 by addition of 5M sodium chloride. The resin was then filtered off on a fritted-glass funnel, and an appropriate volume of the filtrate was taken for the determination of selenium(IV) and metal ions by fluorometry and atomic-absorption spectrometry, respectively.

Sorption isotherm

Bismuthiol-II resin (0.2 mmole/g, 100 mg) was shaken with 50 ml of 0.3M hydrochloric acid containing known amounts of selenium(IV), for 5 hr at 30°. After equilibration, an aliquot of the solution was analysed for selenium(IV) by fluorometry.

Elution of selenium(IV) sorbed on bismuthiol-II resin

Method I. Bismuthiol-II resin (0.2 mmole/g, 200 mg) was shaken with 50 ml of 0.3M hydrochloric acid containing 100 μg of selenium(IV), for 5 hr at 30°. The resin, which completely sorbed the selenium(IV), was packed in a glass tube (7 mm bore). Selenium was eluted with 20 ml of 6–13M nitric acid. An aliquot of eluate was analysed for selenium(IV) by fluorometry after adjustment to pH 1 with ammonia solution.

Method II. Bismuthiol-II resin (0.2 mmole/g, 100 or 200 mg) was shaken with 50 ml of 0.3M hydrochloric acid containing 100 or 500 μg of selenium(IV), for 5 hr at 30°. The resin (which completely sorbed the selenium) was packed in a glass tube (7 mm bore). The eluent under test, 20 ml, was passed through the column at a flow-rate of 1.0 ml/min, and the column was washed with 50 ml of distilled demineralized water. Then 20 ml of 10M nitric acid were passed through the column, and the amount of selenium(IV) eluted was determined. The recovery shown in Table 2 was derived by subtracting the amount of selenium eluted with nitric acid from that sorbed on the resin.

Absorption spectrum of the solution after elution of selenium with penicillamine

Selenium(IV), 0.01 mmole, was sorbed completely on 500 mg of 0.2-mmole/g bismuthiol-II resin, and the resin was filtered off and air-dried, then shaken with 40 ml of 0.01M penicillamine solution at pH 5. After 3 hr, the absorption spectrum of the solution was measured.

Collection of selenium(IV) by column operation

The column (1.0 cm bore) was packed with 0.2-mole/g bismuthiol-II resin to a height of 5.0 cm and washed with 100 ml of distilled demineralized water, then 10-mg/l. selenium(IV) solution in 0.3M hydrochloric acid was passed through the column at a flow-rate of 1.0 ml/min. The amount of selenium(IV) in the effluent was determined by fluorometry. The resin was washed with 50 ml of distilled demineralized water, then eluted with 0.1M penicillamine at pH 5 (flow-rate 1.0 ml/min) and washed with 50 ml of distilled demineralized water. Ater this elution cycle, 10-mg/l. selenium(IV) solution in 0.3M hydrochloric acid was again passed through the column to reuse the bismuthiol-II resin.

Collection of trace amount of selenium(IV)

After addition of 1.0 and 0.1–1.0 μg of selenium(IV) to 500 ml of 0.4M sodium chloride and 1 litre of pure water respectively, the solutions were treated as in the column operation just described. The selenium eluted with 0.1M penicillamine was determined fluorometrically after digestion with perchloric acid–nitric acid or nitric acid–hydrochloric acid–hydrogen peroxide mixture.

Application of bismuthiol-II resin to the collection of trace amounts of selenium(IV) from environmental water samples

The water samples were filtered (Whatman GF/C, 4.7 cm) immediately after they were taken. Concentrated hydrochloric acid was added to the fresh sample to make the acid concentration 0.5M and this solution was applied to a 1-cm bore column packed with the resin, which was loaded with 0.2 or 0.4 mmole of bismuthiol-II per g, to give a resin bed 5.0 or 10.0 cm in height. Selenium collected on the column was eluted with 20 ml of 0.1M penicillamine or 0.05M cysteine (0.1M in hydrochloric acid) at a flow-rate of 1.0 ml/min. Selenium in the eluate was determined by fluorometry after acid digestion.

RESULTS AND DISCUSSION

Conversion of the anion-exchange resin into bismuthiol-II resin

The anion-exchange resin could be converted into bismuthiol-II resin simply by mixing it with an aqueous solution of bismuthiol-II. The exchange-capacity for bismuthiol-II was found to be 3.1 mmole per g of resin, which is comparable with that for chloride, 3.2 mmole/g. The time required for loading of the resin was dependent on the amount of reagent to be immobilized. Loading of 50% of saturation took 30 min. The 0.2-mmole/g bismuthiol-II resin, which required only 5 min for preparation, was mainly used. When bismuthiol-II was reacted with the anion-exchange resin in the chloride form, the ratio of chloride released to bismuthiol-II sorbed was about 1, indicating that bismuthiol-II is bound to the resin by an ion-exchange mechanism.

Bismuthiol-II was found to be retained on the resin, even when the resin was exposed to 0.1, 0.5 and 1.0M sodium chloride, as shown in Table 1, particularly at low loading. The strong immobilization of bismuthiol-II on the resin must therefore be due to some physical interaction besides simple ion-

Table 1. Bismuthiol-II released with sodium chloride

Eluent	Bismuthiol-II released, %		
	0.2 mmole/g of resin	0.4 mmole/g of resin	1.0 mmole/g of resin
0.1M NaCl	0.26	0.32	0.54
0.5M NaCl	0.68	0.77	1.50
1.0M NaCl	0.83	1.09	2.18

Batch operation: bismuthiol-II resin 50 mg; eluent 5 ml; shaking time 24 hr.

exchange. Some chelating agents, such as dithizonesulphonic acid,[2] azothiopyrinesulphonic acid[3] and some formazansulphonic acids[4] have been found to be bound to anion-exchange resin through their sulphonic acid group, and also strongly sorbed on the resin by some physical interaction. The use of these reagents is more advantageous than that of 8-hydroxyquinoline-5-sulphonic acid, which leaks considerably to the solution in the presence of chloride ion, on account of weaker physical sorption.[5,6] In bismuthiol-II, which does not have a sulphonic acid or carboxylic acid group, but is strongly sorbed on the ion-exchange resin, the thiolate anion is considered to act as the ion-exchange group, but after immobilization of the reagent on the resin by physical interaction, the thiol group is able to react with selenium(IV) in acid medium. The terfunctional property of bismuthiol-II is thus explained.

Collection of selenium(IV) with bismuthiol-II resin

The binding-capacity of bismuthiol-II resin for selenium(IV) in 0.5M hydrochloric acid is shown in Fig. 2. The time required for 50% uptake of selenium(IV) was less than 20 min. After the sorption of selenium(IV) had reached equilibrium, no turbidity due to release of elemental selenium was observed in the supernatant liquid, and the colour of the resin changed from light brown to pale yellow. The binding-capacity for selenium(IV) increased linearly with increase of the amount of bismuthiol-II on the resin. The reacting ratio of selenium(IV) to bismuthiol-II was found to be approximately 1:4
under the conditions used, as shown in Fig. 3, which corresponds to the ratio in the reaction of selenium(IV) with bismuthiol-II in solution.[6]

The collection of selenium(IV) was complete at pH below 2, as shown in Fig. 4. Selenite is not sorbed on the resin itself under these conditions, so the sorption on the bismuthiol-II resin can be attributed to formation of selenotrisulphide according to equation (1). The optimum pH range for the collection of selenium(IV) agreed with that for the complete extraction of the selenium–bismuthiol-II complex into chloroform.[7] The reactions of selenium(IV) with some thiols have been expressed as equation (1), although the assumed reaction product (selenotrisulphide) has not been fully characterized, and
Fig. 3. Binding ratio of selenium(IV) to bismuthiol-II loaded on the resin; bismuthiol-II 0.2 mmole/g of resin.

Fig. 2. Binding-capacity of bismuthiol-II resin for selenium(IV).

in most cases is referred to as unstable.[8]

$$4RSH + H_2SeO_3 \rightarrow R\text{-}S\text{-}Se\text{-}S\text{-}R + R\text{-}S\text{-}S\text{-}R + 3H_2O \quad (1)$$
R = free form of bismuthiol-II

The collection of copper(II), manganese(II), chromium(VI), iron(III), zinc(II) and selenium(IV) by bismuthiol-II resin at various pH values is shown in Fig. 4.

At pH below 2, the collection of selenium(IV) is complete, whereas that of the metal ions is low, except for copper(II). The collection of selenium(IV) from strongly acid medium indicates the high selectivity of this reaction.

Sorption isotherms for selenium(IV) in $0.3M$ hydrochloric acid with and without $0.5M$ sodium chloride were almost identical, and the maximum uptake was practically independent of the selenium concentration from 0.001 to about 2 mg/l. Thus the bismuthiol-II resin should be effective for collection of selenium(IV) at very low concentration even from strongly saline samples such as estuarine water and sea-water. Selenium(VI), another important form of selenium, did not react with bismuthiol-II resin under the experimental conditions of this study.

Elution of selenium

There are two possibilities for the elution:

(resin–bismuthiol-II–selenium)→(resin)
        + bismuthiol-II + selenium   (method I)

(resin–bismuthiol-II–selenium)
        →(resin–bismuthiol-II) + selenium   (method II)
Table 2. Elution of selenium from bismuthiol-II resin by method II

Eluent	Recovery, %
$0.01M$ KMnO$_4$	0.0
$0.1M$ KMnO$_4$	3.3
$0.1M$ I$_2$	0.0

$0.1M$ penicillamine	98.2
$0.2M$ penicillamine	98.1

Bismuthiol-II resin 100 mg (0.2 mmole/g of resin); selenium sorbed 100 μg.

where the species in parentheses are in the solid state. Selenium sorbed on bismuthiol-II resin was about 93% eluted with $8-13M$ nitric acid by method I. The eluate, which contains selenium(IV), can be analysed directly by fluorometry after adjustment to pH 1 with ammonia solution. The high recovery indicates that the collection of selenium(IV) was essentially quantitative. The recovery of selenium(IV) decreased by only about 4% if the selenium(IV) was left on the resin for 23 days before elution, indicating that if selenotrisulphide is formed from bismuthiol-II on the resin, it is unusually stable, and that the resin is valuable for use in field work.

Various reagents were tried as eluents (Table 2). Cysteine and penicillamine were found to be best. Sodium borohydride also gives high recovery, but is not suitable because it forms bubbles in the column.
Fig. 5. Elution of selenium from bismuthiol-II resin with penicillamine and cysteine (method II). Bismuthiol-II resin 200 mg (0.2 mmole/g). Selenium sorbed 500 μg. Eluting agent: —O— $0.1M$ penicillamine, —●— $0.05M$ cysteine.

Fig. 7. Break-through curves for selenium(IV). Bismuthiol-II resin: (I) —○— 0.2 mmole/g, (II) ···●···
regenerated with 0.1M penicillamine at pH 5. Resin column 10 × 50 mm. Concentration of selenium(IV)
in the sample solution 10 mg/l., in 0.3M hydrochloric acid. Flow-rate 40 ml/hr.

As shown in Fig. 5, penicillamine can be used over a wider pH range than cysteine. When cysteine was used, a slight red turbidity appeared if the eluate was allowed to stand for a week, but this did not occur with penicillamine, so the selenotrisulphide formed with penicillamine is presumably more stable than that formed with cysteine. When 0.01 mmole of selenium was eluted with 0.01M penicillamine at pH 5 by batch operation, the absorption spectrum of the eluate (Fig. 6) was almost identical with that of a solution of 0.01 mmole of selenium in 0.01M penicillamine at pH 5. The reaction-ratio of penicillamine to selenium(IV) at pH 5 was found to be 4:1 by the molar-ratio method and absorbance monitoring at 260 nm. This result indicates that selenium(IV) reacts with penicillamine in the same way as with bismuthiol-II [equation (1)]. This conclusion is supported by the results of a [77]Se nuclear magnetic resonance study, which will be reported elsewhere.

The recovery of selenium(IV) and the regeneration of bismuthiol-II resin were investigated by column operation. The break-through curve is shown in Fig. 7. When the bismuthiol-II resin was repeatedly

used and recovered, similar break-through curves were obtained and the concentration of selenium in the effluent up to the break-through point was found to be constantly below 1 μg/l.

Application of bismuthiol-II resin to the collection of selenium (IV) from environmental water samples

Bismuthiol-II resin exhibits advantageous features in the selective collection and elution of selenium(IV). The recovery of selenium(IV) from 0.4M sodium chloride is consistently about 95% irrespective of eluent flow-rate from 1.0 to 7.5 ml/min. The recovery from distilled water is also about 95% over the range from 0.1 to 1.0 μg/l. The collection of selenium from river, estuarine and sea water by bismuthiol-II resin was examined. Table 3 shows typical results and a comparision result for one sample, by co-precipitation with tellurium.[9] We have studied extensively the amount and chemical form of selenium in the water of the coast of Nagoya City, which is one of the leading industrial areas in Japan. The results will be reported in detail elsewhere. The values ob-

tained were comparable with those obtained by the tellurium co-precipitation method for samples from other places.[9]

In conclusion, this method for collection of selenium(IV) is advantageous in its selectivity and simplicity, and the stability of the reaction product on the resin. It is also useful for preconcentration prior to fluorometric determination (the currently most widely used method for the determination of selenium).

BINARY DATA ACQUISITION FROM INSTRUMENTATION WITH BCD-CODED OUTPUT: A HARDWARE CONVERTER AND AN EXAMPLE OF THE RELATIVE SOFTWARE CONTROL

L. Lampugnani, D. Guidarini and N. Fanelli

Istituto di Chimica Analitica Strumentale del C.N.R., Via Risorgimento 35, 56100 Pisa, Italia

Summary—Simple hardware for conversion from BCD into binary code is described. The device is of low cost, performs a 16-bit conversion in a maximum time of 400 nsec, and is able to output the converted number to either an 8-bit or a 16-bit data bus. An example of the software necessary to perform data acquisition from a digital voltmeter by using this converter is also presented.

Electronic instruments such as pH-meters, automatic burettes, voltmeters and automatic balances, which have wide utilization in a chemical laboratory, are usually able to supply two kinds of output: one is the digital display that can be read by the user for manual data collection, the other is a digital output whereby the data are coded in an electrical signal train so that they can be utilized for high-speed automatic data collection.

The latter kind of output provides the user with a more efficient utilization of such instruments, once they have been interfaced with a logic processor spanning from a simple microprocessor for data-logging to a multiuser-multitask minicomputer for complete instrumentation control.[1]

For reasons of design simplicity and standardization the most common code used for the digital output from electronic instruments is the one known as BCD (Binary Coded Decimal),[2] which uses four bits for each digit of the decimal number of interest, despite the two significant inconveniences that this code presents.

First, the BCD code is not compact, and requires appreciably more bits than the corresponding binary representation. The saving made by use of binary coding increases with the number of digits, but we shall limit the discussion to 5-digit numbers, since larger numbers are unlikely to occur in instrumental analysis.

Secondly, when a number transmitted from the instrumentation must be handled by the computer, it is necessary to translate the BCD datum into a binary datum, since computers operate with binary arithmetic. This could be done by using a software routine called into use each time a datum is stored, but a routine of this kind, which depends on the logical processor used, would be different for each specific circumstance and might be difficult for an experimenter to write and would certainly be inefficient in the use of computer time and resources.

To overcome both difficulties, we propose a hardware code-converter interface that is simple to build and to use, and is based on a low cost IC, the SN74184,[3] that could fill a gap existing at present in the commercial market.

An example is also given of the software necessary to control a device of this kind in order to carry out data-acquisition from a digital voltmeter.

HARDWARE

Figure 1 shows a diagram of the circuit and the power supply. The 1-kΩ resistors on the output pins are used to pull the open collector output to TTL level.

The algorithm used for the conversion[3] can be outlined as follows. Save the last bit of the input word as the least significant bit of the converted word; divide the bits left into four-bit decades; examine each of these decades and subtract 3 from those containing a binary number larger than 7; save the new last bit of the resultant word as the next least significant bit and continue the process until the last decade left contains a binary number smaller than 8; save these bits as the three most significant bits of the converted word.

Considering that each SN74184 is only able to handle six bits at a time, to implement the algorithm it is necessary to cascade a number of these chips in a combination of series and parallel connections (obviously dictated by the initial number to be converted).

As already said, numbers with more than five digits are not taken into consideration, but a further limitation to numbers between 0 and 65535 will be made, because these can be represented by 16-bit binary numbers. Hence nineteen SN74184 circuits are necessary.

The 16-bit binary numbers can be transferred in two ways, depending on the I/O port available on the processor.

With fairly inexpensive personal computers the I/O port for parallel communications is usually able to accept only eight data lines, but with more sophisticated (and more expensive) computers the I/O port capability easily increases up to sixteen or more bits.

To cope with both possibilities, the sixteen bits forming the converted word can be multiplexed on an 8-bit or a 16-bit bus by using two SN74298s.[4]

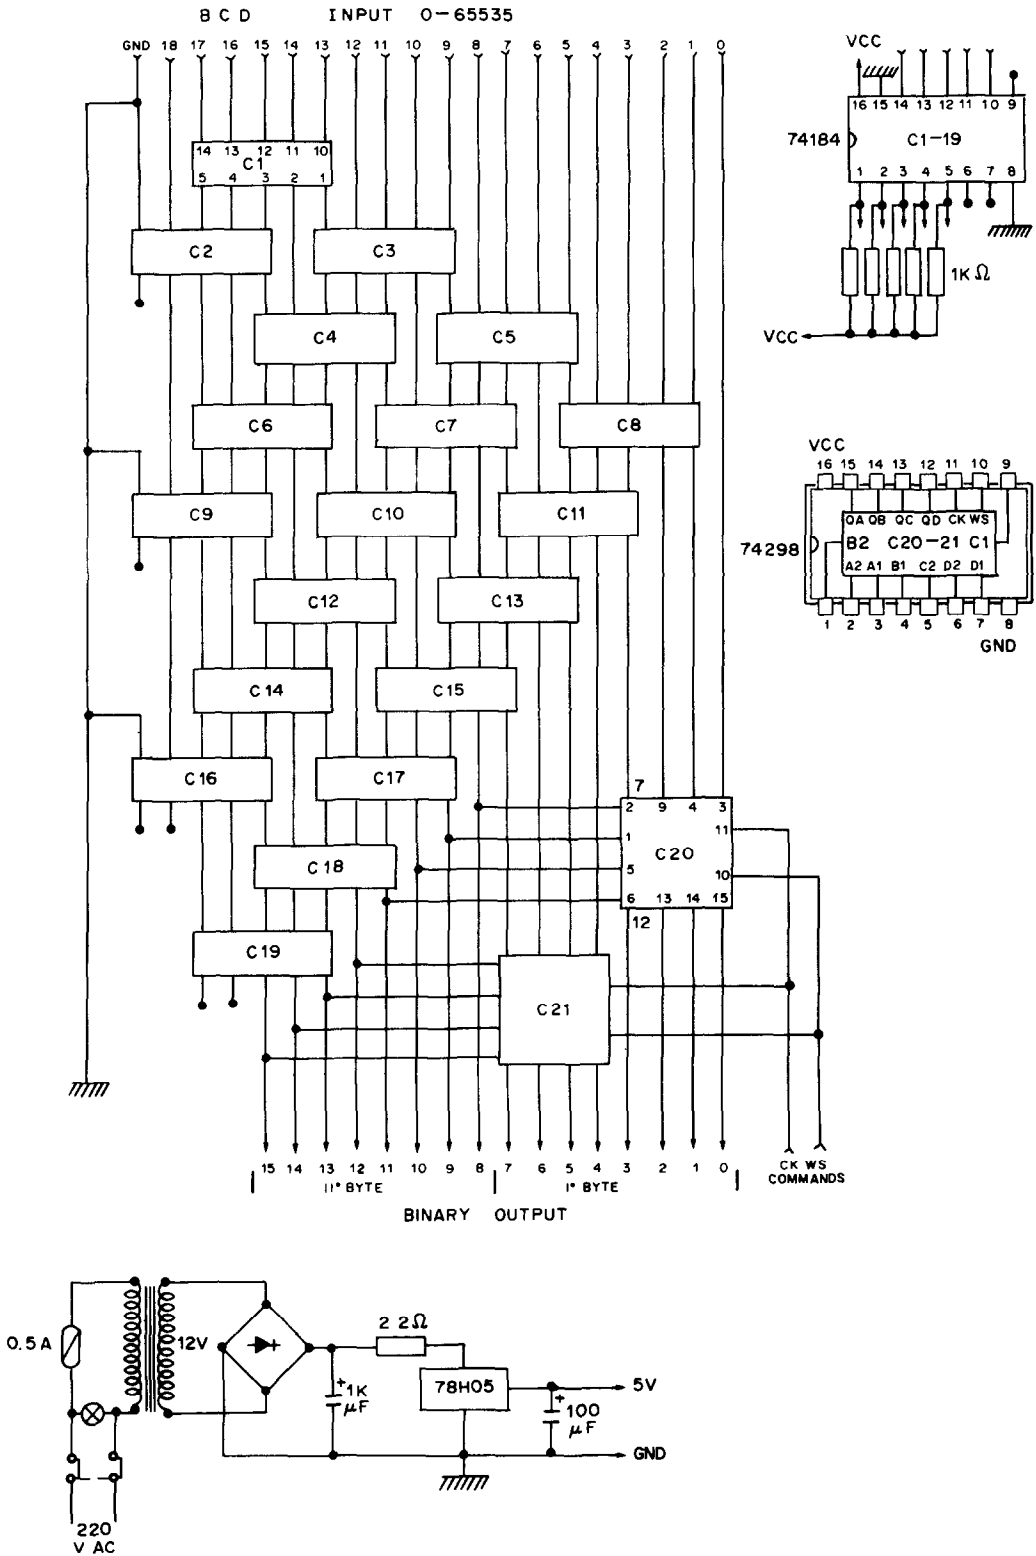
The SN74298s are in fact able to control the transfer of eight input lines to four output lines by using two logical signals. When the word select (WS) line is kept low the first four bits are transferred to the output at the negative edge


Fig. 1. Schematic diagram of circuit and power supply for the BCD-binary converter.

of the clock line (CK); when the WS is kept high the second four bits are again transferred at the negative-going transition of CK while the output remains latched at the levels entered with the last negative transition of CK.

Figure 2 shows the two protocols to be used in the case of a 2-byte transfer or of a complete word transfer. The different timing takes into account the delay introduced by each circuit.
Fig. 2. Transfer time diagrams for (A) 8-bit transfer, (B) 16-bit transfer. Time intervals between events are in nsec and represent the minimum required for reliable operation.

The maximum delay introduced by each SN74184 is 40 nsec; for the eight least significant bits the total delay can be as high as 200 nsec, owing to the five levels of conversion involved for these bits. After 200 nsec, the first CK transition can be applied, the WS being at low level.

As the propagation delay for the SN74298 is 32 nsec, after 232 nsec the least significant byte of the converted number is ready to be loaded.

The most significant byte is correctly converted after 400 nsec (ten levels involved) and is then ready to be loaded after a total of at most 432 nsec from the beginning of the BCD-binary conversion.

Since the microcomputers now on the market can acknowledge an external event in about 1 μsec, the operation performed by this kind of BCD-binary converter is completely transparent to the software program which manages the data acquisition.

Thus the logic of the program will be simpler and the data will be gathered more rapidly, at a rate depending only on the speed at which the instrumentation can supply the data.

SOFTWARE

We shall now describe an example of a rather complex utilization of this converter, from which simpler applications can easily be derived.

To gather data from a calorimetric apparatus used in our laboratory, a Solartron A203 digital voltameter with $4\frac{1}{2}$ digits of resolution (± 19999) was interfaced to an HP 21MX computer.

The data had to be sampled from four different sources by means of an analogue multiplexer, in temporal sequences specified by the characteristics of the kind of experiment performed.

For this purpose a main program written in HP FORTRAN manages the procedures, each time specifying the channel to be sampled, the number of samples to be drawn, the time between each sample, the data storage area, and the kind of bus to be used for the data transfer, in this case always a 16-bit bus.

Each time a data acquisition has to be made, control is transferred to an Assembler subroutine (ACQ1) by a CALL SUBROUTINE statement. Once this task has been done control is returned to the main program, which processes the data gathered or performs another data acquisition. Figure 3 shows the flow chart for the routine ACQ1. This routine initializes the counters for the number of samples and the number of clock intervals between samplings, programs the clock interval length at 1 msec, selects the multiplexer channel for the analogue signal of interest, enables the routines to handle the interrupts and finally sends the start conversion command to the voltameter ACD and the start command to the clock.

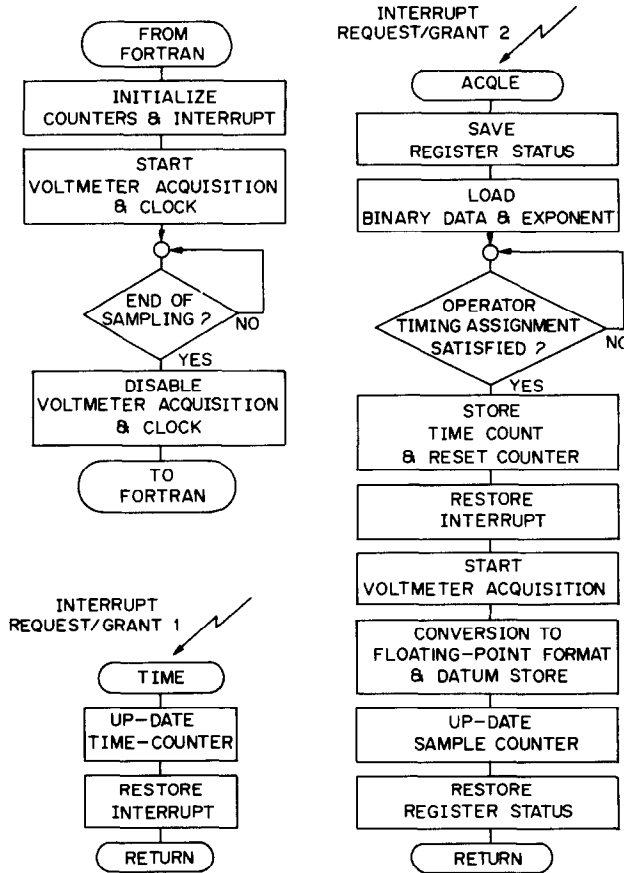
At this point it checks whether the required number of samples has been accumulated. If so, it disables the clock


Fig. 3. Flow-chart diagram of the external Assembler routine ACQ1 for data acquisition from FORTRAN main program.

and the DVM converter in order to return to the MAIN program; otherwise, the "check" becomes a loop which stands waiting for the interrupt signals coming from the clock (time-tick marks) and from the ADC (DVM end of conversion) each being handled by the opportune service routine, the TIME routine and the ACQLE routine respectively.

Whenever the time routine is invoked, it increments in a counter the number of clock-tick marks and re-enables the clock interrupt control to its "ready" condition for the next interrupt.

The ACQLE routine, activated by the ADC interrupts, loads the voltmeter output (as a BCD-to-binary converted number), a sign bit and a 3-bit scale number. It then checks whether the time so far elapsed, i.e., the time between the start and the end of the conversion, is less than the stated interval between two samplings. If so, it continues looping until enough time has passed. When the time reaches the value fixed by the operator, or if the time employed by the ADC conversion has been longer than the interval fixed between two samplings, the routine stores the time-counter value. This is necessary to check whether the DVM conversion has taken more time than the interval-between-sampling specified, for instance if a change of scale were to be performed by the DVM. Then it sets the time-counter at zero, starts a new DVM conversion, and proceeds to convert the binary loaded datum to a floating-point format and store it ready to be used for the following data treatments. It then increments the counter for the number of samples

and returns to the ACQ1 point where it was when the interrupt occurred.

It should be noted that the last operations described for the ACQLE, in particular the conversion from the fixed to the floating point with 97 μsec as maximum execution time, can be performed during the time required by the DVM for a conversion, without creating any recursivity in the normal program flow, if this conversion time is at least ~ 150 μsec.

The ACQ1 routine managed data acquisition at the maximum speed for the DVM used, i.e., 10 points per second, but it could work with a faster DVM up to a speed of 7000 points per second.

The listings for the routines ACQ1, ACQLE and TIME in HP Assembler are available from the authors upon request.

STUDY OF 1,4-DIHYDROXYANTHRAQUINONE AS AN ACID–BASE INDICATOR IN ISOPROPYL ALCOHOL MEDIUM

EVALUATION OF COLOUR-CHANGE LIMITS THROUGH COMPLEMENTARY CHROMATICITY PARAMETERS

J. Barbosa, J. Sanchez and E. Bosch
Department of Analytical Chemistry, University of Barcelona, Barcelona, Spain

Summary—The use of 1,4-dihydroxyanthraquinone as an acid–base indicator in isopropyl alcohol medium is proposed. The acid dissociation constants of the indicator in isopropyl alcohol solution are $pK_{a_1} = 12.95 \pm 0.03$ and $pK_{a_2} = 15.96 \pm 0.07$. The sharpness of the indicator transition is described by means of complementary chromaticity parameters. The indicator is used for determination of weak organic acids, with errors of less than 1%.

At present, there is considerable interest in a search for non-aqueous solvents convenient for the titration of weak acids, because such acids show serious conjugation problems in slightly acidic solvents such as acetonitrile, sulpholane and nitromethane.

It is known that several hydroxyanthraquinones[1-3] are suitable as neutralization indicators in aqueous solutions. It was considered useful to study one of them, 1,4-dihydroxyanthraquinone (quinizarin) as an acid–base indicator in isopropyl alcohol medium, because, in water, it gives a clear colour change at high pH, and because isopropyl alcohol is a solvent that has good solvation properties, a relatively large dielectric constant ($\varepsilon = 19.9$) and weak acidic and basic characteristics ($K_{HS} = 10^{-22.0}$)[4-6] and is hence a good solvent for titration of weak organic acids.[7-9]

The work involved the spectrophotometric study of quinizarin in isopropyl alcohol, the determination of its ultraviolet–visible spectra in different media, and spectrophotometric determination of its dissociation constants and colour-change intervals, together with the study of its analytical applications.

The colours of the limiting forms of the indicator transition are described in terms of the complementary chromaticity system proposed by Reilley *et al.*[10,11] The dissociation constants are recalculated from the complementary chromaticity parameters and comments are made on the quality of the colour change.

EXPERIMENTAL

Apparatus

A Beckman Acta M-VII spectrophotometer and a Radiometer pH-meter with glass and calomel electrodes were used. The calomel electrode was filled with a saturated solution of potassium chloride in methanol, and a salt bridge containing a saturated solution of tetramethylammonium chloride in isopropyl alcohol was used.

Reagents

1,4-Dihydroxyanthraquinone (Merck) solution, $4.37 \times 10^{-4} M$.

Isopropyl alcohol (Koch-Light, analytical grade, 0.1% H_2O).

Tetrabutylammonium hydroxide (TBAH) (Merck). A $0.1 M$ solution in isopropyl alcohol/methanol (4:1 v/v).

Buffer solutions in isopropyl alcohol. Prepared according to Aleksandrov *et al.*[12] from mixtures of $0.01 M$ veronal and $0.01 M$ potassium hydroxide.

Determination of standard potential

The glass electrode was calibrated as described by Kolthoff *et al.*[13] with mixtures of picric acid and tetrabutylammonium picrate, taking into account the incomplete dissociation of the acid ($K = 1.84 \times 10^{-4}$) and the salt ($K = 1.1 \times 10^{-3}$) in isopropyl alcohol in the concentration range used ($\sim 10^{-3} M$). The value obtained for the standard potential was -502 ± 4 mV (*vs.* S.C.E. in methanol, as indicated above). It was shown that the liquid-junction potential of the system is significant only in strongly acid (pH < 4) or strongly basic (pH > 18) solutions and therefore it can be considered negligible in this work.

Procedure

The acid dissociation constants of quinizarin were determined spectrophotometrically by standard procedures, as described by Albert and Serjeant.[14] In the calculation, the formation of ion-pairs was not taken into account according to the considerations of Petrov *et al.*,[12] because of the low concentrations ($10^{-5} M$) of the solutions employed.

The pH range of the colour change and its sharpness were evaluated by titrations of benzoic acid and veronal with $0.1 M$ TBAH in isopropyl alcohol/methanol medium, monitored simultaneously by potentiometry and continuous measurement of the absorbance at 610, 550 and 480 nm (the wavelengths of maximum absorption of the indicator). The titration solution was continuously circulated through the titration vessel and the spectrophotometer cuvette by a peristaltic pump.

The complementary chromaticity co-ordinates were determined by the weighted ordinate method, with absorbance readings between 380 and 700 nm, at 10-nm intervals. The evaluation was based on the CIE table of coefficients for standard illuminant C.[15] Diluted solutions (1/25 and 1/10)

of the quinizarin stock solution were used, and the determinations were made at intervals of approximately 0.2 pH units over the colour-change pH range. The dissociation constants of quinizarin were calculated from the complementary chromaticity co-ordinates.[11,16]

RESULTS AND DISCUSSION

Figure 1 shows the ultraviolet–visible absorption spectra of quinizarin in isopropyl alcohol at various pH values. The three forms **I, II** and **III** show different colours:

Colour-change evaluation

The indicator colours are described by their complementary chromaticity co-ordinates, calculated by the weighted ordinate method, and by the "colour concentration", J, which is the only concentration-dependent term. The values are given in Table 2.

The plot of these values in the complementary chromaticity diagram (Fig. 2) shows two linear segments that correspond to conversion of form (**I**) into (**II**), and of (**II**) into (**III**) respectively. The colour point corresponding to the singly charged form (**II**), which never exists alone because of the closeness of the two pK values, can be found on the complementary chromaticity diagram from the intersection of the two linear segments. This colour point is used for evaluation of the pK values from the chromaticity parameters.

The quality of the colour change at the end-point depends on the distance between the colour points for before and after the transition. However, the actual locations of the points in the diagram are also very important. It can be seen from Fig. 2 that the colour

The dissociation constants obtained by the standard spectrophotometric method[14] are reported in Table 1. Because of the high value of pK_2, the pure doubly dissociated form (**III**) is not reached during a titration, so the colour change observed corresponds to conversion of quinizarin from its molecular form (**I**) (yellow) into a mixture of the singly dissociated (**II**) and doubly dissociated (**III**) forms (blue purple).

The visual colour-change interval in isopropyl alcohol lies between pH 12.5 and 14.3. The photometric colour-change interval (the interval of maximum slope in the absorbance–pH curve) is 12.4–14.6. The agreement between the potentiometric, spectrophotometric and visual end-points was tested in a series of titrations, and the reversibility of the indicator was confirmed in the same way.

doubly charged form (III)	0.447	0.473	0.215

The J values refer to 10-mm path-length and a quinizarin concentration of $1.748 \times 10^{-5}M$.

points for forms (I) and (III) can be joined by a segment that passes through the grey point. This means that the indicator transition takes place between complementary colours, a characteristic of the best visual indicator transitions. Also since both colour points are near the periphery of the chromaticity diagram, the colours are bright, again characteristic of a good visual end-point.

For the determination of the dissociation constants, the expression

$$pK = pH + \log\left[\frac{J_a}{J_b}\frac{(Q_{r,b} - Q_{r,m})}{(Q_{r,m} - Q_{r,a})}\right]$$

was used, where the subscripts a, b and m refer to the acid, basic and intermediate forms of the indicator, Q_r symbolizes the complementary chromaticity co-ordinates (Q_x, Q_y or Q_z) and J is the colour concentration. The advantage of the method is that it allows use of the colour-point co-ordinates of the singly charged form, which appears only in a very restricted pH range. Q_x and Q_y can be determined from the chromaticity diagram and the J value at this point can be found from the intersection of the straight lines on the graph of Q_yJ vs. Q_xJ[11] corresponding to the successive transitions.

The pK results obtained from the chromaticity co-ordinates agree with those found by using the standard method,[14] as can be seen from Tables 1 and 3.

Finally, various acidic organic substances were titrated in isopropyl alcohol medium in order to evaluate the usefulness of quinizarin as a neutralization indicator. Some are of pharmacological interest, such as aromatic acids, aliphatic acids, aromatic heterocyclics, amino-acids and phenols. Amounts between 15 and 50 mg were taken and 5–10 determinations for each substance were made. The relative error was less than 1% in all cases. Table 4 shows the results obtained and the standard deviations (s).

SHORT COMMUNICATIONS

TITRIMETRIC DETERMINATION OF PHENOL RESORCINOL AND PHLOROGLUCINOL

D. AMIN and W. A. BASHIR

Department of Chemistry, College of Science, University of Mosul, Mosul, Iraq

Summary—A new and sensitive titrimetric method with an amplification procedure has been worked out for the determination of 10–1000 μg of phenol, resorcinol or phloroglucinol. The method is based on reaction of the phenols with an excess of bromine to form bromosubstituted aryl hypobromites. After removal of excess of bromine with formic acid, the hypobromites are treated with iodide to liberate an equivalent amount of iodine, which is extracted into chloroform, then reduced to iodide and determined by the Leipert procedure with 6-fold amplification. The coefficient of variation does not exceed 0.4% for amounts of determinand > 100 μg, but increases to 1.5% at the 10-μg level.

Phenol can readily be brominated to tribromophenol,[1] and with an excess of bromine the substitution goes further to tribromophenyl hypobromite, which, however, is decomposed by iodide to give tribromophenol and a corresponding amount of iodine. Titrimetric methods for determination of resorcinol have principally been based on iodometry.[2–4] The bromate–bromide mixture used for determination of resorcinol[1] gives tribromo substitution. However, some of these methods are not sensitive, and others are tedious. Phloroglucinol has also been determined by treatment with excess of bromate–bromide mixture and iodometric determination of the surplus,[5] or by oxidation with excess of ceric sulphate and back-titration with iron(II).[6] We have developed a new, simple, rapid and sensitive titrimetric method with an amplification procedure for the determination of phenol, resorcinol and phloroglucinol, based on the reaction of these compounds with excess of bromine to form tribromoaryl hypobromites:
The tribromoaryl hypobromites react with iodide to give the corresponding substituted tribromophenol and iodine, *e.g.*,
The iodine liberated is extracted with chloroform and reduced to iodide, then determined by iodometric titration of the iodate formed by the Leipert procedure.[7]

EXPERIMENTAL

Reagents

All chemicals used were of analytical grade. Standard solutions (1 mg/ml) of phenol, resorcinol and phloroglucinol were prepared with distilled water. Less concentrated solutions were prepared by dilution. Sodium thiosulphate solutions, 0.01 and 0.001N, were prepared and standardized against potassium iodate solutions of similar normality. Concentrated formic acid, bromine water (saturated), sodium sulphite solution (1%), and potassium iodide solution (5%) were also prepared.

Procedure

Place the sample solution, containing 10–1000 μg of phenol, resorcinol, or phloroglucinol, in a 50-ml separating funnel and dilute to 10 ml with distilled water. Add 1–2 ml of bromine water, stopper the flask and shake it for 2 min. Destroy excess of bromine by shaking with 1 ml of formic acid for 1 min. Add 1 ml of 5% potassium iodide solution, shake for 1–2 min, then extract the liberated iodine with three 10-ml portions of chloroform. Collect the extracts in another funnel and reduce the iodine to iodide by shaking with 10 ml of water containing 1 ml of 1% sodium sulphite solution. Transfer the aqueous layer, containing iodide, into a 50-ml conical flask, add 2 ml of bromine water, shake for 3 min, and add 2 ml of formic acid to remove excess of bromine. Add about 0.5 g of potassium iodide and titrate

Table 1. Accuracy and precision

Compound	Amount taken, μg	Recovery,* %	R.S.D.,* %
Phenol	10	98.2	1.5
	100	99.6	0.3
	1000	99.9	0.2
Resorcinol	10	98.4	1.1
	100	99.5	0.2
	1000	100.0	0.1
Phloroglucinol	10	98.0	1.4
	100	99.2	0.4
	1000	99.0	0.3

*Mean of 5 determinations.

the liberated iodine with $0.01N$ thiosulphate in the usual way, using starch as indicator. For low concentrations (less than 50 μg of determinand) use $0.001N$ thiosulphate. Run a blank determination. 1 ml of $0.01N$ thiosulphate $\equiv 0.078$ mg of phenol or 0.046 mg of resorcinol or 0.068 mg of phloroglucinol.

RESULTS AND DISCUSSION

Preliminary studies confirmed that phenol, resorcinol and phloroglucinol readily undergo bromination to give the tribromo derivatives, and with a large excess of bromine, the substitution goes further to form the tribromophenyl hypobromite. Both OH groups in resorcinol undergo substitution, but in phloroglucinol only two of the three OH groups undergo substitution. This may be due to the introduction of two hypobromite groups decreasing the acidity of the third OH group sufficiently for it not to be converted into a hypobromite group. It was found that the bromination is fast, and complete within 1–2 min. Reduction of the tribromophenyl hypobromite to the tribromophenol can be achieved with 0.5–1.0 ml of 5% potassium iodide solution. A larger excess of iodide hinders the extraction of iodine with chloroform (by tri-iodide formation); complete liberation of the iodine requires 1–2 min.

The working procedure finally developed has been applied successfully to the determination of quantities of phenol, resorcinol or phloroglucinol as low as 10 μg. Table 1 shows the accuracy and precision of the method.

IMPROVEMENT OF END-POINT DETECTION IN THE NON-AQUEOUS TITRATION OF SULPHACETAMIDE SODIUM

SOBHI A. SOLIMAN, SAIED BELAL and MONA BEDIAR

College of Medicine & Allied Sciences, King Abdulaziz University, Jeddah, Saudi Arabia

Summary—The sluggish end-point in the non-aqueous titration of sulphacetamide sodium in glacial acetic acid can be improved by addition of acetic anhydride to the titration medium, and selective determination of sulphacetamide sodium in presence of phenylephrine hydrochloride in eye drops then becomes possible. A mixture of sulphacetamide sodium and the antihistamine drug phenyltoloxamine dihydrogen citrate can also be analysed.

Titration of sulphonamide derivatives with standard perchloric acid in glacial acetic acid medium has been found to give low recoveries and a sluggish indicator colour-change.[1] One way of circumventing such a difficulty is the use of back-titration.[2] Addition of certain aprotic solvents, *e.g.*, benzene, chloroform or carbon tetrachloride, to the glacial acetic acid medium in the back-titration has been found to improve the end-point detection,[3] but the procedure is time-consuming and tedious shaking is required during the titration.

Addition of acetic anhydride to the glacial acetic acid medium has long been known[4,5] to improve end-point detection in the non-aqueous titration of salts of weak acids. We have used this approach to improve the end-point detection in non-aqueous titrimetric determination of sulphacetamide sodium, alone or in admixture with allied drugs.

EXPERIMENTAL

Apparatus

Titrimeter (Pye model 79) equipped with a combination electrode (Pye catalogue No. 401 E07) magnetic stirrer and 10-ml microburette.

Reagents

Perchloric acid (0.1*M*) in glacial acetic acid, 0.02% solution of Gentian Violet in glacial acetic acid, 0.5% solution of C.I. Solvent Blue 19 indicator (Oracet Blue B indicator, Ciba) in glacial acetic acid, 0.2% Quinaldine Red indicator in a mixture of 90 ml of acetic anhydride and 10 ml of methanol, and a 5% solution of mercuric acetate in glacial acetic acid.

Determination of sulphacetamide sodium

An accurately weighed amount (300–900 mg) of sulphacetamide sodium or the residue left after evaporating a known volume of ophthalmic solution containing 100–200 mg of the drug was dissolved in 5 ml of glacial acetic acid and 25 ml of acetic anhydride in a 100-ml beaker. The sample was dissolved by gentle heating, the solution

was cooled and 1 or 2 drops of Gentian Violet, Solvent Blue 19, or Quinaldine Red indicator solution were added. The solution was titrated potentiometrically with 0.1*M* perchloric acid in glacial acetic acid, and the indicator colour-changes coinciding with the potentiometric end-points were noted: the changes were to blue, rose red, and colourless for Gentian Violet, Solvent Blue 19 and Quinaldine Red respectively.

Determination in presence of phenylephrine hydrochloride

Accurately weighed amounts of sulphacetamide sodium (250 mg) and phenylephrine hydrochloride (50 mg) were dissolved in 5 ml of glacial acetic acid and 25 ml of acetic anhydride; 5 ml of mercuric acetate solution were added and the solution was titrated as described above.

Analysis of mixtures of sulphacetamide sodium and phenyltoloxamine dihydrogen citrate

Determination of total base. Accurately weighed amounts of sulphacetamide sodium (100.0 mg) and phenyltoloxamine dihydrogen citrate (100.0 mg) were dissolved in the glacial acetic acid–acetic anhydride mixture, and titrated without addition of mercuric acetate (*A* ml of 0.1*M* titrant required).

Determination of sulphacetamide. Accurately weighed amounts of sulphacetamide sodium (100.0 mg) and phenyltoloxamine dihydrogen citrate (100.0 mg) were dissolved in 5 ml of concentrated hydrochloric acid, and the sulphacetamide sodium content was determined by titration with 0.1*M* sodium nitrite solution according to the B.P. method[6] (*B* ml). Then (*A* − *B* ml) represents the volume of 0.1*M* perchloric acid equivalent to the phenyltoloxamine dihydrogen citrate.

RESULTS AND DISCUSSION

The curve for potentiometric titration of sulphacetamide in glacial acetic acid with perchloric acid gives an ill-defined break (Fig. 1, curve D) that is difficult to use for locating the exact end-point. The colour change of Gentian Violet in this titration is also sluggish. This is to be expected, because of the low basicity of the sulphacetamide molecule.

Figure 1 shows the potentiometric titration curves of sulphacetamide sodium in different solvent systems. The titration of the drug in acetic anhydride–

glacial acetic acid mixture yields an excellent curve (A) with a sharper inflexion than that obtained with either of the other solvents tried (curves B and C). In the acetic anhydride–glacial acetic acid solvent system the visual end-point was also sharp. Results of the titration of sulphacetamide sodium by the proposed procedure are listed in Table 1 and compare favourably with those obtained by the B.P. method. The visual end-points coincided with the potentiometric end-points.

Application of the proposed method to the determination of sulphacetamide sodium in commercial ophthalamic solutions containing 10% w/v of the drug gave results that were equivalent to the results of the B.P. nitrite method in accuracy and precision (Table 1).
Fig. 1. Potentiometric titration curves for sulphacetamide sodium in different solvent systems: A, acetic anhydride–glacial acetic acid; B, dioxan; C, glacial acetic acid; D, sulphacetamide in glacial acetic acid.

In ophthalamic solutions sulphacetamide sodium may be compounded with phenylephrine hydrochloride (added as an adrenergic drug). The sulphacetamide sodium in such mixtures can be determined by taking advantage of acetylation of the secondary amine group of the phenylephrine by acetic anhydride. Complete acetylation of this group can be clearly demonstrated by the absence of an inflexion point on the potentiometric curve for titration of the acetylation product. The proposed procedure gives quantitative and reproducible recoveries for sulphacetamide sodium, without interference from phenylephrine hydrochloride (Table 1).

Sulphacetamide sodium is also frequently encountered in ophthalamic solutions containing phenyltoloxamine dihydrogen citrate as an antihistamine. The latter component contains a tertiary nitrogen atom and therefore application of the proposed method to mixtures of the two compounds gives an end-point corresponding to the total amount of the two drugs. Sulphacetamide sodium can then be selectively determined by the B.P. nitrite method and the phenyltoloxamine dihydrogen citrate calculated by difference. Table 1 shows that acceptable results are obtained.

TITRIMETRIC DETERMINATION OF SOME PHENOTHIAZINE DERIVATIVES, WITH FERRICYANIDE

A. S. Issa and M. S. Mahrous

Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria,
Alexandria, Egypt

Summary—Six phenothiazine drugs (chlorpromazine hydrochloride, promethazine hydrochloride, promazine hydrochloride, perphenazine, acetophenazine maleate and trifluoperazine hydrochloride) have been determined by titration with potassium ferricyanide in phosphoric acid medium with Methylene Blue as a screening indicator. The results were in agreement with those obtained by the official methods.

Various methods have been used for estimation of phenothiazines. Potassium bromate and ceric sulphate have been used for their oxidative titration.[1] Methods based on the protonated nitrogen atom of the molecules include non-aqueous titration,[2] two-phase titration,[3-5] precipitation with tetraphenylborate[6-8] or ammonium reineckate,[9] and titration with the picrates of lead, copper, cadmium and zinc.[10] Potassium iodobismuthate,[11] hexathiocyanatochromate(III),[12] tetracyanozincate[13] and iodine monochloride[14] have also been used for the estimation of phenothiazine derivatives.

Oxidizing agents used for the colorimetric determination of phenothiazine derivatives include ferric

chloride,[15] hydrogen peroxide,[16] p-benzoquinone[17] and chloramine-T.[18] Other reagents used include *cis*-aconitic anhydride[19] and Nitrazine Yellow.[20]

Gas chromatography has also been used for the determination of phenothiazine derivatives.[21-26]

EXPERIMENTAL

Reagents

Potassium ferricyanide, 0.01M.
Orthophosphoric acid, 85% w/v.
Methylene Blue solution, 0.1%.

General procedure

A solution of 5–20 mg of the drug in 10 ml of alcohol is treated with 50 ml of phosphoric acid and 5 drops of Methylene Blue solution. The mixture is titrated with $0.01M$ potassium ferricyanide to a full blue colour.

Procedure for tablets

Twenty tablets are weighed and powdered. A quantity of the powder containing about 100 mg of the drug is transferred to a 100-ml standard flask, 50 ml of alcohol are added and the mixture is shaken for 20 min, then diluted to the mark with ethanol and filtered. An aliquot of the filtrate (containing about 10 mg of the drug) is analysed as in the general procedure.

For injections and liquid preparations

An amount of sample containing about 100 mg of the drug is measured accurately into a 100-ml standard flask and made up to volume with ethanol. An aliquot containing about 10 mg of the drug is analysed as in the general procedure.

RESULTS AND DISCUSSION

Phosphoric acid was found to be the best medium for the oxidation reaction. When sulphuric or hydrochloric acid was used it was very difficult or impossible to detect the end-point. In phosphoric acid medium (70–85% v/v phosphoric acid) the end-point is shown by disappearance of the red colour of the phenothiazine. The addition of Methylene Blue sharpens the end-point, since under the reaction conditions used, the potassium ferricyanide oxidizes only the phenothiazine, first to a red intermediate with loss of one electron and then to a colourless product with loss of a second electron.[1] Hence the end-point is shown by the change to the full blue colour of the Methylene Blue.

The common tablet fillers such as lactose, talc, starch and magnesium stearate do not interfere, as

shown in recovery tests by the standard addition method, the recovery ranging from 99.4 to 101.0% for 5–20 mg of added drug.

All results obtained agreed reasonably well with those obtained by using the B.P. 1980 methods (Table 1). The procedure can be recommended for routine analysis of phenothiazine drugs.

SPECTROPHOTOMETRIC DETERMINATION OF PHENOTHIAZINES, TETRACYCLINES AND CHLORAMPHENICOL WITH SODIUM COBALTINITRITE

M. S. Mahrous and M. M. Abdel-Khalek
Department of Pharmaceutical Chemistry, Faculty of Pharmacy, University of Alexandria,
Alexandria, Egypt

Summary—A spectrophotometric method for determining some phenothiazines, some tetracyclines and chloramphenicol is described. Chlorpromazine hydrochloride, promazine hydrochloride, promethazine hydrochloride, perphenazine and fluphenazine hydrochloride are reacted with sodium cobaltinitrite in phosphoric acid. The red colour developed is measured at 530, 513, 515, 530 and 500 nm, respectively. Tetracycline hydrochloride, oxytetracycline hydrochloride, chlortetracycline hydrochloride, doxycycline hyclate and demeclocycline hydrochloride are reacted with the reagent in aqueous acetic acid. The yellow colour produced is measured at 256, 294, 262, 243 and 246 nm, respectively. Chloramphenicol is determined similarly to the tetracyclines after hydrolysis with 40% sodium hydroxide solution and the colour is measured at 240 nm. The proposed method has been successfully applied to the determination of these drugs in various pharmaceutical preparations.

In the British Pharmacopoeia method,[1] phenothiazine derivatives are determined by titration in non-aqueous media. Phenothiazines have been determined spectrophotometrically, after oxidation with various oxidizing agents.[2,3] The nitration products of phenothiazines can also be measured spectrophotometrically after ether extraction from alkaline medium.[4] Phenothiazines have been assayed by various titrimetric techniques, *e.g.*, photometric titration at 420 nm with ferric sulphate,[5] direct titration with arylsulphonic acids,[6] two-phase titration with Bromophenol Blue[7] or sodium lauryl sulphate.[8] Polarographic,[9] gas-chromatographic[10,11] and thin-layer chromatographic[12] methods have also been reported.

Several methods have been described for the determination of tetracyclines. These include fluorimetric,[13,14] chromatographic[15,16] and titrimetric[17] methods.

Chloramphenicol has been determined spectrophotometrically in acetone–dimethylformamide medium with tetraethylammonium hydroxide.[18] Reduction of the nitro group allows diazotization and coupling with various reagents.[19,20] Other methods include polarography,[21] non-aqueous titration with perchloric acid in glacial acetic acid,[22] and oxidation of its hydrolysis product with sodium periodate[23] or potassium dichromate.[24] Sodium cobaltinitrite has been proved to be a valuable reagent for the detection and determination of several phenolic compounds and drugs.[25-29] This paper describes its use for the spectrophotometric determination of some phenothiazines, some tetracyclines, and chloramphenicol.

EXPERIMENTAL

All chemicals and reagents used were of analytical-reagent or pharmaceutical grade. Distilled water was used throughout.

General procedure for phenothiazines

An ethanol solution containing from 0.2 to 1.0 mg of the drug was transferred to a test-tube and evaporated to dryness on a boiling water-bath. The residue was treated with 1 ml of 0.2% sodium cobaltinitrite solution and 5 ml of phosphoric acid. The mixture was shaken well and then heated in a boiling water-bath for 15 min. The mixture was then transferred into a 25-ml standard flask and diluted to the mark with phosphoric acid. The absorbance was measured at the selected wavelength (Table 1) for the drug, against a corresponding reagent blank.

For tablets. Twenty tablets were weighed and powdered. An accurately weighed portion of the mixed powder, equivalent to about 25 mg of the drug, was shaken with ethanol in a 50-ml standard flask for 20 min. The solution was diluted to the mark with ethanol, mixed well and then filtered through a dry filter-paper into a dry flask, and 1 ml of this solution was analysed as described above for phenothiazines.

For injections. A quantity of sample equivalent to about 50 mg of the drug was transferred into a 100-ml standard flask and diluted to the mark with ethanol. A 1-ml aliquot was analysed by the general procedure.

General procedure for tetracyclines

A solution containing from 0.5 to 1.5 mg of the drug in 2 ml of water was transferred into a test-tube, mixed with 2 ml of glacial acetic acid and 2 ml of 5% sodium cobaltinitrite solution. The mixture was heated in a boiling water-bath for 15 min, cooled, transferred into a 50-ml standard flask and diluted to the mark with water. The absorbance was measured at the selected wavelength (Table 1).

For capsules and tablets. A quantity of the mixed contents of 20 capsules or tablets, equivalent to about 25 mg of the drug, was transferred into a 50-ml standard flask and

Table 1. λ_{max}, concentration ranges, regression equations and correlation coefficients for sodium cobaltinitrite colour reaction with different compounds

Demeclocycline. HCl	246	0.01–0.03	$A = 0.012 + 36.14C$	0.9993
Chloramphenicol	240	0.01–0.03	$A = 0.000 + 43.98C$	0.9999

shaken with 25 ml of water for 20 min. The solution was diluted to the mark with water and then filtered. A 2-ml portion of the filtrate was assayed by the general procedure.

General procedure for chloramphenicol

A quantity of chloramphenicol powder containing 50 mg of the drug was transferred into a test-tube, followed by 10 ml of 40% sodium hydroxide solution. The solution was boiled for 30 min, cooled, transferred into a 50-ml measuring flask and then made up to the mark with glacial acetic acid, with cooling before final adjustment. Serial dilutions containing from 0.5 to 1.5 mg of the drug were analysed by the general procedure for tetracyclines.

For capsules and injections. An accurately weighed portion of the mixed contents of capsules or injections was assayed as just described.

RESULTS AND DISCUSSION

Sodium cobaltinitrite oxidizes chlorpromazine hydrochloride, promazine hydrochloride, promethazine hydrochloride, perphenazine and fluphenazine hydrochloride in acidic solutions to give a red colour. The colour is attributed to formation of a radical cation. This conclusion is supported by the finding that the wavelength of the absorption maximum found experimentally corresponded to that reported in the literature for the free radicals formed by oxidation of phenothiazines.[30-32] The effect of variation in the concentration of sodium cobaltinitrite

§Laboratory-prepared tablets containing the drug, lactose, talc, starch and magnesium stearate.

used was studied and it was found that maximum absorbance was obtained with 1 ml or more of 0.2% sodium cobaltinitrite solution. Phosphoric acid was used as the medium for the reaction; if hydrochloric or acetic acid was used as the medium the colour developed was found to be unstable. Evaporation of the ethanol is essential, since the coloured products are unstable in the presence of ethanol.

Tetracyclines react with sodium cobaltinitrite in aqueous acetic acid to give a yellow colour which is stable for at least 4 hr.

Chloramphenicol is hydrolysed by heating with sodium hydroxide to give p-nitrophenol.[33] Treatment of the hydrolysis product with sodium cobaltinitrite in aqueous acetic acid gives a stable yellow colour, with an absorption maximum of the same wavelength as that observed when p-nitrophenol is reacted with the reagent under the same conditions.

Sodium cobaltinitrite in aqueous acetic acid has been used for the identification of phenols having free positions ortho to the OH-group.[25] Feigl [25] suggested that an o-nitroso derivative was formed which in its tautomeric oxime form yielded a yellow to brown chelate with cobalt(I). The reaction of p-cresol with sodium cobaltinitrite was studied by Smith and Garst,[26] who found that atomic-absorption analysis of the yellow product did not reveal the presence of cobalt. They identified the product as 2-nitro-p-cresol. Accordingly, they categorized sodium cobaltinitrite as acting in acid medium as a nitrating agent rather than a nitrosating agent. A reaction mechanism has been suggested involving the formation of nitro derivatives during the oxidation of tetracyclines of hydrolysed chloramphenicol with sodium cobaltinitrite.[29]

Beer's law is valid over the concentration ranges presented in Table 1. The regression equations in Table 1 were calculated from the standard calibration curve of each drug. The unknown drug concentration in different pharmaceutical formulations can be calculated from their corresponding regression equations.

The proposed method was applied to the determination of phenothiazines, tetracyclines and chloramphenicol in various pharmaceutical preparations. The excipients present did not interfere. The results of the assays of tablets, capsules and injections presented in Table 2 compare favourable with those obtained by the official method.[1,34]

ADSORPTION OF BISMUTH ON HYDROUS LEAD DIOXIDE FROM BISMUTH–EDTA SOLUTION

Shinichi Ito

Kyoto Institute of Public Health and Environment, Kyoto, Japan

Toshio Matsuda and Toyoshi Nagai

Department of Chemistry, Ritsumeikan University, Kyoto, Japan

Summary—The adsorption of bismuth(III) on hydrous lead dioxide (HLD) from solutions of the bismuth-(III)–EDTA complex was studied by differential pulse polarography. It was found that HLD collected bismuth quantitatively from bismuth–EDTA solution over the pH range from 1 to 12, with shaking for 1 hr, even at bismuth–EDTA concentrations as low as $10^{-8}–10^{-7}M$. In addition, the reaction of HLD with EDTA was investigated in order to consider the participation of EDTA with respect to the adsorption behaviour of bismuth. It can be assumed that the adsorption of bismuth on HLD from bismuth-EDTA solution is correlated to the adsorptive property of HLD and to the surface redox process between HLD and EDTA.

The hydroxides or hydrous oxides of various metals have been studied as co-precipitation[1] or ion-exchange[2-4] reagents for separation or concentration of trace inorganic ions. Lead dioxide, though sparingly soluble, has not previously been studied for these purposes.

Recently, the redox reactions of hydrous lead dioxide (HLD), freshly prepared by the hydrolysis of lead tetra-acetate, with sodium oxalate,[5] chromium(III)[6,7] and EDTA[8] have been reported from our laboratory. In another paper,[9] an investigation of the individual adsorption of bismuth(III) and copper(II) on HLD was reported. HLD was found to be a superior adsorbent for bismuth in acidic medium, and used in the determination of trace amounts of bismuth in a copper metal standard (about $10^{-5}\%$) by differential pulse polarography.

In the present work, the adsorption of bismuth on HLD from solutions of bismuth–EDTA is studied. In addition, the reaction of HLD with EDTA is investigated in connection with the role played by EDTA in this adsorption system.

EXPERIMENTAL

Reagents and apparatus

A 0.01M bismuth–EDTA standard solution was prepared by mixing bismuth nitrate of reagent grade with Dotite disodium EDTA in 1:1 molar ratio. This stock solution was accurately diluted as required. A 0.05M lead tetra-acetate solution in glacial acetic acid was standardized by potentiometric titration with sodium oxalate.[10] A 0.01M EDTA stock solution was prepared from the Dotite reagent.

A Princeton Applied Research Model 174A polarograph and a Watanabe Model WX-451 X–Y recorder were used. The lead dioxide suspensions were shaken by means of a Yamato Water Bath Incubator, Model BT-31.

Procedure

HLD was prepared by adding 10 ml of 0.05M lead tetra-acetate solution dropwise to 100 ml of distilled water, and then centrifuging to remove the acetic acid produced. The HLD was washed twice with 100-ml portions of distilled water (separated by centrifugation). About 0.12–0.14 g of HLD (taken as $PbO_2 \cdot 2H_2O$) was used for each adsorption test.

A 200-ml Erlenmeyer flask fitted with a rubber stopper was used as the reaction vessel. HLD, a known amount of bismuth–EDTA solution, an appropriate buffer solution and 10 ml of 1M potassium nitrate were added to the flask and the mixture was diluted to 100 ml with distilled water. The pH of the suspension was adjusted with 0.02M HNO_3–CH_3COOH, CH_3COOH–CH_3COONa, HNO_3–$Na_2B_4O_7$ and $Na_2B_4O_7$–NaOH buffers. The suspension was shaken for 1 hr, at 30°. The HLD was then filtered off with a membrane filter (Toyo Kagaku, Type TM-2, pore size 0.45 μm). The differential pulse polarogram of bismuth in the filtrate was recorded, the supporting electrolyte[11] consisting of 2 ml of 1.5M sodium citrate, 20 ml of 0.2M EDTA and 2.5 ml of 1M potassium nitrate, diluted to 50 ml. The amount of bismuth adsorbed was determined by measurements of the bismuth concentration before and after adsorption.

For direct determination of the adsorbed bismuth, the HLD was dissolved with sodium oxalate, supporting electrolyte was added, the pH was adjusted to 5.0–5.5, and the bismuth in the solution was determined by differential pulse polarography.

For determination of the dissolved lead(II) in the suspension, the filtrate (obtained as already described) was acidified to 0.2M in nitric acid, and then analysed for lead by differential pulse polarography.

The reaction of HLD with EDTA was studied by adjusting the pH of a suspension containing HLD and an appropriate amount of EDTA, and shaking the mixture for 1 hr at 30°. An appropriate amount of the filtered liquid phase was adjusted to pH 4.7 and the lead(II) in it was removed by controlled-potential electrolysis with a mercury pool cathode. The anodic wave of EDTA was then measured by normal pulse polarography.
Fig. 1. Effect of pH on the adsorption of bismuth from $2 \times 10^{-5}M$ bismuth–EDTA solution and $2 \times 10^{-5}M$ bismuth(III) solution on hydrous lead dioxide (HLD). HLD 0.14 g; solution volume 100 ml; shaking time 1 hr; temperature $30°$: ○ bismuth–EDTA; ◑ bismuth(III).

Fig. 2. Relation between the concentration of bismuth–EDTA or bismuth(III) added and the amount of bismuth adsorbed on HLD. HLD 0.14 g; solution volume 100 ml; shaking time 1 hr; temperature $30°$. Bismuth–EDTA: ● pH 1.8, ○ pH 3.9, △ pH 7.3, □ pH 10.0. Bismuth(III): ◑ pH 1.8.

RESULTS AND DISCUSSION

Effect of pH

The effect of pH on the adsorption of bismuth on HLD from $2 \times 10^{-5}M$ bismuth–EDTA solution is shown in Fig. 1. There is almost 100% adsorption over the pH range from 1 to 12. Similar values were obtained for $3 \times 10^{-4}M$ bismuth–EDTA solution.

The effects of shaking time and temperature on the adsorption were also investigated. The adsorption equilibrium was reached within 1 hr, and the adsorption values were practically constant over the temperature range from 30 to $70°$.

Effect of bismuth–EDTA concentration

The relation between concentration of bismuth–EDTA and amount of bismuth adsorbed on HLD is shown in Fig. 2. At each pH tested, there was almost 100% adsorption when the concentration of bismuth–EDTA was less than $4 \times 10^{-4}M$. The adsorption capacity at each pH (except 10) was almost equal to that for adsorption from a simple bismuth (III) solution.[9] A log–log plot of equilibrium concentration of bismuth–EDTA vs. amount of bismuth adsorbed per mole of HLD was linear.

Adsorption at trace concentrations

The effectiveness of adsorptive collection of trace amounts of bismuth(III), present as the

bismuth–EDTA complex, was investigated. HLD, a known amount of bismuth–EDTA solution, 50 ml of $1M$ potassium nitrate and an appropriate buffer solution were added to a 1000-ml Erlenmeyer flask and the mixture was diluted to 500 ml with distilled water. The suspension (bismuth–EDTA concentration from 1×10^{-6} to $5 \times 10^{-8}M$) was shaken for 1 hr at $30°$. The bismuth adsorbed on the HLD was determined directly by the procedure given above. The results obtained for pH 2.5 and 10 are shown in Table 1. The recovery of bismuth was almost 100% at each pH value.

Lead(II) dissolved during the adsorption

The amount of lead(II) dissolved was much higher for adsorption of bismuth from bismuth–EDTA solution than for adsorption from the simple bismuth(III) solution examined previously.[9] The results obtained at pH 2, 4, 7 and 10 are shown in Fig. 3. The amount of lead(II) increased at each pH with increase in the amount of bismuth–EDTA present, but tended to reach a limiting value. From the slopes of the straight lines up to the plateaus, the molar ratio of lead(II) dissolved to bismuth–EDTA taken was found to be about 4 at pH 2, 3 at pH 4 and 0.7 at

Table 1. Recovery of bismuth from the solution of bismuth–EDTA

pH	Initial concentration of bismuth–EDTA, M	Amount of bismuth, µg		Average recovery, %
		Taken,	Found*	
2.5	9.91×10^{-7}	104	101 ± 2	97
2.5	1.98×10^{-7}	20.7	19.7 ± 0.5	95
2.5	0.99×10^{-7}	10.4	10.6 ± 0.8	102
2.5	0.50×10^{-7}	5.2	5.3 ± 0.2	102
10.1	10.01×10^{-7}	105	102 ± 2	97
10.1	2.00×10^{-7}	20.9	21.2 ± 0.4	101
10.1	1.00×10^{-7}	10.5	10.1 ± 0.8	96
10.1	0.50×10^{-7}	5.2	5.4 ± 0.6	104

*Average and deviation are based on two or three replicates.
Fig. 3. Relation between the concentration of bismuth–EDTA or bismuth(III) added and the concentration of lead(II) dissolved into the supernatant liquid. HLD 0.14 g; solution volume 100 ml; shaking time 1 hr; temperature 30°. Bismuth–EDTA: ● pH 1.8, ○ pH 3.9, △ pH 7.3, □ pH 10.0. Bismuth(III): ◑ pH 1.8.

Fig. 5. Relation between the initial concentration of EDTA and the concentration of lead(II) dissolved. HLD 0.14 g; solution volume 100 ml; shaking time 1 hr; temperature 30°.

pH 10. These results suggest that the oxidation of EDTA by HLD proceeds at the interface during the adsorption process.

Reaction of EDTA with HLD

The effect of pH on the decrease in EDTA concentration was investigated, with $2 \times 10^{-4} M$ EDTA. A typical set of results is shown in Fig. 4. About 100% decrease at pH 5 and $23 \pm 3\%$ at pH 10 were observed. Similar results were obtained when the shaking time was increased to 3 hr.

The amount of lead(II) dissolved was also measured (Fig. 5). The molar ratio of lead(II) dissolved to EDTA added was about 3 at pH 5 and about 0.6

at pH 10, in agreement with the results for adsorption of bismuth from bismuth(III)–EDTA solution.

From these results, it is evident that the oxidation reaction of EDTA with HLD proceeds over the pH range from 1 to 12. Though the mechanism has not been fully elucidated, it seems probable that the bismuth–EDTA complex is primarily adsorbed on the HLD and oxidized on the surface, the bismuth ion being retained on the HLD, as a compound such as the hydroxide.

Conclusions

The adsorptive property of hydrous lead dioxide prepared *in situ* by the hydrolysis of lead tetra-acetate has been investigated, with reference to the adsorption of bismuth from bismuth–EDTA solution. The results show that HLD collects bismuth quantitatively over the pH range from 1 to 12, and that bismuth can be collected quantitatively 10^{-8}–$10^{-7} M$ bismuth–EDTA solution in this way.

Fig. 4. Per cent decrease of initial EDTA or the concentration of lead(II) dissolved as a function of pH. EDTA $1.6 \times 10^{-4} M$; HLD 0.14 g; shaking time 1 hr, temperature 30°

FURTHER APPLICATION OF THE DIAZOTIZATION-COUPLING SPECTROPHOTOMETRIC TECHNIQUE TO THE DETERMINATION OF AROMATIC AMINES WITH 8-AMINO-1-HYDROXYNAPHTHALENE-3,6-DISULPHONIC ACID AND N-(1-NAPHTHYL)-ETHYLENEDIAMINE AS COUPLING AGENTS

GEORGE NORWITZ and PETER N. KELIHER*
Chemistry Department, Villanova University, Villanova, PA 19085, U.S.A.

Summary—Twenty-two aromatic amines are determined by the diazotization-coupling spectrophotometric technique, using 8-amino-1-hydroxynaphthalene-3,6-disulphonic acid (H-acid) and N-(1-naphthyl)ethylenediamine (N-na) as coupling agents. The following are determined by both methods: 2- and 4-ethylaniline, 4-aminobenzonitrile, 3- and 4-aminoacetophenone, 4-aminobenzophenone, 4-iodoaniline, 2,5-dichloroaniline, 4-aminohippuric acid, 2-aminobenzyl alcohol, 3-aminobenzamide, sulphathiazole, 2-, 3- and 4-methoxyaniline and 2,4-, 3,4- and 3,5-dimethylaniline. It is possible to determine 2,3- and 2,5-dimethylaniline only by the H-acid method, but 2,6-dimethylaniline cannot be determined by either method. 2-Aminobenzamide can only be determined by the N-na method. In the application of the H-acid method to the methoxyanilines and dimethylanilines, the colour is developed by adding a large excess of sodium bicarbonate and H-acid. In the application of the N-na method to the ethylanilines, methoxyanilines and 2,4-, 3,4- and 3,5-dimethylanilines, the colour is developed by addition of a large excess of N-na reagent and allowing the solution to stand overnight.

We recently proposed methods for the determination of aromatic amines by the diazotization-coupling spectrophotometric technique, using 8-amino-1-hydroxynaphthalene-3,6-disulphonic acid (H-acid) and N-(1-naphthyl)ethylenediamine (also called N-(1-naphthalenyl)-1,2-ethanediamine or N-na) as coupling agents.[1] Subsequently, aminophenols, phenylenediamines, dinitroanilines, trichloroanilines and tetrachloroaniline were determined by using N-na and special techniques.[2] In the present work, 22 more aromatic amines of importance in industry and pharmacology are determined by the H-acid and N-na coupling methods.

EXPERIMENTAL

Apparatus and reagents

A Bausch and Lomb model 70 spectrophotometer (1-cm cell) and a Cary model 219 recording spectrophotometer (1-cm cell) were used.

All chemicals were of reagent grade except where indicated. The aromatic amines were obtained from the Eastman Kodak Co. or Aldrich Chemical Co. and purified by recrystallization or distillation if necessary.

H-acid reagent (0.75%). Purify technical grade H-acid monosodium salt as follows. Dissolve 20 g of the salt in about 200 ml of boiling water. Cool in ice, filter off the precipitate on a Whatman No. 41 paper by suction and wash it four times with cold water and three times with acetone. Let stand in air for 1–2 hr to volatilize acetone. Make-up a 0.75% solution in water fresh every 3 days and store in a brown bottle.

N-na reagent (0.75%, in water). Prepare fresh every 3 days and store in a brown bottle.

Standard aromatic amine solution A (2.50 mg/ml). Dissolve 0.2500 g of the aromatic amine (except 2-aminobenzamide) in methanol and dilute to volume in a 100-ml standard flask with methanol. Dissolve 2-aminobenzamide in a mixture of methanol and 5 ml of concentrated hydrochloric acid and dilute to 100 ml with methanol.

Standard aromatic amine solution B (25 µg/ml). Prepare fresh daily by diluting a 5-ml aliquot of standard aromatic amine solution A to volume in a 500-ml standard flask with water.

Procedures

The following are determined by both methods: 2- and 4-ethylaniline, 4-aminobenzonitrile, 3- and 4-aminoacetophenone, 4-aminobenzophenone, 4-iodoaniline, 2,5-dichloroaniline, 4-aminohippuric acid, 2-aminobenzyl alcohol, 3-aminobenzamide, sulphathiazole, 2-, 3- and 4-methoxyaniline and 2,4-, 3,4- and 3,5-dimethylaniline. 2,4- and 2,5-dimethylaniline can be determined only by the H-acid method and 2,6-dimethylaniline cannot be determined by either method. 2-Aminobenzamide can be determined only by the N-na method.

H-acid method. For all the aromatic amines to which the H-acid method is applicable (except the methoxyanilines and dimethylanilines) proceed as follows. Prepare a calibration curve by transferring portions of standard aromatic amine solution B to 100-ml standard flasks. The volumes should be chosen in accordance with the sensitivities indicated in Table 1, to cover the absorbance range up to 0.6. Dilute to about 75 ml with water, add 2.0 ml of 0.3M hydrochloric acid and 2.0 ml of 1% sodium nitrite solution, swirl and allow to stand for 5 min. Add 2.0 ml of 3% sulphamic acid solution, swirl, wash down the neck of the

*Author to whom correspondence should be addressed.

flask and allow to stand for 10 min. Add 10 ml of 6% sodium bicarbonate solution, swirl, add 2.0 ml of H-acid reagent, swirl again, dilute to the mark, mix, and store in the dark for 15–45 min. Measure the absorbance against water at the wavelength indicated in Table 1. Deduct the blank and plot absorbance against mg of the aromatic amine per 100 ml. For the determination of the methoxyamilines and dimethylanilines, proceed as above but use 1.0 ml of 0.3N hydrochloric acid, 5 g of sodium bicarbonate, 5.0 ml of H-acid reagent, and store in the dark for 60–90 min. For the analysis of samples, transfer an appropriate aliquot to a 100-ml standard flask and proceed as for the calibration curve.

N-na method. For all the aromatic amines to which the N-na method is applicable (except the methoxyanilines and dimethylanilines) proceed as follows. Prepare a calibration curve by transferring portions of standard aromatic amine solution B to 50-ml standard flasks, the volumes being chosen (Table 1) to cover the absorbance range up to 0.6. dilute to 30–35 ml with water, add 3.0 ml of 1M hydrochloric acid and 1.0 ml of 1% sodium nitrite solution, swirl and allow to stand for 5 min. Add 1.0 ml of 3% sulphamic acid solution, swirl, wash down the neck of the flask and allow to stand for 10 min. Add the amount of N-na reagent indicated in Table 1, dilute to the mark and mix. Measure the absorbance against water at the wavelength and time indicated in Table 1. Deduct the blank and plot absorbance against mg of aromatic amine per 50 ml. For the determination of 2,3-, 3,4- and 3,5-dimethylaniline, proceed as above but use 2.0 ml of 1M hydrochloric acid. For the methoxyanilines use 2.5 ml of N-na reagent and 90 min standing for 3-methoxyaniline, and 10 ml of reagent and

overnight standing for the other two. For analysis of samples transfer an appropriate aliquot to a 50-ml standard flask and proceed as for the calibration curve.

RESULTS AND DISCUSSION

Preparation of the stock amine solutions

The stock amine solutions (except 2-amino-benzamide) are prepared with methanol as solvent, but ethanol is equally satisfactory for all the amines tested in this and the previous papers. For the stock solution of 2-aminobenzamide, 5 ml of concentrated hydrochloric acid must be added.

Colours obtained

Many of the H-acid dyes of the aromatic amines tested in this paper are light-sensitive so the solutions should be stored in the dark after addition of the H-acid. The N-na dyes are not light-sensitive. The spectral characteristics of the dyes are shown in Table 1. Beer's law is obeyed for all the systems tested.

Dimethylanilines (xylidines)

For determination of the dimethylanilines by the H-acid method, it is necessary to use only 1.0 ml of $0.3M$ hydrochloric acid for the diazotization (instead of 2.0 ml) and 5 g of sodium bicarbonate to give a pH of 7.7 (instead of 10 ml of 6% sodium bicarbonate solution to give a pH of 7.2). It is also necessary to use 5 ml of H-acid reagent (instead of 2 ml) and allow the solution to stand for 60–90 min for the development of the colour (instead of 15–45 min). The sodium bicarbonate takes 2–3 min to dissolve, but this does not matter, since even a 1 hr interval between addition of the sodium bicarbonate and the H-acid does not affect the result.

For the determination of 2,4-, 3,4- and 3,5-dimethylaniline by the N-na method, it is advisable to use 2.0 ml of $1M$ hydrochloric acid for the diazotization-coupling (instead of 3.0 ml); it is also necessary to use a large excess of N-na reagent (10 ml) and allow the solution to stand overnight for colour development. Little or no colour was produced when the N-na method was applied to 2,3-, 2,5- and 2,6-dimethylaniline and no improvement could be achieved by alteration of the acidity, nitrite concentration and time of diazotization, or by adding a catalyst (sodium bromide) and cooling in ice during the diazotization, using ammonium sulphamate or urea (instead of sulphamic acid) to destroy the excess of nitrite, and heating during the coupling.

The only previous investigator to study the application of the N-na method to the determination of dimethylanilines was Daniel,[3] who treated 1 ml of sample solution with 1 ml of $2M$ hydrochloric acid and 1 ml of 0.25% sodium nitrite solution, and after 15 min added 1 ml of 2.5% ammonium sulphamate

solution. He then allowed the mixture to stand for 1 min, added 1 ml of 1% N-na reagent and diluted to volume in a 10-ml standard flask. Alternatively, after adding the ammonium sulphamate, he added 1 ml of $3M$ sodium acetate and 1 ml of the N-na reagent and diluted to 10 ml. We concur with Daniel that little or no colour is produced by 2,3-, 2,5- and 2,6-dimethyl-aniline in the N-na method. However, we obtained greater colour development than Daniel for 2,4- and 2,6-dimethylaniline and our values for λ_{max} differed significantly from his.

Methoxyanilines

The same H-acid procedure is recommended for methoxyanilines as that for dimethylanilines and the N-na procedure recommended for methoxyanilines is that previously described for aminophenols.[2]

Ease of coupling

Electron-withdrawing groups in the aromatic nucleus tend to facilitate coupling by increasing the positive charge on the diazonium ion. Consequently, aromatic amines which contain CN, $COCH_3$, COC_6H_5, I, Cl and $CONHCH_2CH_2COOH$ groups (all strong electron-withdrawing groups) require only 1 ml of N-na reagent and colour development is complete in 10 min (Table 1). Aromatic amines containing less strong electron-withdrawing groups, or strong electron-donating groups (C_2H_5, OCH_3 or two CH_3 groups) require more N-na reagent and a longer time for development of the colour. For the H-acid method, the effect of strong electron-donating groups (OCH_3 and two CH_3 groups) is such that a larger excess of H-acid reagent and a longer standing time are required for development of the colour. It is not known why the H-acid method is applicable to 3-aminobenzamide but not to 2-aminobenzamide and why the colour for the N-na method develops more readily with 3-aminobenzamide (in 10 min with 1 ml of reagent) than with 2-aminobenzamide (in 90 min with 2.5 ml of reagent). A possible explanation is that 2-aminobenzamide is more basic than 3-amino-benzamide and this may affect the coupling. This difference in basicity is the reason for addition of hydrochloric acid in preparation of the stock 2-aminobenzamide solution.

The accuracy (average relative error about 5%) and precision of the methods is about the same as that obtained previously in the determination of aromatic amines by the H-acid and N-na methods.[1,2]

ANALYTICAL APPLICATIONS OF LIQUID–LIQUID PHASE EQUILIBRIA: ANALYSIS OF BINARY MIXTURES OF CHEMICALLY SIMILAR COMPONENTS

S. K. Suri* and Mohinder Pal

Chemistry Department, Indian Institute of Technology, New Delhi 110016, India

Summary—A new, simple and rapid method based on the principle of liquid–liquid phase equilibria has been developed for the analysis of binary mixtures of chemically similar organic compounds. The method does not require elaborate instrumentation and can be used to analyse mixtures of members of homologous series. The application of the method has been illustrated by analysing binary mixtures of n-hexane and n-octane; the maximum uncertainty in this analysis is ~2%.

Analysis of binary and ternary mixtures of organic compounds by phase titration[1-5] is based on the appearance of a second phase in a homogeneous liquid mixture, giving a turbidimetric end-point. In this communication we describe a method, based on liquid–liquid phase equilibria, for the analysis of binary mixtures made up of chemically similar organic compounds. Many of these mixtures cannot be analysed by procedures based on chemical reactions because these are usually slow or incomplete, and various interfering consecutive reactions may occur when the system is allowed to proceed to equilibrium. The proposed method is illustrated by its application to the analysis of mixtures of n-hexane and n-octane.

THEORY

The phase diagram for a ternary system containing one pair of mutually immiscible or only partially miscible components A and B and a consolute component C is shown in Fig. 1. If a further substance A' is chemically similar to A, it will have similar solubility behaviour towards pure B and C. However, the effect of the consolute component on the miscibility of A' and B will be different from that on the miscibility of A and B, and therefore the binodal curve for the system A'–B–C (dashed line in Fig. 1) will be different from that for A–B–C.[6]

For a pseudo-ternary system composed of (A + A'), B and C, the binodal curve will lie somewhere between the binodal curves for the systems A–B–C and A'–B–C and its locus will depend upon the relative amounts of A and A' in the mixture.

A ternary mixture A–B–C having the composition represented by the point O in Fig. 1 will split into two different phases represented by points L and M (where LM is the tie line). The relative amounts of the two phases are given by the lever rule, *i.e.*,

$$\frac{\text{Amount of phase of composition L}}{\text{Amount of phase of composition M}} = \frac{\text{OM}}{\text{OL}}$$

The corresponding ternary mixture A'–B–C defined by point O will similarly separate into two phases having the compositions represented by the points L' and M', the relative amounts being given by the ratio OM'/OL'. It is, therefore, evident that on gradual replacement of A by A' (*i.e.*, increasing the ratio A'/A), in the pseudo-ternary mixture (A + A')–B–C, the relative amounts of the two phases will move from OM/OL to OM'/OL'. A calibration curve can, therefore, be obtained for the relative amounts of the two phases in the pseudo-ternary mixture (A + A')–B–C as a function of %A/(%A + %A'). From a knowledge of the binodal curves for the ternary mixtures A–B–C and A'–B–C
Fig. 1. Phase diagram and relative amounts of two equilibrium phases corresponding to the ternary composition at point O for the systems A–B–C (——) and A'–B–C (----).

ACETONE

Fig. 2. Binodal curves for the ternary systems n-hexane–acetone–water (O) and n-octane–acetone–water
(●) at 25 ± 0.05°.

a position of point O can be computed that will give
a large difference between the ratios OM/OL and
OM'/OL'. One possible route to obtain optimum
precision is to keep OM fairly small, so that the
difference (OM' − OM) is much larger than the
difference (OL' − OL). The method holds good even
when the tie lines for the ternary mixtures A–B–C
and A'–B–C are not parallel. The effect of the
difference in the slope of the tie lines is taken into
account in the calibration curve.

EXPERIMENTAL

Materials

Analytical-reagent grade samples of n-hexane and n-
octane were purified by drying over sodium metal, followed
by fractional distillation.[7] Laboratory-reagent grade acetone
was refluxed over potassium permanganate, distilled and
stored over anhydrous potassium carbonate. The solvents
were fractionally distilled immediately before use. Distilled
water was used throughout.

*Determination of binodal curves for the ternary mixtures
A–B–C and A'–B–C*

The binodal curves for the hydrocarbon–acetone–water
mixtures were obtained by titrating a set of binary mixtures
of hydrocarbon and acetone with water and another set of
binary mixtures of water and acetone with hydrocarbon, to
a turbidimetric end-point.[8] Details of the apparatus and
experimental technique have been given earlier.[9]

The binodal curves for the two sets of ternary mixtures,
n-hexane–acetone–water and n-octane–acetone–water at
25 ± 0.05° are shown in Fig. 2. It can be observed that
though the miscibilities of n-hexane and n-octane with
water are of the same order of magnitude, the addition of
acetone yields fairly distinct solubility curves, and this
differentiating effect of the consolute allows the new method
to be used for the analysis of binary mixtures of the two
hydrocarbons.
Fig. 3. Calibration curve for the analysis of mixtures of
n-hexane and n-octane at 25 ± 0.05°.

Table 1. Comparison of results for synthetic mixtures

Wt.% n-hexane			Relative standard deviation
Present	Found*	n	%

91.32	90.4	2	—

*Average value of n determinations.

The apparatus used for determining the amount of two immiscible phases in equilibrium is a 50-ml stoppered measuring cylinder (made from a burette) with an outer jacket for the circulation of water from a thermostatic reservoir.

Calibration curves

To obtain the calibration curve, a set of binary mixtures of n-hexane and n-octane covering the entire w/w composition range was prepared. Seven ml of the hydrocarbon mixture, 37 ml of acetone and 6 ml of distilled water were added to the specially designed measuring cylinder described above and the mixture was shaken intermittently until thermal equilibrium at $25 \pm 0.05°$ was obtained. The volumes of the two phases in equilibrium were measured and a calibration curve (Fig. 3) of the ratio of the volumes of the two phases against the composition of the binary mixture was drawn.

A set of synthetic mixtures containing both n-hexane and n-octane, having the same volume ratios of acetone, water and total hydrocarbon as those used to obtain the calibration curve, but with different amounts of n-hexane and n-octane in the hydrocarbon component, was prepared and

subjected to analysis. The volumes of the two phases in equilibrium were measured and the composition of the hydrocarbon mixture read from the calibration curve.

RESULTS AND DISCUSSION

The results obtained for the synthetic mixtures were compared with the actual values (Table 1) and on the whole, the agreement was good. The maximum absolute difference found was $\sim 1\%$ for solutions rich in n-hexane and $\sim 2.2\%$ for solutions rich in n-octane. An examination of the calibration curve reveals that the method will yield more precise results for binary mixtures rich in n-hexane.

Although we have illustrated the method by using water and acetone as the components B and C respectively, there are many alternative choices for these components. Their suitability, however, will depend on the nature of the calibration curve obtained, since this governs the precision of the method.

RAPID PHOTOMETRIC DETERMINATION OF PHOSPHORUS IN IRON ORES AND RELATED MATERIALS AS PHOSPHOMOLYBDENUM-BLUE

OM P. BHARGAVA and MICHAEL GMITRO

Stelco Inc., P.O. Box 2030, Hamilton, Ontario, Canada

Summary—A rapid, simple and accurate method for determining phosphorus photometrically in iron ores and related materials, obviating the use of perchloric acid, is described. The sample is fused with sodium peroxide in a zirconium crucible and the melt dissolved in hydrochloric acid. The molybdenum-blue complex is developed by the addition of ammonium molybdate and hydrazine sulphate and the absorbance is measured at 725 nm. The range of the method is from 0.005 to 1.0% P. A batch of 6 samples can be analysed in about 2 hr.

The molybdate/magnesia method[1] has been the traditional referee procedure for determining phosphorus gravimetrically as magnesium pyrophosphate in minerals and iron ores. The method is quite tedious and cumbersome, and suffers interference from titanium. Both the ASTM method[2] and the British Standard method[3] require digestion of the sample in nitric–hydrochloric–perchloric acid mixture, and treatment of the insoluble matter, including removal of silica, subsequent fusion of the remaining residue, dissolution of the product, and subsequent formation of the phosphovanadomolybdate complex; this complex is then extracted either with isobutyl alcohol or MIBK (methyl isobutyl ketone), prior to photometric measurement. The phosphovanadomolybdate methods are quite tedious and lengthy. An equally accurate but more cost-effective approach is preferred. In general, considerable time and effort are needed for complete dissolution of the sample. We have already reported a technique for rapid dissolution of materials encountered in the steel industry, including iron ores.[4] A procedure for determining phosphorus photometrically was also described. The sample was fused with sodium peroxide and sodium carbonate in a vitreous carbon crucible and the melt dissolved in perchloric acid, the medium used for developing the final molybdenum blue colour for photometric measurements. It is well known that the perchloric acid concentration is quite critical and the usual practice of adding bismuth compounds was found unsuccessful in our other investigations. Further, the use of perchloric acid in the laboratory is becoming rarer, particularly in North America, owing to its hazardous nature and the strict safety control required.

Recently our laboratory was required to determine phosphorus in an unknown sample (refractory in nature), of concern in occupational hygiene. As usual, the sample was fused with sodium peroxide, but the melt could not be dissolved in perchloric acid. It readily dissolved in hydrochloric acid, however, and an attempt to develop the phosphomolybdenum blue in hydrochloric acid medium by addition of molybdate and hydrazine, followed by reduction with sodium sulphite, was successful. However, when this method was applied to phosphorus in iron ores it was found that the concentration of hydrochloric acid in the solution was important and needed investigation. An attempt was also made to replace the expensive vitreous carbon crucible by a zirconium crucible.

EXPERIMENTAL

Reagents

Only reagents that need special preparation are mentioned here. Others are given in the procedure. Pure distilled water is used throughout.

Ammonium molybdate solution, 20 g/l. To 500 ml of water, add cautiously and slowly 300 ml of sulphuric acid and cool. Add 20 g of ammonium heptamolybdate tetrahydrate [$(NH_4)_6Mo_7O_{24}\cdot 4 H_2O$]. Stir to dissolve and dilute to 1 litre with water.

Fusion blank. Dissolve 4 g of sodium peroxide in 40 ml of water. Add 30 ml of concentrated hydrochloric acid. Boil for 2 min. Cool and dilute to volume in a 100-ml standard flask.

Hydrazine sulphate solution, 1.5 g/l.

Molybdate–hydrazine sulphate solution. Add 50 ml of the ammonium molybdate solution to 100 ml of water, followed by 20 ml of the hydrazine sulphate solution, and dilute to 200 ml.

Sodium sulphite solution, 100 g/l. Prepared with anhydrous sodium sulphite.

Standard phosphorus solution. Dry anhydrous disodium phosphate (Na_2HPO_4) at 105°, cool it in a desiccator, then dissolve 0.2292 g of it in 200 ml of water. Dilute to volume in a 1-litre standard flask, and mix. This is the standard 'A' 50-μg/ml phosphorus solution. Transfer 10.00 ml of this solution into a 50-ml standard flask, dilute to the mark with water and mix. This solution 'B' is the 10-μg/ml standard phosphorus solution for calibration. *Note.* Except for the first and last, the reagents should be prepared fresh as needed.

Table 1

P content, %	Weight of sample, g	Sample aliquot, ml	Fusion blank, ml
0.005–0.15	0.3	10.00	none
0.15–0.50	0.1	10.00	none
0.50–1.0	0.1	5.00	5.00

Table 3. Effect of arsenic on phosphorus deter-mination

Iron ore	P (certificate value), %	As added, %	P found, %
NBS 690	0.011	—	0.009
NBS 690	0.011	0.05	0.015
NBS 693	0.056	—	0.056
NBS 693	0.056	0.10	0.064

Procedure

Transfer the amount of test sample (weighed to ± 0.1 mg) specified in Table 1 into a 50-ml zirconium crucible. Add 2 g of sodium peroxide and mix with a dry stainless-steel spatula. Fuse over a burner, swirling the crucible until the melt is cherry red and clear. Remove from the heat and swirl until the melt solidifies on the wall of the crucible. Place the crucible in a dry 250-ml beaker and cool. Cover the beaker with a watch-glass and add about 10 ml of water to the crucible. When the reaction has ceased transfer the crucible contents into the beaker and wash the cover and crucible with water. Add 15 ml of concentrated hydrochloric to the crucible and thence into the beaker. Rinse the crucible with water and add the rinsings to the beaker. Boil for 2 min, cool, transfer the contents into a 50-ml standard flask. Dilute to volume with water and mix. Transfer an appropri-ate aliquot of the test solution and the fusion blank (Table 1) into the same 150-ml beaker. Add 15 ml of sodium sulphite solution, mix and bring to the boil. Add 20 ml of molybdate–hydrazine sulphate solution. Bring to the boil then heat for 10 min in a boiling water-bath. Cool. Transfer to a 50-ml standard flask and dilute to the mark with water and mix. Within the next 2 hr measure the absorbance of the solution and of the calibration standards at 725 nm with water as the reference. Subtract the blank (see below) to obtain the net absorbance, and read off the weight of phosphorus from the calibration graph.

$$\% \, P = \frac{\mu g \text{ of phosphorus}}{\text{sample weight (g)} \times \text{sample aliquot (ml)}}$$

Calibration standards

Into a series of five 150-ml beakers transfer 10.00-ml portions of fusion blank solution and then 0, 0.50 and 2.50 ml of 'B' and 1.00 and 2.00 ml of standard 'A' phosphorus solution, corresponding to 0, 5, 25, 50 and 100 μg of phosphorus respectively. To each beaker add 15 ml of sodium sulphite solution, and continue from this point as described above for the test solution. Plot the net absorb-ance [obtained by subtracting the blank (0-μg P) absorb-ance] against μg of phosphorus in the coloured solution.

RESULTS AND DISCUSSION

Effect of hydrochloric acid concentration

As mentioned earlier, the hydrochloric acid con-centration is important. Varying the volume of con-centrated hydrochloric acid added to the fusion melts

obtained from synthetic mixtures and from NBS 692 iron sample (0.04% P), gave the results shown in Table 2.

Table 2 demonstrates that the 15 ml of hydro-chloric acid used in the procedure is optimal, giving excellent precision for the synthetic solutions as well as for the reference standard iron ore sample.

Effect of zirconium

In our earlier study[4] it was suspected that zir-conium would interfere, as zirconium phosphate is reported to be insoluble; hence the fusion with so-dium peroxide was done in a vitreous carbon cruci-ble. However, further investigation showed that fu-sion in a zirconium crucible gave the same results as those obtained by using a vitreous carbon crucible. The expensive ($70 each) vitreous carbon crucibles, which are also rapidly consumable (18 fusions at the most) can therefore advantageously be replaced by the relatively less expensive zirconium crucibles, which are suitable for several hundred fusions with sodium peroxide. Since zirconium does not interfere, titanium should not either, and it was later found that up to 6.4% of TiO_2 had no effect.

Effect of arsenic and silicon

Normally the arsenic content of iron ores and concentrates is 0.01% or less, but its possible inter-ference was investigated with a much higher level. Two standard reference iron ores (NBS 690 and NBS 693) were analysed with and without addition of arsenic. The results are given in Table 3, and demon-strate that arsenic causes a positive error, approxi-mately 0.01% of phosphorus per 0.1% of arsenic present. Thus the interference of 0.01% of arsenic is equivalent to only 0.001% of phosphorus, which lies well within the acceptable experimental deviation.

Silicon is also a possible (though improbable) source of interference, but up to 20% of SiO_2 was found to have no effect.

Finally the procedure was tested on a number of standard reference iron ores and concentrates encompassing a large variation both in matrix as well as phosphorus content. Table 4 lists the composition of the iron ores analysed and the comparative results are shown in Table 5. There is excellent agreement with the certificate values. The standard deviation was found to be less than 0.001% phosphorus (Table 6).

The method has potential for further application for rapid determination of total phosphorus in effluents, sediments etc., without the use of perchloric acid.

DETERMINATION OF ARSENIC BY POLYURETHANE FOAM EXTRACTION AND X-RAY FLUORESCENCE

A. S. Khan and A. Chow*

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

Summary—A method based on extraction with polyurethane foam and determination by X-ray fluorescence has been developed for the determination of arsenic. Arsenic concentrations as low as 36 μg/ml can be detected in 100 ml of aqueous solution.

The extensive use of arsenic in agriculture, medicine and industry, along with awareness of its carcinogenic effects,[1] has created a need to develop new methods and improve existing methods of arsenic determination at trace levels. Arsenic has been determined by various techniques, including gas chromatography,[2] ion-exchange chromatography,[3] activation analysis,[4] atomic-absorption spectrophotometry (AAS),[5,6] and polarography,[7] and the spectrophotometric method based on formation of a reduced arsenomolybdate complex is one of the recommended methods for trace levels.[8] Formation and extraction of arsenomolybdate is the basis of an indirect atomic-absorption spectrophotometric method.[9,10] The generation of arsine by reduction with sodium tetrahydroborate is often used prior to an atomic-absorption determination.[6]

Although AAS has become the most popular technique for arsenic determination,[6] X-ray fluorescence (XRF) has also been used. Owing to the low sensitivity, however, a preconcentration step is necessary for the XRF analysis of water samples. In one procedure arsenic is extracted with ammonium pyrrolidine dithiocarbamate into chloroform, followed by evaporation of the organic layer on a filter paper for the determination of arsenic by XRF,[11] and in another the arsenic is co-precipitated with dibenzyldithiocarbamate and collected on a membrane filter for XRF analysis.[12] The use of molybdenum sulphide as co-precipitant has also been reported.[13]

It has recently been shown that extraction by polyurethane foam can be used successfully in conjunction with XRF spectrometry for the determination of trace elements.[14-16] This paper describes extension of this technique to determination of arsenic at trace levels. The method involves the formation of arsenomolybdate, its extraction by polyether-based polyurethane foam, and direct determination on the foam by XRF.

EXPERIMENTAL

Apparatus

A Varian 634 UV–visible spectrophotometer was used to determine the arsenomolybdate complex in solution. A Fisher Accumet model 520 pH-meter was used when adjusting the acidity. The foam extractions were done with a multiple automatic squeezer and the arsenic on the polyurethane foam was determined with an energy-dispersive X-ray fluorescence system as described previously.[14]

Reagents

An appropriate amount of arsenic oxide (As_2O_5) was dissolved in a minimum volume of 1.0M sodium hydroxide, and the solution was acidified with dilute hydrochloric acid before dilution to the required volume. A 0.05M sodium molybdate solution and a solution containing 0.25 g of iodine and 0.4 g of potassium iodide per 100 ml were prepared in water.

All chemicals were reagent grade, and the solutions were prepared with doubly distilled, demineralized water and stored in polyethylene bottles. A polyether-based polyurethane foam sheet was obtained locally and cut into circular plugs (~ 2 cm in diameter, ~ 1.5 cm in height and weighing 0.125 ± 0.005 g), with sharpened tubular bits. The foam plugs were washed as previously described.[17]

Procedure

An aliquot of solution containing not more than 0.35 mg of arsenic was transferred to a 100-ml standard flask and 1 ml of the iodine solution was added to oxidize As(III) to As(V) [because As(III) does not form arsenomolybdate] followed by 20 ml of sodium molybdate solution. Water was then added to give a volume of nearly 90 ml and the pH was adjusted to 1.5. After 10 min the solution was made up to volume with water. The arsenomolybdate was extracted into the polyurethane foam plug by squeezing the plug in the solution in an extraction cell for 1 hr, at constant temperature. The foam plug was then removed from the solution, washed with 0.01M hydrochloric acid and then water, and dried by squeezing between paper towels. The area of the arsenic K_α peak was obtained by placing the foam plug on Mylar film stretched across the X-ray source and detector, accumulating the spectrum for 100 sec and integrating the arsenic peak area over a fixed range of channel numbers.

RESULTS AND DISCUSSION

In the preliminary studies arsenomolybdate was extracted from aqueous solution under conditions

---

*Author for correspondence.

similar to those described by Simon and Boltz[18] except that polyether foam was used in place of the organic solvent. Spectrophotometric determination of arsenic in the aqueous sample before and after equilibration with the foam plug showed that the extraction was quantitative. A study in which foam plugs were squeezed for various times from 10 min to 3 hr showed that equilibrium was reached in 30 min of squeezing. In all further studies the squeezing was done for 1 hr to ensure establishment of equilibrium.

Optimum conditions for the determination were established by study of the effects of variables.

The absorbance at 385 nm for a solution $2 \times 10^{-5}M$ in As(V) and $2.5 \times 10^{-3}M$ in MoO_4^{2-} was found to be maximal between pH 1.3 and 2.0; a similar pH for the formation of arsenomolybdate was observed by Boltz and co-workers[9,18] whereas Yamamoto et al.[10] reported that the formation is quantitative between pH 0.5 and 6.0. To establish the optimum pH-range of extraction a series of 100-ml solutions which were $2 \times 10^{-5}M$ in As(V) and $2.5 \times 10^{-3}M$ in MoO_4^{2-} and at different pH values were equilibrated with foam plugs. The results are shown in Fig. 1, along with the results of two other experiments using higher initial molybdate concentrations (0.005 and 0.01M). It is clear that the optimum pH-range for extraction varies with the initial molybdate concentration. However, as can be seen for molybdate concentrations ranging from 2.5×10^{-3} to $1 \times 10^{-2}M$, the extraction of arsenomolybdate by polyether foam is optimal between pH 1.0 and 1.9. A pH of 1.5 was selected for further studies; the extraction of arsenomolybdate into various organic solvents has been reported to be optimal at different pH values.[9,19,20] This difference is due to the fact that the pH range for extraction of heteropolymolybdates depends on the nature of the organic solvent.

The effect of initial molybdate concentration was also studied by equilibrating a series of 100-ml solutions, $2 \times 10^{-5}M$ in As(V), at pH 1.5 ± 0.1 and con-

Fig. 2. Influence of initial molybdate: arsenic ratio on the extraction of arsenomolybdate.

taining various amounts of sodium molybdate, with foam plugs. Figure 2 indicates that no detectable amount of arsenic was extracted with less than a 15-fold ratio of molybdate to arsenic (V), but the extraction increased with molybdate concentration, becoming maximal and constant with a 55-fold or higher ratio of molybdate to arsenic. Although a very large excess of molybdate is usually recommended for the solvent extraction of heteropolymolybdates,[21] the polyurethane foam-extraction of phosphomolybdate has been found to be quantitative even with only a 25-fold ratio of molybdate to phosphorus.[22]

To determine the concentration range for linear X-ray response, a series of 100-ml solutions containing 50–500 μg of arsenic was extracted. The results were linear up to 350 μg of arsenic and the deviation for larger quantities was most likely due to saturation of the foam. The detection limit, calculated as three times the standard deviation of the background, was 5.7 μg/100 ml (i.e., 57 ng/ml). The detection limit can be improved by using smaller foam plugs or larger volumes of sample solution. The results of one such study with small foam plugs showed a linear response up to 100 μg of arsenic and indicated a detection limit of 36 ng/ml under these conditions. It should be noted that the E.P.A. allowable limit for arsenic in drinking water is 50 ng/ml.[23] More sensitive XRF equipment should reduce the detection limit to 1–5 ng/ml for this procedure. To estimate the precision,

Fig. 3. Effect of interferent:arsenic molar ratio on the
determination of arsenic (0.5 μg/ml). ▲ Phosphate; ○
silicate; ◆ germanate.

five 100-ml solutions containing 250 or 50 μg of
arsenic were analysed. The means found were 251
and 52 μg, the standard deviations being 9 and 3.4 μg
respectively, indicating good precision; as expected,
the precision is better at the higher concentration.

Since it was observed earlier that polyurethane
foam is also very effective for the extraction of
phosphomolybdate, silicomolybdate and germano-
molybdate,[24] the effect of these heteropoly anions was
studied. The criterion for non-interference was a
change of less than 10% in the X-ray intensity for a
given arsenic level when the test solution contained
the potential interferent. Figure 3 shows the observed
X-ray intensities of the arsenic K_α radiation for
various P/As, Si/As and Ge/As ratios at a fixed
arsenic concentration (0.5 μg/ml). It is clear that up
to 10-fold molar ratios of phosphate and silicate to
arsenate do not interfere, whereas the germanate
causes 10% interference even when present in concen-
trations only twice that of the arsenic. The positive
deviation caused by the presence of germanate is due
to the poor resolution of the XRF unit used, and
should be eliminated by using a unit with higher
resolution. In the presence of sufficient molybdate
and acid in the aqueous phase, the amount of hetero-
poly interferent that can be tolerated is limited by the
size of the foam plug that can be effectively analysed
by the instrument used.

X-ray fluorescence in conjunction with the use of
polyurethane foam for the preconcentration of

arsenic as arsenomolybdate provides a simple method
of arsenic determination. Although the method is less
sensitive than some, the ease of operation, the low
cost and the simultaneous multielemental capability
of the XRF technique compensate for this.

OPEN WET ASHING OF SOME TYPES OF BIOLOGICAL MATERIALS FOR THE DETERMINATION OF MERCURY AND OTHER TOXIC ELEMENTS

H. F. HAAS and V. KRIVAN

Sektion Analytik und Höchstreinigung, Universität Ulm, Oberer Eselsberg N-26,
D-7900 Ulm/Donau, F.R.G.

Summary—An open wet decomposition procedure for trace element analysis of biological material has been worked out. It is based on the utilization of nitric acid, hydrochloric acid and hydrogen peroxide and is well suited for the determination of As, Bi, Cd, Cr, Hg, Pb, Sb, Se and Tl. For these elements the recoveries were examined by the radiotracer technique, with lichens, pine needles, grass and human hair as representative biological samples. In addition to the conventional labelling technique, use was also made of *in situ* labelling. In all cases, recoveries between 93 and 100% were achieved, which are adequate for quantitative trace element analysis.

Most of the powerful determination methods for trace element analysis of biological and environmental material require decomposition of the sample. Because of the danger of losses, biological samples for the determination of toxic elements, especially of mercury, have usually been decomposed in closed systems,[1-3] or in open systems coupled with means of trapping the volatile elements.[3-5] In many instances, simple, open decomposition procedures would be of advantage. One wet decomposition method[6] provides quantitative recoveries of mercury, but the resulting chloric acid medium is often not suitable for the procedures used for the determination.

In an earlier study of the pre-atomization losses of mercury in graphite tube atomic-absorption spectrometry,[7] it was proved that losses from hydrochloric acid/hydrogen peroxide and nitric acid/ hydrochloric acid/hydrogen peroxide mixtures at temperatures up to 220–250° are undetectable. On the basis of the stabilization effect of these media, a simple wet decomposition procedure for the determination of mercury and a number of other elements in biological materials has been developed and is described in the present paper.

EXPERIMENTAL

Chemicals and apparatus

The concentrated nitric acid and hydrochloric acid used were of "*suprapur*" grade and the 30% hydrogen peroxide was of "*pro analysi*" grade (Merck). The radiotracers ^{51}Cr, ^{75}Se, ^{76}As, ^{124}Sb and ^{203}Hg were prepared by neutron-activation, in the FRG-2 reactor, Forschungszentrum, Geesthacht (thermal neutron flux = 10^{14} n.cm^{-2}.sec^{-1}), of the residues from evaporation of solutions of suitable compounds of the elements in "suprasil" quartz ampoules (Heraeus). The specific activities (μCi/μg) at the end of irradiation were 0.5 for ^{51}Cr, 0.06 for ^{75}Se, 52 for ^{76}As, 30 for ^{124}Sb and 0.4 for ^{203}Hg. After irradiation, the ampoules were opened and the following solutions prepared: a hydro-

chloric acid solution of ^{51}Cr, ^{76}As and ^{124}Sb; a water solution of ^{75}Se; a nitric acid solution of ^{203}Hg. The radiotracer ^{109}Cd was supplied by NEN Chemicals GmbH, Dreieich, F.R.G., as a hydrochloric acid solution with a specific activity of 354 μCi/μg.

The radiotracers ^{202}Tl, ^{203}Pb and ^{206}Bi were prepared by irradiation of HgO, Tl and Pb targets with protons at 22, 20 and 25 MeV, the nuclear reactions being ^{202}Hg(p, n)^{202}Tl, ^{203}Tl(p, n)^{203}Pb and ^{206}Pb(p, n)^{206}Bi, respectively. The irradiations were performed at the isochronous cyclotron at the Nuclear Research Centre, Karlsruhe. Solvent extraction was used for the separation of ^{203}Pb from the thallium matrix and of ^{206}Bi from the lead matrix; ^{202}Tl was isolated from the mercury matrix by ion-exchange.

The radioactive purity of the radiotracers was checked by γ-ray spectrometry, and in no case could any impurity be determined. In the radiotracer experiments, a single-channel analyser (Berthold, Wildbad, F.R.G.) with a well-type NaI(Tl)-detector and a high-resolution γ-ray spectrometer consisting of an Ortec Ge(Li)-detector and a Canberra multichannel analyser were used for counting.

The *in situ* labelling of lichens, hair, grass and pine needles was achieved by their irradiation at the nuclear reactor with the neutron flux given above.

Decomposition procedure

A sample weighing about 0.2 g is placed in a 25-ml Erlenmeyer flask and heated with 3 ml of concentrated nitric acid and 0.15 ml of concentrated hydrochloric acid at 120° for 5–10 min. During the heating, 0.1–0.2 ml of 30% hydrogen peroxide is added dropwise. After the major part of the organic matter has dissolved, 1.5 ml of concentrated hydrochloric acid is added and the temperature is increased to 180°. During the evaporation, 0.1–0.2 ml of 30% hydrogen peroxide is again added dropwise. The evaporation is stopped when the residual solution has a volume of about 0.5 ml (there must be no evaporation to dryness!), and this is then taken up with 3 ml of concentrated hydrochloric acid. This solution is evaporated again, with dropwise addition of 0.1–0.2 ml of 30% hydrogen peroxide, until about 0.5 ml remains. The residue is then taken up with 6M hydrochloric acid, but other concentrations can also be used.

For larger amounts of sample the reagent volumes must be correspondingly increased. Sample amounts up to 0.5 g were examined. In the radiochemical neutron-activation

*Carrier-free radiotracer used.

†Radiotracer contained 100 μg of carrier.

§Pretreatment of the samples with dilute solutions of Se(IV), As(V), Cd(II) and Hg(II) before the irradiation.

‡*In situ* labelling of the original material without pretreatment.

analysis, the irradiated sample is decomposed in the opened quartz ampoule and six times greater reagent volumes are used, after addition of carrier.

Tracer experiments

The yields for the elements As, Bi, Cd, Cr, Hg, Pb, Sb, Se and Tl were checked by the radiotracer technique in the following ways. First, the decomposition was performed on inactive lichen material to which the appropriate radiotracer (carrier-free and with 100 μg of carrier) was added. After decomposition, the resulting hydrochloric acid solution was centrifuged at 3000 rpm for 10 min, and a 5-ml portion was measured either with the single-channel analyser (if labelled with a single radioisotope) or with the γ-ray spectrometer (if labelled with several radioisotopes simultaneously).

In the second mode of labelling, the wet ashing was done on neutron-irradiated lichens, hair, grass and pine needles. In the case of lichens, grass and pine needles, before activation the homogenized material was treated with dilute solutions of Se(IV), As(V), Cd(II) and Hg(II) and then dried under an infrared lamp. After the irradiation, the ashing procedure was applied and the yields of the different elements were determined by measuring the resulting solutions as above.

RESULTS AND DISCUSSION

The proposed decomposition procedure was investigated, grass, pine needles, lichens and human hair being used as representative biological materials. For the determination of the recoveries, the radiotracer technique proved to be best.

In addition to conventional labelling by addition of a small portion of a radiotracer solution to the test material before the decomposition, *in situ* labelling by irradiation of the biological materials with reactor neutrons before the decomposition was also used. Because the content of As, Se, Cd and Hg in lichens, grass and pine needles was at the detection limits of the activation γ-ray spectrometry technique or below, in a series of experiments the content of these elements was increased by a pre-irradiation treatment of the original material with dilute solutions of the corresponding ions of the elements. The amounts of carrier taken up by a sample portion of 150 mg were pproximately 1 μg for As, 10 μg for Se and Hg, and 60 μg for Cd.

The results obtained are summarized in Tables 1 and 2, and are the mean values of at least three separate determinations (the corresponding mean deviations are also given). They show that, in all the experimental modes, the recoveries and their deviations meet the requirements for quantitative trace element analysis. Some important aspects are discussed in more detail below.

In the case of lichens, pine needles and grass, a very slight residue remained after the centrifugation, but it contained no detectable amount of any of the elements in question. In addition, the radiotracer experiments proved that there was no detectable adsorption of the test elements on the vessel walls. Complete decomposition of hair samples was achieved, and direct visual observation indicated similar behaviour for wood, blood and bovine liver, but these materials were not examined by the radiotracer technique.

Comparison of the results obtained by the conventional labelling method for carrier-free radiotracers and radiotracers containing 100 μg of carrier showed that varying the amount of the elements did not cause deviations greater than the mean deviations of the yields.

Since the chemical form of the radiotracers at the beginning of the decomposition was different for the two labelling modes, and probably also in the various matrices after the *in situ* labelling, the results pro-

In situ labelling of the original material without pretreatment.

†Pretreatment of the samples with dilute solutions of Se(IV), As(V), Cd(II) and Hg(II) before the irradiation.

vided some information about the effect of the chemical state of the elements on their recoveries. The results given in Tables 1 and 2 indicate that the chemical form does not affect the recovery of arsenic, cadmium, mercury, antimony and selenium, where the mean yields for the two modes of labelling the lichens (Table 1) and for the *in situ* labelling of hair, grass, and pine needles (Table 2) agree well each with other. In the case of chromium, there is excellent agreement between the results from *in situ* labelling of lichens (94.7 ± 0.5%) and hair (94.1 ± 1.3%), but significantly higher recovery (100.4 ± 2.2%) was obtained if the chromium tracer containing 100 μg of carrier was added as Cr(III) in dilute hydrochloric acid to lichens. The *in situ* labelling could not be applied for thallium, lead and bismuth, since no suitable indicator radionuclides were produced from these elements by neutron activation.

The recovery results for mercury are in good accordance with the results obtained in a study of pre-atomization losses in graphite tube atomic-absorption spectrometry, in which quantitative recoveries were obtained with the decomposition systems hydrochloric acid/hydrogen peroxide and hydrochloric acid/nitric acid/hydrogen peroxide at pretreatment temperatures up to above 200°. They show that this open decomposition procedure is also well suited for decomposition of biological materials for the determination of mercury, which must normally be performed in closed systems.

In the decomposition of some materials such as metals, considerable losses of arsenic have been observed in spite of the presence of an oxidizing medium.[8,9] The high recoveries for arsenic in this work (96.0–99.1%) show that the oxidation power of the nitric acid/hydrochloric acid/hydrogen peroxide medium used in the procedure is sufficient to convert the arsenic of the biological materials into the stable quinquevalent form.

Losses of antimony by formation of difficultly soluble compounds and/or adsorption on the vessel walls have been reported for some decomposition systems,[10] but we did not observe any when using the present procedure.

Recovery data for Co, Cs, Fe, Sc and Zn obtained by the *in situ* labelling technique for lichens and hair are also given in Tables 1 and 2.

It is worth mentioning that the hydrochloric acid solution obtained is, in general, well suited for the further separation, preconcentration and determination step. However, the procedure is suitable for the decomposition of only certain types of biological materials, such as plants. For example, it cannot be used for the decomposition of fats. Further, the yields of the elements in the resulting solutions are given with regard to the total amounts but not to their chemical forms. Only for mercury in the decomposition of lichens was the degree of mineralization in the sample solution checked by ion-exchange, and the separation yields indicated that all the mercury was present in the solution as Hg^{2+}. Because of the somewhat higher reagent volumes used in the present open technique the reagent blanks are expected to be higher than those for the closed decomposition systems. Therefore, all three reagents used should be of highest purity (*e.g.*, the acids obtained by sub-boiling distillation[11] and the hydrogen peroxide by low-temperature vacuum sublimation[12]) and the decomposition should be carried out at a clean-bench, when extremely low contents are to be determined.

ANNOTATION

VERIFICATION OF CERTIFIED SULPHUR VALUES IN STEEL REFERENCE MATERIALS BY ISOTOPE-DILUTION MASS SPECTROMETRY, AND CHARACTERIZATION OF SULPHUR PRESENT ON THE SOLID SAMPLES

KAZUO WATANABE

Analytical Chemistry Laboratory, Japan Atomic Energy Research Institute, Tokai-mura,
Ibaraki-ken, Japan

Summary—Sulphur in a number of steel reference materials has been determined by isotope-dilution mass spectrometry, utilizing both open-beaker and sealed-tube dissolution techniques. It is confirmed that the sulphur present in most samples can be completely converted into sulphate by the conventional open-beaker dissolution technique. The results on reference materials are in good agreement with the certified values for BCS samples and the recent or revised certified values for JSS and NBS samples. It is found that the sulphur concentration in the vicinity of the surface of the sample chips is higher than the average and that a significant amount of elemental sulphur is present on most chip samples. The ratio of elemental sulphur to average sulphur content tends to vary in proportion to the manganese content when this is less than 1%.

Sulphur in steels, even at trace levels, has a deleterious influence on their mechanical properties so a rapid and accurate determination of sulphur is indispensable for production control in steel-making. Instrumental techniques are commonly used for the purpose. As the accuracy depends largely upon the standards used for calibration of the instruments, certified reference materials (CRMs) play an extremely important role in the analyses. The barium sulphate gravimetric method, despite its lack of sensitivity, has long been used for evaluation of the sulphur content in CRMs. For its accurate determination by this method, all the sulphur must be converted into sulphate and recovered as barium sulphate. An isotope-dilution mass spectrometric (IDMS) method has been developed for the accurate and precise determination of sulphur in heat-resisting alloys and steels,[1] but here again all the sulphur must be converted into sulphate. It must also be mixed thoroughly with the spike (enriched ^{34}S) since the spike used is in the form of sulphate because the rate of isotopic equilibration between different chemical forms is normally too slow for other forms to be used for the determination: it takes more than several days to attain isotopic equilibration between sulphate and sulphide, even at 300° and 1000 bars.[2]

Recently, Paulsen *et al.* have developed an isotope-dilution spark-source mass spectrometric procedure (ID–SSMS) for the accurate determination of sulphur in iron-base alloys;[3] they used a sealed-tube dissolution technique to prevent volatilization losses and to effect isotopic equilibration. They found that there was a significant loss of sulphur during open-beaker

dissolution for particular low-alloy steels.[4] We have also employed the sealed-tube dissolution procedure for several low-alloy steel Standard Reference Materials (SRMs) from the National Bureau of Standards (NBS)[5] and confirmed that use of the open-beaker dissolution for SRMs 362 and 364 yields low sulphur results. We found that part of the sulphur present in these samples was lost as sulphur dioxide during the dissolution, and suggested that when the sealed-tube dissolution technique is used, any sulphur dioxide evolved in the closed vessel is absorbed and oxidized to sulphate by the acid mixture at high temperature and pressure.

It is important to know whether the use of the open-beaker dissolution technique always yields low results, because the gravimetric method currently in use is based on open-beaker dissolution. We have applied both the sealed-tube and the open-beaker dissolution techniques to a number of steel reference materials from British Chemical Standards (BCS), Japanese Standards of Iron and Steel (JSS) and NBS, including the samples which we reported on earlier.[6] All the results obtained by the use of both dissolution techniques agree well with each other except for NBS SRMs 362 and 364.

The cause of our earlier low results for reference materials in comparison with the certified values[6] has now been traced to our treatment of the samples before analysis: the sample chips were rinsed with water, ethanol and acetone, and then dried at 80°. We have now found that a significant amount of elemental sulphur, which can easily be removed by the rinsing, is present on the surface of most steel chip

samples, and have investigated the origin of this elemental sulphur.

EXPERIMENTAL

Reagents

Analytical-reagent grade chemicals were used.

Spike solution. Fifteen mg of 94% enriched ^{34}S isotope (Oak Ridge National Laboratory) was dissolved in a mixture of 2 ml of concentrated nitric acid, 1 ml of concentrated hydrochloric acid and 0.1 ml of bromine. One ml of 10% potassium hydroxide solution was then added and the solution evaporated to dryness. The residue was dissolved and diluted to volume with water in a 100-ml standard flask, and standardized by IDMS with a standard potassium sulphate solution (of natural isotopic composition) prepared by weight.

Reducing solution. Hydriodic acid (500 ml, 57% w/v), hypophosphorous acid (245 ml, 50% w/v) and hydrochloric acid (813 ml, 36% w/v) were mixed.[7] Any sulphur compounds present in the mixture were removed by refluxing in a stream (80 ml/min) of pure nitrogen (99.999% pure) for 1 hr before use.

Apparatus

Isotopic analysis of sulphur was performed with a CEC 21-103C mass spectrometer equipped with a Cary 401 vibrating reed electrometer and a recorder.

Spectrophotometric determination of elemental sulphur was done with a Hitachi model 200 double-beam spectrophotometer.

Procedures

Determination of sulphur by IDMS. The analytical procedure used in this study is slightly different from the one used in previous work.[1,6] The amount of acids used for the sample dissolution is decreased; the spike solution is added before the sample dissolution; the combustion procedure for conversion of silver sulphide into sulphur dioxide is simplified.

Sample dissolution in an open beaker. To 0.5–1.5 g of sample in a 200-ml beaker, a weighed aliquot of the spike solution, 0.3 ml of bromine, 4 ml of concentrated nitric acid and 2 ml of concentrated hydrochloric acid were added. After the sample had been left for about 30 min at room temperature, 0.2 ml of bromine and 2 ml of concentrated hydrochloric acid were added. Then the sample was heated on a hot-plate at 80° till the sample had completely dissolved. If dissolution was incomplete, several drops of hydrofluoric acid were added. The solution was evaporated to dryness on a hot-plate at 200°. Nitrogen oxides were removed by repeated evaporation with 4-ml portions of concentrated hydrochloric acid. The residue was finally dissolved in 4 ml of concentrated hydrochloric acid.

Sample dissolution in a borosilicate-glass sealed tube. The procedure is described in detail elsewhere[5] and is similar to the one used by Burke *et al.*[4] so is described here only briefly.

A weighed aliquot of the spike solution was added to 0.5 g of sample in a glass tube (15 mm outside diameter, 2 mm wall thickness and 30 cm long) sealed at one end. The tube was placed in a slush of solid carbon dioxide and ethanol to freeze the contents. Seven ml of concentrated nitric acid and 3 ml of concentrated hydrochloric acid were added and the tube was sealed in an oxygen–gas flame and placed in a stainless-steel shell with about 20 g of solid carbon dioxide. The shell was heated in an oven at 180–200° overnight. After cooling, the tube was placed in the slush to freeze the sample solution.

The tube was then moved into liquid nitrogen, scored and opened. After gradual thawing at room temperature, the solution was transferred to a 200-ml beaker. Nitrogen oxides were removed as described above.

Reduction of sulphate. Twenty-five ml of the reducing mixture were transferred to a 300-ml round-bottomed flask

fitted with a reflux condenser, and boiled for 1 hr while a stream of pure nitrogen at a flow-rate of 80 ml/min was passed through the system. After the solution had cooled, the spiked sample solution was added to the flask and the mixture was again refluxed for 1 hr, with passage of nitrogen. The hydrogen sulphide evolved was carried by the nitrogen stream through water and then absorbed in a mixture of 2 ml of 0.1*M* cadmium acetate and 40 ml of water. Cadmium sulphide was finally converted into silver sulphide by addition of 3 ml of 0.1*M* silver nitrate. After coagulation by heating, the silver sulphide was filtered off on a tightly packed quartz-wool plug inserted in a quartz tube (15 mm outside diameter and 5 cm long, drawn out at one end). The precipitate was washed with water, ethanol and then acetone. A tuft of quartz wool was inserted into the wider end of the tube and the precipitate was dried in an oven at 120°.

Combustion of silver sulphide. The quartz tube was inserted into a second quartz tube (18 mm outside diameter and 15 cm long) sealed at one end. The outer tube was then attached to a vacuum line by means of a vacuum-tight Cajon union (Cajon Co., Solon, Ohio). The tube was flamed under a presure of about 3×10^{-4} Pa for 10 min to remove any volatile compounds, then oxygen was introduced into the tube to give a pressure of about 3×10^4 Pa. The precipitate was heated with a four-burner oxygen torch to about 1000° until the black silver sulphide could no longer be seen; this took about 1 min. The sulphur dioxide evolved was collected in a U-tube cooled with liquid nitrogen, more volatile products being pumped off. The sulphur dioxide was then cryogenically transferred to a sampling bottle for subsequent mass spectrometric analysis.

Determination of elemental sulphur on sample chips. This procedure is a modification of the one used by Koren[8] for the determination of elemental sulphur in ore.

Five ml of chloroform were pipetted into a 20-ml standard flask which contained 3–5 g of sample chips. The sample was subjected to ultrasonic radiation for 1 min. The absorbance of the solution was then measured at 265 nm.

RESULTS AND DISCUSSION

Sulphur in 23 steel reference materials from BCS, JSS and NBS was determined by IDMS, with both the open-beaker and sealed-tube dissolution techniques, and the results were then compared. No significant discrepancy between the results obtained by the two dissolution techniques was observed for most samples, with the notable exception of the low-alloy steel NBS SRMs 362 and 364: the results obtained for these by the open-beaker dissolution were significantly low. The results are shown in Table 1, the "open-beaker" results are included in calculation of the averages except for NBS SRMs 362 and 364. It seems that sulphur in most steel samples can be completely converted into sulphate by the conventional open-beaker dissolution technique; however, it might be desirable to check whether there is a loss of sulphur during the dissolution, by using a completely reliable technique such as the sealed-tube dissolution when sulphur in a new sample has to be determined.

The IDMS results are generally in good agreement with the recent or revised certified values for JSS and NBS, and in excellent agreement for BCS samples irrespective of the year of certification. Our previous suggestion[6] that there was systematic bias in the methods of standardization of BCS, JSS and

¶Disk samples for spectroscopic analysis.

NBS is now seen to arise from our rinsing of the samples.

In an attempt to explain the discrepancy between our earlier IDMS results and theirs, Burke et al. suggested[4] that there was a possibility of loss of sulphur during dissolution before the addition and equilibration of the ^{34}S spike, if the spike was added *after* the sample dissolution. However, it is sulphate sulphur that is determined by the IDMS, since the spike used is in the form of sulphate, and if there were losses of sulphur as volatile compounds during the open-beaker dissolution, it would be impossible to determine them by IDMS even if the spike was added *before* the sample dissolution. We have observed no significant difference between the results obtained, whether the spike was added before and/or after the dissolution, for both the open-beaker and the sealed-tube dissolution techniques. Addition of the spike before sample dissolution may be preferable to prevent loss of sulphate in the sample solution by spillage before the isotopic equilibration.

In attempts to trace the cause of the discrepancy between the two sets of IDMS results, we found that a significant amount of elemental sulphur was present on the surface of most sample chips, and that this was easily removed by rinsing with ethanol and acetone.

Figure 1 shows absorption spectra for elemental sulphur dissolved in chloroform and for chloroform in which chip samples had been soaked for about 1 hr. These spectra strongly indicate the presence of elemental sulphur on the steel surface, and show that it can be determined spectrophotometrically after extraction into chloroform.

In the 5th column in Table 1, the results obtained by IDMS for the rinsed samples are shown. The difference between the two sets of IDMS results for each sample (as received and rinsed) is in good agreement with the spectrophotometric result for elemental sulphur.

To examine the origin of the elemental sulphur on the chip samples, we prepared sample chips from low-alloy steel disks (JSS spectroscopic standards) with a shaper. Spectrophotometric examination of these sample chips soon after they had been prepared showed no elemental sulphur on their surface, but five months after the preparation, elemental sulphur was observed; during that time the sample chips had been stored in a weighing bottle in a desiccator.

To obtain the depth distribution of sulphur in the prepared sample chips, they were dissolved stepwise with a mixture of concentrated nitric and hydrochloric acids and bromine under ultrasonic radiation
Fig. 1. Absorption spectra of elemental sulphur in chloroform and the chloroform extract of some steel reference materials: 1, elemental sulphur (30 μg/ml); 2, BCS 241/2 (4.9 g); 3, NBS SRM 32e (2.9 g); 4, JSS 242-5 (5.5 g); 5, NBS SRM 364 (5.5 g) 6, elemental sulphur (4 μg/ml). Recorder ensitivity factor: 1, ×1; 2, ×2; 3, ×2; 4, ×5; 5, ×5; 6, ×1.

and the sulphur in each fraction dissolved was determined by IDMS; the results are shown in Fig. 2. The concentration of sulphur near the sample surface is very high, but decreases rapidly with depth, becoming considerably lower than the average content. We also examined the distribution of sulphur in some of the standard chip samples in the same manner, and obtained similar results: the sulphur concentration in the vicinity of the surface is extremely high. It seems that sulphur in steels tends to migrate to the surface during the preparation of chips by cutting.

Most of the sulphur in steels is known to be present in the form of iron sulphide and manganese sulphide.[9] It is therefore assumed that the metal sulphides migrate to the surface and are gradually
Fig. 2. Depth distribution of sulphur in the prepared sample chips: low-alloy steel JSS 151-6 (S 166 μg/g).
Fig. 3. Relationship between elemental sulphur on the chip samples and manganese content (less than 1%). ☐ BCS samples; ○ JSS samples; ● NBS SRMs.

oxidized by atmospheric oxygen to elemental sulphur:

$$2MS + O_2 \rightarrow 2MO + 2S$$
The free-energy changes of this reaction are $\Delta G = -36.9$ kcal/mole for manganese sulphide and $\Delta G = -35.4$ kcal/mole for iron sulphide,[10] so it can take place spontaneously. In Fig. 3 the ratio of the elemental sulphur to average sulphur content for each sample is plotted against the manganese content. The elemental sulphur on the surface tends to vary in proportion to the manganese content if this is less than 1% (correlation coefficient 0.69); this suggests an intimate connection between sulphur and manganese. Although the amount of the elemental sulphur may depend largely upon the surface area of the sample, we did not examine this factor in the study reported here, because the steel reference materials are relatively of uniform size. Similar results have been found by Yasuda[11] in work on standards for X-ray fluorescence spectrometry, who found that the X-ray signal for sulphur increased with increasing manganese content. He attributed this to differences in size and shape of the MnS particles, but it may equally be due to the migration effect reported here.

COULOMETRIC TITRATION BY A CONTROLLED-POTENTIAL PULSED-CHARGE POTENTIOMETRIC TECHNIQUE—II*

ACID–BASE, PRECIPITATION AND HOMOGENEOUS REDOX SYSTEMS

Theologos Andronidis, Anna Maria Ghe† and Sergio Valcher

Istituto Chimico "G. Ciamician" dell'Università, Scuola di Specializzazione in Chimica Analitica, Via Selmi 2, 40126 Bologna, Italia

Summary—An unconventional coulometric method, based on electrolysis at controlled potential by means of discrete charge-pulses, with end-point detection obtained by mathematical linearization of potentiometric data, has been applied to various systems. The results appear very satisfactory: very weak acids can be determined with high accuracy; in the case of precipitation reactions the selectivity is high enough to allow titration of the components of halide mixtures; for homogeneous redox systems some problems caused by irreversibility at the indicator electrode are overcome.

An improved method for coulometric titrations, devised to provide selectivity in the separation and determination of metals that can be electro-deposited, was proposed in Part I of this series.[1]

The method is based on electrochemical titration reactions performed at controlled potential by means of discrete charge-pulses, the end-point being located by means of a mathematical linearization of the potentiometric data, which is analogous to Sörensen's method[2] for conventional titrations.

Since the proposed technique, like other conventional and unconventional coulometric methods,[3,4] appears to be suitable for application to a wider field, other types of titration have been examined and the results obtained with acid–base systems, precipitation reactions and a particular type of homogeneous redox reaction are reported here.

EXPERIMENTAL

Titrations were done with the potentiostatic system already described;[1] it was generally used in a "three-electrode" configuration, and connected to a potentiometer equipped with a printer. For acidimetric determinations, however, a "four-electrode" configuration was used, with a glass electrode for potentiometric detection, and an Ag/AgCl electrode as reference electrode, both for electrolytic and potentiometric conditions (see Fig. 1).

All measurements were made at 25° on 10–20 ml samples. Analytical grade reagents were used. The background electrolytes were chosen so that 100% current efficiency and fast equilibration of the indicator electrode were obtained. For the determinations of acids, potassium chloride was used in large excess (100-fold ratio to the test species) and a mixture of potassium sulphate and sulphuric acid at pH 1–2 for redox systems. For halide determinations potassium nitrate was employed, to prevent co-precipitation effects,[5] the pH

being adjusted with ammonia and acetic acid to values suitable for the different species titrated.

Other experimental conditions and details of the potentiometric data treatment were given in previous papers.[1,6]

*The functions $10^{E/0.059}$ and $Q10^{E/0.059}$ were utilized to linearize the potentiometric data obtained with strong and weak acids respectively.
†Evaluation based on a previous H_3PO_4 determination by the same technique.

RESULTS AND DISCUSSION

Acid–base systems

Strong and weak acids were titrated by cathodic reduction of hydrogen ions. The end-point was determined by extrapolation of the potentiometric data, linearized as a function of charge (Q) by means of the equations

$$S = 10^{E/0.059} \qquad (1)$$

$$S' = Q10^{E/0.059} \qquad (2)$$

for strong and weak acids respectively (E = potential). Typical results are shown in Table 1.

The accuracy and precision are quite satisfactory even for acids as weak as phenol. The sensitivity is limited by the linearization method, which does not take into account the autoprotolysis of water, which is not negligible for concentration regions lower than those examined here.

Precipitation reactions

Chloride, bromide and iodide were determined by precipitating them with silver ions coulometrically generated at a silver anode, the potential of which was monitored. The data were then linearized by means of function (1).

The pH must be selectively adjusted to get the best results for the various halides. We found the most suitable ranges to be: pH 9–10 for iodide; pH 7–9 for bromide, and pH ~ 5 for chloride.

The results obtained in the determinations of single halides are shown in Table 2, along with the experimental conditions, including pH.

It was observed that the time required by the electrode to reach equilibrium in the absence of current was not significantly affected by the thickness of the silver halide layer, which may be quite large for high sample concentrations.

The possibility of determining two halides in a mixture was also examined, and typical results are shown in Table 3.

In all cases tested the precision was slightly poorer than that for solutions containing only one halide. The overall error for the sum of the tested species was generally small, but it appears that there is some kind of mutual interference. This fact cannot be explained in terms of co-precipitation, however, since both negative and positive errors are found in the determination of the first ion.

As shown in Fig. 2, quite good results are obtainable for determination of all three halides in a mixture.

Homogeneous redox systems

Among the various redox couples examined, Fe^{3+}/Fe^{2+} and Ce^{4+}/Ce^{3+} deserve attention in view of the peculiarity of the method used (see below) to obtain a correct analytical determination of the oxidized forms.

Attempts at titrations by reduction at a platinum electrode (with a platinum indicator-electrode) were unsuccessful because these redox-couple electrode systems do not behave according to the Nernst equation.

To overcome this difficulty the possibility of utilizing a different redox system for indirect determination of Fe^{3+} and Ce^{4+} was considered.

Table 2. Silver halide precipitation: single-ion determinations

If a silver working-indicator electrode is used, once the reaction

$$nAg + Ox \rightarrow nAg^+ + Red \qquad (3)$$
has taken place, it might be expected from the relative values of the standard potentials that the Ox form initially present could be determined indirectly by titration[1] of the silver ions produced. Such a titration might be expected to be slow, reaction (3) being incomplete if electrolysis is started immediately after the electrode and the test solution come into contact, since a heterogeneous reaction system is involved. In practice, however, titrations done under different time schedules show that the results are not dependent on the time elapsed before the electrolysis is started. In all cases the amount of Ag⁺ found is equivalent to that of Ox initially present.

These facts can be rationalized by considering the dynamics of equilibration of the indicator electrode under these experimental conditions.

Reaction (3) will proceed during the potentiometric phases, throughout the titration, without current at the indicator electrode, mass transport being the limiting factor.

By use of Nernst's approximate concept of the diffusion layer, the flows (at the electrode) of the
Fig. 2. Titration plot of S ($=10^{-E/0.059}$) vs. Q (coulombs) for iodide, bromide and chloride, simultaneously present at equal concentration ($5 \times 10^{-3}M$) in a mixture: Q_T = theoretical equivalence point; Ag working electrode; sample volume 20 ml; electrolysis potentials (mV vs. SCE) −80, −50, +350 respectively for iodide, bromide and chloride. Titration of Br⁻ and I⁻ at pH 9, of Cl⁻ at pH 5.

Working electrode Ag; total sample solution 20 ml; electrolysis potential $+150$ mV *vs.* SCE.
*Values referred to the oxidized species (initial concentration of reduced species $= 0$).

species implicated in reaction (3) may be written as

$$D_{Ox}\left(\frac{[Ox]_\infty - [Ox]_0}{\delta_{Ox}}\right) = D_{Red}\left(\frac{[Red]_0 - [Red]_\infty}{\delta_{Red}}\right)$$

$$= D_{Ag^+}\left(\frac{[Ag^+]_0 - [Ag^+]_\infty}{\delta_{Ag}+}\right) \quad (4)$$

where D is the diffusion coefficient, δ the diffusion-layer thickness (which may be considered proportional to D^γ, with $0 < \gamma < 1$ in a stirred solution) and subscripts 0 and ∞ indicate the electrode surface and the bulk of the solution, respectively. If reaction (3) is shifted completely towards the right (that is $[Ox]_0 \sim 0$), we obtain

$$[Ag^+]_0 = n\left(\frac{D_{Ox}}{D_{Ag^+}}\right)^{1-\gamma}[Ox]_\infty + [Ag^+]_\infty \quad (5)$$

From the charge Q previously exchanged and the partial transformation due to reaction (3), the concentration of Ox in the bulk of the solution at any instant is given by

$$[Ox]_\infty = C_{Ox}^* - \frac{[Ag^+]_\infty}{n} - \frac{Q}{nFV} \quad (6)$$

where C_{Ox}^* is the initial Ox concentration, F is the Faraday constant and V is the volume of solution. If $D_{Ox} \sim D_{Ag^+}$, from (5) and (6) we obtain

$$[Ag^+]_0 = nC_{Ox}^* - \frac{Q}{FV} \quad (7)$$

which indicates that, just as in the case of Ag^+ titration, the concentration of the silver ion at the electrode is only a function of the degree of electrolysis, and not of the chemical reaction.

Furthermore the electrode potential measured in the potentiometric phase will depend on the equilibrium

$$Ag \rightleftharpoons Ag^+ + e^-$$

which will lead to an equation of the type

$$S = 10^{E/0.059} = K(nC_{Ox}^* VF - Q) \quad (8)$$

if equation (7) for $[Ag^+]_0$ is substituted into the Nersnt equation.

It should be noticed that for a truly homogeneous redox system, linearization should be done by means of a function of type (2).

Typical results obtained in the titration of Ce^{4+} and Fe^{3+} with a silver electrode (in a three-electrode configuration), by linearization of the potentiometric data according to equation (8), are reported in Table 4 and show the fairly good accuracy, precision and sensitivity of the procedure proposed. In particular, the narrow range of the confidence limits and the values of the correlation coefficients confirm that linearization according to equation (8) is valid, and that the behaviour of the silver electrode has been correctly interpreted.

These facts show the possibility of overcoming irreversibility problems in reductions by making use of a type-1 electrode with a standard potential more negative than that of the redox couple under examination. It should be pointed out, however, that in the case of the titration of Fe^{3+}, the equilibrium constant of reaction (3) is small (~ 0.33, as calculated from the standard potentials); nevertheless the reaction can be considered sufficiently shifted towards the right for the observed behaviour, provided the iron concentration is much smaller than $0.33M$. This type of indirect titration offers clear advantages with respect to other indirect procedures.

DIFFERENTIAL PULSE POLAROGRAPHIC DETERMINATION OF NITRATE IN ENVIRONMENTAL MATERIALS

Hirotoshi Hemmi

Graduate School of Environmental Science, Hokkaido University, Sapporo 060, Japan

Kiyoshi Hasebe,* Kunio Ohzeki and Tomihito Kambara†

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060, Japan

Summary—Nitrate can be determined with reliable accuracy and sensitivity by differential pulse polarography utilizing the catalytic reaction between nitrate and uranyl ion in the presence of potassium sulphate. The differential pulse polarographic peak-height is proportional to nitrate concentration from 1 to 50 μM. The calculated detection limit for nitrate is $8 \times 10^{-7} M$ in pure aqueous solution. The method has been applied to determination of nitrate in fresh snow, and river waters and animal feeds.

Because of the importance of the role of nitrite and/or nitrate as a precursor in the formation of *N*-nitrosamines, which can be formed in water and sewage, at least *in vitro*,[1-3] it is essential that a sensitive and accurate method be available for the determination of these ions. Many methods have been reported for the determination of nitrate, principally involving colorimetry. These methods have been summarized.[4] They all have limited sensitivity and dynamic range, and frequently depend on unstable colours and long reaction times. Methods based on use of an ion-selective electrode are very simple, but the results vary because of interference from co-existing ions, and because of effects dependent on the previous history of the electrode.[5-8] Determinations of nitrite and of nitrate by polarography have been reported. Chang *et al.*[9] have studied the differential pulse polarographic determination of nitrite, based on nitrosation of diphenylamine in the presence of sodium thiocyanate as catalyst. This method is most sensitive and has been extended to include determination of nitrate subsequent to that of nitrite. Kato *et al.*[10] reported a polarographic determination of nitrite and nitrate by use of the catalytic wave of the 1,2-diaminocyclohexanetetra-acetate (DCTA) complex of vanadium (IV). However, as the determination of nitrate in the mixture was affected by nitrite, a calibration curve for nitrate in the presence of a known amount of nitrite was obtained by using 1–10mM V(IV)–DCTA, and nitrate in the mixture could then be determined. The d.c. polarographic determination of nitrate in the presence of

uranyl ion in acid solution has been described by Kolthoff *et al.*[11] and by Keilin and Otvos.[12] The simultaneous reduction of uranyl ion catalyses the reduction of nitrate in dilute hydrochloric acid medium. The first uranium wave results from the reduction of uranium(VI) to the quinquevalent state, and the second corresponds to reduction of uranium(V) to the tervalent state. The catalytic nitrate wave occurs at the same potential as the second uranium wave. The catalytic mechanism has not been clarified and is complicated: uranium(III) formed at the electrode surface might be the actual nitrate-reducing agent.

In this paper, we have re-examined the catalytic reaction between nitrate and uranyl ion by differential pulse polarography (DPP). The present work aimed at establishing the most suitable and effective conditions for the determination of nitrate in actual environmental samples, with satisfactory sensitivity, precision and simplicity.

EXPERIMENTAL

Reagents

All chemicals used were of analytical reagent grade and were dissolved in demineralized and distilled water. A standard 0.02M uranyl solution was prepared by dissolving 4.2408 g of uranyl acetate [$UO_2(CH_3COO)_2 \cdot 2H_2O$] in 60 ml of 6$M$ hydrochloric acid, and making up accurately to 500 ml with water; it was kept in a polyethylene bottle. Dilute solutions of nitrate were prepared from a stock 1.00 × 10^{-2}M potassium nitrate solution, by appropriate quantitative dilution or direct pipetting into samples. Purified nitrogen was used for deaerating solutions, and keeping them oxygen-free.

Apparatus

Polarographic data were obtained with a Model P-1000 Voltammetric Analyser with a mechanical drop knocker (Yanagimoto Mfg. Co., Japan), and recorded on a

---

Watanabe X–Y recorder, Model WX-4401. The dropping
mercury electrode (DME) used had the following character-
istics: mercury flow-rate $m = 0.9647$ mg/sec in water (open
circuit), and natural drop-time $t_d = 8.50$ sec in $0.1M$ hydro-
chloric acid containing potassium sulphate and $10^{-4}M$
uranyl acetate, at a mercury head $h = 70.0$ cm. An SCE was
used as reference, and a platinum wire as the counter-
electrode. Except for temperature-dependence studies, the
polarographic solutions were kept at constant temperature
$(25 \pm 0.5°)$ in a thermostatic bath.

Analytical procedures

Animal feeds. Weigh accurately about 0.5 g of powdered
sample, previously dried in the oven at 75° for 90 min, and
transfer it into a stoppered flask or bottle with about 120 ml
of water. Shake the mixture for 30 min, then filter with a No.
5A filter paper (Toyo Roshi Co.), and wash the filter paper
with a small amount of water. Filter the extract and
washings through a 0.65-μm membrane filter, and dilute
accurately to 200 ml with water. The yield in a single
extraction is about 98% and a second extraction makes the
yield completely quantitative. Pipette a suitable volume of
the extract into the supporting electrolyte solution, and
deaerate for about 10 min. Measure the catalytic nitrate
reduction wave in the DP mode in the potential range from
-0.75 to -1.1 V vs. SCE, and then calibrate by the
standard addition procedure, or use an appropriate cali-
bration graph. Under typical optimized working conditions,
the corresponding linear regression equation and the
coefficient of correlation, r, are $C = 18.08\,i_p - 25.22$ and
$r = 0.999$, the units being μM for C and μA for i_p.

River waters and snow. Just before analysis, thaw the
frozen samples of river water or snow, stored in the
refrigerator, and filter through a 0.45-μm pore-size mem-
brane filter. Add an appropriate volume of the filtrate to the
supporting electrolyte and use without further treatment,
because there are unlikely to be any interfering substances
present. Complete the determination as described for animal
feeds.

RESULTS AND DISCUSSION

Effect of pH on the catalytic reduction

The reduction of uranyl ion in acid solution by d.c.
polarography gives two waves, the first resulting from
the reduction of U(VI) to U(V) and the second, which
is almost twice as large as the first, corresponding to
a further 2-electron reduction to the tervalent state.
Fig. 1. Differential pulse polarograms of uranyl ion with and
without nitrate present. Conditions: $[UO_2(CH_3COO)_2] =$
$100\mu M$; $[K_2SO_4] = 5mM$; pH 1.0 (HCl); pulse amplitude,
-100 mV; scan-rate, 1 mV/sec; pulse interval, 6 sec. (A):
$[KNO_3] = 0\mu M$. (B): $[KNO_3] = 20\mu M$.
Fig. 2. Effect of pH on the DP peak current. Conditions:
$[UO_2^{2+}] = 100\mu M$; $[KCl] = 0.1M$; pH adjusted with HCl.
(A): $[KNO_3] = 0\mu M$. (B): $[KNO_3] = 100\mu M$. Other condi-
tions are the same as for Fig. 1.

If nitrate is present in the polarographic solution, the
catalytic nitrate wave occurs at the same potential as
the second uranium wave, as shown by the typical DP
polarograms in Fig. 1. However, the height of the
second peak is almost the same as that of the first,
though it is accompanied by a DPP prewave. The
pH-dependence of the height of the catalytic nitrate
peak is shown in Fig. 2. Over the pH range from 0.7
to 1.4, the electrode chemical reaction for the
uranium–nitrate system, and hence the catalytic peak,
is found to be relatively unaffected by the polaro-
graphic measurement time. An optimum pH of 1.0
was chosen for further study in order to characterize
the electrode process and for the development of an
analytical procedure. Above pH 1.5, the second peak
of uranium(V) decreases gradually with increasing
pH, and the catalytic peak current also decreases
because of the decrease of effective concentration of
uranium(V) in the electrical double-layer or possibly
because of a change in the rate of reaction. The slope
of the usual log plot for the first d.c. wave is 60 mV,
corresponding to reversible reduction with $n = 1$. The
peak half-width, $W_{1/2}$, at a pulse amplitude of -100
mV is 128 mV, almost equal to the theoretical value
of 125 mV for $n = 1$. The log plot for the second
wave, however, gives a straight line with slope of 78
mV, so the reduction of uranium(V) to uranium(III)
does not proceed reversibly. The half-width of the
second peak is the same as that for the first peak,
which is 23% larger than the theoretical value of 102
mV for $n = 2$. The second d.c. wave is almost twice
as high as the first wave, which would be expected for
twice the charge transfer. However, the two peaks in
DPP are almost the same in width, because though
the first step is reversible, the second is not.

Effect of uranyl ion concentration

If we use larger amounts of uranyl ion as the
activator, the wave at -0.93 V vs. SCE becomes
correspondingly greater. The minimum uranyl ion
Fig. 3. Effect of uranyl ion concentration on the nitrate reduction peak current. Conditions the same as for Fig. 1 except for uranyl ion concentration.

concentration is that required to maintain linearity between the current and the nitrate concentration. The nitrate limiting current is measured as the difference between the total current at -0.93 V vs. SCE and the limiting current for the uranyl ion, as determined in a blank experiment. The ratio, R, of the nitrate current, D, to the limiting current for the uranyl ion, A, is plotted in Fig. 3 as a function of the uranyl ion concentration: the lower this concentration, the greater the ratio, R. However, we have found a bigger spread of results when low concentrations of uranyl ion are used, and therefore conclude that the uranyl ion concentration is best kept at $100\mu M$.

Effect of chloride and sulphate concentration

The influence of several salts on the peak-height was next studied. The nitrate catalytic reduction wave gradually decreased with increasing chloride concentration above $0.1M$, but at chloride concentrations below $0.1M$, the peak-height remained unchanged. Figure 4 shows the effect of sulphate concentration on the nitrate reduction current. The catalytic peak current reaches a maximum at sulphate concentrations higher than $5mM$. Thus, the current when the chloride concentration is below $0.1M$ and the sulphate is about $5mM$ is about 1.4 times that when no sulphate is present. If we consider the interaction of uranyl ion and nitrate in the presence of chloride in terms of some specific effects of anions in solution and in the electrical double-layer, we can see similarities to the behaviour of Methylene Blue and leuco Methylene Blue in the presence of certain anions.[13,14] Chloride is known to be specifically adsorbed on the mercury electrode.[13,14] The addition of sulphate causes an increase in the catalytic current, suggesting that sulphate displaces chloride from the adsorbed

layer and then itself contributes to the interaction between uranyl ion and nitrate.

Effect of standing time and temperature

Solutions containing potassium nitrate at $50\mu M$ concentration (3.1 ppm) were allowed to stand in the laboratory at room temperature for a month. On analysis the peak height and wave form were found to be unchanged, with a relative standard deviation of 0.5% ($n = 150$) over the period. The temperature-dependence of the catalytic peak was also studied in the range between 5 and 35°. The relative temperature coefficient of the peak-height was 2.8%/deg at 20° because of the catalytic mechanism, but that of the second peak of the uranyl ion was only 1.3%/deg, which is typical of a diffusion-controlled electro-reduction.

Effect of instrumental parameters

In the case of hydrogen evolution catalysed by tellurium(IV), the slower the scan-rate, the greater the peak current and the higher the sensitivity.[15] In this work, the catalytic nitrate reduction peak-current was almost independent of scan-rate from 0.5 to 1 mV/sec. We chose 6 sec as drop-time because the peak-height gradually increased with drop-time. It was also found advantageous to use a large modulation amplitude, e.g., $\Delta E = -100$ mV for these micro determinations.[16]

Interferences

The effects of several common ions on the determination was examined, and tolerances for them are given in Table 1. Nitrite and phosphoric acid interfere seriously and should be absent if accurate results are to be obtained. The tolerance for some interferents
Fig. 4. Effect of sulphate concentration on the DP peak height. Conditions: pH 1.0 (HCl); other conditions the same as for Fig. 2 except for K_2SO_4 concentration and curve (C). (C): without KCl.

Table 1. Permissible concentrations of foreign ions in the determination of 10 μM NO_3^- (to give $< 5\%$ error)

Species	Added as	Concentration, M
Na^+	NaCl	0.1
K^+	KCl	0.1

H_3PO_4	K_2HPO_4	10^{-6}
SiO_2	SiO_2 (carbonate fusion)	0.1
NO_2^-	KNO_2	6×10^{-6}

Polarographic solution $1 \times 10^{-5}M$ $KNO_3 + 10^{-4}M$ $UO_2(OAc)_2 + 5mM$ K_2SO_4 adjusted to pH 1.0 with HCl. Modulation amplitude -100 mV; scan-rate 1 mV/sec; pulse interval 6 sec.

such as heavy metal ions can be improved by addition of masking reagents (e.g., EDTA). The strongest interference is given by phosphoric acid, which is significant even when the acid is present at the same concentration as nitrate, since it forms a stable uranyl salt.

Comparison with another method

To verify the validity of the DPP technique, river water samples were analysed by high-pressure liquid chromatography (HPLC) with a Zorbax Sil ion-association silica-gel column. The agreement between the two sets of results (Table 2) suggests that the DPP method can be used with a fair degree of confidence. Further results for river waters and for snow are shown in Table 3. The river water samples were also tested for nitrite, but no nitrite peak was observed on the HPLC chromatograms. It was concluded that the nitrite content did not exceed $1.5\mu M$ (the detection limit of the HPLC method).

Sample storage and nitrate extraction

All dried plant and silage samples were ground to pass through a 0.5-mm sieve, then stored in sealed

Table 2. The comparison of the DPP and HPLC methods

	Nitrate found, μM

containers at room temperature. According to Milham et al.,[5] water samples stored under atmospheric conditions often show spectacular changes in nitrate content. Therefore, these samples must be analysed as soon as possible, or be frozen to suppress microbial action.

The efficiency of nitrate extraction under various conditions was studied and the extracted nitrate was determined by HPLC. The results of the extraction of nitrate from animal feeds was independent of the phase-volume ratio, and duration of shaking from 10 to 60 min (at 100 strokes/min). Nitrate was extracted quantitatively by all variations of sample treatment. The results obtained by the procedures described are given in Tables 3 and 4. The nitrate concentrations in the upstream river samples show little variation, but increase downstream because of microbial action and run-off from agricultural land that has been treated with fertilizers. The nitrate contents of the plants show a wide variation, which is probably due to breeding and environment rather than the kind of plant.

KINETIC–SPECTROPHOTOMETRIC DETERMINATION OF Cu(II) AND PYRIDINE BY USE OF THE AERIAL OXIDATION OF DIMEDONE BISGUANYLHYDRAZONE

F. Salinas López, J. J. Berzas Nevado and A. Espinosa Mansilla
Department of Analytical Chemistry, Faculty of Sciences, University of Extremadura, Badajoz, Spain

Summary—The synthesis and analytical properties of dimedone bisguanylhydrazone (DIBG) are described for the first time. DIBG is oxidized by aerial oxygen and the reaction is catalysed by copper(II). The catalytic effect of copper(II) is increased by the presence of pyridine. Kinetic methods are described for determining trace amounts of copper(II) and pyridine. The reaction is followed spectrophotometrically by measuring the rate of change of absorbance at 550 nm. The calibration graphs are linear in the range 0.6–9.5 μg for copper(II) and 0.2–8.8 mg for pyridine. The methods have been applied to the determination of copper in galena and of pyridine in piperidine and isoamyl alcohol. The kinetic parameters of the reaction have been determined.

Schiff's bases, including oximes, hydrazones, thiosemicarbazones, *etc.*, are interesting as analytical reagents as they form complexes with transition metals, and also because their oxidation may be catalysed by metal ions, in particular by copper(II).[1] However, guanylhydrazones have not been very much studied as analytical reagents.

We have initiated the study of these Schiff's bases with pyridine-2-aldehyde guanylhydrazone (PAG)[2] which forms yellow complexes with copper, cobalt, palladium, nickel and iron(II). In this paper, the synthesis and analytical properties of dimedone bisguanylhydrazone (DIBG) are described for the first time. DIBG undergoes aerial oxidation at pH ≃ 7, catalysed by copper(II), producing a red-violet colour suitable for a spectrophotometric kinetic determination of trace amounts of copper, in which the rate of change of absorbance at 550 nm is measured. The rate of the catalysed reaction increases in the presence of pyridine, which can therefore also be determined by this approach. The action of pyridine as an activator in catalysis by copper(II) has been discussed by Bontchev[3] and has been used for analytical purposes.[4]

EXPERIMENTAL

Apparatus

A Zeiss DMR 11 spectrophotometer equipped with constant-temperature cell-holders and 1.0-cm glass or quartz cells.

Solutions

All reagents should be of analytical-reagent grade.

Dimedone bisguanylhydrazone reagent solution, 0.1%

Copper(II) solution. Prepare by dissolving copper oxide in nitric acid and diluting with water, and standardize.

Buffer solution, pH 7.9. Dissolve 12.11 g of tris-(hydroxymethyl)aminomethane (Tris) in 42 ml of 1*M* perchloric acid and dilute with water to 1 litre.

Buffer–fluoride solution, pH 7.9. Dissolve 12.11 g of tris-(hydroxymethyl)aminomethane (Tris) and 83.98 g of sodium fluoride, and enough 1*M* perchloric acid to give pH 7.9, and dilute with water to 1 litre.

Aqueous pyridine solutions.

Synthesis of dimedone bisguanylhydrazone (DIBG)

Dissolve 2.15 g of aminoguanidine bicarbonate in 10 ml of water and neutralize with hydrochloric acid. Add the mixture to 1.10 g of dimedone in 40 ml of ethanol, then add 3 ml of concentrated hydrochloric acid, reflux for 2 hr and cool. Filter off the white product and wash it with ethanol–water (4:1 v/v). Yield 60%, m.p. 273°. Found: 31.6% C, 6.1% H, 30.3% N, 28.2% Cl. Calculated for $C_{10}H_{17}N_8 \cdot 3HCl \cdot H_2O$: 31.87% C, 5.84% H, 29.74% N, 28.15% Cl.

Determination of copper

To a solution containing between 0.6 and 9.5 μg of copper, in a 25-ml standard flask, add 1 ml of pH-7.9 buffer, 3 ml of 2.5*M* pyridine and 1 ml of DIBG solution and dilute to volume with water. Mix well, then transfer a portion to a 1.0-cm cell at 25 ± 0.1° and follow the reaction by recording the absorbance (*vs.* a reagent blank) at 550 nm as a function of time, beginning the measurements 1 min after preparation of the sample. Calculate the reaction rate from the slope of the absorbance–time curve.

Determination of copper in galena

Weigh out about 0.2 g of dried sample and dissolve it in a few ml of nitric acid. Add about 10 ml of water and some sodium sulphate to precipitate lead sulphate. Centrifuge the solution to separate the precipitate and transfer the solution to a 25-ml standard flask. Add the washings, then make up to the mark with water. Transfer an aliquot to another 25-ml standard flask, neutralize with sodium hydroxide to the pale pink colour of phenolphthalein as indicator, then add 1 ml of pH-7.9 buffer–fluoride solution, 3 ml of 2.5*M* pyridine and 1 ml of DIBG solution, dilute to volume with water and complete the determination as above.

Determination of pyridine

To an aqueous solution containing 0.2–8.8 mg of pyridine, in a 25-ml standard flask, add 1 ml of pH 7.9 buffer solution, 2 ml of DIBG solution, 5 ml of $3.2 \times 10^{-4}M$

copper(II) and dilute to volume with water. Transfer an aliquot of the reaction mixture to a 1.0-cm cell at $25 \pm 0.1°$ and make the kinetic measurements as for copper determination.

Determination of pyridine in piperidine

To 1 ml of a $2M$ neutralized aqueous solution of piperidine, in a 25-ml standard flask, apply the procedure specified for pyridine determination: 0.3% of pyridine in piperidine can be determined.

Determination of pyridine in isoamyl alcohol

Shake 2 ml of the alcohol with 80 ml of water in a 100-ml standard flask till a single phase is obtained. Dilute to the mark with water, mix well, then transfer 10 ml of this solution to a 25-ml standard flask and follow the procedure for pyridine determination: 0.3% of pyridine in isoamyl alcohol can be determined.

RESULTS

Analytical properties of the reagent

DIBG is very soluble in water, dimethylsulphoxide (DMSO) and dimethylformamide (DMF) and sparingly soluble in ethanol, at room temperature. The infrared spectrum (KBr disc) shows bands assignable to the stretching vibrations of $-NH-$ and $-NH_2$ (3100 and 3400 cm^{-1}), and to the guanidinium group (1610 and 1670 cm^{-1}). The ultraviolet absorption spectrum for DIBG in water shows a maximum at 294 nm. The NMR spectrum indicates the most likely structure to be
The dissociation constant for an aqueous solution of $2.6 \times 10^{-5}M$ DIBG was determined by the Stenström and Goldsmith method[5] at ionic strength 0.1, temperature 20°, and different pH values from 0.5 to 8.0. Solutions of pH > 8 are unstable and the spectrophotometric measurements are no longer reproducible. The average result obtained was $pK = 3.7 \pm 0.2$.

Reactions with inorganic ions

The reactions of DIBG with 40 inorganic ions, up to a concentration of 1 g/l., at various pH values, were tested. The most interesting reactions took place in neutral medium with copper(II) and platinum (IV), a red-violet colour being produced.

Permanganate, dichromate, persulphate, periodate and ferricyanide react with DIBG, giving the same red-violet colour. Mercury(II) gives a violet precipitate which is insoluble in organic solvents (*e.g.*, ethanol, DMF, DMSO).

Spectrophotometric study of the copper(II)–DIBG system

In the preliminary studies of this reaction, we

observed that the sensitivity towards copper(II) was concentration-dependent, and that with more dilute solution the colour was slower to appear. Because the colour obtained with oxidizing species was the same as that produced with copper, we concluded that an oxidation was taking place, with oxidation by aerial oxygen dissolved in the solution, and that the reaction was catalysed by copper ions.

We also found that DIBG in neutral aqueous solutions was slowly oxidized by a stream of air, but was stable under an atmosphere of nitrogen even when small amounts of copper were present. Only when higher concentrations of copper were present was the red-violet colour then observed.

The catalytic behaviour has been used in a new kinetic–spectrophotometric method for determining trace amounts of copper.

Catalytic effect of copper(II)

The catalytic action of copper(II) is favoured in neutral medium by the presence of a few mmoles of pyridine. The absorption spectrum of the complex, and its variation with time are shown in Fig. 1, from which the reaction rate can be calculated.

Effect of reaction variables

The oxidation of DIBG is influenced by the reagent and copper(II) concentrations, pH, buffer composition, pyridine concentration and temperature. All these variables have been investigated, by the tangent method. The fixed time or fixed absorbance methods cannot be applied because the red-violet colour is not sufficiently stable.

The effect of temperature on the reaction rate $(dA/dt = \tan \alpha)$ was studied in the range 10–43° with solutions containing 200 ng of Cu(II), 5 ml of 0.01%
Fig. 1. Variation of absorption spectra of DIBG in presence of Cu(II). (a) DIBG-Cu(II) at 11 min; (b) DIBG-Cu(II) at 15 min; (c) DIBG.
Fig. 2. Absorption vs. time curves as a function of temperature.

DIBG solution, 5 ml of 1M pyridine and 5 ml of pH 7.5 buffer solution. The absorbance–time curves (Fig. 2) show the temperature dependence. The plots of log tan α vs. 1/T are linear between 286 and 303 K. A temperature of 298 K was chosen for subsequent studies. It would be preferable to bring all solutions employed to this temperature before mixing them.

The pH-dependence of the system was studied by use of mixtures of tris(hydroxymethyl)aminomethane (Tris) and perchloric acid. Hydrochloric acid was also tried, but chloride decreases the reaction rate, whereas perchlorate does not.

Two solutions, one of Tris and the other of pro-

tonated Tris (TrisH$^+$), obtained by mixing equimolar solutions of Tris and perchloric acid, were prepared, and with these, two series of samples were made: in one the concentration of Tris was kept constant, and in the other the concentration of TrisH$^+$ was kept constant.

Taking into account that the other reagent concentrations remain constant, the following relationships should be valid:

$$\log(\tan\alpha/[\text{TrisH}^+]^n) = K - x\,\text{pH} \tag{1}$$

$$\log(\tan\alpha/[\text{Tris}]^m) = K' - x\,\text{pH} \tag{2}$$

The absorbance vs. time curves for [Tris] = constant and [TrisH$^+$] = constant are shown in Fig. 3. By plotting equations (1) and (2), for different m and n values, polygonal graphs were obtained, the slopes of which coincided only for $m = -1$ and $n = 0$. From these graphs (Fig. 4), the following x values were obtained:

$$x = -2 \ (\text{pH} < 7.4); \ x = -1 \ (7.4 < \text{pH} < 8.0)$$

and

$$x = 1 \ (8.0 < \text{pH} < 8.4).$$

For pH > 8.4 the solutions are unstable.

The effect of DIBG concentration on the reaction rate was studied in the range from $0.21 \times 10^{-4}M$ to $2.63 \times 10^{-4}M$. A logarithmic plot showed that the reaction rate was independent of the DIBG concentration in the range 0.74–$2.50 \times 10^{-4}M$. For lower
Fig. 3. Absorbance vs. time curves for [Tris] = constant and [TrisH$^+$] = constant at different pH values.
Fig. 4. Determination of pH reaction order for protons at different pH values.

DIBG concentrations an order of 2/3 was found, and for higher DIBG concentrations an order of $-2/3$ (Fig. 5). A $1 \times 10^{-4}M$ DIBG concentration was chosen for subsequent studies; this concentration was obtained by use of 1 ml of 0.1% DIBG solution per 25 ml of final solution.

Pyridine increases the reaction rate. This effect was studied for solutions containing 150 ng/ml copper(II) and different pyridine concentrations. A logarithmic plot showed that the reaction rate depended linearly on the pyridine concentration in the range 0.05–0.4M. The partial order for pyridine in the rate equation is 1. Smaller amounts of pyridine can be used when the copper(II) solutions for analysis are more concentrated, but a 0.3M pyridine concentration was chosen for further work, obtained by use of 3 ml of 2.5M pyridine per 25 ml of final solution.

Rate equation and calibration graphs

The absorbance *vs.* time curves for solutions con-

taining different amounts of Cu(II) were recorded, measured against similar solutions containing no Cu(II). On the basis of the kinetic investigation, the following equation is suggested for the copper(II)-catalysed oxidation of DIBG at pH 7.9 in the concentration range 0.74–$2.50 \times 10^{-4}M$.

$$d(DIBG)_{ox}/dt = K\frac{[\text{pyridine}][\text{Cu(II)}]}{[H^+][\text{Tris}]} \quad (3)$$

The tangent method was applied to the absorbance *vs.* time curves. The calibration graph is linear over

e	159	167

*Mean value for three samples.

the Cu(II) concentration range 25–380 ng/ml. The relative error (95% confidence level) is 0.9% for 200 ng/ml.

Interferences

The influence of foreign ions was examined by the tangent method. The results are summarized in Table 1. Cyanide, EDTA, ferrocyanide and ferricyanide interfere seriously by decolorizing the solution. The interferences from Fe(III), Zr and Be are caused by precipitation of the corresponding hydroxides, but can be eliminated by the addition of fluoride.

Application to the estimation of copper in galena

The interference study shows that the method can be used for determining copper in some natural samples. We have applied the method to galena and compared the results with those obtained by atomic-absorption spectrometry. Five different galenas were tested. The results are shown in Table 2.

Determination of pyridine

Equation (3) shows that pyridine can also be determined by the kinetic-spectrophotometric method. To increase the sensitivity of this determination, higher copper(II) concentrations are used.

We had verified previously that 200 ppm of pyridine will increase the reaction rate for copper concentrations up to 24 ppm. For higher copper(II) concentrations equation (3) is not valid. A 20-ppm copper level was chosen for the determination of pyridine, and a DIBG concentration of $2 \times 10^{-4}M$. Under these conditions, equation (3) remains unchanged.

The absorbance *vs.* time curves for solutions containing different amounts of pyridine were recorded, with measurement against similar solutions containing no pyridine.

The calibration graph (tangent method) is linear over the pyridine range 8–350 μg/ml, becoming convex at higher concentrations. The relative error (95% confidence level) is $\pm 2\%$ for 150 μg/ml.

			3.50	3.53	+0.8
			4.34	4.25	−2.1

*Mean value for three samples.

The influence of various organic compounds on the reaction rate was tested. The results are summarized in Table 3. From the study of piperidine, we concluded that the concentration of piperidine should not be greater than 0.16M since higher concentrations produce an interference, independent of the pyridine concentration. On the other hand, the permissible volume of isoamyl alcohol is limited solely by its solubility in water.

We have therefore applied the method to determination of pyridine in piperidine and isoamyl alcohol. The results are summarized in Table 4. A 0.3%

level of pyridine in piperidine or isoamyl alcohol can be determined with 4% error.

SAMPLING AND ANALYSING MIXTURES OF SULPHATE, SULPHITE, THIOSULPHATE AND POLYTHIONATE

Carl O. Moses*, D. Kirk Nordstrom† and Aaron L. Mills
University of Virginia, Department of Environmental Sciences, Clark Hall, Charlottesville, VA 22903, U.S.A.

Summary—Interpreting the redox chemistry of sulphur in aqueous systems requires the analysis of mixtures of various sulphoxy anions. Previous methods have been too involved to permit high sample throughout if good quality control is to be maintained. Methods based on ion chromatography have been developed for the direct determination of SO_4^{2-}, SO_3^{2-}, $S_2O_3^{2-}$ and SCN^-. The determination of thiocyanate permits the indirect determination of polythionates by treatment with cyanide. Formate, acetate, F^-, Cl^-, CO_3^{2-} and PO_4^{3-} do not interfere, but NO_2^- and NO_3^- interfere with determination of SO_3^{2-}. The sample preservation treatment includes addition of formaldehyde, cation-exchange and cold storage, to retard oxidation of $S_2O_3^{2-}$ and SO_3^{2-}, and inhibits the rearrangement of $SO_3^{2-}/S_2O_3^{2-}/S_nO_6^{2-}$ mixtures caused by bimolecular nucleophilic displacement (S_N2) reactions. Treated samples may be stored for up to 6 weeks with only minor loss of thiosulphate.

The analysis of mixtures of sulphoxy anions in aqueous solution is a valuable and necessary tool for investigating the chemistry of sulphur-rich wastewater effluents such as mining and milling wastes,[1] oil-shale retort wastes,[2] paper pulp wastes,[3] and acid mine drainage.[4] Hydrogeochemical processes also involve mixtures of dissolved sulphur species in various oxidation states, *e.g.*, redox processes in sulphur-rich groundwaters[5] and geothermal waters,[6] pyrite oxidation in alkaline waters,[7] and sulphur oxidation in soils.[8] The present work was aimed at determining concentrations of stable and metastable sulphoxy anions, *viz.*, sulphate, sulphite, thiosulphate and the polythionates (sulphane disulphonates, $S_nO_6^{2-}$, $n = 4–6$).

Numerous methods are available for analysing solutions of the single species sulphite, thiosulphate, sulphate, and polythionate.[9–13] The analysis of solutions that contain mixtures of these species is difficult, owing to similarities in the reactions with the reagents used (*e.g.*, sulphite and thiosulphate with iodine) or because reactions between the sulphoxy species alter the solution composition. Previous methods of analysing mixtures have relied on complicated schemes for determining the ions partly collectively and partly individually; in some cases, one of the species must be determined by difference. Table 1 compares several schemes by which mixtures of sulphoxy anions have been analysed. Their principal limitations are (*a*)

failure to account for all four sulphoxy species dealt with in this study, (*b*) low sample throughput owing to the time that each aliquot requires for analysis, (*c*) complex manipulations that introduce the risk of contamination or other error, and (*d*) failure to stabilize the mixtures properly at the time of sampling. The method developed in the work described here is rapid and reliable, has no complicated manipulations, and includes provision for stabilizing samples for storage. It requires only two aliquots of each sample (total of 7 ml) for the direct determination of sulphite, thiosulphate and sulphate, the indirect determination of total $S_nO_6^{2-}$ ($n = 4–6$) and the average value of n.

Summary of aqueous sulphoxy anion chemistry

There are two general types of reaction that metastable sulphoxy anions readily undergo: redox and bimolecular nucleophilic displacement (S_N2) reactions. In solutions that contain molecular oxygen or other oxidants, these species tend to be oxidized to sulphate. Attainment of stable equilibrium in the aqueous systems may be slow and the metastable species also tend to interact and disproportionate. The result of these reactions is over-recovery of sulphate and under-recovery of the other species, as well as the change in composition of complex mixtures. A survey of the reactions which can alter the sample composition is therefore a necessary part of analytical method development. Sulphite oxidation is mediated by free radicals, catalysed by redox-sensitive transition metal ions [*e.g.*, Fe(III) and Cu(II)], and is fastest when the pH is below 7 and

bisulphite (HSO$_3^-$) predominates over sulphite.[28–32] Oxidation of thiosulphate (to tetrathionate and thence to sulphate) is also mediated by radicals and catalysed by oxidants such as I$_2$, Fe(III), and Cu(II).[33]

Although thiosulphate is not oxidized very rapidly in the absence of transition metal ions, it is prone to acid decomposition at pH < 5 to sulphite and elemental sulphur. The mechanism of this reaction leads to a complex mixture of species and involves a chain of S$_N$2 reactions as shown in Fig. 1.[34,35] If the chain terminates with ring closure (Fig. 1B), the overall stoichiometry is

$$8S_2O_3^{2-} + H^+ \rightarrow S_8 + 7SO_3^{2-} + HSO_3^- \qquad (1)$$
The mechanism in Fig. 1C provides other terminations that lead to polysulphides [very unstable in the presence of S(IV)] and polythionates, as well as fragmentary elemental sulphur chains.

An aqueous mixture of sulphite, thiosulphate and polythionate is known as Wackenroeder's solution. The metastable equilibrium

$$S_nO_6^{2-} + S_2O_3^{2-} \rightleftharpoons S_{n+1}O_6^{2-} + SO_3^{2-} \qquad (2)$$
governs the interactions of these species.[36–41] This equilibrium involves S$_N$2 reactions like the one illustrated in Fig. 1D. Sulphite is a stronger nucleophile than thiosulphate, so pH > 7 favours polythionate chain-shortening, whereas bisulphite formation, at pH < 7, removes sulphite from reaction (2) and favours chain-lengthening. Since reaction (2) is a metastable equilibrium, and thiosulphate and sulphite are so easily removed from the system, the behaviour of Wackenroeder's solution is difficult to predict by applying thermodynamic relationships or to measure

experimentally. Although the qualitative behaviour of metastable sulphoxy species has been extensively reviewed,[12,38,42] much work remains in the development of quantitative models.

Reaction quenching

For analytical results to represent accurately the solution composition at the time of sampling, the redox and S$_N$2 reactions outlined above must be quenched. Ideally, the samples should be analysed immediately after sampling. In practice, this is rarely possible, so the sample composition must be stabilized for storage.

Formaldehyde has proved to be a particularly useful inhibitor of sulphite oxidation. Its most familiar form, an aqueous solution of dihydroxymethane, is produced by the rapid hydration of gaseous formaldehyde upon dissolution in water:[43]

$$H_2C = O + H_2O \rightarrow H_2C(OH)_2 \qquad (3)$$
Dihydroxymethane and bisulphite form an addition product, hydroxymethanesulphonate, which is resistant to oxidation:[44]

$$H_2C(OH)_2 + HSO_3^- \rightleftharpoons H_2C(OH)(SO_3)^- + H_2O \qquad (4)$$
Reaction (4) is reversed at high pH, so the addition product is a convenient means of fixing sulphite as long as the sample pH can be kept below 7 until the time of analysis.[11,23–25] This is particularly convenient for ion-chromatography (IC) methods because there is usually no obstacle to keeping the sample pH below 7, and the IC eluent pH is > 11, causing the reversal of reaction (4). Furthermore, hydroxymethanesulphonate can be crystallized as a sodium salt,

A. Nucleophilic attack of thiosulphate on trisulphane monosulphonate, yielding tetrasulphane mono-sulphonate and sulphite.
B. Ring closure of octasulphane monosulphonate, yielding solid sulphur and bisulphite.
C. Alternative direction of attack of thiosulphate on trisulphane monosulphonate, yielding disulphide and tetrathionate.
D. Rearrangement of Wackenroeder's solution, a mixture of sulphite, thiosulphate, and polythionates.

$NaSO_3H_2COH$, a stable primary standard for sulphite.[23]

Thiosulphate is not as sensitive to air oxidation as sulphite, and the anhydrous sodium salt is suitable as a primary standard. Thiosulphate is, however, easily oxidized in solution by transition metal ions, so this reaction must be quenched. Thiosulphate is most stable at near-neutral pH so its storage at pH 6 is compatible with the storage of hydroxy-methanesulphonate. The sulphur in polythionates is oxidized indirectly, by oxidation of the thiosulphate or sulphite produced from them by reaction (2). To prevent this or an alteration of polythionate chain length by means of reaction (2) the polythionates can be reacted with cyanide, a strong nucleophile:[46-48]

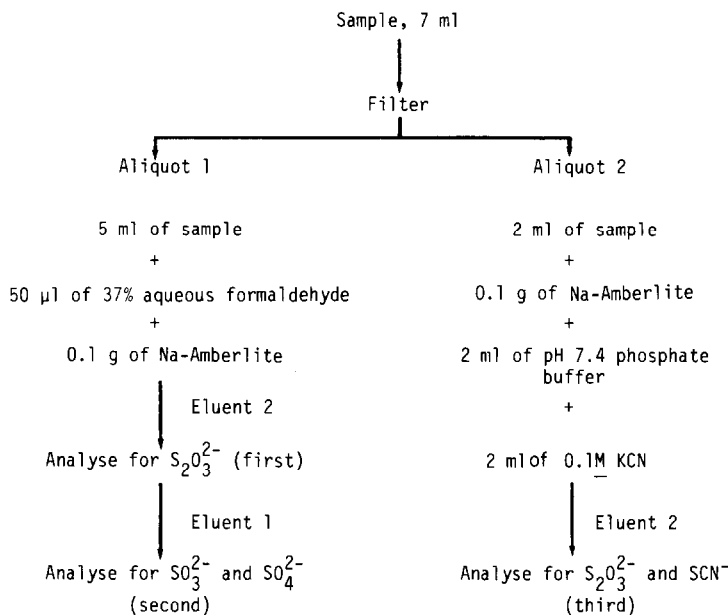
$$S_nO_6^{2-} + (n-3)CN^- + 2OH^- \rightarrow SO_4^{2-} + H_2O$$
$$+ S_2O_3^{2-} + (n-3)SCN^-; \quad n = 4\text{-}6 \quad (5)$$
Reaction (5) is very rapid at room temperature for pentathionate and hexathionate, and requires 1.5 min for tetrathionate.[47] Trithionate, $S_3O_6^{2-}$, can also be cyanolysed, but several hours or heating in a boiling water-bath and an extra determination are required.[14,47] Trithionate was not dealt with in the present work, but the analytical procedure could be modified to include it. Thiosulphate reacts with cy-


Fig. 2. Sample splitting and treatment. Aliquot 1 was used for direct analysis for thiosulphate, sulphite and sulphate; aliquot 2 was used for indirect analysis of cyanolysed polythionates.

anide in the presence of transition metal ions, such as Fe(III) or Cu(II). This reaction would interfere with the direct determination of thiosulphate, resulting in under-recovery. In our method, a sodium-saturated cation-exchange resin was added to the samples to reduce transition metal concentrations and, thereby, to reduce thiosulphate oxidation and cyanolysis.

An advantage of cyanolysis over any direct technique for determination of polythionates is that primary standards are available for thiosulphate and thiocyanate. Only sodium tetrathionate can be obtained commercially, and then not in high purity, and the synthesis of high-purity polythionate salts is tedious. Furthermore, decomposition of polythionate salts during storage is inevitable. Previous studies of cyanolysis have substantiated the 1:1 ratio of recovered thiosulphate to original polythionate, shown in reaction (5),[14,19,48] so it was not considered necessary to have a pure polythionate salt available for the present work. An advantage of ion-chromatographic analysis over spectrophotometric determination of cyanolysis products is that it can determine thiosulphate and thiocyanate simultaneously. This allows the determination of the average polythionic composition from equation (6), which can be derived from the stoichiometry of reaction (5):

$$\bar{n} = ([SCN^-]/[S_nO_6^{2-}]) + 3 \qquad (6)$$

EXPERIMENTAL*

Sample treatment

Samples from laboratory experiments were filtered through 0.45-μm pore-size Gelman or Millipore mem-

---

*The use of brand names in this report is for identification purposes only and does not imply endorsement by the U.S. Geological Survey.

branes, and field samples were filtered through 0.1-μm pore-size filters to exclude sulphur-oxidizing bacteria. The filters were leached with at least 500 ml of distilled water in the laboratory or 500 ml of sample water for field work before the samples were collected. After filtration, samples were immediately split into two aliquots and stabilized, and were analysed within 10 days, as shown in Fig. 2. Between collection and analysis the samples were stored at 2–5°.

Reagents

Phosphate buffer (pH 7.4). Prepared by titrating 0.5M potassium dihydrogen phosphate with 2.0M sodium phosphate to pH 7.4.

Potassium cyanide solution, 0.1M.

Eluent 1. A 0.75mM sodium carbonate + 0.75mM p-cyanophenol solution adjusted to pH 11.4 with 2.0M sodium hydroxide.

Eluent 2. A 3.0mM sodium carbonate + 0.75mM p-cyanophenol solution adjusted to pH 11.8 with 2.0M sodium hydroxide.

Combined $S_2O_3^{2-}/SCN^-$ standards. Prepared with pH-7.4 phosphate buffer in the same dilution as in aliquot 2 (Fig. 2, *i.e.*, 1:2 buffer:standard solution). All standard salts were stored in a desiccator and protected from strong light. Stock solutions were discarded after calibration standards had been prepared from them. New calibration standards were mixed not less frequently than every 4 weeks and reproducibility records were kept to detect deterioration. Solutions were also prepared from Na$_2$SO$_3$ and Na$_2$S$_4$O$_6$ and mixed to simulate the collection of unstable samples. The tetrathionate solutions had to be filtered through 0.45-μm membranes to remove the elemental sulphur formed by decomposition during storage.

Preparation of Na-Amberlite. Amberlite CG-120 cation-exchange resin, sodium-form (chromatographic grade, Mallinckrodt), 100–200 mesh, was washed well with demineralized water, charged with sodium ions by soaking for 24 hr in 1.0M sodium chloride, rinsed with demineralized water until the conductivity of the effluent equalled that of the demineralized water, and allowed to dry thoroughly. The exchange capacity of each batch must be experimentally determined (see Results).

CAUTION. Cyanide and thiocyanate salts and solutions

are toxic and should be handled with care. Formalin is toxic and a suspected carcinogen. Cyanolysis and formalin treatment should be done in well-ventilated areas. p-Cyanophenol is an irritant, and though its toxic status is unclear it should be handled with care.

IC methods

The output of a Dionex Model 14 Ion Chromatograph was recorded on a Honeywell dual-pen 1000-mV strip-chart recorder. Results were quantified by measuring peak height and normalizing with respect to conductivity units (μS/cm). Integrating the peak area does not give better precision than measuring the peak height does.

Two sets of operating conditions were used.

A. For aliquot 1, SO_3^{2-} and SO_4^{2-}

Eluent 1:	0.75mM Na$_2$CO$_3$/0.75mM p-cyanophenol/pH 11.4
Flow-rate	40% (3.1 ml/min)
System pressure:	80–280 psig
Precolumn:	none
Separator column:	4 × 140 mm L-20 anion separator (Dionex No. 30364) trimmed to 72 mm length
Suppressor column:	6 × 250 mm anion suppressor (Dionex No. 30064)
Suppressor regenerant:	1.0N H$_2$SO$_4$
Injection loop volume:	100 μl
Conductivity (full-scale):	300 μS/cm (strip-chart, full-scale: 15–150 μS/cm)

B. For aliquot 1, $S_2O_3^{2-}$ and for aliquot 2, $S_2O_3^{2-}$ and SCN^-: as for *A* above, except:

Eluent 2:	3.0mM Na$_2$CO$_3$/0.75mM p-cyanophenol/pH 11.8
Separator column:	4 × 140 mm L-20 anion separator (Dionex No. 30364), trimmed to 95 mm length.

Calculations

Concentrations were calculated from the slopes of the calibration curves. For the determination of $S_nO_6^{2-}$ in aliquot 2 the following calculations were needed.

(1) Calculate $S_nO_6^{2-}$:

$$[S_nO_6] = [S_2O_3^{2-}] \text{ in aliquot } 2 - [S_2O_3^{2-}] \text{ in aliquot } 1$$

(2) Calculate $\bar{n}$:

$$\bar{n} = ([SCN^-]/[S_nO_6^{2-}]) + 3.$$

Determination of method detection limit (MDL)

The MDL was experimentally determined by the following procedure.[49]

1. A useful estimate of detection limit was obtained by converting the minimum readable recorder deflection (2 chart units in 1000 with our recorder) to an equivalent concentration by use of a previously-obtained calibration graph for the constituent in question.

2. Seven aliquots of a standard of concentration 3–5 times the estimated MDL were handled and analysed according to the procedure given above, and the standard deviation, S_c, was calculated.

3. The S_c value was multiplied by the Student-t value (one-tailed test) for 6 degrees of freedom (d.f.) at the 99% confidence level ($p = 0.01$) to obtain the MDL (MDL = 4.317 S_c).

4. The upper and lower 95% confidence limits (95% UCL and 95% LCL) for the MDL were calculated from the χ^2 distribution:

$$\frac{LCL}{\sqrt{\chi^2_{(p=0.025)}/d.f.}} < MDL < \frac{UCL}{\sqrt{\chi^2_{(p=0.975)}/d.f.}};$$

for d.f. = 6, this reduces to LCL = 0.64 MDL; UCL = 2.20 MDL.

RESULTS AND DISCUSSION

Calibration and sensitivity

Figure 3 shows typical chromatograms obtained by this method. Table 2 summarizes the data on sensitivity, MDL, and retention times.

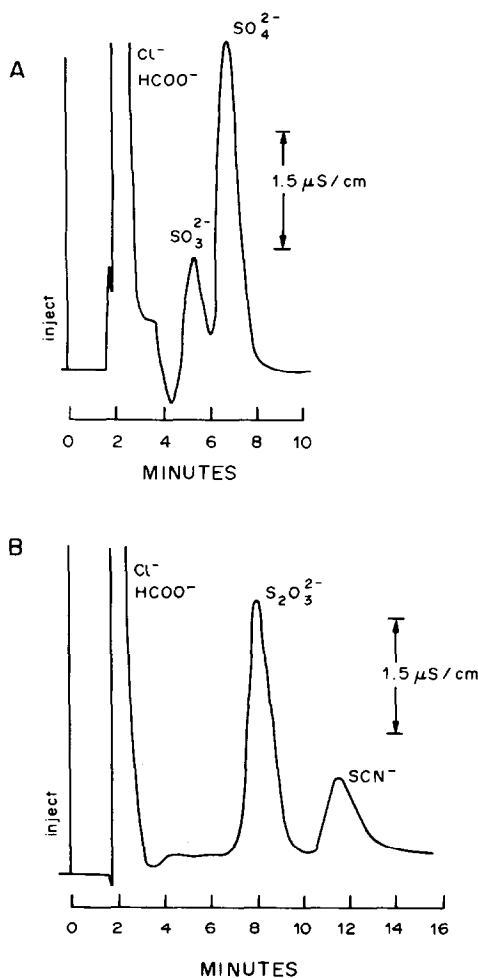
The linear correlation coefficient for calibration of each species was excellent for such a wide range of concentration (in each case, $r > 0.999$, significant at $\ll 1\%$ level), but there was $>9\%$ variability in method sensitivity (defined as ratio of response to concentration) for sulphite and sulphate over this range. There were no trends, however, so, rather than attributing the variability to a gain or loss of conductimetric sensitivity with increasing concentration, we regard it as due to inefficiency of the weak eluent that was used for these species. Calibration over a narrower range (for example, by bracketing standards around a group of samples of similar concentration), gave much-improved precision. For example, the sulphate sensitivity in the range 100–200μM, had a


Fig. 3. Chromatograms obtained by injecting standards mixed in 0.01M NaCl and treated with 37% aqueous formaldehyde (1:100); specific conductance is shown in μS/cm. A, 100μM sulphite and sulphate; B, 100μM thiosulphate and thiocyanate.

†Typical retention time for 100μM standard in 0.01M NaCl.
§Sensitivity = (conductimetric response/concentration), ($\pm$ RSD%) ($N = 6$), measured across the calibration range.
‡Estimated by calculating concentration equivalent to 2/1000 of full-scale deflection (the limit of chart readability) for 300 μS/cm full-scale conductance and 50 mV full-scale voltage.
¶Determined by method of Ref. 49; $N = 7$; defined matrix: 0.01M NaCl, 1% 37% formaldehyde solution, single-species standard about 3 times the concentration of estimated MDL; UCL, LCL = upper and lower confidence limits.

relative standard deviation (RSD) of 0.9% ($N = 5$). If the origin was included (*i.e.*, calibration from 0 to 200μM), the linear regression slope differed from the mean sensitivity by <0.2%. In contrast, the sensitivity for thiosulphate and thiocyanate, which were eluted with a stronger eluent, showed little variability over the range from 10 to 1000μM. The sensitivity differed from the linear regression slope by <0.9% for thiosulphate and <2.1% for thiocyanate.

Cyanolysis calibration (see Table 3) based on a sodium tetrathionate salt of approximately 83% purity also showed very good linearity over the 0–1000μM range ($r > 0.999$, significant at $\ll 1\%$ level). Figure 4 shows a chromatogram of thiosulphate and thiocyanate in the presence of the phosphate buffer. Injections of standard solutions and a blank, prepared in the buffer, were required for the accurate and precise interpolation of the baseline under the thiosulphate and thiocyanate peaks.

Separation and interferences

The L-20 separator columns were essential for rapid analysis, but the two L-20 columns used in this work had very different performance characteristics. This indicates the need to evaluate the column per-

formance at an early stage in development or setting up of the method. Of these two columns, one was "too fast" for sulphite and sulphate, even with very weak eluents. With a strong eluent, however, it separated thiosulphate and thiocyanate into well-
Fig. 4. Chromatogram obtained by injecting a cyanolysed approximately 100μM $S_4O_6^{2-}$ standard in 0.01M NaCl and phosphate buffer; the standard was treated in the same way as aliquot 2 sample.

*These concentrations assume that the $Na_2S_4O_6$ was pure.
†Estimated recovery of $S_4O_6^{2-}$, if the $Na_2S_4O_6$ were pure. If extrapolated to infinite dilution, these data suggest 83% purity and an increase in $S_2O_3^{2-}$ recovery of about 1.1%/100μM $S_4O_6^{2-}$ (these conclusions are significant at <5% level, $N = 5$).
§Based on 83% purity.
‡This ratio gives $\bar{n}$ in $S_nO_6^{2-}$ (n = ratio + 3). Extrapolating to infinite dilution suggests $\bar{n} = 4.139$ and a decrease in ratio of about 1.9%/100μM $S_nO_6^{2-}$ (these conclusions are significant at <5% level, $N = 5$).

resolved, rapidly eluted peaks. The other column was "too slow" for thiosulphate or thiocyanate, except with very strong eluents, and these rapidly expended the suppressor column; this column worked very well for sulphite and sulphate. These columns have plastic bodies and were carefully trimmed in length to optimize retention time and resolution.

Figure 3 shows that chloride (100mM) and formate (100μM) did not interfere in sulphite and sulphate determination. Carbonate could not be detected except at high concentrations (>3mM); even at higher levels it did not interfere, because it was eluted in about 4 min. Eluent 1 eluted acetate (1mM) in about 3 min. Nitrite and nitrate when present at >10μM concentration interfered with sulphite determination. Figure 4 shows that phosphate up to 0.16M did not interfere in thiosulphate or thiocyanate determinations, though baseline extrapolation is needed at high concentrations. Phosphate interfered with determination of sulphate in aliquot 1 if the eluent pH was not adjusted properly; a pH that was too low caused the elution of HPO_4^{2-} at about the same time as sulphate. Raising the pH allowed longer retention of the phosphate and complete resolution of sulphate and phosphate, because of dissociation of HPO_4^{2-} to PO_4^{3-} in the eluent stream. The pK_a for this dissociation is 12.3, but the pH did not have to be raised to this value to resolve sulphate and phosphate. In fact, pH 12.3 (20mM OH^-) gave an eluent that was much too strong for determination of sulphite and sulphate. In the case of eluent 2, adjustment to pH 11.8 was required for the rapid elution of thiosulphate and good resolution of thiosulphate and thiocyanate.

Quenching sulphite and thiosulphate oxidation

The efficacy of a 1% v/v addition of formaldehyde as a fixative for sulphate is demonstrated in Fig. 5. The samples were stored in closed plastic bottles. Even though refrigeration slowed the oxidation of sulphite, it was neither a substitute for, nor a helpful adjunct to, formalin treatment.

To determine whether Na-Amberlite is an effective agent for removing iron from samples, 0.1 g of Na-Amberlite was added to each of five 5-ml aliquots of
Fig. 5. Efficacy of 1:100 v/v addition of 37% aqueous formaldehyde solution as a sulphite fixative. 100% = approximately 100μM SO_3^{2-}; 25°C denotes storage at room temperature; 3°C denotes refrigerated storage.

a 1mM solution of Fe(III) (FeCl_3 · 6H_2O) and, after 24 hr the iron concentration was determined by the Ferrozine method.[50] The Fe(III) concentration was decreased to 18.1μM (r.s.d. 20%) or about 1.8% of the original concentration. This single-point measurement suggests a cation-exchange capacity of about 147 μeq/g. This decrease in iron concentration enabled 100μM thiosulphate/1mM Fe(III) medium (if treated with 1% of formalin and 0.1 g of Na-Amberlite) to be kept for 1 week with a thiosulphate loss of only about 12.5μM (r.s.d. 8.4%, $N = 5$). Refrigeration (at 2–5°) extended this storage period to about 6 weeks, with a similar loss. Addition of formalin alone to the thiosulphate/iron system allowed a loss of almost 100% over 1 week and no treatment at all allowed a loss of almost 95% in only 4 hr.

To determine the potential for sulphate interference resulting from the use of Na-Amberlite, 0.1 g of Na-Amberlite was added to each of five 5-ml aliquots of demineralized water. After 24 hr, the average sulphate concentration was 18.1μM (r.s.d. 2.2%). This concentration is equivalent to 90.5 nmoles of sulphate in the 5 ml of solution. The excellent reproducibility of this sulphate concentration, regardless of time elapsed between addition of Na-Amberlite and analysis (4–30 hr), suggests that this interference was governed by a rapidly attained stable equilibrium. This conclusion is further supported by the fact that addition of 0.1-g portions of Na-Amberlite to 5-ml aliquots of standards covering the 10–1000μM range caused less than 1% change in the slope of the calibration graph, and the amount of sulphate added by the Na-Amberlite decreased with increasing standard concentration. Thus, the process by which Na-Amberlite adds sulphate to samples seems to be controlled by equilibrium with the sulphate in solution. For each batch of analyses, determination of the effect of the Na-Amberlite addition on blanks and on standards with sulphate concentration less than 100μM is recommended.

Analysis of mixtures

The sodium tetrathionate that was used for investigating cyanolysis contained sulphate and sulphite as decomposition products, and therefore solutions made from this salt were really mixtures. Analyses of this mixture over the 0–1000μM range revealed behaviour that was qualitatively consistent with that discussed in the introduction to this paper. The average ratio of recovered thiosulphate to that expected (assuming 100% pure tetrathionate, see Table 3) suggests that this salt was only about 87% pure in terms of tetrathionate. There was, however, a weak trend toward increased recovery at higher tetrathionate concentrations, and extrapolation of this trend to infinite dilution of the salt gave an estimate of 83% purity. The average ratio of thiocyanate to thiosulphate indicated $\bar{n} = 4.08$, but the extrapolation suggested $\bar{n} = 4.14$.

We prefer the extrapolated estimates of purity and $\bar{n}$ to the average values, because the latter were biased by solution chemistry in the calibration standards. The pH of these salt solutions was >7 and, as reaction (2) shows, such a mixture should tend toward chain-shortening; this process would be accelerated at higher concentrations. Chain-shortening before cyanolysis would cause a decrease in thiocyanate recovery and, therefore, in $SCN^-/S_2O_3^{2-}$ ratio. Although the tetrathionate salt contained no detectable thiosulphate impurity, reaction (2) in reverse would yield some thiosulphate, and this could account for the observed increase in thiosulphate recovery at higher concentrations. Similarly, Urban[48] observed a decrease in thiocyanate recovery over 4 days in a solution of hexathionate; he attributed this behaviour to chain-shortening as the solution aged.[48] We have observed concentrated solutions ($500-5000\mu M$) of tetrathionate to precipitate sulphur on standing (equivalent to chain-shortening accompanied by decomposition of the resultant thiosulphate). For example, 1 litre of a $5000\mu M$ solution lost 40.7 mg of elemental sulphur (159 μmoles of S_8) on standing for 2 weeks at room temperature.

Although mixtures of polythionates cannot be expected to remain constant in composition, samples that have been cyanolysed can be expected to maintain a constant ratio of $SCN^-/S_2O_3^{2-}$, subject to the constraints on thiosulphate stability. This ratio showed some variability for a cyanolysed $100\mu M$ tetrathionate standard over 2 weeks (1.086, r.s.d. 9.2%, $N = 5$), but there was no trend towards decreasing or increasing ratio during this period.

To demonstrate the analysis of mixtures of all four sulphoxy anions by this method, three mixtures of SO_3^{2-}, SO_4^{2-}, $S_2O_3^{2-}$ and $S_nO_6^{2-}$ were prepared. The pH of each was adjusted to ~ 6, appropriate for storage of hydroxymethanesulphonate and thiosulphate. Replicate analyses were performed by the procedure given, and the results are presented in Table 4.

If these results are taken to represent typical performance of this method for analysing mixtures, we can make the following observations. Sulphite values

were within 6% of those expected, but the "true" recovery is probably slightly less because some of the sulphite was an artefact produced in the rearrangement of the uncyanolysed polythionate in aliquot 1. We attribute the under-recovery of thiosulphate to the same process, namely chain-lengthening of the polythionate through reaction (2) at pH <7 (see Fig. 1D). The observed increase in thiocyanate/polythionate ratios also suggests that chain-lengthening took place in aliquot 2 before cyanide was added, in which case the polythionate concentrations should not change; Table 4 shows the polythionate recoveries are all close to 100%. Sulphate over-recovery was most likely due to the oxidation of sulphite that took place before the formalin addition (the sulphate expected was that from contamination of the sulphite and polythionate salts). Finally, the over-recovery of total sulphur was due to the great increase in $\bar{n}$ over that expected from the cyanolysis calibration in high pH solutions. The expected value was biased low for a mixture at pH 6. The discrepancy between total sulphur expected and found was less than the discrepancy between $\bar{n}$ expected and found, because of the under-recovery of thiosulphate.

CONCLUSIONS

An IC method has been developed for the direct determination of sulphite, sulphate and thiosulphate in one formalin-treated sample aliquot, by use of two eluents in succession and the same column. Polythionate concentration and composition are determined indirectly in a second aliquot by IC analysis for thiosulphate and thiocyanate produced by cyanolysis. Other sample treatments include filtration, addition of a cation-exchange resin, and storage at $2-5°$. This combination of treatments permits samples to be stored for up to 6 weeks with only slight loss of thiosulphate.

Development of the IC method involved consideration of column length and resin material, eluent strength and pH, and the sampling and storage

§Total S found $= \bar{n}\,[S_nO_6^{2-}] + 2[S_2O_3^{2-}] + [SO_4^{2-}] + [SO_3^{2-}]$, where $\bar{n} = (SCN^-/S_nO_6^{2-}) + 3$.
‡The expected ratio was based on the values extrapolated to infinite dilution from the cyanolysis calibrations.

treatments. An important factor not considered, however, was injection-loop volume. With all other factors kept constant, increase in the loop volume would be expected to increase the sensitivity and decrease the MDL.

In analysis of mixtures, the method has produced results which substantiate the qualitatively known pH-dependent behaviour of mixtures of sulphoxy anions. The method should provide the means to develop a more quantitative understanding of the pH- and time-dependent changes in such complex mixtures, particularly the Wackenroeder equilibrium represented by reaction (2).

MOLECULAR ABSORPTION SPECTROMETRY BY ELECTROTHERMAL EVAPORATION IN THE GRAPHITE FURNACE—X

DETERMINATION OF CHLORIDE TRACES BY AlCl MA IN GRAPHITE CUVETTES AFTER LIQUID–LIQUID EXTRACTION OF CHLORIDE WITH TRIPHENYLTIN HYDROXIDE

Summary—The determination of traces of chloride by means of the molecular absorption of AlCl in graphite cuvettes is described. An extraction method for separation and preconcentration of the chloride has been developed, to avoid matrix effects. Extraction was done with $0.03M$ triphenyltin hydroxide in *o*-xylene, and stripping with $0.025M$ barium hydroxide. The method is sensitive and specific for chloride. The detection limit is about 1.5 ng of chloride, and the chloride content of 20 ml of $10^{-7}M$ solution can be determined. The determination is possible in presence of excess of bromide and iodide.

As indicated in our previous paper on bromide determination,[1] the determination of traces of chloride is an important and difficult practical problem. Sensitive determination is possible by use of ion-selective electrodes, but the accuracy, especially in presence of bromide, is not good. As we have shown,[2] sensitive and selective determination of chloride ions is possible by means of the molecular absorption spectrometry (MAS) of diatomic chloride-containing molecules (*e.g.* AlCl, GaCl, InCl), generated by evaporation in a graphite furnace. Fuwa and co-workers have also worked in this field.[3,4] In recent years this method has been extended to the alkaline-earth metal chlorides.[5,6]

An important disadvantage of MAS with electrothermal vaporization is the significant interference from the matrix, which affects both the MA signals and the background.

It was shown in our previous paper[1] that liquid–liquid extraction, *e.g.*, with triphenyltin hydroxide (TPTH) followed by back-extraction into an aqueous solution of sodium or barium hydroxide, makes it possible to improve the sensitivity and accuracy of determination by MAS. This is achieved by means of the preconcentration by extraction and back-extraction and the simultaneous separation of metal cations and some anions which interfere with the subsequent absorption measurements.

Bock *et al.*,[7,8] and Schweitzer and McCarthy[9] have shown that TPTH solutions in methyl isobutyl ketone (MIBK) or benzene can extract chloride ions at pH 1.6–4.4. In the present work we have studied the extraction of chloride by TPTH from more acidic solutions, for the purpose of preconcentration of chloride and its separation from large amounts of metal cations and also from some anions which can be extracted by organotin compounds.[7–10] *o*-Xylene, which gives higher distribution coefficients than MIBK and benzene for halide ions, was used as diluent. The data obtained were used to develop a method of determining chloride in aqueous solution by MAS.

EXPERIMENTAL

Apparatus

The molecular absorption was measured with a Jarrell Ash double-channel double-beam AA spectrometer, type 811, fitted with a Beckman graphite furnace, type 1268. The light-source was a hydrogen hollow-cathode lamp run at 35 mA. The molecular absorption of AlCl was measured at 261.4 nm. For background correction the two-line method was used, the non-specific wavelength being 260 nm.

The distribution of chloride between the organic and aqueous phase was estimated radiometrically with ^{38}Cl. The radiochemical purity of the ^{38}Cl was tested by means of a Ge(Li) detector and Nokia 800-channel analyser P4840) as well as from half-life measurements. The radioactivity of the organic and aqueous phases was measured with Tesla Liberec NRG 603 automatic gamma spectrometer.

Reagents

TPTH solutions were prepared by equilibration of $0.03M$ triphenyltin chloride (or bromide) solution in *o*-xylene with several portions of $0.1M$ aqueous sodium hydroxide (phase-volume ratio 1:1) until no further chloride was found in the aqueous phase. The organic phase was washed free from the hydroxide with water and then filtered. The concentration of TPTH in the diluent was $0.03M$ and the concentration of
Fig. 1. Molecular absorption spectra of the AlCl molecule (measurement point by point): curve 1, 1 μg
Al^{3+}; 27 μg Ba^{2+} 0.2 μg $Cu^{-}/10$ μl: curve 2, 1 μg Al^{2+}; 27 μg $Ba^{2+}/10$ μl.

chloride in the initial aqueous solution, unless otherwise noted, was $10^{-6}–10^{-4}$ M, for the extraction studies. The following aqueous stock solutions were used: Al^{3+} 10 mg/ml $[Al(NO_3)_3]$; NaOH 0.1M; $Ba(OH)_2$ 0.05M; Cl^- 1 mg/ml (NaCl); X 10 mg/ml (X = Br^-, I^-, SO_4^{2-}, as Na^+ salts); M 10 mg/ml (M = K^+, Mg^{2+}, Ga^{3+}, Co^{2+}, Ca^{2+}, Ni^{2+}, Zn^{2+}, as nitrates).

Procedures

Absorption spectra. The molecular absorption of AlCl was measured between 200 and 400 nm, point by point. Figure 1 shows part of the spectrum.

Analytical investigations without extraction. Micro-volumes (10 μl) of solutions containing Cl^-, Al^{3+} and Ba^{2+} ions were placed in the graphite furnace. After drying and ashing, the substances were evaporated in the so-called evaporation phase, (equivalent to the atomization phase in AAS), and the AlCl MA signal was measured.

Analytical determinations with extraction. Stoppered glass test-tubes or separatory funnels were used for distribution of chloride between the two phases. The extraction was done with different V_o/V_{aq} ratios. When $V_o = V_{aq}$, the volume of each phase was 3 ml. The extraction studies were done at room temperature, and the phases were shaken for 3 min (it was established beforehand that equilibrium was attained in less than 3 min in all the systems studied). An aliquot of each phase was taken for the radioactivity measurement, from which the recovery factors ($R\%$) were estimated.

For the back-extraction 0.05M barium hydroxide was used. After separation of the stripping solution, an appropriate microvolume of aluminium solution was added and an aliquot was placed directly in the graphite furnace.

RESULTS AND DISCUSSION

Investigation of the extraction

The data in Table 1 for the extraction of chloride from 0.01M nitric acid with $V_o/V_{aq} = 1$, as a function of chloride concentration in the initial aqueous solution (C_{Cl^-}) show that high recovery values are achieved if $C_{Cl^-} < 10^{-2}$ M. Increasing the nitric acid concentration in the aqueous phase up to 5M does not affect the extraction with $V_o/V_{aq} = 1$. Even with $V_o/V_{aq} = 0.1$, the recovery of chloride is practically quantitative (Table 2). Large amounts of metal cations such as Ni^{2+} or K^+ (Table 2) and other non-ferrous, alkali-metal and alkaline-earth metal ions do not suppress the extraction of chloride. The metal cations themselves are practically not extracted by TPTH. Other halide ions and some oxo-anions extracted by organotin reagents[7-9] can affect the recovery of chloride, by competition for the reagent. The extraction of chloride from 0.1 and 1M nitric acid in the presence of ammonium or sodium bromide, iodide, sulphate and phosphate at $V_o/V_{aq} = 0.2$ was examined. Bromide and chloride do not influence the recovery of chloride if their concentrations in the aqueous solution are below $3 \times 10^{-3}M$. Phosphate does not suppress the extraction from 1M nitric acid, but for extraction from 0.1M nitric acid $10^{-2}M$ phosphate lowers the recovery for chloride to 90%. Sulphate does not interfere with the extraction from 0.1 or 1M nitric acid even at concentrations as high as 0.1M.

The back-extraction of chloride by sodium and barium hydroxide solutions was studied (Table 3). Both hydroxides strip the chloride quantitatively from the TPTH extracts, which allows the MAS analysis to be done with the most convenient media.[1,2] It should be noted that additional preconcentration of chloride is possible during the back-extraction.

Table 1. Results of extraction of chloride ions by TPTH solution

*$V_o:V_{aq}$

Molecular absorption of AlCl (without extraction)

MA spectra. As we have already shown[2,11] and in
Fig. 1, for the AlCl molecule we found a narrow
absorption band between 261.4 and 262.0 nm with a
maximum at 261.4 nm. This is in agreement with the
literature,[12] which gives the maximum for the A-band
system $(X^1\Sigma^+ \rightarrow A^1\pi)$ as being at 261.4 nm
[$V'/V'' = 0/0$ (Q)]. Because we found a narrow band,
it was possible to correct the background by
difference measurements with the two-line method
(261.4/260.0 nm).

In principle it is also possible to use the molecular
absorption of CaCl,[2] InCl[2] and MgCl[7] for the deter-
mination of chloride, but because the AlCl system
gives the highest sensitivity, we investigated this
system together with extraction.

Optimization of thermal conditions. The tem-
perature of the drying, ashing and evaporation steps
has a great influence on the AlCl MA-signal.[2,11] It is
important to avoid losses of chloride ions in the first
two steps and to obtain simultaneous evaporation of
aluminium and Cl$^-$ in the third step. The best
evaporation temperature is the maximum tem-
perature of the furnace. In the second phase we can
use temperatures up to 1000° without losses of chlo-
ride.

*Optimization of chemical conditions for deter-
mination.* The addition of 0.05M barium hydroxide
up to a concentration of 0.025M influenced the
height of the AlCl MA-signals by decreasing the
volatilization of free chloride species (see also refer-
ences 2 and 11). In the drying phase Ba–Cl species are
formed, as solid residues. These substances are ther-
mally stable and losses of chloride as HCl by thermal
hydrolysis in the ashing phase are avoided. At high
ashing temperatures the solid residues react with the
graphite of the tube, forming carbides containing Ba
and Cl. Therefore the evaporation rate of the chloride
decreases and there is simultaneous evaporation of
Ba, Cl and Al. In accordance with the dissociation
energies[2,11,12] AlCl molecules are formed in the
plasma.

Analytical results of chloride determination by AlCl MA

Pure solutions with and without extraction. First we
established the dependence of the AlCl MA-signal on
the chloride concentration, under the optimal condi-
tions 1 μg of Al^{3+} and 30 μg of Ba^{2+} per 10 μl. The
results are shown in Table 4. The blank absorbance
of 0.03 cannot be compensated for. The reciprocal
sensitivity is 1.5 ng of Cl$^-$ for 0.01 absorbance, which
means that it is possible to determine 1.5 ng of
chloride in 10 μl of aqueous analyte solution (i.e.
$4 \times 10^{-6}M$ solution). The reciprocal sensitivity is
comparable with the 3s detection limit for mea-
surements in graphite furnaces. It is possible to
improve the detection limit by using a larger sample

Table 4. Results of the chloride determination by AlCl MA with and without pre-
liminary extraction of chloride

Sample volume and injection volume	Absolute reciprocal sensitivity, ng for $A = 0.01$	Relative reciprocal sensitivity		Linear working range, ng
		ppm	M	
Without extraction				
10 μl	1.5	0.15	4×10^{-6}	1.5–50
40 μl	1.5	0.038	10^{-6}	1.5–50
With extraction 10 ml*

40 μl	1.5	0.0038	10^{-7}	1.5–50

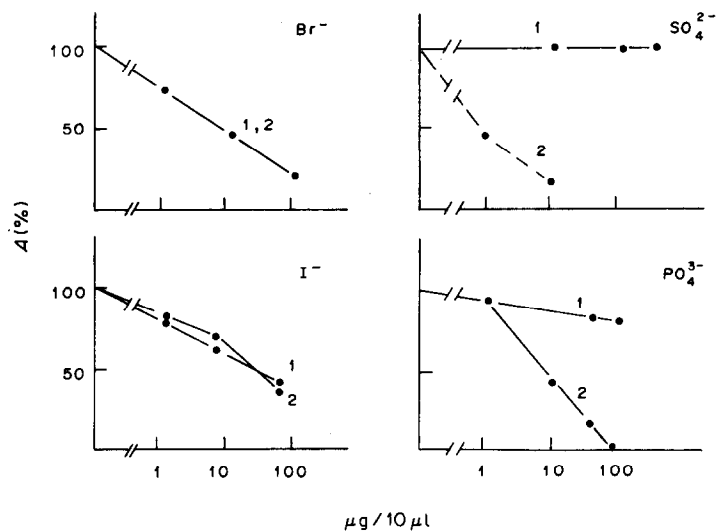
*Preconcentration 5-fold.
†Preconcentration 10-fold.


Fig. 2. Dependence of the AlCl MA on the presence of other anions: 1, with preliminary extraction of the Cl^- ion from $0.1M$ HNO_3 by $0.03M$ TPTH in o-xylene; 2, without extraction.

volume. Extraction was combined with the AlCl determination in the following way. A 10- or 20-ml sample ($0.1M$ nitric acid medium) was extracted with 4 ml of $0.03M$ TPTH solution in o-xylene. Exactly 3 or 3.5 ml of the organic solution were separated and mixed with exactly 1.5 or 1.75 ml ($V_o/V_{aq} = 2$) of $0.025M$ aqueous barium hydroxide solution and shaken to strip the chloride. After separation of the phases $10\,\mu l$ of aluminium stock solution were added to 1 ml of the aqueous phase and the AlCl MA-signal was measured. The results are also shown in Table 4. By comparison of the results obtained with and without extraction, we see that it is possible to improve the reciprocal sensitivity by about an order of magnitude. This sensitivity is also very good in comparison to that of ion-selective electrodes.

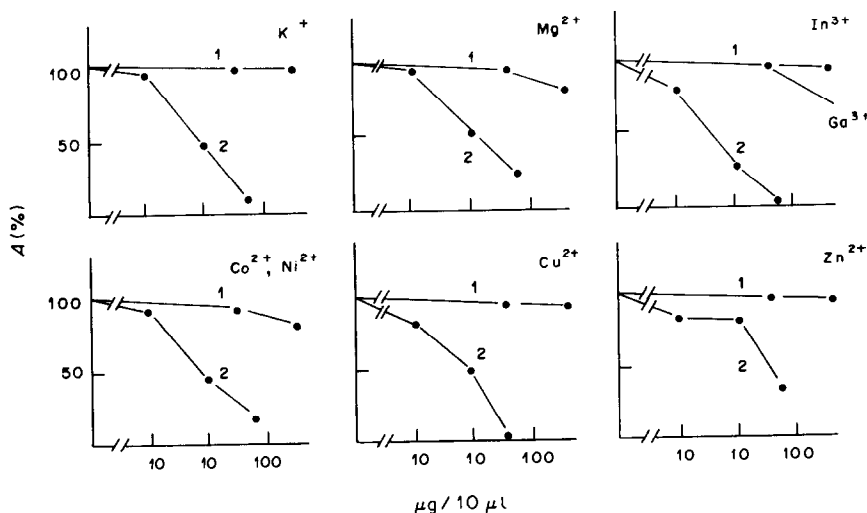
Effects of other anions, with and without extraction. The influence of other anions is shown in Fig. 2. Halides strongly depress the signal both with and without extraction. Nevertheless, it is possible to determine traces of chloride in presence of more than 1000-fold w/w ratio of iodide and bromide ions. The direct determination of chloride in presence of sulphate is impossible because the sulphate forms insoluble barium sulphate with the barium in the stripping solution. If $0.01M$ nitric acid medium is used, sulphate is not extracted by organic TPTH solutions, and the interference of sulphate in the chloride determination is then avoided. Chloride can be determined in the presence of more than 10000 times as much as sulphate. The direct determination of chloride is possible in presence of up to 50-fold


Fig. 3. Dependence of the AlCl MA on the presence of some cations: 1, with preliminary extraction of the Cl^- ion from HNO_3 by $0.03M$ TPTH in o-xylene; 2, without extraction.

Table 5. Results of the chloride determination by AlCl MA with extraction in presence of other salts

Salt	Detection limit, ppm	Salt	Detection limit, ppm
KNO₃	0.1	Ni(NO₃)₂	0.08
Mg(NO₃)₂	0.08	Co(NO₃)₂	0.08
In(NO₃)₃	0.1	Cu(NO₃)₂	0.08
Ga(NO₃)₃	0.15	Zn(NO₃)₂	0.08

w/w ratio of phosphate, which can be improved to 10000-fold ratio by extraction from $1.0M$ nitric acid medium (from which phosphate is not extracted, because of protonation to H_3PO_4).

Effects of other cations, with and without extraction. As shown previously and in Fig. 3, although many cations have an adverse effect on the direct determination of chloride by the AlCl MA method, use of the extraction step improves the tolerance units for these cations by factors of 1000 and more.

By using the optimum preconcentration and conditions and maximum sample concentrations of about $0.1-0.3M$, it is possible to determine traces of chloride in certain metal nitrates at below the ppm level. Some results are shown in Table 5. We can conclude from these results that the combination of TPTH

extraction and selective determination by AlCl MA is a useful new trace technique for the determination of chloride.

A COMPARATIVE STUDY OF FLAME ATOMIC-ABSORPTION METHODS FOR DETERMINATION OF ZINC IN SERUM AND BLOOD PLASMA

M. J. SORIANO and M. DE LA GUARDIA*
Departamento de Quimica Analitica, Facultad de Ciencias Quimicas, Universidad de Valencia, Valencia, España

Summary—Seven selected methods for determination of zinc in blood plasma by flame atomic-absorption spectroscopy have been compared. Analytical characteristics such as sensitivity, detection limit, precision, analytical recovery, accuracy and physical interferences were studied. Two of the seven methods are recommended as the most suitable for the purpose.

Zinc is an essential nutrient and is contained at relatively stable levels in the biological fluids and tissues of healthy subjects. However, several diseases (diabetes, myocardial infarction, liver disorders, atherosclerosis, *etc.*) cause disturbances in zinc metabolism, resulting in an increase or a decrease in the zinc concentration in serum and blood plasma.[1-7] The determination of zinc in these biological fluids is therefore not only interesting, but necessary for proper diagnosis of such diseases.

Zinc has been determined in serum and blood plasma by a variety of techniques, including neutron activation, fluorimetry, colorimetry, atomic-fluorescence, atomic-absorption and plasma atomic-emission spectroscopy. Of these, flame atomic-absorption spectroscopy (FAAS) is the most widely used for routine analysis because it is precise, simple, sensitive and is relatively free from interferences. Table 1 summarizes the methods described in the literature for the determination of zinc in serum and blood plasma by FAAS.

The methods have been classed into four different groups according to the treatment of the samples and the standards.

(1) Methods involving deproteination.

(2) Methods based on sample dilution with demineralized water, and addition of some reagents to aqueous standards to obtain similar physical characteristics for the diluted samples and the standards.

(3) Methods based on sample dilution with demineralized water and use of aqueous standards (without additional reagents).

(4) Methods involving liquid–liquid extraction of a zinc complex and analysis by FAAS.

Procedures in the first three groups are simpler than those in the fourth because they avoid the solvent-extraction step. So, from the methods pro-posed in the literature we have selected seven: two involving sample deproteination[13-29] and five involving sample dilution with demineralized water.[9,10,21,28,30,31] In two of these five methods, standards containing glycerol were prepared,[28,30,31] and in the other three,[9,10,21] aqueous solutions without any additional reagent were used as standards. We have evaluated the seven selected methods in terms of accuracy, precision, detection limit, sensitivity and analytical recovery.

We have also studied the effects of physical interferences by taking into account changes in aspiration rate of samples and standards. Matrix interferences were studied by comparing the results from calibration curves with those obtained by the standard-addition method.

We have followed the published procedures in all cases except for that given by Fuwa *et al.*,[9] where we employed an air/acetylene flame and a conventional burner instead of the flame and instrumentation used by the authors.

Some of the methods selected were proposed only for determination of zinc in blood serum. However, in other publications the methods are said to be applicable to the determination of zinc in blood plasma. Since there is not too much difference between serum and blood plasma from the analytical point of view, we have applied all seven methods to analysis of both materials.

EXPERIMENTAL

Instrumentation

A Perkin–Elmer model 460 double-beam atomic-absorption spectrophotometer was used with a zinc hollow-cathode lamp and a conventional air/acetylene burner.

Reagents

A 1000-ppm zinc standard solution ("DILUT IT", J. T. Baker Chemical Co.) was used as a zinc stock solution. Trichloroacetic acid, glycerol and potassium and sodium

---

*Author for correspondence.

chloride were also used to prepare working standards. A certified serum (CATION-CAL TM-DADE) was used to check the accuracy of the seven selected methods.

General procedure

To avoid any contamination of samples and standards, both glassware and plastic ware were soaked in 50% nitric acid for at least 24 hr, and were then rinsed several times with demineralized water.

Blood plasma samples were kept in tightly stoppered polypropylene vials, frozen at −33°.

Before the zinc determination was started, instrumental settings such as wavelength, slit-width, and lamp current were optimized. Gas-flow settings for air and acetylene, and the burner height, were set to give the greatest sensitivity for each of the seven methods.

The sensitivity was established from the slope of the analytical curve[32] and by means of the zinc concentration required to give 1% absorption (*i.e.*, the characteristic concentration).

The detection limit (X_L) was established from the slope of the analytical curve and the standard deviation of the absorbance readings for a blank solution and calculated from the equation:

$$X_L = X_{bl} + KS_{bl}$$

where X_{bl} is the mean and S_{bl} the standard deviation of the blank readings, and K the numerical factor corresponding to the selected confidence level (we used $K = 3$). The detection limit values were also calculated, taking into account the sample dilution.

To establish the precision of the methods, we did twelve independent analyses of a blood plasma sample on the same day, and calculated the standard deviation and relative standard deviation.

The accuracy of the methods was checked in all cases by doing five independent analyses of the certified serum sample by each method, then comparing the mean of the results with the certified value. The accuracy was expressed in terms of the deviation between the values.

To detect any physical interferences due to differences in the physical properties of the samples and standards, the aspiration flow-rates were measured and compared.

Matrix effects on the accuracy of the methods were examined by means of the results for determination of zinc in a blood plasma sample. The recovery was calculated from the difference in the amount of zinc found in the original sample and in samples spiked with a known amount of zinc. Matrix effects were further studied by comparison of the results obtained by the calibration graph and standard-addition methods.

RESULTS AND DISCUSSION

All concentrations are given in ppm and all absorbance readings in absorbance units.

The use of the same instrumental conditions for all the methods could cause disadvantages in some cases, so we first determined the best instrumental settings for each method (Table 2).

We found little difference between the optimal atomization conditions for purely aqueous standards and standards containing low concentrations of trichloroacetic acid (TCA) or glycerol. Generally, the utilization of standards containing these reagents presupposes the use of a flame richer in acetylene than one employed for the analysis of purely aqueous solutions.

Sensitivity

All in one day, working with the optimized instrumental settings for each, we measured the absorbances of the standards, took the mean of the readings for each, and established the analytical curve by a regression least-squares fit.

The sensitivities, estimated from the slopes of the analytical curves, were 0.35 for the methods involving purely aqueous zinc standards, 0.40 for methods involving standards containing 5 and 10% of TCA or 5% of glycerol. For the method using standards containing 20% of glycerol, the value was 0.30 (14% less). The corresponding characteristic concen-

trations were 0.013 ppm for aqueous solutions, 0.011 ppm for the TCA standards, 0.012 ppm for the 5% glycerol standards and 0.014 ppm for the 20% glycerol standards.

Detection limits

While there is no great difference in the sensitivities of the selected methods, there is a significant difference in the limits of detection, which range from 0.018 ppm of zinc in serum or plasma by the Sprague and Slavin method[10] involving simply a 1:1 dilution of the sample, to 0.090 ppm by the method of Fuwa et al.,[9] which uses 1:9 dilution and aqueous standards (Table 3).

Precision

The precision was expressed as the standard deviation and relative standard deviation, which were calculated from the results obtained by carrying out several independent analyses. These values usually vary, depending on both the number of independ-

 dently performed analyses and the nature of the sample.

We analysed twelve independent aliquots of normal human plasma (zinc content 700–1000 ng/ml), to compare the selected methods with respect to precision, and the results obtained (shown in Table 3) were all similar. These results indicated that the differences in sample treatment required for each method did not affect the precision. However, day-to-day instrumental and gas-flow fluctuations do influence the precision.

Accuracy

The accuracy of the selected methods was established by comparing the results obtained for zinc in a certified serum sample, by application of each method, with the certified value.

The results obtained for the method proposed by Arpadyan and Kachov[30] show a mean error of +10.3%, in agreement with the high recovery found (116%) and the higher aspiration rate measured for

*Direct and standard-addition methods.
†Values refused for a 95% statistical confidence level.

the diluted samples compared with that for the standards.

For the method proposed by Sprague and Slavin,[10] we found a low recovery (85%) and a mean error of -13.8%. In this case the aspiration rate of the standards is higher than that of the diluted samples.

Because of these errors, we think that these two methods cannot be recommended for the determination of zinc in serum or plasma. Moreover, we later confirmed the inadequacy of these two methods by comparing the calibration graphs obtained by application of the direct method and the standard-addition method: they were not parallel.

The method proposed by Pekarek et al.,[21] showed -6.9% mean error but the recovery was good. We also found very similar aspiration rates for the diluted samples and standards.

For the other selected methods, the accuracy found was good.

Interferences

We did not find any influence from other ions on the atomization of zinc. However, albumin and other matrix components cause a viscosity increase. Hence the most important interference in zinc determination in serum and blood plasma is caused by physical properties of the solutions. There is a significant difference between the aspiration rates for samples and standards for methods involving a 1:1 sample dilution with demineralized water. When aqueous standards containing 20% of glycerol were used, sample aspiration rates were higher than those of standards, but when aqueous standards were used, sample aspiration rates were lower than those of standards. For both these methods, we observed that the results were in agreement with the recoveries found for plasma samples and for a certified serum sample.

		$T_{tab.} = 2.306$ $P = 0.95$ $n = 5$; $N = 8$	$F_{tab.} = 50.7$ $k = 5$; $n = 4$; $v = n - 1 = 3$	$F_{tab.} = 0.232$ $F_{tab.} = 3.85$ $k = 5$; $n = 4$; $v = 2$	$F_{tab.} = 3.95$ $F_{tab.} = 0.070$ $v = 3$; $v = 18$	$T_{tab.} \pm 2.080$ $v = 21$

For other selected methods, we found very similar aspiration rates for samples and standards.

We also studied the influence of the sample matrix on the zinc atomization process, by comparing the direct and the standard-addition methods. The results obtained are shown in Table 4.

Using the optimal instrumental settings for each method, we analysed the same sample five times by the direct method (according to the recommended procedure) and five times by the standard-addition method, all on the same day.

The variance homogeneity for the five analytical curves obtained by the standard addition method was checked by the Hartley test.[33] We also checked the parallelism of these analytical curves by a global test.[33] From these five analytical curves another analytical curve was calculated, and this was compared with the analytical curve obtained by the direct method.

For five methods, we checked both types of analytical curve for variance homogeneity by Snedecor's test and for parallelism by Student's t-test.[33]

For two methods, those of Arpadyan and Kachov[30] and a Sprague and Slavin[10] we found that the analytical curves were not parallel, and hence think these methods are not adequate for determining zinc in serum and blood plasma.

Finally, we compared by Fisher's test[34] the results for five analyses performed by the direct method with those for five analyses by the standard-addition method, and found they were comparable.

All statistical tests were applied for the 95% probability level.

CONCLUSIONS

We have found that five of the seven flame atomic-absorption methods tested were adequate for zinc determination in serum and blood plasma.

All the methods are comparable with respect to sensitivity but the addition of 5% or 10% of glycerol to aqueous standards of zinc gives a sensitivity higher than that with aqueous standards, whereas addition of 20% of glycerol gives a lower sensitivity. The less the sample dilution, the better the detection limit.

The precision obtained is similar for all the methods and depends more on the characteristics of the analysed samples and daily variation in the experimental conditions, than on the manipulation required for each method. All the methods have good accuracy, except two, both of which involved 1:1 sample dilution, one using aqueous standards and the other using standards containing 20% of glycerol.

Methods involving simple sample dilution are quicker than those requiring a deproteination step.

The most exact and precise methods are those proposed by Smith et al.[28,31] and Fuwa et al.[9] The first

is more sensitive than the second, but requires the use of standards containing 5% of glycerol.

SEPARATION AND CONCENTRATION OF MOLYBDENUM(VI) AND TUNGSTEN(VI) WITH CHELATING ION-EXCHANGE RESINS CONTAINING SULPHUR LIGANDS

CHUEN-YING LIU* and PENG-JOUNG SUN

Department of Chemistry, National Taiwan University, Taipei, Taiwan

Summary—Three chelating ion-exchange resins based on macroreticular polyacrylonitrile-divinylbenzene copolymers with thioglycollic acid and cysteine as functional groups have been tested for separation of molybdenum(VI) and tungsten(VI). On a short column of the thioglycollic acid resin, molybdenum(VI) and tungsten(VI) can be selectively sorbed from pH-4.3 acetate buffer and eluted with $2M$ hydrochloric acid and a mixture of $0.1M$ sodium hydroxide and $0.1M$ sodium chloride, respectively, with quantitative recovery even at very low concentrations. Simulated sea-water samples have been analysed.

The synthesis and characterization of chelating ion-exchange resins containing thioglycollic acid and cysteine as functional groups, and their analytical applications to noble metals, have been described.[1,2] As part of a systematic survey of the behaviour of metal ions with these resins, the chromatography of molybdenum(VI) and tungsten(VI) species has now been studied.

EXPERIMENTAL

Instrumentation

A Radiometer pH-meter was used with saturated calomel (Type K 401) and glass (Type G 202 B) electrodes, and calibrated with Beckman standard buffers of pH 4.00 and 7.00. A Hitachi model 624 digital spectrophotometer connected to a Hitachi model QD_{15} recorder was used, with 10-mm quartz cells.

Reagents

Previously published procedures were used to synthesize the macroreticular polyacrylonitrile—divinylbenzene copolymers.[1,2] The nitrile groups were hydrolysed to carboxylic acid groups. The carboxylic acid resin (200 g) was mixed with 600 g of molten 1,6-hexanediol (m.p. 41°) or 500 g of ethylene glycol, and 40 ml of concentrated sulphuric acid (as catalyst), and kept at 70° for 30 hr for the first esterification. Then a mixture of 150 g of this product with 460 g of thioglycollic acid and 40 ml of concentrated sulphuric acid was reacted at 70° for 30 hr for the second esterification. The 1,6-hexanediol or ethylene glycol served both as linking agent and reaction medium, the products being Resins I and II respectively.[1] The carboxylic acid resin was similarly treated with 1,6-hexanediol and L-cysteine in a two-step esterification to give Resin III.[2] The final product was collected by filtration under suction and washed sequentially with water, concentrated hydrochloric acid, water and acetone.

Spectrophotometric determination of molybdenum(VI) and tungsten(VI)

The procedures used were essentially those reported by Sandell.[3] Maximum colour development and stability were obtained with ascorbic acid as reducing agent for the determination of molybdenum(VI). The sensitivity was increased by extraction of the molybdenum(V) and tungsten(V) thiocyanate complexes into n-butyl acetate.

Sorption by the batch method

Exactly 0.3 g of dry polymer was pre-equilibrated with 20 ml of $1M$ sodium perchlorate–$0.5M$ sodium acetate mixture, the pH being periodically adjusted to the required value with perchloric acid or sodium hydroxide until it had remained constant for 6 hr. The solution was removed by filtration. The metal ion solution (10 ml, $0.062M$) was then added to 10 ml of $2M$ sodium perchlorate and 10 ml of $1M$ sodium acetate, and the pH adjusted to the required value. The prepared metal ion solution, diluted to 50 ml, was added to the pre-equilibrated polymer and stirred for 18 hr. The pH was then checked for constancy, and the resin was filtered off and washed with the appropriate acetate buffer. The filtrate and washings were combined and analysed for molybdenum(VI) or tungsten(VI).

The distribution coefficient for molybdenum(VI), as a function of hydrochloric acid concentration, was also determined by a batch equilibrium method; 25 ml of a mixture containing various amounts of acid and 0.4 mmole of metal ion were stirred with 0.2 g of air-dried resin for 18 hr at 25°. The resin was filtered off and washed, and the molybdenum(VI) in the filtrate was determined.

Equilibration rates

From the capacity studies, the total capacity of each resin for molybdenum(VI) and tungsten(VI) at the optimal pH was known. Twice the quantity of molybdenum(VI) or tungsten(VI) corresponding to saturation of 0.3 g of resin at pH 4.3 was diluted in the appropriate buffer to give $0.03M$ metal ion concentration. Then 0.3 g of the air-dried resin was introduced into this solution and equilibrated. Samples of solution were removed at intervals and their metal ion content was determined.

---

*Author for correspondence.

Separation of molybdenum(VI) and tungsten(VI)

Resin I was packed into a glass tube (10 × 0.6 cm) and conditioned with 20 ml of 1M acetate buffer (pH 4.3). After conditioning, 9.3 μmoles each of molybdenum(VI) and tungsten(VI) were loaded on to the column, and molybdenum(VI) was eluted with 2M hydrochloric acid at 0.5 ml/min. Tungsten(VI) was retained on the column and then eluted with 0.1M sodium hydroxide–0.1M sodium chloride mixture at the same flow-rate.

Concentration of trace metals

Portions (500 ml) of water containing various amounts of molybdenum(VI) or tungsten(VI) were adjusted to pH 4.3 and passed at 0.5 ml/min through a preconditioned 7.0 × 0.6 cm resin column, and the molybdenum(VI) and tungsten(VI) eluted as above and determined. Recovery of 9.70 μg of molybdenum(VI) and 0.01 μg of tungsten(VI) from 1 litre of simulated sea-water[4] was similarly determined.

RESULTS AND DISCUSSION

The pH-dependence of the sorption behaviour of Resins I–III towards molybdenum(VI) and tungsten(VI) was tested by the batch equilibrium method. Table 1 shows the distribution coefficients obtained. Resins I and II, which contained the same functional groups but different linking agents, behaved similarly. The length of the linking agent slightly influenced the capacity. The similarity of the distribution coefficients for molybdenum(VI) and tungsten(VI) at pH 2–7 prevents simple separation of the metals in this pH range. The distribution coefficients for molybdenum(VI) between hydrochloric acid and Resins I–III are shown in Table 2. Tungsten(VI) precipitated from the acid solution, so could not be studied. Molybdenum(VI) or tungsten(VI) at pH 4.3 was used to assess the kinetics of sorption, 50% of the

available sites of Resin I being occupied by molybdenum(VI) and tungsten(VI) in 12 min and 21 min, respectively. From the results of the batch equilibrium study, the possibility of separating molybdenum(VI) and tungsten(VI) by using a Resin I column was obvious. The molybdenum(VI) and tungsten(VI) sorbed can be easily stripped quantitatively from the resin column in succession by 2M hydrochloric acid and 0.1M sodium hydroxide–0.1M sodium chloride mixture, respectively. Figure 1 shows such a separation.

The effect of foreign ions on the recovery of molybdenum(VI) and tungsten(VI) with Resin I was studied. The results are reported in Table 3. Since the sulphur content of Resin I was 1.56 mmole/g, the silver(I) capacity was 1.52 mmole/g, the mercury(II) capacity was 0.80 mmole/g, the molybdenum(VI) capacity was 0.75 mmole/g, and the tungsten(VI) capacity was 0.35 mmole/g, silver(I) and mercury(II) interfered severely, even if the mole ratio to molybdenum or tungsten was reduced to 1, whereas copper(II), zinc(II) and tin(IV) did not interfere at this concentration ratio. The resin exhibited no affinity for the alkali and alkaline-earth metals studied. Small quantities of the resin can therefore be used to concentrate trace metals from samples with a high electrolyte content, such as sea-water and biological

Molybdenum(VI) can be reduced to molybdenum(V) in $2M$ hydrochloric acid and to molybdenum(III) at higher acid concentrations.[5] The colours imparted to the solution by the chelating ion-exchange resins in presence of molybdenum(VI) species are listed in Table 6. The colours, taken in conjunction with those of chemical forms of molybdenum(V) at various concentrations of hydrochloric acid,[5] suggest that molybdenum(VI) is reduced by the resins, e.g. to molybdenum(V) in $0.5M$ hydrochloric acid. Because of this reductive behaviour of the resin, the possibility of using the Mo–thioglycollic acid and Mo–cysteine resin systems for catalysing hydrogenation reactions is obvious. Investigation of the catalytic behaviour of these systems in the nitrogenase reaction as model are in progress.

APPLICATIONS OF LIGAND-EXCHANGE—III

PREPARATION AND PROPERTIES OF PHENOL–FORMALDEHYDE-BASED RESIN IN THE IRON(III) FORM

B. M. Petronio, A. Laganà and G. D. Andrea
Department of Chemistry, University of Rome, Rome, Italy

Summary—A number of resins containing ethylenediamine acetic acid groups have been prepared, and these intermediates (resin-EDTA) converted into the iron(III) form. The capacities of these exchangers in the formation of iron(III)–phenol complexes have been studied and compared with those of the Chelex–iron(III) resin. The character of the exchanger matrix is very important in connection with the retention of phenols and with the elution order. The modified Amberlite CG 4B in the iron(III) form can be used for the quantitative separation of phenolic compounds, a separation that is not possible with the Chelex–iron(III) resin.

As reported in a previous work[1] we have performed the chromatographic separation of a number of phenolic compounds (phenol, 2-nitrophenol, 2,4-dichlorophenol, pentachlorophenol) on a chelating ion-exchanger containing iminodiacetic acid groups, in the presence of iron(III) as complex-generating metal ion, with sodium hydroxide solution as mobile phase.

From the distribution coefficients of the phenols between the resin phase and the eluent it is possible to predict the course of the separation and the optimum conditions. In some cases quantitative separation of the compounds is not possible, because the difference between the separation factors is too small.

Since the nature of the exchanger matrix is an important factor in the strength of binding of a particular ligand and therefore the elution order for compounds of the same class,[2] an important aspect of research into the resolution of mixtures compounds capable of producing complexes is the preparation of resins having different matrices but the same functional groups.

On this basis we propose the preparation of stationary phases with different matrices and containing iminodiacetic acid groups and have examined their capacities in the formation of iron(III)–phenol complexes and the matrix effect on the elution order.

EXPERIMENTAL

Reagents

Standard solutions (1 mg/ml) of phenol, 3,4-dichlorophenol, 2,4-dichlorophenol, 4-chlorophenol, 2-chlorophenol, 2,4,6-trichlorophenol, 2,3,4,6-tetrachlorophenol and pentachlorophenol were prepared by dissolving weighed amounts of the pure compounds in acetone. Portions of these solutions were then diluted with distilled water to give the test solutions. All chemicals were analytical grade.

Iron(III) solution was prepared by dissolving the reagent grade chloride in water.

Ethylenediaminetetra-acetic acid solution was prepared by dissolving the reagent grade disodium salt in water.

Preparation of the iron(III) resins

An intermediately basic anion-exchange resin of the cross-linked acrylic copolymer type (Amberlite IRA 68, Carlo Erba) and a weakly basic anion-exchanger of the phenol–formaldehyde copolymer type (Amberlite CG 4B, Carlo Erba) were used; this second resin also contains phenolic groups. The resins (100–200 mesh) were stirred for 10 hr with 1*M* EDTA, then the solution was decanted and the sorbent washed with water until the washings were EDTA-free. These intermediates (resin–EDTA) were converted into the iron(III) form by mechanical shaking for 3 hr with 100 ml of 1*M* iron(III)chloride. After filtration the resin obtained was washed with distilled water until the effluent was free from iron(III). In a second set of experiments the Amberlite CG 4B resin, a weakly acidic chelating resin of polystyrene type (Chelex 100, Bio-Rad) and a weakly acidic resin of acrylic type (Bio-Rex 70, Bio-Rad) were used. The resins were converted into the iron(III) form in the same way as the EDTA-modified resins.

Retention of phenolic compounds

The prepared resins [4 g, iron(III) form] were packed into 10-mm bore glass tubes. A solution containing 20 μg each of phenol, 2,4-dichlorophenol, 3,4-dichlorophenol, 2-chlorophenol, and 4-chlorophenol in water (100 ml) was passed through the resin column at a flow-rate of 2 ml/min. The column was washed with 10 ml of water and the amount phenolic compounds remaining in the effluent was determined by gas chromatography. The effluent and an equal volume of test sample were both acidified and extracted with methylene dichloride, dried with granular anhydrous sodium sulphate and, after addition of a known amount of 2,4-xilene as an internal standard, were concentrated to a volume of approximately 0.3 ml and analysed.

The same procedure was used with a water solution containing 20 μg each of 2,4,6-trichlorophenol, 2,3,4,6-tetrachlorophenol and pentachlorophenol, and chromatographic columns packed with Chelex–iron(III), Amberlite CG 4B–EDTA–iron(III) and Amberlite CG 4B–iron(III); internal standard, hepatodecanoic acid.
Fig. 1. Retention of phenolic compounds on different resins in the iron(III) form. 1 = Phenol; 2 = 2-chlorophenol;   S = internal   standard;   3 = 2,4-dichlorophenol,   4 = 4-chlorophenol, 5 = 3,4-dichlorophenol; A = standard solution, B = Chelex–iron(III), C = Bio-Rex 70–iron(III), D = IRA 68–EDTA–iron(III), E = CG 4B–EDTA–iron(III), F = CG 4B–iron(III).

The conditions for the gas chromatography were as follows[3]

> Column: glass (190 × 0.2 cm) loaded with 0.2% w/w FFAP on glass microbeads (80–100 mesh).
> Carrier gas: Nitrogen saturated with formic acid; flow-rate 5 ml/min.
> Injector temperature: 185 or 230°.
> Volume injected: 0.5 μl.
> Column temperature: 165 or 210°.

Effect of pH on the distribution coefficients

To a glass bottle containing 3 g of resin in the iron(III) form, 100 ml of water containing 0.5 μmole of a phenol were added. The mixture was shaken at room temperature for a given time (20 min), the aqueous phase was decanted and the resin was washed with water. The amount of phenol remaining in the filtrate was determined by means of its absorbance at 283 nm (2,3-dichlorophenol), 275 nm (3,4-dichlorophenol), 270 nm (phenol), 265 nm (2,3,4,6-tetrachlorophenol), 250 nm (pentachlorophenol), measured with a Perkin-Elmer 320 spectrophotometer and 1.0-cm cells.

The resin was then shaken with 100 ml of sodium hydroxide solution and when this mixture had reached equilibrium, the resin was filtered off on glass-wool and the concentration of the phenol in the aqueous phase was determined spectrophotometrically as before. The pH of the aqueous phase was also measured.

The distribution coefficient K_d was calculated from:

$$K_d = \frac{\text{mg of phenol in resin–iron(III) phase/g of dry resin}}{\text{mg of phenol in solution phase/ml of solution}}$$

Separation of phenols

The Amberlite CG 4B–EDTA–iron(III) resin (2 g) was packed into a 10-mm bore glass tube, and 500 ml of a water solution containing 50 μg each of phenol, 2,3,4,6-tetrachlorophenol and pentachlorophenol were passed through the column at a flow-rate of 2 ml/min. The phenols retained on the column were eluted with 200 ml of a $3.2 \times 10^{-3}M$ sodium hydroxide (pH 11.5). The phenols separated by this stepwise elution were determined spectrophotometrically in successive 10-ml fractions of eluate.

RESULTS AND DISCUSSION

The results for retention of the phenolic compounds on the different resins in the iron(III) form are shown in Fig. 1. The anionic resin of acrylic type in the EDTA–iron(III) form (Fig. 1D) was not able to retain all the phenolic compounds tested: only 2,4-dichlorophenol and 4-chlorophenol were totally bound, phenol and 2-chlorophenol were partially retained and 3,4-dichlorophenol was not retained at all. On the other hand, the Amberlite CG 4B–EDTA–iron(III) showed high affinity for phenols (Fig. 1E, Fig. 2B) as did Amberlite CG 4B–iron(III) resin (Fig. 1F, Fig. 2B) and the results obtained were comparable to those for the Chelex–iron(III) resin (Fig. 1B, Fig. 2B).

Particularly interesting is the behaviour of Amberlite CG 4B in the iron(III) form and in the EDTA–iron(III) form during the elution with sodium hydroxide. There is no elution of phenols from Amberlite–iron(III) with 200 ml of $3.2 \times 10^{-3}M$ sodium hydroxide, but complete elution from the resin in the EDTA–iron(III) form. The difference between the behaviour of same resin in the two forms

can be attributed to the difference in the anionic functional groups, chloride in the first case, and EDTA–iron(III) in the second. The iron(III) present in the Amberlite–EDTA–iron(III) resin is bound either to EDTA or to phenolic ions, whereas in the Amberlite–iron(III) resin it is bound only to phenolic ions and the anionic groups (chloride) are free. On introduction of relatively high concentrations of hydroxide ions the chloride ions are desorbed, and displacement of the phenols by ligand-exchange chromatography is not possible even with 200 ml of $3.2 \times 10^{-3}M$ sodium hydroxide. This is demonstrated by the difference in the pH of the eluent before (11.5) and after (4) passage through the chromatographic column, and by the absence of phenolic compounds but presence of chloride ions in the eluate.

The phenols were also not retained on the acrylic-type cation-exchanger in the iron(III) form (Fig. 1C).

The effect of pH on the distribution coefficients was examined, and Fig. 3 compares the results obtained
Fig. 2. Retention of phenolic compounds on different resins in the iron(III) form. 1 = 2,4,6-Trichlorophenol, 2 = 2,3,4,6-tetrachlorophenol, S = internal standard, 3 = pentachlorophenol.

Fig. 3. Effect of pH (NaOH concentration) on the distribution coefficients of phenols: 1 = phenol, 2 = 3,4-dichlorophenol, 3 = 2,4-dichlorophenol, 4 = 2,3,4,6-tetrachlorophenol, 5 = pentachlorophenol. (a) Chelex–iron(III); (b) CG 4B–EDTA–iron(III).
Fig. 4. Elution curve of a mixture of phenol (1), 2,3,4,6-tetrachlorophenol (2), and pentachlorophenol (3): eluent $3.2 \times 10^{-3} M$ NaOH.

with Amberlite CG 4B–EDTA–iron(III) and iron-(III)–Chelex resin. The K_d values for the phenols examined with both sorbents decrease with increasing pH but the separation factors calculated from the K_d values are not the same for the two exchangers. The elution order differs for the two resins; the sequence for iron(III)–Chelex is phenol > 3,4-dichlorophenol > 2,4-dichlorophenol > 2,3,4,6-tetrachlorophenol = pentachlorophenol and for Amberlite–EDTA–iron(III) it is 2,4-dichlorophenol > phenol > 3,4-dichlorophenol > 2,3,4,6-tetrachlorophenol > pentachlorophenol.

From these distribution coefficients it is possible to predict the course of the separation. For example, the small separation factor for tetrachlorophenol and pentachlorophenol on the Chelex–iron(III) resin indicates that ligand-exchange separation with sodium hydroxide is not possible. On the other hand, the values obtained for the Amberlite system are also not very large but it is possible to achieve the separation with 200 ml of $3.2 \times 10^{-3} M$ sodium hydroxide at pH 11.5 (Fig. 3B, Fig. 4). In contrast, 3,4-dichlorophenol can be separated from 2,3,4,6-tetrachlorophenol on Chelex resin.

Conclusions

It is possible to retain phenolic compounds on an exchanger by a chromatographic process that involves iron(III) bound to the stationary phase, but the character of the exchanger matrix is very important. On an acrylic-type matrix the retention of phenols is poor, whereas it is very good on a styrene–divinylbenzene copolymer or on a phenol–formaldehyde copolymer. With the proper matrix the resin in the iron(III) form may be used for the analytical separation of phenolic compounds.

THE SURFACTANT-SENSITIZED ANALYTICAL REACTION OF NIOBIUM WITH 8-HYDROXYQUINOLINE-5-SULPHONIC ACID

J. I. Garcia Alonso, M. E. Diaz Garcia and A. Sanz Medel*
Department of Analytical Chemistry, Faculty of Chemistry, University of Oviedo, Oviedo, Spain

Summary—Cationic surfactants, such as cetylpyridinium bromide (CPB), sensitize the colour reaction of Nb(V) with 8-hydroxyquinoline-5-sulphonic acid (H_2L). The formation of a ternary complex of stoichiometry $1:3:3$ (Nb–L–CPB) is responsible for the observed enhancement in absorptivity and the quenching in the fluorescence of the Nb–L chelate, when a surfactant is present. The ternary complex exhibits maximum absorption at 383 nm ($\varepsilon = 1.46 \pm 0.01 \times 10^4$ l.mole^{-1}.cm^{-1}) at pH 5.7, and Beer's law is obeyed up to 6-μg/ml Nb concentration. Conditional formation constants of the niobium chelate in the presence and absence of CPB have been determined. On the basis of a detailed spectrophotometric and fluorimetric study the nature of the chromophoric reagent–surfactant interaction and the peculiar features of the sensitization by CPB are discussed.

The enhancement (sensitization) of the colour reactions of metal ions with chelating dyes by the presence of surfactants (usually of the cationic type) provides an inexpensive alternative to atomic spectroscopy methods, for meeting the present demands for determination of ever lower concentrations of elements. The coloured complexes formed in micellar media are characterized by high molar absorptivities (often greater than 10^5 l.mole^{-1}.cm^{-1}) and high stability over a wide pH range, and usually by a large bathocromic shift caused by addition of surfactants to the binary complex formed in water.[1,2] Moreover, some fluorescent binary chelates may dramatically increase their quantum yield in micellar media, thus providing exceptionally sensitive fluorimetric methods.[3]

A deep knowledge of the fundamental aspects of these "surfactant sensitized" reactions should be invaluable in the understanding and design of new analytical methods. Unfortunately, however, very little attention has been paid so far to the study of the mechanism and nature of such micellar effects.

In the course of our search for new methods of Nb(V) determination[4,5] we have studied several 8-hydroxyquinoline derivatives[5,6] which form coloured and fluorescent chelates with niobium. The 7-sulphonic and 5-sulphonic acids of 8-hydroxyquinoline, and 7-iodo-8-hydroxyquinoline-5-sulphonic acid (ferron) should provide surfactant-sensitized reactions with Nb(V) because all of them are strong acids readily yielding a negatively charged group (sulphonate) to interact with the positive head of cationic surfactants. We have found that the 7-sulphonic acid does not give a positive reaction with Nb(V), but the other two reagents do. However, in fluorimetric work

there is the possibility of "heavy atom" effects with ferron (due to the iodine in this reagent), so we decided to study 8-hydroxyquinoline-5-sulphonic acid (H_2L).

In this paper we report a detailed spectrophotometric and fluorimetric study of its reaction with Nb(V), sensitized by cetylpyridinium bromide (CPB). The analytical characteristics of the colour reaction are given and the nature of the interactions of the reagent with surfactant and of the binary chelate with surfactant is discussed.

EXPERIMENTAL

Reagents

Nb(V) stock solution (200 μg/ml; 2.14 × 10^{-3}M). Prepared as described elsewhere.[4] Standard Nb(V) solutions were prepared fresh, by appropriate dilution of the stock solution with 2% tartaric acid solution.

CPB solution, 0.2%; 4.7 × 10^{-3}M. Prepared by dissolving the surfactant in water by warming. The surfactant concentration was determined by titration with tetraphenylborate.[7]

H_2L solution; 2.14 × 10^{-3}M. Made by dissolving 0.5180 g of the reagent in 1000 ml of water, and standardized by titration with sodium hydroxide.

Buffer solution (pH 5.7). Acetic acid (1M) adjusted to pH 5.7 with 1M sodium acetate (pH-meter control).

All reagents were of analytical-reagent grade and were used as received. Distilled demineralized water was used throughout.

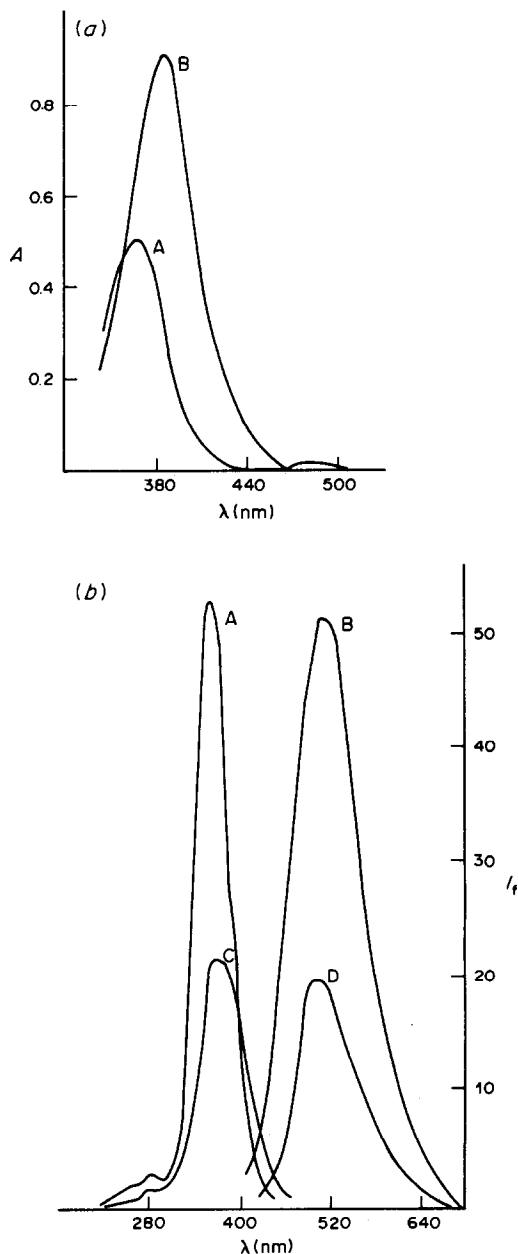
Apparatus

Absorption measurements and spectra were obtained with a Perkin–Elmer model 124 spectrophotometer with automatic recording; 1.00-cm quartz cells were used. Uncorrected fluorescence spectra were recorded and measurements made on a Perkin–Elmer MPF-44 spectrofluorimeter, with a high-pressure xenon tube and standard 1.00-cm quartz cells. A WTW pH-meter, model 391, calibrated against Radiometer buffers, was used for pH determinations. The conductivity measurements were made with a Beckman RC-18A bridge, at 25°. A conventional stalagmometer was used for surface-tension measurements.

---

*Author for correspondence.

General procedure

Pipette standard Nb(V) solutions (containing up to 60 μg of the metal) into a series of 10-ml standard flasks. To each flask, add in the order shown and mixing after each addition: 3 ml of H$_2$L solution, 3 ml of acetate buffer solution and 1 ml of CPB solution. Mix thoroughly and dilute to the mark with water. Allow 5 min for development of the colour, then measure the absorbance at 383 nm, and/or the fluorescence intensity ($\lambda_{em} = 500$ nm and $\lambda_{ex} = 355$ nm). For both types of measurement run a parallel reagent blank, without Nb(V).


RESULTS AND DISCUSSION

Spectral characteristics

Figure 1 shows the absorption spectra (1a) and the uncorrected excitation and fluorescence spectra (1b) for the binary and ternary systems. The addition of surfactant leads to a bathocromic shift of 18 nm in the absorption maximum of the binary complex (365 nm), accompanied by a hyperchromic effect. In contrast, the fluorescence is considerably quenched by the surfactant.

Trimethylcetylammonium bromide gave analogous results, but non-micelle-forming voluminous cations (N,N'-diphenylguanidinium and tetraethylammonium) or the non-ionic surfactant Triton X-100, did not produce any change in the absorption and emission maximum wavelengths or in the absorptivity of the binary complex.

The Nb(V)-L complex is sensitized by cationic surfactants, but enhancement is observed only in the absorptiometric mode. Therefore, optimum working conditions were studied for a spectrophotometric determination of the metal in micellar CPB media.

Effect of experimental conditions on colour development

The influence of pH on the absorbance of the ternary system and the corresponding blank is shown in Fig. 2. The optimum pH range for formation of the sensitized complex is 5–6. We selected a pH of 5.7 because the blank absorbance is minimal at this pH.

The absorbance of the ternary complex Nb(V)–L–CPB depends slightly on the order of addition of the reagents, the best order being cation, H$_2$L, buffer, CPB. Under the experimental conditions of the general procedure, full colour development takes less than 5 min, and the absorbance does not change for at least two days. Increasing the ionic strength from 0.1 to 0.5M with the buffer solution has no noticeable effect.

Fig. 1. (a) Absorption spectra of the binary (A) and ternary (B) complexes. (b) Excitation and fluorescence spectra of the binary (A and B) and ternary (C and D) complexes: pH = 5.7, [Nb] = 6.42 × 10⁻⁵M, [L] = 8.56 × 10⁻⁴M, [CPB] = 7.05 × 10⁻⁴M.
Fig. 2. Influence of pH on complex formation. (A) Ternary complex against reagent blank. (B) reagent blank against water. [Nb] = 5.35 × 10⁻⁵M, [L] = 8.56 × 10⁻⁴M, [CPB] = 7.05 × 10⁻⁴M, λ = 383 nm.

Maximal and constant absorbance was obtained with H_2L concentration at least 10 times that of Nb(V), in the presence of excess of CPB. With a 10-fold ratio of H_2L to Nb(V), maximal reproducible absorbances are obtained when the CPB concentration ratio to Nb(V) is at least 6. Even very high surfactant:Nb(V) concentration ratios did not decrease the absorbance, in contrast to many other micellar systems.[8]

Beer's law, sensitivity and precision

The calibration graph showed that the complex obeys Beer's law up to 6 μg/ml of Nb(V). The apparent molar absorptivity was calculated to be 1.46 (± 0.01) $\times 10^4$ l.mole^{-1}.cm^{-1} at 383 nm. The relative standard deviation, evaluated from ten independent determinations of 5 ppm of Nb(V), was 0.8%.

Interference studies

The influence of those metals which can be associated with niobium in natural or manufactured niobium materials is shown in Table 1. As can be seen, the selectivity is poor (owing to the relativity high pH of the determination), although the addition of EDTA as masking agent clearly improves the situation.

Among the anions tested (fluoride, citrate, oxalate, EDTA and phosphate), only phosphate prevented the formation of the ternary complex, and did so even at very low concentrations. EDTA can be tolerated up to 0.016M concentration.

Table 1. Tolerance for interfering ions (Nb 3 ppm)

Ion	Ratio to Nb (w/w)*	Absorbance	Ratio to Nb (w/w)†	Absorbance
None	—	0.455	—	0.455

MECHANISMS OF THE SURFACTANT ACTION

Chromophoric reagent—surfactant interaction

The marked spectral changes observed on adding the cationic surfactant CPB to H_2L solutions (Fig. 3) clearly demonstrate a chemical interaction. Increasing the amount of CPB gradually shifts the characteristic two-peak spectrum of H_2L at pH = 3.2 towards a single absorption maximum at around 310–315 nm (typical of the free reagent spectrum at pH 6).

According to the values of $pK_{a1} = 3.8$ and $pK_{a2} = 8.4$, determined by us from spectrophoto-
Fig. 3. Absorption spectra of L at pH = 3.2 (curves A–D) and at pH = 6 (curve E) for varying CPB concentrations. (L) = 2.14 $\times 10^{-4}M$; [CPB] = 0 (A, E); 4.7 $\times 10^{-4}M$ (B); 1.41 $\times 10^{-3}M$ (C), 2.35 $\times 10^{-3}M$ (D).

metric data (and in good agreement with those reported in the literature[9]), at pH 3.2 most of the reagent will be present as H_2L whereas at pH 6 virtually all will be in the form HL^-. Therefore, it seems clear that the surfactant promotes dissociation of the chromophoric reagent and the chemical interaction can be formulated as:

$$H_2L + CP^+ \rightleftharpoons (HL^- \cdot CP^+) + H^+ \qquad (1)$$
That is to say, an equilibrium is established between the undissociated form H_2L and an ion-association complex of HL^- with the surfactant (as indicated by the isosbestic point at around 335 nm, the same wavelength as for the corresponding H_2L/HL^- acid–base pair). The existence of this equilibrium is confirmed by conductivity experiments of the type used in the determination of critical micelle concentrations (cmc) of surfactants: the conductivity of surfactant solutions plotted as a function of CPB concentration shows a clear break at $6.39 \times 10^{-4}M$ (Fig. 4, curve A: cmc value). Analogous experiments in the presence of $8.56 \times 10^{-4}M$ H_2L show much higher conductivities for corresponding surfactant concentrations (Fig. 4, curve B). This enhancement must be due to the release of protons, according to equilibrium (1), and the chromophore–surfactant association seems to be relatively weak, as suggested by the gradual change in the slope of the "titration curve" (Fig. 4, curve C).

The chromophore–surfactant interaction may be due to electrostatic attraction between the sulphonate group of the reagent and the cationic head group of the surfactant, resulting in soluble ion-association complexes, even at concentrations below the cmc of

the CPB. This "neutralization" of the sulphonate group would promote the splitting off of the proton from the nitrogen atom of the quinolinium zwitterion:
It is worth noting that at pH $\geqslant 8.5$ addition of CPB does not appear to promote deprotonation of the –OH group. On the contrary, it has been observed that in this pH-range the absorption spectrum of the chromophore gradually flattens with increasing surfactant concentration until it coincides with the spectrum of the ion-association complex.

Goto et al.[10] reported a similar tendency of the hydroxyl group of ferron to remain undissociated in micellar media.

Critical micelle concentrations of CPB solutions

To clarify the role of micelles in sensitized reactions it is important to know the surfactant concentration at which they form (the cmc).

The cmc of CPB in pure water, as determined by us, was $6.39 \times 10^{-4}M$ and $6.86 \times 10^{-4}M$ by conductivity and surface tension measurements respectively (in good agreement with published data[11]). The presence of $8.56 \times 10^{-4}M$ H_2L decreased the cmc to $3.76 \times 10^{-4}M$ (surface tension measurements).

Decrease in the cmc in the presence of dyes seems to be due to formation of mixed micelles of dye ions and surfactant at well below the cmc. In these cases, it is said that the dye induces micelle formation[12] and the "spectral change dye method" for determining surfactant cmc values gives values much lower than those obtained by conductivity and surface tension measurements (without dye). The spectral change method seems to reveal only the first appearance of such mixed aggregates.

In fact, our results on the cmc of CPB, with eosin as the dye,[4] indicate the formation of such mixed dye/surfactant micelles, as the first spectral change (cmc) is observed at $6.55 \times 10^{-6}M$ surfactant concentration, well below the usual cmc of CPB (for homomicelle formation).

Nature of the ternary complex

The molar ratio of Nb(V) to chromophore in the binary complex, determined by Job's method, is 1:3. The composition of the ternary complex was investigated by the continuous-variations and molar-ratio methods, initially with a large excess of CPB. A molar ratio of Nb(V) to chromophore of 1:3 was found for the ternary system by Job's method (Fig. 5) and by the molar-ratio method (by varying the concentration of metal). No definitive conclusion can be reached by varying the concentration of chromophore in the molar-ratio method because the exact
Fig. 4. Variation of the conductivity with CPB concentration in water (A) and in presence of $8.56 \times 10^{-4}M$ L (B). Curve C, difference (B − A).
Fig. 5. Continuous variations method for Nb/L ratio. Total concentration $= 1.28 \times 10^{-4}M$ (A) and $2.14 \times 10^{-4}M$ (B); $[CPB] = 7.05 \times 10^{-4}M$; $\lambda = 383$ nm; pH $= 5.7$.

break in the plot depends on the Nb(V) concentration used. Figure 6 shows the effect of CPB concentration on the absorbance of solutions containing constant amounts of Nb(V) and chromophore. Maximum colour development is reached at an Nb(V):CBP ratio close to 1:4, but the exact ratio depends on the Nb(V) concentration. These facts can be explained as due to reaction (1) acting as a side-reaction between the chromophore and CPB.

Additional information on the composition of the ternary complex was provided by the continuous-variation method applied to isomolar solutions of surfactant and previously formed 1:3 binary complex. A binary complex/CPB molar ratio of 1:3 was found. Thus, it can be concluded that the ternary complex has a metal–chromophore–CPB molecular ratio of 1:3:3.

To gain additional insight into the surfactant sensitization mechanism, changes in the fluorescence intensity of the Nb(V)–H$_2$L complex on addition of CPB were studied. The results, illustrated in Fig. 7, indicate that a constant degree of quenching appears at the same surfactant concentrations (below the cmc) as those for complete sensitization of absorbance (compare Figs 6 and 7). As bromide itself did not significantly diminish the fluorescence of the complex, the quenching observed has to be attributed to the phenomenon responsible for the enhanced absorption: the chemical interaction between CP$^+$ and the NbOL$_3^{3-}$ complex. In other words, the fluorescence quenching arises from formation of the ternary species NbOL$_3$(CP)$_3$ which seems to be much less fluorescent than the NbOL$_3^{3-}$ complex (alkylpyridinium compounds are known to quench the fluorescence of aromatic compounds).[13]

Comparative stability constants

As a quantitative estimate of the effect of CPB on the Nb(V)–H$_2$L reaction, the conditional stability constants (at pH 5.7) of the binary and ternary complexes were evaluated.

The constant, for the $\beta'_{1,3,0}$ binary complex NbOL$_3^{3-}$ was found from the experimental data for absorbance as a function of ligand concentration. The corresponding constant $\beta'_{1,3,3}$ for the ternary complex NbOL$_3$(CP)$_3$ was similarly calculated from the data for constant metal and surfactant concentrations, and from the isomolar Job's method data.

The values obtained are $\beta'_{1,3,0} = 2.5 \times 10^{10}$ and $\beta'_{1,3,3} = 1.4 \times 10^{14}$. The corresponding molar absorptivity coefficients, extrapolated to complete formation of the complexes are: $\varepsilon_{1,3,0} = 1.00 \times 10^4$ and $\varepsilon_{1,3,3} = 1.46 \times 10^4$ l.mole^{-1}.cm^{-1}.
Fig. 6. Influence of CPB concentration on complex absorbance at pH $= 5.7$. [L] $= 8.56 \times 10^{-4}M$; [Nb] $= 6.42 \times 10^{-5}M$ (A); $4.28 \times 10^{-5}M$(B); $2.14 \times 10^{-5}M$ (C). $\lambda = 383$ nm.
Fig. 7. Influence of CPB concentration on relative fluorescence of the complex at pH $= 5.7$. [L] $= 8.56 \times 10^{-4}M$; [Nb] $= 6.42 \times 10^{-5}M$ (A); $4.28 \times 10^{-5}M$ (B); $2.14 \times 10^{-5}M$ (C). $\lambda_{ex} = 355$ nm; $\lambda_{em} = 500$ nm.

CONCLUSIONS

Cationic surfactants sensitize the reaction of Nb(V) with 8-hydroxyquinoline-5-sulphonic acid, typical features of surfactant-sensitized reactions[1,2] being observed, *viz.* bathochromic shift and absorptivity enhancement on addition of CPB (surfactant interaction favours the charge-transfer transition responsible for absorption). Non-detergent cationic counter-ions do not alter the binary-complex spectral characteristics. Moreover, the assumed ternary complex is more stable than the binary complex and forms at pH values at which the binary complex is hardly formed.

The reaction mechanism with CPB, however, is quite peculiar because: (*a*) below the surfactant cmc no precipitation or turbidity is observed, in contrast with most cases;[8,14] (*b*) it is not necessary to reach the "normal" cmc critical micelle concentration of the surfactant to get maximum sensitization; (*c*) a fixed 1:3 ratio of metal chelate to surfactant is observed. It is clear that if sensitization by surfactant were due to a simple inclusion of the complex into the micelles[8] it would be essential to ensure homomicelle formation (*i.e.*, [CPB] > cmc) and a fixed stoichiometry would be meaningless.

Summing up our results, a possible mechanism for the reaction could be that the positive head group of the surfactant interacts with the binary $NbOL_3^{3-}$ complex, through the negatively charged sulphonate groups of L^{2-}, building up the ion-association ternary complex $NbOL_3(CP)_3$. The surfactant in that complex does not behave as a simple counter-ion, however. In fact, it appears that the resulting species is a true ternary complex, but behaves like a soluble mixed micelle of low aggregation number.[15] In such mixed micelles the niobium complex would be isolated from the bulk aqueous solution by the hydrophobic long chains of the surfactant, twisting towards the hydrophobic complex. In this way a hydrophobic environment, similar to that found in a typical micelle, would be created around the chromophore. This new environment and the electrostatic interactions, acting together, would account for the absorbance and fluorescence changes observed.

TWIN-SPRAY FLAME ATOMIC-ABSORPTION SPECTROMETRIC DETERMINATION OF ANTIMONY, BISMUTH AND MERCURY IN GEOCHEMICAL SAMPLES

Yu Xian-An, Dong Gao-Xiang and Li Chun-xue

Shenyang Institute of Geology and Mineral Resources, Shenyang, Liaoning, People's Republic of China

Summary—A new flame atomic-absorption method for determination of antimony, bismuth and mercury, called the twin-spray method, has been established. The operating conditions and potential interferences have been investigated in detail. Under the optimized conditions the sensitivities obtained are 20, 30 and 70 times higher for antimony, bismuth and mercury respectively, than those of conventional AAS. The method can be used to determine as little as $0.00n\%$ of antimony, $0.000n\%$ of bismuth and $0.0n\%$ of mercury in geochemical samples. The procedures are very simple and easy and need no extra apparatus for hydride generation.

Flame atomic-absorption spectrophotometry is well established for determination of antimony and bismuth, but the sensitivity is poor. Because the sensitivity for mercury is also low, up till now flame atomic-absorption spectrometric determination of mercury has not found wide practical application. However, a new method called twin-spray flame atomic-absorption spectrometry has been established,[1] based on the simultaneous aspiration of a solution containing the element to be determined (*e.g.*, Sb, Bi, Hg) and of a solution of potassium borohydride, into an air–acetylene flame. The antimony or bismuth hydride or the elemental mercury generated during the continuous mixing and nebulization of sample solution and reducing reagent solution is carried with the mixed spray into the flame, where the hydride (or metal) is atomized. The aim of the present work was to study the determination of antimony, bismuth and mercury by the twin-spray technique and apply the method to analysis of geochemical samples having various matrix compositions, such as rocks, sediments, copper ores, iron ores and pyrites. As little as $0.00n\%$ of antimony, $0.000n\%$ of bismuth and $0.0n\%$ of mercury can be determined simply and easily in this way.

EXPERIMENTAL

Apparatus

A model WFD-Y$_2$ atomic-absorption spectrometer with a model WF-3 digital read-out system, made by the Second Optical Instrument Factory in Beijing, was used.

A schematic diagram of the twin-spray apparatus is shown in Fig. 1. It is very simple, and easy to make. Three stainless-steel capillaries, A, B, C, are fixed in a piece of plastic (*e.g.*, polyacrylamide) to form a Y-piece. The capillary C is connected to the entry-port of the AAS instrument. A plastic capillary (E) is connected to A and carries a syringe needle (F) at its other end; F dips into the potassium borohydride solution; a second capillary (E) connected to B

dips into the sample solution. The ratio of the flow-rates through A and B is 1:4.

Reagents

Standard working solutions (antimony and bismuth 20 μg/ml; mercury 100 μg/ml) were prepared by diluting stock solutions with water.

The potassium borohydride solution contained one pellet of potassium hydroxide per 200 ml.

Determination of antimony in ores and pyrites

Weigh 0.1 g of powdered sample into a 50-ml beaker and add 15 ml of concentrated nitric acid, 5 drops of concentrated sulphuric acid and 1 ml of 70% perchloric acid. Cover the beaker with a watch-glass, heat to dissolve the sample, then evaporate the solution to fumes of perchloric acid. Cool, add 10 ml of hydrochloric acid (1 + 1), warm gently and transfer the solution and residue into a 50-ml standard flask. Add 5 ml of 25% thiourea–5% ascorbic acid–0.5% potassium iodide solution. Dilute to the mark with water and mix thoroughly.
Fig. 1. Schematic diagram of twin-spray apparatus, A, B and C are stainless-steel capillaries (length 20 mm, bore 0.6 mm); D is a piece of polyacrylamide plastic (20 × 10 × 5 mm); E is plastic capillary tubing (bore 0.9 mm); F is a No. 7 syringe needle (length 32 mm, bore 0.2 mm); a is the solution of potassium borohydride and b is the test solution.
Fig. 2. The calibration graph for antimony.

For the determination the 0.2% potassium borohydride solution is drawn up through A and the sample (or 10% hydrochloric acid for zero adjustment) through B. A typical calibration graph is shown in Fig. 2.

Determination of bismuth in water sediments

Weigh 0.5 g of powdered sample into a 100-ml beaker and add 15 ml of concentrated hydrochloric acid and 5 ml of concentrated nitric acid. Cover the beaker with a watch-glass, boil to dissolve the sample, then evaporate the solution nearly to dryness. Add 10 ml of nitric acid (1 + 1) and heat to dissolve the salts. Transfer the resulting solution and residue into a 50-ml standard flask, dilute the solution to the mark with water and mix thoroughly. Set it aside until the solution becomes clear. Make the measurements as for antimony, but use 0.3% potassium borohydride solution. A typical calibration graph for bismuth is shown in Fig. 3.

Determination of bismuth in copper ores (>2% *of copper*)

Decompose a 0.5-g sample as for sediments, then evaporate the solution nearly to dryness. Add 10 ml of water and 1 ml of hydrochloric acid (1 + 1) and heat to dissolve the salts. Add 1 ml of 2.5% lanthanum nitrate solution followed by 20 ml of ammonia solution (1 + 1). Check that precipitation is complete. Filter off the precipitate, wash it three times with 20% ammonia solution, then redissolve it in 20 ml of nitric acid (1 + 1) heated just to boiling. Collect the solution in the original beaker and transfer it into a 50-ml standard flask, dilute to the mark with water and mix. Complete the determination of bismuth as before.

Determination of bismuth in pyrites containing gold (>50 *g/ton*)

Decompose a 0.5-g sample as for sediments, and evaporate the solution to about 2 ml. Add 10 ml of water, warm, and pour the solution into a funnel having a 6-cm stem containing a chromatographic column (shown in Fig. 4, and prepared as follows). Treat 5 g of PTFE with 10 ml of 15% tributyl phosphate solution in ether, let the ether evaporate, then soak the material in dilute hydrochloric acid and pack
Fig. 4. Chromatographic column funnel.

it in the funnel stem between cotton-wool plugs, to give a flow-rate of 1–2 ml/min. Condition the column for use by washing it first with an acid mixture consisting of 15 ml of concentrated hydrochloric acid and 5 ml of concentrated nitric acid diluted to 100 ml with water, and then once with 10 ml of 1*M* hydrochloric acid, collecting the sample solution and washings in a 100-ml beaker. Evaporate the solution nearly to dryness. Add 10 ml of nitric acid (1 + 1) and measure as for sediments.

Determination of mercury in ores

Weigh a 0.1-g sample into a 100-ml beaker. Add 5 ml each of concentrated hydrochloric acid and nitric acid, cover the beaker with a watch-glass, boil gently for 5 min, then remove the watch-glass and continue heating gently for 10–15 min. After cooling, transfer the solution into a 50-ml standard flask, dilute it to volume with water and mix. For the determination use 0.05% potassium borohydride solution and "10% mixed acid" (see Table 1) solution to adjust the zero point. The calibration graph is linear up to 500 μg of mercury in the final 50 ml of solution.

RESULTS AND DISCUSSION

Optimization of operating conditions

The effects of acetylene flow-rate, observation height, and concentrations of potassium borohydride and acids, on determination of antimony, bismuth and mercury were studied systematically. The effect of potassium borohydride concentration is shown in Fig. 5. It was found that the response signals were practically constant at hydrochloric acid, nitric acid or sulphuric acid concentrations between 5 and 20%

Fig. 3. The calibration graph for bismuth.
Fig. 5. Effect of concentration of potassium borohydride on determination of (I) 2 ppm of antimony, (II) 1 ppm of bismuth and (III) 2 ppm of mercury.

for antimony, at concentrations of hydrochloric acid and nitric acid between 5 and 20% for bismuth and at concentrations of hydrochloric acid and nitric acid between 5 and 20% (in 1:1 v/v mixture) for mercury. An acid concentration of 10% (as listed in Table 1) was chosen as the best compromise. To vary the ratio of flow-rate through A and B, syringe needles of different bore were employed. When a No. 7 needle (0.2 mm bore, 32 mm long) was used, the absorption signal was maximal, so this needle was selected to control the flow-rate through A. The ratio of flow-rates through A and B was then about 1:4.

Sensitivity of twin-spray methods

It was found (Fig. 5) that the simultaneous mixing and nebulization of the two solutions caused the atomic-absorption signal to increase sharply only if

the concentration of potassium borohydride was very low. The characteristic concentrations under the optimized conditions are shown in Table 2. They are improved by factors of about 20 for antimony, 30 for bismuth and 70 for mercury, by use of the very simple twin-spray apparatus.

Effect of other cations

The effects of different cations on the determination of antimony, bismuth and mercury were investigated.

There was no interference in determination of antimony (2 μg/ml) at the following levels of other cations: 5 mg of Co(II), Cd, Ni, Cu(II), Zn, Pb, Ca, Mg, Mn(II), Ti(IV), Al; 1 mg of As(III), Bi; 0.5 mg of Sn(IV); 0.1 mg of Se(IV), Te(IV), Ag, Hg(II). The interference of 100 mg of Fe(III) and 100 μg of Au(III) (which decrease the antimony signal) could be minimized by using thiourea and ascorbic acid as masking agents.

In determination of bismuth (0.4 μg/ml) the tolerances for other elements were: 50 mg of Fe(III); 25 mg of As(III); 10 mg of Cu(II), Pb, Zn; 5 mg of Co(II), Cd; 1 mg of Sn(IV); 0.25 mg of Ag; 0.1 mg of Hg(II); 30 μg of Se(IV), Te(IV); 20 μg of Au(III). Larger amounts of iron slightly increased the bismuth absorbance, and larger amounts of copper, gold, selenium and tellurium seriously suppressed the response. Copper can be removed by co-precipitation with lanthanum hydroxide,[2] and gold by extraction chromatography with TBP.[3] However, the concentrations of selenium and tellurium are unlikely to exceed 50 ppm in normal geochemical work. The effect of a large amount of iron can be compensated for by adding about the same amount to the calibration solutions. For example, for a 0.5-g sample of

Table 4. Comparison of results of determination

	Rock A Sb	Rock B Sb	GSD* 2 Bi	GSD* 6 Bi	Copper ore 4C Bi	Mercury ore A Hg	Mercury ore B Hg
Mean value, %	0.007	0.017	0.00022	0.00052	0.00038	0.060	0.229
Recommended value, %	0.005	0.022	0.00016	0.00050	0.00039	0.058	0.223

*Sediment sample.

pyrite, 250 mg of Fe(III) needs to be added to each of the standard solutions.

The following amounts of various elements had no significant effect on determination of mercury (4 μg/ml): 25 mg of Fe(III), Cu(II), Ca, Mg; 10 mg of Pb, Zn, Cd, Al, Ti(IV), Mn(II), As(III), Sn(IV), La; 5 mg of Co(II), Ni; 2.5 mg of Sb(III); 0.2 mg of Bi; 0.1 mg of Se(IV), Ag; 10 μg of Te(IV), Au(III). Generally speaking, there is no need to separate mercury from cations commonly accompanying it, if the sample weighs not more than 0.1 g, because the gold and tellurium concentrations very rarely exceed 100 μg/g in normal rocks.

Applications

The method has been used to determine traces of antimony and bismuth and low levels of mercury in geochemical samples and some standard samples. The values obtained are compared with the certified values for standard reference samples, in Table 4.

Determination of antimony and bismuth in pyrites was also tested, by the method of standard-additions. The amounts of antimony and bismuth added to samples before decomposition were recovered quantitatively.

CONCLUSIONS

The operating conditions for "twin-spray" atomic-absorption spectrometric determination of antimony, bismuth and mercury have been established. Many elements commonly accompanying these metals show no significant interference. The effects of large amounts of iron and gold on the determination of antimony may be minimized by adding thiourea and ascorbic acid as masking reagents. The main interferences from copper and gold in determination of bismuth can be overcome by prior separation of copper by co-precipitation[2] and separation of gold by extraction chromatography with the TBP–PTFE–HCl system.[3] Under the optimized operating conditions the sensitivities of the twin-spray method are 20, 30 and 70 times higher for antimony, bismuth and mercury respectively, than those of conventional AAS methods. Trace amounts of antimony and bismuth and low amounts of mercury in various geochemical samples can be satisfactorily determined. The relative standard deviations are 2% for mercury, and 5–10% for antimony and bismuth. The procedures are very simple and easy, and a special feature is that they need no additional apparatus for hydride generation.

DETERMINATION OF CADMIUM BY DIFFERENTIAL PULSE ANODIC-STRIPPING VOLTAMMETRY AFTER SALTING-OUT EXTRACTION INTO ACETONITRILE

Yukio Nagaosa and Toshihiro Yamada
Faculty of Engineering, Fukui University, 3-9-1 Bunkyo, Fukui 910, Japan

Summary—A selective and specific method is presented for anodic-stripping voltammetric determination of cadmium after extraction with $0.1 M$ tetrabutylammonium iodide solution in acetonitrile from aqueous ammonium sulphate solutions. The detection limit of this method is 0.2 ng/ml (in the acetonitrile extract). Interference from matrices or large amounts of elements reduced at more positive potentials can be eliminated by prior extraction. The method has been applied to trace analysis for cadmium in zinc, lead and indium metals, and some inorganic salts.

Although numerous voltammetric methods have been developed for the determination of cadmium in various samples,[1-4] anodic-stripping voltammetry (a.s.v.) in the differential pulse mode is widely utilized because of its low detection limits (of the order of 0.1 ng/ml) and its relative freedom from matrix effects.[5-10] Our preliminary experiments showed that serious interferences were caused by the presence of lead, indium, nickel or zinc in the conventional a.s.v. determination of cadmium. Like polarography, the a.s.v. method applied in aqueous medium suffers from interferences by large amounts of matrix elements or cations reduced at more positive potentials than the analyte. In such cases a preliminary separation is usually necessary to isolate the analyte (in this work, cadmium) from interfering elements prior to the a.s.v. determination, particularly in the analysis of complicated matrices.

Fujinaga and Nagaosa have overcome the problem of poor selectivity by utilizing a salting-out extraction followed by polarography in acetonitrile as solvent.[11] Exploitation of differential pulse polarography after such an extraction, however, often seems inadequate for trace analysis of real samples.

The aim of the present work was to demonstrate the capability of the proposed, a.s.v. method following extraction into acetonitrile, for the determination of cadmium in aqueous solutions containing interfering elements. The cadmium is extracted as its iodide complex from an aqueous ammonium sulphate solution into a salted-out acetonitrile phase containing tetrabutylammonium iodide (TBAI) $(0.1 M)$, then determined by direct differential pulse a.s.v. measurement on the non-aqueous phase. It has been shown that this method can be applied to the determination of cadmium in zinc, lead, aluminium and inorganic salts with good results. This a.s.v.

method would have potential for application to a wide range of trace analyses for metals, particularly in steels, alloys and environmental samples.

EXPERIMENTAL

Apparatus

All voltammetric measurements were made with a Princeton Applied Research (PAR) Model 174A polarographic analyser with a Model 303 static mercury-drop electrode assembly. A Riken Denshi Model F-3EP X–Y recorder was used to obtain current–potential curves in the cyclic and a.s.v. experiments. The three-electrode system consisted of a hanging mercury-drop electrode as the working electrode, a silver–silver chloride reference electrode and a platinum-wire auxiliary electrode. The a.s.v. analyses were performed with a Fuso Model 915 controller, at the following settings: deposition potential, -0.95 V; deposition time, 180 sec; rest period, 30 sec; modulation amplitude, 25 mV; scan-rate, 5 mV/sec; drop-size, medium.

Reagents

Acetonitrile, ammonium sulphate and TBAI were as described previously.[11] The other reagents used were of guaranteed reagent grade from Wako Pure Chemicals Co., Ltd. The 50% ammonium sulphate solution used as aqueous phase was stripped of any cadmium in the salt used, by extraction with three 10-ml portions of $0.1 M$ TBAI in acetonitrile. Standard cadmium nitrate solution (1 μg/ml) was diluted as required, to give the working solutions. The high-purity water used throughout was produced by a Millipore Milli-Q system.

Procedure

An aliquot of the sample solution (not exceeding 5 ml) was taken in a 50-ml stoppered centrifuge-tube, and 20 ml of 50% ammonium sulphate solution and 20 mg of ascorbic acid were added, and the volume was made up to 25 ml with water. Ten ml of $0.1 M$ TBAI solution in acetonitrile were added and the two phases shaken vigorously to extract the tetraiodocadmate-TBA ion-pair. Exactly 8.0 ml of the acetonitrile phase were transferred into an electrolytic cell. After deaeration of the acetonitrile solution with nitrogen (saturated with acetonitrile) for 5 min, the a.s.v. determination of cadmium was performed at 25°, with continued passage of the nitrogen over the solution surface.

Fig. 2. Effect of deposition potential on peak current. Cd(II) 8.0 ng/ml; deposition time 3 min.

Sample dissolution

About 1 g of a metal sample, in a 100-ml beaker, was dissolved in 10 ml of concentrated nitric acid by heating at *ca.* 50°, and this was followed by evaporation almost to dryness. After cooling, the residue was dissolved in 10 ml of 2M nitric acid and diluted to volume in a 100-ml standard flask with water. Inorganic salt samples were dissolved in moderately concentrated hydrochloric acid and diluted to standard volume.

RESULTS AND DISCUSSION

Voltamperograms

The degree of extraction of cadmium with TBAI into a salted-out acetonitrile phase was sufficiently high (99.5% in a single extraction) for the purpose of this study.[11] The amount of cadmium present in commercially available ammonium sulphate was large enough to be detectable by our extraction–a.s.v. procedure under the chosen conditions. The ammonium sulphate solution was therefore purified by extraction with 0.1M TBAI solution in acetonitrile.

Figure 1 shows a cyclic voltamperogram and a differential pulse a.s.v. curve for the cadmium complex extracted into the acetonitrile phase. The difference between the two peak potentials on the cyclic voltamperogram, 30 mV, indicates a quasi-reversible electrode reaction with two-electron transfer. The anodic wave, which is about three times as high as the corresponding cathodic wave, is more suitable for analytical use. It is probable that the presence of iodide from the TBAI facilitates stripping of the deposited cadmium into the acetonitrile solution. A differential pulse a.s.v. peak was obtained at −0.78 V *vs.* Ag/AgCl and was ten times as sensitive as that obtained in 0.1M hydrochloric acid medium. Selectivity as well as sensitivity is shown to be improved by the acetonitrile extraction method using the salting-out technique.
Effect of experimental conditions on a.s.v. peak heights

It is clear from the data shown in Fig. 2 that the cadmium peak height is approximately constant only for the narrow range of deposition potentials from −0.90 to −0.95 V *vs.* Ag/AgCl. Outside this range, the peak height decreases sharply. This result can be understood from the fact that the tetraiodocadmate complex gives a minimum d.c. wave at potentials between −1.1 and −1.5 V; in this potential range, the cadmium complex anion undergoes coulombic repulsion by the negatively charged mercury. A deposition potential of −0.95 V was used for the determination of cadmium.

As shown in Fig. 3, the cadmium peak height increases linearly with increasing deposition time up to 8 min, beyond which the increase is more gradual. A deposition time of 3 min was used in this study, though longer deposition times are recommended for ultratrace analysis if necessary.

The cadmium peak height was found to increase by a factor of about 3 as the scan-rate was decreased from 10 to 1 mV/sec. With decreasing scan-rate, the peak potential shifted to more positive values and the peak width became narrower. The serious effect of scan-rate on peak height may be due to the irreversible electrode reaction of the cadmium complex in the acetonitrile extract. A scan-rate of 5 mV/sec
Fig. 3. Effect of deposition time on peak current. Cd(II) 4.0 ng/ml; deposition potential −0.95 V.

was therefore chosen as optimal for the determination of cadmium.

Sensitivity and reproducibility

Calibration graphs for cadmium under the chosen conditions showed good linearity up to a concentration of 50 ng/ml in the acetonitrile extract. Higher concentrations of cadmium can be determined directly by differential pulse polarography of the extract. A relative standard deviation of *ca.* 5% was found for 5 replicate determinations at the 1-ng/ml level and *ca.* 10% at the 0.4-ng/ml level (10 replicates). The cadmium peak height obtained in the blank test was 8 nA, corresponding to 0.2 ng/ml Cd: this may be due to cadmium in the mercury and reagents used. A detection limit of 0.2 ng/ml was estimated, on the basis of the detection limit being twice the standard deviation of the blank signal.

Standard-additions method

The cadmium in indium metal (99.99% purity) was determined by the standard-additions method, with aqueous cadmium solution added to the acetonitrile extract. The cadmium content thus found, 0.10 ppm, was in good agreement with the value (0.12 ± 0.02 ppm) obtained from the calibration graph. Application of the standard-additions method in this way was found to be satisfactory: the cadmium–TBAI complex is formed in the acetonitrile phase.

Interferences

The effect of foreign ions on the a.s.v. determination of 4.0-ng/ml cadmium was studied under the established conditions. Table 1 gives the results. A 10^4-fold w/w ratio (to cadmium) of iron(III), bismuth, cobalt(II), chromium(VI), antimony(III), manganese(II), tin(II), aluminium, nickel and silver (as their nitrates or sulphates) was tolerated, along with 200 mg of chloride and 40 mg of nitrate. The tolerance limit for these ions is expected to be much higher than the amount usually present in the test samples. Copper(II), which is reduced and co-extracted as the iodide complexes of copper(I), tends to reduce the peak height of cadmium, but a concen-

fortunately does not interfere, since the peak is well separated from that for cadmium. Salts such as sodium chloride, ammonium sulphate and potassium nitrate were also analysed for cadmium (Table 3), about 1 g of sample being used.

Applications

The samples selected for study were zinc, indium, lead and their salts, because these metals often interfere in the determination of cadmium by the conventional a.s.v. method. Table 3 summarizes the results obtained. Those for the NBS zinc samples agree satisfactorily with the certified values. As in the case of the analysis of lead and indium, the method seems applicable to other samples with good selectivity. We hope that some problems in the a.s.v. or polarographic method have been resolved by the preliminary separation in the solvent extraction step; it is, however, a somewhat tedious procedure.

Summary—A method for a serological diagnosis of syphilis is presented, in which a thin-layer ion-selective electrode is used for monitoring the complement-mediated immune lysis of antigen-sensitized phospholipid liposomes in microlitre sample volumes. The liposomes are loaded with tetrapentylammonium ions (TPA^+) which are then released from the liposomes by the immuno reaction and are monitored by a TPA^+ ion-selective electrode. This is a direct but much amplified measure of the syphilitic antibodies to be assayed. The principles and evaluation of the method are given. The results have been compared and correlated with those of a conventional method.

The most important factors in potentiometric immunoassay are the achievement of two critical requirements: (1) high selectivity without interference from other proteins, and (2) use of as small a sample volume as possible. Recently, we have developed a novel method for fulfilling these requirements. It uses a thin-layer ion-selective electrode (ISE)[1] to monitor the complement-mediated immune lysis of antigen-sensitized phospholipid liposomes[2] in microlitre volumes of solution. The liposomes are loaded with a concentrated solution of water-soluble membrane-impermeable molecules or ions as a marker. The marker retained within the liposomes will not cause a response in the corresponding ISE. Complement-mediated lysis of the liposomes releases the marker ions to a dilute solution, where the relevant ISE can respond sufficiently rapidly, under the conditions used, for the rate of response to be a valid measure of the rate at which the marker is released from the liposomes.

In the present paper, the proposed method is applied to the serological diagnosis of syphilis.

PRINCIPLE

Membrane immunochemistry

Liposomes prepared from a mixture of the pure lipids, cholesterol, lecithin and cardiolipin, are able to bind antibodies active against the spirochaete causing the disease (*Treponema pallidum*).[3] In the presence of complement, an immunological lysis of the membrane takes place (Fig. 1). This membrane lysis can be monitored by first trapping marker ions or mole-cules inside the liposomes and then using an appropriate ISE or species-selective electrode, to follow their release, which is a direct but much amplified measure of the antibodies to be assayed. In the present study, the tetrapentylammonium ion (TPA^+) was chosen as marker, and a TPA^+ ion-selective electrode was used. This ion was chosen as marker because it is large enough for its background leakage to be negligible during an experiment and because its selectivity coefficients towards Na^+ and K^+ are 5.0×10^{-6} and 6.2×10^{-6} respectively, so interference by Na^+ and K^+ in sera will be negligible.

Thin-layer potentiometry

A μl-sample solution is held as a thin-layer in a narrow space between the flat bottom of the ISE sensor and a plate-shaped silver/silver halide reference electrode (Fig. 2). With this arrangement the necessary sample volume can be reduced by three or four orders of magnitude (to the μl level) from that for ordinary ISE measurements (1–10 ml level) without miniaturizing the ISE itself. This assembly makes potentiometric measurements of immunological systems practicable.

EXPERIMENTAL

The multilamellar liposomes were prepared from chloroform solutions of dipalmitoyl phosphatidylcholine (DPPC, Sigma), cardiolipin (CL, Sigma), cholesterol (CH, Nakarai Co.) and stearylamine (SA, Sigma) in molar ratio 2:0.02:1.5:0.21. After evaporation of the chloroform, the dried lipids were swollen in aqueous 0.15M TPA^+ solution (pH 7.4). Untrapped marker ions were removed by centrifugation (17400 g) for 10 min each time, at 0°, with five portions of modified veronal saline (VBS) (3.12mM barbital, 1.82mM barbital sodium salt, 0.15mM $CaCl_2$, 0.5mM $MgCl_2$, 0.147M NaCl). The liposomes were prepared according to Kinsky *et al.*[4] A plate-shaped Ag/AgCl reference

*Author for correspondence.
Fig. 1. Immune lysis of sensitized liposomes by antibody and complement, and resulting leakage of
marker ion, TPA^+ (tetrapentylammonium ion).

electrode was made by anodic oxidation of a silver plate
(4 × 7 cm, 2 mm thick) in $0.1M$ potassium chloride at
$+0.5$ V vs. SCE for 5 min. A TPA^+ ISE was made with PVC
and dioctyl phthalate, in the body of an Orion Model 95
electrode. The electrode response was Nernstian over the
TPA^+ range from 1 to $10^{-6}M$. Seropositive and normal
human sera were provided by the Japan Red Cross Blood
Centre (Tokyo). The titre value for the seropositive sera
used was determined to be 1:512 by a standard semi-
quantitative method, SST (Serodiagnosis of Syphilis Test,
Iatron Co. Tokyo). The SST method is based on careful
observation by the naked eye of the extent of precipitates
composed of antigen–antibody complexes and fine carbon
powder. The reagents used for the SST method are the same
lipids as those for the constituents of liposomes mentioned
above, except for the stearylamine (which was added to
increase the trapping efficiency of liposomes for positively
charged marker ions). All human sera used were treated at
56° for 30 min before testing, in order to eliminate the
complement activity from the human serum itself. The
complement used was from guinea pig serum, which was
stored at $-80°$. The titre value for this was found to be 267
CH50/ml by a simplified Mayer method.[5]

A typical procedure was as follows. To a 50-μl or other
(suitable) liposome aliquot were added an equal volume of
Wassermann-seropositive serum and an equal volume of
fresh guinea pig serum (source of complement). After 30 min
incubation at 25°, typically 20–50 μl of the mixture was
placed on the Ag/AgCl reference electrode and the ISE
body (in an upright position) was lowered onto the sample
droplet. Thus, the sample solution was kept in a thin layer
between the flat bottom of the ISE and the reference
electrode, for e.m.f. measurement. The e.m.f. were measured
on a millivolt meter (Model HM-5bs, TOA Electric Co.,

Fig. 2. Thin-layer potentiometry for microlitre samples.

Tokyo) at 21° after a wait of 3 min for equilibrium to be
attained.

It is known that the phase-transition temperature for
liposomes differs according to the kinds of phospholipids
used. Thus, it seems important to choose an appropriate
temperature for incubation. We selected an incubation
temperature of 25° for the immune lysis reaction, as a
trade-off between the greater possibility of background
release of marker ions at higher temperatures and the
optimum temperature of around 37° for the immuno-
reaction. Indeed, the release of marker ions was 11, 14 and
85% greater at 30°, 37° and 55° respectively, than at 25°. It
should be noted, however, that this release of TPA^+ ions
refers to incubation, in which rather vigorous stirring under
warm conditions is general. In contrast, in the static condi-
tions of the thin-layer ISE measurement in the present case,
such background release of marker ions was quite negligible
during the course of the experiment.

RESULTS AND DISCUSSION

*Maximum potential change and optimum complement
level*

The crucial point for obtaining maximum potential
change was found to be minimization of the anti-
complement reaction induced by unidentified constit-
uents in human sera. To do this, the haptenic antigen-
sensitized liposome was first complexed with the
corresponding antibody (Wasserman antibody), and
any unwanted components in the sera were separated
from the system. The procedure was to bind the
antigen-sensitized liposome sufficiently with the anti-
serum by heating at 37° for 30 min, and then wash it
adequately with VBS by centrifugation, with two
changes of VBS. It was assumed that after this, most
of the active haptenic antigen sites on the surface of
the liposome membrane were occupied by corre-
sponding antibodies. The haptenic antigen-sensitized
liposomes thus made were then reacted with various
concentrations of guinea-pig serum (complement
source) so that the effect of complement concen-
tration was accurately measured. The results are
shown in Fig. 3, where ΔE is the difference between
E_c (the e.m.f. reading when the active complement
Fig. 3. Effect of complement concentration on TPA$^+$ release from the antigen–antibody sensitized liposomes (200 μl) (see text). G.P.C.—guinea-pig serum as complement source (100 μl). $\Delta E = E_c - E_c'$.

Fig. 5. Correlation between the present method and a conventional (SST) method for the diagnosis of syphilis. Twenty different human sera (both from normal persons and patients) were collected from the Japan Red Cross Blood Centre, Tokyo. ● Positive serum (1:5 dilution); ○ negative serum (1:5 dilution); G.P.C. 1:3 dilution.

was used) and E_c' [the e.m.f. when the inactive complement (heat-treated at 56° for 30 min) was used but under otherwise identical conditions]. The advantage of using ΔE is that the background correction is accurate, because the total protein concentration is the same for the sample (with active complement) and the blank solution (with deactivated complement) even if the level of complement has to be changed. As seen in Fig. 3, the maximum change in potential thus obtained as about 45 mV, at rather high complement levels.

Dependence on antibody concentration

The ISE potential was measured as a function of dilution (concentration) of seropositive human sera (titre 1:512) (Fig. 4). Blank values were again obtained by use of an identical concentration of deactivated complement but under otherwise identical conditions, as in the preceding section. Also, the same

Fig. 4. Effect of seropositive serum (titre 1:512) dilution (concentration) on TPA$^+$ release from liposomes. G.P.C. 1:3 dilution.

experiments were performed, for comparison, with normal human sera, which of course show no potential changes with dilution. However, it was found that even with use of normal human sera, ΔE values of 4–5 mV were observed, in contrast to expectation. The reason for this is not clear at the moment, but probably some components of unknown nature in the guinea-pig serum (complement source) rather than of normal human serum may cause lysis of liposomes to a certain extent, because normal human sera at varied levels gave similar ΔE values. Also, the fact that the relation between ΔE and normal sera concentration becomes parallel to the abscissa suggests that the influence of serum concentration on the potential change of the Ag/AgCl reference electrode is negligible, even though the latter is in direct contact with the sample solutions. It should also be pointed out here that although the Ag/AgCl electrode is by itself a chloride ion-selective electrode, unwanted shifts of the reference potential due to possible variations of chloride ion activity from one sample to another was strictly eliminated by use of saline buffers. As shown in Fig. 4, the potentials with positive sera change with dilution, levelling off at $\Delta E = 30$ mV. The maximum potential change obtained in this case is somewhat smaller than that in Fig. 3. This may be due to inhibition of the lysis reaction, caused by an anti-complement component in human sera, the influence of which was carefully eliminated experimentally in the case of Fig. 3.

Correlation with a standard method

In an attempt to judge the present method for assaying anticardiolipin antibodies, a series of different seropositive syphilitic sera was examined both by the standard procedure (a standard semi-quantitative method, SST, see experimental section) and the present method. The results, which are correlated in Fig. 5, are mainly in good agreement.

With normal sera in which antibody activity is negative, ΔE is only 0–3 mV, whereas positive sera give an appreciable increase in ΔE with increasing titre values. It should be noted, however, that one point (marked with an asterisk) in Fig. 5 does not fit this correlation. The exact reason for this is not clear, but it may be attributed to some basic differences between the two methods; for instance, it is known that depending on the extent of syphilitic disease, corresponding antibodies in the sera change in composition from IgM-rich to IgG-rich.[6,7] It is also reported that in the complement-fixation reaction, IgM antibody can be detected more sensitively than IgG. In the ISE method, the leakage of marker ions is observed through the complement-mediated immune lysis of liposomes, whereas in the SST method the quantity of the antigen–antibody complex is directly measured. Also, it should be noted that the potential change for less sero-positive sera (titre values between 1:1 and 1:4) is smaller than expected from the value in Fig. 4, where a 100-fold dilution of a seropositive serum (titre, 1:512) gives a ΔE value of 14 mV. The crucial difference in these two cases is the extent of dilution of human sera; more dilution gives higher potential change, although the final titre values are the same. This is caused by an anti-complement reaction induced by unknown components in human sera. For preventing this anomaly, the procedure mentioned in the first section of the discussion is recommended. However, a simple 8-fold dilution of human samples rather than 2–4-fold is a more convenient trade-off. Greater sensitivity would be expected if single lamellar liposomes were used.

APPLICATION OF THE DEFORD AND HUME METHOD MODIFIED FOR QUASI-REVERSIBLE AND IRREVERSIBLE PROCESSES TO THE CHELATES OF Bi(III) WITH AZOMETHINE DERIVATIVES OF 2-BENZOYLPYRIDINE

M. A. Gomez-Nieto,* J. L. Cruz Soto,† M. D. Luque de Castro* and M. Valcarcel*

*Department of Analytical Chemistry and †Department of Mathematics, Faculty of Sciences, University of Córdoba, Spain

Summary—The polarographic behaviour of the bismuth complexes of the oxime, hydrazone and thiosemicarbazone of 2-benzoylpyridine has been studied by differential pulse polarography. The DeFord and Hume method, modified for use with quasi-reversible and irreversible processes, has been applied for the calculation of the formation constants of these chelates, which exhibit different degrees of reversibility in their electroreduction.

We have studied the electroreduction of the azomethine derivatives of 2-benzoylpyridine at the dropping mercury electrode, by d.c. polarography and differential pulse polarography.[1-3] We have also developed a modification to the DeFord and Hume method that is applicable to quasi-reversible and irreversible systems, and have written three computer programs for calculation of complex-formation constants from the results obtained by the method.[4]

In the present work we first made a photometric study of three of these reagents with 37 metal ions to detect which combinations gave complexes (Table 1), then a polarographic study to find which complexes gave reduction waves that were in the polarographically useful region and not overlapped by the ligand reduction wave (Table 2). In this way we identified the systems suitable for study by DPP.

A preliminary literature survey brought out the following points.

(1) The ligands used in earlier studies have almost all been not reducible at the working potential. The others had a reduction potential more cathodic than that of the complex; otherwise the measurements necessary for calculation of the stability constants had to be made on the diffusion plateau for the ligand, with the consequent disadvantages of ligand adsorption on the electrode surface and the impossibility of obtaining constants other than that for the first complex, without determination of the free metal concentration.

(2) The ligands were small, to minimize adsorption on the electrode, since adsorption effects on the value of the constants obtained are not clearly defined.[5,6]

(3) The ligands had to be fairly soluble since the investigations were based on the effect of the ligand

concentration on the reduction potential of the complex.

(4) The choice of cations was limited to those giving reversible reduction.

(5) Only three bismuth complexes had been studied: those with EDTA,[7] 5-methoxymethylquinoline[8] and nitrilotriacetic acid.[9]

(6) DPP was very little used for this type of study.[10-12]

In view of these features, the present research represents an important departure from previous practice.

EXPERIMENTAL

Apparatus

A Metrohm E-505 polarograph and E-506 recorder system, with Ag/AgCl electrodes as reference and auxiliary electrodes, in conjunction with conventional dropping mercury and hanging drop electrodes. A Perkin-Elmer 575 spectrophotometer with 1.0-cm glass cells and an electronic thermostat. A Beckman 3500 pH-meter with combined calomel–glass electrode.

Reagents

Ethanolic solutions of 2-benzoylpyridine oxime (BPO) (0.05M) and 2-benzoylpyridine hydrazone (BPH) (0.1M) and a dimethylformamide solution of 2-benzoylpyridine thiosemicarbazone (BPT) (0.05M). Aqueous solutions (1.0M) of sodium perchlorate, potassium nitrate, potassium chlorate, potassium chloride and tetramethylammonium bromide were used as supporting electrolytes.

Britton and Robinson buffers (pH 1–12). Gelatine solution (1%).

Aqueous standardized Bi(III) solution (1000 ppm). More dilute solutions were prepared as required. All solvents were of analytical grade.

Study of experimental variables

Unless otherwise specified, the working conditions were as follows.

RESULTS AND DISCUSSION

Influence of type and concentration of supporting electrolyte

$NaClO_4$, $KClO_3$, KNO_3, KCl and $Br(CH_3)_4N$ solutions covering the concentration range 0.05–0.70M were used. The KCl solution gives more reversible processes (smaller peak-width) for the Bi–BPH and Bi–BPT systems. For Bi–BPO, KNO_3 was used as supporting electrolyte because, although the peak-width is slightly greater than when KCl is used, the peak is less overlapped by that for mercury oxidation and by the first reduction peak of the oxime. Since the fundamental parameters of DPP are not altered when the supporting electrolyte concentration is varied in the interval studied, a concentration of 0.5M was used for all further experiments, so that the electrode process remained the same throughout, and the migration current was constant.

Effect of surfactants

The reagents were examined in the concentration range 0.004–0.040%, and found to modify the reversibility of the processes, shifting the peak potential to more negative values and exponentially increasing the peak-width, W, with increasing concentration of surfactant.

Effect of pH

The influence of pH in the range 1.9–12.0 on the fundamental parameters of the DPP technique is very different for each system, as shown in Table 3 and Fig. 1. We can offer no explanation for the fluctuations in W with pH, but they have been repeatedly observed. The effect seems too large to be explainable in terms of localized irreversible chemical changes occurring during the pH adjustment. The pH values chosen for subsequent experiments are also shown in Table 3. The number of protons exchanged per mole of complex was calculated on the assumption that the systems are mononuclear.

Influence of temperature

The interval 20–50° was examined for all three systems. Figure 2 shows the change in peak-current, I_p, and peak-width, W, as a function of temperature (T). Table 3 gives the equations of the straight lines $I_p = f(T)$, the temperature coefficients, and the temperatures used for further experiments (chosen so that deviations would have minimum influence on the fundamental parameters and so that the reversibility of the processes would be maximal). At temperatures above 35° the Bi–BPT system shows anomalous behaviour, probably as a result of adsorption of the complex on the electrode surface. We have observed similar behaviour for the Co–BPT system.[14]

Organic solvent

The solvents used to increase the ligand solubility were ethanol (Bi–PBO and Bi–BPH systems) and dimethylformamide, DMF, (Bi–BPT system). Figure 3 shows there was a decrease in I_p and an increase in W when the proportion of organic solvent in the test solution was increased.

Height of mercury column (h)

The variation of $\ln I_p$ with $\ln h$ was linear, but the slopes were between 0.7 and 0.85 (Table 4). Since the life-time of the mercury drop is constant in pulse polarography, a change in mercury head affects only the rate of mercury flow.

Drop-time, pulse amplitude and scan-rate

These parameters were studied to establish the working conditions for maximal reversibility of the electrode processes.

In all cases I_p increases and E_p becomes more positive when the drop-time t_d is increased, for all values of pulse amplitude (ΔE) and scan-rate (V), though the effect is higher for the Bi-BPO system; ln I_p is a linear function of $\ln t_d$ for all the systems (Table 4). For the Bi-BPO and Bi-BPT systems, the slopes of the straight lines increase with the pulse amplitude, indicating diffusion-controlled processes. For the Bi-BPT system, the slopes at high pulse-amplitudes are greater than 2/3 because of adsorption effects under these working conditions. For the Bi-BPH system the slopes go through a maximum. The W values decrease with increasing t_d (ΔE and V kept constant), which indicates greater reversibility of these processes when the drop life-time is increased. The W value that corresponds to a reversible three-electron process is not attained for any working conditions, although for the Bi-BPT system W is very close to this theoretical value when the pulse amplitude is small. The plot of E_p vs. $\ln t_d$ is nearly linear
Fig. 1. Variation of W and E_p with pH.

Table 3. Study of the experimental variables for the Bi–azomethine systems

for the Bi–BPO system, but not for the others, which shows a higher degree of reversibility for these two systems.

Increasing ΔE, with t_d and V kept constant, results in increase in I_p and a shift of E_p to more negative values, and a plot of I_p vs. $(\sigma - 1)/(\sigma + 1)$ [where $\sigma = \exp(2nF/RT\Delta E)$] for the Bi–BPT system is linear, corroborating the reversibility of the electrode process,[15] but the plots for the other two systems are non-linear (Fig. 4).

$^*I_p$ in μA, h in cm, t in sec.
Fig. 4. Reversibility of the electrochemical processes for the Bi–azomethine systems.

If the potential scan-rate is decreased, with ΔE and t_d kept constant, E_p shifts to less negative values, I_p increases and W decreases.

Metal ion concentration and stoichiometry

The range of concentration for this study was limited by the solubility of the ligands and by the acidic character of Bi(III), which promotes its precipitation as hydroxide when it is not complexed. The ligand concentration was kept constant and the cation concentration varied as follows.

System	[Ligand], $10^{-4}M$	[Bi(III)], $10^{-5}M$
Bi–BPO	1.0	2.0–20.0
Bi–BPH	1.0	1.5–20.0
Bi–BPT	1.0	1.9–48.0

E_p and W are practically independent of the cation concentration in the Bi–BPO and Bi–BPH systems, but not in the Bi–BPT system. Plots of I_p against [ligand]/[Bi(III)] ratio, Fig. 5, allow the deduction of the stoichiometry of the complexes formed under these conditions.

For the Bi–BPO and Bi–BPH systems the ligand–bismuth ratio is 1.5, which could correspond to a 3:2 stoichiometry, but the existence of such a complex is unlikely, in view of the scant tendency of bismuth to form polynuclear complexes, and the restrictive conditions for the existence of these systems. It is much more probable that this ratio is due to the formation of two complexes (1:1 and 2:1) that predominate in the concentration range used for the study.

The plot for the Bi–BPT system clearly indicates a 2:1 complex.

Effect of ligand concentration and calculation of stability constants

Table 5 gives the data for this study. The low
Fig. 5. Stoichiometries of the Bi–azomethine systems.

solubility of the ligands permits their concentration to be varied over only a very narrow range, so the change in reduction potential is small; it is also a function of the stability constant of the complex and this explains why the BPH system gives the smallest shift although it is the most soluble of the reagents, and the least soluble (BPT) gives the biggest shift.

The bismuth concentration was fixed at $2.0 \times 10^{-5}M$, the drop-time at 1.2 sec, pulse amplitude at 25 mV and the scan-rate potential at 2.5 mV/sec. The other conditions were as follows.

	Bi–BPO	Bi–BPH	Bi–BPT
pH	3.45	4.00	3.36
Temperature, °C	30.0	22.0	25.0
Organic solvent, %	5	6	3

The data in Table 5 were treated in the following way. The peak-potential values were obtained by means of the program F0(I)[4] which applies the weighted least-squares method to the equation of the Tomes lines for a.c. polarography and DPP.[13] By means of this program the intensity and potential measurements for each peak are weighted by a factor, ω_i, given by:

$$\omega_i = \frac{4I_p I_i^2 (I_p - I_i)}{I_p^2 + I_i^2}$$

where I_p is the peak current and I_i the current at the ith potential. The currents were directly measured on the polarograms. The program also calculated the number of electrons involved in the electrode process and the values of the F0 term in the DeFord and Hume equation and of the corresponding term F1 in

our modification of the DeFord and Hume method for use with quasi-reversible and irreversible systems.[4]

$$F0 = \exp[\frac{nF}{RT}\Delta E_{1/2}] + \ln\frac{I_{dM}}{I_{dC}} = \sum_{j=0}^{N} \beta_{ML_j} C_L^j$$

$$= 1 + \beta_1 C_L + \beta_2 C_L^2 + \ldots + \beta_N C_L^N \quad (1)$$

$$F1 = \frac{I_{pM}^{(n\alpha)_j/(n\alpha)_0}}{I_{pC}} \exp\left[\frac{(E_{pM} - E_{pC})(n\alpha)_j F}{RT}\right]$$

$$= \sum_{j=0}^{N} \beta_{ML_j} C_L^j = 1 + \beta_1 C_L + \beta_2 C_L^2 + \ldots + \beta_N C_L^N \quad (2)$$

As can be observed in Table 5, the F0 values are higher than the F1 values, because the theoretical value of 3 for the number of electrons involved (considered in F0) is never attained by the product $n\alpha$. On the other hand the variation of F0 with ligand concentration is higher than that for F1, which means in practice that the coefficients of the C_L polynomial (stability constants of the complexes) are smaller than those calculated when the theoretical number of electrons is considered; moreover, the constants that correspond to lower stoichiometries have a greater weight (which is shown graphically by smaller slopes for the curves).

Three computer methods were used for solving equations (1) and (2) for determination of the formation constants. They are described here only briefly, since a detailed description has been given elsewhere.[4]

The programs GIP(II) (Gauss iteration program) and F0W (F0 weighted) are based on application of the method of weighted least-squares to equations (1)

and (2). GIP linearizes the equations by approximative and initially estimative values of the constants; these values are called $\delta\beta_j$ and are refined by an iterative method until a preselected convergence criterion is satisfied. F0W directly linearizes equations (1) and (2) by minimizing the errors through weighting the F0 and F1 values by the factor ω_i, given by:

$$\omega_i = 1/[F0(i)]^2$$

where $[F0(i)]^2$ is the value obtained for the first member of the DeFord and Hume equation (or our equation), from the ith experiment.

The third program, MSE (minimal sum of errors) is based on a numerical approximation method which gives the values of the stability constants which minimize the difference between the experimental and theoretical values of F0 and F1.

The results are given in Table 6 and the following comments may be made.

Bi–BPO system

Similar values for the stability constants are obtained by all three programs. When the theoretical number of electrons is considered [equation(1)], only one formation constant is obtained, corresponding to 1:2 cation–ligand stoichiometry. Application of our proposed modification to the DeFord and Hume method gives significant values of β_1, as well as of β_2, which is in agreement with the stoichiometry shown in Fig. 5 (1:1.5), and with the molar fraction of the 1:1 and 1:2 complexes, obtained for each ligand concentration by the MSE program.

Table 6. Formation constants for the Bi–azomethine systems

System	Program	β_1	β_2
			Original method
BPO–Bi	GIP II	0	$(27.4 \pm 0.8) \times 10^5$
	F0W	0	$(26.6 \pm 1.30) \times 10^5$
	M.S.W.	0	$(28.7 \pm 0.1) \times 10^5$
			Modified method
	GIP II	$(15.4 \pm 1.7) \times 10^2$	$(83.0 \pm 44.4) \times 10^3$
	F0W	$(16.2 \pm 1.7) \times 10^2$	$(59.8 \pm 45.3) \times 10^3$
	M.S.E	$(16.8 \pm 0.1) \times 10^2$	$(49.8 \pm 0.1) \times 10^3$
			Original method
BPH–Bi	GIP II	20.4 ± 16.2	$(49.2 \pm 33.8) \times 10^2$
	F0W	21.0 ± 6.2	$(47.7 \pm 13.0) \times 10^2$
	M.S.E.	24.0 ± 1.0	$(47.6 \pm 0.1) \times 10^2$
			Modified method
	GIP II	16.4 ± 8.5	$(37.7 \pm 17.7) \times 10^2$
	F0W	16.5 ± 5.1	$(37.4 \pm 10.8) \times 10^2$
	M.S.E.	18.0 ± 1.0	$(37.5 \pm 0.1) \times 10^2$
			Original method
BPT–Bi	GIP II	0	$(9.2 \pm 1.80) \times 10^8$
	F0W	0	$(4.1 \pm 0.30 \times 10^8$
	M.S.E.	0	$(8.67 \pm 0.01) \times 10^8$
			Modified method
	GIP II	0	$(2.0 \pm 0.3) \times 10^8$
	F0W	0	$(1.3 \pm 0.1) \times 10^8$
	M.S.E.	0	$(1.79 \pm 0.01) \times 10^8$

A value of zero was obtained throughout for β_3.

Bi–BPH system

Both the DeFord and Hume method and ours give significant values of β_1 and β_2, in total agreement with the stoichiometry found and the molar fraction values calculated by using the MSE program. The constants are lower than those for Bi–BPO system, and the uncertainty in the values is therefore higher.

Bi–BPT system

Both methods gave only one significant value, for the constant corresponding to 1:2 cation–ligand stoichiometry. The relative errors are of the order of 10%, which is reasonable in view of the characteristics of the system.

CONCLUSIONS

The study of the effect of the cation concentration is important, since it provides information about the types of complex formed; the number and degree of the possible constants are necessary input data for the programs.

In none of the systems is a stoichiometry greater than 1:2 observed. In the absence of the ligand the Bi(III) begins to form hydroxo-complexes at a pH close to zero; hence the E_{pM} values are not the same for the three systems, since each is examined at a different pH.

The three systems studied show a variable degree of reversibility as a function of the ligand concentration; that is why the DeFord and Hume method is not really suitable, as is demonstrated by its failure to detect some of the complexes that are experimentally shown to be present (in the study of the effect of cation concentration). These complexes are detected, however, by use of our modification.

The MSE program gives smallest uncertainty in the constants, and is the one recommended.

BACKGROUND-CURRENT SUBTRACTION
IN VOLTAMMETRIC DETECTION FOR
FLOW-INJECTION ANALYSIS

Joseph Wang* and Howard D. Dewald
Department of Chemistry, New Mexico State University, Las Cruces, NM 88003, U.S.A.

Summary—A new approach for background-current subtraction for flow-injection systems using potential-scanning voltammetric detection is described. The method is based on recording voltamperograms while the sample and carrier solutions flow through the cell, and taking the difference as the net response for the sample. Background currents due to hydrogen evolution, oxygen reduction, solvent oxidation or surface processes are thus compensated, and detection limits at submicromolar levels can be obtained. The compensation for oxygen reduction current means that samples do not need to be deaerated. The method has been evaluated for reproducibility, concentration dependence, detection limit, *etc*. A flow-cell with a stationary disk electrode, a 200-μl sample volume, and rapid differential pulse scanning are used. At a flow-rate of 0.3 ml/min about 15 samples can be assayed per hour. Chlorpromazine, phenol, acetaminophen, norepinephrine, lead, cadmium, bismuth and zinc were used as test species.

Flow-injection analysis (FIA) is a versatile and fast method of automated analysis, based on the injection of reproducible sample volumes into a continuously flowing carrier stream.[1,2] The use of electrochemical transducers as detectors in FIA is growing rapidly.[3] Most electrochemical transducers utilize constant-potential amperometric detection, mainly because of its inherent sensitivity. The increasing demand for improved selectivity and multi-component determinations in flow-injection systems has resulted in the incorporation of dynamic voltammetric detection based on rapid potential scanning.[4,5] A voltamperogram recorded during passage of the sample plug through the detector gives instantaneous electroanalytical data. Thus, the resolution of voltammetry adds selectivity to flow-injection systems, the peak potentials serving for identification. However, there is a loss in sensitivity as a result of background currents associated with the potential scan.

This paper reports a subtractive approach for background-current correction in FIA with voltammetric detection. Subtractive techniques, based on subtracting the blank voltamperogram from the sample response, have been applied in anodic-stripping voltammetry[6,7] and conventional a.c. polarography.[8] The flow manifold of FIA systems can easily be exploited to obtain a subtractive response. By subtraction of the voltamperogram for the carrier stream from that for the sample plug, a net signal for the analyte can be obtained, free from background effects (provided that the background electrolyte content of the sample matches that of the carrier). Two systems can be used: (1) placing two "identical" working electrodes before and after the injection port, and subtracting the carrier response from that of the sample plug; (2) using a single working electrode, and recording the "background" and "sample" voltamperograms while the carrier and sample plugs, respectively, flow through the cell. The second option seems the more promising, since it eliminates problems associated with matching two electrodes and the need for an additional polarograph. The characteristics and applications of this procedure are described below.

EXPERIMENTAL

Apparatus

The flow-injection system consisted of carrier and sample reservoirs (400-ml Nalgene beakers), a Model RP-SY FMI reciprocating piston pump (Fluid Metering, Inc.), a Rheodyne Model 7010 injection valve with a 200-μl sample loop, and the electrochemical detector. All connections were made with 0.5-mm bore Teflon tubing and fittings (Pierce Chemical Co.). The tubing connecting the valve to the detector was 8 cm long.

The electrochemical detector has already been described.[5] A solution flow channel was drilled through the plexiglas body. Various 3-mm diameter disk working electrodes were employed, including mercury-coated glassy carbon, bare glassy carbon and carbon paste. The Ag/AgCl reference electrode (Model RE-1, Bioanalytical Systems) joined the working-electrode compartment close to the face of the working electrode.[5] The carbon-rod auxiliary electrode dipped into the solution in the outlet channel. All measurements were made with a Sargent-Welch Model 4001 polarograph.

Reagents

Millimolar stock solutions of phenol, acetaminophen and norepinephrine were made up fresh each day. Standard bismuth and zinc solutions were stored in polyethylene containers. Supporting electrolytes were 0.05M phosphate buffer and 0.1M potassium nitrate. Other chemicals and reagents used have already been described.[9,10]

*Author for correspondence.

Procedure

The carrier solution was pumped continuously at constant rate (usually in the range 0.2–0.4 ml/min). After gravity filling of the injection loop with sample, the valve was turned into the injection position. Rapid (1–2 V/min) differential pulse scans were initiated 15–40 and 120–150 sec after the injection, to record the "sample" and "background" voltamperograms, respectively. The optimum times for initiating the potential scans depend upon the experimental conditions and the species measured, as will be described later. For measurements in the cathodic region, the glassy-carbon electrode was coated with a mercury film by passing $5 \times 10^{-5}M$ mercury(II) in the carrier solution through the detector at a rate of 0.2 ml/min for 20 min, with a potential of -0.8 V imposed on the working electrode; a gravity flow was used in these cathodic experiments. The subtractive voltamperograms were obtained by using a time-sharing computer as described previously.[10]

RESULTS AND DISCUSSION

Though the differential pulse waveform effectively corrects for the non-faradaic charging current, various faradaic background currents remain and limit the detection power. The subtractive mode corrects for these background currents, and was first tested with single-species systems. Figure 1 shows FIA voltamperograms for various species, recorded in the conventional way and also after background-current subtraction. The species were chosen to illustrate compensation of background currents from different sources: zinc (hydrogen evolution and reduction of oxygen); chlorpromazine and phenol (oxidation of

water and redox reactions of the carbon surface functional groups); bismuth (reduction of oxygen). Well-shaped and easily measured peaks, with relatively flat base-lines, are obtained in the subtractive mode. Correction for oxygen reduction (curves C and D) is of special interest because removal of oxygen from small volumes of injected solutions requires a relatively cumbersome procedure,[11] and is not effective if the flow analyser is constructed from Teflon tubing, which is readily permeated by oxygen. All the data reported in this paper were obtained with samples that had not been deaerated.

For effective background-subtraction, however, careful matching of the electrolyte content and pH of the sample and carrier solutions is essential. For example, for background currents that are pH-dependent (*e.g.*, hydrogen evolution, oxygen reduction) solutions of different pH would yield incompletely corrected base-lines. Partial matching of the sample and carrier solutions (especially when real samples are concerned) can be done by diluting the sample with the carrier (supporting electrolyte) solution, or by adding to the carrier some of the sample macro constituents; if matching is essential but incomplete, the base-line will not be flat.

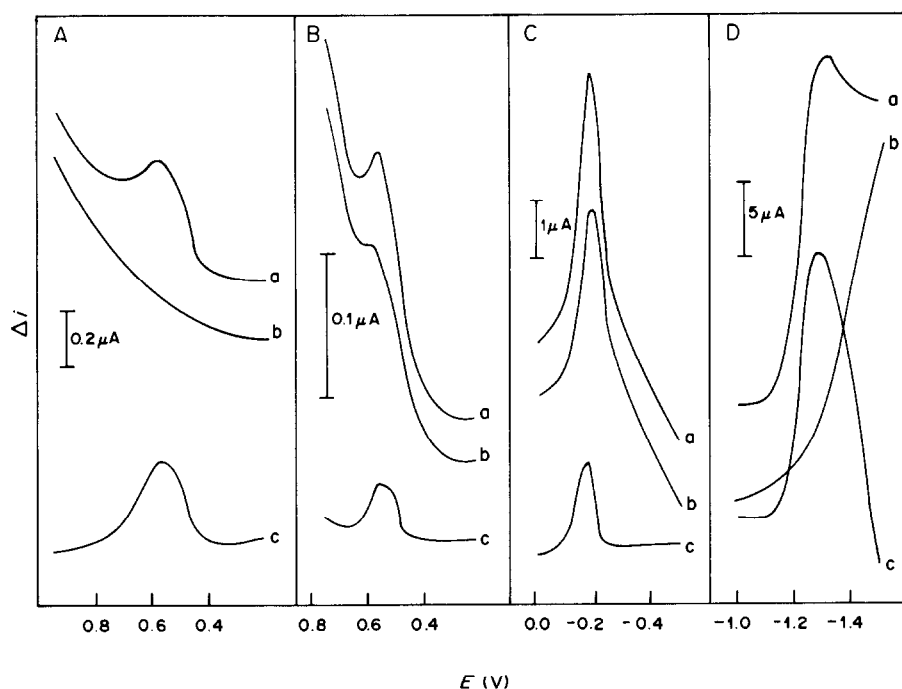
Because of the dispersion process in FIA systems, careful and reproducible timing is required for recording the two voltamperograms, so that the appropriate solution is in the detector. For this, exact knowledge of the concentration profile of the sample


Fig. 1. FIA/differential pulse measurements of $5 \times 10^{-5}M$ phenol (A), $5.2 \times 10^{-5}M$ chlorpromazine (B), $3.6 \times 10^{-5}M$ bismuth (C), and $1 \times 10^{-4}M$ zinc (D). zone is required; this is usually obtained by preliminary measurement of the current–time profile or by initiating the potential scan at different times after sample injection. To allow scanning of a 1.0-V potential region during passage of the peak concentration sample zone (60–100% of the concentration maximum) through the detector, a flow-rate of 0.2 ml/min and a scan-rate of 2 V/min were used.[5] Obviously, when mixtures of species with different redox potentials are analysed, some species are measured before and some after their concentration peak has passed the detector. To minimize carry-over, the "background" voltamperogram must not be initiated earlier than 120 sec after sample injection. For analytes that interact (by adsorption or extraction) with the electrode surface, e.g., chlorpromazine [Fig. 1(B)], longer delay times are required to ensure removal of these surface species. As a compromise between sensitivity and speed, a delay time of 150 sec has been used for such species, resulting in a partial loss of the analytical signal (as the peak for residual chlorpromazine, shown in the "background" response, is subtracted from that of the "analytical" one). The influence of the experimental variables affecting the voltammetric scan and the dispersion of the sample plug has been discussed elsewhere in detail.[5]

Figure 2 compares voltamperograms recorded in the conventional and subtractive modes for lead solutions of increasing concentration. The con-

ventional current peaks are affected by the background current, associated mainly with oxygen reduction, whereas well-defined peaks and a horizontal base-line are obtained in the subtractive mode. The peak currents in the subtractive mode are proportional to the lead concentration (least-squares analysis yields a slope of 0.12 $\mu A.1.\mu mole^{-1}$ (correlation coefficient 0.9997, intercept -0.16 μA). Similar calibration experiments for cadmium, zinc and dopamine (concentration ranges 10–50, 100–200 and 50–125 μM, respectively) also yielded linear plots. From the signal-to-background characteristics of the response [Fig. 2(f)] the detection limit for lead would be near $5 \times 10^{-7}M$ (corresponding to 20 ng in the volume injected).

The precision of the method was estimated by repeated injection of $2.5 \times 10^{-5}M$ lead (conditions as in Fig. 2). The mean peak current was 2.78 μA, range 2.77–2.80 μA, relative standard deviation 0.4% (7 replicates).

Figure 3c illustrates application of the method to analysis of mixtures. The bismuth, lead, cadmium and zinc mixture (micromolar concentrations) yields well-defined and separated peaks, over a relatively flat base-line. Comparison with the conventional voltamperogram (curve a) shows the superiority of the subtractive mode, especially for zinc and bismuth. Similar improvement was obtained for a mixture of oxidizable species: $5 \times 10^{-5}M$ norepinephrine, ace-
Fig. 3. Response for the injection of a sample mixture ($2 \times 10^{-5}M$ bismuth, lead and cadmium and $5 \times 10^{-5}M$ zinc). (a) "Analytical" curve; (b) "background" curve; (c) the subtractive response, (a) − (b). Differential pulse ramp, flow-rate, working electrode, and supporting electrolyte as for Fig. 1C; scan-rate 2 V/min.

taminophen and chlorpromazine. Depending on the peak potentials and peak half-widths of the sample components, up to 6 species can be measured in one injection.

These results confirm the utility of the approach. The method is applicable to other dynamic FIA detection modes, e.g., scanning spectroscopy. The approach may also be used with segmented flow systems. Because of the time required to record the voltamperograms, the method has a slower injection rate (about 15 samples per hour) than FIA with amperometric detection, but this is offset by the multi-component detection capability. Higher injection rates could be achieved by using faster potential pulse techniques, e.g., rapid square-wave voltammetry,[12] and by recording the "background" voltamperogram at given time intervals (e.g., every 30 min) rather than after each injection (or at the beginning of a series of injections). As in all FIA studies, highly reproducible timing is essential. An extension of this methodology toward subtractive anodic stripping voltammetry, with depositions during the passage of the sample and carrier solutions through the detector, has been accomplished recently in our laboratory.[13]

SHORT COMMUNICATIONS

DETERMINATION OF ULTRA TRACE CONCENTRATIONS OF NITRITE IN POLLUTED WATERS AND SOIL

Abha Chaube, Anil K. Baveja and V. K. Gupta*
Department of Chemistry, Ravishankar University, Raipur (M.P.), 492010 India

Summary—The nitrite is used to diazotize *o*-nitroaniline and the *o*-nitrophenyldiazonium chloride formed is coupled with *N*-(1-naphthyl)ethylenediamine dihydrochloride. The red-violet dye (absorption maxima at 545 nm) is stable and extractable into isoamyl alcohol. Beer's law is obeyed in the range 0.1–0.6 ppm nitrite in the original sample if the aqueous system is measured, and 0.025–0.15 ppm in the sample if extraction is used. The molar absorptivity is $6.04 \times 10^4 \, l.mole^{-1}.cm^{-1}$.

Industrial effluents and the nitrogen cycle add to contamination of the environment with nitrite. Nitrite is undesirable in water owing to its toxicity.[1,2] The maximum permissible in potable water is fixed by the U.S. Public Health Service at 0.06 ppm.[3]

Most spectrophotometric methods for determination of nitrite in water and waste water are based on the Griess–Ilosvay reaction[4,5] and some include use of solvent extraction to enhance the sensitivity.[6,7] Here we introduce *o*-nitroaniline as the substrate for diazotization. The *o*-nitrophenyldiazonium chloride formed is coupled with *N*-(1-naphthyl)ethylenediamine dihydrochloride in acid medium to give a red-violet dye (absorption maxima at 545 nm), extractable into isoamyl alcohol. The molar absorptivity is $6.04 \times 10^4 \, l.mole^{-1}.cm^{-1}$. The method is more sensitive than some recently reported methods.[8-11]

EXPERIMENTAL

Reagents

All reagents used were of analytical-reagent grade.

Standard 1000 µg/ml nitrite solution. Prepared in deaerated doubly distilled water from reagent dried for 4 hr at 110°, and standardized;[12] a small amount of chloroform was added as stabilizer. A 1-µg/ml working standard was prepared by dilution with deaerated, doubly distilled water.

o-Nitroaniline solution, 0.001 M. Prepared in 20% aqueous ethanol from a twice recrystallized commercial reagent.

N-(1-Naphthyl)ethylenediamine dihydrochloride solution, 0.1%.

Solutions of foreign ions were prepared according to West.[13]

Procedure

To a known volume of water sample (containing 2.5–15 µg of nitrite) in a 25-ml standard flask, add 1 ml of *o*-nitroaniline solution and adjust to 1*M* hydrochloric acid concentration. Shake the flask occasionally during the next 2 min to ensure complete diazotization. Add any masking agent needed and 2 ml of NEDA solution, and make up to the mark with 5*M* hydrochloric acid. Measure the absorbance at 545 nm against distilled water after 5 min. Prepare

*Senior author, to whom correspondence should be addressed.

a calibration graph for 2.5–15 µg of nitrite in a similar manner.

Solvent extraction

Place a known volume of sample (up to 100 ml, containing 2.5–15 µg of nitrite) in a 250-ml separatory funnel and form the red-violet dye as described above, except that the final acidity is adjusted to 2.5*M* hydrochloric acid. Extract the dye with two 10-ml portions of isoamyl alcohol, dry the combined extracts with anhydrous sodium sulphate and dilute to volume in a 25-ml standard flask with the solvent. Measure the absorbance at 545 nm against a reagent blank similarly treated. Prepare a calibration graph by treating standards in a similar manner.

RESULTS AND DISCUSSION

The absorption spectrum of the red-violet dye shows maximum absorption at 545 nm. Under the recommended conditions the dye is stable for up to 20 hr, and the absorbance varies by not more than 2% over a period of up to 30 hr.

Reaction conditions

The effect of acidity on the diazotization was studied. A hydrochloric acid concentration of at least 1*M* was found necessary for complete diazotization; a 1–6*M* acidity range gave constant absorbance. Constant absorbance values were obtained for diazotization reaction times from 1 to 90 min, and the minimum time for the coupling reaction was found to be 2 min.

The effects of varying the molar ratio of *o*-nitroaniline (*O*NA) and NEDA to nitrite were examined. For *O*NA and nitrite, the absorbance was constant for *O*NA:NO$_2^-$ molar ratios $\geqslant 1:1$. Similarly maximum absorbance was obtained with NEDA:NO$_2^-$ ratios $\geqslant 10:1$.

Analytical characteristics

The colour system was found to obey Beer's law in the range 2.5–15 µg of nitrite per 25 ml of initial aqueous sample for the direct procedure, and 2.5–15 µg per 100 ml of sample when the extraction procedure was used. The molar absorptivity was found

§Masked with H_2O_2.

to be 6.04×10^4 1.mole^{-1}.cm^{-1} for both systems. The reproducibility was studied by replicate analysis of a standard nitrite solution over a period of 7 days. The relative standard deviation was found to be 1.1% and 1.5% for the direct and extraction procedures respectively.

Effect of foreign species

Since the method was developed mainly for the analysis of water samples, the effects of foreign species at the levels commonly present in tap water, river water and tank water were studied. The tolerance limits shown in Table 1 are the concentrations of foreign species that cause ≤2% error in the determination of 0.1 ppm of nitrite by the extraction method (100-ml samples). Cu(II), Fe(II) and SO_2 interfere but the interference of up to 100 ppm of SO_2 can be eliminated by oxidizing it to sulphate with hydrogen peroxide. Bismuth and Fe(III) require masking with tartrate.

Solvent extraction

The limit of detection can be lowered by employing solvent extraction. Of the solvents tested, isoamyl alcohol was found the best. The molar absorptivity was lower when higher alcohols such as hexanol and octanol were used, and the dye was unstable in chloroform. Extraction was incomplete with benzene, dichlorobenzene or carbon tetrachloride. By use of a large sample (100 ml) and extraction of the dye into isoamyl alcohol, very low concentrations of nitrite (0.025 μg/ml) can be determined.

Application to polluted waters and soil

Samples were collected in wide-mouthed plastic vessels at different points upstream and downstream from the source of industrial effluents. Samples of potable water were collected from different tanks. Mercuric chloride (4 mg per 100 ml of sample) was used for preservation and samples were frozen at 0° within 1 hr of sampling. Samples were filtered through a Whatman No. 41 paper before analysis.

Soil samples of manured garden soil, farmland soil and roadside soil were taken. Each sample was broken up into lumps, and a 5-g portion dried at 55° in an oven for 12–16 hr. The heating stops further changes.[14] The dried sample was ground, passed through a 2-mm mesh sieve and transferred to a Whatman No. 50 filter paper on a Buchner funnel. Sufficient water (containing 1 or 2 drops of concentrated sulphuric acid) was poured on to soak the soil completely. After a few minutes gentle suction was applied and the soil was washed with doubly distilled water until about 250 ml of filtrate had been collected. The filtrate was made up to a standard volume and aliquots were analysed.

Two sets of experiments were performed to check the validity of the method. In the first set, the volume of test solution was varied and the absorbance was plotted vs. volume taken. For all the samples linear plots were obtained, which could be extrapolated to the same point as that obtained for demineralized water; this indicates that the determination was quantitative. In the second set, recovery of nitrite was checked by adding various amounts of nitrite to a

pH-effects and interference by a large group of foreign ions are advantages of the method. The extraction method is advantageous because it lowers the detection limit by the concentration effect. A further improvement might be obtained by using a longer path-length cell.

fixed volume of test solution. Recoveries were between 98.7 and 100%. The results are given in Tables 2 and 3.

Comparison with standard method[3]

The values obtained for the water and soil samples by the standard method and the proposed method were compared (Tables 4 and 5). The coefficients of correlation of the two methods were found to be 0.986 and 0.99 for 12 samples from the river Kharoon and the soil samples respectively. The results of the two methods were almost identical, so the accuracy of the method is satisfactory.

Conclusion

The proposed method is about 30% more sensitive than the standard method. The rapid colour development, excellent reproducibility, and freedom from

A SENSITIVE SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF METHYL ALCOHOL IN AIR AND WATER

PRATIMA VERMA and V. K. GUPTA*
Department of Chemistry, Ravishankar University, Raipur 492010, India

Summary—A sensitive spectrophotometric method for the indirect determination of methyl alcohol in air and water is described. The methyl alcohol is oxidized to formaldehyde which is then determined in acidic medium with *p*-aminoazobenzene and sulphur dioxide. Beer's law is obeyed in the range 100–600 μg of methyl alcohol in 25 ml of final solution and the wavelength of maximum absorption is 505 nm. The lower limit of determination is 5 μg/ml in the sample. Several common organic co-pollutants do not interfere. The method can be used for determination of methyl alcohol in blood.

Methanol is used extensively as an industrial solvent, particularly in the lacquer industry, and as a starting material for chemical syntheses. Ingestion of large amounts can cause blindness, intoxication and death.[1] The threshold limit value (TLV) for methanol in air is 200 ppm.[2]

A survey of the literature reveals only a few methods for the direct determination of methanol. Most of them are not specific, and involve reaction of the –OH functional group.[3] Various methods used for the determination of formaldehyde have been modified for the determination of methanol.[4-10] Jephcott[4] used acidic potassium permanganate to oxidize methanol to formaldehyde and added oxalic acid to remove the excess of oxidant before finally developing a colour with Schiff's reagent. Bhatt and Gupta[5] also oxidized methanol with acidic potassium permanganate but removed the excess by reaction with hydrogen peroxide, then used the colour reaction with oxalyldihydrazide (ODH) and copper(II) in acetate buffered medium. Boss,[6] and Rayner and Jephcott,[7] used chromotropic acid and Schiff's reagent for the estimation of formaldehyde. Barns and Speicher[8] determined formaldehyde by Schryver's method with phenylhydrazine. Edvin[9] used chromotropic acid for the determination of oxidized methanol.

In the present communication a new combination is described for the indirect spectrophotometric determination of methanol. The methanol is again oxidized with acidic potassium permanganate[6] and the formaldehyde formed is determined with the *p*-aminoazobenzene and sulphur dioxide reagent system,[11] which was originally used for the estimation of sulphur dioxide.[12] The pink dye formed in acidic medium exhibits maximum absorption at 505 nm.

EXPERIMENTAL

Apparatus

A Carl Zeiss Spekol and an ECIL spectrophotometer model GS-865 with 10-mm matched silica cells were used for all spectral measurements. Midget impingers of 35-ml capacity were used for air sampling. Calibrated rotameters (PIMCO) were used for measuring flow-rates.

Reagents

Standard methanol solution. Dilute 0.5 g of analytical grade methanol to 100 ml with demineralized water and further dilute 4 ml of this solution to 100 ml to obtain a working standard solution containing 200 μg of methanol per ml.

Oxidizing solution. Dissolve 3 g of potassium permanganate in 20 ml of distilled water plus 15 ml of concentrated phosphoric acid and dilute to 100 ml.

Sulphite solution. Prepare a 3% solution of analytical grade anhydrous sodium sulphite in distilled water.

p-Aminoazobenzene. Prepare a 0.02% solution in 25% aqueous ethanol, with recrystallized reagent.

Absorption solution. Dilute 1 ml of oxidizing solution to 5 ml with doubly distilled water.

Phosphoric acid, 50% v/v. Dilute 50 ml of concentrated phosphoric acid to 100 ml with water.

Procedure

Water samples. Transfer a measured volume of sample (*x* ml, not exceeding 5 ml), containing 100–600 μg of methanol, to a 25-ml standard flask, add 1 ml of oxidizing solution and (*x*–5)/15 ml of 50% v/v phosphoric acid, mix and let stand for 10 min. Then remove the excess of potassium permanganate by adding sodium sulphite solution dropwise. Add 1 ml of *p*-aminoazobenzene solution. After 20 min add 1 ml of concentrated hydrochloric acid and make up to the mark with distilled water. Measure the absorbance and also that of a reagent blank, at 505 nm, against distilled water. Prepare a calibration graph in a similar manner.

Air samples. Connect two midget impingers, containing 5 ml of absorption solution, in series. Draw the air sample through the absorption solution at a rate of 500 ml/min for 20 min. After sampling, develop the colour with *p*-aminoazobenzene as described for water samples. Between 96 and 100% of the methanol is absorbed in the first impinger.

Acetaldehyde (0.62), benzaldehyde (12.5), aniline (1.25), toluene (20), benzene (37), urea (25), phenol (12.5), formic acid (2.5), acetic acid (3.7), ethanol (25), ethylamine (2.5), ammonia (0.62), nitrobenzene (12.5), nitrogen dioxide (1.1), isobutyl methyl ketone (2.5), acetone (25), hydrogen sulphide (6.2), ethoxyethanol (1.2), methoxymethanol (1.0)

*The weight of foreign species in the solution measured, which will cause not more than ±2% error.

RESULTS AND DISCUSSION

The oxidation mixture consists of potassium permanganate and phosphoric acid, the latter being used because it inhibits colour production by other aldehydes.[10] The excess of potassium permanganate is reduced with sodium sulphite solution, which also serves as a source of sulphur dioxide for the colour reaction,[12] which makes it preferable to other reducing agents.[13] An excess of sodium sulphite has no effect on the absorbance.

The acidity of the solution for oxidizing the methanol is maintained with phosphoric acid; an acid concentration of at least $0.5M$ is necessary for complete oxidation and no change in the measured absorbance is observed over the range $0.5-1.5M$ phosphoric acid. After oxidation, the acidity during colour development is increased by addition of hydrochloric acid, it was observed that maximum absorbance was obtained in the range $0.4-1.2M$ hydrochloric acid.

The effect of time and temperature on the colour development was studied: maximum colour was obtained after 30 min, and remained stable for 2 hr in the temperature range from 15 to 40°.

Beer's law, reproducibility and sensitivity

The absorption maximum of the pink dye is at 505 nm. The colour system was found to obey Beer's law over the concentration range 100–600 µg of methanol per 25 ml of final solution. The reproducibility of the method was checked by replicate analysis of a solution containing 300 µg of methanol, over a period of 7 days. The results showed that the method is fairly reproducible, with a relative standard

Table 2. Recovery of methanol from blood (sample size 0.5 ml)

Table 3. Comparison with other methods

Method	Reference	Lower limit of determination, ppm	Reaction time	Colour stability	Sample	Medium	Limit of determination for formaldehyde, ppm	Reference
Schiff's reagent	4	100	3 hr	30 min	Air, 60 ft³	HCl	0.10	7
Schryver's method	3	75	—	15 min	—	HCl	1.00	8
ODH method	5	60	55 min	150 min	Water, 9–10 litres	Acetate buffer (pH 5.8–7)	0.60	14
Chromotropic acid method	15	4	—	24 hr	—	H₂SO₄	1.00	9
p-Aminoazobenzene method (present method)		4	30 min	120 min	Water, 10 litres	H₃PO₄ (0.5–1.5M) HCl (0.4–1.2M)	0.08	11

deviation of 1.7%. The method is fairly sensitive for methanol.

Effect of foreign species

Other organic compounds which yield formaldehyde on oxidation interfere with this and most other methods. Ethanol, the major co-pollutant, does not interfere. Hydrocarbons, aldehydes, phenol, various organic pollutants, several metal ions, esters such as ethyl acetate and diethyl malonate do not interfere. Diethyl oxalate causes negative errors. Glycol and glycerol, which on oxidation both yield formaldehyde, cause positive errors. Results are given in Table 1. The interference of nitrite can be removed by adding 1 ml of 3% sulphamic acid solution and sulphide can be removed from air sample by passing the air through a tube containing lead acetate solution. Sulphur dioxide does not interfere with this method.

Determination in air

A modification of Wilson's procedure[14,15] was used to simulate air samples containing methanol: purified air was passed through an evaporation chamber preheated to 60–70°, and known amounts of methanol were added gradually dropwise with the help of a microburette and evaporated from the chamber, the air stream sample being sampled as described, with two 35-ml impingers connected in series to an air-sampling train fitted with a rotameter and vacuum pump.

Determination of methanol in blood

The method can be applied for the detection and estimation of methanol in biological fluids: it is separated from biological materials by distillation,[16,17] and absorbed in a solution of acidic potassium permanganate, then the resulting formaldehyde is determined by reaction with p-aminoazobenzene as described. The method was tested with known amounts of methanol added to blood samples which had been shown to be free from methanol. The recovery is shown in Table 2, which suggests that

there is some loss of methanol during distillation. This has been reported before.[16,17]

Comparison with other methods

The present method compares favourably with the Schiff's reagent method,[4,7] Schryver's method,[3,8] ODH method[5,15] and the chromotropic acid method,[9,13] in all of which methanol is estimated after its conversion into formaldehyde. The data summarized in Table 3 show that the present method is far more sensitive. It is simple and can be used satisfactorily for industrial hygiene work. The method is free from common organic interferences.

SIMULTANEOUS DETERMINATION OF ACETAMINOPHEN AND DEXTROPROPOXYPHENE NAPSYLATE IN PHARMACEUTICAL PREPARATIONS BY REVERSE PHASE HPLC

S. Sa'sa' and A. Rashid
Yarmouk University, Irbid, Jordan

I. Jalal
Al-Hikma Pharmaceuticals, P.O. Box 182400, Amman, Jordan

Summary—The method reported provides a fast, sensitive, accurate and reproducible reverse-phase HPLC assay for acetaminophen and dextropropoxyphene simultaneously. The total elution time is < 5 min. The method is stability-indicating since it can also determine *p*-aminophenol, a degradation product of acetaminophen, in a concentration as low as 0.005% of the acetaminophen concentration.

Acetaminophen (AAP, paracetamol, *p*-hydroxy-acetanilide) is a widely used non-prescription analgesic. Dextropropoxyphene napsylate (DPN) is a widely prescribed analgesic for mild to moderate pain, either alone or in combination with acetaminophen or aspirin. AAP has been determined in dosage forms by various methods such as gas chromatography (GC),[1] reverse-phase HPLC with detection at 254 nm,[2–5] and HPLC with electrochemical detection.[6] Recently, a normal phase HPLC method[7] has been used.

AAP in biological fluids has been determined by GC[8] and HPLC.[9–14] The current USP method for the determination of AAP in dosage forms is too lengthy, since it requires separation by silica gel column chromatography, followed by detection at 249 nm.

DPN has been determined in biological fluids by GC.[15–19] In pharmaceutical preparations, propoxyphene hydrochloride has been determined by extraction followed by normal phase HPLC.[20] The degree of contamination of propoxyphene by its carbinol diastereomers has been detected by HPLC.[21]

The present USP assay for AAP and DPN[22] involves extraction followed by GC with helium as carrier gas for the determination of compounds related to DPN, GC with nitrogen as carrier gas for the determination of DPN, and separation followed by derivative formation and GC with helium as carrier gas for the determination of AAP. This method, though specific, is time-consuming.

The method described in this paper provides a fast, sensitive and reliable reverse-phase HPLC assay for AAP and DPN simultaneously. The method is stability-indicating since it can determine *p*-aminophenol (PAP), a degradation product of AAP, at a concentration as low as 0.005% of that of the AAP.

EXPERIMENTAL

Materials

Reagent-grade potassium dihydrogen phosphate, ammonium formate and disodium hydrogen phosphate were obtained from BDH, England. *p*-Aminophenol (reagent grade) was obtained from Riedel-de-Haen, Hanover. HPLC grade methanol (Fluka) and distilled, demineralized water were used. Standards of AAP (Graesser Salicylates, Deeside, England) and DPN (Siegfried, Basle, Switzerland) were used as received.

Apparatus

The Varian 5000 LC HPLC system, equipped with a Valco Instruments manual loop injector, was connected to a Varian UV-50 variable-wavelength detector and a Varian 9176 chart-recorder. A Varian Micropak MCH-10 reverse-phase octadecylsilane column was used.

Chromatographic conditions

The mobile phase was prepared by dissolving 1.361 g of potassium dihydrogen phosphate and 1 g of ammonium formate in 700 ml of water and 300 ml of methanol. The solution was adjusted to pH 6 with a saturated solution of disodium hydrogen phosphate. The mobile phase was always filtered through a Gelman 0.45-µm membrane and degassed under reduced pressure before use. The flow-rate was 2 ml/min and the pressure about 2200 psig. The detector sensitivity was 0.5 absorbance units full-scale for AAP and DPN, and 0.02 for PAP. The chart-speed was 0.5 cm/min.

Standards

A two-component standard solution (AAP 325 µg/ml and DPN 100 µg/ml) was prepared in methanol. For the determination of PAP a 1.625 µg/ml standard solution was prepared in methanol. The solutions were filtered through a 0.45 µm membrane before use.

Sample preparation

For the assay, 20 capsules were emptied and the contents weighed. The average content of a capsule was weighed out and dissolved in 100 ml of methanol. The solution was filtered (0.45-µm membrane) and 5 ml of the filtrate were diluted to 50 ml with methanol. For the PAP assay, the average content of a capsule was weighed out and dissolved in 10 ml of methanol and the solution filtered (0.45-µm membrane).

*Mean ± RSD; $\bar{X}$ = mean ± RSD for 20 readings. A and B are two different samples of Dolostop (a pharmaceutical preparation containing 325 mg of AAP and 50 mg of DPN per capsule). C and D are two different samples of Dolostop Forte (a pharmaceutical preparation containing 325 mg of AAP and 100 mg of DPN per capsule).

Assay

Equal volumes (10 µl) of standard and sample preparations were injected and chromatographed under the conditions described above. The sample concentrations was calculated by simple proportion from the peak heights for the sample and standard. The amounts injected were always within the range giving linear response.

RESULTS AND DISCUSSION

To determine the linearity of the detector response, calibration standards of AAP, DPN and PAP were

*Nominal content ± RSD for 6 samples of Dolostop Forte.

prepared and quantities ranging from 0.2 to 5 µg of compound were injected. A plot of peak height vs. amount injected was linear up to 5 µg for AAP and PAP and 1 µg for DPN, with correlation coefficients of 0.9954, 0.9957 and 0.9968 respectively.

To determine the accuracy, each standard was spiked with a placebo and subjected to HPLC analysis at least 6 times. In all cases, satisfactory recoveries and reproducibility of peak heights were obtained (Table 1). No interference due to the placebo formulation was detected in the chromatograms produced. Furthermore the sensitivity of the method is illustrated by the high recovery of very low concentrations of PAP relative to AAP (Table 2).

It is well known that acetaminophen degrades to yield p-aminophenol. The specificity of the analytical method is illustrated by the complete separation of AAP, DPN and PAP in less than 5 min (Fig. 1).

The detection limit was determined by diluting the standard solutions with methanol and injecting 1 µl of each solution into the column. The detection limits were found to be 2.8, 2.4 and 2.0 ng for AAP, DPN and PAP, respectively.

The reproducibility of the HPLC procedure was determined by analysing day-to-day results. The results of the analysis on commercial products presented in Table 3 show excellent reproducibility with no statistical difference at the 5% level.

A stability study was performed on commercially available products, by placing samples in tubes in a humid atmosphere at 80°. A sample was taken daily and assayed. The data presented in Table 4 reveal no significant loss in activity throughout the study.

The accuracy of the method was further supported by the closeness of the results to the nominal content and to those obtained by the following modified BP 80 procedure performed in another laboratory. DPN was extracted into chloroform from aqueous alkali, which retained AAP. DPN was then determined by non-aqueous titration as in BP 80 for DPN capsules.[23] The aqueous alkaline layer was used to determine AAP spectrophotometrically as in BP 80 for

paracetamol (AAP) tablets.[24] Results obtained are listed in Table 5.

The principal objective of this study was to develop an HPLC method involving minimum sample manipulation, maximum resolution and minimum elution time. This was achieved, with a run time of 5 min. The method is reliable, accurate, specific, fast and stability-indicating.

EXTRACTION OF CATECHOL VIOLET, CHROME AZUROL S AND ERIOCHROME CYANINE R WITH CHLOROFORM SOLUTIONS OF LIQUID ANION-EXCHANGERS

S. Przeszlakowski and H. Wydra

Department of Inorganic and Analytical Chemistry, Medical School, 20-081 Lublin, Poland

Summary—The extraction of Catechol Violet, Chrome Azurol S and Eriochrome Cyanine R with chloroform solutions of tri-n-octylamine (TOA), TOA hydrochloride and Aliquat 336 has been investigated. From the extraction isotherms, absorption spectra of the organic phases and dependence of the extraction coefficients on extractant concentration, it was found that the singly-charged anions HL^- are extracted preferentially, but acidic groups other than sulphonate can also form ion-pairs with alkylammonium cations at higher pH values of the aqueous phase, and at high acidity these dyes can be extracted other than by an anion-exchange reaction. The three dyes (especially Eriochrome Cyanine R and Chrome Azurol S) were strongly extracted with the liquid anion-exchanger used and Aliquat 336 was a better extractant than TOA or TOA hydrochloride. The absorption spectra for the organic phases containing Chrome Azurol S and Eriochrome Cyanine R depended on the extractant used.

Many sensitive spectrophotometric methods for metals are based on the formation of ion-association complexes composed of anionic complexes and large organic cations. In addition to methods based on ternary complexes involving chelating agents and cationic surfactants, methods utilizing the extraction of anionic metal–sulphonated chelating agent complexes by solutions of liquid anion-exchangers in organic solvents often give better sensitivity and selectivity than the conventional spectrophotometric methods.[1] Although excess of sulphonated chelating agent can also be extracted by a liquid anion-exchanger, only a few such cases (nitroso-R salt,[2] ferron[2,3] and some sulphonated formazans[4]) have been investigated. It therefore seems important to study such systems in order to improve the design of extraction–spectrophotometric methods for metals, and of selective metal-sorbents consisting of chelating anion/alkylammonium cation combinations.[5,6]

Sulphonated triphenylmethane dyes are important reagents for spectrophotometric determination of metals, and as metallochromic indicators.[7] The ternary complexes formed from metal ion, sulphonated triphenylmethane dye and organic cationic surfactant in aqueous solution have been utilized in several very sensitive spectrophotometric methods for metals.[8,9] Tertiary amines and quaternary ammonium salts have been used similarly. Thus a very sensitive method for determination of tin is based on extraction of the anionic tin(IV)–Catechol Violet complex with diphenylguanidine in butanol.[10] Molybdenum has been determined with Catechol Violet directly in the organic phase after extraction from sulphuric acid with tri-n-octylamine in toluene.[11] Shijo[12] developed a very sensitive method for iron ($\epsilon = 1.73 \times 10^5$

$1.mole^{-1}.cm^{-1}$) based on extraction of the iron-(III)–Eriochrome Cyanine R complex by tridodecylethylamine bromide in xylene.

Our earlier results obtained chromatographically (paper extraction chromatography and the "moist paper" technique)[13] suggested that Catechol Violet, and especially Chrome Azurol S and Eriochrome Cyanine R, can be effectively extracted from aqueous acidic solutions with ternary amines and quaternary alkylammonium salts in benzene or chloroform; however, the rather strong adsorption of these reagents on cellulose makes it difficult to interpret the chromatographic data quantitatively. Therefore the corresponding water/chloroform extraction systems were investigated in the present work.

EXPERIMENTAL

All experiments were done at room temperature ($21 \pm 2°$).

Reagents

Pure tri-n-octylamine (TOA) was purified by vacuum distillation, the fraction boiling at 192–198° (11–12 mmHg) being collected. TOA hydrochloride was made by shaking a $0.1M$ solution of the free amine in chloroform with an equal volume of $0.2M$ hydrochloric acid; after separation, the organic phase was washed twice with doubly distilled water and filtered through a cellulose filter. More dilute TOA or TOA hydrochloride solutions were prepared by dilution with freshly distilled chloroform.

Aliquat 336 (93.3% w/w quaternary alkylammonium chloride) was freed from iron by shaking its $0.1M$ chloroform solution with an equal volume of $0.01M$ hydrochloric acid, then the organic phase was washed five times with an equal volume of doubly distilled water; finally the organic phase was filtered through a cellulose filter. More dilute solutions were prepared by dilution with freshly distilled chloroform.

The chloroform solutions of Aliquat 336 and TOA hydrochloride were standardized by potentiometric titration (after
Fig. 1. Effect of pH on the extraction of Catechol Violet
($5 \times 10^{-4}M$). Extractants: $10^{-3}M$ TOA (●---●), $10^{-3}M$
TOA hydrochloride (O---O) in chloroform, $2 \times 10^{-4}M$
Aliquat 336 (△---△) in chloroform.

evaporation of chloroform) with $0.01M$ silver nitrate in
ethanol–water (70:30 v/v).

All other reagents were of analytical grade.

Procedure

Catechol Violet (CV), Chrome Azurol S (CAS) and
Eriochrome Cyanine R (ECR) were extracted by shaking
together for 10 min equal volumes (usually 5 or 10 ml) of
the aqueous reagent (previously adjusted to an appropriate
pH with $0.1M$ hydrochloric acid or $0.1M$ sodium hydroxide)
and chloroform or a chloroform solution of TOA, TOA
hydrochloride or Aliquat 336, in cylindrical separating
funnels. The lower (organic) phase was then filtered through
a cellulose filter to remove the remaining aqueous solution
and the aqueous phase was centrifuged. The reagents were
determined spectrophotometrically in the aqueous phase by
use of calibration graphs obtained for aqueous solutions of
appropriate pH, at the wavelength of the absorption maxi-
mum. Since the absorbance of the aqueous CV solution was
not stable at pH > 7, and the absorption maximum of the
organic phase changed with time, alkaline aqueous solutions
of CV, after extraction, were adjusted to pH 3.8–3.9 with
dilute hydrochloric acid; CV was then determined at 445 nm
from a calibration graph obtained analogously. Also, the
aqueous phase after extraction of CAS was always adjusted
to pH 1 with hydrochloric acid and the absorbance
measured at 465 nm.

RESULTS AND DISCUSSION

Preliminary experiments with equal concentrations
of the triphenylmethane dyes in acidic aqueous solu-
tions and a constant concentration of TOA, TOA
hydrochloride or Aliquat 336 in the organic phase
indicated very rapid extraction—shaking for 15 sec
was sufficient for equilibrium to be reached. Since all
the three dyes contain a sulphonate group and pheno-
lic groups, and CAS and ECR also have two carbox-
ylate groups, it was expected that pH would have a
strong influence on the extraction.

It was found that CV is not extracted with pure
chloroform at the pH values studied, and ECR is
only partially extracted (extraction coefficients ~ 0.1
at pH 1, whereas CAS is feebly extracted from acidic
or neutral solutions. However, all three are quite well

extracted from acidic aqueous solutions with chloro-
form solutions of the liquid anion-exchangers, if the
concentration of the latter is sufficient to neutralize
the charge of the sulphonate group of the reagent.
The degree of extraction of ECR and CAS decreases
with increasing equilibrium pH of the aqueous phase,
whereas for CV the extraction is maximal at 3.4–4.9,
depending on the extractant used (Figs. 1–3). TOA
and TOA hydrochloride behave similarly, and the
extraction is very low at pH > 8 (the TOA hydro-
chloride is then converted into the free amine). Ali-
quat 336 is a better extractant and is the only one of
the three that extracts the dyes from alkaline solution.
This seems to confirm that anion-exchange is the
major mechanism in the extraction process.

The extraction isotherms (Figs. 4–6) confirm that
Aliquat 336 has the best extraction properties. Erio-
chrome Cyanine R was practically quantitatively
extracted with $10^{-3}M$ chloroform solutions of the
liquid anion-exchangers used, when its concentration
in the initial aqueous solution was below about
$10^{-3}M$. Aliquat 336 and TOA hydrochloride in
chloroform (except for extraction of Chrome Azurol
S with TOA hydrochloride) will extract more of the
dyestuffs than corresponds to a 1:1 complex. For
example, the mole ratio of dyestuff to Aliquat 336 can
attain the value 1.2 for Chrome Azurol S, 1.3 for
Catechol Violet and 5.9 for Eriochrome Cyanine R.
The extraction isotherm for Chrome Azurol S seems
to indicate that when the pH of the aqueous phase is
4.6, only the sulphonate group of the reagent is
bound with the alkylammonium cation in the ion-
pair, although the anions H_3L^- and H_2L^{2-} should be
present in the aqueous solution (the carboxyl group

TOA (O---O), TOA hydrochloride (□---□), Aliquat
336 (●---●); or chloroform (×---×).
Fig. 3. Effect of pH on the extraction of Eriochrome Cyanine R $(5 \times 10^{-3}M)$. Extractants: $10^{-3}M$ chloroform solutions of TOA (●---●), TOA hydrochloride (○---○) or Aliquat 336 (□---□).

would be partially dissociated).[14] Although chloroform does not extract Catechol Violet or Eriochrome Cyanine R (at pH > 1), the presence of the ion-pair consisting of the dyestuff anion and an alkylammonium cation should change the physical properties of the chloroform and some of the dyestuff might then be extracted by a mechanism other than simple anion-exchange. The extraction of a "superstoichiometric" amount of Eriochrome Cyanine R from aqueous solution at pH 1 can be explained if the "neutral" (zwitterion) species H_4L present along with the H_3L^- anions in the aqueous solution is also extracted.[15] Chrome Azurol S is also almost quantitatively extracted from aqueous solution at pH 1 when the concentration of Aliquat 336 in the organic phase is half the concentration of the reagent in the aqueous solution before extraction (see Table 1). Further association of carboxylate dyestuffs in the organic phase cannot be excluded (especially when acidic aqueous media are used) and the extraction of such aggregates could also lead to the apparent superstoichiometric extraction of the dyestuff.

The high degree of extraction of Chrome Azurol S and Eriochrome Cyanine R from aqueous acidic solutions just discussed prevents investigation of the extraction mechanism by slope analysis. For Cate-
Fig. 4. Extraction isotherms for Catechol Violet (pH ~ 3). Extractants: $5 \times 10^{-3}M$ chloroform solutions of TOA (curve 1), TOA hydrochloride (curve 3) or Aliquat 336 (curve 2). C_o and C_a are the equilibrium concentrations in the organic and aqueous phases respectively.
Fig. 5. Extraction isotherms for Chrome Azurol S (pH 4.7). Extractant: $5 \times 10^{-3}M$ chloroform solutions of Aliquat 336 (curve 1) or TOA hydrochloride (curve 2). C_0 and C_a are defined as for Fig. 4.

chol Violet a slope of 1.0 was found at pH 2.23 for log D vs. log [Aliquat 336]; this suggests that only the sulphonate group binds to the alkylammonium cation, as expected for a simple anion-exchange reaction (at pH 2.2 the anion H_3L^- should be predominant in the aqueous solution[16]):

$$H_3L^- + \overline{R_4N^+, Cl^-} \rightleftharpoons \overline{R_4N^+, H_3L^-} + Cl^-$$
Woodward and Freiser[17] suggested that in strongly alkaline media not only the sulphonate groups but also the phenolate groups of sulphonated azo-dyes can bind to alkylammonium cations. The experimental results for the extraction of Chrome Azurol S from aqueous solutions at pH 11.1 (Fig. 7) seem to confirm this. The slope of 3.8 suggests that along with the sulphonate group, two carboxylate groups and, partially, the phenolate group of the reagent are neutralized with alkylammonium cations and the ion-association complex $(R_4N^+)_4 \cdot L^-$ is formed in the organic phase.

If sulphonated triphenylmethane dyes are extracted by anion-exchange reactions, chloride ions should be transferred into the aqueous phase when the extraction is done with alkylammonium chlorides. Therefore, chloride was determined in the aqueous and organic phases after extraction of Catechol Violet, Chrome Azurol S and Eriochrome Cyanine R with chloroform solutions of Aliquat 336 or TOA hydrochloride. The results obtained are collected in Table 2.

It should be noted that the ratio of the chloride concentrations in the organic and aqueous phase increased when an excess of the dyestuff (relative to the alkylammonium salt) was used. For instance,

chloride was transferred into the aqueous phase quantitatively after extraction of an $8 \times 10^{-3}M$ aqueous solution of Eriochrome Cyanine R with a $10^{-3}M$
Fig. 6. Extraction isotherms for Eriochrome Cyanine R (pH 1.0). Extractants: chloroform ($\square$---$\square$) or $10^{-3}M$ chloroform solutions of TOA ($\bullet$---$\bullet$), TOA hydrochloride ($\bigcirc$---$\bigcirc$) or Aliquat 336 ($\triangle$---$\triangle$). For the upper three curves the C_0 values correspond to the difference between the total concentration of Eriochrome Cyanine R in the organic phase containing amine, and the concentration when the dyestuff is extracted with chloroform alone; C_a is the equilibrium concentration in the aqueous phase.

*pH of the aqueous phase.

solution of Aliquat 336 or TOA hydrochloride in chloroform. This confirms that anion-exchange is occurring in the extraction process. However, for equal initial concentrations of the dyestuff in the aqueous solution and the extracting agent in the organic phase (see Table 2), the extraction coefficients were always higher than the final $[Cl^-]_{aq}/[Cl^-]_o$ ratios (especially for Eriochrome Cyanine R). This confirms the observation that some of the dyestuff can be extracted by a mechanism other than anion-exchange.

The colours of the organic phases containing the sulphonated triphenylmethane dyes and alkyl-ammonium cations were sometimes different from the colours of the aqueous solutions of the dyestuffs at the same pH values.

Absorption spectra for organic solutions containing Catechol Violet and an excess of alkylammonium salt (necessary to ensure quantitative extraction) are shown in Figs. 8 and 9. The organic phases were yellow when the extraction was done from sufficiently acidic solutions and a single absorbance maximum at 440 nm was found for Catechol Violet extracted with TOA or TOA hydrochloride from aqueous solutions in the equilibrium pH range 0.9–3.9. It should be added that the absorbance depends on the pH of the aqueous solution and attains maximal and constant values when the equilibrium pH range is 2.8–3.7, over which the yellow anion H_3L^- is predominant in the aqueous solution.[16] The shapes of the spectra for Catechol Violet extracted with Aliquat 336 depend on the equilibrium pH value of the aqueous phase (Fig. 9) and a single absorbance maximum at 445 nm was found only on extraction from distinctly acidic solutions of the reagent (pH 0.9–2.0). At an equilibrium pH of 3.8, a second maximum appears at 620 nm (the organic phase is then green). The absorbance at 445 nm decreases and the absorbance at 620 nm

increases with increasing pH of the aqueous phase and attains a maximum (at 620 nm) at pH 7.35; at pH 8.3 the maximum at 445 nm disappears and a third maximum at 360 nm appears (curve 6 in Fig. 9). The lack of isosbestic points is probably due to inadequate purity of the dyestuff.

The absorbance of Catechol Violet in the organic phase was stable only when TOA hydrochloride was used as extracting agent; then no changes in absorbance were found even after 24 hr. The absorbance of Catechol Violet extracted with Aliquat 336 was stable only at an equilibrium pH of 5.6; when extraction was done from more acidic or more alkaline solutions, the absorbance at 445 nm increased very slightly and the absorbance at 620 nm distinctly decreased in 24 hr.
Fig 7. Log–log plot of the extraction coefficients (D) for Chrome Azurol S ($5 \times 10^{-3}M$, pH 11.1) vs. concentration of free Aliquat 336 in chloroform.

Table 2. The ratio of the chloride concentration in the aqueous and organic phases after extraction of Catechol Violet, Chrome Azurol S and Eriochrome Cyanine R with chloroform solutions of Aliquat 336 and TOA hydrochloride: the initial concentrations of the dyestuff in the aqueous solution and of the alkylammonium salt in the organic phase were $5 \times 10^{-3}M$ for Catechol Violet and Chrome Azurol S and $10^{-3}M$ for Eriochrome Cyanine R

		Aliquat 336		TOA.HCl	
	pH	$\dfrac{[Cl^-]_{aq}}{[Cl^-]_o}$	D	$\dfrac{[Cl^-]_{aq}}{[Cl^-]_o}$	D
Catechol Violet	2.3	5.25	15.1	1.1	4.6
Chrome Azurol S	4.6	9.0	32	6.1	8.2
Eriochrome Cyanine R	3.0	2.85	> 250	2.57	> 250
Fig. 8. Absorption spectra for organic phases after extraction of Catechol Violet ($5 \times 10^{-5}M$) with a $5 \times 10^{-3}M$ chloroform solution of TOA hydrochloride. Equilibrium pH values of the aqueous phases: 0.9—curve 1; 1.9—curve 2; 2.8 or 3.65—curve 3; 3.85—curve 4.

The absorption spectra for organic solutions of Catechol Violet seem to indicate that various anions of the dyestuff can be transferred into the organic phase; their charge is neutralized by alkylammonium cations. Extraction of Catechol Violet from distinctly acidic aqueous solutions leads to formation of a yellow ion-pair $R_4N^+.H_3L^-$. When the pH increases, the anions H_2L^{2-} are formed in the aqueous solution (the absorbance maximum for this anion is at 590 nm)[16] and these can probably also be extracted as an ion-association complex with two alkylammonium cations.

Absorption spectra for Chrome Azurol S extracted with TOA hydrochloride and Aliquat 336 in chloroform differ significantly (Fig. 10). The organic phases are pink (λ_{max} 510 nm, $\varepsilon = 1.38 \times 10^4\ 1.mole^{-1}.cm^{-1}$) after extraction of the dyestuff from acidic aqueous solutions with TOA hydrochloride in chloroform. The organic phase containing Chrome Azurol S and
Fig. 9. Absorption spectra for organic phases after extraction of Catechol Violet ($5 \times 10^{-5}M$) with a $5 \times 10^{-3}M$ chloroform solution of Aliquat 336. Equilibrium pH values of the aqueous phases: 0.87—curve 1; 1.93—curve 2; 3.84—curve 3; 5.6—curve 4; 7.35—curve 5; 8.3—curve 6.
Fig. 10. Absorption spectra for organic phases after extraction of Chrome Azurol S ($5 \times 10^{-5}M$) with a $5 \times 10^{-4}M$ chloroform solution of TOA hydrochloride (pH$_{equil}$ 3.4—curve 1) or Aliquat 336 (pH$_{equil}$ 3.6—curve 2).

the equivalent amount or an excess of Aliquat 336 is violet for the pH range 3.6–7.4. The organic phase obtained on extraction of the dyestuff from a strongly alkaline medium (pH 12.65) with a chloroform solution of Aliquat 336 is initially yellow; after separation the yellow colour changes to violet, irrespective of the concentration ratio of Aliquat 336 to dyestuff in the range from 1:2 to 10:1. The colour of the organic phase changes immediately on removal of water from it by addition of anhydrous sodium sulphate or filtration through a cellulose filter. In the equilibrium pH range 3.6–7.4, the absorbance of the organic phase at 600 nm is constant ($\varepsilon = 1.6 \times 10^4$ l.mole^{-1}.cm^{-1} and the absorbances obtained at 1:1 and 10:1 mole ratios of Aliquat 336 to Chrome Azurol S are practically the same. The absorbance of the organic phases remains unchanged for at least 24 hr. These results seem to suggest that only the ion-pair $R_4N^+ \cdot H_3L^-$ is formed on extraction of the dyestuff from acidic and moderately alkaline solutions; however, the high stability of the absorbance of the organic phases obtained by extraction of Chrome Azurol S from acidic aqueous solutions is rather surprising, because it is well known that the orange H_3L^- (λ_{max} 480 nm) and red H_2L^{2-} (λ_{max} 510 nm) are not stable in aqueous solution, unlike the yellow HL^{3-} and violet L^{4-}.[14] It is also difficult to explain the marked differences in λ_{max} between organic phases containing Chrome Azurol S bound with TOA and those with it bound with Aliquat 336, at almost identical equilibrium pH values of the aqueous phase.

The absorption spectra for organic phases containing Eriochrome Cyanine R bound with TOA or Aliquat 336 (Fig. 11) are somewhat similar to the corresponding spectra for Chrome Azurol S. The absorbance of the organic solutions of Eriochrome

Cyanine R was not stable and was constant only when measured within 0.5–1 hr of extraction; subsequently it increased with time, especially when the extractant was Aliquat 336 in chloroform. The absorbance values for the lilac organic phases depend also on the pH of the aqueous phase. The absorbance for Eriochrome Cyanine R extracted with TOA hydrochloride or Aliquat 336 reached a maximum at an equilibrium pH of 2.1 (H_3L^- is then predominant in the aqueous solution[15]). The absorbance maximum was at 510 nm ($\varepsilon = 6.8 \times 10^3$ l.mole^{-1}.cm^{-1}) for the dyestuff extracted with TOA hydrochloride and at 570 nm ($\varepsilon = 8.2 \times 10^3$) for Eriochrome Cyanine R extracted with Aliquat 336. The organic phase was initially yellow when Eriochrome Cyanine R was extracted with Aliquat 336 from aqueous solution at pH 12.5; after 30 min the colour changed to red-violet ($\varepsilon_{570} = 5.3 \times 10^3$) and the absorbance of the organic phase then remained unchanged for at least 9 hr.

The differences between the absorption spectra for Eriochrome Cyanine R and Chrome Azurol S (and also the differing stabilities of the absorbance of the organic phase) extracted with TOA hydrochloride and Aliquat 336 seem to be important when an extractant for extraction–spectrophotometric determination of metals is to be chosen, since an excess of reagent is always used in the determination and the reagent is then extracted together with the anionic metal complex.

The extraction data confirm the earlier supposition based on chromatographic data[13] that Eriochrome Cyanine R and Chrome Azurol S are more strongly extracted than Catechol Violet with liquid anion-exchangers; however, all three dyestuffs can be ex-
Fig. 11. Absorption spectra for organic phases after extraction of Eriochrome Cyanine R ($10^{-4}M$) with a $10^{-3}M$ chloroform solution of TOA hydrochloride (pH$_{equil}$ 2.05—curve 1) or Aliquat 336 (pH$_{equil}$ 2.05—curve 2 or 11.5—curve 3). The absorbance was measured 30 min after separation of the phases.

tracted quantitatively with just a small excess of TOA hydrochloride or Aliquat 336. The high degree of extraction of the reagents (especially with Aliquat 336) suggests that ion-pairs composed of a sulphonated triphenylmethane dye and a hydrophobic alkylammonium cation could find application in the preparation of selective sorbents for some metal ions.[5]

LINEAR TITRATION PLOTS FOR THE ANALYSIS OF MIXTURES OF THREE WEAK ACIDS OR BASES

Derek Midgley

Central Electricity Generating Board, Central Electricity Research Laboratories, Kelvin Avenue,
Leatherhead, Surrey, England

Colin McCallum

University of Edinburgh, Edinburgh Regional Computing Centre, The King's Buildings, Mayfield Road,
Edinburgh, Scotland

Summary—Linearly related functions have been derived which enable mixtures of three weak acids or bases in solution to be analysed by means of pH-titration data. This theory has been tested with data from the titration of a variety of mixtures of acids. The data required for the functions are pH, volume of titrant, the equilibrium constants relevant to the mixture, and an independently determined equivalence volume. This may be the equivalence volume for one of the components of the mixture or the sum of the equivalence volumes for any two or all three of the components. It is immaterial how this equivalence volume is obtained, but it is usually possible to obtain the total equivalence volume from data in another part of the same titration curve (when a large excess of titrant has been added).

A linear titration plot is a means of transforming titration data so that the information contained within a set of data can be extracted more easily than is the case for the conventional S-shaped titration curve of pH or e.m.f. plotted against volume of titrant added. The aim is always to derive two functions that are linearly related and can be calculated from the titration data and known constants. When one function is plotted against the other, the equivalence volumes of titrant for the components in the sample are obtained from the intercept and gradient of the resultant straight line.

Linear titration plots have the advantage of being in a form that provides an obvious visual warning that the interpretation of the results may be suspect: curvature in the plot indicates either that the sample contains substances different from (or additional to) those expected, or that the experimental technique is in error. Linear titration plots have been derived that are capable of allowing for the finite solubility of a precipitate,[1] polyfunctionality of an acid or base,[2] partial neutralization of an acid or base,[3] and mixtures of two polyfunctional weak acids.[4]

In contrast to the conventional S-curve, linear titration plots require an accurate and precise determination of pH and a certain amount of calculation in preparing the functions for plotting. In most cases the functions can be calculated with a "scientific" calculator although for the most rigorous and general treatment a computer would be necessary.

It is implicit in the linearity of the plots that only two unknowns can be determined simultaneously. For analysing mixtures of three components by linear titration plot, therefore, one concentration, or the sum of any two or all three concentrations, must first

be found independently. In many cases a selected portion of the titration data can be made to yield the required concentration and the rest of the data then used to calculate the remaining concentrations.

Midgley[5] analysed a mixture of nitric acid, acetic acid and ammonium ion by applying a plot[4] for two-component analysis, first in the pH range 3.5–4.9 to give the concentrations of nitric and acetic acids, and then in the range pH 8.5–9.7 to give the ammonium ion concentration and the combined concentration of nitric and acetic acids.

This paper treats the problem more generally and develops linear titration plot functions for ternary mixtures of either acids or bases. The new functions can resolve two of the unknown concentrations simultaneously, given an independently determined quantity which may be the concentration of the third component or the sum of all three or of any two concentrations. The theory is developed for all these possibilities. In most cases the independently determined quantity can be obtained from data taken from the same titration, and one experiment, therefore, serves for the determination of all three unknown concentrations.

THEORY

Notation

Both acids and bases are represented by the general formulae H_aXP_p, H_bYQ_q and H_cZR_r. X, Y and Z represent the unprotonated radicals to which a, b and c protons respectively are attached. P, Q and R are univalent ions of charge j_P, j_Q and j_R respectively, present in the numbers p, q and r necessary to maintain electrical neutrality. The numbers p, q and r depend on the number of negative charges, n_X, n_Y

and n_Z on the unprotonated radicals and the number of protons attached. Note that the number of association steps, k_X, k_Y or k_Z, for each radical is not identical with the proton number a, b or c respectively, but is characteristic of the radical itself. This notation applies to acids, salts and bases, as shown by the following examples: acetic acid, $n_X = k_X = a = 1$, $p = 0$; sodium acetate $n_X = k_X = p = 1$, $a = 0$; ammonia $n_X = a = p = 0$, $k_X = 1$.

Three weak acids

Consider the titration of V_0 ml of a mixture of three acids, $H_a XP_p$, $H_b YQ_q$ and $H_c ZR$, with a strong base of normality C_B. For each acid there exists a series of *overall association* constants:

$$K_{X_i} = \{H_i X\}/\{X\}\{H\}^i$$
$$= [H_i X]F_{X_i}/[X]f_X\{H\}^i; \quad i = 1 \rightarrow k_X$$
$$K_{Y_i} = \{H_i Y\}/\{Y\}\{H\}^i$$
$$= [H_i Y]F_{Y_i}/[Y]f_Y\{H\}^i; \quad i = 1 \rightarrow k_Y$$
$$K_{Z_i} = \{H_i Z\}/\{Z\}\{H\}^i$$
$$= [H_i Z]F_{Z_i}/[Z]f_Z\{H\}^i; \quad i = 1 \rightarrow k_Z$$

In the equations above, $\{\ \}$ denotes an activity and $[\ ]$ a concentration; f_X, f_Y and f_Z are the activity coefficients of the fully deprotonated forms X^{n_X-}, Y^{n_Y-} and Z^{n_Z-} respectively and F_{X_i}, F_{Y_i} and F_{Z_i} are the activity coefficients of the ith protonated form of each ion. With this notation, a strong acid is automatically covered by the theory since it is regarded as a weak acid with $K_X = 0$. Discrimination between strong acids is not possible. We can now derive the functions from the mass- and charge-balance equations for each data point (V, pH), where V is the volume of titrant added.

Mass balances

Total X, $T_X = [X] + [HX] + \ldots [H_i X]$
$$+ \ldots [H_{k_X} X]$$
$$= [X](1 + \beta_X)$$
$$= C_B V_X/a(V_0 + V)$$
Total Y, $T_Y = [Y] + [HY] + \ldots [H_i Y]$
$$+ \ldots [H_{k_Y} Y]$$
$$= [Y](1 + \beta_Y)$$
$$= C_B V_Y/b(V_0 + V)$$
Total Z, $T_Z = [Z] + [HZ] + \ldots [H_i Z]$
$$+ \ldots [H_{k_Z} Z]$$
$$= [Z](1 + \beta_Z)$$
$$= C_B V_Z/c(V_0 + V)$$

In the equations above, V_X, V_Y and V_Z are the volumes of titrant equivalent to each acid and β_X, β_Y,

β_Z are given by

$$\beta_X = \sum_{i=1}^{k_X} K_{X_i}\{H\}^i f_X/F_{X_i}$$
$$\beta_Y = \sum_{i=1}^{k_Y} K_{Y_i}\{H\}^i f_Y/F_{Y_i}$$
and
$$\beta_Z = \sum_{i=1}^{k_Z} K_{Z_i}\{H\}^i f_Z/F_{Z_i}$$

Total titrant

$$T_B = C_B V/(V_0 + V)$$
$$j_P[P] = (n_X - a)T_X$$
$$j_Q[Q] = (n_Y - b)T_Y$$
$$j_R[R] = (n_Z - c)T_Z$$

Charge balance

$$i_P[P] + i_Q[Q] + i_R[R] + [H] + T_B - [OH]$$
$$= n_X[X] + (n_X - 1)[HX] + \ldots$$
$$(n_X - i)[H_i X] + \ldots (n_X - k_X)[H_{k_X} X] +$$
$$n_Y[Y] + (n_Y - 1)[HY] + \ldots$$
$$(n_Y - i)[H_i Y] + \ldots (n_Y - k_Y)[H_{k_Y} Y] +$$
$$n_Z[Z] + (n_Z - 1)[HZ] + \ldots$$
$$(n_Z - i)[H_i Z] + \ldots (n_Z - k_Z)[H_{k_Z} Z]$$

Substituting for [P], [Q] and [R] on the left and collecting terms on the right, we obtain

$$(n_X - a)T_X + (n_Y - b)T_Y + (n_Z - c)T_Z$$
$$+ T_B + [H] - [OH]$$
$$= n_X T_X - \alpha_X[X] + n_Y T_Y - \alpha_Y[Y]$$
$$+ n_Z T_Z - \alpha_Z[Z] \tag{1}$$

where

$$\alpha_X = \sum_{i=1}^{k_X} iK_{X_i}\{H\}^i f_X/F_{X_i},$$
$$\alpha_Y = \sum_{i=1}^{k_Y} iK_{Y_i}\{H\}^i f_Y/F_{Y_i}$$
and
$$\alpha_Z = \sum_{i=1}^{k_Z} iK_{Z_i}\{H\}^i f_Z/F_{Z_i}.$$

Rearranging (1) gives

$$T_B + [H] - [OH] = aT_X + bT_Y + cT_Z - \alpha_X[X]$$
$$- \alpha_Y[Y] - \alpha_Z[Z]$$
$$= T_X\left(a - \frac{\alpha_X}{1 + \beta_X}\right)$$
$$+ T_Y\left(b - \frac{\alpha_Y}{1 + \beta_Y}\right)$$
$$+ T_Z\left(c - \frac{\alpha_Z}{1 + \beta_Z}\right)$$

Substituting for T_X, T_Y, T_Z and T_B from the mass-balance equations gives

$$\frac{C_B V}{V_0 + V} + [H] - [OH] = \frac{C_B V_X}{a(V_0 + V)}\left(a - \frac{\alpha_X}{1 + \beta_X}\right)$$

$$+ \frac{C_B V_Y}{b(V_0 + V)}\left(b - \frac{\alpha_Y}{1 + \beta_Y}\right)$$

$$+ \frac{C_B V_Z}{c(V_0 + V)}\left(c - \frac{\alpha_Z}{1 + \beta_Z}\right)$$

Hence

$$\frac{(V_0 + V)([H] - [OH])}{C_B} + V = \frac{V_X}{a}(a - \theta_X)$$

$$+ \frac{V_Y}{b}(b - \theta_Y) + \frac{V_Z}{c}(c - \theta_Z) \quad (2)$$

where

$$\theta_X = \frac{\alpha_X}{(1 + \beta_X)}, \quad \theta_Y = \frac{\alpha_Y}{(1 + \beta_Y)}, \quad \theta_Z = \frac{\alpha_Z}{(1 + \beta_Z)}.$$

Since pH $= -\log\{H\}$, and the autoprotolysis constant for water is $K_w = \{H\}\{OH\}$, we obtain

$$[H] = \{H\}/f_H = 10^{-pH}/f_H \quad \text{and}$$

$$[OH] = \{OH\}/f_H = \frac{K_w}{10^{-pH}f_H},$$

where f_H is the univalent-ion activity coefficient.

Rewriting equation (2), we obtain

$$\frac{(V_0 + V)(\{H\} - K_w/\{H\})}{f_H C_B} + V = \frac{V_X}{a}(a - \theta_X)$$

$$+ \frac{V_Y}{b}(b - \theta_Y) + \frac{V_Z}{c}(c - \theta_Z) \quad (3)$$

In equation (3) the left-hand side and the functions θ_X, θ_Y and θ_Z can all be calculated from measured variables and known constants, and a, b and c are known, leaving the unknown equivalence volumes V_X, V_Y and V_Z. Since a linear titration plot can resolve only two unknowns, we need a further piece of information, which will usually be obtainable from a different treatment of the same titration data or may come from the use of another analytical technique. This extra information may be any one of

$$V_X, \ V_Y, \ V_Z, \ V_{XY} = V_X + V_Y, \ V_{XZ} = V_X + V_Z,$$

$$V_{YZ} = V_Y + V_Z \quad \text{and} \quad V_E = V_X + V_Y + V_Z.$$

One equivalence volume known

Suppose one of the equivalence volumes, say V_Z, is known, then rearranging equation (3) gives the calculable function U_0:

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) + Vf_H C_B}{f_H C_B(a - \theta_X)}$$

$$- \frac{V_Z(c - \theta_Z)}{c(a - \theta_X)}$$

$$= \frac{V_X}{a} + \frac{V_Y}{b} U_A$$

where $U_A = (b - \theta_Y)/(a - \theta_X)$. Plotting U_0 against U_A enables V_X and V_Y to be calculated from the intercept and slope respectively.

Exactly analogous functions (U_0, U_A) will be obtained if V_X or V_Y is known.

Sum of two equivalence volumes known

Suppose $V_{YZ} = V_Y + V_Z$ is known, then rearranging equation (3) gives a calculable function U_0

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) + Vf_H C_B}{f_H C_B(a - \theta_X)}$$

$$- \frac{V_{YZ}(c - \theta_Z)}{c(a - \theta_X)}$$

$$= \frac{V_X}{a} + \frac{V_Y}{b} U_A$$

where

$$U_A = \left(\frac{b}{c}\theta_Z - \theta_Y\right)/(a - \theta_X).$$

Plotting U_0 against U_A enables V_X and V_Y to be calculated from the intercept and slope respectively. Analogous functions (U_0, U_A) will be obtained if V_{XY} or V_{XZ} is known.

Total equivalence volume known

If V_E is known, rearranging equation (3) gives a calculable function U_0

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) + Vf_H C_B}{f_H C_B\left(\frac{a}{c}\theta_Z - \theta_X\right)}$$

$$- \frac{V_E(c - \theta_Z)}{\frac{a}{c}\theta_Z - \theta_X}$$

$$= \frac{V_X}{a} + \frac{V_Y}{b} U_A$$

where

$$U_A = \left(\frac{b}{c}\theta_Z - \theta_Y\right)\Big/\left(\frac{a}{c}\theta_Z - \theta_X\right).$$

Plotting U_0 against U_A enables V_X and V_Y to be calculated from the intercept and slope respectively.

Choice of plot

The choice between the plots derived above depends on which equivalence volume can be determined independently, but that leaves several variations for each type of plot, depending on nomination of the acids as X, Y and Z.

With perfectly accurate data, the nomination of acids would not matter, but with real pH values and

association constants some choices are more convenient than others. Of the functions θ_X, θ_Y and θ_Z above, θ_X occurs the most frequently. If one of the acids is a strong acid it is convenient to nominate it as acid X, since this makes $\theta_X = 0.0$ and saves calculation.

The weakest of the three acids, i.e., that with the largest association constants, should not normally be chosen as acid Y, since the large constants exaggerate the effect of any errors, especially at the extremes of the plot. With a graphical solution the outlying points are easily seen and can be ignored but with a computed solution the selection of points becomes more difficult.

It is also found that for graphical solution, nominating the acids as X, Y and Z in order of increasing association constants gives the set of values for U_0 and U_A that can most conveniently be handled, since the numbers tend to be neither very large (as when the weakest acid is Y) nor very small (as when the weakest is X) and negative numbers are avoided.

Since the general theory involves activity coefficients, the problem can only be solved iteratively if the ionic strength is kept constant. In dilute solution ($<10^{-4}M$) it is, however, usually valid to assume that activity coefficients can be set to unity, which makes iteration unnecessary. Experimental verification is given below.

Three weak bases

The derivation and notation are almost identical with that for three weak acids, except that C_B is now the concentration of the acidic titrant. One of the bases may be a strong base, e.g., an alkali metal hydroxide, but no discrimination is possible between different strong bases.

Instead of equation (3) for three weak acids, we obtain from the mass- and charge-balance equations

$$\frac{(V_0 + V)(\{H\} - K_w/\{H\})}{f_H C_B} - V$$

$$= \frac{V_X}{(k_X - a)}(a - \theta_X) + \frac{V_Y}{(k_Y - b)}(b - \theta_Y)$$

$$+ \frac{V_Z}{(k_Z - c)}(c - \theta_Z) \qquad (4)$$

To obtain any two of the equivalence volumes we need to know from some other source one of the following:

$$V_X, \quad V_Y, \quad V_Z$$
$$V_{XY} = V_X + V_Y,$$
$$V_{YZ} = V_Y + V_Z,$$
$$V_{XZ} = V_X + V_Z,$$
$$V_E = V_X + V_Y + V_Z.$$

One equivalence volume known

If V_Z is known, we obtain a calculable function U_0

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) - Vf_H C_B}{f_H C_B(a - \theta_X)}$$

$$- \frac{V_Z(c - \theta_Z)}{(k_Z - c)(a - \theta_X)}$$

$$= \frac{V_X}{k_X - a} + \frac{V_Y}{k_Y - b} U_A$$

where

$$U_A = (b - \theta_Y)/(a - \theta_X).$$

A plot of U_0 against U_A enables V_X and V_Y to be determined from the intercept and slope respectively. Analogous functions result if V_X or V_Y is known.

Sum of two equivalence volumes known

If V_{YZ} is known, we obtain by rearrangement of equation (4) a calculable function U_0:

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) - Vf_H C_B}{f_H C_B(a - \theta_X)}$$

$$- \frac{V_{YZ}(c - \theta_Z)}{(k_Z - c)(a - \theta_Y)}$$

$$= \frac{V_X}{(k_X - a)} + \frac{V_Y}{(k_Y - b)} U_A$$

where

$$U_A = \left(\frac{b}{c}\theta_Z - \theta_Y\right)/(a - \theta_X),$$

A plot of U_0 against U_A allows V_X and V_Y to be determined from the intercept and slope respectively. Analogous functions result if V_{XY} or V_{XZ} is known.

Total equivalence volume known

If V_E is known, we obtain by rearrangement of equation (4) a calculable function U_0:

$$U_0 = \frac{(V_0 + V)(\{H\} - K_w/\{H\}) - Vf_H C_B}{f_H C_B\left(\frac{a}{c}\theta_Z - \theta_X\right)}$$

$$- \frac{V_E(c - \theta_Z)}{\left(\frac{a}{c}\theta_Z - \theta_X\right)}$$

$$= V_X + V_Y U_A$$

where

$$U_A = \frac{\frac{a}{c}\theta_Z - \theta_Y}{\frac{a}{c}\theta_Z - \theta_X},$$

A plot of U_0 against U_A allows V_X and V_Y to be determined from the intercept and slope respectively.

Special case of strong bases

With a strong base as X, say, in the general derivation, we would have $[X] = [OH]$, but $[OH]$ already occurs because of the autoprotolysis of water and no meaningful value can be given to K_{X_1} and hence α_X, β_X and θ_X.

Carrying out the derivations for this special case gives sets of functions (U_0, U_A) corresponding to those for the general case. Assuming that the strong base is X, these special functions are obtained from the general ones shown above by assigning θ_X a value of 1 (with $a = 0$, $k_X = 1$, $K_X = 0.0$).

Choice of plot

As with weak acids, the plots can take various forms, depending on the assignment of the bases as X, Y or Z. Similar considerations as those for acid mixtures apply; the strongest base (largest acid association constant) should be X, the next strongest, Y and the weakest, Z. Completely dissociated hydroxides such as sodium hydroxide are entered as X with $K_X = 0.0$ and $\theta_X = 1$.

EXPERIMENTAL

Apparatus

Measurements were made with a Radiometer PHM64 digital pH-meter, with Radiometer G2040C and K4040 glass and calomel electrodes respectively. The sample solution was contained in a water-jacketed glass titration cell (Radiometer V535) and the titrant was added from a Radiometer ABU.13 piston burette.

Reagents

Stock solutions of $1M$ nitric and acetic acids were prepared from concentrated volumetric solutions (B.D.H.). Stock solutions of $0.1M$ ammonium chloride, $0.01M$ benzoic acid, $0.1M$ tris(hydroxymethyl)methylamine and $0.1M$ sodium acetate were prepared from analytical-grade chemicals. More dilute stock solutions, which were used to make up the titrated mixtures, were prepared by dilution of the stock solutions.

Standard sodium hydroxide solution was prepared by dilution of saturated sodium hydroxide solution, which was dispensed under a nitrogen blanket into a container of deaerated demineralized water. This dilute solution was standardized potentiometrically against nitric acid.

Titration procedure

Different mixtures of acids or bases for titration were prepared by pipetting appropriate volumes of their standard solutions into the titration vessel and adding demineralized water to give an accurately known total volume of about 20 ml. Water (at 25°) was circulated through the water-jacket surrounding the titration vessel.

The solution was stirred mechanically by the Radiometer TTA60 titration assembly. Nitrogen was passed over the surface of the solutions throughout the titration in order to prevent the absorption of atmospheric carbon dioxide during the alkaline phase of the titration.

The titrant solution was added from a piston burette equipped with a digital counter. The volume added and the corresponding e.m.f. were noted when a steady trace was observed on a chart recorder connected to the pH-meter. Titrations with acid were continued until the pH was less than 4, those with base until the pH was greater than 9.5.

The glass electrode was calibrated before each titration by reference to standard NBS buffer solutions (pH 4.008 and 9.180 at 25°).

Calculations

Calculations were done with the aid of an IBM 370 computer and a FORTRAN program TREBLE. This program can first calculate the total equivalence volume by using Gran's method[6] and then automatically apply this result to the calculation of the functions U_0 and U_A required for resolving the mixture into its components. Literature values of equilibrium constants were used.[7]

PROPERTIES OF THE LINEAR TITRATION PLOTS

The effect of systematic errors in pH and the association constants was investigated with computer-generated data for a hypothetical titration of 100-ml portions of solution containing equal concentrations of either three monobasic acids ($K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$ or $K_Y = 0.0$, $K_Y = 10^4$, $K_Z = 10^6$) or three monoacidic bases ($K_X = 0.0$, $K_Y = 10^9$, $K_Z = 10^5$). Base X was sodium hydroxide and the titrant was $1.0N$ strong base or acid as appropriate.

In all the examples below, V_E is the independently determined equivalence volume, but the functions are such that similar causes would produce similar deviations from the theoretical plots if V_Z or V_{YZ} were known.

Effect of an error in the association constants

Figure 1 shows plots for the titration of a hypothetical acid solution with $K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$. Use of an overestimate of K_Y produces deviations above the theoretical line over most of the plot and the effect of errors in K_Z is seen only as U_A tends to its limiting value ($b/a = 1$ in this example). This is best seen in the inset. An overestimate of K_Z produces positive deviations and an underestimate results in
Fig. 1. Effect of errors in the association constants on the plot for the titration of three acids ($V_0 = 100$ ml, $K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$, $T_X = T_Y = T_Z = 10^{-2}N$). —— theoretical line; $\bigcirc$—$K_Y = 1.1 \times 10^5$, $K_Z = 0.9 \times 10^9$; $\blacktriangle$—$K_Y = 1.1 \times 10^5$, $K_Z = 1.1 \times 10^9$. $\blacktriangle$—coincidence of $\blacktriangle$ and $\bigcirc$.

negative deviations. The effect of an underestimate of K_Y is not shown, but the points are almost symmetrically displaced to the opposite side of the theoretical line, from the positions shown in Fig. 1, except where the effect of errors in K_Z predominates (the points then remain as shown in the inset).

The titration of a hypothetical basic solution produces plots that differ little from those in Fig. 1, except that overestimates of K_Y or K_Z produce negative deviations from the theoretical line and underestimates produce positive deviations, *i.e.*, deviations are in the opposite direction from those for acidic solutions.

Effect of an error in pH

Figure 2 shows the plot for the titration of an acidic solution ($K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$) when the pH values used are in error by $+0.05$ (V_E known). As U_A tends to a constant value (unity in this case), the deviations from the theoretical line become large but these points are easily discerned and would be ignored in a graphical solution of the plot. Low pH values produce deviations above the theoretical line and the effect of an error of -0.05 pH units would be virtually a mirror image of that shown.

In the titration of bases, the deviations produced by an error in pH are opposite to those for the titration of acids. An error of -0.05 pH units in titration of a mixture of bases ($K_X = 0.0$, $K_Y = 10^9$, $K_Z = 10^5$, each base $0.01N$) would give a plot virtually indistinguishable from that shown in Fig. 2 for an error of $+0.05$ pH units in the hypothetical titration of acids.

Figure 2 shows that although a systematic error of 0.05 pH units produces considerable deviations from the theoretical line as U_A tends to its limiting value, deviant points can be easily identified and the plot remains useful over 95% of its range. Titrating an acidic solution when the pH has a negative bias results in an overestimate of the strongest acid (X) and an underestimate of the weakest acid (Z). Titrating an alkaline solution when the pH has a negative bias results in an underestimate of the strongest base (X) and an overestimate of the (Z) weakest base. The effect on the intermediate (Y) acid or base is unpredictable, since a real titration produces only a limited number of data points, which cannot be guaranteed to be symmetrically distributed within the range $0 < U_A < b/a$. Depending on this distribution, the intermediate acid or base may be either over- or underestimated.

A positive bias in pH produces errors opposite and almost equal to those described above. Random errors in pH result in scattered plots and hence less precisely known but unbiased concentrations.

The errors produced by as large a bias in pH as 0.05 units are still fairly small, *e.g.*, for the results shown in Fig. 2, a least-squares fit of the points in the range $0 < U_A < 0.997$ gave errors of -1.6%, $+0.6\%$ and $+1.0\%$ for acids X ($K_X = 0$), Y ($K_Y = 10^5$) and Z

($K_Z = 10^9$) respectively. With stronger acids the errors are larger, *e.g.*, the results in Fig. 2 for X ($K_X = 0$), Y ($K_Y = 10^4$) and Z ($K_Z = 10^6$) gave errors of -2.3%, -0.5% and $+2.8\%$ when fitted by least-squares over the range $0 < U_A < 0.97$; the bigger deviations in this case are more clearly seen as U_A tends towards unity.

Effect of an error in V_E

Since an independently determined equivalence volume is required in all the plots, an error in this volume will influence the ordinates of the plots. Figure 3 shows the effect of an underestimate of the total equivalence volume on the plot for a mixture of three acids ($K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$). The effect of the error in V_E is seen only as U_A approaches its maximum possible value (*i.e.*, $U_A > 0.99$), the plot then deviating above the theoretical line. For an overestimate of V_E, the deviation would be below the line. In practice there would be no difficulty in using a plot such as that in Fig. 3 to determine V_X and V_Y accurately, but the error in V_E would be transmitted to V_Z. This problem is worse when $V_X + V_Y \gg V_Z$.
Fig. 2. Effect of an error of $+0.05$ in pH on plots for the titration of three acids ($T_X = T_Y = T_Z = 10^{-2}N$). $\bullet$—$V_0 = 100$ ml, $K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$; $\triangle$—$V_0 = 100$ ml, $K_X = 0.0$, $K_Y = 10^4$, $K_Z = 10^6$; —— theoretical line for both plots.
Fig. 3. Effect of an error in V_E. $V_0 = 100$ ml, $K_X = 0.0$, $K_Y = 10^5$, $K_Z = 10^9$, $T_X = T_Y = T_Z = 10^{-2}N$ acid. —— theoretical line ($V_E = 3.0$ ml) $\bullet$—calculated with $V_E = 2.5$ ml.

RESULTS

Acidic solutions

Table 1 shows that moderately concentrated mixtures of three acids (each $1–5 \times 10^{-3}N$) with widely spaced association constants can be analysed with errors of 1–2% for two of the components and 1–10% for the third (Runs 1.1 and 1.2). When two of the acids have similar association constants, e.g., acetic and benzoic acids, the analysis tends to be less accurate (Run 1.3), although even with three similar acids (Run 1.4) the error for one component can be less than 10%.

In more dilute mixtures (each acid $10^{-5}–10^{-4}N$) the results were less accurate, since the errors for acids with widely spaced association constants (Runs

2.1–2.3 of Table 2) could exceed 10% and resolution of acetic and benzoic acids (Runs 2.4 and 2.5) was poor.

Effect of neglecting activity coefficients

Since the time required for calculation is much reduced if activity coefficients can be neglected, linear titration plots for Runs 1.1 and 2.1 were calculated with and without activity-coefficient corrections. The results and a selection of data points from these runs are shown in Table 3. At the lower ionic strength ($\sim 10^{-4}$) of Run 2.1, activity coefficients have a negligible effect on the co-ordinates (U_A, U_0). Least-squares fitting of the results gives equivalence volumes that differ by less than 2% from the values with activity corrections, but it is doubtful whether the

†$V_0 = 25$ ml, $C_B = 0.00361N$.

co-ordinates could be plotted precisely enough for this difference to be discernible in a graphical evaluation of the equivalence volumes.

At the higher ionic strength ($\sim 7 \times 10^{-3}$) of Run 1.1, the effect on the co-ordinates is more noticeable, especially for U_A, but the difference in the equivalence volumes is at most 2.5%.

Determination of the total equivalence volume

All the results in Tables 1 and 2 were obtained with plots that used V_E as the independently determined equivalence volume. V_E was determined by Gran's method,[6] with pH data from the extremes of the titration curves. With solutions containing no ammonium ions, V_E could be determined accurately from data at pH > 9, but when ammonium ions were present, data in the pH range 10.2–11.0 were needed for accurate results. In the runs in Table 2 it was not possible to add enough titrant to reach such high pH values and V_E was underestimated by 30% when calculated from data at pH below 9.5, so the expected value of V_E was used for the calculations. The inability to reach the required pH was peculiar to these runs and is not a general problem.

Alkaline solutions

Results for mixtures of sodium hydroxide, ammonia and sodium acetate showed low (70–80%) recoveries of sodium hydroxide, although the errors in the other components were smaller. It was decided that with the apparatus used, protection against contamination with carbon dioxide was inadequate and that acidification of the solutions, followed by back-titration, was more practical.

DISCUSSION

Linear titration plots have been used to analyse mixtures of three acids, a titration problem for which a solution has not been reported, even with use of such theoretically powerful methods as multiparametric curve-fitting.[8] Moreover, the method has been applied at concentrations below $10^{-4}N$. The method requires that one of the equivalence volumes (or the sum of two or three of them) can be determined independently. If this is possible the resultant plot is little more complicated than that for a mixture of two acids and the co-ordinates can easily be calculated with the aid of a programmable calculator if activity coefficients are either kept constant or, in dilute solution, neglected. As with all linear titration plots, the method can cope with polyfunctional acids or bases and is independent of the existence of points of inflexion in the conventional titration curve of pH against volume added.

ETUDE POLAROGRAPHIQUE DU NIOBIUM DANS LES MELANGES EAU–FLUORURE D'HYDROGENE EN PRESENCE D'IONS TETRAALKYLAMMONIUM

Hugues Menard et Rejean Beaudoin

Département de chimie, Faculté des sciences, Université de Sherbrooke, Sherbrooke, Québec, Canada

Résumé—On a étudié la réduction polarographique du niobium sous forme du complexe NbF_6^- dans les mélanges eau–fluorure d'hydrogène jusqu'à 50% p/p. L'addition d'ions tétraalkylammonium dans ce mélange permet le déplacement du potentiel de réduction de l'hydrogène et le dosage du niobium par polarographie impulsionnelle différentielle à une limite de détection inférieure à 1 ppm. En présence d'ions tétraalkylammonium, on observe une hausse importante du courant de réduction du niobium aux concentrations en HF où le complexe non réductible $NbOF_5^{2-}$ est prépondérant.

Il est connu qu'en polarographie le potentiel de dégagement d'hydrogène se déplace dans le sens positif lorsqu'on augmente la concentration en acide de l'électrolyte de support, ce qui peut devenir gênant pour l'analyse d'un ion métallique dont le potentiel de demi-vague est assez négatif. La réduction du niobium[1] s'effectue à un potentiel proche de la réduction de l'hydrogène, ce qui limite le seuil de détection. Il est clair que tout déplacement négatif du potentiel du dégagement de l'hydrogène qui n'affecterait pas le potentiel de demi-vague du niobium améliorerait la limite de détection.

Dans le but de déplacer le potentiel du mur de réduction de l'hydrogène et d'étendre le domaine utile dans les mélanges eau–fluorure d'hydrogène de l'ordre de 50%, nous avons ajouté des hydroxydes de tétraalkylammonium. La concentration du HF étant de 24M, le pH de la solution est inchangé par l'addition d'une faible quantité d'hydroxyde.

Gierst *et al.*[2] ont déjà effectué une étude du comportement des ions tétraalkylammonium à l'interphase mercure–solution. Les travaux ont démontré que (1) ces ions sont spécifiquement adsorbés, (2) l'adsorption est principalement localisée dans le domaine de charges négatives; (3) l'adsorbabilité croît avec la longueur de la chaîne carbonée, c'est-à-dire avec le caractère hydrophobe de l'ion; (4) la cinétique de l'adsorption aux faibles concentrations peut être contrôlée par le transfert massique vers la surface.

PARTIE EXPERIMENTALE

Les produits utilisés sont du KF certifié de Fisher, Me_4NOH et Et_4NOH reagent de B.D.H., Pr_4NOH reagent de Eastman et Bu_4NOH reagent de Baker, Nb_2O_5 99,9% de Alfa Product, et HF J. T. Baker 49,1%.

La cellule polarographique est constituée d'un bécher en polyméthylpentane d'une capacité de 50 ml surmonté d'un couvercle de Teflon qui sert à maintenir les électrodes. L'électrode de référence au calomel saturé est munie d'une double jonction séparée de la solution par une gaine de Teflon et un disque de polyéthylène poreux. L'électrode

auxiliaire est un fil de platine. L'électrode de travail est un capillaire polarographique Sargent-Welch S-2417 recouvert de polyéthylène[3] et dont la période de chute est contrôlée par un dispositif électronique réalisé dans nos ateliers. Tous les potentiels se réfèrent à l'électrode de calomel saturé. L'analyseur polarographique PAR est le modèle 364 (ou 174); la table traçante est une Techneurop, Sefram T.G.M. 101.

Les solutions de niobium sont préparées de la façon suivante: le Nb_2O_5 est dissous dans du HF puis la solution est évaporée, le résidu est ensuite redissous dans HF 49,1%. La solution-mère est diluée avec de l'eau déminéralisée ou du HF pour obtenir la concentration en acide et en niobium désirée. La solution de tétraalkylammonium est ajoutée immédiatement avant la mesure.

RESULTATS ET DISCUSSIONS

En milieu fluorure d'hydrogène 50%, le niobium sous forme de complexe NbF_6^- se réduit de façon réversible à un potentiel de $-0,880$ V *vs.* E.C.S. [équation (1)].[1]

$$Nb(V) + e^- \rightleftharpoons Nb(IV) \qquad (1)$$
On peut donc prévoir que le potentiel de réduction ne sera pas déplacé par addition d'espèces adsorbées à l'électrode, mais que la valeur du courant de diffusion sera susceptible de varier. Le courant de réduction mesuré varie dès qu'il y a présence d'une faible concentration d'ions tétraalkylammonium. La vague de réduction de l'hydrogène est déplacée cathodiquement, permettant une meilleure définition de l'onde du niobium.

L'augmentation graduelle de la concentration en ions tétraméthylammonium (Me_4N^+) provoque un accroissement de la hauteur de la vague de réduction du niobium, en polarographie impulsionnelle différentielle (P.I.D.) et un déplacement du mur de réduction de l'hydrogène vers des potentiels plus négatifs.

La figure 1 montre les polarogrammes P.I.D. obtenus pour plusieurs concentrations de Me_4N^+.
Fig. 1. Polarogrammes (P.I.D.) d'une solution de niobium $2,25 \times 10^{-3}M$ dans: (1) HF 49,1%, (2) HF 49,1% $+ Me_4NOH$ 0,012M; (3) HF 49,1% $+ Me_4NOH$ 0,17M.

L'augmentation du pic de réduction est rapide jusqu'à 0,25M et le déplacement du mur de réduction de l'hydrogène suit une progression semblable.

Ce gain de courant de pic est attribué à la soustraction du courant résiduel constitué principalement par la réduction de l'hydrogène. Bond et Grabaric[4] ont mis au point un système de traitement mathématique pour soustraire le courant résiduel en polarographie impulsionnelle différentielle. L'approche consiste à calculer, à l'aide d'un ordinateur, l'équation de la courbe du courant résiduel et soustraire sa valeur du pic de réduction de l'espèce électroactive. Dans notre cas, l'addition de l'ion tétraalkylammonium déplace le mur de réduction de l'hydrogène et diminue le courant résiduel sous la vague de réduction du niobium.
Par ailleurs, le déplacement du mur de réduction de l'hydrogène suit la même progression que la hauteur de la vague de réduction du niobium. Nous sommes donc dans un cas où le déplacement du mur de réduction de l'hydrogène peut être attribué à un effet $\psi_{\delta*}$, (le potentiel au plan externe d'Helmholtz modifié par l'espèce adsorbée), alors que le taux de recouvrement de l'électrode est faible.[2]

Dans le cas de l'ion tétraéthylammonium (Et_4N^+) la vague du niobium diminue, puis se stabilise. La figure 2 montre la diminution rapide du pic en P.I.D. pour des concentrations allant jusqu'à $3,5 \times 10^{-2}M$ Et_4N^+. Le déplacement du mur de réduction de l'hydrogène est le plus important de tous ceux mesurés dans la série des quatre ions tétraalkylammonium étudiés.

L'explication de ces résultats est liée à l'importance du recouvrement de l'électrode pour cette concentration. Nous avons une diminution du courant jusqu'à ce que le recouvrement soit maximal, après quoi la vitesse de réduction demeure constante. Nous pouvons donner une explication semblable pour le déplacement du mur de réduction de l'hydrogène lorsque le recouvrement de l'électrode est maximum, le potentiel $\psi_{\delta*}$ de l'électrode devient constant et le potentiel observé pour la réduction de l'hydrogène ne se déplace plus. Le déplacement est plus important que dans les autres cas, parce que le retard est à la fois dû à l'effet $\psi_{\delta*}$ et au recouvrement de l'électrode.[2]

L'ion tétrapropylammonium (Pr_4N^+) agit de la même façon que le Et_4N^+. La figure 3 montre que la hauteur du pic en P.I.D. diminue rapidement jusqu'à la concentration de $3,5 \times 10^{-4}M$ pour ensuite se stabiliser à une valeur très faible. Le déplacement du mur d'hydrogène présente une tendance analogue. On explique ce comportement par le fait que cet ion est beaucoup plus volumineux que le précédent dans la série alkyl et qu'il recouvre beaucoup plus l'électrode.

Fig. 2. Polarogrammes (P.I.D.) d'une solution de niobium $2,25 \times 10^{-3}M$ dans: (1) HF 49,1%; (2) HF 49,1% $+ Et_4NOH$ $0,69 \times 10^{-2}M$; (3) HF 49,1% $+ Et_4NOH$ $1,39 \times 10^{-2}M$; (4) 49,1% $+ Et_4NOH$ $2,08 \times 10^{-2}M$; (5) HF 49,1% $+ Et_4NOH$ $3,43 \times 10^{-2}M$.
Fig. 3. Polarogrammes (P.I.D.) d'une solution de niobium $2,25 \times 10^{-3}M$ dans: (1) HF 49,1%; (2) HF 49,1% $+ Pr_4NOH$ $1,18 \times 10^{-4}M$; (3) HF 49,1% $+ Pr_4NOH$ $3,35 \times 10^{-4}M$; (4) HF 49,1% $+ Pr_4NOH$ $9,41 \times 10^{-4}M$.
Fig. 4. Polarogrammes (P.I.D.) d'une solution de niobium 2,25 × 10⁻³M dans: (1) HF 49,1%; (2) HF 49,1% + Bu₄NOH 1,44 × 10⁻⁵M; (3) HF 49,1% + Bu₄NOH 4,16 × 10⁻⁵M; (4) HF 49,1% + Bu₄NOH 6,68 × 10⁻⁵M; (5) HF 49,1% + Bu₄NOH 7,87 × 10⁻⁵M.

Fig. 5. Résolution des polarogrammes P.I.D. du niobium en fonction de la concentration en HF et en présence de Me₄N⁺: (a) $0M$; (b) $0,05M$; (c) $0,20M$; (d) $0,32M$.

L'ion tétrabutylammonium (Bu₄N⁺) agit de manière beaucoup plus importante comme le montre la figure 4. Le pic en P.I.D. diminue rapidement pour disparaître complètement à une concentration de 9 × 10⁻⁵M. Il n'y a pas de stabilisation de la hauteur du pic comme dans les autres cas car sa disparition survient avant que le recouvrement soit maximal. Ceci est démontré par le fait que le mur de réduction de l'hydrogène se déplace encore régulièrement dans la région de concentration en tétrabutylammonium où le pic du niobium disparaît.

Nous avons quantifié l'effet des ions Me₄N⁺ et Et₄N⁺ sur le pic P.I.D. de réduction du niobium à plusieurs concentrations de HF en calculant la résolution du pic. On calcule la résolution en mesurant la hauteur du pic (H_{pic}) divisée par la largeur (l) à 10% de la hauteur et par la valeur du courant résiduel ($H_{rés}$) après le pic:

$$\text{résolution} = \frac{H_{pic}}{lH_{rés}} \qquad (2)$$

Dans HF commercial 50%, la présence de ces ions permet d'augmenter de 30% la résolution du pic de réduction du niobium. Un excès de ceux-ci provoque l'effet contraire en diminuant sensiblement le courant de réduction.

La concentration en HF a un effet important sur la hauteur du pic de réduction du niobium à cause de l'équilibre entre le complexe réductible NbF₆⁻ et le complexe non réductible NbOF₅²⁻.[1,5,6]

$$HNbF_6 + H_2O \rightleftharpoons H_2NbOF_5 + HF \qquad (3)$$

Les espèces HNbF₆ et H₂NbOF₅ sont des espèces ionisables fortement solvatées.

Les courbes (a) des figures 5 et 6 montrent l'effet de la concentration en HF sur la résolution du pic obtenu en absence d'ions tétraalkylammonium. La résolution est maximale pour une concentration en HF de 40%. Dans cette région, le mur de réduction de l'hydrogène est assez loin du pic de réduction du niobium pour permettre une bonne résolution et l'équilibre entre les espèces NbF₆⁻ et NbOF₅²⁻ favorise encore l'espèce réductible.

La résolution pour des concentrations en HF plus faibles que 40% est meilleure que pour HF 50% mais la hauteur du pic est diminuée par l'équilibre entre les deux complexes du niobium. Dans HF 40% et en présence de 0,015M Et₄N⁺, on peut doser 1 ppm comme le montrent les polarogrammes de la figure 7.

L'addition des ions Me₄N⁺ et Et₄N⁺ améliore beaucoup plus la résolution lorsque la concentration en HF diminue. Les figures 5 et 6 montrent que la résolution du pic dans la région de 25 à 35% en HF devient suffisamment élevée pour permettre le dosage du niobium. Cependant, la résolution n'est pas modifée par le déplacement du mur d'hydrogène mais par une augmentation du courant de réduction comme le montrent les figures 8 et 9. Le dosage du niobium dans ces solutions est rendu difficile à cause de l'équilibre entre les deux complexes qui peut être modifié par les espèces en solution.
Fig. 6. Résolution des polarogrammes P.I.D. du niobium en fonction de la concentration en HF et en présence de Et₄N⁺: (a) $0M$; (b) $0,025M$; (c) $0,10M$; (d) $0,30M$.
Fig. 7. Polarogrammes P.I.D. du niobium, 1 ppm: (a) HF 40%; (b) HF 40%, Et₄N⁺ 0,015M.
Fig. 8. Hausse du courant de réduction du niobium en présence de Me_4N^+ pour des solutions de HF: (a) 49,1%; (b) 39,3%; (c) 29,5%; (d) 25,5%; (e) 19,6%.

Fig. 9. Hausse du courant de réduction du niobium en présence de Et_4N^+ pour des solutions de HF: (a) 49,3; (b) 39,3%; (c) 29,5%; (d) 25,5%; (e) 19,6%.

Conclusions

Les ions Me_4N^+ et Et_4N^+ déplacent le mur de réduction de l'hydrogène et affectent peu le pic en P.I.D. de réduction du niobium. Les ions Pr_4N^+ et Bu_4N^+ provoquent la disparition de la vague du niobium. La résolution du pic en P.I.D. peut être améliorée de 30% dans HF commercial à 50%. Pour des concentrations en HF plus faibles, la résolution est accrue par une augmentation du courant de réduction. L'ion Et_4N^+ donne le plus grand déplacement de mur de réduction de l'hydrogène et donne accès à une limite de détection inférieure à 1 ppm de Nb(V) dans HF 40%.

L'ion Et_4N^+ donne des résultats plus intéressants que le Me_4N^+ parce que la quantité nécessaire est plus faible (0,01M par rapport à 0,1M) et le déplacement du mur de réduction de l'hydrogène est le plus important dans la série des ions tétra-alkylammonium.

DIFFUSION COEFFICIENTS AND COMPLEX EQUILIBRIA IN SOLUTION—IV. EXPERIMENTAL DETERMINATION AND MANIPULATION OF DIFFUSION DATA

D. R. CROW

Department of Physical Sciences, The Polytechnic, Wolverhampton, England

Summary—An experimental method for effectively measuring the change of diffusion current of a metal ion in the presence of increasing concentration of a complexing ligand is described and applied to five metal–ligand systems. The method has been applied to cases of reversible and irreversible electrochemical behaviour and is shown to provide reliable formation-curve data. The systems selected have formation constants which range over some ten orders of magnitude and in most cases the values obtained agree satisfactorily with those reported in the literature. In one case equilibrium data have been calculated for the first time.

There are a number of practical problems associated with manipulation and measurement in the examination of a large number of solutions containing a given metal ion, supporting electrolyte and complexing agent. If a great many data points are needed for use in subsequent calculations, the many solutions required can prove very costly in the case of some ligands and must always prove costly in terms of time. Further, the parameters measured may depend in a particularly sensitive way upon the concentration of metal ion; this is noticeable in the case of diffusion currents. It can prove to be an extremely difficult matter to ensure that precisely the same analytical concentration of metal ion is present in each separate solution.

Dilution techniques have been used, but in differing ways. Aggarwal *et al.*[1] "titrated" a solution containing metal ion, supporting electrolyte and the maximum amount of ligand with a solution containing the same concentration of supporting electrolyte and metal ion as the "titrand". In this case, however, half-wave potentials were of prime concern. Lane *et al.*[2] used a similar method for complexes of thiourea and substituted thioureas. Again, these authors' main aim was the determination of half-wave potentials, although they reported current variations which subsequent analysis appears to support as entirely reliable. Crow and Fonseca[3] have even applied a similar dilution method in cases where an indicator ion is used to supply information regarding the complexation of a further metal ion.

It is noticeable that the diffusion-current data reported by authors who have worked with individually prepared solutions often vary in an erratic manner with increase in ligand concentration. This is undoubtedly due not only to the difficulty in reproducing in a large number of solutions an identical (and usually very low) concentration of metal ion, but also to the difficulty of exactly restoring electrode parameters after replacement of working solutions. The fewer the disturbances introduced during the whole process of measuring either currents or potentials as a function of ligand concentration, the more satisfactory are the resulting data likely to be. Any method which starts with, and maintains during its application, a single sample of metal ion while additions of ligand are made in stages (as with titrations based on pH-measurements) offers attractive advantages.

An extremely simple and economical technique based upon this principle, and intended for measurements of polarographic diffusion currents, has been successfully applied to a large number of complexation systems, with equilibrium data which cover many orders of magnitude. It amounts to a titration technique; the "titrand" consists of a solution containing the metal ion in question (normally at a concentration of $10^{-3}M$) together with a suitable non-complexing supporting electrolyte (normally $0.1M$). The "titrant" consists of a solution containing exactly the same concentration of the supporting electrolyte and as high a concentration of the required ligand as is consistent with its solubility and the expected stability and extent of co-ordination with the metal ion.

EXPERIMENTAL

A very carefully measured volume (usually 50 ml) of "titrand" was placed in a *dry* polarographic cell. The various electrodes were dried before insertion into the solution, which was deoxygenated by passage of a gentle stream of oxygen-free nitrogen for 20 min. Care was taken over the drying, in order to avoid any dilution by means other than addition of "titrant". The temperature of the solution was maintained at $25 \pm 0.1°$ by means of a water

jacket fed from a bath by a thermostatically controlled circulator (Grant Instruments Type SU5). After the solution had stood for 2 min with nitrogen passing *gently* over the surface, a polarogram was run on a Princeton Applied Research Model 174A Polarographic Analyzer. The settings controlling current range, start potential, scan-rate, damping, drop-time, *etc.* were adjusted as appropriate and thereafter were kept unchanged during the remaining measurements.

Small increments of "titrant" were then added and between additions careful deoxygenation (for 3 min, which also ensured restoration of temperature equilibrium) was followed by standing for 2 min with nitrogen passing over the surface and then a polarogram was run. Each dilution and deoxygenation phase was reproduced as exactly as possible. The essential features of the technique are as follows.

(*i*) Wave heights decrease during the addition of "titrant" due to (*a*) dilution and (*b*) complexation of the metal ion with the ligand component of the "titrant".

(*ii*) The supporting electrolyte concentration remains constant so that, for neutral ligands, the ionic strength remains constant.

(*iii*) Observed diffusion currents, i_{obs}, (measured at a constant potential throughout the range of ligand concentration used) may be corrected for the dilution effect by means of the "amperometric" relationship involving the initial (V) and incremental (v) volumes, *viz.*

$$i_{corr} = i_{obs}\left(\frac{V+v}{V}\right)$$

(*iv*) The concentration of ligand ([X]) in each effective working solution produced after each addition of "titrant" may be estimated from the relation:

$$[X] = C\left(\frac{v}{V+v}\right)$$

where C is the concentration of ligand in the titrant solution.

RESULTS AND DISCUSSION

Cadmium–thiourea

Figure 1 shows the values of diffusion current, obtained from experimental data, plotted against the calculated values of thiourea concentration. Although there is scatter of the points, as expected, the large number of points allows a more reliable curve
Fig. 1. Corrected diffusion current values plotted against calculated values of ligand concentration for the system cadmium–thiourea.

to be drawn through them. For subsequent analysis—either from the pseudo-formation curve or from the functions $(\bar{D} - D_{MX_j})$—interpolated values of i_d at convenient values of free ligand concentration were used. Values of the diffusion coefficients for the various complex species were calculated by the methods described earlier[4] and the methods of graphical analysis were applied. The values $\beta_1 = 20 \pm 2$; $\beta_2 = 142 \pm 30$; $\beta_3 = (4.5 \pm 1.0) \times 10^2$; $\beta_4 = (1.2 \pm 0.2) \times 10^3$ compare very favourably with the previously reported data.

Cadmium–urea

Although the shift in half-wave potential of the cadmium ion induced by a $2M$ urea concentration was only about 0.01 V (and so made estimation of formation constants, and even perhaps the assumption of complexation, dubious) the change in diffusion current was quite substantial; Δi_d was about $2\,\mu A$, approximately 15% of the value for the simple metal ion (Fig. 2). "Titration" with $2M$ urea/$0.1M$ potassium nitrate solution yielded the data shown in Fig. 3.

At first sight this polarographic behaviour is very unusual; the almost negligible change in half-wave potential suggests that the extent of complexing between cadmium ion and urea is negligible, whereas the relatively large change in diffusion current would suggest that significant association between the two species had occurred. It is possible that the reduction in current could have arisen from causes other than complexation, such as adsorption of the ligand at the electrode surface so that the environment within which the aquo ion underwent reduction was changed. If this or some other such effect was operative, it would *not* be expected that a realistic analysis for equilibrium data would be possible. In practice, however, very clearly defined data emerged. In any case, urea complexes are not unknown and there have been investigations made of the distinguishing features of those containing oxygen- or nitrogen-bonded urea.[5]

The graph of calculated log F_0' data *vs.* log [urea] shows a limiting slope of 1.9 in the region corresponding to the maximum amount of urea (Fig. 4). At this stage there is no indication whatever of the extent of co-ordination, but since the limiting slope should approximate to N/k (N being the maximum co-ordination developed and k being defined by $k \log F_0' = \log F_0$) it is clear that k can have the values 1.05, 1.58 or 2.11, corresponding to $N = 2$, 3 or 4. Somewhat surprisingly, graphical analysis (by the methods described previously) was only successful for $k \sim 2.11$ and the following preliminary set of equilibrium data was obtained: $\beta_1 = 7.0$; $\beta_2 = 18$; $\beta_3 = 30$; $\beta_4 = 144$. Subsequent analysis in terms of $(\bar{D} - D_{MX_j})$ functions yielded the values $\beta_1 = 7.0$; $\beta_2 = 23$; $\beta_3 = 44$; $\beta_4 = 88$. The two sets of data agree satisfactorily enough and show the common characteristic noticed earlier, *viz.* that analysis by means of the pseudo
Fig. 2. Polarograms (d.c.) of $10^{-3}M$ Cd^{2+} in $0.1M$ KNO_3 in the absence (a) and presence (b) of $2.0M$ urea. Both waves start at -0.4 V $vs.$ SCE.

formation-curve tends to produce an overestimate in the value for the highest complex.

Cadmium–imidazole

For this system reliable formation-constant data from a number of sources are reported in the literature. The values are so high that when cadmium ions are present the difference between total and free imidazole concentration is by no means negligible unless the total cadmium concentration is very small indeed relative to that of the ligand. The overall changes in diffusion current are small[6] and, because of the higher stability of the complexes, are maximal at fairly low ligand concentrations. These features were seen as providing a particular challenge to both the methods of calculation and the experimental technique for obtaining the small changes in current.

A preliminary range of Δi_d $vs.$ [imidazole] data was obtained by means of manually plotted polarograms on individually prepared solutions containing $5 \times 10^{-4}M$ cadmium, $0.1M$ potassium nitrate and imidazole varying up to a maximum of $0.04M$. Although co-ordination with $0.04M$ imidazole was incomplete ($\bar{n} \sim 2.5$), the results could be analysed to

obtain equilibrium data corresponding to four complexes.

Selected F_0 and derived data are given in Table 1. Values for the first three formation constants are of the same order as reported previously, although that for β_4 is more than an order of magnitude higher than expected. This is undoubtedly due to two causes, (i) the general tendency for calculation by means of the pseudo formation-curve to produce a high result for the highest complex, (ii) the manipulation of data obtained for ligand concentrations corresponding to the lower complexes in order to generate equilibrium data for complexes of higher co-ordination.

Since only a very low cadmium concentration was used in the investigations above, the difference between total and free ligand concentration is not very great except at the lowest values of the latter. However, when using the "titration" technique it was desirable to have large diffusion currents and accordingly a metal ion concentration of $2 \times 10^{-3}M$ was used. This fairly high value caused a significant difference between the total and free imidazole concentrations and provided a useful means of testing the methods adopted for correction of the experi-
Fig. 3. Graphs of observed (○) and corrected (□) diffusion currents vs. calculated ligand concentration for the system cadmium–thiourea. Inset shows the derived pseudo-formation curve.

mental data. Further, correction of the observed currents to allow for any variation in residual current at the potential at which values of Δi_d were determined, was of less significance. In fact, the base-lines were virtually horizontal for the experimental polarograms at the sensitivity settings required. A plot of corrected diffusion current vs. imidazole concentration is shown in Fig. 5. Although the scatter of points increases at the highest concentrations, this is offset by the large number of data points obtainable, giving enhanced confidence in the final curve drawn.

A plot of directly observed Δi_d values vs. $\bar{n}$ values estimated from literature values of the stability constants, though approximately linear, does not pass through the origin. This is to be expected since the free imidazole concentrations for which the $\bar{n}$ values were calculated did not correspond to the actual free ligand concentrations at which the Δi_d values were obtained. In the case of a system for which the equilibrium data are quite unknown, it is necessary to have a reliable means of deducing the free concentration of complexing agent. The results which follow show how this can be done.

Integration of the pseudo-formation curve, drawn simply as a plot of Δi_d vs. total analytical concentration of imidazole, provides F_0 data according to

Table 1. Selected values of F_0 and derived functions estimated from the pseudo-formation curve for the cadmium–imidazole system at 25°: $[Cd^{2+}] = 5 \times 10^{-4}M$, $[KNO_3] = 0.1M$

the method described.[6] Although this procedure uses erroneous values of free ligand concentration, the F_0 data obtained may be used to generate provisional values of formation constants for four complexes. Some selected data obtained by this treatment are prsented in Table 2.

It is clear that the values of the apparent overall constants are considerably lower than the reported values. However, the various derived curves show very little scatter and some confidence may be placed in the conditional data obtained by these means. This confidence is augmented by recalculation of the data in terms of $(\bar{D} - D_{MX_j})$ functions. From the clearly defined limiting value of Δi_d shown by the pseudo-formation curve it was possible to infer an approximate value of 4.92×10^{-6} cm^2/sec for the diffusion coefficient of the MX_4 species and hence to interpolate values for all intermediate complexes. The graphical analysis was extremely satisfactory for this

case (Fig. 6); selected tabulated data are given in Table 3. The constancy of the ratio $G_4/(\bar{D} - D_{MX_4})$ is quite remarkable.

Assuming that the highest value of Δi_d corresponds approximately to $\bar{n} = 4$, estimates of $\bar{n}$ were made at the analytical concentrations of ligand used. These were then used to assess the approximate concentration of imidazole bound to Cd^{2+}. Use of the free imidazole concentration thus calculated caused a significant change in the shape of the pseudo-formation curve (Fig. 7).

Integration of this new curve provided refined F_0 data, the functions derived from which showed little

the characteristic initial positive shift of half-wave potential induced by the complexation of nickel was clearly seen. A selection of polarograms obtained for one titration is shown in Fig. 8. No attempt was made to remove the large maximum which featured prominently on polarograms obtained from solutions containing ligand. The diffusion current was observed at a constant potential (-1.3 V vs. SCE) for all solutions. Great care was required to ensure that the titration/deoxygenation routine was repeated in as nearly identical a manner as possible at each addition of "titrant". The change in current, even allowing for that due to the dilution effect, was small, so that the final corrected values for Δi_d were very small indeed.

The combined effects of very high values for formation constants, very small observed changes in current, the large difference between $[Im]_{total}$ and $[Im]_{free}$ and the inherent complications present in many systems involving nickel complexes probably represent the ultimate test of both the experimental techniques and the principles of calculation employed. Equilibrium data obtained under such constraints are unlikely to be of the standard realized in the other systems reported. However, the following values were obtained: $\beta_1 \sim 1.5 \times 10^3$; $\beta_2 \sim 6 \times 10^5$; $\beta_3 \sim 1.3 \times 10^8$; $\beta_4 \sim 2 \times 10^9$; $\beta_5 \sim 1 \times 10^{10}$; $\beta_6 \sim 5.5 \times 10^{11}$. These are of the same order of magnitude as those reported by Li et al.[9] and by Sklenskaya et al.[10]

Cadmium–thiocyanate

Although the titration technique described above is rather more difficult to apply realistically to complexes with charged ligands, it was considered appropriate at least to *attempt* to apply it to the very first system treated by the DeFord and Hume method. In nitrate media the values of the overall formation constants do not increase regularly with n, and it was required to establish whether the variations in diffusion current would reflect this. Despite the fact that the solutions produced by the titration procedure showed a considerable range of ionic strengths, the values estimated for the first three overall formation constants followed very closely the irregular trend reported by Hume et al.[11] The value of β_4 was obscured at lower thiocyanate concentrations by the uncertainty in the values of the higher derived functions; at higher ligand concentrations the effects of

scatter, and in their turn yielded a new set of formation constants. These partially corrected values were used to calculate more refined $\bar{n}$ data and a final correction to the formation curve. The four sets of data obtained are collected with some literature values in Table 4; the agreement between the latter and those obtained by the successive refinement described is entirely satisfactory.

Nickel–imidazole

The titration technique described above was used again. Particular care was required in this case since

increasing ionic strength become very significant. This is clearly seen in a comparison of the graphs of F_0 values $vs.$ [SCN$^-$] obtained by Hume et $al.$ and from the observed currents obtained in the present study (Fig. 9). Evidently, below a thiocyanate concentration of $0.65M$, the effect of ionic strength on the values of F_0 and the derived functions is negligible: above this value the effect becones increasingly marked.

Hume et $al.$[11] made no attempt to determine values of F_4 for thiocyanate concentrations below $0.7M$; it is, however, interesting to see that the present analysis, at [SCN$^-$] = 0.6 and $0.65M$ (just before the region where the effects of increasing ionic strength become significant), gives values of F_4 of 62 and 61.5 respectively. These values are very close to the value of 60 for β_4 determined and reported earlier.

Table 4. Apparent and refined equilibrium data for the cadmium–imidazole system

(e) Data of Tanford and Wagner,[7] for $I = 0.15$.
(f) Data of Li, White and Doody,[8] for $I = 0.15$.

It is well known that in a perchlorate supporting medium the formation constants have quite different values. The diffusion current data reported for the cadmium–thiocyanate system by Senise and de Almeida Neves,[12] for $2M$ sodium perchlorate medium, yielded a pseudo-formation curve which could be used to generate two alternative sets of formation data, $viz.$ $\beta_1 = 23$; $\beta_2 = 75$; $\beta_3 = 80$; $\beta_4 = 450$ or $\beta_1 = 23$; $\beta_2 = 75$; $\beta_3 = 0$; $\beta_4 = 570$.

These authors obtained the following values from the potential data: $\beta_1 = 25$; $\beta_2 = 75$; $\beta_3 = 85$; $\beta_4 = 240$.

Conclusions

The titration method described has proved to be successful for systems involving uncharged ligands. Variations in diffusion current estimated from observed values are reliable and have even been used with very fair success in the case of an ionic ligand, with no corrections made for the effects of increasing ionic strength.

Unlike earlier dilution methods, the one described here does not maintain a constant concentration of metal ion. In terms of the $observed$ current signal this offers a practical advantage for systems such as those involving imidazole or other molecules inducing only very small changes in the diffusion coefficients of metal ions. In terms of the possible non-ideality of the solutions obtained and interference of the titration process with metal–ligand equilibria, the technique might still be shown to involve undesirable complications in some instances. The main advantages are those to be gained by use of the large number of working solutions which are obtainable. This feature is already revealing subtleties in the shapes of Δi_d $vs.$ ligand concentration curves, which have previously

been obscured by the considerable scatter of a small number of data points. Indeed, it is due to the larger number of such points, coupled with the newer methods of calculation (which are able to make more reliable use of data for lower ligand concentrations than has been the case with more traditional methods), that the problems associated with varying ionic strength are reduced.

The current changes are markedly sensitive to variations in metal–ligand interaction, as is shown by the efficiency with which irregular sequences of over-all formation constants may be dealt with. It is doubtless true that the observed differences between the values of the formation constants of cadmium complexes of thiocyanate in nitrate and in perchlorate media, arise to some extent from inter-ference in the former case from interaction between Cd^{2+} and NO_3^- ions, as has been investigated quan-titatively.[13] However, there could well be a further complication. Unusual sequences of formation data appear to be a fairly common feature of systems involving sulphur-containing ligands; the irregu-larities seem to be more pronounced when the mea-surements involve mercury electrodes.

Equilibrium data deriving from measurements of potential reflect the nature of the complex species and
Fig. 9. Comparison of F_0 values of different origin: ○—calculated from pseudo-formation curve; ■—values reported by Hume *et al*.;[11] □—values interpolated from experimental data of Hume *et al*.[11]

their behaviour *at the electrode surface*. Under the necessary conditions of reversibility, complexes either react rapidly and directly with the electrode, or they dissociate and the resulting aquo-ions react with the electrode (both processes rapid). If complications should arise on account of interaction of either the ligand or the complexes with the mercury of the electrode, the potentials and the data derived from them reflect such interactions as well as those of metal ion and ligand in the bulk solution. That such interactions are possible is shown by the effects on the anodic dissolution curve of mercury in the presence of sulphur-containing ligands such as thiocyanate, thiosulphate,[14] thiourea *etc.*; effects of this sort are even evident in the presence of urea.[15] Analysis by means of diffusion coefficients under these conditions should give different values for formation constants from those estimated from potentials. Diffusion coefficients reflect the nature of various species in bulk solution—a nature which is presumably retained at least until their entry into the diffuse double-layer.

POLYURETHANE FOAM FOR THE EXTRACTION OF RHODIUM AND ITS SEPARATION FROM IRIDIUM

S. J. AL-BAZI and A. CHOW

Department of Chemistry, University of Manitoba, Winnipeg, Manitoba, Canada

Summary—The rate of reaction of rhodium with thiocyanate at 90° in the presence of lithium chloride or sufficient hydrochloric acid and the subsequent extraction of the metal from hydrochloric acid medium by polyether-type polyurethane foam was investigated. The effect of the chloride salts of different cations decreased in the order $Li^+ > Na^+ > K^+$ indicating that $Rh(SCN)_6^{3-}$ is extracted through a simple solvent-extraction mechanism rather than the "cation-chelation" mechanism. The separation of rhodium and iridium was also examined and the results indicated that in the presence of 5-fold excess of iridium, an average of $95 \pm 2\%$ iridium remained in the aqueous phase while an average of $93 \pm 2\%$ rhodium was retained by the foam.

Many difficulties arise in the solvent extraction of rhodium, owing to its characteristic feature of forming inert complexes with many ligands, including chloride. Thus the use of a catalyst[1-4] and/or heating the aqueous phase before extraction[5-10] has been required except when the extraction took place by an ion-association mechanism.

Solvent extraction has been widely used to separate rhodium and iridium. The greater lability of rhodium in the formation of chelates or solvent complexes has played an important role in their separation.[1,11-15]

The purpose of the present work was to study the kinetic behaviour of the reaction of rhodium with thiocyanate, and the subsequent extraction of the metal by polyether-type polyurethane foam. The study also included the mechanism of distribution of the rhodium–thiocyanate complex between foam and aqueous phase, and a method for the separation of rhodium and iridium.

EXPERIMENTAL

Apparatus and reagents

Rhodium was determined with a Perkin–Elmer model 306 atomic-absorption spectrometer. A Baird-Atomic model 530A single-channel gamma-ray spectrometer fitted with a Harshaw well-type NaI(Tl) crystal was used for iridium-192 measurements. Spectrophotometric measurements were made with a Varian model 634S spectrophotometer.

Polyether-type polyurethane foam (No. 1338 M) was obtained from G. N. Jackson Ltd., Winnipeg, Manitoba, and washed by the procedure previously reported.[16]

Stock solutions of $4.9 \times 10^{-3}M$ rhodium(III) (freshly prepared for each experiment to minimize the hydrolysis of $RhCl_6^{3-}$ to $[RhCl_{6-x}(H_2O)_x]^{x-3}$ ($x = 1$–6) ions[17-19]) and $2.6 \times 10^{-3}M$ iridium were made from $Na_3RhCl_6 \cdot 12H_2O$ and $Na_2IrCl_6 \cdot 6H_2O$ (Johnson-Matthey Ltd.) in $0.1M$ hydrochloric acid. [192]Ir was obtained as $(NH_4)_2IrCl_6$ in $3M$ hydrochloric acid from Amersham-Searle Ltd., Ontario. A $5.0M$ solution of potassium thiocyanate was prepared in doubly distilled demineralized water.

Extraction procedure

A known volume of the stock solution of rhodium or iridium and the desired amounts of the other reagents were placed in a 100-ml standard flask and diluted to about 60 ml. Sufficient ^{192}Ir tracer was added to the iridium samples to yield a count-rate of at least 150 cps for 10 ml of sample in a 15-mm internal diameter test-tube. The solution was heated at 90° for a measured time, cooled to room temperature and finally diluted to volume. The extraction of 95 ml of this solution with 50 ± 1 mg of foam for a minimum of 10 hr and the calculations of percentage extraction (%E) and distribution coefficient (D, l./kg) were performed as described previously.[16]

RESULTS AND DISCUSSION

When rhodium chloride solutions containing sufficient thiocyanate were heated, two different complexes were formed, depending on the acidity of the solution.[16] $Rh(SCN)_6^{3-}$ was formed at low acidity, whereas a different complex was produced at high acidity. The latter was not characterized and will be denoted as RhY. These complexes have been reported to be highly extractable by polyether-type polyurethane foam.[16] The rates of formation and subsequent extraction of these complexes by the foam were investigated.

The formation and extraction of $Rh(SCN)_6^{3-}$

Varying the heating time for solutions at pH 2.4 ± 0.1 showed (Fig. 1) an increase in the extraction from 4% (log $D = 1.78$) without heating to 80% (log $D = 3.77$) at 2 hr and 92% (log $D = 4.22$) after 5 hr of heating. The absorbance at 288 nm, which corresponds to the $Rh(SCN)_6^{3-}$ complex,[20] increased with heating time and was found to be proportional to the amount of rhodium extracted.

When the effect of heating time was investigated with different concentrations of lithium chloride, both the formation of the complex (Fig. 2) and its subsequent extraction (Fig. 3) increased with increasing salt concentration and heating time. The degree of extraction of rhodium [94% (log $D = 4.46$) and 95% (log $D = 4.54$)] from $2M$ lithium chloride
Fig. 1. Effect of heating time on the formation and extraction of rhodium–thiocyanate complex. (□) Formation; conditions: 60-ml solutions at pH 2.4 ± 0.1 containing 24.5 μmoles of Rh(III) and 0.6 mmoles of KSCN, heated at 90°. (○) Extraction; conditions: 97 ± 2 mg of foam; 145 ml of solution $2M$ in HCl added after heating.

medium with heating for 30 and 60 min, respectively indicated that the rate of formation of Rh(SCN)$_6^{3-}$ is increased by the presence of lithium chloride in the solution.

We have reported[16] that the labile character of rhodium toward complexation with thiocyanate increases with decreasing number of water molecules in the initial [RhCl$_{6-x}$(H$_2$O)$_x$]$^{x-3}$ complex. Furthermore, the kinetics of the aquation of RhCl$_6^{3-}$ and of replacement of the water in [RhCl$_5$(H$_2$O)]$^{2-}$, i.e.,

$$\text{RhCl}_6^{3-} + \text{H}_2\text{O} \underset{K_2}{\overset{K_1}{\rightleftharpoons}} (\text{RhCl}_5(\text{H}_2\text{O}))^{2-} + \text{Cl}^-$$
have been described by the rate law:[21]

$$-\text{d}[\text{RhCl}_6^{3-}]/\text{d}t = K_1[\text{RhCl}_6^{3-}]$$
$$- K_2[\text{RhCl}_5(\text{H}_2\text{O})^{2-}][\text{Cl}^-]$$

($K_1 = 0.11$ min^{-1} and $K_2 = 0.013$ min$^{-1} \cdot$l$\cdot$mole^{-1} at 25°).

Thus, in the presence of lithium chloride, the decrease in time of heating required for the formation of Rh(SCN)$_6^{3-}$ is due to the decrease in the rate of

Fig. 3. Effect of lithium chloride, added before heating of solutions for different times, on the extraction of rhodium; conditions: 50 ± 1 mg of foam; 95 ml of solutions of $1.6 \times 10^{-4}M$ Rh(III), $4 \times 10^{-3}M$ KSCN, made $2M$ in HCl after heating at 90° for (○) 10 min, (□) 30 min, (△) 60 min.

aquation of RhCl$_6^{3-}$ to [RhCl$_{6-x}$(H$_2$O)$_x$]$^{x-3}$, caused by heating the solution. Similar observations have been made for the formation of the Ru(SCN)$_6^{3-}$ complex,[22] which is also labile towards aquation.

The formation and extraction of the RhY complex

Since formation of the RhY complex depends on the concentration of thiocyanate and hydrochloric acid as well as on the heating schedule, two experiments were performed to establish the minimum heating time required before its extraction. Varying the thiocyanate concentration with different heating times indicated (Fig. 4) that the degree of extraction increases both with increasing thiocyanate concentration (though this must be less than $2 \times 10^{-2}M$, to minimize thiocyanic acid interference) and with heating time, reaching a maximum at 95% (log $D = 4.54$) for a solution initially $1.6 \times 10^{-2}M$ in thiocyanate and heated for 60 min.

Replotting of these results as percentage extracted vs. initial thiocyanate concentration, for solutions
Fig. 4. Effect of heating time of solutions containing different concentrations of thiocyanate on the extraction of rhodium when some of the acid was added before heating; conditions: 49 ± 1 mg of foam; 95 ml of $1.6 \times 10^{-4}M$ Rh(III), total HCl $2M$ (30 mmoles of HCl added before heating); KSCN: (●) $1.6 \times 10^{-2}M$; (△) $8 \times 10^{-3}M$; (□) $4 \times 10^{-3}M$; (○) $2 \times 10^{-3}M$.
Fig. 5. Effect of thiocyanate on the extraction of rhodium from solutions heated for different times and containing some hydrochloric acid added before heating; conditions: 49 ± 1 mg of foam; 95 ml of $1.6 \times 10^{-4}M$ Rh(III), total HCl $2M$ (30 mmoles of HCl added before heating); heating time: (●) 10 min; (○) 15 min; (□) 30 min; (△) 45 min; (○) 60 min.

heated for different times (Fig. 5), makes it clear that for solutions with an initial thiocyanate concentration $>6 \times 10^{-3}M$ and heated for more than 30 min, the extraction of rhodium is almost independent of thiocyanate concentration. The ultraviolet spectra indicated that the absorbance band at 288 nm and the band at 246 nm (which corresponds to RhY) increased with increasing amounts of thiocyanate and heating time. Furthermore, at high thiocyanate concentrations and longer heating times, the absorbance at 288 nm decreased while that at 246 nm continued to increase with larger thiocyanate concentrations and longer heating; this can be attributed to the conversion of $Rh(SCN)_6^{3-}$ into RhY.

The contribution of hydrochloric acid in reducing the necessary heating time was studied at the optimum thiocyanate concentration. The results (Fig. 6) indicated that the extraction of rhodium increased
Fig. 6. Extraction of rhodium as a function of time of heating solutions containing different concentrations of hydrochloric acid initially added before heating; conditions: 49 ± 1 mg of foam; 95 ml of $1.6 \times 10^{-4}M$ Rh(III), $1.2 \times 10^{-2}M$ in KSCN, total HCl $2M$ [HCl added before heating: (○) 0.1 mmole; (□) 10 mmoles; (○) 30 mmoles; (●) 80 mmoles; (△) 160 mmoles HCl].

with longer heating times and with larger amounts of hydrochloric acid added before heating the solution. The ultraviolet spectra showed that for solutions of low acidity the absorbance at both 288 nm [$Rh(SCN)_6^{3-}$ complex] and 246 nm [RhY complex] increased with increasing heating time, whereas for highly acidic solutions the absorbance at 288 nm decreased while that at 246 nm still increased. In addition, when solutions which initially contained as little as 80 mmoles of hydrochloric acid per 60 ml were heated for more than 30 min, another absorption peak, at 306 nm (also due to RhY) was observed and both absorbances for RhY increased with heating time up to 60 min. The maximum absorbance at both 306 and 246 nm was observed for solutions with initially 160 mmoles of hydrochloric acid per 60 ml, when these were heated for a minimum of 30 min.

Since high thiocyanate and acid concentrations produced hydrogen sulphide in solution, the increase in the rate of formation of the RhY complex might be due to the reduction of Rh(III) to Rh(II), which acts as a soft acid[23] and hence will have a high affinity toward the soft base thiocyanate. The reduction of Rh(III) to Rh(II) has also been proposed by Ryan[5] to explain the increase in the rate reaction of rhodium with 2-mercapto-4,5-dimethylthiazole when a hydrochloric acid solution of tervalent rhodium is boiled with excess of reagent.

Mechanism of the extraction of Rh(III)–thiocyanate complex

The possibility of a "cation-chelation" mechanism[24,25] as a mode for the extraction of $Rh(SCN)_6^{3-}$ by the foam was investigated. With $4 \times 10^{-3}M$ thiocyanate solutions at pH 2.5 ± 0.1, the effect of different concentrations of sodium or potassium chloride added after heating for 4 hr was studied. The extraction increased from 38% (log $D = 3.07$) with no salt to 47% (log $D = 3.22$) at $0.5M$ sodium chloride and then remained constant. For solutions containing potassium chloride, the extraction increased to 52% (log $D = 3.32$) at $0.4M$ salt concentration and then decreased to 41% (log $D = 3.12$) for $2M$ salt.

In a second experiment, solutions at pH 2.5 ± 0.1 were heated for 4 hr before addition of different chloride salts and adjustment of the hydrochloric acid concentration. The results (Fig. 7) indicated that for all the acid concentrations, the extraction of rhodium decreased according to the salt cation added, in the order $Li^+ > Na^+ > K^+$, which is the order of decreasing hydration number of these cations.

In the ultraviolet spectra of the solutions in both these experiments the absorption band at 288 nm had the same shape and intensity, indicating that the influence of the solution conditions was on the distribution of $Rh(SCN)_6^{3-}$ between foam and aqueous phase rather than on the formation of the complex.

No appreciable increase in the extraction of $Rh(SCN)_6^{3-}$ was observed with increased concentrations of sodium or even potassium ions. Further-
Fig. 7. Effect of the size of the alkali metal on the distribution of rhodium–thiocyanate complex between foam and aqueous solutions containing different concentrations of hydrochloric acid added after heating; conditions: 50 ± 1 mg of foam; 95 ml of $1.6 \times 10^{-4}M$ Rh(III), $4 \times 10^{-3}M$ in KSCN, $2M$ in salt; [HCl]: ($\square$) $3 \times 10^{-3}M$; ($\triangle$) $0.5M$; ($\bigcirc$) $1M$.

Fig. 8. Effect of thiocyanate on the extraction of rhodium and iridium from solutions containing acid added after heating; conditions: 49 ± 1 mg of foam; 95 ml of $2M$ HCl, $1M$ in LiCl; ($\bigcirc$) $1.6 \times 10^{-4}M$ Rh(III); ($\triangle$) $8 \times 10^{-5}M$ Ir(IV).

more, the results in Fig. 7 did not show the increase in extraction in the order $Li^+ < Na^+ < K^+$ that has been observed for the thiocyanate complexes of palladium,[26,27] platinum,[28] ruthenium and osmium,[22] which are extracted through the "cation-chelation" mechanism. Consequently, it is concluded that there is not a significant contribution from the "cation-chelation" mechanism[24,25] in the extraction of the rhodium complex(es) by polyether foam.

A minimum hydrochloric acid concentration of $2M$ was required for the extraction of rhodium by the foam,[16] which is significantly greater than the $0.5M$ acid required for the $Pd(SCN)_4^{2-}$ complex[26] and the Pt(II)–thiocyanate complex.[28] However, this effect of acid concentration is in agreement with that reported for rhodium extraction from thiocyanate solutions by many organic solvents,[7,9] and because $H_3Rh(SCN)_6$ can be formed at high acid concentrations,[7] the distribution of $Rh(SCN)_6^{3-}$ between the foam and aqueous phase may be regarded as a simple solvent extraction, probably of $H_3Rh(SCN)_6$. This mechanism has been suggested by several workers[29,30] for the extraction of some metals by polyurethane foam and explains the increasing extraction of rhodium with increasing hydration number of the salt cation added (*i.e.*, there was a simple salting-out mechanism).

Separation of rhodium and iridium

To determine the degree of extraction of iridium as a function of the amount of lithium chloride added before heating, solutions at pH 2.5 ± 0.1 containing 8.66 μmoles of iridium, 3.0 mmoles of thiocyanate and different volumes, up to 40 ml, of $10M$ lithium chloride in approximately 60 ml total volume were

heated at 90° for 1 hr, then cooled to room temperature, made $2M$ in hydrochloric acid and finally diluted to 100 ml. A foam cube weighing 50 ± 1 mg was then equilibrated with 90 ml of final solution for 15 hr. The results indicated that the extraction decreased from 11.3% (log $D = 2.36$) with no lithium chloride to 4.5% (log $D = 1.94$) at $4M$ salt concentration. This decrease in extraction is most likely due to the decrease in the amount of iridium–thiocyanate complex formed, which is analogous to results obtained for osmium[22] and may be attributed to competition between thiocyanate and chloride ions for iridium.

The effect of thiocyanate on the extraction of iridium and rhodium was investigated, with 100 mmoles of lithium chloride added before heating for 1 hr. The results (Fig. 8) showed low extraction of iridium over the thiocyanate range studied, whereas a high extraction of rhodium was obtained at low thiocyanate concentrations.

An average extraction of $5.0 \pm 1.2\%$ (log $D = 1.67 \pm 0.12$) for iridium and $94 \pm 1\%$ (log $D = 4.18 \pm 0.06$) for rhodium was obtained, independently of pH, when solutions containing 0.20 mmole of thiocyanate, 200 mmoles of lithium chloride and 8.66 μmoles of iridium or 16.3 μmoles of rhodium were adjusted to various pH values from 1.7 to 6.0 with hydrochloric acid or lithium hydroxide before heating for 30 min. Furthermore, when the amount of lithium chloride was increased to 400 mmoles, an average of $4.0 \pm 0.6\%$ (log $D = 1.58 \pm 0.08$) iridium was extracted. When the experiments were repeated with rhodium, the extraction increased from 90% (log $D = 3.94$) at $1.5M$ lithium chloride to a maximum of 95% (log $D = 4.20$) at $3M$, then decreased to 91% (log $D = 3.98$) at $4M$ lithium chloride.

The extraction of iridium showed a slight increase when a series of solutions at pH 2.5 ± 0.1 containing 0.20 mmole of thiocyanate and 300 mmoles of lithium chloride were adjusted to hydrochloric acid concen-

Table 1. Separation of rhodium and iridium from thiocyanate solutions by polyurethane foam

[Rh(III)], M	[Ir(IV)], M	Rhodium, %E	Log D	Iridium, %E	Log D
1.5×10^{-4}	tracer only*	94	4.17	6.2	1.78
1.5×10^{-4}	1.3×10^{-4}	94	4.16	6.2	1.77
1.5×10^{-4}	2.6×10^{-4}	95	4.22	5.8	1.75
1.5×10^{-4}	5.2×10^{-4}	93	4.11	3.2	1.47
1.5×10^{-4}	7.8×10^{-4}	90	3.92	3.5	1.51

*Less than $1 \times 10^{-12} M$.

trations up to $3M$ after 30 min of heating. Only 3.0% (log $D = 1.45$) of iridium was extracted from $1M$ acid solutions and this increased to 4.5% (log $D = 1.62$) for $1.5M$ acid and then remained independent of acidity at higher acid concentration. Under the same conditions, the extraction of rhodium increased from 85% (log $D = 3.72$) at $1M$ initial acid to 93% (log $D = 4.11$) at $2M$ and stayed almost constant at higher concentrations.

The separation of the two metals was studied under the best conditions for the extraction of rhodium and almost the worst for iridium. Solutions containing up to 78 μmoles of iridium at pH 2.5 ± 0.1 with 14.7 μmoles of rhodium, 0.20 mmole of thiocyanate and 300 mmoles of lithium chloride in about 60 ml were heated at 90° for 30 min, then cooled to room temperature; 200 mmoles of hydrochloric acid were added and the solutions diluted to 100 ml. A foam cube weighing 100 ± 1 mg was then equilibrated for 15 hr with 90 ml of a solution thus prepared. The results (Table 1) indicate that up to a 5-fold molar ratio of iridium to rhodium has little or no effect on the extraction of rhodium. These results indicate that rhodium and iridium can be separated with reasonable success, considering the difficulty of their separation, and in comparison with other techniques.

Conclusions

The presence of lithium chloride or hydrochloric acid accelerates the reaction of rhodium with thiocyanate to form an extractable species. Furthermore, while the effect of lithium chloride is to facilitate the formation of the rhodium thiocyanate complexes it inhibits that of the iridium complexes and therefore makes the separation more efficient and quantitative.

PHOTOMETRIC AND FLUORIMETRIC KINETIC DETERMINATION OF MANGANESE BY MEANS OF THE OXIDATION OF SODIUM 4,8-DIAMINO-1,5-DIHYDROXYANTHRAQUINONE-2,6-DISULPHONATE

A. Navas and F. Sanchez Rojas

Department of Analytical Chemistry, Faculty of Sciences, University of Málaga, Spain

Summary—Three kinetic methods for the determination of manganese, two of them by photometric monitoring and another by fluorimetric monitoring, based on the oxidation of sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate are described. A critical comparative evaluation of both monitoring techniques and their effect on the analytical figures of merit of the methods has been made. Manganese contents between 6.5 and 21.7 ng/ml can be determined with relative standard deviation of ±3.7%. Under appropriate working conditions, the fluorimetric method can be satisfactorily applied to the determination of manganese in environmental samples of tap water and workroom metallic fumes.

Although the general advantages and limitations of kinetic methods of analysis have been discussed,[1-8] study of the influence of the reaction monitoring technique on the analytical characteristics of kinetic methods is very interesting in evaluation of the analytical figures of merit of two kinetic methods based on the same chemical reaction.

Molecular absorption spectrophotometry and spectrofluorimetry are both widely used as monitoring techniques in kinetic methods of analysis.[9] Usually the intrinsically higher sensitivity of fluorimetry is offset by the low degree of completeness of reaction when initial-rate kinetic measurements are used, and the overall sensitivity depends on both the monitoring technique and the mode of calculation.

This paper reports the spectrophotometric kinetic determination of manganese by means of the oxidation of sodium 4,8-diamino-1,5-dihydroxyanthraquinone-2,6-disulphonate (DADHADS) in acidic medium. The reaction is characterized by the appearance of a pink oxidized product ($\lambda_{max} \sim 500$ and 540 nm) and disappearance of the blue colour of DADHADS ($\lambda_{max} \sim 570$ nm).

The oxidized product presents a pink fluorescence ($\lambda_{max} \sim 580$ nm) when excited at 525 nm, and this may be used for fluorimetric monitoring and kinetic determination of traces of managanese.

In the present work, the method has been applied to determination of manganese in fumes in industrial work places. Welding operations generate fumes containing very small solid particles, a high percentage of which are in the respirable size-range, and produce the risk of poisoning, given the known toxicity of manganese.[10-13] The threshold limit value (TLV) for environmental manganese[14] is 1 mg/m^3, so adequate control of the manganese concentration in the environment is needed for worker protection in workshops.

EXPERIMENTAL

Reagents

DADHADS stock solution, 0.01%. The solution is stable for at least 1 month.

Standard manganese(II) solution, 50.0 μg/ml. Prepared by dissolving manganese sulphate monohydrate in 0.1M hydrochloric acid, and standardized by EDTA titration.

All chemicals used were of analytical-grade, and demineralized distilled water was used throughout. The dilute solutions were prepared immediately before use, and all reagents and analyte solutions were brought to the same temperature in a thermostatically controlled water-bath.

Apparatus

A Perkin-Elmer MPF-43A spectrofluorimeter equipped with a 150-W xenon lamp, 1 × 1 cm quartz cells and a Hamamatsu R-777 photomultiplier was used, and no spectral corrections were made. A Shimadzu UV-240 Graphicord spectrophotometer was used. The analytical signals were recorded with a chart-recorder.

Procedure

Pipette 10 ml of DADHADS solution (1 × 10^{-4}M for photometric measurement or 1.05 × 10^{-5}M for fluorimetric measurement), and an aliquot (1–10 ml) of sample (pH 3–10) containing 3–11 μg of manganese (photometric procedure) or 0.16–0.54 μg of manganese (fluorimetric procedure) into a dry 25-ml standard flask. Add 2 ml of 0.2M sodium hydroxide and mix. Make up to volume with 0.5M hydrochloric acid and monitor the absorbance at 518 nm or 606 nm, or the fluorescence intensity ($\lambda_{exc} = 525$ nm, $\lambda_{em} = 585$ nm), starting 60 sec after the addition of hydrochloric acid.

Collection and treatment of samples

Fume samples were collected in workshop environments according to the NIOSH Manual,[15] in 37-mm three-body cassettes with mixed cellulose-ester membrane filters (0.8 μm cellulose-ester membrane filters (0.8 μm pore size,

MSA). Battery-powered personal sampling pumps (MSA, model G) were used at flow-rates of 1.5 l./min. Each filter was treated with 10 ml of concentrated nitric acid; the acid was evaporated to dryness by heating on a hot-plate in a clean-air fume-cupboard and the residue dissolved in 5 ml of 10% v/v nitric acid. The clear solution was quantitatively transferred to a 50-ml standard flask and diluted to volume with demineralized water. An aliquot of this solution was then subjected to the kinetic procedure.

Tap water samples were collected in Málaga and stored in polyethylene bottles, which had been previously washed with 20 ml of saturated potassium permanganate solution, emptied, left for 10 min, then repeatedly washed with the inner surface in contact with concentrated sulphuric acid (10 ml). The bottles were then repeatedly filled with the tap water, before a sample was retained. Tap water samples were concentrated tenfold by evaporation before analysis if the standard-addition method was not used.

RESULTS AND DISCUSSION

It has been found that in strongly acidic media DADHADS undergoes very slow reaction with the oxygen dissolved in water, and this is catalysed by certain cations,[16,17] or by the action of oxidants such as cerium(IV).[18] The DADHADS–Mn(II) reaction does not occur in either alkaline or acidic media, but, if a solution containing both reagents in an alkaline medium is acidified with hydrochloric acid, the oxidation process takes place.

This suggests that a Winkler-type mechanism is the most likely route of the oxidative reaction of DADHADS with manganese, as follows:

$$2Mn(II) + O_2 + 4OH^- \longrightarrow 2MnO_2 \cdot H_2O \quad (1)$$

$$MnO_2 \cdot H_2O + DADHADS_{red} + 4H^+$$
$$\longrightarrow Mn(II) + DADHADS_{ox} + 3H_2O \quad (2)$$

$$DADHADS_{ox} + H_2O \xrightarrow{H^+} AHADQDS + NH_3 \quad (3)$$
in which the hydrolysis product (AHADQDS) is a fluorescent diquinone-type compound.[16] It is consistent with this hypothesis, that the reaction goes only after acidification of an alkaline solution.

This transformation is rather slow and permits the photometric and fluorimetric monitoring of the kinetic curves. Figure 1 shows the absorption (b) and excitation and emission (a) spectra of DADHADS and its oxidation product, from which it can be seen that DADHADS does not fluoresce and is blue in colour ($\lambda_{max} = 606$ nm), and the pink ($\lambda_{max} = 518$ nm) oxidation product is a fluorescent compound that shows an excitation maximum at 525 nm and emission maximum at 585 nm.

Effect of the reaction variables

The effect of the concentration of each reagent on the initial rate and on the standard deviation of the initial rate was studied, for the optimization of variables. The optimum concentration of a species was taken as the concentration at which the relative standard deviation of the initial rate measurement was minimal, the remaining variables being fixed. The optimum concentration will be that for which the reaction order of the species is zero or as close to it as possible, since small fluctuations in concentration will not affect the initial rate of a zero-order reaction.
Fig. 1. (a) Uncorrected excitation and emission spectra of DADHADS (1, 1′) and its oxidation product (2, 2′). [NaOH] 0.016M; [DADHADS] 8 × 10^{-6}M; [Mn^{2+}] 7.3 × 10^{-4}M; [HCl] 0.4M. Effect of the acidity of the initial reaction rate: A ($\lambda = 518$ nm) and B ($\lambda = 606$ nm), photometric method; [DADHADS] $1.6 \times 10^{-5}M$; [Mn^{2+}] $1.9 \times 10^{-5}M$; [NaOH] $0.016M$. C, fluorimetric method; [DADHADS] $8 \times 10^{-6}M$; [Mn^{2+}] $1.9 \times 10^{-5}M$; [NaOH] $0.016M$.

Fig. 4. Influence of the reagent concentration on the initial rate (fluorimetric method). A, [Mn^{2+}] $4.7 \times 10^{-7}M$; B, [Mn^{2+}] $2.4 \times 10^{-7}M$. [NaOH] $0.016M$; [HCl] $0.16M$.

Since manganese and sodium hydroxide must be present before the reaction is started by the addition of hydrochloric acid, the effects were studied of sodium hydroxide concentration and standing time before acidification on the initial reaction rate. The results obtained show that these variables are not critical, since the reaction is zero-order with respect to [NaOH] over the range studied ($0\cdot004$–$0\cdot12M$) and standing times up to 30 min do not affect the initial reaction rate. For further work, a sodium hydroxide concentration of $0.016M$ (2 ml of $0.2M$ alkali per 25 ml) was selected as it ensures an alkaline medium for moderately acidic samples (pH > 3) and provides reproducible results.

The effect of [HCl] on the initial reaction rate is shown in Fig. 2. The log–log plot indicates an ample range of concentrations in which the reaction rate is zero-order with respect to this variable. A hydrochloric acid concentration between 0.04 and $0.4M$ ensures reproducible results, which implies 2–20 ml of $0.5M$ acid per 25 ml of final solution.

The influence of [DADHADS] on the initial rate (photometric monitoring) is shown in Fig. 3; the initial rate increases steadily with [DADHADS]. The

relative standard deviation in the initial rate was 2–3% (measurement at 606 nm) for [DADHADS] between $2.8 \times 10^{-5}M$ and $8 \times 10^{-5}M$. Since the rates were lower at lower [DADHADS], and the standard deviation of the initial rate began to be significant, the precision decreased at lower [DADHADS].

The log–log plot for measurement at 518 nm shows zero-order reaction order with respect to DADHADS over the concentration range 3.2–$4.8 \times 10^{-5}M$, so [DADHADS] $= 4 \times 10^{-5}M$ was selected for further photometric work.

Figure 4 shows the influence of [DADHADS] on the initial rate measured fluorimetrically. Curves for two concentrations of manganese are shown. For both, the initial rate is zero-order with respect to [DADHADS] in the range 2–$4.5 \times 10^{-6}M$. For [DADHADS] $> 4.5 \times 10^{-6}M$, the initial reaction rate falls as a consequence of pre- and post-filter effects, as the absorption spectrum of DADHADS and the excitation and emission spectra of the reaction product overlap (Fig. 1). This effect increases with [DADHADS], as seen in Fig. 4, curve B, in which the reagent excess is higher. From these results [DADHADS] $= 4.2 \times 10^{-6}M$ has been selected as optimal for fluorimetric measurements.

Analytical parameters

Under optimal conditions, the log–log calibration graph is linear for manganese(II) concentrations ranging from 6.5 to 21.7 ng/ml for the fluorimetric procedure, and from 0.22 to 0.54 μg/ml ($\lambda = 518$ nm, oxidized product monitored) or from 0.13 to 0.44 μg/ml ($\lambda = 606$ nm, reagent monitored) for the photometric procedures. Further details of the analytical methods are summarized in Table 1.

It should be noted that, in spite of the higher sensitivity, the fluorimetric method is more precise than the photometric methods. The reasons for the poorer accuracy and precision of the photometric methods can be related to the spectral overlap at both monitoring wavelengths. As can be seen in Fig. 1, at

Fig. 3. Influence of the reagent concentration on the initial rate (photometric method). A. $\lambda 606$ nm; B, $\lambda 518$ nm. [Mn^{2+}] $1.9 \times 10^{-5}M$; [NaOH] $0.016M$; [HCl] $0.16M$.

Table 1. Analytical parameters of the kinetic methods for the determination of manganese

Method	Analytical response	Wavelength, nm	Range, ng/ml	Taken, ng/ml	Found ($\bar{x}$), ng/ml	n	S, ng/ml	RSD, %	G, %

Selectivity study

The effect of various ions on the determination of manganese(II) at the 0.33-μg/ml level (photometric monitoring of the oxidized product at 518 nm) and at the 0.015-μg/ml level (fluorimetric method) was investigated. The criterion for interference was a variation in the initial rate of more than ±6.4% (photometric monitoring) or ±3% (fluorimetric monitoring), from the value expected for manganese alone. The results are given in Table 2.

Interferences in these methods arise from four main chemical sources: (1) oxidizing substances act-

ing on DADHADS [Ce(IV), BrO_3^-, Hg(II)]; (2) catalysts of the oxidation process [V(V), Au(III), Fe(III), Cr(III)]; (3) species causing a decrease in the DADHADS concentration by complexation reactions, [Cu, Co, Pd];[19] (4) substances reducing manganese(III), [I^-, Fe(II)]. Spectral interferences should be minimal in the fluorimetric method owing to the inherent selectivity of fluorimetry. For the fluorimetric method, the interference of cobalt up to a C_{Co}/C_{Mn} ratio of 25 can be eliminated by addition of 1 ml of $1.9 \times 10^{-3}M$ tartrate or up to $C_{Co}/C_{Mn} = 50$ with 1 ml of $1.25 \times 10^{-3}M$ citrate. Cu(II) up to a ratio of $C_{Cu}/C_{Mn} = 25$ can be masked by addition of 1 ml of $1.25 \times 10^{-3}M$ citrate, and of Cr(III) up to $C_{Cr}/C_{Mn} = 10$ by addition of 1 ml of $8.9 \times 10^{-3}M$ fluoride.

Applications

To test the reliability of the proposed fluorimetric method, it was applied to the determination of manganese in environmental samples and tap water.

The results of analysis of four different environmental samples, a synthetic mixture and tap water are presented in Table 3. The standard-addition graphs were analysed by regression procedures to obtain the intercepts. The results obtained indicate the existence of a more pronounced matrix effect in the environmental samples and demonstrate the reliability of the fluorimetric method for the determination of manganese in these samples.

IMPROVED TRIBENZYLAMINE–SILVER BROMIDE EXTRACTION/ATOMIC-ABSORPTION SPECTROPHOTOMETRIC METHOD FOR THE DETERMINATION OF SILVER IN ORES, RELATED MATERIALS AND ZINC PROCESS SOLUTIONS

Elsie M. Donaldson

Mineral Sciences Laboratories, Canada Centre for Mineral and Energy Technology, Department of Energy, Mines and Resources, Ottawa, Canada

Summary—An improved tribenzylamine extraction/atomic-absorption method for the determination of silver in ores, related materials and zinc process solutions is described. The method, which involves the separation of silver by a single methyl isobutyl ketone extraction of the tribenzylamine–silver bromide ion-association complex from ~ 0.5–$2M$ sulphuric acid–$0.14M$ potassium bromide, is simpler and more rapid than a previous method based on a triple chloroform extraction of the complex. Silver is stripped with $12M$ hydrochloric acid containing 1% thiourea as a complexing agent. Thiourea is destroyed with nitric and perchloric acids and silver is ultimately determined by atomic-absorption spectrophotometry in an air–acetylene flame, at 328.1 nm, in a 10% v/v hydrochloric acid–1% v/v diethylenetriamine medium. Cadmium and bismuth are partly co-extracted but do not interfere. Results obtained by this method are compared with those obtained previously by the tribenzylamine/chloroform extraction method and with those obtained by a direct acid-decomposition/atomic-absorption method.

The objective of a current CANMET project, which involves a study of the behaviour, form and distribution of silver in conventional zinc hydrometallurgical processes (designed to recover metallic zinc from zinc ores and concentrates), is to increase the recovery of this valuable by-product in Canadian zinc plants. Recently, as part of this project, a solvent extraction/atomic-absorption spectrophotometric (AAS) method for the determination of ~ 0.1 $\mu g/g$ or more of silver in ores and concentrates and ~ 0.001 $\mu g/ml$ or more in zinc process solutions was developed.[1] In this method, silver is separated from the matrix elements by a triple chloroform extraction of the tribenzylamine (TBA)–silver bromide ion-association complex from $\sim 2M$ sulphuric acid–$0.08M$ potassium bromide. It is subsequently stripped from the chloroform phase with $9M$ hydrobromic acid and ultimately determined by AAS in a 10% v/v hydrochloric acid–1% v/v diethylenetriamine medium. However, in more recent work it was found that this method was not applicable to some industrial zinc process solutions of very high salt content, because of the severe emulsification encountered during the extraction step. Consequently, a similar method based on the use of TBA in conjunction with a solvent of much lower specific gravity (<1) than chloroform was sought.

The proposed method involves the separation of silver by a single extraction of the TBA–silver bromide complex into methyl isobutyl ketone (MIBK) from ~ 0.5–$2M$ sulphuric acid–$0.14M$ potassium bromide. Silver is then stripped with $12M$ hydrochloric acid containing thiourea. Results obtained for ores and concentrates are compared with those obtained by the TBA/chloroform extraction method and with those obtained recently by a direct acid-decomposition/AAS method.[2]

EXPERIMENTAL

Apparatus

A Varian-Techtron model AA6 spectrophotometer was used under the conditions described previously.[1,2]

Reagents

Standard silver solution, 100 μg/ml. Prepare the solution as described previously[1] but add ~ 10 ml of 50% v/v sulphuric acid instead of 1 ml and evaporate the solution to fumes of sulphur trioxide. Cool the solution, dissolve the salts by heating gently with ~ 100 ml of concentrated hydrochloric acid, then dilute the solution to volume with water in a 1-litre standard flask containing ~ 300 ml of concentrated hydrochloric acid.

Potassium bromide, 20% solution.
Potassium chloride, 0.2% solution.
Tribenzylamine. A 0.5% solution in MIBK.
Hydrochloric acid–thiourea solution. A 1% solution of thiourea in concentrated hydrochloric acid.
Phenolphthalein. A 0.2% solution in ethanol.
Chloroform. Analytical reagent-grade.

Procedures

Calibration solutions. Prepare as described previously.[1] (Notes 1 and 2).

Ores and related materials. Decompose up to 1 g of powdered sample, containing up to ~ 100 μg of silver and not more than 10 mg of calcium and ~ 400 mg of lead, as described previously,[1] but add 15 ml of 50% sulphuric acid,

10 ml of concentrated hydrochloric acid and 5 ml of concentrated perchloric acid (Note 3) after the bromine–nitric acid treatment. After the removal of silica and antimony, if necessary, by volatilization as the fluoride and bromide, respectively, evaporate the solution to fumes of perchloric acid, then cover the beaker and continue to heat for ~ 15 min. Remove the cover, wash down the sides of the beaker with water and evaporate the solution to ~ 3 or 4 ml. Cool, add 10 ml each of water and 50% sulphuric acid, heat to dissolve the salts, then, if necessary, filter the solution (Whatman 11-cm No. 40 paper) into a 125-ml separatory funnel marked at 50 ml. Wash the beaker and the paper and residue with 25% ammonia solution as described previously[1] (Note 4), using 3- or 4-ml portions each time, then wash the paper with ~ 3 ml of 5% sulphuric acid. Discard the paper, dilute the solution to ~ 50 ml with water and mix thoroughly.

Add 5 ml each of methanol (Note 5) and 20% potassium bromide solution and 50 ml of 0.5% tribenzylamine solution to the resulting solution, stopper the funnel and shake it for 2 min. Allow several min for the layers to separate (Note 6), then drain off and discard the lower (aqueous) phase. Wash the MIBK phase by shaking it gently for ~ 20 sec with 5 ml of water. Discard the wash solution. Add 15 ml each of chloroform and concentrated hydrochloric acid containing 1% of thiourea, stopper tightly and, using a wrist-action shaker, shake for 5 min. Allow the layers to separate, then drain the lower (aqueous) layer into a 150-ml beaker and wash the stem of the funnel with water. Wash the MIBK-chloroform phase twice by shaking it for ~ 1 min and then for ~ 30 sec with 5-ml portions of hydrochloric acid–thiourea solution and add the washings to the beaker. Wash the stem of the funnel with water each time. Add 1 ml of 0.2% potassium chloride solution, cover the beaker, add 5 ml of concentrated nitric acid and heat the solution to destroy thiourea (Note 7). Evaporate the solution to ~ 20 ml, then add 5 ml of concentrated nitric acid and 3 ml of concentrated perchloric acid and evaporate the solution to fumes of perchloric acid. Continue to heat the solution for ~ 10 min to destroy organic material, then remove the cover and, without baking, evaporate the solution to dryness. Depending on the expected silver content, proceed with the additions of concentrated hydrochloric acid (Note 8) and 10%) diethylenetriamine solution and the subsequent determination of silver as described previously (Note 9).[1]

Zinc process solutions. Transfer up to 25 ml of solution, containing up to ~ 100 μg of silver, to a 125-ml separatory funnel marked at 50 ml (Note 10) and add 3 ml of 50% sulphuric acid (Note 11). Dilute the solution to the mark with water, add 5 ml each of methanol and 20% potassium bromide solution, then proceed with the extraction (Note 6) of silver as described above. Wash the MIBK phase twice with 5-ml portions of water, then strip and determine silver as described.

Notes

1. All glassware should be washed with $\sim 25\%$ ammonia solution, followed by water.

2. The solutions in the first series (*i.e.*, up to 1 μg of silver per ml) are stable for at least 2 weeks. Those in the second series should be prepared fresh every day because their absorbance slowly decreases on standing.[2]

3. The use of perchloric acid is recommended because recent work[2] with some zinc-processing products such as jarosites and iron-leach residues showed that a small amount of silver may remain in the residue after the sample is decomposed with nitric and sulphuric acids alone as described previously.[1] Hydrochloric acid is also recommended to help to decompose iron oxides in these materials.[2] The subsequent addition of hydrofluoric acid may not be necessary if the sample contains little or no silica. In this case, a pyrex beaker can be used for the decomposition.

4. To wash the residue effectively, any that adheres to the sides of the paper should be gently loosened with a glass rod. The total volume of ammonia solution used should not exceed ~ 25 ml.

5. Methanol helps to prevent emulsification.

6. If emulsification occurs or the layers do not separate quickly enough, add 5 ml more of methanol and shake the solution gently for ~ 5 sec.

7. Destruction of thiourea with nitric acid results in the formation of globules of liquid (probably carbon disulphide) which is volatilized during the subsequent evaporation of the solution. Because of the foul odour produced, an efficient fume-hood should be used for this step.

8. Usually the salts dissolve most readily if the solution is heated gently after the addition of concentrated hydrochloric acid and about an equal volume of water. Subsequently the solution should be cooled to room temperature before the addition of diethylenetriamine solution. Not too much water should be added, because silver may precipitate as the chloride if the hydrochloric acid concentration is less than $\sim 25\%$ v/v.

9. Sample solutions containing more than ~ 1 μg of silver per ml should be analysed the day they are prepared (Note 2).

10. If the solution is basic, add 1 drop of 0.2% phenolphthalein solution, neutralize with 50% sulphuric acid, then add 3 ml in excess and proceed as described.

11. In the case of ores and concentrates silver is extracted from ~ 1.5–$2M$ sulphuric acid. However, the addition of less 50% sulphuric acid is recommended for zinc process solutions because some solutions can contain up to ~ 150 g of sulphuric acid per litre.

RESULTS AND DISCUSSION

Separation of silver by tribenzylamine/MIBK extraction

In the TBA/chloroform extraction method described previously,[1] three extractions are required for the complete separation of up to ~ 500 μg of silver as the bromide–TBA ion-association complex from large amounts of iron, zinc and other elements. Because zinc process solutions do not usually contain a large amount of silver, a simpler and more rapid extraction procedure was sought in which up to ~ 100 μg of silver could be completely extracted as the TBA–silver bromide complex in a single extraction into a solvent of specific gravity < 1. Non-polar solvents such as toluene, heptane and xylene were found to be unsuitable as diluents for TBA because it forms a white addition compound with bromide which is relatively insoluble in these solvents.[3] Although this compound can be kept in solution by adding sufficient methanol before the extraction step, tests with heptane and toluene containing 0.5%. TBA showed that, at the 100-μg level, silver is not completely extracted in one extraction with an equal volume of these solvents under approximately the conditions of acidity and potassium bromide concentration used previously.[1] Xylene was not tested because of its noxious nature.

Because MIBK is a good diluent and extractant for metal halide–amine systems,[4] tests were done to determine whether MIBK containing TBA would be an effective extractant for silver from bromide media. These tests, in which silver was added in the form of a dilute sulphuric acid solution, showed that up to at

least 100 μg of silver can be quantitatively extracted in one extraction from ~0.1–4.5M sulphuric acid that is at least 0.04M in potassium bromide by shaking for 2 min with an equal volume of MIBK containing ~0.5% TBA. Higher concentrations of TBA than this (~0.017M) cannot be used because of the precipitation of the insoluble bromide addition compound during the extraction step. At higher concentrations of sulphuric acid, the extraction of silver is incomplete. Because concentrated hydrobromic acid, previously used for stripping silver from the chloroform extract,[1] is miscible with MIBK, concentrated ammonia solution was used in these tests and the excess was removed by boiling before the AAS determination of silver. However, an acidic stripping solution was sought because bismuth, which is co-extracted, forms an insoluble hydrous oxide in ammoniacal solutions. Concentrated hydrochloric acid containing thiourea as a complexing agent for silver was found to be effective if chloroform was added to the organic phase to increase its density and aid in phase separation. However, in subsequent tests with pure silver solutions and with synthetic zinc process solutions of high sodium content (composition given in Table 1), low and erratic results were obtained for silver when the final solutions were treated with nitric and perchloric acids to destroy thiourea and TBA and then evaporated to dryness. In these tests the extracts were washed twice with 5-ml portions of water to remove mechanically entrained sodium and/or potassium. Ultimately, it was found that evaporation of the solutions to dryness in the presence of perchloric (or sulphuric) acid results in the formation of a refractory silver compound, presumably an oxide, which does not dissolve completely when the residue is heated with 50% hydrochloric acid. This error can readily be eliminated by adding ~1 mg of potassium (as ~2 mg of the chloride) to the solution before it is evaporated to dryness. Although the hydrobromic acid strip solutions obtained previously[1] were treated in a similar manner, negative errors were not observed, probably because the chloroform extracts were not washed to remove entrained ions and/or because chloroform may retain more of the aqueous phase containing potassium and other ions than MIBK does.

Complete recovery of silver (100 μg) was obtained when the procedural steps described above were applied to synthetic zinc process solutions that were ~0.5–2M in sulphuric acid and ~0.08M in potassium bromide. However, low results were obtained for some industrial zinc process solutions, particularly thickener overflows of very high salt content, to which the same amount of silver was added. It was found that with these solutions more potassium bromide was required during the extraction step. Complete recovery of the added silver was obtained when the bromide concentration was increased to ~0.14M. Under these conditions, and when silver is extracted in the range of sulphuric acid concentration

mentioned above, very little zinc and iron are co-extracted.

Effect of diverse ions

As found previously,[1] bismuth and cadmium are partly co-extracted as bromide ion-association complexes into MIBK containing TBA, under the conditions used for the extraction of silver. At the 25- and 200-mg levels, respectively, these elements will not interfere with the extraction of silver, and the amounts co-extracted will not affect its determination by AAS even if a 10-ml final volume is used. Little or no molybdenum(VI) is co-extracted at the 200-mg level. However, at this level, a white insoluble compound forms when the solution is shaken with MIBK containing TBA. This compound, which is probably an addition compound of TBA and molybdic acid, can be readily dissolved by adding sufficient methanol to the solution.

Up to at least 2 g of zinc, 500 mg of copper(II) and iron(III), 400 mg of lead, 200 mg of magnesium and the same quantities of all the other ions mentioned previously,[1] including chloride, will not interfere in the determination of silver by the proposed method. Interference from antimony(V) is avoided as described previously. Co-extraction of any chromium(VI),[5] present in solutions derived from ores and concentrates and resulting from the evaporation of the solution to fumes of perchloric acid, can be avoided by reducing it to chromium(III) with hydrogen peroxide. Several drops of 30% w/v peroxide solution should be added to the solution obtained after dissolution of the salts in dilute sulphuric acid, and the solution should then be boiled vigorously or evaporated to fumes of sulphur trioxide to destroy the excess of hydrogen peroxide before the filtration and extraction steps. Because some of the industrial[1] zinc process solutions investigated contained a large amount of sodium, washing the MIBK extract several times with 5-ml portions of water is recommended to reduce the amount of mechanically entrained sodium in the final solution. This also reduces the amount of entrained iron and other ions. At the 50-μg silver level, the loss of silver to the wash solution under these conditions does not exceed ~0.2 μg. The magnitude of this loss depends on the amount of salts stripped into the wash solution. No loss of silver occurs if the extract does not contain entrained ions.

Tests with MP-1 (composition given in Table 3), in which low (~5–8 μg/g) and erratic results were obtained when 1-g subsamples were taken, indicated that calcium sulphate retains silver and that, unlike the case with lead sulphate, this occluded silver cannot be completely removed by washing the precipitate with 25% ammonia solution. This was verified with pure silver solutions containing calcium. This interference was not apparent in the earlier work,[1] probably because the sample solution was diluted much more before the filtration step than in the

Table 1. Recovery of silver from synthetic zinc process solutions

	100.4	$100._4$

*Triplicate determinations of silver (present in the $ZnSO_4$) in 25-ml aliquots of the solution (without added silver) gave 0.4_3, 0.4_1 and $0.4_3 \mu g$. The sulphuric acid concentration of the test solutions was adjusted to 2M before extraction.

prent method and, under these conditions, calcium sulphate is more soluble. Consequently, less would be present in the residue and less silver would be occluded. These findings show that calcium can be a source of error in the TBA/chloroform extraction method.[1] In the proposed method, up to 10 mg of calcium can be present in the sample without producing appreciable error in the result.

Applications

Tables 1 and 2 show that the results obtained by the proposed method for a series of synthetic zinc process solutions in which the added silver was varied from 2 to 100 μg, and for industrial solutions to which 5 and 100 μg were added, agree favourably with the calculated amount present. In these tests, silver was added as a solution in dilute sulphuric acid. Table 3 shows that the results obtained for seven diverse Canadian Certified Reference Materials Project (CCRMP) certified reference ores and concentrates are in excellent agreement with those obtained recently by a direct acid-decomposition/AAS method[2] and, except for MP-1 and MP-1a, with those obtained by the TBA/chloroform extraction method.[1] From the findings regarding the occlusion of silver by calcium sulphate, it is considered highly probable that this is the reason for the slightly low results

obtained for MP-1 and MP-1a by the TBA/chloroform extraction method. Except for PTM-1 and MP-1, the results are also in good agreement with the certified values. Those obtained for SU-1a and PTM-1 support recent conclusions[2] that the certified values for these ores are too low and that they should be ~ 4.6 and ~ 75 $\mu g/g$, respectively. Similarly, the results obtained for MP-1, in conjunction with those obtained previously[2] by a direct acid-decomposition method and those obtained by similar methods during the interlaboratory certification programme, suggest that the certified value for this ore should also be slightly higher, *viz.* ~ 59–62 $\mu g/g$. The results shown in Tables 1–3 are the means of five AAS measurements. All the results shown in Tables 2 and 3 are for individual subsamples.

The precision for silver at about the 4–100 $\mu g/g$ levels was determined by analysing five subsamples each of SU-1a, MP-1a and CZN-1. The results obtained (standard deviations of 0.14, 1.53 and 0.38 $\mu g/g$, respectively) showed that the proposed method yields slightly more precise results than the TBA/chloroform extraction method. It is also quicker and simpler because only one extraction is required and both the extraction and stripping steps are performed in the same separatory funnel. The

silver bromide–TBA complex is considerably more soluble in MIBK than in chloroform, and up to $500\,\mu g$ of silver can be extracted essentially quantitatively (99.5%) in one extraction.

Although the possibility of determining silver directly in the extract by AAS was mentioned in the earlier work,[1] this was not investigated at the time because it was considered that aqueous calibration solutions are easier to prepare and more convenient to use for routine work. In the present work, tests made with synthetic zinc process solutions (composition given in Table 1) to determine whether this approach would be more feasible for solutions of low silver content yielded poor precision and low results. Probably, this negative error was caused by the greater viscosity of the extracts[4] derived from the synthetic solutions, from which cadmium was co-extracted, compared with calibration extracts prepared by extracting known amounts of silver under the same conditions but in the absence of matrix elements.

The proposed method is suitable for silver in ores and related materials at levels as low as $\sim 0.1\,\mu g/g$ and in zinc process solutions down to the ~ 0.004-$\mu g/ml$ level. It is emphasized that reliable results can only be obtained if a small amount of potassium is added to the final solution before it is evaporated to dryness in the presence of perchloric acid. Care should also be taken that the subsample used does not contain more than 10 mg of calcium. If TBA is not available, tri-n-octylamine can probably be used instead under essentially the same conditions.[4]

Summary—The review discusses the problems of rational combination of solvent-extraction separation and preconcentration of trace elements with their determination by electrothermal atomic-absorption spectrometry.

Atomic-absorption spectrometry (AAS) is currently one of the most widely used techniques in analytical chemistry. The high selectivity and sensitivity of this technique in many cases enable direct analysis of samples. However, when the elements to be determined are present in very small amounts in materials of complex composition, preconcentration is necessary. Liquid–liquid extraction is a very versatile and convenient method of obtaining both separation and preconcentration.

The reason for the wide use of extraction in combination with flame AAS is the improvement in sensitivity arising partly from the increased element concentration but partly because nebulization of organic solvents can produce a more finely-dispersed aerosol.[1] With electrothermal atomization (ETA), however, the use of organic extracts instead of aqueous solutions does not, as a rule, enhance the atomic-absorption signal. Nevertheless, the tendency nowadays is an increasing use of hybrid methods based on combinations of element extraction and ETA, thanks mostly to the higher sensitivity of the determination method itself.

It has been suggested[2] that in the analysis of extracts ETA should have a number of advantages over flame atomization. Those authors believed that the absence of a nebulizer would permit viscous extracts to be analysed and that the complete removal of organic solvents from the electrothermal atomizer by drying would eliminate the non-specific light absorption during the atomization step, as well as the effect of solvent on the AA-signal amplitude. It has also been suggested that non-flammable chlorine-containing solvents can then be included in the range of extractants suitable for use in atomic-absorption analysis.[1]

Later investigations have shown, however, that the nature of the organic solvent has a strong effect on the AA-signal amplitude. Soaking of the extract into the graphite or its spread over the atomizer surface, the volatility of certain extracted compounds at elevated temperatures, and other factors may also hinder the combination of extraction with ETA–AAS. The literature data concerning the behaviour of organic extracts in ETA are largely contradictory. One of the reasons for this is the considerable sensitivity of the extracts (compared to aqueous solutions) to atomizer parameters (geometry and material),[3] shield-gas composition and the method used for recording the AA-signal.

It should be noted that some of the AAS techniques involving extraction of the determinand elements from the matrix have become obsolete, since they were originally adapted to the first ETA models which were not as perfect as the modern ones. Improved ETA characteristics also considerably improve the sensitivity of extract analysis.[4]

To date there has been only one review published which deals with certain aspects of the effect of the nature of the extracted complex on elemental analysis by ETA–AAS.[5] The effect of the nature of the organic solvent on the AA-signal amplitude in ETA has been studied in work devoted specifically to the analysis of petroleum products by ETA–AAS.[6]

In this paper we consider the most important aspects of the analysis of organic extracts by ETA–AAS.

EFFECT OF ORGANIC SOLVENT

Extract sampling and behaviour on the atomizer surface

Analysis by ETA is accompanied by a number of effects that are common to all organic extracts and are due to their good wetting ability with respect to graphite, plastics and metals.

The wetting of plastic micropipette tips with the extracts results in a sampling error of as much as 7% (compared to 1.5% with aqueous solutions).[7] The amount of extract remaining in the tip may depend largely on the reactant concentration and be as high as 30% of the total amount added.[8] Extract-sampling reproducibility may be improved if the micropipette tip is made to touch the atomizer surface. This can

be done by enlarging the sampling orifice,[9] using a bent tip[10] or a graphite platform. An alternative is to wash the tip with acetone or chloroform and add the washings as well.[11]

The reliability of extract analysis may be improved by automatic sampling. For instance, the Perkin–Elmer AS-1 autosampler ensures a sampling reproducibility of better than 1%.[12] The capillary of the autosampler can be treated with an organofluorine compound which will decrease wetting of the capillary by the organic extract and thereby improve the sampling reproducibility.[13]

When automatic sampling is used, the recommended practice is to use organic solvents that are denser than water; to prevent evaporation, the extracts may then be covered with a supernatant layer of water[14] or the aqueous phase.[12] For solvents less dense than water it is recommended to alternate the sample extracts in the autosampler with extracts containing reference amounts of the determinand elements, which allows corrections to be made for concentration variations due to solvent evaporation.[15]

The good wetting of graphite by organic solvents promotes its penetration by the extracts. Partial penetration, observed even in analysis of aqueous solutions[16,17] may give rise to signals of complicated shape. To prevent this undesirable effect, organic extracts[18] and petroleum products[17] can be added to the electrothermal atomizer heated to the "drying" temperature, and this will also prevent sample from spreading over the atomizer surface.[19]

In some cases, however, the spread of extracts over the atomizer surface may somewhat improve the sensitivity. It has been shown[20,21] that by starting the temperature control programme 2.5 min after addition of the extract to the ETA (HGA-2000) and using temperatures below the solvent (methyl isobutyl ketone; MIBK) boiling point for slow drying, a better spread of the extract may be achieved. In this way the signals of Ni, Co and Cd extracted as their pyrrolidine dithiocarbamates (PDTC) are enhanced by a factor of 1.2–2.

As a rule, however, the spreading of extracts on the atomizer surface hampers analysis, distorts the AA-signals, renders the analytical curve non-linear[22] and decreases the sensitivity.[23] Owing to the tendency of extracts to spread, their analysis is affected to a greater extent than that of aqueous solutions by the presence of a temperature gradient along the heated graphite tube (GT).[24,25]

It appears to have been sample-spreading that was responsible for the considerably poorer precision reported for analysis of extracts (than for analysis of aqueous solutions)[26–28] (in this work the first commercial ETA models, the HGA-70 and HGA-2000, were mostly used). It was found possible to improve the precision considerably by using a "grooved" GT allowing localization of the sample in the central part of the tube.[26] For example, the relative standard deviation for 0.1-μg/ml copper in MIBK extracts was

2% for the "grooved" GT (HGA-70) but 10% for the standard GT.[27] It has also been proposed to use a graphite boat or a tantalum cup for localizing the sample in the central part of the electrothermal atomizer[7,29] or to restrict the volume of solvent fed into the ETA.[30,31]

Normally, the use of a GT with a coating to prevent the penetration but not the spreading of the extract does not allow a high precision to be obtained. For example, covering a GT with tantalum foil to improve the sensitivity of barium determination[32] resulted in an increase of the relative standard deviation from 3% for aqueous solutions to 8% for MIBK extracts of barium thenoyltrifluoracetonate, and this was attributed primarily to the spreading of the extract over the atomizer (HGA-70) surface. Similar effects have been observed for a GT with a pyrolytic coating.[33] For example, the relative standard deviation in the determination of lead and cadmium extracted as diethyldithiocarbamates (DDTC) into carbon tetrachloride is 14%, compared to 3% when a porous graphite tube is used.[34]

Hence, the suggestion that the deterioration of the precision of extract analysis by ETA–AAS is due to soaking into the graphite[35] and that it may be prevented by using a pyrographite-coated GT (reference 1, p. 30), is not necessarily correct. That the pyro-coated GT can successfully be used for analysis of extracts has been attributed primarily to localization of the sample at the centre of the atomizer.[36]

Attempts have been made to establish a correlation between the precision of the analysis of extracts and the physical properties of the analysis solution (surface tension, viscosity, density).[37,38] For example, Young and Baldwin,[39] for the determination of cobalt by AAS after extraction of the PDTC complex, tried several solvents (benzene, chloroform, carbon tetrachloride, MIBK, ethyl acetate) and selected the last because it had the lowest surface tension. However, the advantages offered by solvents selected on the basis of the surface tension criterion have not been discussed in this work.

By use of modern ETA apparatus having a small geometrical size and furrows for sample localization, it has been possible to reduce considerably the adverse effect of sample spreading. Thus with the HGA-70 the relationships between the absorbance and extract volume fed into the atomizer are linear up to a sample volume of 10 μl,[31] and for the HGA-74 up to 50 μl.[40] The precision of extract analysis with modern ETA equipment is largely determined by sampling precision,[12] the chemical composition of the solvent and the extracted complex,[41] and may be as good as that of AAS analysis of aqueous solutions.[42]

Chemical and spectral interferences

Recently more and more evidence has been gathered that confirms the strong effect of the nature of the organic solvent on ETA analysis. With a few exceptions the mechanism of the effect is not yet

clear, so generalized recommendations for use of one or another solvent in ETA methods have been rare and contradictory. For instance, Dornemann and Kleist[43] hold MIBK to be an unsuitable solvent for ETA–AAS, whereas Fuller[24] recommends the use of xylene and MIBK as solvents for organometallic compounds, and Elson and Albuquerque[44] regard MIBK as having good compatibility with ETA.

Determination of elements in the presence of halogen-containing solvents may involve considerable difficulties. Even in one of the first works on extract analysis by ETA[2] it was reported that the use of chloroform and carbon tetrachloride was apparently responsible for the poor sensitivity of determination of a number of elements and made the charring step necessary. The adverse effect of halogen-containing solvents on the determination of Pb,[31] Cd,[4] Ge,[45] Co,[46] Fe,[47] Ga and In,[48–52] Cd, Fe, Ag, Ni and Co,[3] Be[53] and Sn[54] has also been shown experimentally.

The depressive influence of solvents such as chloroform, di(2-chloroethyl) ether (DCEE) or carbon tetrachloride may be quite considerable. This can be seen from determination characteristics of gallium and indium oxinates in MIBK and chloroform medium, and of their halide complexes in MIBK and DCEE.[52] The suppression and distortion of the AA-signals in the presence of halogen-containing solvents[47] are usually attributed to formation of thermally stable and volatile halides which are partially carried away from the electrothermal analyser, undissociated. The formation of halides is promoted by the existence of halogen compounds with graphite of the type $C_n^+X^-\cdot 3X_2$ that are stable at temperatures of up to 2000°.[55] It should be noted, however, that AA-signal suppression in the presence of carbon tetrachloride has also been observed when a tungsten atomizer was used.[45]

Volland et al.[3] assume that the depressive effect of halogen-containing solvents on AA-signals may be due to the formation of volatile organometallic compounds such as CF_3ZnI. Using radioactive isotopes, they have shown for Fe and Co that the presence of chloroform lowers the temperature at which these elements begin to be lost, the loss being proportional to the duration of the charring step.

In some cases the depressive effect of chlorine-containing solvents can be eliminated by introducing ascorbic acid into the ETA, especially when a furnace-platform atomizer is used.[52] Table 1 gives the signals obtained in the analysis of gallium and indium extracts in an HGA-74 atomizer in which graphite disks, 4 mm in diameter, 1.25 mm thick and having a 1-mm deep groove, were used as the platform. For chloroform extracts, the combination of a platform and ascorbic acid greatly enhances the signal (76-fold for indium acetylacetonate).[52] Attempts to eliminate the depressive influence of chloroform on the AA-signals of Cd and Fe by feeding mineral acids and hydrogen peroxide into the graphite-tube furnace[3] were unsuccessful.

Determination of tin in the presence of chlorine-containing solvents ($CHCl_3$, CCl_4) is accompanied by the appearance of a maximum on the signal vs. charring-temperature curve (the charring curve).[54] The sensitivity may be improved if the charring step is continued for a period of 40–60 sec, but in view of the maximum, control is necessary to maintain the charring temperature (T_{char}) at the optimum level. If a 5% aqueous ascorbic acid solution is added to the atomizer (HGA-76B) before the analysis a plateau is obtained on the charring curve; the charring step may be shortened to 10 sec and the sensitivity for tin improved.

In analysis of carbon tetrachloride extracts containing cobalt-DDTC the AA-signal is not only strongly suppressed but also shifted to a temperature 300° higher.[46] These authors believe that this shift can, in part, be attributed to modification of the properties of graphite by the chlorine that is formed on decomposition of carbon tetrachloride. For example, the penetrability of graphite increases, enhancing the diffusion of cobalt compounds into its bulk. These effects disappear when a tantalum boat, which precludes interaction between carbon tetrachloride and the graphite, is used. The degree of interference can also be reduced by adding water together with the chlorine-containing solvents, to the graphite atomizer.[46,47] On heating, the water reacts with the graphite to form hydrogen, which combines with the chlorine to give hydrogen chloride, which is carried away from the GT during the charring treatment. Hydrogen can

Table 1. Effect of ascorbic acid (asc) on the AA-signal for indium and gallium (0.1 and 0.08 μg/ml, respectively) in extracts and aqueous solutions; atomization from the GT wall (A_w) and disk (A_d)

Solution or extract	In			Ga

Oxinate in $CHCl_3$	0.008	0.021	0.310	0.006	0.071	0.228

also be formed in ETA through thermal decomposition of hydrocarbons.[46] To eliminate chlorine interference in determination of lead, Frech and Cedergren[56] added hydrogen to the shield gas.

However, in the case of certain elements, viz. copper,[38,57] gold and palladium[58] and selenium,[59] chlorine-containing solvents tend to increase the AA-signal. Absence of any depressive effect of chloroform and carbon tetrachloride on the signals of Fe, Cd, Cu, Ni, V, Pb has been recorded.[31,38]

Solvents of other types generally have less effect than the halogen-containing compounds on ETA-AAS determinations, but the effects do not, as a rule, lend themselves to any reasonable explanation.[3] It is not yet clear why for the chloride and bromide complexes of indium and gallium the sensitivity follows the order MIBK > butyl acetate (BAC) $\geq$ amyl acetate (AAC), whereas for indium iodide it is BAC = AAC > MIBK.[49,50] It has been found[53] that the signals obtained for beryllium in organic solvents decrease in the order aromatic hydrocarbons > esters = alcohols $\geq$ MIBK > chlorine-containing hydrocarbons; the order is practically the same for the N-cinnamoyl-N-phenylhydroxylamine and acetylacetone complexes.

We have found[54] that in analysis of extracts containing tin oxinate in chloroform, tin losses occur at $T_{char} > 500°$, and for extracts in o-xylene at $T_{char} > 800°$. Also, the dependence of the AA-signal on the ETA heating rate during charring is considerably decreased when o-xylene is used. Kamada et al.[59] believe that selenium diethyldithiocarbamate can be sublimed along with MIBK during charring. To improve the sensitivity for selenium they proposed use of carbon tetrachloride as the organic solvent.

In recent years, more and more attention has been given to investigation of non-specific light-absorption caused at the atomization stage by residues of an organic solvent.[49,50,58,60] Until recently it was common to believe that no such problem existed at all, since the organic solvents used for extraction usually have relatively low boiling points and hence should be completely removed from the electrothermal atomizer during drying of the extract. Nevertheless, investigations of the relationship between non-specific light-absorption and wavelength in the region of 200–350 nm for a number of organic solvents have shown[61] that even after charring (at 800° for 30 sec) the non-specific absorption occurring during the atomization step may not be always compensated by the deuterium background-corrector. The non-specific absorption was particularly intense in the presence of cyclohexane. However, cyclohexane does not cause non-specific light absorption at wavelengths shorter than 200 nm in ETA.[62]

The extent of non-specific absorption in the presence of organic solvent residues may also depend on the material the atomizer is made from. We have found that with a GT coated with a layer of pyrolytic graphite, a non-specific absorption is observed in the presence of o-xylene at the tin resonance-line wavelength (224.6 nm), which could not be compensated for by the deuterium background corrector ($T_{char} = 800°$, for 40 sec). On the other hand, no difficulties of this kind arise in analysis of o-xylene tin extracts when a porous graphite tube is used.

EFFECT OF THE NATURE OF THE EXTRACTED COMPLEX

Volatility and thermal stability of compounds in ETA

It is well known that many chelates, halides and some other metal compounds can be sublimed undecomposed (e.g., Sokolov[63]). Aggett and West,[2] who were apparently the first to observe the effect of organic reagents on sensitivity, assumed that it was due to the incomplete atomization of chelates which underwent sublimation. They hypothesized that interferences of this kind would result in particular difficulties in analysis of extracts by use of ETA systems. This opinion is currently advocated by Sturgeon et al.[64] Pelosi and Attolini[48] preferred cupferron as an extracting reagent for gallium because its chelates are non-volatile.

There have been only a few cases, however, where this effect has been experimentally observed. Keil[65] believes that the partial sublimation of chelates during the charring step is responsible for the low sensitivity and poor precision of thallium determination in MIBK extracts of its DDTC complex. Kamada et al.[59] who observed that the sensitivity for selenium was higher for the diethyldithiocarbamate than the pyrrolidine dithiocarbamate (solvent MIBK), assumed that the latter complex has a higher volatility. According to our results,[54] certain tin chelates (the diethyldithiocarbamate and oxinate) can undergo sublimation when their extracts are analysed with the HGA-76B. This both lowers the sensitivity and tends to decrease the maximum T_{char} from the 800° permissible for aqueous solutions and extracts containing chloride complexes and non-volatile tin chelates (cupferronate, N-benzoyl-N-phenylhydroxylaminate) to 500° for the oxinate and 700° for the diethyldithiocarbamate (solvent chloroform).

It is really difficult to analyse extracts in which the elements to be determined are present as iodide complexes. For example, Clark and Viets[66] found that of 18 elements (including In, Sn, Pb, As, Sb, Bi, Se) extracted as iodide-complexes by means of amine solutions in MIBK, only Pt and Pd could be determined by direct ETA analysis. In view of the high volatility of metal iodides, it has been recommended to use stripping when working with this kind of extraction system.[66,67] Aruscavage,[9] however, was able to analyse directly a toluene solution of the As, Se and Sb iodide complexes by using nickel nitrate as a matrix modifier for the determination of As and Se. The iodide system (with amyl or butyl acetate as extractant) has been recommended[50] for the extrac-

tion and AAS determination (HGA-74) of indium, since the sensitivity is higher and the extraction is quantitative over a broader acid concentration range for the iodide complexes than for the chloride and bromide systems. There are reports of the possibility of direct determination of Sn,[68] Pb,[69] Bi,[70,71] and Se[72] in iodide extracts.

Data about the volatility of compounds of other classes have been published. It has been shown[73] that the drying temperature should not be higher than 40° for isoamyl alcohol extracts of the platinum–tin(II) chloride complex. Startseva et al.[74] believed that it was high volatility which prevented direct determination of molybdenum in phosphomolybdic acid (MPA) extracted into a 1:3 mixture of n-butanol and carbon tetrachloride; they were compelled to strip the molybdenum. On the other hand, Tyson and Stewart[75] could directly analyse an MPA extract by use of the A3700 atomizer (graphite rod); perhaps the analysis was facilitated because they used a different solvent (isobutyl acetate).

To improve the sensitivity of tin determination by means of its volatile chelates we used slow heating during the charring step, to cause thermal decomposition of the complexes.[54] For example, when we changed the heating rate from 600°/sec to 8°/sec (heating-rate selector of the HGA-76B changed from zero to the 2×30 setting), the magnitude of the AA-signal of tin (oxinate in chloroform) increased 2.8 times ($T_{char} = 900°$). Considerable improvement in sensitivity was also achieved by adding ascorbic acid. In the analysis of aqueous solutions of tin or of MIBK extracts containing its chloride complexes or non-volatile chelates the addition of aqueous ascorbic acid to the GT enhanced the signal by as little as 20–30%, whereas in the case of volatile chelates (oxinate, diethyldithiocarbamate) the signal was enhanced 2.0–2.8 times.[54] The sensitivity for tin may be further improved by using a tungsten carbide-coated GT and a graphite platform.

Cases have been reported in which chelate volatility did not have any significant effect on extract analysis with ETA. It has been shown[76] that the sensitivities and charring curve shapes obtained for analysis (with the HGA-74) of extracts containing different cobalt chelates do not differ much. On the other hand, a correlation has been observed between the cobalt chelate volatility and the magnitude of the AA-signal when a tantalum boat is used for flame atomization. According to Borggaard et al.,[13] cobalt diethyldithiocarbamate (solvent xylene) is not sublimed during the charring step, over a temperature range of 175–1100°, although according to thermal data this chelate should sublime at 267°.

By extraction of its dithizonate into chloroform Halász et al.[77] were able to make mercury much less volatile than it is in the form of inorganic compounds. Extraction in this case not only separated the determinand from the matrix but also prevented its loss during the drying step.

Also important in ETA–AAS are the thermal stability and volatility of the molecules formed in thermal destruction of the compounds containing the analyte elements. The lower permissible T_{char} and sensitivity for lead and cadmium determination when extracts of the PDTC complexes were used instead of aqueous solutions was attributed[31] to the formation of the volatile sulphides CdS and PbS by thermal decomposition of the chelates in the inert atmosphere used (argon). If an oxidizing atmosphere is used during the charring step, the less volatile oxides and oxysulphides are formed, and the lead signals for extracts and aqueous solutions are similar. The low sensitivity of tin determination in DDTC extracts and in the presence of a number of sulphur-containing substances (sulphuric acid, cysteine) is also attributed to the formation of the thermally stable and volatile monosulphide.[78]

Halide ions tend to interfere with the determination of gallium and indium in aqueous solutions and extracts containing halide complexes of these elements.[49,50] With a view to finding the reasons for such effects, the absorption spectra of the GaO, GaX, InO, InX (X = Cl, Br) molecules formed in the graphite atomizer during the charring and atomization of halide aqueous solutions and MIBK based extracts, were recorded.[51] It has been shown that the higher the halide ion concentration in the analysis solution the greater is the ratio MeX/MeO (Me = In, Ga). Since the dissociation energy of MeO is lower than that of MeX, the formation of the monohalides is liable to decrease the sensitivity. The reduction of the gallium signal in the order oxinate > dichloro-oxinate > dibromo-oxinate (extraction with $0.02M$ reagent solutions in o-xylene) is also apparently due to the formation of the monohalides. The signal for the dichloro-oxinate is also lower than that for the oxinate (solvent toluene) for beryllium.[53]

Dependence of the atomization mechanism on the nature of the donor atom

The composition of the extractable complex may have a strong effect on the atomization mechanism. Hulanicki et al.[7] have investigated the mechanisms of atomization of copper and nickel, using a broad range of reagents. For chelates containing the same donor atoms the log A vs. $1/T$ relationships have practically the same slopes. On these grounds the following atomization mechanisms were proposed for complexes with nitrogen, oxygen and sulphur as donor atoms:

$$\begin{array}{l} N \\ \diagdown \\ \diagup Me \rightarrow Me(solid) \rightarrow Me(gas) \\ N \end{array}$$

$$\begin{array}{l} O \\ \diagdown \\ \diagup Me \rightarrow Me(solid) \xrightarrow{\text{reduction}} Me(gas) \\ O \end{array}$$

$$\begin{array}{l} S \\ \diagdown \\ \diagup Me \rightarrow MeS(solid) \rightarrow MeS(gas) \rightarrow Me(gas) \\ S \end{array}$$
The AA-signal magnitude has also been compared with the bond type in the complex by Komárek et al.[76]

The number as well as the nature of the atoms that directly react with the metal in the chelate is important. Atomization of cobalt from an hydrochloric acid solution and from a solution of cobalt–DDTC in MIBK follows, apparently, the same mechanism.[46] However, if an aqueous solution of cobalt is analysed with a graphite tube which has been impregnated with carbon disulphide, the atomization activation energy is increased by an amount about equal to the heat of formation of cobalt sulphide. The effect of the sulphur-containing reagent concentration on arsenic determination in a molybdenum microtube has been reported.[79] Signals of different shape were obtained for two chelates containing As–S bonds (diethyldithiocarbamate and thionalide complexes). The authors attributed this to the different solubilities of the reagents in organic solvents: the readily soluble thionalide creates an excess of sulphur in the ETA, and this tends to change the atomization mechanism.

When lead was determined in aqueous solutions and organic extracts (with ETA as a molybdenum microtube) it was found that for naphthenate, oxinate and diethyldithiocarbamate the AA-signal was maximal at a lower atomization temperature than for inorganic compounds of lead.[80] In this case the sensitivity for the oxinate and DDTC was better than for chloride or nitrate solutions of lead. The authors assumed that decomposition of these chelates produced free metal rather than its oxide.

Ishizaki and Ueno[81] advanced a hypothesis that the size of the chelate had a strong effect on ETA analysis of extracts. The larger the molecular volume of the organic reagent used, the less the chelate will soak into the graphite, and therefore the higher the AAS sensitivity. However, in later work[53,82] this hypothesis was not verified experimentally.

Non-specific light absorption

Incomplete removal of organic materials during the charring step may cause considerable difficulties in the ETA analysis of extracts. Charring conditions have been found for extracts of different nature, under which there is no non-specific light-absorption at the analytical lines of gallium (287.4 nm) and indium (303.9 nm) during the atomization step,[49,50] but when such poorly volatile extractants as tributyl phosphate (TBP) and trioctylamine were used, an extra (initial) charring cycle (500° for 45–90 sec) was necessary to remove the bulk of the extractant. Nevertheless, the temperatures for the second charring cycle had to be 1400° and 1050°, respectively. There is evidence that whatever its original form in the solution (TBP included) phosphorus cannot be carried away from the ETA at a temperature <800°.[83] Fishkova et al.[62] were unable to detect selenium after its extraction as 4,5-benzopiazselenol into TBP, even though the deuterium corrector was

used. Probably, the reason was that even at relatively high atomization temperatures much of the phosphorus is transferred into the gas phase in the form of species (P_2, PO, PO_2, etc.)[84] which result in a structured background. The sensitivity of ETA–AAS determination of elements in TBP-based extracts is usually significantly poorer than that in aqueous solution.[49,50,85] Therefore, the use of organophosphorus compounds for the extraction of elements of high and medium volatility that are to be determined by the ETAA technique is attended by apparent hindrances.

A structured background which hampers analysis also appears in the determination of arsenic in dialkyltin dinitrate extracts.[86] Matrix modification with nickel nitrate allows T_{char} to be increased to 800°; at this temperature all the organic components of the extracts are totally decomposed, but significant amounts of tin remain in the graphite tube, and also hamper the AA analysis. The non-specific absorption at the analytical line of arsenic (193.7 nm) may be reduced to a level that can be compensated for by the deuterium background-corrector only by using a graphite platform and modification of the sample with nickel nitrate.

Saturated solutions of ammonium pyrrolidine dithiocarbamate and hexamethyleneammonium hexamethylenedithiocarbamate in MIBK cause an insignificant background absorption in ETA–AAS over the wavelength range 200–300 nm.[61] However, during storage of PDTC solutions, products are formed that give rise to non-specific light-absorption that cannot be fully counterbalanced by the deuterium corrector. Therefore, only fresh PDTC solutions should be used for extraction/atomic-absorption analysis. Non-specific absorption by organic reactants may also increase with aging of the graphite tube.[58]

COMPARISON OF SENSITIVITIES FOR AQUEOUS SOLUTIONS AND ORGANIC EXTRACTS

Fuller[24] (p. 48) states that during extract analysis by ETA most complexes decompose into stable inorganic compounds in the charring step, which ensures about the same sensitivity as in analysis of aqueous solutions. He determined Fe, Ni, Co and Cu in extracts containing the DDTC complexes of these elements or their complexes with 4,7-diphenyl-1,10-phenanthroline (solvent MIBK), using aqueous standard solutions (HGA-70, grooved graphite tube).[87,88] Calibration with aqueous solution standards, which possess some advantages over extracts (longer shelf-life, ease of preparation), has also been used in others.[2,10,11,89,90]

Several papers have reported that ETA–AAS sensitivity is better for extracts than for aqueous solutions.[41,80,91–96] Most of these investigations used a metal tube (molybdenum or tungsten) for the ETA;

perhaps in these cases the better sensitivity was due to the construction of the atomizer structure, and was not in fact higher for all the extracts investigated.

Bratzel et al.[91] obtained interesting results when they determined gold and silver in geological and metallurgical samples (with a CRA-61). The analyte elements were first extracted into MIBK as their chloride and thiophosphoric acid tri-iso-octyl ester complexes respectively. It was found that the characteristic gold concentration (i.e., the concentration giving 1% absorption) is three times as large for aqueous solutions as for extracts; for silver the characteristic concentrations were the same. Exposure of the atomizer to a diffusion hydrogen flame did not affect the sensitivity for silver in aqueous solutions, whereas in the case of extracts the characteristic concentration decreased by as much as three orders of magnitude. The authors assumed that under these conditions direct atomization of silver occurred as its complex burned.

Very often the literature contains contradictory data about sensitivity of analysis of extracts by ETA–AAS. For determination of tin in aqueous, water–ethanol and heptane solutions with an HGA-2100, Trachman et al.[97] obtained almost the same sensitivity with all the solutions investigated, whereas Varnes and Gaylor[98] found AA-signals for aqueous and water–alcohol solutions were about the same, but half the size for 3% acetic acid media and only a sixth as large for heptane solutions.

All in all, the problem of the relative sensitivities for analysis of aqueous solutions and organic extracts by ETA has not yet been thoroughly studied. Comparison of our results with others allows us to conclude that in most cases the sensitivity is somewhat poorer for organic extracts than for aqueous solutions, and that this is due to various combinations of the causes we have already discussed, viz. spreading of the extract on the ETA surface, volatility of the extracted compound, effects of the nature of solvent and organic reagent, etc.

SOME OTHER FEATURES OF EXTRACT ANALYSIS

In a number of cases it is very difficult to differentiate between the effects of organic solvent, of the form of the element in the extract, of the atomizer material and geometry, and other factors, on the ETA analysis of extracts. We will now consider the combined effects of these factors.

The products of incomplete combustion of the organic matrix may strongly affect the ETA analysis. Margulis et al.[99] attempted to determine platinum and palladium in the third phase formed in the hexadiantipyrylmethane–chloroform (benzene) system with the hope of increasing the preconcentration factor by 1–2 orders of magnitude. They diluted the viscous third phase with ethanol and applied it to the GT. However, after evaporation of the solvent an organic residue remained in the GT which was hard to decompose and therefore hampered the AA analysis. For more complete destruction of the organic matrix during determination of ruthenium in extracts, Dornemann and Kleist[100] blew air through the HGA-500 used, during the charring step.

The same authors assume that in ETA, MIBK shows a tendency towards polymerization and coking, which affects the atomization reproducibility, especially in the case of highly volatile elements;[43] they propose use of a 7:3 v/v di-isopropyl ketone/xylene mixture (instead of MIBK), which is completely evaporated when the electrothermal atomizer is heated. The lower sensitivity for vanadium when extracts of certain of its chelate and thiocyanate complexes are subjected to charring in a tungsten atomizer has been attributed to the formation of vanadium carbide through reaction of the element with the organic matrix residue.[95]

There is evidence concerning a positive effect of the carbon that is formed on decomposition of the extract in the atomization process. Thus it has been suggested[76] that in analysis of cobalt extracts CoO is more effectively reduced to the metal in this way, and for this reason the sensitivity is higher for determination of cobalt in extracts than in an aqueous solution of cobalt acetate.

Data concerning the effect of organic extracts on the lifetime of the graphite tube are scarce and contradictory.[61,101,102]

ADDITIONAL TREATMENT OF EXTRACTS

When the extraction system used is insufficiently selective, the co-extracted components may give rise to considerable non-specific light-absorption[103] or suppress the analytical signal;[37] for equal interferent concentrations these effects may be larger for extracts than for aqueous solutions.[104] Also, the preconcentration achieved by extraction may fall short of meeting detection limit requirements.[105,106] Therefore, various treatments are resorted to in extraction/atomic-absorption analysis, apart from optimization of the AAS conditions, use of more powerful and selective extraction systems,[107] or the analyte-addition technique.[26]

Modification of matrix

This approach has become rather commonly used owing to the small labour requirement and the possibility of using the same modifiers as those used in analysis of aqueous solutions. The use of transition metal compounds for increasing T_{char} and improving the sensitivity of determination of selenium, arsenic and antimony[9,72,86,108-111] is a typical example. For example, the analysis element (selenium) and the modifying element (copper) are extracted simultaneously as the DDTC and PDTC complexes.[112,113]

After extraction of the platinum group elements (Me) with a solution of 1,1-hexamethylene-3-phenyl-thiourea (HMPTU) in chloroform, the presence of a copper/HMPTU complex (Me:Cu = 1:200) in the extract eliminates the considerable mutual effects of the platinum metals themselves.[114]

To concentrate bismuth for determination in water and urine samples, it can be extracted as the iodide complex into MIBK.[71] By using palladium chloride solution as a modifier it is possible to raise the charring temperature to 1000° and substantially improve the sensitivity of bismuth determination in the extract. It was mentioned that there should be physical contact between the analyte and the solution of the modifier element (100 μl of aqueous palladium chloride were added to 20 μl of the extract).

Selenium losses during charring following the extraction of its compound with 1,2-diamino-4-nitro-benzene into chloroform were prevented by using a GT coated with zirconium carbide.[96]

Apart from transition element compounds, organic and inorganic acids, chelating agents, etc. may be used as matrix modifiers. We have discussed above the effect of ascorbic acid on aqueous solutions and extracts containing In, Ga and Sn.[52,54] When analysing extracts and aqueous solutions of Pb, Bi, As, Sb with a metallic electrothermal analyser, Ohta and Suzuki[70,79,94,115] were able to eliminate the interference from the matrix and improve the determination sensitivity, by adding a solution of thiourea.

A sulphuric acid solution was added to the electro-thermal atomizer to prevent thallium losses during the charring step, in its determination in aqueous solutions and in toluene extracts containing the ion-association complex of $TlCl_4^-$ and Brilliant Green.[90] Keil[65] could determine thallium in extracts containing its DDTC complex in MIBK only after addition of 0.5 ml of 2M nitric acid and 3.5 ml of ethanol to 1 ml of extract. Extract modification has also been used by others.[72,113,116]

Back-extraction

Such multi-purpose measures as back-extraction of determinand[74,117] and washing extracts free from interferents[9,75,99] are often used to improve the quality of the extraction/atomic-absorption determination of elements in ETA–AAS. Back-extraction allows the use of extraction systems that contain the analyte element as a volatile compound,[118] use of aqueous standards for calibration, further preconcentration of the element to be determined,[28,119] and can considerably increase the shelf-life of test solutions.[64] Fitchett et al.[120] succeeded in separating organic and inorganic arsenic compounds at the back-extraction stage. Various modifiers are used in analysis of back-extracts, to improve the determination sensitivity and eliminate interferences.[121–124] The drawbacks of methods relying on back-extraction of the analyte elements include more complicated procedures and higher blank corrections.

Increase in preconcentration factor

To obtain a higher concentration of the determinand, such techniques as extract evaporation,[106,107,125–127] back-extract evaporation,[128] and a series of successive "extraction–stripping" cycles[53,129] are used; the preconcentration factor may then be as high as 10^4.[106]

Combined separation methods

Combination of solvent extraction with other separation and concentration methods or combination of two different extraction systems has been used for increasing the selectivity of separation of the elements to be determined. For example, the main interferents (Fe, Cu, etc.) have been removed by extraction as cupferronates and the elements to be determined subsequently extracted (nickel as its hexa-methylenedithiocarbamate with a mixture of di-isopropyl ketone and xylene,[130] tellurium as its chloride complex,[28] and manganese as its cupferronate into MIBK[131]).

For its determination in biological samples, selenium has been separated from the matrix with Amberlite IR-120 cation-exchanger and subsequently extraction as selenium dithizonate into carbon tetrachloride, permitted the element to be concentrated.[110] Extraction of the platinum elements with a solution of n-octylaniline in chloroform has been used for additional concentration after a fire assay with nickel sulphide as the collector.[25]

Co-precipitation with bismuth and ferric hydroxides was used for separation of chromium in different oxidation states;[132] before determination of the chromium by ETA the macroelements were separated by extraction of their chloride complexes with a 5% solution of tri-iso-octylamine in p-xylene. Combined separation methods based on precipitation (co-precipitation) and solvent extraction have also been described.[21,133]

CONCLUSION

The combination of liquid–liquid extraction and ETA–AAS is a rather effective and versatile hybrid technique for trace analysis. The difficulties arising in its practical applications are due primarily not to any limitations of the principle of the method but to its being insufficiently developed. The choice of the extraction system with regard to its particular behaviour under the conditions used in ETA, and application of such techniques as modification, atomization from a graphite platform, and variation of the ETA heating rate at all analysis stages, permit the determinations to be carried out with good sensitivity, accuracy and precision.

DETERMINATION OF URANIUM IN WET PHOSPHORIC ACID

Helena Górecka and Henryk Górecki

Institute of Inorganic Technology and Mineral Fertilizers, Technical University of Wrocław, Poland

Summary—A method for quantitative determination of uranium in wet phosphoric acid containing 0.001–0.02% of uranium has been developed. After reduction with Fe or $FeSO_4 \cdot H_2O$, uranium(IV) is extracted with a kerosene solution of an equimolar mixture of mono- and dinonylphenylphosphoric acids. The uranium is stripped with an oxidizing medium consisting of $10M$ H_3PO_4 containing $NaClO_3$. The uranium stripped is determined spectrophotometrically with Arsenazo III.

Phosphate minerals contain 0.001–0.020% of uranium. In the decomposition of these minerals with sulphuric acid (widely used in most of the wet production methods) about 80% of the uranium contained in the minerals is dissolved. The rest remains in the phosphogypsum wastes. Many methods for uranium recovery in the wet phosphoric acid industry have already been developed and applied on the commercial scale, mainly in the USA, Canada, France and Japan.[1-4]

The need for process control as well as determination of material balance requires a sensitive and accurate analysis for uranium in phosphoric acid.

Determination of uranium in the presence of different mineral impurities is a difficult analytical problem, especially as the uranium content being determined is much smaller than the content of impurities coming from the different minerals present and from the solutions used for their decomposition. Many analytical methods for uranium, making use of various laboratory and instrumental techniques, have already been published, but so far, none of them is universal enough to be directly applied to determination of uranium in wet phosphoric acid, phosphogypsum and phosphate rocks. Most of them refer to determination of uranium in specific materials, *e.g.*, sulphuric acid,[5] aluminium nitrate solutions,[6] protective materials used in nuclear power-plants,[7] Portland cement,[8] sea-bottoms,[9] rocks and minerals,[10-15] uranium ores,[16] soils,[17] sea-water[9,18] and natural water.[19]

Methods for determination of uranium in phosphate rocks[20] and aqueous solutions obtained by their decomposition with mineral acids[21] are also known. The methods are often based on solvent extraction[22] with reagents such as tributyl phosphate[23,24] or trialkylamines.[25]

Many methods for uranium determination can be used in the presence of thorium,[6,9,11] iron, copper, thorium, molybdenum, vanadium and chromium,[26] or thorium and zirconium.[13,27]

The highest sensitivity is provided by the methods developed by Korkisch,[12,14] based on use of Arsenazo III, but they have the disadvantage that most heavy metals, fluorine compounds and phosphate (the main component of wet phosphoric acid) cause errors. Although procedures for diminishing these effects have been suggested,[28] their direct application still yields unsatisfactory results.

Thus the fundamental problem is to separate uranium from wet phosphoric acid with an extraction system characterized by a high distribution coefficient and good phase separation, together with an effective method of stripping with a medium in which uranium can be determined by a sensitive colorimetric method. Kerosene solutions of mono- and dinonylphenylphosphoric acids (NPPA)[29] seem suitable for this purpose.

EXPERIMENTAL

Preparation of the liquid ion-exchanger NPPA

The phosphorylation was performed in a four-necked 2-litre flask equipped with a stirrer, thermometer and bubbler for the nitrogen supply. The contents of the flask were heated with a 375-W infrared lamp. Three moles of nonylphenol (375 g) were placed in the flask and constantly stirred while 1.1 mole of phosphorus pentoxide (156.9 g) was introduced in small portions at such a rate that the temperature in the flask did not exceed 70°. The mixture was then heated for 5 hr at 95–105° under a nitrogen atmosphere. After cooling, the product was a dark, brown-orange liquid, and was diluted with extraction grade kerosene (Polish standard 68/C–96040). The solution of NPPA is resistant to orthophosphoric acid and acidic hydrolysis at temperatures up to 90°, and characterized by low solubility in water (which minimizes loss during the extraction). This liquid ion-exchanger effectively extracts U(IV) from strongly acidic solution and does not form kerosene-insoluble salts or complexes.

Uranium extraction

Add 2 g of $FeSO_4 \cdot H_2O$ to 50 ml of "wet" phosphoric acid containing 20–30% of P_2O_5 (3.3–5.3M H_3PO_4). Shake this solution with 10 ml of 0.16M NPPA solution in kerosene at 25–35° for 1 hr. After phase separation strip the kerosene phase by shaking it with three 25-ml portions of 10M

phosphoric acid containing 0.2% of sodium chlorate, at 55°, for 30 min in each extraction. Combine the extracts and analyse them for uranium as below.

Spectrophotometric determination of uranium

The Korkisch method[12,14] is used, modified to allow for presence of phosphoric acid in the samples.

Dilute 5 ml of the combined stripping solutions to volume with distilled water in a 100-ml standard flask. Transfer 2.5 ml of this solution (containing 2–20 μg of uranium) into a 50-ml conical flask and add 7.5 ml of concentrated hydrochloric acid (bringing the solution to $9M$ HCl concentration). Add 0.3 g of oxalic acid to eliminate the effect of iron and then 1.1 g of zinc powder to reduce uranium(VI) to uranium(IV). After adding the zinc, carefully plug the conical flask and mix the contents until the zinc has completely dissolved. Then add 1 ml of 0.1% aqueous solution of Arsenazo III. Measure the absorbance at 665 nm after 15 min. Optimum results are obtained for 2–10 μg of uranium.

RESULTS AND DISCUSSION

The extraction of uranium was performed in a thermostatic shaker unit (UNIPAN type 357) at temperature T_e, with phase-volume ratio (aqueous to organic) f_e, for a time t_e. The uranium was extracted from phosphoric acid, concentration $C_{P_2O_5}$, to which $FeSO_4 \cdot H_2O$ had been added. The back-extraction was done in n steps (each with shaking for 30 min) at 55°, with phase-volume ratio (aqueous to organic) f_r, $10M$ phosphoric acid containing 0.2% sodium chlorate being used as the stripping agent.

All experiments were done three times and the points shown in the figures are the arithmetic means. The results presented are equilibria data, and indepen-
Fig. 2. The effect of phosphoric acid concentration on the distribution coefficient K_U and uranium recovery η_U (%) when using $0.16M$ solution of NPPA.

dent of the duration of the equilibrium. Experiment showed extraction equilibrium was reached in 10 min.

Figure 1 presents the effect of the NPPA concentration in the organic phase on the distribution coefficient K_U, the degree of extraction η_e (%) and the degree of uranium recovery η_u (%) in the extraction and stripping processes. In this case a single 30-min back-extraction was used, with $f_r = 5.0$. It is seen that the NPPA concentration should be kept in the range 0.1–0.2M. Higher concentrations of NPPA make it difficult to strip the uranium from the organic phase, but do not appreciably increase the initial extraction efficiency.

The effect of phosphoric acid concentration on the uranium recovery η_u, and on K_U, is shown in Fig. 2. The extraction was done in a single step at 40° with $f_e = 5.0$ and 0.2% Fe(II) in the aqueous phase. Stripping was also done in a single step (30 min shaking) with $f_r = 5.0$. It is seen that the stripping is most effective when the concentration of phosphoric acid in the aqueous phase is at least $7M$.

It should be noted, however, that the values of η_U and K_U also depend markedly on the Fe(II) concentration and the temperature, though these factors do not significantly affect the shape of the graph of dependence on acidity.

Figure 3 shows the effect of Fe(II) concentration on the extraction (η_e) and stripping (η_r) by triple back-extraction with $f_r = 2.5$. It shows that in the presence of 0.15% Fe(II) in the phosphoric acid solution, over 80% uranium extraction is possible. Higher concentrations of Fe(II) give a higher degree of extraction but would require higher concentrations of sodium chlorate in the aqueous phase for the back-extraction. From the dependence of K_U on temperature (Fig. 4) it is evident that the extraction is best done in the temperature range 25–30°. For the stripping, the presence of not less than 0.2% of

Fig. 1. The effect of NPPA concentration on the distribution coefficient K_U, uranium extraction η_e (%) and uranium recovery η_u (%) from a solution of phosphoric acid containing 28% P_2O_5 (4.9M H_3PO_4) and 0.026% U(IV). $T_e = 21°$, $n_e = 1$ and $f_e = 5.0$.
Fig. 3. The dependence of extraction yield η_e (%) and degree of back-extraction η_r (%) on concentration of Fe(II) introduced as ferrous sulphate. Uranium extracted from phosphoric acid solution containing 28% P_2O_5 (4.9M H_3PO_4) and 0.012% U. $T = 20°, f = 5.0, \tau = 1$ hr and $n = 1$.

Fig. 4. The dependence of the distribution coefficient K_U on temperature for NPPA concentrations of 0.04, 0.08 and 0.13M. $C_{P_2O_5} = 28\%, f = 5.0, \tau = 1$ hr and Fe(II) = 0.3%.

sodium chloride in the acid used is indispensable, but higher concentrations do not increase the stripping yield. The stripping was found to work best within the temperature range 45–60°.

In the analysis of acids containing a higher amount of organic compounds (*e.g.*, black acid from Florida or Morocco) 1–2% of activated charcoal should be added and the analysis performed after the charcoal has been filtered off on paper. Tests have shown that 90–95% of the impurities contained in wet phosphoric acid are not stripped along with the uranium.

To determine the tolerance limits for potentially interfering species, various amounts were added to a stripping solution containing 4 μg of uranium per ml, and the uranium was determined. The results listed in Table 1 indicate that only iron(II) has a serious effect.

From these results it follows that the direct determination of uranium in wet phosphoric acid

and phosphogypsum with an error below 5% is impossible.

A major problem in the analysis is the effect of phosphoric acid on the absorbance of the Arsenazo III–uranium(IV) complex since the w/w ratio of P_2O_5 to U in the sample is between 6×10^4 and 5×10^5. Figure 5 shows the effect of increasing phosphoric acid content on the absorbance for 5, 10 and 15 μg of uranium. Figure 5 shows that the amount of phosphoric acid used must be closely controlled and should be as identical as possible for all samples and standards.

CONCLUSIONS

The method presented seems attractive for determination of uranium in crude wet phosphoric acids. The calibration can be done by applying the entire procedure to known amounts of uranium in phosphoric acid of concentration not exceeding 30% P_2O_5 (5.3M H_3PO_4). An alternative which completely eliminates the effect of mineral impurities is based on determination of the calibration graph for the particular kind of wet phosphoric acid being analysed.

Table 1. The effect of foreign ions on the determination of 10 μg of uranium in the presence of 92 mg of P_2O_5 (127 mg of H_3PO_4) and 0.625 mg of $NaClO_3$

Quantity of foreign ions, μg	Uranium found, μg

Fig. 5. The dependence of absorbance A on phosphoric acid content in samples containing 5, 10 and 15 μg of uranium.

It involves preliminary extraction of the uranium contained in the test-acid, with a kerosene solution of NPPA, followed by addition of standard amounts of uranium to portions of the "cleaned up" acid, and determination by the entire procedure. The relative standard deviation found for 15 independent measurements of 0.01% U was 2.8%. The limit for detection for uranium is 10 μg/g in wet phosphoric acid. Fifty samples of wet phosphoric acid containing from 0.0004 to 0.0098% U were analysed by the method described and by X-ray fluorescence. The results obtained by the X-ray fluorescence method were lower by an average of about 5%.

The method can also be used for determination of uranium in the waste phosphogypsum and for monitoring the distribution of uranium in the decomposition of phosphate raw materials with sulphuric acid.

SHORT COMMUNICATIONS

DISCRETE MICROSAMPLE INJECTION INTO A GASEOUS CARRIER

ABDULRAHMAN S. ATTIYAT

Chemistry Department, Yarmouk University, Irbid, Jordan

and

GARY D. CHRISTIAN

Department of Chemistry, University of Washington, Seattle, WA 98195, U.S.A.

Summary—Discrete injection (DI) of μl-volume liquid samples into a continuous flow of air as carrier is demonstrated. Atomic-absorption (AA) detection is used. Calibration graphs for zinc, obtained by using the DI–AA–air carrier method have a slope 1.8 times that of graphs obtained by the flow-injection analysis (FIA)–AA–air carrier method. The DI–AA–air carrier signals are higher and sharper than the FIA–AA–water carrier signals, and even exceed the AA steady-state signals for the same zinc solutions, owing to improved nebulization/atomization. The air-carrier method is more rapid than the liquid-carrier method. Measurement rates of 600/hr are possible. The signals show precision comparable to that attainable with water as carrier. The method is particularly useful for flame or plasma detectors and is potentially useful with different gases or vapours as carriers, and for gas–liquid reactions in FIA.

Flow-injection analysis (FIA) is a technique in which the sample is introduced, in the form of a liquid plug, into a flowing liquid stream.[1] This liquid stream either serves merely to carry the sample to the detector, or includes a reagent or a mixture of reagents to produce a detectable product from the sample and transport it to the detector.[2] The FIA signal depends on the reaction time and the dispersion of the sample. The longer the reaction time, the more the amount of product, but increased reaction time also increases the dispersion and dilution of the sample.[1,3] Consequently, the optimum conditions for flow-rate and length of the mixing (dispersion) coil, will be a compromise between longer reaction time and lower dispersion. It would sometimes be of great advantage to the analyst to be able to limit the dispersion and also increase the reaction time. The use of gaseous reagents and carriers would enable the analyst to achieve this goal because a liquid sample transported by a gaseous carrier has very limited dispersion. Gardner and Malczyk [4] recently described discrete injection of liquid samples in an AutoAnalyzer flow system with colorimetric detection, to allow the use of smaller samples. We describe here the discrete injection (DI) of liquid samples into a continuous flow of air as carrier stream for atomic-absorption (AA) detection and compare the results with those obtained by using water as carrier stream.

EXPERIMENTAL

Reagents

Zinc stock solution (Fisher certified atomic-absorption standard, 1000 ppm) was used to prepare 1, 2, 4, 5 and 10 ppm zinc standards. Demineralized water was used throughout for solution preparation and as liquid carrier.

Apparatus

A Perkin-Elmer model 403 atomic-absorption spectrophotometer with a strip-chart recorder was used for the AA measurements. A Rheodyne loop injection-valve was used for sample introduction. Teflon tubing of 0.5 mm bore was used in the DI–AA flow system and for sampling loops, and for connecting the sample injector to the capillary of the AA spectrophotometer. No pump was used in the AA system; the negative pressure of the nebulizer provided the necessary flow. Plastic syringes (1 and 3 ml) were used for filling sampling loops. The operating conditions for DI–AA are listed in Table 1.

Generation of the signals

The FIA signals obtained with the liquid-carrier system were generated by pumping distilled demineralized water into the detector system, and injecting the sample solution into the carrier stream by means of the injection port. Zinc standards were injected for FIA–AA.

Table 1. Experimental conditions for the FIA– and DI–AA system

Atomic-absorption settings:	
Wavelength	213.8 nm
Lamp current	15 mA
Slit-width	0.1 mm
Flame	Air–acetylene
Gas flow	Air 8 l./min
	Acetylene 1./min
Burner	Premix nebulizer-burner
Observation height	8 mm above burner
Recorder output	10 mV
Injection system:	
Liquid carrier	Water
Gaseous carrier	Air
Flow-rate of liquid carrier	2.5 ml/min
Length of dispersion coil	15 cm
Bore of dispersion coil	0.5 mm
Bore of pumping tube	0.5 mm
Volume of sample loop	100 μl

TAL. 31/6—E
Fig. 1. Calibration graphs for the determination of zinc by FIA–AA–liquid carrier (A) and DI–AA–gas carrier (B).

DI signals obtained with the gaseous carrier system were generated in the same way, but with air pumped through the carrier system at the same rate as for the liquid carrier.

RESULTS AND DISCUSSION

Figure 1 depicts the calibration plot for the determination of zinc by FIA–AA with liquid carrier (A) and by DI–AA with gaseous carrier (B), for 100-μl injections. The slope of B is 1.8 times that of A. The precision was similar for both methods, 2.1% relative standard deviation for the measurements with liquid carrier and 2.7% for those with gaseous carrier. Figure 2 shows the DI–AA signals with air as carrier

for the repeated injection of the five zinc standards used in constructing the calibration curves. Care must be taken to remove traces of the previous sample from the injector tubing connecting the injection port to the sample loop, or carry-over will cause a slight error in the signal for the next sample if the two samples differ appreciably in concentration (*e.g.*, see the first peak in each batch in Fig. 2). This precaution is common when liquid carriers are used.

Figure 3 shows the FIA–AA signal with liquid carrier (B), the DI–AA signal with gaseous carrier (C) and the steady-state AA signal (A), all for a 5-ppm zinc solution. The signal with air as the carrier stream is significantly higher than that with water as carrier and somewhat higher than the steady-state signal. Also, the DI–air carrier peaks are sharper than the FIA–liquid carrier peaks, the widths at half height being 3 and 6 sec respectively. The reason for the DI–air carrier peaks being higher and narrower is believed to be enhanced vaporization/atomization of the sample, combined with diminished dispersion.

Effect of sample volume

Figure 4 shows the dependence of the AA signal (with air as carrier stream) on the sample volume. The signal increases rapidly with sample volume up to 100 μl, then starts to level off. This means that if the amount of sample is limited, the sample volume can be reduced from 200 to 100 μl without significant sacrifice in sensitivity. When water was used as
Fig. 2. DI–AA–air carrier peaks for five zinc standards, 1 ppm (A), 2 ppm (B), 4 ppm (C), 5 ppm (D) and 10 ppm (E and F).
Fig. 3. Atomic-absorption signals for a 5-ppm zinc solution. (A) Steady state signal, (B) FIA–AA–liquid carrier signals, and (C) DI–AA–air carrier signals.
Fig. 4. The dependence of DI–AA–air carrier signals on the volume of sample injected.

carrier, the signal was still increasing with sample volume even at volumes $> 200 \,\mu l$.

Effect of the length of the dispersion coil

Figure 5 depicts the dependence of the AA peak height, with air as carrier, on the length of the
Fig. 5. The dependence of the DI–AA–air carrier signals on the length of the dispersion coil.

dispersion coil. The decrease in signal is significant but relatively small. The total decrease was about 20%, compared with a decrease of about 70% with water carrier, for the range of lengths shown. This will be of great benefit when the carrier gas also acts as a chemical reagent in gas–liquid reactions in FIA.

Analysis time

The DI–AA–air carrier peak emerges within 3 sec after the injection (compared to 4 sec with water as carrier). The average peak width at the base-line is about 6 sec. In principle, this permits up to 600 measurements per hour, and readily gives 350 per hour.

The DI–AA–gas carrier method is more sensitive and rapid than the liquid carrier method. It has good reproducibility and many potential applications. It is particularly well suited for flame or plasma detectors. The gas carrier technique has potential for application with different gases or vapours as carriers and for utilization of gas–liquid reactions in flow-injection analysis.

DETECTION AND DETERMINATION OF PHENYLHYDRAZINE

N. Krishna Murty,* V. Jagannadha Rao and N. V. Srinivasa Rao
Department of Engineering Chemistry, Andhra University, Waltair, India

Summary—Cacotheline has been employed successfully as a new qualitative and quantitative reagent for phenylhydrazine. The spot-test is performed at pH 4.5–5.5 with a limit of detection of 0.5 μg/ml in the sample solution. The method can be extended to the colorimetric estimation and photometric titration of phenylhydrazine with cacotheline. Beer's law is obeyed over the range 0.1–2 mg.

Among the few reagents proposed for the detection of phenylhydrazine may be mentioned 2,6-dichloro-*p*-benzoquinone-4-chloramine,[1] pyridine-2-aldehyde,[2] Devarda's alloy and Raney alloy,[3] and silver nitrate in presence of sodium hydroxide.[4] Some of these methods are indirect, or involve the use of rare chemicals and heating. A direct and simple method is now proposed for the detection of phenylhydrazine with cacotheline, a nitro-derivative of brucine, as reagent. Few methods have been proposed for the spectrophotometric estimation of phenylhydrazine,[5-7] so the new spot-test is extended to the colorimetric estimation and photometric titration of phenylhydrazine.

EXPERIMENTAL

Reagents

Cacotheline solution is prepared and standardized as described earlier.[8] Phenylhydrazine solution is prepared and standardized[9] with potassium iodate (carbon tetrachloride end-point detection).

Procedures

Detection of phenylhydrazine. Mix 1 ml of 0.2*M* sodium acetate and 1 ml of 0.2*M* acetic acid in a test-tube, and add 1 ml of cacotheline solution and 1 ml of test solution. An immediate pink colour, stable for more than 30 min, indicates the presence of phenylhydrazine. The limit of detection is 0.5 μg in the 1 ml of sample.

Alternatively place 0.05 ml of 0.2*M* sodium acetate and 0.05 ml of 0.2*M* acetic acid in a cavity on a spot-plate, add 0.05 ml of cacotheline solution and 0.05 ml of test solution and mix with a glass rod. An immediate pink colour, stable for more than 30 min, indicates the presence of phenylhydrazine. The limit of detection is 0.25 μg in the 0.05 ml of test solution.

Colorimetric estimation. In a 50-ml standard flask place 10 ml of 0.2*M* sodium acetate and 10 ml of 0.2*M* acetic acid, and add 5 ml of cacotheline solution. Add a suitable known volume of test solution or phenylhydrazine standard solution and dilute to the mark with water. Measure the intensity of the pink colour with a photoelectric colorimeter fitted with a green filter, or measure the absorbance at 530 nm. Prepare a calibration graph.

Photometric titration. Mix 2 ml of 0.2*M* sodium acetate and 2 ml of 0.2*M* acetic acid in a suitable titration cell, and add 2 ml of test solution containing 0.5–2 mg of phenylhydrazine. Pass carbon dioxide through the mixture for

about 10 min, then titrate with cacotheline solution, added in portions of 0.1–0.2 ml. Stop the passage of carbon dioxide before measurement. Apply a volume correction when plotting the titration curves.

RESULTS AND DISCUSSION

Preliminary tests showed the optimal acidity to be in the range pH 4.5–5.5. The absorption spectrum of the product obtained by reduction of cacotheline with phenylhydrazine under these conditions has a maximum at 530 nm. The stoichiometry of the reaction is 1:1, each component undergoing a 2-electron reaction and the course of the reaction is the same whether the cacotheline or phenylhydrazine is added first. The apparent molar absorptivity of the reduced cacotheline is 3.3×10^3 1.mole^{-1}.cm^{-1}. Beer's law is obeyed over the range 0.1–2 mg of phenylhydrazine.

Hydrazine, hydroxylamine, 2,4-dinitrophenylhydrazine, phenylhydrazine-4-sulphonic acid hemihydrate, *o*-phenylhydroxylamine hydrochloride, semicarbazide hydrochloride, isonicotinic acid hydrazide, chloralhydrazine, benzoylhydrazine, salicyloylhydrazine and nicotonylhydrazine, have no effect on the determination of phenylhydrazine. Various species such as Sb(V), Sb(III), V(V), V(IV), Mo(VI), W(VI), chloride, bromide, acetate and citrate do not interfere, but U(IV), Sn(II), Ti(III) and Mo(V) interfere when present at any concentration.

The relative error was found to be 1% or less for the colorimetric determinations, and 0.5% or less for the photometric titration.

ION-CHROMATOGRAPHIC DETERMINATION OF CHLORIDE AND FLUORIDE IN ELECTROLYTE FROM THE HALOGEN TIN-PLATING PROCESS

W. Korth and J. Ellis

Department of Chemistry, University of Wollongong, P.O. Box 1144, Wollongong, N.S.W. 2500, Australia

Summary—A simple and rapid procedure is proposed for the determination of chloride and free fluoride in tin electroplating fluid. Suppressor-column ion-chromatography is used after oxidation of hexafluorostannate(II) to hexafluorostannate(IV) with hydrogen peroxide. Concurrent determination of tin(II) and total tin then allows calculation of the concentrations of fluoride, hexafluorostannate(II) and hexafluorostannate(IV).

In common with many large tin-plate plants, the electrotinning line at Australian Iron and Steel (Port Kembla) uses a fluoride electrolyte consisting predominantly of sodium chloride and sodium hexafluorostannate(II). In addition, small amounts of ferrocyanide (to scavenge heavy metals) and other compounds such as organic brightening agents are present. Typical concentrations are given in Table 1.

During use, the electrolyte concentrations of tin(II) and free fluoride are depleted progressively by the oxidation of tin(II) to tin(IV), which is converted into the electrochemically inactive hexafluorostannate(IV). Periodic additions of tin(II) and fluoride are therefore required to maintain the specified concentration ranges for these ions. In particular, a free fluoride/tin(II) ratio of at least 6:1 is required. This necessitates regular monitoring of the electrolyte for tin(II), tin(IV), fluoride and chloride. At present, both chloride and fluoride are determined by titrimetric analysis.[1,2] This paper describes a simple ion-chromatographic procedure which is faster and more precise than the titrimetric methods and which could be adapted to automated process control.

EXPERIMENTAL

Apparatus

The ion-chromatography system consisted of a solvent-delivery pump (6000A, Waters, U.S.A.), a pneumatic high-pressure injection valve (7000, Rheodyne, U.S.A.) fitted with a 10-μl loop, an anion separator column and cation-exchange suppressor column (Dionex, U.S.A), a conductivity meter (P/N9505, Phillips, U.S.) and a chart recorder (EB5247-15, Houston Instruments, U.S.A.). A flow-rate of 3.0 ml/min was employed, with the detector at 10 μS/cm full-scale deflection, recorder at 0.1 V full-scale deflection and a chart-speed of 0.25 cm/min.

Procedure

Filter a sample of electrolyte (Whatman 541) and pipette 5.00 ml of the filtrate into a 500-ml standard flask containing 10 ml of aqueous hydrogen peroxide (30% w/v). Dilute to volume, inject 10 μl into the Dionex anion separator column and elute with sodium carbonate (3.0mM)/sodium bicarbonate (2.4mM) solution. Convert peak areas into concentrations by use of calibration graphs obtained by injecting a solution of sodium chloride and sodium fluoride. Determine tin(II) and total tin by titrimetry.[3]

DISCUSSION

Fluoride is present in the electrolyte in three forms: free fluoride, hexafluorostannate(II) and hexafluorostannate(IV). Hexafluorostannate(II) is labile and hexafluorostannate(IV) is inert. Ion-chromatography will thus detect the free fluoride and also the fluoride dissociated from the tin(II) complex. Dissociation of the SnF_6^{4-} ion is forced to completion by the binding of the released tin(II) by the resin of the suppressor column, which must consequently be regenerated more frequently. With a single-column (electronic suppression) system, the tin(II) interferes more, since heavy-metal ions poison the column. Accordingly, attempts were made to prevent this interference, including precipitation of tin with sulphide, or sodium hydroxide or ammonia; use of a cation-exchange resin or a chelating ion-exchange resin; and complexation with EDTA. All these methods were successful, but either were too lengthy to be practical or caused subsequent interferences.

Therefore, the hexafluorostannate(II) was oxidized to kinetically inert hexafluorostannate(IV). The free fluoride ([F^-]) was then readily detected (along with chloride). The dual-column system gave a constant baseline between chromatographic peaks and a faster

Table 1. Composition of electrolyte (pH 4.0)

Table 2. Comparison of ion-chromatography and titrimetric analysis
for Cl^- and F^-

Sample	Cl^-,* $g/l.$	F^-,* $g/l.$		Sn(II), $g/l.$	Sn(IV), $g/l.$
		a	b		
1	42.7 (42.5)	13.5	26.0 (25.7)	9.0	4.0
2	42.2 (41.5)	13.3	25.8 (25.7)	8.5	4.5
3	38.3 (39.0)	15.7	32.5 (33.7)	11.0	6.5
4	38.7 (39.5)	14.3	30.6 (31.3)	11.0	6.0
5	43.0 (42.5)	14.2	27.6 (28.1)	9.5	4.5
6	38.0 (37.0)	17.6	32.5 (31.8)	11.0	4.5

*Titrimetric values given in parentheses.
a = free fluoride after oxidation of tin; b = total fluoride.

separation than the single-column system, and was used in all subsequent work. The concurrent titrimetric determination of tin(II) and total tin[3] allowed the total fluoride concentration to be calculated from

$$[F^-]_{total} = [F^-] + 0.960[Sn]_{total}$$

where all concentrations are expressed in units of g/l.
Hexafluorostannate(II) was calculated from:

$$[SnF_6^{4-}] = ([F^-]_{total} - [F^-]) \times 2.04 \times \frac{[Sn(II)]}{[Sn(IV)]}$$

Table 2 compares mean ($n = 3$) values for fluoride and chloride concentrations determined by titrimetry with those determined by hydrogen peroxide oxidation/ion-chromatography (a) before and (b) after oxidation of tin(II). Actual electrolyte samples were used in each case, over the concentration ranges (g/l.) 8.5–11.0 [tin(II)], 4.5–6.5 [tin(IV)], 25.8–32.5 [F^-] and 38.0–43.0 [Cl^-].

The ion-chromatographic analysis gave complete resolution of the chromatographic peaks and linear calibration graphs for chloride and fluoride over the concentration ranges 0–350 and 0–250 mg/l. respectively. The precision was determined by replicate analysis of a solution containing 283 mg/l. of chloride and 189 mg/l. of fluoride; relative standard deviations were 0.5% ($n = 10$) and 0.8% ($n = 10$) respectively. Because of the poor precision of the titrimetric analysis for fluoride (± 2 g/l. for [F^-] $\sim$ 28 g/l.), the

accuracy of the ion-chromatographic procedure was checked by using a synthetic electrolyte prepared by dissolving NaCl, NaF and $SnCl_2 \cdot 2H_2O$ in water and oxidizing the tin with hydrogen peroxide. The mean chloride concentration found was 472 mg/l. (470 mg/l. taken) and fluoride concentration 239 mg/l. (237 mg/l.).

CONCLUSION

The ion-chromatography procedure provides simultaneous measurement of fluoride and chloride with a precision that for chloride is comparable with titrimetry, and for fluoride is much better. Sample pretreatment is minimal and the analysis time (< 5 min) is much shorter than that for the titrimetric method (> 30 min). Because of its minimal requirements for sample handling and addition of reagents, it should be readily adaptable for automated on-line analysis and process control.

SELECTIVE COMPLEXOMETRIC DETERMINATION OF TIN, WITH MERCAPTANS AS RELEASING AGENTS

K. N. Raoot and Sarala Raoot

Defence Metallurgical Research Laboratory, Kanchanbagh, Hyderabad-500258, India

Summary—A method is proposed for selective complexometric determination of tin, mercaptans being used as releasing agents. To a solution containing tin and other cations, excess of EDTA is added and the surplus is back-titrated at pH 5–6 with lead nitrate (Xylenol Orange as indicator). Thioglycollic acid or mercaptopropionic acid is then added to decompose the tin–EDTA complex and the liberated EDTA is titrated with lead nitrate. The interference of various cations has been studied and the method has been employed for the estimation of tin in a variety of alloys.

Gravimetric methods for tin are normally subject to errors caused by adsorption, co-precipitation or occlusion of other elements present and require more or less elaborate separations or purification of the final oxide.[1] The titrimetric determinations based on oxidation to the quadrivalent state by means of a standard solution of iodate or other suitable oxidant are definitely superior, but complete reduction of tin to the bivalent state and subsequent prevention of aerial oxidation to tin(IV) are mandatory,[1,2] and demand special care and apparatus

EDTA[3–5] forms strong complexes with both tin(II) and tin(IV) and thus complexometric methods for tin are expected to be free from problems of oxidation or reduction. EDTA methods, in general, are also more convenient and rapid. Surprisingly, the number of complexometric methods for tin is comparatively small[5,6] and those capable of determining tin in the presence of other cations with the help of selective masking agents, are still fewer in number. Oxalate,[7,8] fluoride,[8,9] and lactic acid[10] appear to be the only reagents used for selective decomposition of the tin–EDTA complex.

Tartaric acid[11] has been used for masking tin during the EDTA titration of other cations. We recently reported the use of tartaric acid and citric acid as selective releasing agents for tin.[12] During earlier work[13] in which thioglycollic acid and mercaptopropionic acid were used for the decomposition of the copper(II)–EDTA complex, serious interference was caused by tin. A detailed investigation was therefore undertaken to examine the usefulness or otherwise of these mercaptans for the quantitative release of EDTA from its tin complex. The results are presented in this paper.

EXPERIMENTAL

Reagents

Tin(II) chloride solution. Prepared by dissolving 1.92 g of stannous chloride in 20 ml of concentrated hydrochloric acid and making up to 1 litre, and standardized.

Tin(IV) chloride solution. Prepared by dissolving 1.00 g of pure tin metal in 150 ml of hydrochloric acid (1 + 1) and diluting to 1 litre with 1*M* hydrochloric acid, and standardized.

*EDTA solution, 0.01*M.

*Lead nitrate solution, 0.01*M.

Xylenol Orange indicator. A 0.1% aqueous solution.

Thioglycollic acid and mercaptopropionic acid, 20% solutions in water.

Glycerol, 50% aqueous solution.

Hexamine buffer. A 30% aqueous solution.

Solutions of various metal ions (concentration 1 mg/ml) were prepared from suitable salts. All chemicals were of analytical-reagent grade.

Estimation of tin in presence of other cations

To a solution containing 5–50 mg of tin(II) or tin(IV) and various amounts of foreign ions, add excess of 0.01*M* EDTA and dilute to 70–80 ml with distilled water [when tin(IV) is present add 10 ml of 20% glycerol solution]. Adjust to pH 5–6 with hexamine solution. Add a few drops of Xylenol Orange indicator and back-titrate the excess of EDTA with 0.01*M* lead nitrate to the sharp colour change from yellow to red. Add 5–25 ml of 20% solution of thioglycollic acid or mercaptapropionic acid. Heat the solution to boiling and boil for 4–5 min, cool and titrate the liberated EDTA with 0.01*M* lead nitrate.

Determination of tin in alloys

Dissolve 0.2–0.5 g of sample in 10–20 ml concentrated hydrochloric acid and 2–4 ml of concentrated nitric acid and dilute to 100 ml in a standard flask. Take a suitable aliquot containing 5–50 mg of tin in a 250-ml conical flask, and determine tin as described above.

RESULTS AND DISCUSSION

Both tin(II) and tin(IV) are known to form strong complexes with EDTA, but tin(IV) is reported to hydrolyse in alkaline or even neutral medium in presence of EDTA.[3–6] This fact has been used for the separation of tin from other metal ions.[14–16] In the EDTA methods for tin(IV), the metal is mostly estimated[8,17,18] at lower pH such as 2, and in those few cases where back-titration is done at pH 5–6, a caution is invariably given that the pH should be adjusted to 2 and then slowly and homogeneously be brought to 5 by small additions of the buffer.[4,10,19] To

overcome this limitation Ottendorfer[20] suggested the addition of potassium chloride, which causes an initial shift in pH and also prevents dissociation of the tin(IV)–EDTA complex. We have found that glycerol is more effective than potassium chloride, since it is capable of keeping tin(IV) in solution even up to pH 10, whereas with potassium chloride a slight turbidity appears at about pH 6. Addition of 5 ml of 50% glycerol solution was found to be adequate for 10 mg of tin. Glycerol has also been used for masking iron(III) and chromium(III) in EDTA titration of some bivalent cations[21] and tin(IV)[22] respectively.

Various dissolution procedures have been suggested for the alloys of tin[1,2,23] and the choice mainly depends on the oxidation state of tin required by method of analysis. Earlier chelatometric methods also appear to have such requirements, some being for tin(II)[24-26] and others for tin(IV).[17-19] In the most common dissolution procedures, employing mineral acids, nitric acid and atmospheric oxygen tend to oxidize the tin,[1] whereas the associated metals such as zinc, lead, etc. in the alloys exert a reducing effect on it.[1,27] It is therefore most likely that the solution thus obtained will contain a mixture of tin(II) and tin(IV). The mercaptans used in the present investigation are equally effective for bivalent and quadrivalent tin and hence the present method is superior to the earlier ones using oxalate,[7,8] fluoride[8,9] and lactic acid[10] as releasing agents, which are reported to be useful only for tin(IV). It was observed during the preliminary experiments that 5 ml of 20% thioglycollic or mercaptopropionic acid will release the EDTA combined with 10 mg of tin, on heating at 100° for 4–5 min. A larger volume has no adverse effect, but a smaller amount will require the boiling period to be longer.

A number of cations have been examined for their possible interference in the present titration and it has been found that large amounts of lead, zinc, nickel, cobalt(II), cadmium, iron(III), aluminium, indium, arsenic(V), antimony(V), vanadium(IV), zirconium and rare-earths do not interfere. However, when aluminium is present, to ensure its complete complexation with EDTA it is necessary to boil the solution for 2–3 min after addition of the excess of EDTA and adjustment to pH 3. Copper(II)–EDTA is also quantitatively decomposed by the mercaptans used[13] and hence copper will interfere, but this can easily be obviated by masking the copper with thiourea,[28] so larger samples can be used for alloys containing smaller percentages of tin. Manganese(II), owing to the low stability of its EDTA complex under the experimental conditions, caused difficulty in the endpoint detection, particularly when more than 5 mg of it was present. Bismuth(III) interfered seriously. An interesting feature of the present method is that it remains unaffected by large amounts of titanium(IV), which seriously interferes with all the masking or releasing agents used earlier.[7-11] The method can thus be used for the estimation of tin in titanium alloys. The results for tin in alloys are presented in Table 2.

Titanium-base alloy	2.47	2.46*	−0.4
NBS No. 176		2.50†	+1.2

*With thioglycollic acid.
†With mercaptopropionic acid.

It is seen that the maximum relative error, 1.2%, is for an alloy containing only 2.5% tin. For alloys with higher percentages of tin, the relative errors were much smaller. A suite of three alloy samples can conveniently be analysed in 1 hr. It can thus be concluded that the method is simple, selective, accurate and fairly rapid.

APPLICATION OF ANION-EXCHANGE TECHNIQUES TO THE DETERMINATION OF TRACES OF MOLYBDENUM IN SEA-WATER

Tetsuya Kiriyama

Laboratory for Chemistry, Faculty of Education, Kagoshima University, Kagoshima, Japan

and

Rokuro Kuroda

Laboratory for Analytical Chemistry, Faculty of Engineering, University of Chiba, Chiba, Japan

Summary—A combined ion-exchange spectrophotometric method has been developed for the determination of molybdenum in sea-water. Molybdenum is sorbed strongly on Amberlite CG 400 (Cl^-) at pH 3 from sea-water containing ascorbic acid and is easily eluted with $6M$ nitric acid. Molybdenum in the effluent can be determined spectrophotometrically with potassium thiocyanate and stannous chloride. The combined method allows selective and sensitive determination of traces of molybdenum in sea-water. The precision of the method is 2% at a molybdenum level of $\sim 10\,\mu g/l$.

Because of the low abundance of molybdenum in natural waters, preliminary isolation methods have usually been employed in its determination. Co-precipitation[1–3] and solvent extraction [4–6] separations are most often used for this purpose. The other preconcentration methods available for molybdenum include co-crystallization,[7] sorption on chitosan and modified cellulose,[8] cation-exchange sorption on Zeo-Karb 225[1] and Chelex 100,[9,10] concentration on Sephadex G-25[11] and (as the pyrrolidine dithiocarbamate complex) on charcoal.[12]

Kuroda and Kawabuchi have concentrated molybdenum by anion-exchange from sea-water containing acid and thiocyanate[13] or hydrogen peroxide[13,14] and determined it spectrophotometrically. Korkisch *et al.*[15] have concentrated molybdenum from natural waters on Dowex 1-X8 in the presence of thiocyanate and ascorbic acid. A sodium citrate and ascorbic acid system[16] has also been worked out for the concentration of molybdenum on Dowex 1-X8 (citrate form) as a citrate complex from tap and mineral waters.

In this work it has been found that molybdenum can be concentrated from sea-water simply on the strongly basic anion-exchange resin to which only ascorbic acid has been added. The anion-exchange concentration, coupled with the thiocyanate–stannous chloride method, allows sub-ppm levels of molybdenum to be determined successfully.

EXPERIMENTAL

Reagents

A stock solution (10 mg/ml) of molybdenum (as sodium molybdate dihydrate) was prepared with demineralized water and standardized chelatometrically. One g of ferrous ammonium sulphate and 0.5 ml of concentrated sulphuric acid were dissolved in demineralized water and the mixture was diluted to 100 ml with water.

The strongly basic anion-exchange resin Amberlite CG 400 in the chloride form (100–200 mesh) was used. A slurry of 5 g of the resin in water was poured into a conventional ion-exchange tube (2.5 cm diameter) to make a bed 2.3 cm long.

A Hitachi Model 101 spectrophotometer with 1-cm glass cells was used.

Determination of distribution coefficients

The distribution coefficients of molybdenum(VI) were determined by the batch equilibrium method. Weighed portions of air-dried resin (1.0 g each) were mixed with 1.00 ml of molybdenum solution [0.110 mmole of Mo(VI)] and 40.0 ml of buffer solution containing ascorbic acid at various concentrations. The buffer solutions used were $0.1M$ potassium chloride–$0.1M$ hydrochloric acid for pH 2, and $0.1M$ sodium acetate–$0.1M$ acetic acid for pH 3–6. The mixtures were shaken for 20 hr and the distribution coefficients determined as described earlier.[17]

Procedures

Ion-exchange concentration. Filter the water sample through a membrane filter (0.45-μm, Millipore). Take a 500-ml portion of the filtrate, add 0.9 g of ascorbic acid and adjust the pH to 3.0 ± 0.1. Pass the mixture through the ion-exchange column at a flow-rate of 5 ml/min. Wash the column with 250 ml of $0.01M$ ascorbic acid (pH 3). Strip the molybdenum by elution with 70 ml of $6M$ nitric acid.

Spectrophotometric determination. Evaporate the effluent to dryness. Add 2 ml of concentrated nitric acid and again evaporate to dryness. Take up the residue with 2 ml of hydrochloric acid and a small amount of water. Transfer the solution to a separatory funnel, add 1 ml of 1% ferrous ammonium sulphate solution and 3 ml of 10% potassium thiocyanate solution. Swirl, add 2 ml of 10% stannous chloride solution in $1M$ hydrochloric acid and immediately extract with 5.0 ml of di-isopropyl ether, shaking for 30 sec. Measure the absorbance of the organic layer at 460 nm against a reference blank.

Table 1. Distribution coefficients of molybdenum on Amberlite CG 400 (Cl⁻ form) in ascorbic acid and 0.5M sodium chloride

*Ascorbic acid concentration.

RESULTS AND DISCUSSION

The distribution coefficients of molybdenum on Amberlite CG 400 in the chloride form are listed in Table 1 as a function of ascorbic acid concentration in the pH range 2–5. Molybdenum sorbs very strongly from dilute ascorbic acid solutions ($\leq 0.1M$) over the pH range 3–5, the coefficient reaching $> 10^4$ under these conditions. The distribution coefficients of molybdenum in the presence of 0.5M sodium chloride are also shown in Table 1 for the pH range 2–6, as a function of ascorbic acid concentration. Generally the coefficients are lower in sodium chloride–ascorbic acid media than those in

ascorbic acid alone, in the pH range 2–5. However, the coefficients in the mixed media are sufficiently high to allow traces of molybdenum to be concentrated from large volumes of brine.

Korkisch and Krivanec[16] claim that the ready displacement of ascorbate ion by the anions contained in natural water is one of the disadvantages of ascorbic acid when employed alone for concentrating molybdenum and vanadium from water samples by anion-exchange. However, the distribution coefficient of molybdenum is sufficiently high to allow its strong retention on Amberlite CG 400 even when the resin is in the chloride form (Table 1).

†Average recovery of total present after addition of Mo.

Chakravorty and Khopkar[18] attempted to separate uranium(VI) from thorium, zirconium, titanium and other elements, including molybdenum, in ascorbate media (pH 4.5). In their procedure, uranium was eluted with $1M$ hydrochloric acid followed by molybdenum with dilute ammonia $(1 + 7)$ containing 3% ammonium persulphate. We attempted to remove the molybdenum by elution with $4M$ perchloric acid, but recoveries were often about 25% lower than expected, owing to volatilization of some molybdenum during the strong fuming with perchloric acid.[19] A gentle, careful evaporation did not yield serious loss of molybdenum. However, we found that molybdenum can be easily stripped from the column by elution with 70 ml of $6M$ nitric acid in accordance with the anion-exchange sorption characteristics of molybdenum in nitric acid media.[20]

The high distribution coefficients of molybdenum in ascorbate media and its strong sorption in the presence of high concentrations of sodium chloride indicate that molybdenum should be sorbed on the resin from large volumes of natural water samples. To evaluate the feasibility of using the ascorbate system as the concentration method, a brine simulating sea-water ($0.5M$ sodium chloride) spiked with a known amount of molybdenum was analysed by the present procedure and the results are given in Table 2. As can be seen, the recoveries for the $8\,\mu g$ of molybdenum added to 500 or 1000 ml samples are satisfactory.

The sorption of an ascorbate complex and subsequent elution with $6M$ nitric acid is not specific for molybdenum. Some information is available on the sorption of several other metals on anion-exchange resins in ascorbate media.[18,21] In this study those elements which interfere with the determination of molybdenum by the thiocyanate–stannous chloride method and are at least as abundant in sea-water as molybdenum have been chosen and their interferences examined. The results suggest that titanium ($130\,\mu g$), vanadium(IV) ($200\,\mu g$), vanadium(V) ($170\,\mu g$), iron(III) ($1000\,\mu g$), nickel ($480\,\mu g$), copper(II) ($130\,\mu g$), zinc ($300\,\mu g$), arsenic(III) ($290\,\mu g$), tin(IV) ($260\,\mu g$), lead ($60\,\mu g$) and uranium(VI) ($440\,\mu g$), in the amounts shown in brackets, do not interfere with the determination of $8\,\mu g$ of molybdenum (error within $\pm 3.8\%$). These quantities are more than 50 times those present in 1 litre of seawater. Even if they behave the same as molybdenum in the anion-exchange concentration and elution steps, these metal ions do not interfere with the determination of molybdenum in a 1 litre sea-water sample.

The results of repeated determinations of molybdenum in three sea-water samples are given in Table 2. The accuracy of the method was tested by adding molybdenum and determining overall recoveries. The recoveries and precision (r.s.d. 1.4–2.2%) of the method are satisfactory.

ANALYTICAL DATA

DISSOCIATION CONSTANTS, NEUTRALIZATION ENTHALPIES AND REACTIONS OF 3-STYRYL-2-MERCAPTOPROPENOIC AND 3-(1-NAPHTHYL)-2-MERCAPTOPROPENOIC ACIDS

A. Izquierdo, E. Bosch and J. L. Beltran

Department of Analytical Chemistry, University of Barcelona, Barcelona, Spain

Summary—Dissociation constants (pK_{a1} and pK_{a2} in water–ethanol medium for 3-styryl-2-mercaptopropenoic and 3-(1-naphthyl)-2-mercaptopropenoic acid have been determined potentiometrically, and pK_{a2} for both in aqueous medium, spectrophotometrically. Neutralization enthalpies in water–ethanol medium have been determined by thermometric titration. The reactions with metal ions have been studied, and the main reactions are described. The most sensitive reactions are with titanium-(IV) ($pD = 7.00$) and nickel(II) ($pD = 6.50$).

Studies of some 3-aryl-2-mercaptopropenoic acids have been reported in previous papers, in which the aryl groups (Ar) were phenyl,[1] 2-furyl,[2] 2-pyrrolyl, 2-thienyl and 2-hydroxyphenyl.[3]

These compounds react with many metal ions. The conjugated double bond between the carboxyl and aryl groups makes the complexes more stable than those formed from reagents without this double bond. In the present work 3-styryl-2-mercaptopropenoic acid (3S2MP) and 3-(1-naphthyl)-2-mercaptopropenoic acid (3N2MP) have been studied to find the effects of extending the unsaturated chain and enlarging the 3-aryl group.
Potentiometric and thermometric titrations with alkali were used to determine the two acid groups (–SH and –COOH). The enthalpies of neutralization were determined by thermometric titration.

EXPERIMENTAL

Apparatus

Crison Digilab 517 and Radiometer PHM 84 pH-meters were used with a Radiometer G 202 B glass electrode,

Metrohm EA 120 combined glass electrode, an Ag/AgCl reference electrode,[4] and a Wilhelm-type salt bridge.[5] The spectrophotometer was a Beckman Acta M-VII and the thermometric titration assembly was that described in the previous work.[6]

Solutions

All solutions were deaerated with nitrogen before use, and all reagents were of analytical grade. The buffers for the spectrophotometry ($0.01M$ ionic strength) were prepared according to Perrin.[7] The ionic medium ($NaClO_4$) was prepared by a literature method.[8]

Carbonate-free sodium hydroxide solution was standardized against potassium hydrogen phthalate, and protected from atmospheric carbon dioxide.

Perchloric acid, stock solutions, $0.05–0.1M$ were standardized against sodium carbonate. The Gran method[9] was used for both sets of standardizations.

Ethanolic solutions of the mercapto acids ($0.1–1\%$) were prepared with deaerated ethanol.

Mercapto acids

These were synthesized as described by Campaigne and Cline,[10] by condensation of cinnamaldehyde or 1-naphthaldehyde with rhodanine, subsequent hydrolysis in alkaline medium, and acidification with mineral acid. Recrystallization from benzene or toluene under nitrogen yielded products with m.p. 159° (3S2MP) and 178° (3N2MP). The purity was tested by thin-layer chromatography, and determined by potentiometric and thermometric titrations with sodium hydroxide in aqueous ethanol (purity > 99.5%).

For 3S2MP analysis gave C 63.9%, H 4.8%, S 15.4%; $C_{11}H_{10}O_2S$ requires C 64.05%, H 4.89%, S 15.51%. For 3N2MP analysis gave C 64.7%, H 4.3%, S 13.7%; $C_{13}H_{10}O_2S$ requires C 64.60%, H 4.38%, S 13.90%.

The solubilities (g per 100 ml of solution at 25°) were determined by the Wittenberger technique,[12] and were (3S2MP given first): water (0.05, 0.07); ethanol (1.20, 5.45); isoamyl alcohol (1.42, 1.90); acetone (3.70, 6.30); methyl isobutyl ketone (1.38, 3.91); chloroform (3.19, 2.98); diethyl ether (1.80, 3.97); toluene (1.16, 0.75); benzene (0.90, 0.95); hexane (0.01, 0.02). The ultraviolet–visible spectra were in accordance with the literature.[10] The infrared spectra (KBr

Table 1. pKa values in water–ethanol medium at $25 \pm 0.1°$

discs) had characteristic bands (cm^{-1}) at 1275 (C–O), 1410 (O–H), 1660 (C = O) and 2560 (S – H) for 3S2MP, and 1255 (C–O), 1330 (O–H), 1645 (C = O) and 2600 (S–H) for 3N2PP.

Procedures

Acidity constants. The dissociation equilibria were studied at $25 \pm 0.1°$ by titration[13] in 50% v/v water–ethanol with sodium hydroxide, because the compounds are poorly soluble in water, at two ionic strengths (0.2 and 1.0M) with sodium perchlorate as ionic medium. Before and during the titration pure nitrogen[14] was passed through the solution to remove dissolved oxygen.

The pK_{a_2} value was also determined spectrophotometrically[15] with $5 \times 10^{-5}M$ mercapto acid in aqueous medium containing 1% ethanol and at 0.01M ionic strength. Great care was taken to avoid oxidation, but some did occur. Therefore, absorbance measurements at the analytical wavelengths were made immediately after preparation of the solutions.

Thermometric titrations and heats of neutralization. The mercapto acids were titrated thermometrically with sodium hydroxide in water–ethanol medium at 0.2M ionic strength (sodium perchlorate), and the heats of neutralization were determined. The procedure has already been described.[6]

The enthalpies of neutralization were determined from the heat capacity of the cell (Q), measured by means of a reaction of known enthalpy [neutralization of hydrochloric acid with sodium hydroxide ($\Delta H = -13.35$ kcal/mole at 25°),[16] which in 50% v/v water–ethanol has the same value[6]]. The temperature increments were measured by the Barthel method.[17] The heat capacity of the cell was found by means of the equation for an adiabatic system.

$$n \Delta H + Q \Delta T = 0$$

where n moles of HCl are titrated, ΔH is the enthalpy change of the reaction (cal/mole) and ΔT the temperature change. The value of Q was found to be 37.0 ± 0.1 cal/deg

under the conditions used. From this value the heats of neutralization of the mercapto acids can be determined from the temperature increase in their titration.

Reactions with metal ions. These were investigated by the Benedetti-Pichler technique[18] for the whole pH range, with a 1% ethanolic solution of the reagent and 1-g/l. solutions of the metal ions.

RESULTS AND DISCUSSION

Dissociation equilibria

The pK_a values in water–ethanol medium were determined from the overall protonation constants β_1 and β_2, calculated by the linearization method of Irving and Rossotti.[19] The experimental data were treated by the least-squares program MINIPOT.[20]

Table 1 shows the pK_a values for the two acids, and Figs. 1 and 2 show the theoretical formation curves ($\bar{n}$ *vs.* log h) and the experimental points for the titrations done at 1.0M ionic strength.

The pK_{a_2} values were also determined spectrophotometrically because the experimental conditions (aqueous medium with 1% ethanol, low concentration and ionic strength) are such that the experimental pK_a values are close to the thermodynamic values and can be compared with those for other 3-aryl-2-mercaptopropenoic acids. Figures 3 and 4 show the spectra of 3S2MP and 3N2MP solutions at various pH values. The wavelengths of the absorption maxima were used as analytical wavelengths. Table 2 shows the results obtained.
Fig. 1. Formation curve for 3S2MP (solid line = theoretical curve). $\triangle$, [3S2MP] = $1.752 \times 10^{-3}M$; $\bigcirc$, [3S2MP] = $1.997 \times 10^{-3}M$; $\square$, [3S2MP] = $2.899 \times 10^{-3}M$.
Fig. 2. Formation curve for 3N2MP. $\bigcirc$, [3N2MP] = $1.297 \times 10^{-3}M$; $\triangle$, [3N2MP] = $3.361 \times 10^{-3}M$; $\square$, [3N2MP] = $2.418 \times 10^{-3}M$.
Fig. 3. Spectra for the determination of pK_{a2} of 3S2MP. For this compound, some oxidation has occurred during the recording of each spectrum and this accounts for the poor isosbestic points.

Table 2. pKa_2 values in aqueous medium at 22 ± 0.5 and $I = 0.01M$

pKa_2	7.96 ± 0.03	8.73 ± 0.02

were formed with many cations that form insoluble sulphides, and some colour reactions were obtained with transition metals. The complexes formed were readily extracted with polar organic solvents (isoamyl alcohol, MIBK, diethyl ether).

Notable reactions are the red colour with Ti(IV) ($pD = 7$ by extraction, *i.e.*, dilution limit is $\sim 0.1\ \mu g/ml$) in acetic acid–acetate medium (this reaction does not occur with saturated aryl mercaptoacids). Another interesting reaction is that of Ni(II) in alkaline medium ($pD = 6.5$) because the few interfering ions are easily removed. Table 3 lists the most sensitive reactions. The sensitivity of reactions is expressed in terms of pD [*i.e.*, $-\log$(dilution limit)].

Reactions with metal ions

The reactions are similar to those of other 3-aryl-2-mercaptopropenoic acids.[2,3] Precipitates

Thermometric titrations

The titration curves for both mercapto acids display two equivalence points, corresponding to the successive neutralization of the carboxylic and thiol groups. From the shapes of the curves it is concluded that both mercapto acids can be determined by thermometric titration. The titration error was found to be less than 1%.

A CONTRIBUTION TO THE USE OF THORIN AS AN ANALYTICAL REAGENT: SPECTROPHOTOMETRIC STUDY OF ITS COMPLEXATION WITH BARIUM AND APPLICATION TO SULPHATE DETERMINATION IN ATMOSPHERIC PARTICULATES*

P. Bruno, M. Caselli, A. Traini and A. Zuffianò
Dipartimento di Chimica, Università di Bari, 70126 Bari, Italia

Summary—The complexation of Ba^{2+} by Thorin in the pH range 2–9 in aqueous ethanol medium has been investigated. The dissociation constants of Thorin in the ethanolic medium have been determined spectrophotometrically and the distribution of the protonated species has been used to explain the behaviour of the apparent complexation constant. On the basis of the apparent constants found, and mass-balances, the effect of sulphate on the absorbance has been calculated, and the best conditions for determination of sulphate have been established. Cation and anion interferences have been studied and means of overcoming them are proposed. The method developed has been applied to sulphate determination in atmospheric particulates. As little as 1 μg of sulphate can be measured.

Since its introduction by Kuznetsov,[1] 1-(*o*-arseno-phenylazo)-2-naphthol-3,6-disulphonic acid (Thorin) has found wide application in analytical chemistry. It forms complexes with practically all metals. Thorium,[2] lithium,[3] bismuth,[4] lanthanides[5] and beryllium[6] have been detected by reaction with Thorin. The complexes with uranium(VI),[7] and magnesium, calcium and strontium[8] have been studied and the reagent has been recommended as an indicator in the titrimetric determination of sulphate[9,10] and for the determination of sulphur dioxide,[11] sulphur trioxide[12] and sulphuric acid.[13]

Although an extensive investigation on the effect of pH and alcohol concentration has been reported by Haartz,[14] the titration method is not the most suitable for small quantities of sulphate, and concentrations below $10^{-4}M$ give erroneous results.

A colorimetric Thorin method for sulphate has been proposed by Persson[15] and reviewed by Bertolaccini,[16] but the optimum pH and barium concentration were not thoroughly considered in either paper.

Here we present a study on the complexation of barium by Thorin at pH 2.0–9.0 in 60% v/v ethanol medium (54% w/w). The dissociation constants of Thorin in this solvent have been determined spectrophotometrically and the results used to interpret the behaviour of the apparent complexation constant. The effect of sulphate on the absorbance has been calculated and the optimum conditions for sulphate determination predicted.

The method thus designed has been applied to determination of sulphate in real samples of atmospheric particulates. Quantities of sulphate as small as 1 μg can be determined.

EXPERIMENTAL

Apparatus

A Perkin–Elmer 555 spectrophotometer and an Orion 901 Ionanalyzer were used. The glass electrode was standardized with acetic acid/sodium acetate and ammonium perchlorate/ammonia buffers prepared in 60% v/v ethanol medium. The pK_a values for acetic acid (5.97) and ammonium ion (8.55) in aqueous ethanol were calculated by the relationships:[17]

$$\Delta pK_a(HA) = \log f_{H+} + m_- y_-$$

$$\Delta pK_a(BH^+) = \log f_{H+} + m_0 y_0$$

Values for $\log f_{H+}$, m_-, y_-, m_0, y_0 are reported in (or can be easily calculated from) the literature.[17–19] Once standardized in this way, the electrode reproduced within 0.02 units the pH values calculated by these equations for acetic acid/sodium acetate, ammonium/ammonia and formic acid solutions.

The dissociation and complexation constants were measured at 25°, but no temperature control was used for analytical determinations.

Airborne particulates were sampled with Millipore 0.45-μm filters in a Tecora Ecol CTE electronic atmospheric sampler.

Reagents

The Thorin (RPE, C. Erba) was recrystallized from water. A standard stock solution was prepared and checked by titration.[20] All other reagents were of analytical grade.

RESULTS

pK_a of Thorin in aqueous ethanol

The absorbances of Thorin in aqueous ethanol were measured at 520 (Fig. 1A) and 430 nm as a
Fig. 1. Absorbance of $6.45 \times 10^{-5}M$ Thorin vs. pH. (A) Experimental curve at variable ionic strength; (B) at $\mu = 0.1M$ (NaClO$_4$); (C) Curve calculated from data reported in Table 1.

function of pH, and also (Fig. 1B) with the ionic strength kept constant at 0.1 with sodium perchlorate. For Fig. 1A the sodium concentration was the minimum compatible with the pH values; for pH < 11 it was $< 5 \times 10^{-4}M$. The pH-shift on increase of the sodium concentration is too large to be ascribable to an ionic strength effect, and clearly shows complexation of sodium by Thorin. This effect will be described and evaluated later, but for the moment we can say that sodium has no substantial influence on the absorbance if its concentration is $< 10^{-4}M$. The pK_a values for the various protonated Thorin species were obtained from curve A in Fig. 1 and are reported in Table 1 together with the molar absorptivities of the conjugate bases, and other results. The first proton is completely dissociated even at the lowest pH. The real value of pK_5 is probably higher than 13.3 because at this pH level the sodium concentration is high enough to produce a shift towards lower pH. The value reported in Table 1 is

merely indicative. However, if pK_5 is ≥ 13.3 it does not influence the distribution of the protonated species at pH < 11. The averages of the pK_a values in aqueous solution[20,21] give a meaningful linear correlation ($r = 0.9965$) with the pK_a values in the mixed solution:

$$pK_{\text{EtOH(54\%)}} = 1.52 + 1.02\, pK_{\text{H}_2\text{O}} \qquad (1)$$

This is rather surprising because the extent of ionization of a given acid in two different media is determined by (a) the basicity of the solvent and (b) the dielectric constant. Water is 400 times as basic as ethanol,[22] irrespective of the acid ionized, but (b) depends on the electrostatic energy involved in the charge separation. According to Wynne-Jones[23] the electrostatic contribution to ΔpK between two media can be expressed by

$$\Delta pK_{\text{el}} = \frac{e^2}{4.6KTr} \frac{(D_2 - D_1)}{D_1 D_2} \left(1 - \frac{2z_B + 1}{R}\right) \qquad (2)$$

where r is the radius of H_3O^+, $R = r_{AH}/r_{H_3O^+}$, z_B the charge on the conjugate base of the acid AH, and D_1 and D_2 are the dielectric constants of the two media. Therefore ΔpK_{el} should increase with increasing z_B and ΔpK should increase for successive dissociations of a polyprotic acid. However, if R is large enough, the second term in parentheses in equation (2) can be neglected, and in that case, for Thorin the sum of ΔpK_{el} and of the basicity effect (assumed roughly proportional to the mole fraction of ethanol) is very close (1.33) to the intercept of equation (1).

Figure 2 is a distribution diagram for the protonated species of Thorin (α_i) as a function of pH. In this calculation the pK_2 determined at 520 nm is used, since the first inflexion is poorly defined in the measurements made at 430 nm. From the α_i and ϵ_i values reported in Table 2, the absorbance vs. pH curve can be recalculated (dashed line, C, in Fig. 1).

Determination of the Ba^{2+}–Thorin apparent complexation constants

When a barium salt is added to an aqueous ethanol solution of Thorin the absorbances near 520 and 430 nm increase and decrease respectively. Between these

wavelengths there is an isosbestic point (Fig. 3), behaviour typical of a metal–ligand complex.

Figure 4 plots the absorbances for $6.45 \times 10^{-5}M$ Thorin mixed with various concentrations of barium (C_{Ba}) for different values of pH obtained by addition of $HClO_4$, CH_3COOH/CH_3COONa, NH_4ClO_4/NH_4OH, according to the pH required. When cations were added in the buffers, their concentration was kept below $10^{-3}M$. As shown later, this concentration does not produce detectable error in the equilibrium constant, provided that $C_{Ba} > 4 \times 10^{-5}M$ is used for the calculations and the absorbances at a given pH in absence of barium (A_0) are taken from curve A in Fig. 1. Figure 4 shows that for pH > 7 the plots are linear for low C_{Ba} and give constant absorbance at high C_{BA}. The extrapolated linear portions intersect at a C_{Ba} value practically equal to the Thorin concentration, indicating a 1:1 complex with a relatively high formation constant. At lower pH the plots become more rounded and do not reach a constant absorbance. For $C_{Ba} > 4 \times 10^{-4}M$, and after a period of time depending on the pH, a red precipitate appears, which is found by atomic-absorption analysis to contain 20.6% barium, in good agreement with a 1:1 complex. The infrared spectrum shows changes

from that of Thorin, in the ranges 1230–1120 and 1080–1025 cm^{-1}, corresponding to the SO-stretching of RSO_3^- groups.[24]

The curves in Fig. 4 have been analysed to obtain K_{app}, according to the relationship

$$K_{app} = \frac{(A - A_0)(A_\infty - A_0)}{(A_\infty - A)\{C_{Ba}(A_\infty - A_0) - C_T(A - A_0)\}} \quad (3)$$

where A_∞ is the limiting absorbance, A the absorbance corresponding to C_{Ba}, and C_T is the analytical Thorin concentration. Equation (3) is readily obtained by taking into account the complex and free ligand absorbances and the mass balance. As will be shown in the discussion, equation (3) is still valid even if several 1:1 complexes with different ionic forms of a polyprotic acid are formed simultaneously, but in this case K_{app} is a function of α_i and K_i. When the absorbance reaches no limiting value in the range of possible barium concentrations, equation (3) can be put into the form:[25]

$$F(A) = \frac{[Ba^{2+}]C_T}{A - A_0} = \frac{1}{K_{app}(\epsilon_{app} - \epsilon_0)} + \frac{[Ba^{2+}]}{(\epsilon_{app} - \epsilon_0)} \quad (4)$$

where $\epsilon_{app} = A_\infty/C_T$. As $[Ba^{2+}]$ is unknown, in prin-

Fig. 3. Spectrum of Thorin in the presence of Ba^{2+}. $C_T = 6.45 \times 10^{-5}M$; pH = 5.7; (1) Thorin; (2–6) increasing concentration of Ba^{2+}.

ciple an iterative convergence process can be used, starting from the analytical barium concentration.

Examples of the linear plots obtained for $F(A)$ vs. $[Ba^{2+}]$ are shown in Fig. 5. The K_{app} and ϵ_{app} values are collected in Table 2, together with the α_i values corresponding to a given pH. The K_{app} values were found to be reproducible within $\pm 10\%$ for the lower pH levels and within 50% for pH > 7. At pH = 9.1 the fraction of uncomplexed barium is only about 10% when $C_{Ba} = C_T$ and the error in K_{app} can then be
Fig. 4. Absorbance *vs.* C_{Ba} at $\lambda = 520$ nm; pH reported on each curve; $C_T = 6.45 \times 10^{-5}M$.

greater. The K_{app} reported in Table 2 for this pH must be considered as only indicative; an error of 100% is possible. For pH > 9, K_{app} becomes too high to be obtained by spectrophotometric methods.

DISCUSSION

True Ba–Thorin complexation constant determination

The behaviour of K_{app} in Table 2 is such that it cannot be explained by assuming complexation by only one of the ionized forms of Thorin (since K_{app} should then be proportional to one of the sets of α_i values). Both α_2 and α_3 present a maximum (at pH 4.6 and 7.7 respectively); α_4 has monotonic behaviour in the pH range considered, but does not show any proportionality to K_{app}. However, if we suppose that barium forms 1:1 complexes with more than one form of Thorin we shall have:

$$A = \sum_{i=0}^{i=5} (\epsilon_i^T [T_i] + \epsilon_i^C [BaT_i]) \qquad (5)$$

where

$$[T_i] = [H_{5-i}T^{i-}] = \alpha_i C_{NC} = \alpha_i (C_T - \Sigma[BaT_i]) \quad (6)$$

$$[BaT_i] = K_i[Ba^{2+}][T_i] \qquad (7)$$

C_{NC} is the concentration of non-complexed Thorin and ϵ_i^T and ϵ_i^C are the molar absorptivities of T_i and BaT_i respectively. From (6) and (7), we have

$$C_{NC} = \frac{C_T}{1 + [Ba^{2+}]\Sigma\alpha_i K_i} \qquad (8)$$

From (7) and (8) we can rewrite (5) as

$$A = \frac{C_T(\Sigma\alpha_i\epsilon_i^T + [Ba^{2+}]\Sigma\epsilon_i^C\alpha_i K_i)}{1 + [Ba^{2+}]\Sigma\alpha_i K_i} \qquad (9)$$

Putting $\Sigma\alpha_i K_i = K_{app}$ and $\Sigma\epsilon_i^C\alpha_i K_i/\Sigma\alpha_i K_i = \epsilon_{app}$, we

can write (9) in the form

$$A - A_0 = \frac{C_T[Ba^{2+}](\epsilon_{app} - \epsilon_0)K_{app}}{1 + [Ba^{2+}]K_{app}} \qquad (10)$$

where $A_0 = C_T\epsilon_0 = C_T\Sigma\alpha_i\epsilon_i^C$. Equation (10) is the same as (4). Alternatively, since

$$\Sigma[BaT_i] = C_T - C_{NC} = \frac{C_T K_{app}[Ba^{2+}]}{1 + K_{app}[Ba^{2+}]} \qquad (11)$$

equation (10) can be written as

$$A - A_0 = (\epsilon_{app} - \epsilon_0)\Sigma[BaT_i]$$
$$= (A_\infty - A_0)\frac{\Sigma[BaT_i]}{C_T} \qquad (12)$$

or

$$\frac{A - A_0}{A_\infty - A} = \frac{\Sigma[BaT_i]}{C_{NC}} = K_{app}[Ba^{2+}]$$
$$= K_{app}(C_{Ba} - \Sigma[BaT_i]) \qquad (13)$$

If $\Sigma[BaT_i]$ from (12) is substituted in (13), solving for K_{app} gives equation (3).

The K_i value can be obtained from $\Sigma\alpha_i K_i = K_{app}$ by iteration if there are ranges where a single complex strongly predominates. In this case a straight line with a slope very close to unity will be obtained for a log–log plot of K_{app} against the right α_i. This happens for pH 2.0–4.2 if log α_2 is taken as abscissa. Further, in this pH range the relatively low solubility and the infrared spectrum are in agreement with formation of the neutral salt H_3BaT.

Once a first approximation is obtained for K_2, it is possible to obtain first approximations for K_3 and K_4 by plotting log $(K_{app} - \alpha_2 K_2)$ vs. log α_3 in the range pH 5–7 and log $(K_{app} - \alpha_2 K_2 - \alpha_3 K_3)$ in the range pH 7–9. The values can then be refined by iteration. Figure 6 shows the final straight lines for

$$\log\left(K_{app} - \sum_{j\neq i} \alpha_j K_j\right) \text{ vs. } \log \alpha_i.$$

Final values for K_i are: $K_2 = 6.9 \times 10^4$, $K_3 = 2.0 \times 10^5$ and $K_4 = 1.0 \times 10^7$. The slope for the K_4 plot is 0.8 and this can be attributed to the low precision for K_{app} at the highest pH.

In Fig. 7 experimental values for log K_{app} (circles) are compared with those calculated from $\Sigma\alpha_i K_i = K_{app}$ (continuous line).

Effect of complexation by buffer cation

Univalent ions are complexed by Thorin though less strongly than bivalent ions. To evaluate their effect, the apparent complexation constants were measured at various pH levels for Na^+ and NH_4^+ (Table 3). It is rather surprising that even for univalent ions equation (3) gives a constant value of K_{app} for a 1:1 (T_iM^+) complex but not a 1:2 complex. However, a plot of absorbances vs. $[M^+]$, at pH 8.0, gives a plateau and then an absorbance increase when the cation concentration exceeds $10^{-2}M$.
Fig. 5. $F(A)$ (see text) vs. $[Ba^{2+}]$ for different values of pH.
Fig. 6. Final iteration for

$$\log \left(K_{app} - \sum_{j \neq i} K_j \alpha_j \right) \text{ vs. } \log \alpha_i.$$

Numbers in parentheses are the corresponding pH values.

In presence of both barium and a univalent ion, equation (10) becomes

$$A - A_0 =$$
$$\frac{C_T \{ [Ba^{2+}] K_{app}^{Ba} (\epsilon_{app}^{Ba} - \epsilon_0) + [M^+] (\epsilon_{app}^{M} - \epsilon_0) K_{app}^{M} \}}{1 + [Ba^{2+}] K_{app}^{Ba} + [M^+] K_{app}^{M}}$$

$$(14)$$

Fig. 7. Experimental log K_{app} (circles) *vs.* pH compared with the values calculated by equation (9) (continuous line).

Of course the M^+ effect is negligible if $K_{app}^{Ba}[Ba^{2+}] \gg K_{app}^{M}[M^+]$. To evaluate the influence of M^+, theoretical absorbances were calculated from equation (14), taking into account the mass balances for the chemical species. Numerical values introduced into equation (14) were: $K_{app}^{Ba} = 6.0 \times 10^4$, $K_{app}^{Na} = 70$, $C_{NA} = 4.0 \times 10^{-3} M$, $C_T = 6.45 \times 10^{-5} M$, $\epsilon_{Ba} = 1.67 \times 10^4$, $\epsilon_{Na} = 1.25 \times 10^4$, $\epsilon_T = 7.13 \times 10^3$ $1.mole^{-1}.cm^{-1}$. These data correspond to pH = 4.6, where the ratio K_{Ba}/K_{Na} is the most unfavourable. The calculated absorbances, when introduced into equation (3) (used without correction for the presence of Na^+) gave $K_{app}^{Ba} = 6.1 \times 10^6$, for Ba concentrations > 4.0 $\times 10^{-5} M$.

Fig. 8. Absorbance of a Ba–Thorin solution during a precipitation by SO_4^{2-}, calculated for different values of K_s. $C_T = 6.45 \times 10^{-5} M$; $C_{Ba} = 4.0 \times 10^{-5} M$; $C_{Na} = 4.0 \times 10^{-3} M$; $K_{app}^{Ba} = 4.6 \times 10^5$; $K_{app}^{Na} = 330$; $\epsilon_0 = 1.02 \times 10^4$; $\epsilon_1 = 1.86 \times 10^4$; $\epsilon_{Na} = 1.27 \times 10^4$ $1.mole^{-1}.cm^{-1}$; (A) $K_s = 5 \times 10^{-11}$; (B) $K_s = 9 \times 10^{-12}$; (C) $K_s = 5 \times 10^{-12}$; (D) $K_s = 1 \times 10^{-12}$.

Effect of sulphate on Ba–Thorin complex

When sulphate is added to a soultion containing Thorin and a barium salt, buffered at a given pH, in such a quantity that the solubility product for barium sulphate is exceeded, the concentrations are ruled by the relationships:

$$C_T = \Sigma[BaT_i] + \Sigma[MT_i] + \Sigma[T_i];$$

$$[SO_4^{2-}] = C_{SO_4} - C_{Ba} + \Sigma[BaT_i] + [Ba^{2+}];$$

$$C_M = \Sigma[MT_i] + [M^+];$$

$$K_{app}^{Ba} = \frac{\Sigma[BaT_i]}{[Ba^{2+}]\Sigma[T_i]};$$

$$K_{app}^{M} = \frac{\Sigma[MT_i]}{[M^+]\Sigma[T_i]};$$

$$K_s = [Ba^{2+}][SO_4^{2-}]$$

Figure 8 shows the calculated absorbance vs. analytical concentration of sulphate when the initial total barium concentration is $4.0 \times 10^{-5}M$. Curves are calculated for pH 8.0 and different values of the solubility product. The pH is supposedly buffered by NH_4^+/NH_3, assuming $[NH_4^+] = 4.0 \times 10^{-3}M$. Values of K_{app}^{Ba} and K_{app}^{Na} are taken from Fig. 7 and Table 3. The absorbance is a linear function of C_{SO_4} practically up to the equivalence point if the solubility product is $K_s < 2.0 \times 10^{-12}$.

Figure 9 shows the calculated differences $(A_i - A)$ plotted vs. C_{SO_4} where A_i is the absorbance of the barium–Thorin solution in absence of sulphate. The curves can be obtained experimentally if the barium–Thorin solution is positioned in the spectrophotometer sample compartment and the barium–Thorin–sulphate mixture in the reference compart-

ment. Different pH levels and initial concentrations of barium are considered in Fig. 9. A value of 1.0×10^{-12} was used for K_s, on the basis of the better fit between the experimental and calculated curves. The curves for low pH are linear for a wide range of initial Ba concentration, but the sensitivity is low. The curves for pH 5 present the best sensitivity. They are linear up to $C_{SO_4} = 2.5 \times 10^{-5}M$ if $C_{Ba} = 4.0 \times 10^{-5}M$ and present no linearity at all if $C_{Ba} = 8.0 \times 10^{-5}M$. The curves for pH 8 have slightly lower sensitivity but better linearity than those at pH 5.

ANALYTICAL APPLICATIONS

Calibration plots and foreign ion effects

The equations reported above allow some prediction of the best conditions for analytical use of Thorin. For instance, calculation of the curves for titration of sulphate with barium (Fig. 10) shows that the error rapidly increases as the sulphate concentration decreases. The limiting sulphate concentration for acceptable error is $1.0 \times 10^{-4}M$. In effect the relative error decreases with decrease of Thorin concentration, but a limit is set by the ability to discriminate the colour change visually. Moreover,

titrations at pH < 3 involve a great excess of titrant, as shown experimentally for propyl alcohol medium.[14] Some of these difficulties can be overcome by a spectrophotometric determination. Table 4 gives the relevant parameters for calibration plots at 520 nm, for pH 5 and 8. The sensitivity is slightly better at pH 5, but the choice of pH effectively depends on the interferences. To verify, this the effect of cations and anions was studied. Cations were added as the perchlorate salts, since this anion has a negligible effect on the absorbance. Univalent cations give negative errors and can be tolerated at up to ten times the sulphate concentration. The tolerance limits for bivalent cations are much lower, so their preliminary removal by ion-exchange is practically essential.

The effect of the anions most frequently present in atmospheric particulates is reported in Fig. 11. The error due to phosphate is the most serious. If present, phosphate must be removed, for instance with magnesium carbonate. Other anions generally give positive errors. Should the quantity of nitrate or chloride be large, a separation of sulphate on a weakly basic anion-exchanger, with a dilute carbonate solution as eluent, is advisable, but this is a time-consuming operation. Hence, a larger margin of error may be tolerated as the price of a more rapid analysis. Alternatively, the error in the sulphate determination can be minimized if the same amount of interfering anions is added to the Ba–Thorin reference solution. Under these conditions a level of nitrate up to fifty

times that of the sulphate gives a negligible error. This procedure is not always possible, however, e.g., for phosphate, and demands a previous analysis for interfering anions. In some cases, however, e.g., for atmospheric particulates, such analyses are more or

*Without compensation for interfering anions.

less routine. Interference of anions is generally higher at pH 8 than at pH 5, so this pH is chosen for atmospheric particulate analysis.

Analysis of atmospheric particulates

Since the sulphate fraction in atmospheric particulates essentially consists of soluble sulphates,[26,27] the filter was leached with 10 ml of boiling water. Then 2 ml of the extract were passed through a cation-exchange column (10 cm × 0.7 cm i.d., packed with a Dowex 50W-X8, 100/200 mesh, hydrogen-form exchange resin); the effluent and ~3 ml of rinsing water were collected in a 25-ml standard flask; 15 ml of ethanol, 500 μl of $0.2M$ sodium acetate, 3 ml of $0.2M$ acetic acid, 400 μl of 0.2% Thorin solution and 100 μl of $1.0 \times 10^{-2}M$ barium perchlorate were added, the volume was adjusted to the mark and the absorbance was read in a 500-μl microcell against a corresponding Ba–Thorin solution after 10 min.

Sulphate was determined by standard addition of $5.0 \times 10^{-3}M$ sulphate (0.2–1 μl). Results of five analyses are reported in Table 5. The results for the chloride analysis (turbidimetric method), nitrate (Saltzman method[28] after reduction with zinc) and phosphate (molybdenum blue method[29]) are also presented in Table 5. Since the phosphate/sulphate ratio was lower than 0.1 and the maximum quantity of nitrate was such that 10% maximum error could be estimated (see Fig. 11) no anion-exhanger was used, but the nitrate effect was compensated for as described above.

CONCLUSIONS

The absorbance of the barium–Thorin complexes in presence of sulphate allows the determination of small amounts of sulphate. Attention to the effect of pH and buffer composition on the complexation allows choice of the best conditions for the analysis. For analysis of atmospheric particulates the best results are obtained at pH 5. The detection limit is about 0.15 μg/ml and quantities as low as 1 μg of sulphate can easily be detected.

This method can be used for the determination of other anions (for instance phosphate) giving insoluble barium salts.

CHROMATOGRAPHIC ANALYSIS OF PHOSPHOLIPID AND CHOLESTEROL OXIDATION

Ulrich J. Krull, Michael Thompson and Anita Arya
Chemical Sensors Group, Department of Chemistry, University of Toronto, 80 St. George Street,
Toronto, Ontario, Canada

Summary—Capillary thin layer and gas chromatographic methods for analysis of the extent of oxidation in phosphatidyl choline/cholesterol samples are described. Examples of systems suitable for qualitative and quantitative analysis, based on use of unmodified samples or of their derivatives, are illustrated. A method for concurrent quantitative determination of phospholipid and sterol without preseparation is introduced and is based on extension of a previous lipid trans-methylation technique.

The analysis of the various classes of lipids, including the sterol group, has been the subject of intensive study for the last thirty years. Separation and determination are often difficult, owing to the chemical similarity of the large number of species present in most natural samples, and the amphipathic (asymmetrically polar) and often zwitterionic nature of these molecules. Numerous methods have been developed for separation of lipids into well defined groups, followed by use of more specialized techniques and methods for identification within a particular class.

Qualitative analysis can be accomplished through use of derivative formation coupled with techniques such as thin-layer chromatography (TLC) on plates treated with silver nitrate or reverse-phase TLC gas chromatography, and reverse-phase high-pressure liquid chromatography.[1] Identification generally involves acyl chain determinations since particular lipid classes are defined in terms of their polar head-groups. Formation of derivatives by means of head-group cleavage followed by acetylation or silylation,[2] or by trans-esterification[3] at the ester linkages connecting fatty acid moieties to the head-group region encompasses the most prevalent methods of sample preparation. Many products, including cholesterol derivatives (of which there are more than 50 because of autoxidation[4]), free fatty acids and esters, can be readily chromatographed on TLC plates and can be detected by use of specific spray reagents and compared with known standards.[5] Lipids which contain unsaturated acyl chains are also susceptible to autoxidation through an autocatalytic process.[6–10] The reactivity of such species is partially determined by the number of double bonds in a chain. For example, a linoleic hydrocarbon is twentyfold more reactive than an oleic chain, and susceptibility to oxidation increases at least twofold for each additional double bond.[6] One method of determining the extent of acyl chain oxidation for chains with two or more double bonds is based on the fact that autoxidation produces compounds with conjugated systems which can be determined by ultraviolet spectrophotometry.[11] A more general quantitative method involves the use of gas chromatographic techniques for separation of lipid acyl chain methyl esters, which are the derivatives of choice in such analyses.[1]

Gas chromatographic analysis of lipid and sterol derivatives has been performed, for the most part, on packed column systems, although capillary columns, particularly those constructed from glass, have been used with considerable success.[12] Lipid derivatives in common use for gas chromatography include those obtained by boron trifluoride–methanol treatment,[13] and acid[14] and base[3] catalysed trans-esterifications. Difficulties encountered with the first two methods include dependence of the reaction on sample size, and undesirable side-reactions.[15] The base-catalysed reactions are rapid, clean and efficient and are suitable for sample sizes as small as 1 mg.

Gas chromatographic analysis of cholesterol and its oxidation products is commonplace, though proper resolution of such compounds usually necessitates preseparation from other lipid materials in the sample matrix.[1,4] A typical approach involves preparative TLC followed by sample isolation, formation of the silyl or acetyl derivatives and dissolution in a volatile organic solvent.

This paper reports procedures for routine evaluation of the extent and nature of oxidation in lipid/sterol samples, a critical factor in lipid membrane technology. Concurrent quantitative analyses for lipid and sterol are performed by high-efficiency capillary gas chromatography without preseparation. In addition, rapid TLC methods for quality control are described.

EXPERIMENTAL

Reagents

The lipid employed exclusively in this work was phosphatidyl choline derived from eggs (Avanti Biochemicals

Table 1. Thin-layer chromatographic solvent systems for separation of cholesterol and lipid oxidation products

Method	Number of plate irrigations	Solvents	Solvent ratios, v/v	Detection system	Purpose
1	1	$CHCl_3/MeOH/H_2O$	4/1/0.1	Acidic phosphomolybdate spray, 150° char (where applicable for reference standard)	Separation of lipid and cholesterol for subsequent capillary chromatographic analysis
2	1	$CHCl_3/MeOH/H_2O$	3/1/0.1	As above	Analysis of lipid oxidation
3	2	Ethyl acetate/heptane	1/1	UV characterization followed by cerium/H_2SO_4 char at 150°	Analysis of cholesterol oxidation
4	2	Ethyl acetate/heptane	1/2	As above	As above
5	1	Ethyl acetate/heptane	7/1	As above	As above
6	1	Benzene/ethyl acetate	3/2	As above	As above
7	2	Hexane/diethyl ether	92/8	Cerium/H_2SO_4 char at 150°	Separation of lipid acyl chain methylates with 0–2 ethylenic residues
8	2	Hexane/diethyl ether	40/60	As above	As above, for separation of chains with 3–6 ethylenic residues

Inc., Birmingham, AL). Reagent-grade cholesterol (Research Plus Inc., Bayonne, NJ) was used as the primary sterol from which oxidized products were evolved.

Trans-methylation was performed with 0.5M sodium methoxide freshly prepared by reaction of sodium metal with methanol. Silylation was accomplished with Tri–Sil–Z (Pierce Chemical Company, Rockford, ILL). All other solvents were of reagent grade and were kept anhydrous.

Apparatus

Thin-layer Chromatography. Two types of glass-based chromatographic plate were employed for separation of cholesterol and lipid oxidation products. These were Anasil GF-250 (Analabs, North Haven, CT) and Sil G-25 HR (Macheray-Nagel, Duren, Germany), both 250-μm silica gel, and Sil G-25 UV254, a 250-μm silica gel hardened with gypsum and treated with a fluorescent agent with excitation maximum at 254 nm (Macheray–Nagel). The thickness of the plate coatings was chosen to optimize analytical separation while maintaining sufficient loading for subsequent extraction. The Anasil plates employed for lipid analysis required further preparation for methylate separation, which was based on resolution of lipid acyl chains having varying degrees of unsaturation. The procedure consisted of saturating the plates with 0.1M silver nitrate solution in 1:1 v/v methanol/water mixture. The solvent was removed with a warm air stream, then the plates were immediately baked at 110° for 20 min. This provided sufficient activation for methylate separation if the plates were used immediately after the baking.

Capillary gas chromatography. A conventional packed-column Varian Aerograph 2740-10 gas chromatograph (Varian Associates, Walnut Creek, CA) was modified for capillary gas chromatographic investigation of lipid oxidation. A glass-lined splitter assembly (Inlet Splitter System; Chromalytic Technology P/L), including a septum-purge and a buffer-volume to reduce gas viscosity effects, replaced the conventional inlet. The stainless-steel glass-lined inlet tubing and nickel outlet tubing were of 0.25 mm internal diameter and included a T-junction for make-up gas at the end of the column to reduce dead-volume effects. All tubing connectors were chosen to minimize dead-volume effects. The detector was based on a sensitive flame-ionization electrometer assembly, with hydrogen/air fuel mixture and helium as carrier and make-up gas. A separate gas-flow controller (Pressure Control System, Chromalytic Technology) was used because of the low volumes of gas required. The column employed was a 30 m × 0.25 mm ID Durabond fused-silica column with DB-1 (equivalent to SE-30) 0.25-μm coating and a practical efficiency of $N_{eff} = 10^5$ (J + W Scientific, Inc., Rancho Cordova, CA). Data analysis was performed with a Hewlett–Packard model 3390A reporting integrator.

Procedures

Thin-layer chromatographic techniques. Several solvent systems were employed for various separations of cholesterol and lipid oxidation products in decane solutions. These are summarized in terms of function and detection system in Table 1. Irrigation was performed in closed glass chambers which were initially purged with nitrogen. The solvent front was allowed to advance 12 cm, after which the detection system was applied or, after momentary warm-air drying, the plates were re-irrigated to increase separation and resolution before detection. Detection by means of charring consisted of evenly spraying the plates with a 1:1 v/v mixture of concentrated sulphuric acid and saturated aqueous ceric ammonium sulphate solution and heating to 150° for 10 min to produce a uniform black-brown char.

Routine TLC methods were employed for separation of phospholipid from sterols for standard gas chromatographic analysis. Table 1 gives some suitable systems

for the preseparation. Sterol products on the silica gel were manually removed from the TLC plates by scratching, then extracted with chloroform; the solutions were concentrated by evaporation and finally analysed by gas chromatography.

Derivative formation. The sterol products isolated in the TLC procedure could be chromatographed directly or first be modified by silylation to limit problems caused by thermal decomposition. A few mg of sterol product were placed in a dry Teflon-lined septum vial and 20 μl of Tri–Sil–Z (trimethylsilylimidazole in dry pyridine, 1.5 meq/ml) were added. After the mixture had been heated in a water-bath at 60° for 30 min (during which the vial was capped under a nitrogen blanket) the excess of pyridine was removed in dry conditions under nitrogen to concentrate the sample before gas chromatography of the silyl ethers.

Phospholipid modification for TLC and gas chromatographic analysis consisted of trans-methylation to produce methyl esters of the lipid acyl chains. Numerous methods of doing this have been described, but the best method for complete concentration-independent conversion of small samples employs a base-catalysed reaction.[3] The following method is a modification of a standard methylation procedure. The lipid sample (1–10 mg) was reacted for 15 min at 22° with a mixture of 1 ml of freshly prepared 0.5M sodium methoxide (in methanol) and 1 ml of dry benzene. The product was extracted with 3 ml of diethyl ether, which was then washed with two 3-ml portions of 1M aqueous sodium chloride. The diethyl ether/benzene extract was then dried over anhydrous sodium sulphate, concentrated with a stream of nitrogen and submitted to gas chromatography.

RESULTS AND DISCUSSION

Thin-layer chromatography

Thin-layer chromatography is the simplest and most versatile method suitable for general separation of the major oxidation products of both lipid and cholesterol. The results obtained for lipid/sterol mixtures by use of the preferred separation systems listed in Table 1 are summarized in Table 2. It must be emphasized that no universal method for complete separation exists and choice of method is determined by the resolving ability for a desired component. For unmodified samples a maximum of 3 lipid products and 15 sterols can be routinely separated.

The autoxidation of cholesterol involves initiation and propagation processes that act to produce reactive intermediates such as hydroperoxides and cholest-5-en-3-one,[4] which react to form the other commonly observed products. The sterols separated have been tentatively identified by use of standards and of various literature sources describing similar product mixtures and chromatographic systems.[5,16] Retention indices relative to cholesterol provide reproducible data suitable for identification of products, but confidence in the identification can be greatly increased by use of spray reagents or fluorescence methods selective for functional groups.[5,16]

Phospholipid analysis by TLC is a much more difficult task, since the molecules are amphipathic and also contain ionized groups in the head-group zone. Standard procedures can separate classes of

phospholipids only poorly, and determination of structural unsaturation is generally not possible. A number of enzymatic methods have been employed to cleave the charged groups from phosphatidyl cholines and ethanolamines, resulting in mixtures which can be separated by conventional TLC systems;[2] however, identification of acyl chain unsaturation remains difficult. Such work can be readily performed after treatment of the phospholipid to form methyl esters of the acyl chains. Base-catalysed trans-methylation provides a clean, efficient one-step process which is apparently not concentration-dependent and does not cause isomerization at the double bonds.[1,3] Specially prepared TLC plates are required for analysis of the unsaturated methyl esters, since separation must be largely based on the subtle differences between similar long-chain hydrocarbons. Plates treated with silver nitrate provide active silver sites for binding with the π-orbital electrons of ethylenic or acetylenic bonds. The sample migration rate on the plate is almost entirely determined by the number of available unsaturation sites, since retention increases with π-orbital complexation. Plates are conventionally prepared by mixing solid silver nitrate (5–10% w/w) with the silica gel G/water slurry employed for plate-coating. The simplified method of plate preparation employed in this work also achieved reproducible results but was extremely sensitive to plate activation by the baking process.[17]

Table 3 presents typical data obtained with these TLC plates and illustrates the value of changing the solvent ratio for separation of unsaturated acyl chains. All the TLC methods described here are generally only suitable for qualitative analysis, though quantitative work by means of a scanning densitometer is possible.

Capillary gas chromatography

Gas chromatographic analysis optimizes qualitative results and simplifies determination since the concentrations of similar materials can readily be

Fig. 1. Capillary gas chromatogram of cholesterol and autoxidation products after sterol silylation. The column was a 30 m × 0.5 mm G SCOT/B system coated with OV101. Separation under isothermal conditions with a column temperature of 280°C and an injection temperature of 300°C.
Fig. 2. Capillary gas chromatogram of unmodified cholesterol and autoxidation products. The column was a 30 m × 0.25 mm fused silica system permanently coated with DB-1 (equivalent to SE-30). The injection temperature was 325°C, and temperature programming was started on injection, from 200°C to 280°C at 4°C/min. The initial attenuation factor was 16, reduced to 2 after 8 min, and 1 after 12 min.

found by normalization of the peak areas. The problems encountered in the separation of closely related materials are alleviated by use of high-efficiency capillary columns. The inherent sensitivity of flame-ionization detection is sufficient to measure nanogram quantities of the lipid materials investigated.

Sterol analysis is conventionally performed by TLC separation of the sterols from other lipids, followed by extraction and derivative formation before gas chromatographic analysis. Derivatives such as the silylated products employed in this work give chromatograms like that in Fig. 1. The sterol derivatives are well separated and thermal decomposition is minimized.[18] Sterol samples, in a volatile solvent, can be directly injected into the chromatograph without prior conversion into derivatives, though the common cholesterol autoxidation products often decompose at the temperatures required to vaporize them. With constant injector and column temperature, a reproducible chromatogram of native and pyrolysed sterol products is obtained, as shown in Fig. 2. Identification of some of the major products has been attempted by analysis of sterol products preseparated by TLC and also through use of commercially available standards. The tentative identifications are listed in Table 4. Comparison of Figs. 1 and 2 indicates that silylation is best for optimal sterol resolution, but

both methods produce chromatograms which are suitable for quantitative analysis when the chromatographic conditions are carefully controlled and reproduced, and the pyrolysis peaks are linked to the appropriate parent compound. Control of the chromatographic conditions is particularly important for the pyrolysis chromatogram, which under good con-

ditions produces quantitative results with a variability of 5–10%. A major technical problem in measurement of peak areas occurs when an electronic integrator is not available, since many of the sterols are present in extremely low concentrations relative to the parent cholesterol. To record all these species concurrently and quantitatively, a two-channel recorder with one channel attenuated by a factor of 10 is sufficient for determination of cholesterol and other oxidized sterol products.

Sterol analysis of lipid/sterol mixtures is conventionally accomplished by the techniques above, preceded by TLC separation. Phospholipid acyl chain analysis is also routinely performed by gas chromatography after trans-methylation, but usually is performed only on samples separated from the sterol. This work has established that concurrent phospholipid/sterol analysis can be performed quantitatively by gas chromatography when the trans-methylation procedure is employed. The reaction procedure for methylating the acyl chains gives complete conversion into the required product in the presence of the sterol. One difficulty in the procedure arises from the extraction steps required to isolate the methylate and remove free fatty acids. The solvent systems employed are suitable for the extraction of unwanted fatty acids and also sterols. The extraction step removes most of the sterol present, so variable attenuation of the chromatographic signal is required, because of the small sample quantities routinely used. Sufficiently large signals are readily
Table 5. Identification of lipid acyl chain methylates separated by capillary gas chromatography, as shown in Fig. 3

Product	Retention factor relative to cholesterol	Identification (alkene position)
A	1.00	16:0
B	1.33	18:2
C	1.37	18:1
D	1.46	18:0
E	1.85	20:4
F	2.70	22:6

achieved for the methylation products, but the maximum sensitivity of the flame-ionization detector is required for detection of the minute amounts of sterol. A typical chromatogram is shown in Fig. 3, and is similar to that shown in Fig. 2 for analysis of the unmodified sample obtained by initial TLC extraction. The methyl esters identified in Table 5 are much more volatile than the sterols, so temperature programming is valuable for increased efficiency. The operating conditions shown for Fig. 3 are readily and reproducibly achieved.

One critical area of concern is the accuracy of the combined phospholipid/sterol analysis compared to that of the conventional methods requiring TLC preseparation. Extensive study of in-situ oxidation has established that the best results are obtained only with carefully controlled oxygen-free separations and reactions. TLC separations for rigorously quantitative lipid or sterol determinations are performed in developing tanks which are nitrogen-purged and with solvents that are degassed and contain about 0.05% BHT.[19] Our results indicate that such protective measures are generally unnecessary if relative errors of 5–10% can be tolerated. Similar protective measures have been employed in the trans-methylation procedure and have proven successful in eliminating oxidation, though the BHT does tend to complicate the gas chromatographic analysis since it has a retention value close to that of the C22:6 methyl ester. The capability for performing complete trans-methylation at room temperature should also be noted, since it is of considerable advantage in view of the lability of the compounds of interest.

Even though identical total quantitative evaluation of the parent cholesterol is obtained, one area in the chromatograms shown in Figs. 2 and 3 does differ significantly. It involves the multiplet of oxidized-sterol signals which appear before the cholesterol peak and are produced by the 7-diol and epoxy species, and also some pyrolysis decomposition products. Since the peak distributions and areas for the two methods of analysis differ even when controlled conditions which prevent oxidation are used, the effect must be due to differences between the gas-phase pyrolysis patterns or between the extraction procedures. The invariability of results with change in the solvents used for extraction indicates that the effect is not related to a difference in selective solu-

Fig. 3. Capillary gas chromatogram of a mixture of phosphatidyl choline, cholesterol and autoxidation products after methylation. Column and conditions as for Fig. 2.

bility in the extraction steps. Table 4 gives the relative retention indices of the compounds responsible for the envelope of peaks. One of these oxidized sterol products is the reactive epoxy compound, which is expected to be sensitive to variations in procedure. Further analysis (by use of clean standards) of all the chromatogram peaks associated with the epoxy compound itself, indicates that the methylation procedure tends to induce conversion of the epoxy compound into products which are chromatographically identical to the 7-diol compound and its associated decomposition envelope. Proper determination of each of these individual species would be difficult, and the results are best expressed as sums of the combined 7-diol and epoxy signals, when the unmodified sterols are analysed by gas chromatography. Since the region located before the cholesterol signal is not usually well defined with respect to identifiable compounds and is associated with the pyrolysis products, the differences between the results of the two techniques are not critical provided they are reproducible and the remaining well-defined portions of the chromatograms are not significantly affected.

Rapid and quantitative analysis of concurrent lipid/sterol chemistry is vitally important in the understanding of the physical properties of bilayer lipid membranes (BLM), which are formed from mixtures of these compounds. Significant changes in BLM electrochemistry occur as oxidation progresses, reflecting changes in chemical and electrical-potential energy barriers in the membrane. Applications of the techniques described in this work will allow assessment of the influence of oxidization products and will be presented in a future article.

SELENIUM IN HUMAN URINE
DETERMINATION, SPECIATION AND CONCENTRATION LEVELS

H. J. Robberecht* and H. A. Deelstra

Department of Pharmaceutical Sciences, University of Antwerp (UIA), Universiteitsplein, 1, 2610 Wilrijk,
Belgium

Summary—Procedures for determination of selenium in urine samples are reviewed. Basic problems encountered in sampling and sample-treatment are discussed. Concentration levels and speciation of the element are summarized.

Since the discovery that selenium is an essential element[1] and plays a role in glutathione peroxidase activity[2] there has been increased interest in this element. Earlier it was its toxicity that was of interest[3–5] and this must still be remembered.[6–10] Current interest in the element stems mainly from the following four observations.

First, selenium has been reported to inhibit carcinogenesis by chemical agents such as aminoazo compounds, polycyclic aromatic hydrocarbons, nitrosamines, *etc.*,[7,11–22] and this has been extensively reviewed.[23–29] Variations in dietary selenium intake have been suggested as an explanation for differences in the incidence of cancers in various human populations.[30–32]

Secondly, selenium may play an important role in the prevention of cardiovascular diseases and myocardial infarction: selenium is reported to be important in experimentally induced heart diseases in animals;[33–35] inverse epidemiological relationships have been observed between human heart disease and environmental or blood selenium;[36–41] Keshan disease,[42–46] a cardiomyopathy that affects children in certain areas of the People's Republic of China, is reported as virtually eliminated in the population groups at risk, after a large-scale intervention with selenium supplements.

A third effect of selenium in different organisms is its reported antagonistic action towards various toxic metals,[47] such as arsenic,[48] cadmium,[49–56] copper,[57] lead,[58,59] inorganic mercury[60–73] or methylmercury compounds,[74–81] silver,[71] tellurium,[58] tin[58] and zinc.[72] Magos and Webb have published an excellent review[54] on this topic.

Finally, for several conditions in patients receiving parenteral alimentation, selenium deficiency has been claimed to have played a role,[82–92] and alcoholic cardiomyopathy to be aggravated or accelerated by the concomittant occurrence of selenium deficiency.[93]

These literature data indicate that there is a range of selenium intake that is consistent with health, and outside this range deficiency or toxicity effects can occur. Since it is the element with the narrowest difference between the two levels, reliable methods are needed to check the selenium status of man and to monitor the occupational exposure to this element by measuring its concentration in body fluids. Serum, plasma or whole blood are usually taken as samples for measurement, although several authors[83] claim the glutathione peroxidase activity as being the best parameter.

For trace element levels in man, blood and hair are normally taken as indicator samples,[94] but for selenium hair has to be omitted since selenium is added to certain shampoos as an antidandruff agent and may be adsorbed on the hair, which would vitiate the analysis.[95–97] In cases of intoxication or to provide information on the balance between intake and output, the selenium level in the urine is taken as an indicator, since the kidney is an important feature in body homeostasis.[98] Moreover, urine specimens are readily available and easy to sample.

In this paper the sampling, sample treatment, determination procedures and concentration levels of selenium in urine are reviewed and the scarce data on selenium species in urine are discussed.

SAMPLING AND STORAGE

As with most analyses for urine components, the selenium determination must be done on the urine collected during a 24-hr period. One reason for this is that many constituents exhibit diurnal variation, with variable peak excretions as a result of variation in drinking patterns.

At the beginning of the collection period (usually when the patient awakens) the bladder should be emptied, that specimen being discarded, and the time noted. All urine specimens passed during the next 24

---

*Present address: Provincial Hoger Technisch Instituut voor Scheikunde, Kronenburgstraat, 47, B-2000 Antwerp, Belgium.

hr are collected in an appropriate container. Usually precleaned polyethylene or polypropylene bottles are used, to prevent contamination or adsorption losses. At the end of the collection period the bladder is emptied, this specimen being added to those already collected. Transfer of the urine from the body into the vessel can introduce contamination from clothes and skin, but for selenium this may be not as critical as for other elements.[99] Determination of total creatinine excretion in the 24-hr period may be used as a guide to the adequacy of the collection. This is particularly useful if several 24-hr urine specimens are collected from the same person, since the 24-hr creatinine excretion, largely a function of muscle mass, is relatively constant from day to day. Since the data are often expressed in $\mu g/24$ hr the total volume of urine must be measured to allow comparison of selenium contents or daily excretions when various units are used. As a preservative, to prevent bacterial growth and especially to minimize adsorption losses, concentrated hydrochloric acid,[100,101] boric acid, nitric acid,[102,103] benzoate[44] or toluene[104,105] can be added. The bottles must be stored in the refrigerator when not actually in use during the collection, and the samples must be frozen if the analysis cannot be done immediately. Greger and Marcus[106] found that the concentration of selenium in fresh urine samples and in the same samples after 6 months storage in the freezer was similar.

Cornelis et al.[99] have proved that selenium can be enriched in urine sediments, so the bottles must be shaken very vigorously after thawing, to homogenize the suspension before the sample treatment is begun. The precipitate occurring after extended standing of the sample or after thawing, contains about 15% of the total selenium in the urine, according to Fodor and Barnes.[107]

SAMPLE TREATMENT

All manipulations should be performed in specially designed hoods in dust-free rooms (clean-rooms) to minimize introduction of contamination. All vessels etc. used should be cleaned by extensive washing with a succession of reagents and finally with doubly distilled water; all reagents and solvents must be of ultrapure quality.

Treatment of the urine samples depends on the method of analysis. Except for neutron-activation analysis, where simple lyophilization of a few ml of urine can be applied,[99] the whole sample must be brought into solution and all the selenium converted into the quadrivalent state. Wet oxidation is of particular interest for this purpose, most commonly with nitric acid–sulphuric acid,[102,105] nitric acid–hydrogen peroxide,[108] nitric acid–perchloric acid,[109–111] or a suitable combination thereof.[112] Satisfactory use of these mixtures depends on satisfying two potentially troublesome demands: complete conversion of the native forms of selenium into selenite

or selenate, and prevention of significant loss of selenium during the oxidation.

Several investigators have shown that loss of selenium in open wet oxidation systems can be prevented if charring of samples is avoided,[109,112,113] but this may be difficult when sulphuric acid is a component of the mixture. Sometimes mercuric oxide is added to prevent volatilization losses.[114,115] Unless both requirements are met, accurate analysis for urine selenium cannot be obtained. For instance, some investigators have found that part of the urinary selenium resists acid digestion.[110–116] Janghorbani et al.[117] have recently shown that complete oxidation of rat urine requires use of nitric acid–perchloric acid and that other mixtures such as nitric acid–hydrogen peroxide or nitric acid–sulphuric acid are not suitable. This is due, at least in part, to the presence of the trimethylselenonium ion (TMSe$^+$) in the urine,[118–121] which resists oxidation[110] except with nitric acid–perchloric acid. The other forms of selenium in the urine, as far as been ascertained, do not appear to require perchloric acid for their oxidation.

Janghorbani et al.[117] extensively studied the kinetics and reproducibility of the TMSe$^+$ conversion, and finally recommended adding 5 ml of concentrated hydrochloric acid and 20 ml of concentrated nitric acid to 25 ml of sample and boiling for about 20 min (air condenser) until colourless. Since in most determination procedures selenium(IV) is the mandatory form, complete conversion of selenate into selenite is necessary. This is mostly achieved by boiling the wet-ashed sample in $6M$ hydrochloric acid for a suitable length of time.[110,112,117,118] A similar digestion procedure with gradual heating up to 210° has been shown to give less than 10% loss of metabolically incorporated selenium in rat urine.[111]

DETERMINATION PROCEDURES

Spectrophotometry

This was probably the technique most often used in the past, but is not always sensitive enough for the determination of selenium in trace amounts and is prone to several interferences. Only in two older publications is this technique mentioned for the determination of selenium in urine. Roquebert and Truhaut[119] dry-ashed urine in the presence of nitric acid and magnesium nitrate but found serious losses of the element, whereas Lott et al.,[120] starting with a 10-ml urine sample and mineralization with nitric, perchloric and sulphuric acids, and forming the selenium–diaminonaphthalene complex, found no native selenium present; added selenium, however, was completely recovered.

Spectrophotometric methods based on catalytic reactions are generally much more sensitive than those based on stoichiometric reactions. Most catalytic methods involve oxidation–reduction reactions in which the catalyst, usually a multivalent ion, changes its oxidation state.

Feigl and West[121] proposed a very sensitive qualitative test for selenium, based on its catalysis of the reduction of Methylene Blue by sodium sulphide, and regarded the catalyst as being elemental selenium. West and Ramakrishna[122] later used selenite for calibration. De Moor[123] clearly demonstrated that the decolorization strongly depends on the chemical form of the selenium, and since not all the chemical forms of selenium metabolites are known and hence are not available for calibration, this method cannot be recommended for urine analysis.

Fluorimetry

3,3'-Diaminobenzidine (DAB) is used as a sensitive fluorimetric reagent for selenium, since the piazselenol formed with selenium(IV) shows strong fluorescence. 2,3-Diaminonaphthalene (DAN) is even more frequently used for the same purpose, since it gives greater sensitivity and better extractability into organic solvents from acidic media. Although the fluorimetric method is sensitive, it is lengthy and pH-dependent, and the reagent solutions must generally be prepared daily. Strong oxidizing or reducing agents must be absent, and the addition of masking agents[124] or EDTA[125] is necessary. Nevertheless the method is frequently used for selenium determination in many materials, including urine. All the procedures include a digestion step, followed by a reduction to bring all selenium into the quadrivalent form, a complexation and extraction step, and finally the spectrophotometric measurement with excitation at 360 nm and emission measured at 520 nm. Watkinson's method[109] for analysis of biological material is often used for urine samples.

Nitric–perchloric acid mixture is mostly used for the digestion step, DAN as the fluorimetric reagent, and cyclohexane for the extraction. Reduction with hydrochloric acid under defined conditions is used to bring all the selenium into the selenite form. If the Schöniger flask combustion is used, no reduction step is necessary, as proved by Taussky et al.[126] Chen et al.[127] omitted the reduction step in their single-tube process for selenium determination, but hence risked obtaining low results for hair, serum and urine samples.

All the methods require only a small amount of sample (0.4–4 ml) and the precision is mostly better than 7%. The detection limit can be as low as 0.4 ng/ml.[125]

Atomic-absorption spectrometry methods (AAS)

The use of AAS has increased during the last two decades and now covers a large fraction of selenium determinations. Robberecht and Van Grieken[128] have recently reviewed AAS determinations of selenium in water samples, and Verlinden et al.[129] have reviewed the AAS-procedure for determination of selenium in various materials, including biological samples.

Flame AAS (FAAS). This technique in its conventional form is not sensitive enough for direct determination of selenium in urine samples. Background absorption at 196 nm, interfering cations and anions, and severe scattering in the 180–220 nm region by inorganic salts, which are highly concentrated in urine, make digestion and separation of selenium from the urine matrix necessary.

Urine samples are wet-ashed, either with a mixture of nitric, perchloric and sulphuric acids[114] or a nitric–perchloric acid mixture.[130,131] Generation of hydrogen selenide by reduction with sodium tetrahydroborate in acid medium is used in nearly all methods for the separation of selenium from the matrix. Previous conversion of all selenium into selenite is then necessary, and usually obtained by boiling with hydrochloric acid.

Electrothermal AAS (ETAAS). This technique is especially suitable for direct analysis because of its high sensitivity (detection limit 90 pg of selenium), but it is not simple, nor free from interferences or volatilization losses. Pyrolytic coating of the graphite furnace or addition of various metal salts, such as those of nickel,[114,132–135] molybdenum[132] or silver[132] has been shown to diminish the chemical interferences in urine analysis, allow use of higher temperatures without losses of selenium, and result in a significantly enhanced sensitivity. A heated silica cell[9,136–138] can be used instead of a graphite furnace[133–135] for the atomization.

After acid decomposition of the sample, selenium can be preconcentrated by the generation of hydrogen selenide, complexation with aromatic *o*-diamines and extraction into toluene[133] or complexation with dithizone and extraction into carbon tetrachloride.[134,135] Boiling with hydrochloric acid[133,136,137] or hydroxylamine hydrochloride[134,135,138] is necessary to reduce selenate to selenite, which is essential for the following complexation or hydride-generation step.

Procedures for speciation of selenium in urine are scarce. The only procedure for trimethylselenonium ion (TMSe+), "free state selenium-ion" (presumably selenite + selenate) and total selenium in human urine, is the graphite-furnace AAS method of Oyamada and Ishizaki,[134,135] based on a procedure established by Ishizaki.[139] The TMSe+ was separated on a Dowex 50 W-8X ion-exchange column. Nickel nitrate was used as matrix modifier in the ETAAS analysis, and the detection limit for TMSe+ was 1 μg/l.

Atomic-emission spectroscopy. The use of an inductively-coupled plasma (ICP) as an excitation source in optical atomic-emission spectroscopy (AES) for single and multielement inorganic trace analysis is becoming widespread. The recent availability of commercial instruments has stimulated its use for the determination of metals and metalloids in diverse environmental materials, ranging from airborne particulates and fly-ash to industrial effluents and waste waters. The capabilities and limitations of ICP-AES in water pollution analysis have been re-

viewed by Barnes.[140] Robbins and Caruso[141] have summarized the development of hydride-generation methods for atomic spectroscopic analysis, including ICP–AES, and Thompson et al.[142] have described the possibility of simultaneous determination of trace concentrations of arsenic, antimony, bismuth, selenium and tellurium in aqueous solutions, by hydride-generation and ICP–AES. Unfortunately, the technique has a number of disadvantages. One of the most serious (in urine analysis) is that the power of detection for hydride-forming elements is insufficient for direct determination of ultratrace concentrations of these metals in many biological materials, even under optimized conditions. For the determination of such trace elements in urine by ICP–AES, Barnes and Genna[143] used preconcentration with a poly-(dithiocarbamate) chelating resin. Fodor and Barnes[107] reported the use of complexation of Se, As, Fe, Bi, Sb and Sn by poly(dithiocarbamate) resin in the determination of these elements with a combined hydride–ICP–AES technique and application of this approach for distinguishing the oxidation states of Se and Te in urine. The detection limit, based on the integrated peak-area for a 10-ml sample with a tenfold resin preconcentration was as low as 0.04 μg/l., and recovery at the μg/l. level ranged from 80 to 108% for both selenate and selenite.

X-Ray emission analysis

As with most other techniques, it is impossible to determine selenium directly by X-ray emission methods at the concentration levels in urine samples: the detection limits are around 200 μg/l., for elements such as selenium,[144] with secondary target energy-dispersive X-ray fluorescence analysis or X-ray emission spectrometry (XES).

A single evaporation enrichment step is not very helpful: even under optimized conditions, spotting on a cellulose filter paper and drying results in a detection limit of 30 μg/l. and the risk of selenium losses is severe.[145] For highly saline samples, such as urine and brine, heterogeneity problems make accurate analysis improbable.

Clearly, there is a need for chemical preconcentration techniques to boost the sensitivity of X-ray emission analysis sufficiently for application to urine. Vos et al.[146] tried using chelating DEN-filters[147,148] for multi-element analysis of urine, but abandoned this approach because nitrogen compounds in the urine interfered in the complexation step. They therefore adapted and extended the method proposed by Nielson and Kalkwarf,[149] but did not obtain quantitative recovery.

Several authors[150–152] have adapted the small-sample X-ray fluorescence system of Alfrey et al.,[153] in which the sample is lyophilized, oven-dried and ashed at 450°, after which 250 μg of the ash are used for target preparation. Alfrey et al.[153] did not give any values for selenium, but Tsongas and Ferguson[150] claimed to determine selenium down to the 1 μg/l.

level. Holynska and Lipinska-Kalita[154] used an acid decomposition followed by selective reduction of selenium compounds with a mixture of stannous chloride and hydroxylamine and co-precipitation with tellurium, and finally XES determination.[156] With a 250-ml sample they were able to detect selenium at the μg/l. level. However, if the solution is too acid the precipitation with tellurium can be incomplete,[154] so there is a risk of low results. A similar preconcentration procedure based on reduction of selenite by ascorbic acid was proposed by Robberecht and Van Grieken;[156] activated carbon was used as a strong adsorbent and collector for the elemental selenium. Their destruction procedure, using nitric and perchloric acid and gradual heating to 210°, was tested on different biological tissues in which selenium was metabolically incorporated.[111] For urine samples the average recovery was 95% and under optimal conditions with a 20-ml urine sample a limit of detection of 1 μg/l. could be obtained.[156]

Neutron-activation analysis (NAA)

Because of its high sensitivity (1–10 ng of Se) and the simple pretreatment of the sample, this technique is widely used for determination of selenium, especially in biological materials. Thermal neutrons are most often used for the activation, giving radioactive selenium isotopes by (n, γ) reactions. Hence, ^{77m}Se and ^{75}Se are predominantly utilized in activation analysis of biological material. ^{77m}Se, which gives the highest sensitivity thanks to its very short half-life (17.5 sec), is used only in instrumental neutron-activation analysis (INAA). Although this technique is well established for biological tissues,[157] hair,[158] serum and semen,[158] it does not seem to have been applied to urine, probably because there would be a relatively large Compton background from ^{38}Cl and ^{24}Na. Pre-irradiation dialysis against demineralized water might partly solve this problem[159] but could cause losses of selenium, though these were not noted after dialysis of serum samples.

^{75}Se is used more often because its long half-life (120.4 days) allows chemical separation, but long activation and cooling times are required. The sample material is usually irradiated in a nuclear reactor for at least one day with a flux of 10^{13}–10^{15} n.cm^{-2}.sec^{-1}. The activity of the irradiated samples is measured with a high-resolution Ge(Li) γ-ray detector coupled to a multi-channel analyser or sometimes with an NaI(Tl) detector.

Multi-element analysis has been done after non-destructive analysis of 20-ml urine samples, enclosed in quartz vials,[160–162] or after lyophilization of 10-ml aliquots.[99] Extensive separation schemes, based on ion-exchange procedures, have been developed by Wester et al.[163] for multi-element analysis of smaller urine aliquots and applied in several balance studies.[164–166] After irradiation and cooling, the sample is decomposed with sulphuric acid and hydrogen peroxide, followed by HBr distillation and acid precip-

itation for the selenium determination. Recoveries of 80% are obtained.[164]

Another selective procedure for selenium in urine, sensitive down to 0.6 μg/l., was presented by Weingarten et al.,[167] but it included some critical and potentially error-producing preconcentration steps, such as evaporation of the urine, addition of sulphuric acid and evaporation to dryness (danger of charring), and reduction by ascorbic acid (which is only effective if all the selenium is present in the quadrivalent form) and the maximum recovery was only 81%, which fell to 50% if a digestion time of 45 min was used.

Janghorbani et al.[108,168] have used stable isotopes for the study of selenium metabolism in healthy adults. The conversion of urinary selenium into selenium(IV) by wet oxidation with different acid mixtures was checked and proved to be satisfactory only with a nitric–perchloric acid mixture and subsequent reduction with hydrochloric acid.[117] Ammonium pyrrolidine dithiocarbamate has been used for precipitation of Se(IV).[169] The chemical yield was not quantitative and ^{75}Se tracer of high specific activity had to be used for correlation. in this way an analytical method was developed for the study of selenium metabolism in healthy adults, by use of the stable isotope [74]SeO_3^{2-}.[108]

Gas–liquid chromatography (GLC)

Determination of selenium in urine by GLC is based on formation of a volatile piazselenol by reaction of selenium(IV) with an aromatic diamine. Piazselenols can readily be extracted from water and injected into a gas chromatograph, and are usually detected with an electron-capture detector, which gives the highest sensitivity and selectivity for such compounds.

Young and Christian[103] digested 10 ml of urine with a mixture of nitric, sulphuric and perchloric acids, with molybdate as catalyst, and used DAN as complexing agent without a prior reduction step, and then extraction into hexane. Down to 0.5 ng of selenium could be determined. A low value was found for the only urine sample analysed, probably owing to the omission of a reduction step.

Poole et al.[170] used a similar detection technique after sample decomposition with a mixture of nitric acid and magnesium nitrate. 5-Nitropiazselenol was formed after conversion of all selenium into selenite by boiling with hydrochloric acid. The complex was extracted into toluene.

Cappon and Smith[171] produced a scheme of analysis for specific forms of selenium in biological materials, including human urine. The method was based on selective reaction of selenium(IV) with 4-nitro-o-phenylenediamine to form the 5-nitro-piazselenol, which was extracted into benzene and measured by GLC (with electron-capture detection). For organoselenium plus selenium(IV) the sample was digested with concentrated nitric acid. Total

selenium was determined by applying the same digestion procedure and boiling the resulting solution with hydrochloric acid. The difference between the last two values obtained represented the selenium(VI) content. The selenium recovery ranged from 75 to 90% and was assessed by using a ^{75}Se-labelled tracer (Na_2SeO_3) for a liquid scintillation spectrometric assay. The method permitted detection of selenium down to 1 μg/l., with a mean deviation of 2.3%. The limitations of this method will be discussed in the section on speciation, below.

Reamer and Veillon[172] have shown that selenium in biological materials can be determined by stable isotope dilution and GLC–mass spectrometry. Urine samples were digested with nitric acid, phosphoric acid and hydrogen peroxide, then 5-nitropiazselenol was formed and extracted into toluene for gas-chromatography–mass spectrometric analysis after spiking of the samples with enriched [82]Se. The isotopic ratio of [80]Se to [82]Se was measured by dual ion monitoring and made it possible to determine selenium at the μg/l. level. Human urine samples, spiked with ^{75}Se, showed a recovery of 86%

Electrochemical methods

Faulkner et al.[102] tried polarography over a concentration range of 0.5–14 mg/l., which is far too high to be useful for urine analysis. The same applies to the complicated procedure developed by Patriarche[173] which used a coulometric back-titration and had a detection limit of 100 μg/l.

Titrimetric method

Glover[115] digested 300 ml of urine with a sulphuric–nitric acid mixture, plus mercuric oxide to prevent escape of volatile selenium compounds. Distillation with hydrobromic acid–bromine solution separated the selenium as the tetrabromide, which was reduced with sulphur dioxide to the elemental form; this was filtered off, dissolved and converted into selenite, and determined by titration with iodine and thiosulphate. The method was judged accurate down to a selenium level of 20 μg/l. of selenium.

CHEMICAL SPECIES OF SELENIUM IN URINE

Knowledge of the different selenium species present in urine is important, because it can give definite indications about the biochemical conversion of the element and the detoxification mechanisms, and also about the selenium status.[174] Nearly all information on selenium species in urine refers to rats and mice; studies on selenium metabolites in human urine are very scarce and prone to several inconsistencies.

Excretion in the breath[175-183] and urine[174,177,180,184-190] and through the gastrointestinal tract[188] has been found to account for most of the elimination of toxic doses of selenium compounds. Trimethylselenonium

ion (TMSe$^+$), a detoxification metabolite of selenium, that is excreted in the urine, was first isolated and identified in rat urine.[184-186] It was found to be only about a tenth as toxic as inorganic and other organic selenium species.[191] It was also found that TMSe$^+$ itself is inactive and easily and almost completely excreted in the urine when fed to selenium-deficient animals.[192] The stability of this metabolite is further demonstrated by the fact that it is not converted into selenite by boiling with a mixture of concentrated nitric acid and hydrogen peroxide. Since TMSe$^+$ is excreted in urine at both high and low levels of selenium, it is suggested[185] to be a normal metabolite of selenium.

Nahapetian et al.[174] have presented a study on urinary selenium metabolites of ^{75}Se-labelled selenite, selenomethionine and selenocystine fed to rats at both low and high dose levels. The purpose was to assess the significance of TMSe$^+$ in relation to the normal homeostasis of body selenium metabolism. TMSe$^+$ was the major urinary selenium metabolite (57–69% of urinary ^{75}Se and 16–25% of the oral ^{75}Se dose) at high levels, and a minor metabolite (10% of urinary ^{75}Se; 3–4% of oral dose) at low, for all three compounds tested. These authors hypothesized that when the intake is at requirement level, trace or no TMSe$^+$ is excreted in the urine, but it becomes a major excretory metabolite when the intake exceeds requirement level, probably serving as a means of detoxification. They were not able to characterize the non-TMSe$^+$ metabolites. Free selenite was not detected, although selenite bound to sulphur-containing amino-acid,[193,194] and selenate,[188,185] could not be excluded.

Burk[116] has reported some findings on the major urinary metabolites of selenium in man. Urine from a young man who had a testicular tumour and was given ^{75}Se-labelled selenite, was analysed by two-dimensional paper chromatography with phenol/water (73:27 w/w) and butanol/acetic acid/water (4:1:1 v/v) as solvent systems. The R_f-values of the TMSe$^+$ ion agreed with those of a major ^{75}Se spot for the urine sample, and the R_f-values for the other main urinary spot were similar to those for the "U-2" compound present in rat urine.[186] The TMSe$^+$ ion and the U-2 component accounted for 14–21% and 19–34% of the urinary radioactivity, respectively, and the percentages of selenium in these two fractions appeared to increase over a 10-hr interval. These results strongly suggest that the major selenium metabolites are similar for rat and man. Palmer and Olson[187] have reported that other excretory forms of selenium were found in poultry, so other species cannot be ruled out for man.

The type of animal tested is obviously important, but the chemical form of selenium used in the metabolic experiments can also be of major significance, as will be discussed (in a complementary review[196]). For human urine samples, all but three[107,137,174] of the literature reports deal only with the total selenium

content. Cappon and Smith[171] reported a scheme for the determination of organoselenium and selenite, total selenium and selenate, but it was prone to some failures, mainly because the nitric acid oxidation of the organic material could disturb the equilibrium of the naturally existing species. Selenium species found after the acid treatment are not necessarily present in the same form before the treatment. These investigators also checked their procedure by tracer work with only one selenium species, $Na_2^{75}SeO_3$.

No details of the organoselenium forms were presented. Oyamada and Ishizaki[134] were able to give more valid data for the different selenium metabolites. No "free state" selenium (oxidation state not specified) was detected in human urine, collected before luncheon, whereas TMSe$^+$ constituted 10–47% of the total selenium content. Fodor and Barnes[107] have been able to separate selenate and selenite from urine samples by using different pH-values for complexation by a poly(dithiocarbamate) resin. For the urine of 11 healthy persons the selenite content (8.6 μg/l.) was on average about three times the selenate concentration (3.1 μg/l.). About 15% of the total selenium occurred in the precipitate resulting after extended standing of the sample or after thawing of the frozen urine. For patients receiving total parenteral nutrition both selenite and selenate concentrations were below the 0.1-μg/l. limit of detection. Hence, in this case all the selenium apparently occurred exclusively in the sample precipitate. Two criticisms can be made of the speciation procedure: no information concerning organoselenium compounds was obtained, and the addition of 50 ml of concentrated hydrochloric acid per litre of urine, could have resulted in a definite redistribution of the original species equilibrium.

CONCENTRATION LEVELS

Literature values for the concentration level of total selenium in urine samples taken from healthy persons are listed in Table 1, along with method of analysis, number of persons tested and other specific characteristics, when mentioned in the studies. Most of the concentrations are simply expressed as μg/l., but as the selenium concentration is a function of the volume excreted, and subject to climate, fluid intake and transpiration, it is felt that a more reliable basis for comparison may be given by the total urinary selenium excreted in 24 hr. Hojo[198] considers it advantageous to express the concentration in μg of Se per g of creatinine excreted, claiming this unit is less susceptible to variation in conditions, and on this basis used individual urine samples instead of 24-hr samples in the estimation of urinary selenium levels. Relative selenium concentrations are not especially useful for comparison, and readers are probably best advised to consult the original articles and assess their validity themselves. The selenium content reported for urine samples varies widely (Table 1) but the

mean amounts of selenium in 24-hr samples are generally below the 30-μg level, except where there is exposure to high environmental selenium levels, which is probably the most important cause of an enhanced urinary excretion level. Likewise, the suggested[142] maximum allowable concentration of 100 μg/l. is generally not exceeded.

No significant sex-related differences in selenium excretion have been found by some authors,[99,125,134,137] but others[151,204,205] have found definitely lower excretion figures for females than for males, whether the concentration is expressed as μg/l. or μg/24 hr.

Although no extended studies have been made on selenium excretion as a function of age, preliminary results for Belgium indicate that the urinary concentration level is lower for older people than young adults,[137] perhaps because of lower intakes and/or increased diuresis.

Selenium figures for urine samples from populations exposed to industrial selenium or an environment with a highly seleniferous soil were published more than forty years ago,[209-211] but the techniques of analysis were certainly not sensitive enough, and hence these data have to be treated with reserve.

Table 2 summarizes some selenium concentration levels for urine from patients with pathological conditions, together with comparison values for healthy volunteers, some of whom were exposed to various occupational hazards.

The selenium content shows much the same pattern for both the patients and the healthy volunteers, and although Hojo[199] reported that cancer and epilepsy patients showed significantly lower selenium levels than those for any other group examined, the results quoted in Table 2 seem to indicate a skew distribution. Factory workers exposed to heavy metals were found to have significantly higher urinary selenium levels than other groups. This may partly be due to enhanced intake of selenium, which occurs in substantial quantity in sulphide minerals, and partly because ingested minerals accelerate excretion of body selenium as the metal selenides (possibly without interaction with body fluids).

Chlorthalidone treatment of hypertensive patients in Sweden[168,169] was found not to alter the urinary selenium excretion. Nine alcoholic subjects were reported to show a lower mean daily urinary excretion of selenium compared to normal subjects.[206] Urinary selenium excretion appeared to increase during hospital treatment and cessation of alcohol consumption, which might, of course, simply be a consequence of change in intake levels.

Significant selenium depletion has been reported to occur in burn patients and to persist until at least one month after injury, as monitored by urinary selenium excretion,[208] but again the distribution seems skewed.

In this type of study there is always the question of whether a lower or higher selenium excretion is a cause or a consequence of a pathological condition. Several diseases may seem to be aggravated or allevi-

ated by changes in selenium status, as has been claimed for alcoholic cardiomyopathy,[93] but selenium is not necessarily the causative agent and care must be taken to avoid spurious correlations. It is interesting, for example, that in an extensive study of a seleniferous zone,[101] it was reported that mean selenium levels of 636 μg per g of creatinine did not pose severe health hazards for the children who formed the sample populations.

The relation between selenium intake, the chemical form of the element and the daily excretion and selenium levels in urine will be discussed in more detail in the further review[196] already mentioned, which includes more details on the medical aspects and clinical implications.

CONCLUSION

Fluorimetric analysis is the most commonly applied technique for selenium determination in urine samples, but whatever technique is used, except nondestructive neutron-activation analysis, the procedure used for decomposition of the samples has to be checked carefully to prevent volatilization losses and to obtain complete destruction of $TMSe^+$, a major selenium metabolite in urine.

Information concerning the speciation of selenium in urine is scarce and contradictory, and often subject to several inconsistencies. Literature data on selenium levels in urine, which must be checked carefully with regard to the units used for expression of results, reveal that the maximum allowable concentration level of 100 μg/l. is seldom exceeded. The normal selenium values for urine are below 30 μg/l. Only in some cases of intoxication or exposure to high environmental selenium levels are enhanced urinary excretion values obtained. Changes in urinary selenium levels in pathological conditions have been reported, but whether such changes are associated with the cause of the pathological condition is open to question.

The daily excretion level is the best indication of selenium content in urine, but several other parameters must be taken into account in assessing selenium status in man.

Much of the information in the literature is based on analysis of very limited numbers of samples, and information is not always given about the reproducibility and accuracy attained in the research. Possible skewness in distributions may pass without comment (which is regrettably all too often the case in work of this nature) and significance is sometimes attached to results for as few as two samples. Much more work, with bigger sample populations, seems needed before definitive conclusions can be drawn.

COMPARISON OF THE SUB- AND SUPER-EQUIVALENCE AND SUBSTOICHIOMETRIC METHODS OF ISOTOPE DILUTION ANALYSIS FOR THE DETERMINATION OF A TRACE AMOUNT OF ANTIMONY

H. Yoshioka and T. Kambara

Radiochemistry Research Laboratory, Faculty of Science, Shizuoka University, 836 Ôya, Shizuoka 422, Japan

Summary—The sub- and super-equivalence methods of isotope dilution analysis (SSE–IDA) have been compared with substoichiometric isotope dilution analysis (Subst-IDA) for the determination of a trace amount of antimony by means of a redox reaction. For this comparison, the difference between the amount separated and the theoretical value was determined under various conditions. Under conditions in which the substoichiometric reaction and separation gave unsatisfactory results, accurate determination could still be performed by SSE-IDA. The reason for this is discussed.

Since substoichiometry[1–3] was introduced into isotope dilution analysis (IDA), various modifications of this method (Subst-IDA)[4–6] have been developed because of its accuracy, sensitivity and relative freedom from interference. Trace amounts of antimony in a metal have been determined by use of an oxidation–reduction reaction in substoichiometric activation analysis (Redox Subst-NAA[7] and Redox Subst-IDA[8]).

Subst-IDA requires that the amounts of reagent reacted and product separated must always be constant. Ideally, more than 99% of the reagent should be converted into product, but even if the reagent does not react quite so quantitatively, the method can still be used provided that the amount separated is constant (such cases are not common).

The "sub- and super-equivalence" method of isotope dilution analysis (SSE-IDA) was therefore proposed by Klas *et al.*,[9] and is applicable under conditions other than those listed above. Various types of SSE-IDA[9,10] have been thought out, and theoretical studies[11] and applications to the determination of Co, vitamin B_{12}, Se, Tl, Fe and Zn[12] have been reported. We too have examined this method, applying Redox SSE-IDA for the determination of a trace amount of antimony.[13]

However, no detailed analysis has been made of why (in contrast to Subst-IDA) SSE-IDA makes accurate determination possible when the basic conditions are not strictly fulfilled. We have therefore examined the degree of reaction under various conditions and the effect of departure from the required conditions, and have determined antimony in the presence of an interfering species [As(III)].

PRINCIPLE OF THE METHOD

The principle of SSE-IDA[10] is explained below in parallel with the experimental procedure.

Two series of solutions are necessary. In the first, each solution contains the same amount of sample (x) and the same amount of radioactive isotope (A). In the second, each solution contains k times the amount of sample and radiosotope used in the first series. It is not essential to use replicate analysis for the second series, but doing so will give a more reliable average value.

The solutions in the first series are isotopically diluted by the addition of regularly increasing amounts of carrier (iy, where $i = 1, 2....$), so that their specific activities become $A/(x + iy)$. No carrier is added to the solutions in the second series, so their specific activities are all A/x.

All solutions of both series are brought to the same volume and acid concentration by addition of the solvent and an appropriate amount of acid. Next, the same substoichiometric amount of the reagent which is to react with the analyte is added to all the solutions in both series.

After completion of the reaction, the products are isolated and the radioactivities (a_x, a_{x+iy}, a_{kx}) of the isolated products (masses m_x, m_{x+iy}, m_{kx}) are measured.

As the total activity of the analyte is not changed by the separation, the specific activity in the first series is defined by

$$A/(x + iy) = a_{x+iy}/m_{x+iy} \tag{1}$$

Similarly, for the second series

$$A/x = a_{kx}/m_{kx} \tag{2}$$

Hence

$$a_{kx}/a_{x+iy} = iym_{kx}/xm_{x+iy} + m_{kx}/m_{x+iy} \tag{3}$$

As the extent of chemical reaction is dependent on the concentrations of the reactants, the degree of reaction of a fixed substoichiometric amount of re-

agent will depend on the concentration of the element to be determined. However, for a solution with the same total analyte concentration in both series, the degree of reaction and separation should also be the same, so in principle a solution could be prepared in the first series with j increments of carrier such that

$$m_{x+jy} = m_{kx} \qquad (4)$$

Under these conditions

$$a_{kx}/a_{x+jy} = k \qquad (5)$$

From equations (3)-(5), we obtain

$$x = jy/(k-1) \qquad (6)$$

The quantity x is then obtained graphically as shown in Fig. 4, by plotting a_{kx}/a_{x+iy} against iy and finding the abscissa value (jy) corresponding to $a_{kx}/a_{x+iy} = k$ for any value of k, and applying equation (6).

If $m_{x+iy} = m_{kx}$, which is the condition required for conventional substoichiometry, equation (7) can be derived:

$$a_{kx}/a_{x+iy} = iy/x + 1 \qquad (7)$$

This is one limiting case of SSE-IDA.

EXPERIMENTAL

Reagents

$^{125}Sb(III)$ *tracer solution.*[14,15] ^{125}Sb (100–300 μg, ca. 1 μCi/100 μl in 6M hydrochloric acid) was mixed with 10 ml of concentrated hydrochloric acid and refluxed for 30 min in order to reduce the antimony. This $^{125}Sb(III)$ tracer solution in 6M hydrochloric acid was always prepared just before use, for labelling the sample solution.

Synthetic sample solution. The solution of inactive Sb(III) to be determined was labelled with the $^{125}Sb(III)$ tracer solution and was used as the labelled synthetic sample solution [Sb(III) + $^{125}Sb(III)$, ca. 10 μg/ml in 6M hydrochloric acid]. It was stored in a brown bottle and kept in the dark to avoid self- and photo-oxidation[15] of the $^{125}Sb(III)$.
Fig. 1. Effect of $[HCl]_{ox}$ on the amount of Sb(V) separated. A, Theoretical line; B, Sb(III) 8×10^{-2} μeq; C, Sb(III) + As(III) 8×10^{-2} μeq + 4×10^{-1} μeq. Vol$_{ox}$ 8.5, 4.5, 2.5 and 1.5 ml for $[HCl]_{ox}$ 1, 2, 3 and 5N respectively. $K_2Cr_2O_7$ 3×10^{-2} μeq, $[HCl]_{ex} = 0.8N$, Vol$_{ex}$ = 10.5 ml. $[HCl]_{ox}$ Vol$_{ox}$ are the acid concentration and total volume respectively after the addition of $K_2Cr_2O_7$; $[HCl]_{ex}$ and Vol$_{ex}$ are the acid concentration and total volume for the extraction stage.

This solution was stable for at least a week, without change in the oxidation state of the antimony.

Sb(III) carrier solution. Prepared by dissolving reagent grade Sb_2O_3 (99.999% pure) in 6M hydrochloric acid, and standardized by bromate titration.

Oxidant. Commercially available 0.1N potassium dichromate, suitably diluted.

Separation reagent. A 0.05M solution of N-benzoyl-N-phenylhydroxylamine (BPA) in chloroform was used for separation of Sb(III) from Sb(V).[16]

Activity measurements

The activity of ^{125}Sb was measured with a scintillation counter, NaI(Tl), well-type, to eliminate interference by the activity of the daughter nuclide ^{125m}Te ($t_{\frac{1}{2}} = 58$ days; 35 and 110 keV).

Procedure

1st series. Aliquots (0.1 ml) of the synthetic sample solution [Sb(III) + $^{125}Sb(III)$, 24.1 μg/ml in 6M hydrochloric acid], were placed in seven brown test-tubes equipped with ground-in stoppers, and 0, 0.1,....0.6 ml of carrier solution [non-radioactive Sb(III) solution, 24.1 μg/ml in 6M hydrochloric acid] were added. Then 1.1, 1.0,...0.5 ml of 6M hydrochloric acid were added so that all the solutions had the same volume and acidity.

2nd series. Pairs of 0.2, 0.3, 0.4, 0.5 and 0.6 ml portions (i.e., $k = 2, 3, 4, 5, 6$) of the synthetic sample solution were placed in test-tubes of the type used for the first series.

All the solutions in both series were adjusted to the same volume and acid concentration by addition of 2.0 ml of 1.8M hydrochloric acid.

Oxidation and separation. Exactly 0.1 ml of $0.6 \times 10^{-4}N$ potassium dichromate was added to each tube, to give a total volume of 3.3 ml and acidity of 3.27M. The solutions were mixed and then stood for 15–30 min to complete the oxidation. The acid concentration was then reduced to 1.0M by addition of 8.0 ml of 0.001M hydrochloric acid, and the unreacted antimony was extracted with 3.0 ml of 0.05M BPA solution in chloroform.

The radioactivity of the antimony(V) in each aqueous phase was then measured.

RESULTS AND DISCUSSION

As stated in the introduction, the amounts of reagent and product separated must be strictly controlled in Subst-IDA, so the concentration ranges of the reagents, interfering elements and the species to be determined are narrow, and large errors are caused by any deviation from the permitted range. In contrast, these limitations do not apply to SSE-IDA. We therefore examined the effect of the concentrations of the interfering element As(III), of hydrochloric acid and the reactant Sb(III) in order to define a set of the conditions under which Subst-IDA would not be practicable, but SSE-IDA would. Determination of the amount of product (m) is usually difficult, but it was possible here because we used a synthetic sample; m was calculated by means of the equation for Subst-IDA, since the radioactivities before separation (A) and after separation (a), the quantity of Sb(III) to be determined (x) and that of non-radioactive carrier (iy) added to x, had already been measured.

Effect of acidity

The relationship between the amount of Sb(V) produced and the acid concentration was examined
Fig. 2. Effect of the molar ratio, As(III)/Sb(III), on the amount of Sb(V) separated.
A, Theoretical line.

	Sb(III) μeq	$[HCl]_{ox}$ M	Vol_{ox} ml	$[HCl]_{ex}$ M	Vol_{ex} ml
B	4×10^{-2}	1.0	8.5	0.8	10.5
C	12×10^{-2}	5.4	1.5	0.8	10.5
D	8×10^{-2}	5.4	2.0	0.9	11.8
E	4×10^{-2}	5.4	1.5	0.8	10.5

$K_2Cr_2O_7$ 3×10^{-2} μeq.

under the conditions shown in Fig. 1, by use of the procedure above.

The curves in Fig. 1 show that the amount separated decreases with increasing C_{HCl} and the difference from the expected value becomes remarkable. This suggests that some of the dichromate may react with the hydrochloric acid or that the equilibrium constant of the redox reaction between Sb(III) and $K_2Cr_2O_7$ becomes smaller with increasing acidity. In either case, the amount of Sb(III) oxidized would decrease.

The values near $C_{HCl} = 1M$ are almost equal to the theoretical in each case, but the decrease in oxidation at higher acidities is larger when arsenic(III) is also present. It is concluded that the dichromate reaction with 3–5 μg of antimony(III) is quantitative when done at around $C_{HCl} = 1M$, in agreement with previous results,[8] and the interference of arsenic(III) is negligible at this acidity, but conspicuous at $C_{HCl} > 2M$, suggesting that arsenic(III) is also oxidized.

Although the effect of C_{HCl} on the oxidation of Sb(III) can be very large, it can be made practically constant if the hydrochloric acid concentration is kept the same for all the solutions tested, as shown before.[13]

Effect of $C_{As(III)}$

The effect of $C_{As(III)}$ on the oxidation of Sb(III) was examined under the conditions indicated in Fig. 2.

In $1M$ hydrochloric acid medium, As(III) does not interfere in the oxidation of Sb(III) over the range
Fig. 3. Effect of amount of Sb(III) on amount of Sb(V) separated.
$K_2Cr_2O_7$ 4×10^{-2} μeq; $[HCl]_{ox} = 3.3M$; $Vol_{ox} = 4.4$ ml; $[HCl]_{ex} = 0.7M$; $Vol_{ex} = 19.4$ ml.

tested. However, at high acid concentration, As(III) takes part in the oxidation and its effect becomes larger with increasing $C_{As(III)}$ at constant $C_{Sb(III)}$ and C_{HCl}. On the other hand, if $C_{As(III)}/C_{Sb(III)}$ and C_{HCl} are kept constant, its effect becomes smaller with increasing $C_{Sb(III)}$.

Effect of $C_{Sb(III)}$

Under the conditions shown in Fig. 3, the amount of Sb(V) separated increases with increasing $C_{Sb(III)}$ at constant $C_{As(III)}$ and C_{HCl}. This follows from the results shown in Fig. 2, and confirms that As(III) interferes by competing with Sb(III) for oxidation with $K_2Cr_2O_7$.

Determination by SSE-IDA under conditions unsuitable for Subst-IDA

To illustrate the usefulness of SSE-IDA, it was tested under conditions unsuitable for the use of conventional Subst-IDA.
Fig. 4. An example of the determination of Sb(III) in the presence of an interfering element [As(III)] by Redox SSE-IDA: 0.2 ml of [Sb(III) + ^{125}Sb(III)] 12.04 μg (total) + As(III) 7.49 μg]/ml solution in $6M$ HCl was taken.
$K_2Cr_2O_7$; 6×10^{-2} μeq; $[HCl]_{ox} = 3.3M$; $Vol_{ox} = 3.3$ ml; $[HCl]_{ex} = 0.9M$; $Vol_{ex} = 11.3$ ml.

Table 1. Results of determination of 2.41 μg of antimony(III) by Redox SSE-IDA (conditions as for Fig. 4)

k	Found, μg	Error, %
2	2.32	− 3.7
3	2.40	− 0.4
4	2.47	2.5
5	2.44	1.2
6	2.47	2.5

Table 3. Radioactivities of the Sb(V) isolated from each aliquot ($A = 14690$ cpm; conditions as for Fig. 4)

	Activities of separated Sb(V)	
Amount of Sb(III)	1st series	2nd series
$x + iy$, μg	a_{x+iy}, cpm	a_{kx}, cpm
$x = 2.41$	$a_x = 9291$	
$x + y = 4.82$	$a_{x+y} = 5011$	$a_{2x} = 10227$
$x + 2y = 7.23$	$a_{x+2y} = 3489$	$a_{3x} = 10508$
$x + 3y = 9.64$	$a_{x+3y} = 2726$	$a_{4x} = 10672$
$x + 4y = 12.05$	$a_{x+4y} = 2284$	$a_{5x} = 11337$
$x + 5y = 14.46$	$a_{x+5y} = 1968$	$a_{6x} = 11632$
$x + 6y = 16.87$	$a_{x+6y} = 1736$	

An example of the graphical method for calculating the result is shown in Fig. 4, and the values obtained by use of various k-values are shown in Table 1. Table 2 shows the values calculated by means of various equations[17] for Subst-IDA, from the data obtained for each aliquot in the first series in this experiment, on the assumption that the amounts of Sb(V) separated are equal to the theoretical quantities. As expected, a large error is introduced in the Subst-IDA results, whereas SSE-IDA permits accurate determination within the expected error limit.

The amounts separated were measured in order to confirm the reason given for the difference between the two sets of results. The amounts, m_i, separated under the conditions for Fig. 4, were calculated on the basis of the radioactivities (Table 3) by use of equation (1) in Table 2. These values are plotted in Fig. 5 against the total amount of Sb(III) in each aliquot in both series. The curves shows that m_{x+iy} increases with increasing $x + iy$ and kx as in Fig. 3, and that the strict conditions for Subst-IDA are no longer fulfilled. At the same concentrations in both series, $x + 1y = 2x$, ... $x + 5y = 6x$, however, the amounts separated are equal over the whole range. This result accords with the principle of SSE-IDA and ensures the accurate determination under conditions not suitable for Subst-IDA.

SSE-IDA obviously has many advantages over Subst-IDA and is a promising method for determination of trace amounts of metals in various substances. We are now planning to determine metals in living bodies by this method.
Fig. 5. Relationship between the amount of Sb(V) separated, m, and the total amount of Sb(III) in each aliquot in both series. Sb(III) taken ($= x$) = 2.41 μg; $iy = 2.41 \times i$ μg, $i = 1, 2, ...6$. The conditions are the same as for Fig. 4.

Table 2. Results of determination of 2.41 μg of antimony(III) by Redox Subst-IDA (conditions as for Fig. 4)

Equation Subst-IDA	Found, μg	Error, %	Data used† (see Table 3)

EXTRACTIVE FLUORIMETRIC DETERMINATION OF ULTRATRACES OF LEAD WITH 18-CROWN-6 AND EOSIN

A. Sanz-Medel, D. Blanco Gomis, E. Fuente and S. Arribas Jimeno

Departamento de Química Analítica, Facultad de Química, Universidad de Oviedo, Oviedo, España

Summary—A highly sensitive and selective spectrofluorimetric procedure for the determination of lead in the range 0.003–0.5 ppm, based on solvent extraction of the ion-pair formed between the eosinate anion and the cationic complex of Pb^{2+} with 18-crown-6, has been developed. The relative standard deviation is 3.7% at the 0.1 ppm level. The metal:ligand:counter-ion molecular ratio in the ion-pair extracted is 1:1:1, but aggregation of the complex may occur in the organic phase. The system proposed is exceptionally selective for extraction of lead in the presence of other cations frequently associated with it. The proposed method has been tested in the determination of lead in tap water. The results show good agreement with those found by the more common extractive atomic-absorption method using ammonium tetramethylenedithiocarbamate.

Reports have been published on the complexation of bivalent cations with synthetic macrocyclic polyethers, showing that lead(II) forms markedly stable complexes with some 18-crown-6 polyethers.[1,2] Moreover, such cationic lead complexes exhibit a high degree of extractability into several organic solvents, with picrate as counter-ion.[3,4] The solvent extraction of the ion-pair formed by these crown ether complexes and a suitable highly fluorescent organic anion could form the basis for a sensitive fluorimetric determination of lead.

We have already reported the impressive sensitivity and selectivity that can be achieved by using this principle in the fluorimetric determination of potassium with 18-crown-6 and eosin.[5] Alkali metal ions can be similarly determined spectrophotometrically by use of a highly coloured counter-ion.[6,7] A spectrophotometric determination of this type, using the cryptand 2.2.2, has recently been published for lead.[8] As far as we know, however, no fluorimetric determination of lead has yet been based on macrocyclic compounds. In our work on extraction and determination of potassium with 18-crown-6 we found that all the colorimetric methods for potassium that we tested[6] were analytically less satisfactory (poorer sensitivity and selectivity) than our fluorimetric one.[5] We also found a strong positive interference from lead[5,6] in agreement with the high values of the reported stability of the binary complex of 18-crown-6 with lead, and its extractability as an ion-pair. Subsequent investigation showed that with eosinate as counter-ion, the lead/18-crown-6 complex is extractable from alkaline media, whereas the alkali metal complexes are extracted only from slightly acidic solution.[5] As other cations frequently associated with lead form only very weak 18-crown-6 complexes, if any, the method should be highly selective for lead.

We have therefore undertaken a detailed investigation on the extraction of Pb(II) with 18-crown-6 and eosin into different organic solvents. As a result a new fluorimetric determination of lead, with high sensitivity and selectivity, is proposed. The method has been tested for the determination of lead in tap water.

EXPERIMENTAL

Apparatus

Fluorescence intensity measurements were made on a Perkin–Elmer MPF-44A spectrofluorimeter; 2-nm bandwidths were used in both the excitation and emission systems.

Reagents

All reagents were of analytical grade and redistilled and demineralized water was used.

18-Crown-6 stock solution. An aqueous stock solution ($3.6 \times 10^{-3}M$) of the crown ether was diluted as required, every day, before use. The 18-crown-6 used was prepared by the Pedersen method[9] with the second step of the synthesis modified as recommended by Gokel and Cram.[10] The product was purified either by recrystallization from petroleum ether or by the Gokel *et al.* method[11] of complexation with acetonitrile. The latter purification technique proved to be the more efficient for eliminating metal traces in the final product. The fluorimetric blanks obtained with the 18-crown-6 thus purified were considerably lower than those observed for the commercial 18-crown-6 reagent tested.

Pb(II) stock solution (1000 ppm). Prepared by dissolving 1.598 g of lead nitrate in water, and diluting to 1 litre, and standardized gravimetrically by precipitation of lead sulphate. All standard lead solutions were freshly prepared by dilution of this stock solution.

Eosin solution $5.4 \times 10^{-3}M$. A solution of the disodium salt (as received from Merck), prepared daily to avoid possible dimerization of the dye.

Buffer solution (pH 8.5). Prepared by dissolving 38.14 g of sodium tetraborate 10-hydrate in about 800 ml of redistilled and demineralized water, adjusting to the required pH with $1M$ hydrochloric acid and diluting to 1 litre with water.

Dichloromethane. Merck "Uvasol" grade for fluorimetry.

General procedure

Transfer into 50-ml separating funnels known volumes of standard lead solution (containing from 0.025 to 2.5 μg of lead). To each funnel add 0.5 ml of the 18-crown-6 stock solution, 1 ml of buffer solution, 0.5 ml of eosin solution, and dilute to 5 ml with redistilled and demineralized water (final pH 8.5 ± 0.1). After mixing, add 5 ml of dichloromethane (previously equilibrated with lead-free buffered aqueous phase) and extract the complex by shaking for 2–5 min. Allow the phases to separate and measure the fluorescence intensity, I_F, of the organic phase at 549 nm (excitation wavelength 537 nm).

Run a reagent blank in the same way and subtract its fluorescence from that of the sample. The plot of the corrected fluorescence against amount of lead should be a straight line passing through the origin.

Procedure for lead determination in tap water

Pipette 2 ml of the sample into a 50-ml separating funnel, add the 18-crown-6 solution and other reagents and continue as described for the general procedure. If the water sample was acidified for conservation, add enough tetramethylammonium hydroxide solution to neutralize most of the acidity before adding the buffer.

RESULTS AND DISCUSSION

Choice of organic solvent

Toluene, chlorobenzene, isobutyl methyl ketone, 1,2-dichloroethane, dichloromethane, chloroform and carbon tetrachloride were tested as solvents in the extraction. The fluorescence intensities, corrected for the corresponding blank, for 0.7 μg of lead were in the order: dichloromethane > 1,2-dichloroethane > chloroform > isobutyl methyl ketone > chlorobenzene. No fluorescence was observed when toluene or carbon tetrachloride was used. Therefore, dichloromethane was selected as the organic solvent.

Absorption and emission spectra

Figure 1 shows the excitation and emission spectra of the blank and the complex extracted into dichloromethane from an aqueous medium of pH 8.5. These spectra are uncorrected for variations in the emission characteristics of the xenon lamp and the response characteristics of the photomultiplier. The complete excitation spectrum exhibits two maxima: the more intense one (at 537 nm) is shown in Fig. 1; the other maximum (at 318 nm) is not shown. The emission maximum appears at 549 nm. The blank spectra observed exhibit the same shape and characteristics, indicating unwanted extraction of eosin. To obtain the largest difference in fluorescence emission between the complex and the blank when extraction is done at pH 8.5, the excitation wavelength of 537 nm is used, with 2-nm spectral band-pass for both excitation and emission, to minimize possible first-order scatter.

Effect of pH

The influence of pH on the extraction was evaluated by measuring the fluorescence intensity due to 0.2 ppm of lead in the test solution, and that of the corresponding blanks, over the pH range from 4 to 11 (adjusted by addition of acetic acid, lithium carbonate, lithium hydroxide or tetramethylammonium hydroxide).

Maximum fluorescence is obtained for extraction at pH 8.5 ± 0.1, as shown in Fig. 2. Lead is extracted at a much higher pH than are alkali metals with this system (as shown in Fig. 2, and in our earlier work,[5] potassium extraction is optimal at pH 5.9). Atomic-absorption analysis of the two phases shows that in
Fig. 1. Excitation (a) and emission (b) spectra of blank (B) and ion-association lead complex (A); I_F in arbitrary units.
Fig. 2. Variation of fluorescence intensity with pH. (A) Potassium ion-association complex (4 ppm K); (B) lead ion-association complex (0.2 ppm Pb); I_F in arbitrary units.
Fig. 3. Variation of fluorescence intensity as a function of reagent concentration: (A) molar concentration of 18-crown-6; (B) molar concentration of eosin; I_F in arbitrary units.

the extraction at pH 8.5, all the potassium remains in the aqueous phase. This is in accordance with formation of the doubly charged eosinate anion at pH > 5–6.[12]

Reagent concentrations

The influence of the crown ether and eosin concentrations on the fluorescence signal of the extracted ion-pair was studied with a fixed amount of lead (1 μg) and a single extraction step. The results are plotted in Fig. 3, which shows that the signal becomes constant at a total 18-crown-6 concentration of $2.0 \times 10^{-4}M$ (for a fixed eosin concentration of $3.0 \times 10^{-3}M$), and constant maximum fluorescence intensity is observed at eosin concentrations higher than $1.4 \times 10^{-4}M$ (with a fixed 18-crown-6 concentration of $3.6 \times 10^{-4}M$).

Rate of extraction and stability of the extract

A plot of corrected I_F vs. shaking-time shows that the degree of extraction is constant and reproducible after 1 min of shaking. The green fluorescence produced in the dichloromethane layer remains constant for at least 4 hr. The order of addition of the reagents

is unimportant, provided that the crown ether is added before the pH adjustment. Separation of the phases is rather slow, however, as the organic layer appears quite cloudy (especially if the room temperature is low) and, without centrifugation, it takes about 30 min to become clear and ready for fluorescence measurements.

The experiments were usually done at $20 \pm 1°$, but no significant influence of the temperature on the fluorescence was noted over the range $20 \pm 5°$.

Precision and recovery

The efficiency of the extraction, under the conditions of the general procedure, was found by determining the lead extracted from five independent samples and blanks. ICP emission photometry was used for the analysis and the recovery of lead in a single extraction was found to be $92.6 \pm 2.6\%$.

The recommended procedure was applied to the repetitive determination of 0.7 μg of lead during a period of several days. Ten determinations produced a relative standard deviation of 3.7%.

Selectivity

We have studied the effect of several metal ions, selected from those capable of forming stable complexes with 18-crown-6 (i.e., alkali and alkaline-earth metals) and those most commonly associated with lead (i.e., Hg, Zn, Cd, etc.) and disturbance of many of the colorimetric/fluorimetric methods for its determination.

Except for sodium, the maximum amounts tested for the alkali and alkaline-earth ions were 1000-fold molar ratio to lead. For the rest of the potential interferents a 100-fold molar ratio was initially tested. Ions which were found to interfere at these levels were then tested at lower concentrations. An ion was considered to interfere when it changed the fluorescence intensity for 0.7 μg of lead by more than twice the relative standard deviation (i.e., by more than $\pm 8\%$).

The results are shown in Table 1. As can be seen, for alkali and alkaline-earth metal cations the observed degree of interference is in agreement with the values of the stability constants of the corresponding LM^{n+} complexes in aqueous solution.[1,13] Only Sr^{2+} and Ba^{2+} constitute an exception to the general trend: as shown in Table 1 the effect of both metals on the lead determination is virtually the same despite the fact that the stability constants reported (log $K_f^{LSr} = 2.72$, log $K_f^{LBa} = 3.87$) indicate that the strontium complex is much the weaker.[1] This result is in agreement with our previous findings[5] for extraction at pH 5.9 ± 0.1, and with Takeda and Kato's observations for picrate as counter-ion:[3] knowledge of the stability constant of the LM^{n+} complex is not enough for prediction, even qualitative, of the degree of extraction (interference) of metal M, because the extractability of the corresponding ion-pair complex $LM^{n+}A^{n-}$ sometimes becomes the dominant factor.

Table 1. Effect of foreign ions (M) on the determination of 0.7 μg of lead

Cation	M:Pb (molar ratio)	Apparent recovery, %
Li^+	1000	103.7
Na^+	1000	102.1
K^+	200	101.4
Cs^+	100	104.7
NH_4^+	100	96.3
Tl^+	100	104.4
Ag^+	100	101.1
Mg^{2+}	1000	102.6
Ca^{2+}	500	103.7
Sr^{2+}	50	108.0
Ba^{2+}	50	107.3
Ni^{2+}	100	97.3
Cu^{2+}	100	100.4
Zn^{2+}	100	106.6
Cd^{2+}	100	96.7
Hg^{2+}	100	108.0
Co^{2+}	100	98.1
Mn^{2+}	100	98.5
Fe^{3+}	5	97.0
Al^{3+}	100	98.4
Cr^{3+}	50	94.1
Bi^{3+}	50	97.4

Curiously enough, Fe^{3+}, which is not known to form complexes with 18-crown-6, can be tolerated at only a relatively low level. Increasing iron concentration [even of Fe(II)] inhibits the extraction of lead. This effect is attributed to the relatively high working pH, which results in the precipitation of iron hydroxide, the adsorption characteristics of which would hinder the formation and extraction of the lead complex [relatively high levels of Cr(III) and Bi(III) also tend to hinder the extraction, probably for a similar reason]. Several masking agents were tested as a means of keeping the iron in solution, fluoride being the most effective [a 25-fold molar ratio of iron to lead can be tolerated in the presence of $1.1M$ $N(CH_3)_4F$]. In any case, for samples with a high content of iron the best choice is to extract the Fe(III) first, at pH 1.5 with a 1:1 mixture of acetylacetone and chloroform, and finally wash the aqueous layer with chloroform.[14] Analysis for lead in the remaining aqueous layer by the recommended procedure has demonstrated that iron in up to 400-fold molar ratio to lead can be eliminated in this way.

An inspection of Table 1 indicates that most of the elements likely to be found associated with lead in drinking water do not interfere. The proposed extraction would also be very useful for determination of lead in biological materials. In fact, the ubiquitous element sodium in amounts up to 2×10^5 times that of the lead present had no noticeable effect on the lead determination.

The effect of the common anions fluoride, chloride, nitrate and sulphate was negligible, even for amounts higher than 5×10^4 times that of the lead.

Except for the indirect influence of iron, the method proposed is highly selective for lead.

Stoichiometry of the extracted complex

Job's method, with fluorescence measurements, was used to establish the stoichiometry of the lead complex extracted in the presence of eosin. The results obtained with excess of eosin present are shown in Fig. 4, and indicate a 1:1 lead–crown ether molar ratio. These results agree with those previously obtained by Takeda and Kato[3] with picrate as counter-ion.

The molar ratio of lead to eosin in the ion-pair was initially determined by the "equilibrium-shift" and Job methods (Figs 4 and 5). Both methods indicate a 1:2 lead–eosin molar ratio, although the Job method also indicates the possible presence of a 1:1 complex. From the dissociation constants of eosin[12] and the pH used (8.5), only a neutral complex (1:1:1

lead:crown:eosin) should be extracted. Therefore, to clear up this point, we made measurements of the distribution ratio of lead and eosin between the organic and aqueous phase at pH 8.5. The lead concentrations in both phases were measured by atomic-absorption and ICP emission for two series of experiments, one with 200 ppm and the other with 50 ppm of lead. Equilibrium eosin concentrations in each case were determined by spectrophotometry at 516 nm. The results obtained are summarized in Fig. 6 and Table 2. Figure 6 shows clearly the existence of two different situations: apparently a 1:1:1 complex is extracted at low eosin concentrations, but a 1:1:2 complex forms at higher eosin concentrations. However, determination of the total concentrations of lead and eosin actually present in the organic phase for every experiment (Table 2) demonstrated that in all cases the actual molar ratio of lead to eosin was 1:1 (allowance has to be made, from reagent blanks, for extraction of eosin itself, which accounts for the values obtained being slightly higher than 1.0).

The species extracted has a metal:ligand:counter-ion molecular ratio of 1:1:1. The observed change in slope of the $\log D$ vs. $\log[eosin]$ plots at higher eosin concentrations can be attributed to aggregation processes in the organic phase (cf. Sekine and Hasegawa,[15] and Müller and Diamond[16]).

Determination of lead in tap water

Lead was determined in tap water from the Asturias district. The proposed method was tested, without any preconcentration step, and the results compared with those obtained by the extractive atomic-absorption method using a ten-fold preconcentration with ammonium tetramethylenedithiocarbamate.[17]

The results obtained are summarized in Table 3. It can be concluded that similar accuracy and precision are obtained by both methods. The fluorimetric method proposed here, however, is more sensitive and would allow the use of much smaller sample volumes.

Fig. 6. Dependence of the lead distribution ratio on the eosin concentration in the aqueous phase. (A) $C_{Pb} = 9.66 \times 10^{-4}M$, $C_L = 9.66 \times 10^{-2}M$, $C_{eosin} = 10^{-4}-10^{-3}M$; (B) $C_{Pb} = 2.42 \times 10^{-4}M$, $C_L = 2.00 \times 10^{-1}M$, $C_{eosin} = 3.15 \times 10^{-5}-2.50 \times 10^{-4}M$; I_F in arbitrary units.

EXCHANGE EQUILIBRIA BETWEEN BICARBONATE, CARBONATE, CHLORIDE AND BROMIDE ON DOWEX 1 × 8

Ulla Lundström and Åke Olin

Department of Analytical Chemistry, University of Uppsala, P.O.B. 531, S-751 21 Uppsala, Sweden

Summary—The exchange reaction $2R^+HCO_3^- + CO_3^{2-} \rightleftharpoons R_2^+ CO_3^{2-} + 2HCO_3^{2-}$ has been studied on Dowex 1 × 8 in the presence of bicarbonate solution in equilibrium with atmospheric carbon dioxide (open system). The experiments showed, as theory predicts, that the composition of the resin phase is independent of the concentration of the bicarbonate solution. The mole fraction of carbonate at equilibrium is about 0.4 and the equilibrium constant is $0.15M$ at 20°. With this value of the constant, the composition of the ion-exchanger for various bicarbonate concentrations has been calculated for a closed system. At $[HCO_3^-] < 0.01M$ a substantial part of the resin is in the carbonate form, whereas for $[HCO_3^-] > 0.05M$ the resin is present almost exclusively in bicarbonate form. The exchange constants of bromide at trace level have been determined for the bicarbonate and mixed carbonate forms of the ion-exchanger. The exchange constant $K_{Cl}^{HCO_3}$ has been determined over the whole composition range and the results can be represented by $K_{Cl}^{HCO_3} = 0.428 - 0.063x_{Cl} - 0.115x_{Cl}^2$, where x_{Cl} is the mole fraction of chloride in the resin. The constants are used to discuss the conditions for the chromatographic enrichment of bromide from fresh water.

A method for the determination of bromide has recently been presented,[1] based on oxidation of bromide to bromate by peroxodisulphate, followed by reaction of the bromate with excess of iodide in the absence of air, and spectrophotometric measurement of the iodine liberated. The sensitivity of the method is 2.25 absorbance units (AU) per μmole of bromide, or, in terms of the bromide concentration of the original sample, 0.0225 AU.l.μmole^{-1}. For determination of low levels of bromide an enrichment of the ion is therefore necessary. In the analytical procedure developed for the determination of trace amounts of bromide in fresh water, this was accomplished by chromatographic enrichment of Dowex 1 × 8 in chloride form.[2] The uptake of bromide in the presence of the main constituents of fresh water was studied and the results of the investigations with chloride and sulphate were reported.[2] The direct influence of the normally predominant anion, bicarbonate, on the enrichment was eliminated in the analytical procedure by acidifying the sample. The ion-exchange equilibria involving the bicarbonate ion have now been investigated and are reported here.

The equilibrium constant of the reaction

$$R^+Cl^- + HCO_3^- \rightleftharpoons R^+HCO_3^- + Cl^- \qquad (1)$$
has been determined by both the batch[3] and the column[4] technique. The practical constant defined by

$$K_{Cl}^{HCO_3} = \frac{[HCO_3^-]_R[Cl^-]}{[Cl^-]_R[HCO_3^-]} \qquad (2)$$

is about 0.3–0.5, depending on the composition of the resin phase (subscript R denotes concentrations in this phase). In similar measurements with bromide instead of chloride, we found that when a solution containing bicarbonate and bromide was passed through a column containing Dowex 1 × 8 in chloride form, there was a considerable drop in pH in the first portions of the effluent. It was therefore suspected that the ion-exchanger was partly converted into the carbonate form even though the carbonate activity is small in bicarbonate solutions. Apparently this possibility has not been considered before, and our investigation showed that a considerable part of the ion-exchanger was present in the carbonate form.

These findings could be of importance for the accuracy of previously determined values of $K_{Cl}^{HCO_3}$. Therefore, this constant was redetermined under conditions where no carbonate was present in the resin phase. Under the same conditions, the constant for the reaction

$$R^+HCO_3^- + Br^- \rightleftharpoons R^+Br^- + HCO_3^- \qquad (3)$$
was determined at high bicarbonate loadings on the resin. This constant is of importance for the uptake of bromide from fresh water of high alkalinity.

EXPERIMENTAL

The experiments were done at 20°.

Chemicals

All solutions were prepared by dissolving Merck analytical-grade reagents in demineralized distilled water. The ion-exchange resin, Dowex 1 × 8 (100–200 mesh, pract., Serva Feinbiochemica), was treated before use, as already described.[2]

Apparatus

In the experiments where the column technique was used for equilibration, the ion-exchange tube already described[2] was employed. The batch equilibrations were performed in 250-ml glass-stoppered Erlenmeyer flasks, which were continuously shaken for 24 hr. The potentiometric titrations for the determination of carbonate and chloride were performed with the Metrohm Titroprocessor, E636, equipped with a Dosimat burette, E635.

Analysis

The resin phase was eluted with $2M$ sodium perchlorate. The eluate and the solution in equilibrium with the resin were analysed by the following methods. Bromide was determined as previously described,[2] chloride by a potentiometric titration with standard silver nitrate, carbonate by a potentiometric titration with standard acid to the bicarbonate end-point, and total carbonate by titration with standard acid in the usual way. Prior to elution the resin was thoroughly drained. The residual liquid causes an error of at most 1% in the composition found for the resin.

Determination of $K_{2HCO_3}^{CO_3}$

The column technique, with 2 ml of resin, originally in chloride form, was utilized. Air was passed through sodium bicarbonate solutions of known concentrations until a constant pH was reached, before they were passed through the column. The air was presaturated with water vapour by passing it through wash-bottles containing bicarbonate solution of the same concentration as the test solution. The attainment of equilibrium in the column was established by measurement of the pH of the inflowing and outflowing solutions. The resin was then analysed for carbonate and total carbonate.

Determination of $K_{HCO_3}^{Br}$ and $K_{CO_3}^{2Br}$

The same procedure was used as for the determination of $K_{2HCO_3}^{CO_3}$. The solution passed through the column also contained bromide at a concentration of $1 \times 10^{-5}M$. The resin was analysed for bromide, carbonate and total carbonate.

Determination of $K_{HCO_3}^{Br}$

The batch technique was used, 200 ml of a solution containing known varied amounts of bromide and bicarbonate being shaken with 2 ml of the resin in bicarbonate form. All solutions were saturated with carbon dioxide (at 1 atm pressure) and the equilibration took place in a CO_2 atmosphere. The bicarbonate form of the resin was prepared by treating the resin (in chloride form) first with 100 ml of $0.2M$ bicarbonate solution, and then with 20 ml of a solution having the bicarbonate concentration used in the equilibration experiment. The resin was analysed for bicarbonate and bromide.

Determination of $K_{Cl}^{HCO_3}$

Essentially the same technique was used as for the determination of $K_{HCO_3}^{Br}$. For $x_{Cl} < 0.5$ the resin was initially in the bicarbonate form and for $x_{Cl} > 0.5$ in the chloride form. The resin and the equilibrium solution were both assayed for chloride and bicarbonate.

CALCULATIONS AND RESULTS

The $HCO_3^- - CO_3^{2-}$ exchange

The equilibrium constant of the reaction

$$2R^+HCO_3^- + CO_3^{2-} \rightleftharpoons R_2^+CO_3^{2-} + 2HCO_3^- \quad (4)$$
is given by

$$K_{2HCO_3}^{CO_3} = \frac{\{CO_3\}_R\{HCO_3\}^2}{\{HCO_3\}_R^2\{CO_3\}} \quad (5)$$

Brackets are used to denote activities, charges have been left out, and subscript R denotes the resin phase. In the following, mole fractions will be used instead of activities in the resin phase. The practical equilibrium constant written with the use of mole fractions will be denoted by K_R. It is not a true constant. The carbonate species also take part in the acid–base equilibria

$$K_1 = \frac{\{H\}\{HCO_3\}}{\{H_2CO_3\}} \quad (6)$$

$$K_2 = \frac{\{H\}\{CO_3\}}{\{HCO_3\}} \quad (7)$$

By combining equations (5)–(7) we obtain

$$K_R K_2 = \frac{x_{CO_3}}{x_{HCO_3}^2}\{HCO_3\}\{H\} \quad (8)$$

and

$$\frac{K_R K_2}{K_1} = \frac{x_{CO_3}}{x_{HCO_3}^2}\{H_2CO_3\} \quad (9)$$

In the first experiments bicarbonate solutions were passed through the ion-exchange column with the resin initially in the chloride form. The approach towards equilibrium was followed by measurement of the pH of the inflowing and outflowing solutions. The pH-values varied erratically, however, and constant values could not be reached. This can be understood by considering the autoprotolysis of the bicarbonate ion, $2HCO_3^- \rightleftharpoons CO_3^{2-} + H_2CO_3$, in conjunction with equation (9). A solution of bicarbonate will generally be over- or under-saturated with respect to the partial pressure of carbon dioxide in air. Hence the concentration of carbonic acid in the test solution will vary and the exchange equilibrium will shift continuously.

As a consequence of the experience gained from the first series of measurements, air presaturated with water vapour was passed through the bicarbonate solution until a constant pH was reached. The equilibrium $CO_2(g) + H_2O \rightleftharpoons H_2CO_3$ ensures a well-defined and constant carbonic acid activity in the test solution (provided there is no large variation in the CO_2 concentration in the ambient air). From equation (9) it follows that the composition of the ion-exchange resin should be constant and independent of the concentration of the bicarbonate solutions. This was verified by our results for the three concentrations used (Table 1).

The value of K_R was calculated from equation (9), $\{H_2CO_3\} = 1.28 \times 10^{-5}M$, $K_1 = 4.16 \times 10^{-7}M$, and $K_2 = 4.20 \times 10^{-11}M$.[5] It was also obtained from equation (8) with $\{HCO_3^-\}$ calculated from

$$\{HCO_3^-\} = \frac{y_1 C}{1 + 2y_1 K_2/y_2\{H\}} \quad (10)$$

where C is the total concentration of sodium bicarbonate in the test solution, and y_1 and y_2 are the activity coefficients of the bicarbonate and carbonate

Table 1. Determination of the exchange constant, K_R, of the reaction $2R^+ HCO_3^- + CO_3^{2-} \rightleftharpoons R_2^+ CO_3^{2-} + 2HCO_3^-$ on Dowex 1 × 8 at 20°C; open system in equilibrium with aerial carbon dioxide; x_{CO_3} is the mole fraction of carbonate in the resin

Mean values: x_{CO_3} 0.399 ± 0.018; K_R 0.146 ± 0.014 mole/l.

ions, calculated in the usual way. The results are presented in Table 1. Both methods of calculation yield concordant values of K_R. The mean values of x_{CO_3} and K_R are 0.399 ± 0.018 and $0.146 \pm 0.014 M$, respectively (16 determinations). The somewhat low precision reflects the difficulty of obtaining true equilibrium in the system and of determining carbonate in the presence of bicarbonate by a conventional titration. Our measurements demonstrate that in an open system a considerable part of the ion-exchanger is in the carbonate form. Reckoned in equivalents, the carbonate form will constitute about 60% of the exchange capacity.

No measurements have been performed on a closed system i.e., a system where no exchange of carbon dioxide with the atmosphere takes place. In practical enrichment work, the conditions are expected to be somewhere in between those of a closed and an open system. Therefore theoretical calculations of the composition of the resin phase have been made for a closed system. In these calculations, $K_R = 0.146 M$ and activities for the species in the aqueous phase were used. The results are presented in Fig. 1. They show that a considerable part of the ion-exchanger can be expected to be present in the carbonate form at low bicarbonate concentrations. This fraction rapidly diminishes with increasing bicarbonate concen-
Fig. 1. The calculated mole fraction of bicarbonate, x_{HCO_3}, in Dowex 1 × 8 as a function of the total bicarbonate concentration in the external solution, for a closed system. Equilibrium constants given in the text were used.

tration and for $[HCO_3^-] > 0.05 M$ the ion-exchanger is almost entirely in the bicarbonate form. Since the normal bicarbonate concentration in fresh water is below $0.005 M$, our findings suggest that equilibria involving also the carbonate form of the ion-exchanger will be of importance in the chromatographic enrichment of trace anions from such water.

The $HCO_3^- - CO_3^{2-} - Br^-$ exchange

The equilibrium constant of reaction (1) is about 0.4. In a fresh water of standard composition[6] the ratio $[HCO_3^-]/[Cl^-]$ is about 7.5. Hence the ratio x_{HCO_3}/x_{Cl} would be about 3 at equilibrium. From the results of the previous section we infer that an even larger part of the ion-exchanger will be present in carbonate forms than indicated by this figure. Thus equilibria between carbonate, bicarbonate and bromide will be of importance for the enrichment of bromide from fresh waters.[2] The pertinent equilibrium constants are defined by

$$K_{HCO_3}^{Br} = \frac{x_{Br}\{HCO_3\}}{x_{HCO_3}\{Br\}} \qquad (11)$$

$$K_{CO_3}^{2Br} = x_{Br}^2 \{CO_3\}/x_{CO_3}\{Br\}^2 \qquad (12)$$

we also have

$$K_R = (K_{HCO_3}^{Br})^2/(K_{CO_3}^{2Br}) \qquad (13)$$

$K_{HCO_3}^{Br}$ was determined for an open system in equilibrium with the partial pressure of carbon dioxide in air. Solutions with varying total concentrations of bicarbonate between 0.003 and $0.02 M$ in equilibrium with air and containing bromide at $1 \times 10^{-5} M$ concentration were passed through ion-exchange columns until equilibrium was reached. From the analysis of the resins and the known compositions of the equilibrium solutions, $K_{HCO_3}^{Br}$ was found to be 14.4 ± 0.8 $(n = 12)$. This constant refers to a resin with $x_{CO_3} \approx 0.4$. The mole fraction of bromide is very small. From equation (13) $K_{CO_3}^{2Br}$ is calculated to be $(1.42 \pm 0.16) \times 10^3$ l./mole.

$K_{HCO_3}^{Br}$ was also determined in batch experiments for a resin with $x_{HCO_3} = 1$, in the presence of an atmosphere of pure carbon dioxide. This ensures that no carbonate will be present in the resin phase. The value of $K_{HCO_3}^{Br}$ was found to be 10.1 ± 0.2, $(n = 5)$.

The $HCO_3^- - Cl^-$ exchange

In previous determinations[3,4] of $K_{Cl}^{HCO_3}$ the possible formation of carbonate in the resin phase was not considered. The constant was therefore redetermined under conditions (see experimental) that precluded the formation of carbonate as counter-ion in the resin. The value of $K_{Cl}^{HCO_3}$ was found to increase steadily from 0.25 at $x_{Cl} = 1$, to 0.43 at $x_{Cl} = 0$. The same trend was observed by Fekete and Inczédy,[4] who report 0.33 $(x_{Cl} = 1)$ and 0.52 $(x_{Cl} = 0)$. Their value of log $K_{Cl}^{HCO_3}$ was linearly dependent on x_{Cl}. Our

data do not fit this relationship. The equation

$$K_{Cl}^{HCO_3} = 0.428 - 0.063x_{Cl} - 0.115x_{Cl}^2 \qquad (14)$$

can be used to find $K_{Cl}^{HCO_3}$ at intermediate x_{Cl}.

The numerical values of the constant obtained in the two investigations agree quite well, which indicates that the extent of carbonate formation was small in the column experiments.[4] This agrees with our calculations for a closed system (Fig. 1), since the bicarbonate concentrations in the external solution were in the range $0.1-0.015M$.

For an ion-exchanger in equilibrium with a solution containing bicarbonate and chloride, the following expression for the adjusted retention volume, V_R', can be derived for the ion A^{z-} at trace levels:

$$V_R' = \frac{E}{1 + x_{CO_3}} \left(\frac{x_{CO_3}}{[HCO_3]}\right)^z K_{zHCO_3}^A \qquad (15)$$

where E is the total exchange capacity of the resin bed in meq. For bromide in fresh water of standard composition, the values of V_R' are estimated from our

constants to be 4.2 litres for an open system and 5.8 litres for a closed system. These values pertain to a 2-ml resin bed with a capacity of 3.2 meq. The larger value for the closed system is due to the increased concentration of carbonic acid, which leads to a smaller value of x_{CO_3} and a larger value of x_{HCO_3} as compared to the open system. If the formation of the carbonate form of the ion-exchanger is neglected, V_R' becomes 6.5 litres. For an open system the carbonate formation thus reduces V_R' by about 35%.

SPECTROPHOTOMETRIC STUDIES ON ION-PAIR EXTRACTION EQUILIBRIA OF THE IRON(II) and IRON(III) COMPLEXES WITH 4-(2-PYRIDYLAZO)RESORCINOL

HITOSHI HOSHINO and TAKAO YOTSUYANAGI

Department of Applied Chemistry, Tohoku University, Aoba, Aramaki, Sendai, 980 Japan

Summary—The ion-pair extraction equilibria of the iron(II) and iron(III) chelates of 4-(2-pyridylazo)resorcinol (PAR, H_2L) are described. The anionic chelates were extracted into chloroform with benzyldimethyltetradecylammonium chloride (QCl) as counter-ion. The extraction constants were estimated to be $K_{ext1}^{Fe(II)} = [Q\{Fe^{II}(HL)L\}]_o/[Q^+][\{Fe^{II}(HL)L\}^-] = 10^{8.59 \pm 0.11}$, $K_{ext2}^{Fe(II)} = [Q_2\{Fe^{II}L_2\}]_o/[Q^+]^2[\{Fe^{II}L_2\}^{2-}] = 10^{12.17 \pm 0.10}$ and $K_{ext}^{Fe(III)} = [Q\{Fe^{III}L_2\}]_o/[Q^+][\{Fe^{III}L_2\}^-] = 10^{6.78 \pm 0.15}$ at $I = 0.10$ and 20°, where [ ]$_o$ is concentration in the chloroform phase. Aggregation of $Q\{Fe^{III}L_2\}$ in chloroform was observed and the dimerization constant $(K_d = [Q_2\{Fe^{III}L_2\}_2]_o/[Q\{Fe^{III}L_2\}]_o^2)$ was evaluated as log $K_d = 4.3 \pm 0.3$ at 20°. The neutral chelates of $\{Fe^{II}(HL)_2\}$ and $\{Fe^{III}(HL)L\}$, and the ion-pair of the cationic chelate, $\{Fe^{III}(HL)_2\}ClO_4$, were also extracted into chloroform or nitrobenzene. The relationship between the forms and extraction properties of the iron(II) and iron(III) PAR chelates are discussed in connection with those of the nickel(II) and cobalt(III) complexes. Correlation between the extraction equilibrium data and the elution behaviour of some PAR chelates in ion-pair reversed-phase partition chromatography is also discussed.

Spectrophotometric determination of iron(II) and iron(III) with 4-(2-pyridylazo)resorcinol (PAR, H_2L) has been proposed,[1-5] but data on the structures and acid properties of these chelates do not seem to be consistent. For example, Nonova *et al.* reported the formation equilibria of $\{Fe^{II}(HL)L\}^-$ and $\{Fe^{III}(HL)L\}$, but paid no attention to any other iron–PAR complexes in solution.[4] Russeva *et al.*[5] reported the formation of Fe(III)–PAR complexes, but did not describe that of the 1:2 Fe:PAR complexes which are predominant under analytical conditions, *i.e.*, in the presence of PAR in large excess.

In our studies on extraction of the PAR chelates of some transition metal ions, as ion-pairs with quaternary ammonium cations,[6-10] we noticed that the extraction behaviour varied markedly, according to the nature of the central metal ion.[9,10] Equilibrium studies on these extraction systems should yield important information about the sometimes puzzling nature of PAR chelates, as well as understanding of the basis for these extractive colorimetric determinations.[6-13] Such equilibrium data may also serve for prediction of the order of elution of PAR chelates in ion-pair reversed-phase partition chromatography.[14]

In this paper, the extraction equilibria of the PAR complexes of iron(II) and iron(III) with benzyldimethyltetradecylammonium chloride (BDTACl, QCl) are reported and interpreted.

EXPERIMENTAL

Apparatus

A Hitachi model 124 double-beam recording spectrophotometer with 1-cm glass cells, and a Hitachi-Horiba M-5 pH-meter were used.

Reagents

Aqueous stock solutions of iron(II) and iron(III) ammonium sulphate were made from guaranteed reagent grade salts, with a few drops of concentrated sulphuric acid added to prevent hydrolysis. The solutions of PAR and QCl were prepared as previously reported.[9] Chloroform and nitrobenzene were purified by distillation and saturated with water before use. All other reagents used were of analytical grade.

Procedure

The extraction procedure has already been described.[9] To prevent aerial oxidation of iron(II) during the extraction, a small amount of L-ascorbic acid (enough to give a concentration of about $10^{-4}M$) was added. The metal–PAR ratio was found to be 1:2 by the molar-ratio method, for both Fe(II) and Fe(III). An ionic strength of 0.10 was maintained with sodium sulphate unless otherwise stated. The formation constants, $\beta_2 = [\{FeL_2\}]/[Fe][L^{2-}]^2$, for both chelates, are so large, $10^{31.4}$ and $10^{34.2}$ for Fe(II) and Fe(III) respectively,[15,16] that hydrolysis of the PAR chelates in neutral and slightly alkaline solutions was negligible if excess of PAR was present and the absorbance was measured within 2 hr. The formation of sulphate, chloride and ascorbate complexes can also be neglected under the conditions used. All studies were made at 20°.

RESULTS

The extraction equilibrium scheme is shown in Fig. 1. In the discussion below, the complexes present in the aqueous phase will be indicated by use of braces ({ }), as in the summary.

Extraction of Fe(II)–PAR chelates

The absorbance–pH curve (Fig. 2, curve A) for aqueous solution shows two distinct changes over the pH range 2–10 and the spectral change at higher pH

Fe(II)

$$\{Fe^{II}(HL)_2\} \rightleftharpoons \{Fe^{II}(HL)_2\}_o$$

$\updownarrow -H^+, pK_{a1} = 6.47$

$$\{Fe^{II}(HL)L\}^- \xrightleftharpoons[]{Q^+,\, \log K_{ex1}^{Fe(II)} = 8.59} Q\{Fe^{II}(HL)L\}_o$$

$\updownarrow -H^+, pK_{a2} = 7.66$

$$\{Fe^{II}L_2\}^{2-} \xrightleftharpoons[]{2Q^+,\, \log K_{ex2}^{Fe(II)} = 12.17} Q_2\{Fe^{II}L_2\}_o$$

Fe(III)

$$\{Fe^{III}(HL)_2\}^+ \xrightleftharpoons[]{ClO_4^-} [\{Fe^{III}(HL)_2\}ClO_4]_o$$

$\updownarrow -H^+, pK_{a1}$ (intro nitrobenzene)

$$\{Fe^{III}(HL)L\} \rightleftharpoons \{Fe^{III}(HL)L\}_o$$

$\updownarrow -H^+, pK_{a2} \sim 5$ (intro nitrobenzene)

$$\{Fe^{III}L_2\}^- \xrightleftharpoons[]{Q^+,\, \log K_{ex1}^{Fe(III)} = 6.78} [Q\{Fe^{III}L_2\}]_o$$

$\updownarrow \log K_d = 4.3$

$$[Q_2\{Fe^{III}L_2\}_2]_o$$
Fig. 1. Equilibrium scheme for extraction of iron(II) and iron(III) PAR chelates into chloroform.

agrees well with that found in a previous investigation.[4] The Fe(II)-PAR species in acidic solution is expected to be the neutral $\{Fe^{II}(HL)_2\}$, because at pH 3–5 the red chelate is partly extracted into chloroform even in the absence of Q^+.

The absorption spectra (Fig. 3) and the absorbance–pH curves (Fig. 2, curves B and C) show that at least two kinds of PAR chelate are involved in the extraction process. The Job plots indicate that the species extracted at pH 8.0 is $Q\{Fe^{II}(HL)L\}$. The species extracted from more alkaline solution is expected to be $Q_2\{Fe^{II}L_2\}$. The absorbance–pH curve when a slight excess of Q^+ is present has maximal absorbance at about pH 7 (curve B), whereas with a large excess of Q^+ the absorbance is highest at pH 9–10 (curve C). This suggests that $Q_2\{Fe^{II}L_2\}$ is less
Fig. 2. Absorbance–pH curves for the iron(II)–PAR–QCl system. (A) Absorbance in aqueous solution, $C_{Fe} = 9.99 \times 10^{-6}M$, $C_L = 2.05 \times 10^{-5}M$, $I = 0.10$ (H,Na)ClO$_4$], at 495 nm. (B) Absorbance in chloroform, $C_{Fe} = 1.00 \times 10^{-5}M$, $C_L = 2.00 \times 10^{-5}M$, $C_Q = 2.14 \times 10^{-5}M$, $I = 0.10$ (Na$_2$SO$_4$), at 505 nm. (C) Absorbance in chloroform, concentrations and conditions the same as for Fig. 3, at 505 nm.
Fig. 3. Absorption spectra of the extracted species in chloroform for the iron(II)–PAR–QCl system in the pH range 2.36–9.05. pH: (1) 2.36, (2) 3.38, (3) 4.41, (4) 6.10, (5) 9.05. $C_{Fe} = 9.99 \times 10^{-6}M$, $C_L = 2.05 \times 10^{-5}M$, $C_Q = 5.35 \times 10^{-4}M$, $I = 0.10$ (Na$_2$SO$_4$).

extractable than $Q\{Fe^{II}(HL)L\}$. The molar absorptivities (ε) of $Q\{Fe^{II}(HL)L\}$ and $Q_2\{Fe^{II}L_2\}$ in chloroform were found to be 4.00×10^4 l.mole^{-1}.cm^{-1} at 500 nm and 4.50×10^4 at 510 nm, respectively.

A quantitative description of the extraction equilibria of the Fe(II)–PAR chelates with Q^+ at pH 7–10 requires consideration of the reactions:

$$\{Fe^{II}(HL)L\}^- \rightleftharpoons \{Fe^{II}L_2\}^{2-} + H^+$$

$$K_{a2} = \frac{[H^+][\{Fe^{II}L_2\}^{2-}]}{[\{Fe^{II}(HL)L\}^-]} \quad (1)$$

$$\{Fe^{II}(HL)L\}^- + Q^+ \rightleftharpoons Q\{Fe^{II}(HL)L\}_o$$

$$K_{ex1}^{Fe(II)} = \frac{[Q\{Fe^{II}(HL)L\}]_o}{[Q^+][\{Fe^{II}(HL)L\}^-]} \quad (2)$$

$$\{Fe^{II}L_2\}^{2-} + 2Q^+ \rightleftharpoons Q_2\{Fe^{II}L_2\}_o$$

$$K_{ex2}^{Fe(II)} = \frac{[Q_2\{Fe^{II}L_2\}]_o}{[Q^+]^2[\{Fe^{II}L_2\}^{2-}]} \quad (3)$$
as well as the distribution of the ion-pairs of QCl and QHL,[9]

$$Q^+ + Cl^- \rightleftharpoons QCl_o \quad K_{ex}^{Cl} = \frac{[QCl]_o}{[Q^+][Cl^-]} \quad (4)$$

$$Q^+ + HL^- \rightleftharpoons QHL_o \quad K_{ex}^{HL} = \frac{[QHL]_o}{[Q^+][HL^-]} \quad (5)$$
where the subscript o indicates the species in the organic phase.

The chelate formation constant in the aqueous phase is large ($\log \beta_2 = 31.4$),[15] so formation of the iron(II) chelate should be almost quantitative at pH 7–9 in the presence of a small excess of PAR. Evaluation of the relevant equilibrium constants provides a check on the validity of the assumptions made above.

From equations (1)–(3), the following expression is obtained:

$$\frac{K_{ex2}^{Fe(II)} K_{a2}}{K_{ex1}^{Fe(II)}} = \frac{[H^+][Q_2\{Fe^{II}L_2\}]_o}{[Q^+][Q\{Fe^{II}(HL)L\}]_o} \quad (6)$$
Fig. 4. Plots of equation (9). (●) $C_{Fe} = 1.99 \times 10^{-5}M$, $C_L = 4.01 \times 10^{-5}M$, $C_Q = 5.35 \times 10^{-5}M$; (○) $C_{Fe} = 9.93 \times 10^{-6}M$, $C_L = 4.01 \times 10^{-5}M$, $C_Q = 1.07 \times 10^{-4}M$. C_{borate} or $C_{phosphate} = 2.5 \times 10^{-3}M$, $I = 0.10$ (NaCl).

The values of the constants in equation (6) cannot be determined simultaneously. Hence the values of K_{a2} and $K_{ex1}^{Fe(II)}$ were estimated in $0.10M$ sodium chloride medium, where the extraction of $Q_2\{Fe^{II}L_2\}$ can be neglected since its extractability relative to that of the chloride ion-pair is expected to be sufficiently low (see Appendix I).

The ion-exchange extraction is expressed by

$$QCl_o + \{Fe^{II}(HL)L\}^- \rightleftharpoons Q\{Fe^{II}(HL)L\}_o + Cl^-$$
$$K = \frac{[Q\{Fe^{II}(HL)L\}]_o[Cl^-]}{[QCl]_o[\{Fe^{II}(HL)L\}^-]} = \frac{K_{ex1}^{Fe(II)}}{K_{ex}^{Cl}} \quad (7)$$

and the distribution ratio of iron(II), $D_{Fe(II)}$, is given by

$$D_{Fe(II)} = \frac{[Q\{Fe^{II}(HL)L\}]_o}{[\{Fe^{II}(HL)L\}^-] + [\{Fe^{II}L_2\}^{2-}]} \quad (8)$$

where the concentrations of the ion-pair and the neutral chelate $\{Fe^{II}(HL)_2\}$ in the aqueous phase are neglected. From equations (1), (7) and (8), and the material-balance equation for Q^+, we obtain

$$\frac{[QCl]_o}{D_{Fe(II)}[Cl^-]} = \frac{1}{K} + \frac{K_{a2}}{K[H^+]} \quad (9)$$

where $[QCl]_o = C_Q - [QHL]_o - [Q\{Fe^{II}(HL)L\}]_o$, C_Q being the total concentration of Q^+. The data plotted in Fig. 4 are taken over the pH range 7.4–9.0. From the slope and intercept, the values of the constants in equation (9) were found to be $K_{a2} = 10^{-7.66 \pm 0.10}$ and

$K = 10^{3.48 \pm 0.08}$ at $I = 0.10$ (NaCl). Thus, $K_{ex1}^{Fe(II)} = K K_{ex}^{Cl} = 10^{8.59 \pm 0.11}$.

Under conditions in which both the chelate and HL^- are quantitatively extracted [$C_Q > 2 \times 10^{-4}M$ is required at $I = 0.10$ (Na$_2$SO$_4$)], the change in absorbance, A, over the pH range 7–10 (Fig. 3, curve C) can be used to evaluate $K_{ex2}^{Fe(II)}$ by means of equation (6):

$$K_{ex2}^{Fe(II)} = \frac{K_{ex1}^{Fe(II)}[H^+]}{K_{a2}[Q^+]}\left(\frac{A - A_1}{A_2 - A}\right) \quad (10)$$

where A_1 and A_2 are the constant absorbances at pH < 7.5 and > 9.5, respectively. From equation (11), the value of $[Q^+]$ can be calculated:

$$K_{ex}^{Cl}[Q^+]^2 + \{1 + K_{ex}^{Cl}\alpha\}[Q^+] - (C_Q - \alpha) = 0 \quad (11)$$

where $\alpha = C_L - C_{Fe}[(A_2 - A)/(A_2 - A_1)]$, C_L and C_{Fe} being the total concentrations of PAR and Fe(II), respectively. Derivation of equation (11) is given in Appendix II. The results of the calculations are shown in Table 1 and lead to $K_{ex2}^{Fe(II)} = 10^{12.17 \pm 0.10}$ at $I = 0.10$ (Na$_2$SO$_4$).

At total concentrations of $Q\{Fe^{II}(HL)L\}$ and $Q_2\{Fe^{II}L_2\}$ in chloroform up to $2 \times 10^{-5}M$, the results gave no evidence for dimer formation.

Extraction of Fe(III)–PAR chelates

The absorption spectra of the species extracted in the Fe(III)–PAR–QCl system at various pH values are shown in Fig. 5. In the presence of a large excess of Q^+, the extracted species has an absorption maximum at 495 nm ($\varepsilon = 6.03 \times 10^4$ l.mole^{-1}.cm^{-1}) with a distinct shoulder at 540 nm, and maximum and constant absorbance is obtained over the pH range 4–9 (Fig. 6, curve B). For comparison, the absorbance–pH curve in aqueous solutions is given as curve A in Fig. 6.

Two other kinds of iron(III)–PAR chelates are extractable into nitrobenzene, *viz.* the cationic $\{Fe^{III}(HL)_2\}^+$, with perchlorate as counter-ion ($\lambda_{max} = 535$ nm, Fig. 6, curve C), and the neutral $\{Fe^{III}(HL)L\}$ ($\lambda_{max} = 496$ nm, curve D).

The form of the ion-pair with Q^+ in chloroform was confirmed by continuous-variation plots at pH 8.2 to be $Q\{Fe^{III}L_2\}$.

					9.78	12.00		

$\log K_{ex2}^{Fe(II)} = 12.17 \pm 0.10$ (average value of 30 experiments).
Fig. 5. Absorption spectra of the extracted species in chloroform for the iron(III)–PAR–QCl system in the pH range 1.95–6.08. pH: (1) 1.95, (2) 2.60, (3) 2.89, (4) 3.21, (5) 4.22, (6) 6.08. $C_{Fe} = 5.05 \times 10^{-6}M$, $C_L = 1.22 \times 10^{-5}M$, $C_Q = 4.83 \times 10^{-4}M$, $I = 0.10$ (Na$_2$SO$_4$).

The distribution ratio of the $Q^+\{Fe^{III}L_2\}^-$ ion-pair into chloroform significantly increased with total concentration of the chelate, owing to the extensive aggregation of the ion-pair in chloroform. The extraction constant of the $\{Fe^{III}L_2\}^-$ chelate was obtained from the extraction data at concentrations of the chelate lower than $6 \times 10^{-6}M$, where the contribution of dimerization (or higher aggregation) was found to be negligible. The extraction constant of the ion-pair is given by

$$\{Fe^{III}L_2\}^- + Q^+ \rightleftharpoons Q\{Fe^{III}L_2\}_o$$
$$K_{ex1}^{Fe(III)} = \frac{[Q\{Fe^{III}L_2\}]_o}{[Q^+][\{Fe^{III}L_2\}^-]} \quad (12)$$

The extraction curve with nitrobenzene (Fig. 6, curve D) indicates that the pK_{a2} value of the chelate [equation (13)] is smaller than 5.5.

$$\{Fe^{III}(HL)L\} \overset{K_{a2}}{\rightleftharpoons} \{Fe^{III}L_2\}^- + H^+ \quad (13)$$

Thus, the predominant Fe(III)–PAR species con-
Fig. 6. Absorbance–pH curves of the iron(III)–PAR chelates in the several extraction systems. (A) Absorbance in aqueous solution at 495 nm. $C_{Fe} = 5.70 \times 10^{-6}M$, $C_L = 1.60 \times 10^{-5}M$, $I = 0.10$ [(H,Na)ClO$_4$]. (B) Absorbance in chloroform at 495 nm. Concentrations and conditions are the same as for Fig. 5. (C) Absorbance in nitrobenzene at 535 nm. With 0.1M NaClO$_4$, $C_{Fe} = 1.01 \times 10^{-5}M$, $C_L = 2.10 \times 10^{-5}M$. (D) Absorbance in nitrobenzene at 495 nm. C_{Fe} and C_L are the same as for (C).

cerned in the extraction at pH 8.2 is $\{Fe^{III}L_2\}^-$. Since the aqueous concentrations of free ferric ion and the ion-pair, $Q\{Fe^{III}L_2\}$ can be neglected, the distribution ratio of Fe(III), $D_{Fe(III)}$ is given by

$$D_{Fe(III)} = \frac{[Q\{Fe^{III}L_2\}]_o}{[\{Fe^{III}L_2\}^-]} \quad (14)$$

Substitution of (14) in (12) gives the extraction constant

$$K_{ex1}^{Fe(III)} = \frac{D_{Fe(III)}}{[Q^+]} \quad (15)$$

and $[Q^+]$ can be obtained from the material-balance equations (see Appendix II):

$$K_{ex}^{Cl}[Q^+]^2 + \{1 + K_{ex}^{Cl}\alpha\}[Q^+] - (C_Q - \alpha) = 0 \quad (16)$$

where $\alpha = [QHL]_o + [Q\{Fe^{III}L_2\}]_o$. The concentrations of $[QHL]_o$ and $[Q\{Fe^{III}L_2\}]_o$ were determined by solving the simultaneous equations for the absorbances measured at 400 and 495 nm.

The logarithmic plot of equation (15) gave a straight line with a slope of unity, and the value of $K_{ex1}^{Fe(III)}$ was evaluated by least-squares calculation: $K_{ex1}^{Fe(III)} = 10^{6.78 \pm 0.15}$ at $I = 0.10$ (Na$_2$SO$_4$).

When dimer formation takes place, the distribution ratio of the Fe(III) at pH 8.2 is described by

$$D_{Fe(III)} = \frac{[Q\{Fe^{III}L_2\}]_o + 2[Q_2\{Fe^{III}L_2\}_2]_o}{[\{Fe^{III}L_2\}^-]} \quad (17)$$

The dimerization constant is defined as

$$K_d = \frac{[Q_2\{Fe^{III}L_2\}_2]_o}{[Q\{Fe^{III}L_2\}]_o^2} \quad (18)$$

From equations (12), (17) and (18), we obtain

$$\frac{D_{Fe(III)}}{[Q^+]} = K_{ex1}^{Fe(III)} + 2K_d(K_{ex1}^{Fe(III)})^2[\{Fe^{III}L_2\}^-][Q^+] \quad (19)$$

The concentration of free Q^+ was calculated from equation (16), with $\alpha = [QHL]_o + [Q\{Fe^{III}L_2\}]_o + 2[Q_2\{Fe^{III}L_2\}_2]_o$. Since the data were scattered to some extent, as shown in Fig. 7, the value of K_d could be determined only with poorer precision, as $10^{4.3 \pm 0.3}$ from the linear plot of equation (19) by least-squares calculation in which the $K_{ex1}^{Fe(III)}$ value obtained from equation (15) was put on the corresponding position of the ordinate in Fig. 7.
Fig. 7. Plots of equation (19).

DISCUSSION

The equilibrium constants obtained in this work are listed in Table 2 with those for some other metal–PAR chelates. The relative order of the ion-pair extraction constants can be established as $\{Fe^{II}(HL)L\}^- > HL^- > \{Fe^{III}L_2\}^- > \{Fe^{II}L_2\}^{2-}$ by considering the exchange equilibrium

$$\{M(HL)_xL_y\}^{n-} + nQHL_o \overset{K'}{\rightleftharpoons} Q_n\{M(HL)_xL_y\}_o$$

$$+ nHL^- \quad K' = \frac{K^M_{exn}}{(K^{HL}_{ex})^n} \quad (20)$$
This order seems to be reasonable for $\{Fe^{II}(HL)L\}^- > HL^- > \{Fe^{II}L_2\}^{2-}$ with respect to the size and charge-type effects,[18,19] but the position of $\{Fe^{III}L_2\}^-$ is unusual on the basis of these criteria. Furthermore, no evidence for dimerization was observed in the $\{Fe^{II}L_2\}^{2-}-Q^+$ and $\{Ni^{II}L_2\}^{2-}-Q^+$ systems, though it was in the $\{Fe^{III}L_2\}^--Q^+$ system ($\log K_d = 4.3$). Very similar behaviour to that of $\{Fe^{III}L_2\}^-$ was also found for the $\{Co^{III}L_2\}^--Q^+$ system [$\log K^{Co(III)}_{ex1} = 6.37$ and $\log K_d = 4.04$].[10] The closeness of the values K_{ex} and K_d for Fe(III) and Co(III) should be attributed to the similarity in the nature of the ion-pairs. The situation may be similar for the PAR chelates of $\{M^{II}L_2\}^{2-}$ [M = Fe(II) and Ni(II)], since their extraction constants are $\log K^{Fe(II)}_{ex2} = 12.17$ and $\log K^{Ni(II)}_{ex2} = 11.16$. From comparison of the extractability of the different types of PAR chelates, it is concluded that the 1-hydroxy groups (*para* to the azo group) in the chelates play an important role in the extraction process, both in ion-pair formation and in solvation of the ion-pairs.

As shown in the discussion above, detailed data for the ion-pair extraction equilibria provide useful information about the forms of some analytically important metal chelates in solution, as well as the quantitative basis for understanding the extractive colorimetric determination of metal ions with PAR and the separation of some PAR chelates by ion-pair reversed-phase partition chromatography.[14] For example, there is a linear correlation (Fig. 9) between the extraction constants of the PAR chelates and their capacity factors (k') calculated from the chromatogram shown in Fig. 8.
Fig. 8. Separation of PAR chelates by ion-pair reversed-phase partition chromatography. $C_M = 2 \times 10^{-6}M$, $C_L = 8.0 \times 10^{-5}M$, pH 7.5 ($5 \times 10^{-3}M$ sodium acetate), 0.100 ml injected. Column, Yanapak ODS-T column (Yanagimoto Mfg., 4 mm bore, 250 mm length); mobile phase 47 w/w% aqueous methanol containing tetrabutylammonium bromide (0.01 mole/kg), sodium acetate (0.04 mole/kg) and EDTA (10^{-4} mole/kg); flow-rate 1.0 ml/min. Detection at 500 nm, 1 mV = 0.04 absorbance.
Fig. 9. Relationship between $\log K_{ex}$ and $\log k'$ for singly negatively-charged PAR chelates. The capacity factor, k', is given by $k' = (t_r - t_0)/t_0$, where t_0 and t_r are the retention times of a non-retarded component (solvent front) and of the separated species, respectively.

APPENDIX I

Extractability of $\{Fe^{II}L_2\}^{2-}$ *chelate from* 0.1M *sodium chloride solution*

Equation (3) is combined with equation (4), and with use of the values in Table 2, the following relation is derived:

$$\frac{K_{ex2}^{Fe(II)}}{(K_{ex}^{Cl})^2} = \frac{[Q_2\{Fe^{II}L_2\}]_o[Cl^-]^2}{[QCl]_o^2[\{Fe^{II}L_2\}^{2-}]} = 10^{1.95} \quad (A\text{-}1)$$

Under the conditions $[Cl^-] = 0.10M$ and $[QCl]_o = 5 \times 10^{-4}M$ (approximately similar to those for Fig. 4), the value of $[Q_2\{Fe^{II}L_2\}]_o/[\{Fe^{II}L_2\}^{2-}]$ is estimated to be $10^{-2.65}$, so only 0.2% of the $\{Fe^{II}L_2\}^{2-}$ can be extracted.

Equation (6) is multiplied by the reciprocal of equation (4):

$$\frac{[Cl^-][H^+][Q_2\{Fe^{II}L_2\}]_o}{[QCl]_o[Q\{Fe^{II}(HL)L\}]_o} = 10^{-9.19} \quad (A\text{-}2)$$

Under the conditions above for $[Cl^-]$ and $[QCl]_o$, even at the highest pH in Fig. 4, pH 9.0, the ratio $[Q_2\{Fe^{II}L_2\}]_o/Q\{Fe^{II}(HL)L\}]_o$ is estimated to be only $10^{-2.49}$.

APPENDIX II

Derivation of equations (11) *and* (16)

Here α is the sum of the concentration terms which can be spectrophotometrically determined in the material-balance equation for Q^+ ion.

For equation (11) four mass-balance equations are needed:

$$C_Q = [Q^+] + [QCl]_o + \alpha \quad (A\text{-}3)$$

where

$$\alpha = [QHL]_o + [Q\{Fe^{II}(HL)L\}]_o + 2[Q_2\{Fe^{II}L_2\}]_o \quad (A\text{-}4)$$

$$C_{Cl} = C_Q = [Cl^-] + [QCl]_o \quad (A\text{-}5)$$

$$C_{Fe} = [Q\{Fe^{II}(HL)L\}]_o + [Q_2\{Fe^{II}L_2\}]_o \quad (A\text{-}6)$$

$$C_L = [QHL]_o + 2C_{Fe} \quad (A\text{-}7)$$

where the aqueous concentrations of ferrous ion, its chelates, HL^- and their ion-pairs with Q^+ ion are neglected. By use of equation (4), equation (A-3) is rewritten as

$$C_Q = [Q^+](1 + K_{ex}^{Cl}[Cl^-]) + \alpha \quad (A\text{-}8)$$

From equations (A-3) and (A-5):

$$[Cl^-] = [Q^+] + \alpha \quad (A\text{-}9)$$

If equation (A-9) is substituted in (A-8), a quadratic equation with respect to $[Q^+]$ is obtained:

$$K_{ex}^{Cl}[Q^+]^2 + (1 + K_{ex}^{Cl}\alpha)[Q^+] - (C_Q - \alpha) = 0 \quad (A\text{-}10)$$

From equations (A-4), (A-6) and (A-7), the following equation is obtained:

$$\alpha = C_L - [Q\{Fe^{II}(HL)L\}]_o \quad (A\text{-}11)$$

The absorbances A_1, A_2 and A can be written as

$$A_1 = \varepsilon_1 C_{Fe}$$

$$A_2 = \varepsilon_2 C_{Fe}$$

$$A = \varepsilon_1[Q\{Fe^{II}(HL)L\}]_o + \varepsilon_2[Q_2\{Fe^{II}L_2\}]_o \quad (A\text{-}12)$$

where ε_1 and ε_2 are the molar absorptivities of the ion-pairs, $Q\{Fe^{II}(HL)L\}$ and $Q_2\{Fe^{II}L_2\}$, respectively, in chloroform. With use of equations (A-11) and (A-6), rearrangement of equation (A-12) gives

$$[Q\{Fe^{II}(HL)L\}]_o = \left(\frac{A_2 - A}{A_2 - A_1}\right)C_{Fe}$$

which is substituted into equation (A-10) to give the final equation for α as

$$\alpha = C_L - C_{Fe}\left(\frac{A_2 - A}{A_2 - A_1}\right) \quad (A\text{-}13)$$

Equation (16) is readily derived in a similar manner, by using the material-balance equation

$$C_Q = [Q^+] + [QCl]_o + [QHL]_o + [Q\{Fe^{III}L_2\}]_o \quad (A\text{-}14)$$

Here, α is defined as $\alpha = [QHL]_o + [Q\{Fe^{III}L_2\}]_o$, where $[QHL]_o$ and $[Q\{Fe^{III}L_2\}]_o$ are directly determined by measuring the absorbance at 400 nm (for $[QHL]_o$) and 495 nm (for $[Q\{Fe^{III}L_2\}]_o$). The term $2[Q_2\{Fe^{III}L_2\}_2]_o$ is added to equation (A-14) when dimer formation takes place.

URANYL COMPLEXES OF
n-ALKANEDIAMINOTETRA-ACETIC ACIDS

M. L. Simões Gonçalves,* A. M. Almeida Mota and J. J. R. Frausto da Silva

Centro de Química Estrutural, Instituto Superior Técnico, 1096 Lisboa Codex, Portugal

Summary—The uranyl complexes of n-propanediaminetetra-acetic acid, n-butanediaminetetra-acetic acid and n-hexanediaminetetra-acetic acid have been studied by potentiometry, with computer evaluation of the titration data by the MINIQUAD program. Stability constants of the 1:1 and 2:1 metal:ligand chelates have been determined as well as the respective hydrolysis and polymerization constants at 25° in 0.10M and 1.00M KNO_3. The influence of the length of the alkane chain of the ligands on the complexes formed is discussed.

In a previous paper[1] we reported the results of a potentiometric study of the complexes formed by the uranyl ion UO_2^{2+} with EDTA. Using graphical plots,[2] we concluded that both mononuclear and binuclear complexes are formed, which are subsequently hydrolysed to give the corresponding hydroxo species and more complex products resulting from successive condensations. Hence, for 1:1 molar ratio mixtures of UO_2^{2+} and EDTA the composition of the solutions was interpreted in terms of the formation of MHL, MHLOH, MLOH and (MHLOH)$_2$ complexes, where M stands for UO_2^{2+}; in 2:1 molar ratio mixtures of UO_2^{2+} and EDTA, the results were better interpreted in terms of a "core + links" mechanism[3] where the complexes formed corresponded to the general formula $M_2L[M_2(OH)_2L]_{n-1} \cdot 2H_2O$, with $n_{min} = 1$ and $n_{max} \rightarrow \infty$, although the species corresponding to high values of n are unlikely.

This study has now been extended to other n-alkanediaminetetra-acetic acids, corresponding to the general formula

$$(HOOCCH_2)_2N\text{---}(CH_2)_n\text{---}N(CH_2COOH)_2$$

where $n = 3$, 4 and 6, *i.e.*, n-propanediaminetetra-acetic acid (PDTA), n-butanediaminetetra-acetic acid (BDTA) and n-hexanediaminetetra-acetic acid (HDTA), thus affording the possibility of examining the influence of the length of the hydrocarbon chain of the ligands on the type and stability of the various complexes formed.

In these cases, the fitting of the experimental results to the theoretical curves by graphical procedures is not satisfactory, contrary to what happens with the UO_2^{2+}–EDTA system. We have therefore used a computational method, namely the MINIQUAD program,[4,5] which selects the set of products that gives best correspondence to the experimental results on the basis of the statistical criteria chosen (as discussed later in the results and discussion section) and calculates the formation constants. For comparison, we have re-examined the UO_2^{2+}–EDTA system with this program.

EXPERIMENTAL

Reagents

PDTA and BDTA were prepared by condensation of n-propanediamine and n-butanediamine with mono-chloroacetic acid, following the current procedures.[6] The products were recrystallized from aqueous ethanol.

HDTA and uranyl nitrate were commercial products of analytical grade (Fluka) and used without further purification. The concentration of the stock UO_2^{2+} solutions was confirmed by gravimetric analysis. The potassium hydroxide solutions used as titrants were prepared under nitrogen from Merck "titrisol" vials, with CO_2-free demineralized water. The concentration of these solutions and the absence of carbonate was checked regularly by potentiometric titration with standard hydrochloric acid.

Potentiometric measurements

A Corning-Eel 112 digital potentiometer was used with Corning electrodes (pH triple-purpose, Ag/AgCl internal and calomel reference electrodes, both No. 476022). The readings of potential were converted into log [H$^+$] values according to the expression $E = K + \alpha \log [H^+]$. The experimental value of α determined at 25.0° was 59.2 ± 0.1 mV, in good agreement with the theoretical value of 59.15 (the drift of the liquid-junction potential during the measurements in the pH-range of the titrations was found to be negligible and was not considered in the expression used). The cell constant K was calculated from a previous titration of hydrochloric acid in the appropriate medium with potassium hydroxide, by Gran's method.[7] The calibration was repeated before and after each series of titrations, at regular intervals during the day.

The ionic product of water in 0.10M and 1.00M potassium nitrate media was determined from these titrations; the values obtained at 25.0° were 1.68 × 10^{-14} and 1.86 × 10^{-14} respectively, in good agreement with those reported previously.[8]

Method

A range of ligand and metal concentrations between 5 × 10^{-4} and 4 × 10^{-3}M was used, to allow the study of polymeric species. At concentrations below 5 × 10^{-4}M no polymeric species are formed and at concentrations above 4 × 10^{-3}M the polymeric species precipitate as soon as they are formed.

In all cases the ionic strength of the medium was kept constant at 1.00M with potassium nitrate.

Some titrations were also performed with concentrations of ligand and metal below 10^{-3}M but the ionic strength at 0.10M (KNO_3). These were aimed particularly at the study of the simple MHL and M_2L complexes.

The titrations were performed in a double-walled titration-cell at a temperature controlled at $25.0 \pm 0.1°$ by circulating water from a thermostat. The titrant was added from a 10.00 ± 0.01 ml Brand burette provided with soda-lime guard-tubes.

After each addition of base, the equilibrium potential was reached within 30–120 sec.

RESULTS AND DISCUSSION

The potentiometric curves of the n-alkanediaminetetra-acetic acid in the presence of uranyl ion (1:1 and 1:2 molar ratios) are analogous for all the ligands and the titration curves of BDTA are presented as an example (Fig. 1); the onset of precipitation of the hydroxo complexes occurs at a lower degree of neutralization as the hydrocarbon chain of the ligand increases.

Referring to this figure, it can be seen that curve (b), corresponding to the titration of a 1:1 molar mixture of UO_2^{2+} and the ligand, has an inflection at $a = 3$, which suggests the formation of a protonated complex MHL, where M represents UO_2^{2+} and L the deprotonated ligand. This is the only inflection point, in contrast to the corresponding situation for EDTA, where a second inflection point is apparent at $a = 5$.[1]

Curve (c), corresponding to the titration of 2:1 molar mixtures of UO_2^{2+} and the ligand, has an inflection point at $a = 4$, indicating the formation of an M_2L complex. Both MHL and M_2L are subsequently hydrolysed, but since the inflections of the curves are not well defined, the hydrolysed species are already present before $a = 3$ or $a = 4$ in curves (b) and (c), as can be seen from the curves showing the distribution of the different species (Fig. 2).

The set of species to be considered, apart from MHL and M_2L, is not obvious, since the number of possibilities is large. The initial choice for an unknown system must be based on chemical grounds but, in the present case, the task is made simpler since a considerable amount of information is already available from the study of the UO_2^{2+}–EDTA system.[1]
Fig. 1. Titration curves of BDTA (a) and BDTA + uranyl ion in the ratio 1:1 (b) and 1:2 (c), at 25° and ionic strength $0.1M$ KNO_3. $C_{BDTA} = 10^{-3}M$; $a = $ moles of base per mole of acid (degree of neutralization); ↓ indicates the precipitation of hydroxo complexes.

The formation constants of the complexes were obtained by a least-squares refinement process using the MINIQUAD program. This program also calculates the standard deviations of the constants and an agreement factor R defined as:[9]

$$R = \left[U \Big/ \sum_{i=1}^{m} (C_{M_i}^2 + C_{L_i}^2 + C_{H_i}^2) \right]^{1/2}$$

where U is the sum of squared residuals for all the mass-balance equations:[4]

$$U = \sum_{i=1}^{m} [(C_M - C'_M)_i^2 + (C_L - C'_L)_i^2 + (C_H - C'_H)_i^2]$$

m represents the number of experimental points and the values C_M, C_L, C_H are the experimental values for the total concentration of metal, ligand and hydrogen ion; C'_M, C'_L and C'_H represent the same concentrations calculated from the mass-balance equations.

The best set of species is selected by analysing the values of the statistical outputs of the program.

A certain chemically probable set of species is unusually acceptable if the agreement factor R is less than 0.004, which is the permitted deviation from a calculated R, based on the experimental errors.[10] The relative deviation of the formation constants should be less than 10%, although when many species are present values up to 25% may still be acceptable.

The formation constants of the species are defined as

$$\beta_{p,q,r} = \frac{[M_pL_qH_b(OH)_a]}{[M]^p[L]^q[H]^r}$$

where $r = b - a$, and correspond to the reactions

$$p\,M + q\,L + a\,H_2O \rightleftharpoons M_pL_qH_b(OH)_a + (a - b)H^+$$

Solvation of the species is not considered, for the sake of simplicity. Each species is defined by three numbers—p, q, r—which represent the number of metal ions, ligand ions and the sum of the hydrogen($+$) and hydroxide($-$) ions in the complex.

The ionization constants of the ligands (Table 1), the ionic product of water and the hydrolysis constants of the uranyl ion at $\mu = 0.1M$ and $1.0M$ (KNO_3)[11,12] (Table 2) were included as fixed values in the data to be dealt with by the program.

The best sets of results for the various systems at ionic strength $1.00M$ (KNO_3) are presented in Table 3 together with the calculated standard deviations of the constants (log β) and the values of the R factor. The results for EDTA presented in Table 4 have been redetermined by using the MINIQUAD program, for comparison.

For all the systems, the value of the R parameter decreases significantly when the polymeric species due to hydrolysis of the complexes are considered. This supports the postulation of existence of these species in solution.

The results obtained for ionic strength $0.10M$ are not so conclusive, although there is a slight decrease

of R with the addition of the polymeric species to the set considered. Since in this case we did not change, at least significantly, the total metal and ligand concentrations (the supporting electrolyte would hardly keep the ionic strength constant) not enough data were obtained to allow distinction between monomers and the corresponding dimers. Nevertheless the best set of species found for ionic strength 1.00M has been accepted by the program (except for the dimer 42-2), and the formation constants of the species are consistent (Table 5).

From the plots of the percentages of the ligand and metal in each species, as a function of pH, for the 1:1 and 2:1 metal/ligand molar ratio mixtures, which are similar for all the ligands, it can be seen that the species MHL and M$_2$L, with general formula

$$(^-OOCCH_2)_2\overset{+}{N}H-(CH_2)_n-N(CH_2COO)_2M$$

and

$$M(OOCCH_2)_2N-(CH_2)_n-N(CH_2COO)_2M$$

are present in solution up to about pH 6, being dominant between pH 3.00 and 5.00 (Fig. 2 for PDTA and HDTA ligands). At pH above 4 the hydrolysed species of these complexes begin to form. The M$_2$LOH (21-1) species, with one water molecule hydrolysed, is the first complex to be formed; its importance decreases from EDTA to HDTA, whereas the concentration of the dimer 42-2, with two bridging hydroxyl groups, increases.

For EDTA the equilibrium seems to favour the higher complex 63-4 of the "core + links" mechanism, instead of 42-2 for which the formation constant has a large error. For PDTA there are some doubts as to the existence of the second or third species of the series, i.e., 42-2, or 63-4, the co-

Fig. 2. Fraction of total metal, present in each complex, as a function of pH, for the systems: A, 2:1 UO_2^{2+}/PDTA; B, 1:1 UO_2^{2+}/PDTA; C, 2:1 UO_2^{2+}/HDTA; D, 1:1 UO_2^{2+}/HDTA.

existence of both being rejected by the program. The reason for the discrepancy cannot be ascertained; we believe that the tendency to form 63-4 decreases along the series and may be significant only for EDTA.

The species 42-4 is an intermediate between 42-2 and 63-4; on the basis of the behaviour of UO_2^{2+} aminocarboxylate complexes in solution[13] it is likely to be formed by two M_2L molecules bound by two hydroxyl groups and with one hydrolysed water molecule co-ordinated to each UO_2^{2+} group. This species becomes clearly dominant at pH above 5 for all the systems.

For the same reason, the dimer 220 probably corresponds to two MHL molecules bound by two hydroxyl groups rather than to M_2L_2, but the potentiometric data are not sufficiently conclusive to indicate the real structure. This species (more significant at the 1:1 metal/ligand ratio) is detectable for the EDTA and PDTA systems but for the BDTA and HDTA its existence in solution is doubtful.

The hydrolysis of the uranyl ion becomes more important in the systems involving ligands with longer $-CH_2-$ chains. The products of hydrolysis of

UO_2^{2+} together with the H_2L^{2-} and 42-4 species are the reason for the less satisfactory fit of the experimental points to the theoretical curves established assuming only the "core + links" mechanism. As Fig. 3 shows, their importance increases from the EDTA to the HDTA system, and their fraction of the total metal concentration passes through a minimum between pH 4 and 5.
Fig. 3. Distribution curves (as functions of pH) for the systems A, 2:1 UO_2^{2+}/EDTA and B, 2:1 UO_2^{2+}/HDTA for (a) fraction of total metal present in all "core + links" species; (b) fraction of total metal present in the other species.
Fig. 4. Fraction of free H_2L, as a function of pH, for BDTA in the presence of uranyl ion in molar ratio of M:L 1:1 (a) and 2:1 (b). Curves (c) and (d) are the corresponding curves [to (b) and (a) respectively] after subtraction of hydrolysed uranyl ion species.

A curious result is obtained when the mass balance of species is considered in terms of L. The distribution curves of H_2L species as a function of pH have an analogous shape for all the ligands, with a minimum between pH 4.0 and 5.0, this being clearer for the 1:1 metal/ligand ratio (Fig. 4a, b). This behaviour is not the usual, since these curves generally increase to a maximum value and then decrease until they practically disappear owing to the competitive formation of other species. For the 2:1 metal/ligand ratio the increase of H_2L species after the minimum may be due mainly to the hydrolysis of uranyl ion, which increases the concentration of H^+ and displaces the equilibrium $H + MHL \rightleftharpoons H_2L + M$ to the right. This hypothesis has been confirmed by comparison of the H_2L distribution curves with the hypothetical ones obtained from a model without the hydrolysed species $M_2(OH)_2$, $M_3(OH)_5$ and $M_4(OH)_7$ (Fig. 4c). For the 1:1 metal/ligand ratio the minimum can be explained in terms of the increasing concentration of the 2:1 M:L species, which gives more free ligand available in the form of H_2L species. The hydrolysis of the uranyl ion does not affect the distribution curves within experimental error (Fig. 4d).

From the results in Table 4 it can be seen that the two sets of species—one obtained by graphical methods and the other by using the MINIQUAD program for the EDTA + UO_2 system—are similar, although the formation constants for the well-defined species

common to both methods differ by up to 1.5 log units (log M_{MHL} and log β_{M_2L}). The set obtained with the computer program also considers the species 21-1 (monomer of 42-2) and 42-4 that do not belong to the "core + links" mechanism. On the other hand it does not consider the dimer 42-2 or the monomers 11-1 and 110 (monomer of 220) postulated in the graphical methods (since graphical methods used for the study of 1:1 mixtures do not include the 2:1 species, the 11-1 complex had to be introduced to fit the experimental points and the theoretical curves in the high pH range). It is worth noting that the 2:1 metal ligand species have a strong weight even when 1:1 mixtures are considered, as can be seen in Figs. 2 and 3. These seem to be the reasons why our present values for the EDTA system differ from those presented in our previous paper.[1] It must also be pointed out that in the present work more experimental data were used. In fact, when computer calculation is used, the entire titration curve is considered, whereas with graphical plots different parts of the curve are used for calculating the stability constants of the hydrolysed species and of the MHL or M_2L species.

A similar set of species obtained with the MINIQUAD program is reported for EDTA at ionic strength $0.10M$ by other authors[14] but the dimers 42-4 and 220 are replaced by their monomers 21-2 and 110 since in the experimental conditions used no polymeric species due to hydrolysis were found.

From these results we can conclude that all the systems can be interpreted in terms of the same set of species: 111, 210, 21-1, 220, 42-2 and 42-4, where only 210 and 42-2 belong to the "core + links" series of general formula $M_2L[M_2L(OH)_2]_{n-1} \cdot 2H_2O$. As remarked before, for EDTA the 63-4 species of this mechanism may still exist, whereas 42-2 is doubtful. For PDTA, the existence of 63-4 is less likely and for the other systems this species was not accepted by the computer program. This seems to mean that species of the "core + links" series for $n > 1$ become progressively less probable the longer the chain of the ligand. The same happens with the dimer 220, which is also favoured by ligands with shorter chains, namely EDTA and PDTA. This effect is expected

Table 6. Hydrolysis constants of the UO_2L complexes, defined in terms of the species 210 or 111 [(A) 25°, $0.1M$ KNO_3; (B) 25°, $1.0M$ KNO_3]

	Ligand	$-\log K_{220}^{111}$	$-\log K_{12-1}^{210}$	$-\log K_{42-2}^{210}$	$-\log K_{42-4}^{210}$	$-\log K_{63-4}^{210}$
(B)	EDTA	7.52	4.81	—	16.94	14.12
	PDTA	7.83	4.89	—	16.73	13.61
	BDTA	8.22	4.95	6.97	17.61	—
	HDTA	7.98	5.65	6.68	17.73	—
(A)	PDTA	7.39	4.61	—	16.75	—
	BDTA	8.18	5.26	—	18.35	—
	HDTA	8.55	5.20	—	16.68	—
Reaction type		I	II $m = n = 1$	II $m = n = 2$	II $m = 2$ $n = 4$	II $m = 3$ $n = 4$

I $2MHL \cdot H_2O \rightleftharpoons (MHLOH)_2 + 2H$.
II $mM_2L \cdot nH_2O \rightleftharpoons (M_2L)_m(OH)_n + nH$.
because a longer chain length corresponds to an increased basicity of the ligands (nitrogen donors) and the resulting electron density in the uranyl ion is higher; the ionization of the water molecule bonded to the central atom becomes more difficult and so does hydrolysis. The same reason explains the decrease of the hydrolysis constants (defined in terms of M_2L or MHL) with increase in the chain-length of the ligands, *i.e.*, with the basicity of their nitrogen atoms, as measured by pK_{HL} values (Table 6).

A final comment on these and similar results may be in order: although various sets of species may, in certain cases, be statistically possible, the comparison of a series of analogous systems can be of help to decide on the most probable set, particularly if and when they conform to chemical thinking.

ORGANIZATION AND EVALUATION OF INTERLABORATORY COMPARISON STUDIES AMONG SOUTHERN AFRICAN WATER ANALYSIS LABORATORIES

R. SMITH

National Institute for Water Research, Council for Scientific and Industrial Research, P.O. Box 395, Pretoria 0001, South Africa

Summary—Interlaboratory comparison studies provide a useful "external" supplement to the various "internal" quality-control procedures which must be employed in the water-analysis laboratory in order to maintain a high degree of reliability in the production of analytical results. Such studies have been made regularly for many years by various overseas organizations, and were introduced in South Africa in 1976. Since that time 16 studies have been made, involving more than 40 laboratories. In this paper the various factors involved in the successful organization of interlaboratory comparison studies are discussed, and details are given of the sample-preparation, analysis-instruction and result-reporting procedures used in the southern African studies. Techniques used for the statistical evaluation of the analytical results submitted are described and discussed, for example, methods for the rejection of outliers, measures of accuracy and precision, determination of total error, tests of significance, Greenberg's assessment technique, Madden's ranking technique and Youden's graphical technique. A brief review is given of the studies made to date, along with specific findings and recommendations arising from them. The need for a recognized updated set of standard methods for use by water and wastewater analysis laboratories in southern Africa is highlighted.

The main function of a laboratory engaged in water and wastewater analysis is the provision of data which indicate the concentrations and characteristics of constituents in water samples submitted to that laboratory. These data are often employed as the basis for important decisions concerning, for example, process control of water and wastewater treatment or the assessment of the value and progress of research investigations. It is essential, therefore, to ensure the reliability of all analytical results produced. In order to achieve a high degree of reliability, effective quality-control procedures must be applied, for example, the use of appropriate sampling and sample-preservation techniques and recognized standard methods of analysis, frequent calibration of apparatus, and the application of a regular system of data verification.

An extremely useful "external" supplement to these "internal" quality-control procedures is the use of interlaboratory comparison ("calibration" or "collaborative" or "round-robin") studies, in which identical reference samples are distributed to all participating laboratories for analysis for designated constituents, and submission of the results for statistical evaluation and comparison (the concentrations of the constituents of the samples are known only to the originator of the study).

Interlaboratory comparison studies can be of considerable benefit to the laboratories taking part. As well as providing the means by which each laboratory can compare its ability with that of other laboratories in the production of acceptable results, the information gained can also enable the participants to assess the reliability of their particular analytical methods and to initiate improvements or alterations where necessary. Certain studies can also provide a mechanism for evaluating the reliability of specific analytical procedures.
